Abstract
The order *Jiangellales* was created by elevation of suborder *Jiangellineae* of Tang et al. (Int J Syst Evol Microbiol 61:194–200, 2011), mainly based on signature nucleotide patterns and phylogenetic criteria (Tang et al. The order *Jiangellineae*. In: Whitman WB, Goodfellow M, Kämpfer P, Busse H-J, Trujillo M, Garrity G, Ludwig W, Suzuki K-I (eds) Bergey's manual of systematic bacteriology, vol 5, 2nd edn. Springer, New York, p 555, 2012). The order contains the sole suborder *Jiangellineae*. As such, their members are Gram-positive, aerobic, halophilic, or nonhalophilic filamentous actinomycetes. *Jiangellineae* contains the family *Jiangellaceae*, which embraces the genera *Haloactinopolyspora* and *Jiangella*, and for which one and four species each, have been described.

Ji.ang.el 'la.les. N.L. fem. n. *Jiangella* type genus of the order; suff. *-ales* ending to denote an order; N.L. fem. pl. n. *Jiangellales* the *Jiangella* order.

Taxonomy: Historical and Current

Short Description of the Order, Suborder, and the Family

The genus *Jiangella* was first proposed by Song et al. (2005) and assigned to the family *Nocardioidaceae* within the suborder *Propionibacterineae*. Then, another novel genus, *Haloactinopolyspora*, was described by Tang et al (2011), on the basis of phylogenetic reconstruction. The genera *Jiangella* and *Haloactinopolyspora*, forming a monophyletic deep branch at the periphery of the evolutionary radiation occupied by the suborder *Propionibacterineae*, were clearly different as compared to other described suborders of the class *Actinobacteria* and showed that the genera *Jiangella* and *Haloactinopolyspora* did not belong to the suborder *Propionibacterineae* nor to any other described suborders within the phylum Actinobacteria. Representatives of this phylum showed less than 93.1 % 16S rRNA gene sequence similarities to the genera *Jiangella* and *Haloactinopolyspora*. The 16S rRNA gene sequences of all suborders of the class *Actinobacteria* (Zhi *et al.* 2009) and the genera *Jiangella* and *Haloactinopolyspora* were scanned for signature nucleotides. Both genera *Jiangella* and *Haloactinopolyspora* had several unique 16S rRNA gene signature nucleotides as compared to sequences of members of other suborders, particularly reflected in 11 different positions, namely, in 127:234 (G-C), 598:640 (C-G), 672:734 (G-C), 831:855 (U-A), 833:853 (G-C), 840:846 (A-U), 950:1231 (G-C), 952:1229 (G-C), 955:1225 (G-U), 986:1219 (U-G), and 987:1218 (C-G). Thus, the genus *Jiangella* together with the genus *Haloactinopolyspora* has been proposed to be classified as *Jiangellaceae* fam. nov. and *Jiangellineae* subord. nov (Tang et al. 2011). Later, the order *Jiangellales* was created by elevation of suborder *Jiangellineae* of Tang et al (2010), mainly based on signature nucleotide patterns and phylogenetic criteria (Tang et al. 2012).

Jiangellineae Tang, Zhi, Wang, Shi, Lou, Xu and Li 2011, 198[VP]

Jiangellaceae Tang, Zhi, Wang, Shi, Lou, Xu and Li 2011, 198^{VP}

Ji.ang.el.la.ce'ae. N.L. fem. n. *Jiangella* type genus of the family; *-aceae* ending to denote a family; N.L. fem. pl. n. *Jiangellaceae* the family of the genus *Jiangella*.

The 16S rRNA nucleotide signatures are as that of the suborder.

The family accommodates the genera *Jiangella* (Song et al. 2005) and *Haloactinopolyspora* (Tang et al. 2011). The pairwise similarities of 16S rRNA gene sequences between members of the two genera are about 96.6–96.9 %.

Type genus: *Jiangella* Song, Li, Wang, Chen, Zhang and Xu 2005, 883^{VP}.

The discriminating properties for these two genera are indicated in *Table 24.1*.

Phylogenetic Structure of Suborder and the Family

Although the genus *Jiangella* proposed by Song et al. (2005), was assigned to the family *Nocardioidaceae* within the suborder *Propionibacterineae*, the phylogenetic analysis based on 16S rRNA gene sequences of members of the phylum Actinobacteria revealed that the genera *Jiangella* and *Haloactinopolyspora* form a deep branch, clearly distinguished from other described suborders of the phylum Actinobacteria (*Fig. 24.1*). Representatives of members of the phylum Actinobacteria shared less than 93.1 % of 16S rRNA gene sequence similarities with the genera *Jiangella* and *Haloactinopolyspora*. Although the genera *Jiangella* and *Haloactinopolyspora* clearly belong to the order *Actinomycetales*, they do not belong to any of the described suborders within the *Actinomycetales*. Accordingly, the genera *Jiangella* and *Haloactinopolyspora* are closely related phylogenetically but distinct from other suborders. Thus, a novel family *Jiangellaceae* fam. nov. and a novel suborder *Jiangellineae* subord. nov. were proposed to accommodate the genera *Jiangella* and *Haloactinopolyspora*.

Molecular Analyses

DNA-DNA hybridization (DDH) studies have been performed on four *Jiangella* type strains, most extensively among *J. muralis* 15-Je-017^T and the other three type strains of the genus. The phylogenetic neighbors strain 15-Je-017^T and *J. alba* YIM 61503^T, sharing 99.7 % 16S rRNA gene sequence similarity, exhibit 48.1 % DDH similarity, while the other type strains

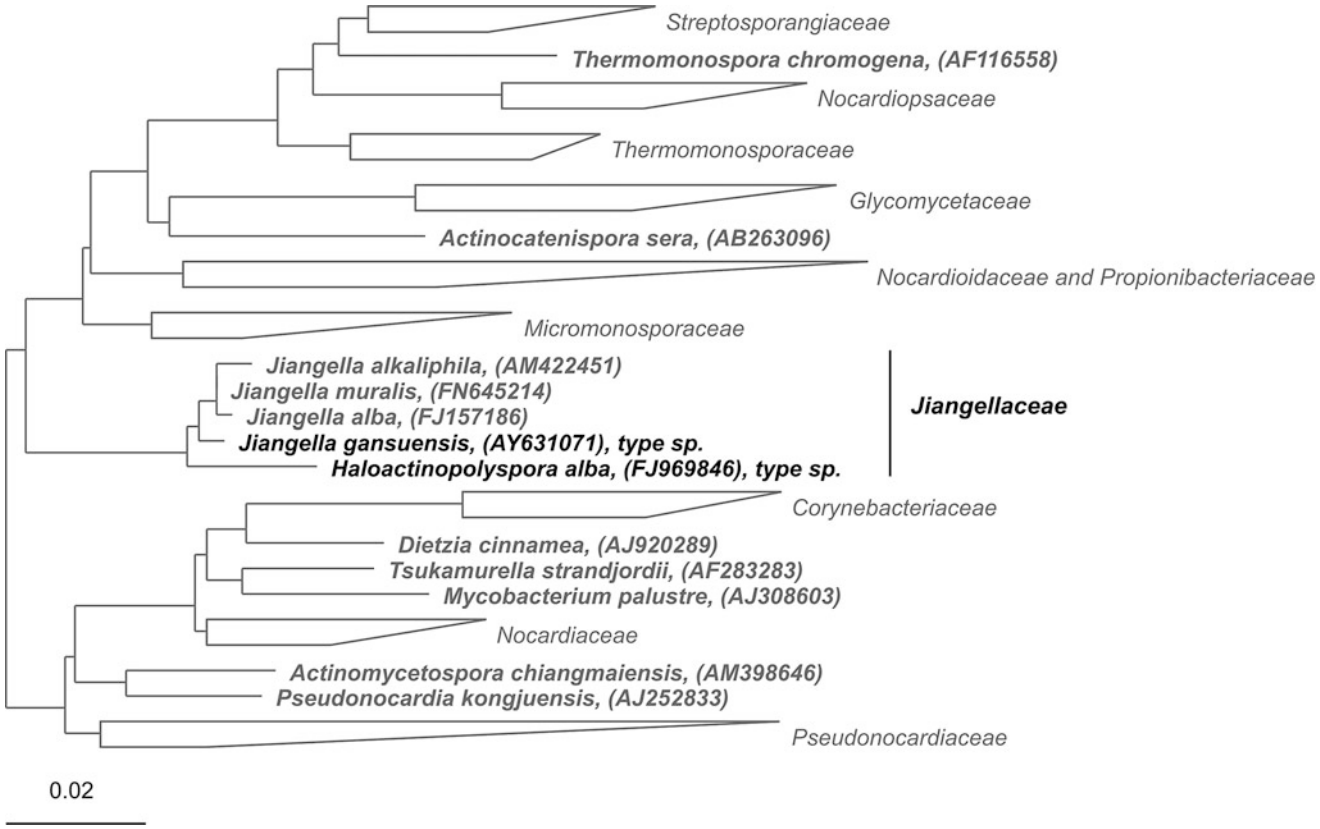

Fig. 24.1

Phylogenetic reconstruction of the family *Jiangellaceae* based on 16S rRNA and created using the maximum likelihood algorithm mRAxML(Stamatakis 2006). The sequence datasets and alignments were used according to the All-Species Living Tree Project (LTP) database (Yarza et al. 2010; http://www.arb-silva.de/projects/living-tree). Representative sequences from closely related taxa were used as outgroups. In addition, a 40 % maximum frequency filter was applied in order to remove hypervariable positions and potentially misplaced bases from the alignment. *Scale bar* indicates estimated sequence divergence

show DDH values below 40 % (Kämpfer et al. 2011). Additional DDH values are available for the neighboring species *J. alba* YIM 61503^T and *J. alkaliphila* D8-87^T and *J. gansuensis* YIM 002^T, sharing 98.8 % and 98.6 % 16S rRNA gene sequence similarity (45.4 %, 41 % DDH similarity, respectively) (Qin et al. 2009b). No DDH studies were done for other *Jiangella* species nor for members of *Haloactinopolyspora* as the 16S rRNA gene sequence similarities among the type strains of the respective genera were below the threshold value of 97 %, indicative of separate genomic species (Stackebrandt and Goebel 1994).

No DNA fingerprinting method was performed on the members of the genera *Jiangella* and *Haloactinopolyspora*.

Genome Analyses

No full genome has been sequenced completely in the genera *Jiangella* and *Haloactinopolyspora*.

The four 16S rRNA gene sequences of the genus *Jiangella* were used as AY631071, AM422451, FJ157186, and FN645214 of *J. gansuensis* YIM 002^T, *J. alkaliphila* D8-87^T, *J. alba* YIM 61503^T and *J. muralis* 15-Je-017^T, respectively (Song et al. 2005; Lee et al. 2008; Qin et al. 2009b; Kämpfer et al. 2011). While, the single species of the genus *Haloactinopolyspora* was used as FJ969846 of *H. alba* YIM 93246^T.

Phenotypic Analyses

Jiangella Song, Li, Wang, Chen, Zhang and Xu 2005, 883^{VP}

Ji.ang.el'la. N.L. fem. dim. n. *Jiangella* named after the Chinese microbiologist Cheng-Lin Jiang in recognition of his work on actinomycete taxonomy.

Gram-positive filamentous actinomycete. Aerobic, with a strictly respiratory type of metabolism. Catalase positive. The substrate mycelium fragmented into short and elongated rods. Cell wall contains LL-A_2pm as the diamino acid in the peptidoglycan. MK-9(H_4) as the predominant menaquinone.

The mol% G + C of the DNA is 70–71.9 %.

The type species is *Jiangella gansuensis* Song et al. 2005. The type strain is YIM 002^T. Type strains of the other species are indicated in *Tables 24.1* and *24.2*.

All strains were positive for hydrolysis of aesculin, ρ-nitrophenyl (pNP) phenylphosphonate, 2-deoxythymidine-5′-pNP phosphate, L-alanine ρ-nitroanilide (pNA) and L-proline pNA and assimilation of *N*-acetyl-D-glucosamine, L-arabinose, parbutin, cellobiose, D-glucose, maltose, D-ribose, sucrose, trehalose, adonitol, and pyruvate. All strains were negative for hydrolysis of onitrophenyl b-D-galactopyranoside and L-glutamate-γ -3-carboxy pNA and assimilation of gluconate, melibiose, D-sorbitol, putrescine, propionate, *cis*- and *trans*-aconitate, adipate, 4-aminobutyrate, azelate, citrate, itaconate, mesaconate, suberate, b-alanine, L-leucine, L-ornithine, L-serine, L-tryptophan, 3-hydroxybenzoate, 4-hydroxybenzoate, and phenylacetate (Kämpfer et al. 2011).

Haloactinopolyspora, Tang, Zhi, Wang, Shi, Lou, Xu and Li, 2011, 199^{VP}

Ha.lo.ac.ti.no.po.ly.spo'ra. Gr. n. *hals halos*, salt; Gr. n. *actis actinos*, a ray; Gr. adj. *poly*, many; Gr. n. *spora*, a seed and, in biology, a spore; N.L. fem. n. *Haloactinopolyspora*, salt-loving and the many spored ray.

Gram-positive, aerobic, moderately halophilic filamentous actinomycete. The substrate mycelium fragments into rod-like elements, and the aerial mycelium has long spore chains and forms root-like spores heap at maturity. The whole-cell hydrolysates contain LL-DAP, alanine, glycine, and glutamic acid as the cell-wall amino acids; glucosamine, glucose, galactose, mannose, and arabinose are the major cell-wall sugars. Other chemotaxonomic properties are indicated in ❯ *Table 24.1*. The genus contains a single species, *Haloactinopolyspora alba*, the type strain is YIM 93246^T.

The growth was good on GTY agar and potato agar, moderate on Czapek's agar, inorganic salts-starch agar (ISP 4), and oatmeal agar (ISP 3), weak on nutrient agar and glycerol/asparagine agar (ISP 5), but no growth was observed on yeast extract-malt extract agar (ISP 2). The color of the aerial mycelium was white and that of the substrate mycelium was white-yellow. No soluble pigments were produced. Grows at 15–45 °C (optimum 28–37 °C), at pH 4.0–9.0 (optimum pH 7.0–8.0) and with 7–23 % (w/v) NaCl (optimum 10–15 % NaCl), and no growth occurs in the absence of NaCl. Aesculin, Tweens 40, 60, and 80 are decomposed, but casein, starch, dextrin, chitin, Tween 20 and urea are not. Tests for milk peptonization and coagulation are positive, but gelatin liquefaction, nitrate reduction, starch hydrolysis, H_2S, and melanin production are negative. Utilizes the following substrates as sole carbon sources: cellobiose, dulcitol, D-fructose, inositol, lactose, maltose, D-mannose, rhamnose, sucrose, sorbitol, and trehalose. The following substrates are not utilized: erythritol, galactose, D-glucose, glycerol, glycine, mannitol, raffinose, D-ribose, sodium propionate, trisodium citrate, xylitol, and D-xylose. Adenine, L-arginine, L-histidine, hypoxanthine, L-lysine, L-methionine, L-proline, L-serine, and L-threonine are utilized as sole nitrogen sources, whereas growth on L-alanine, D-arabinose, L-asparagine, L-phenylalanine, L-tyrosine, and xanthine is not observed. In the API ZYM system, tests are positive for alkaline phosphatase, esterase(C4), esterase lipase(C8), lipase (C14), α- and β-galactosidase, α- and β-glucosidase, α-mannosidase, and *N*-acetyl-β-glucosaminidase, but negative for acid phosphatase, α-chymotrypsin, cystine arylamidase, α-fucosidase, β-glucuronidase, leucine arylamidase, naphthol-AS-BI-phosphohydrolase, trypsin, and valine arylamidase.

The type species is *Haloactinopolyspora alba*.

Isolation, Enrichment, and Maintenance Procedures

Isolation and Enrichment

Jiangella gansuensis YIM 002^T (Song et al. 2005) was isolated from a desert soil sample, by using the dilution plating method. The medium used for selective isolation was glycerol-asparagine agar (ISP medium 5), which was incubated at 28 °C for about 2 weeks.

Jiangella alba strain YIM 61503^T (Qin et al. 2009b) was isolated from surface-sterilized stems of *Maytenus austroyunnanensis*. Stem samples were air-dried at room temperature after being thoroughly washed under tap water and surface sterilized according to the five-step sterilization procedure. Samples were then pulverized in a ceramic mortar and processed with a calcium carbonate enrichment method. The samples were serially diluted in sterile distilled water and spread-plated on glycerol-asparagine agar (ISP medium 5). Strain YIM 61503^T was isolated after incubation at 28 °C for 21 days.

Jiangella alkaliphila D8-87^T (Lee 2008) was isolated from a soil of a natural cave, by using dilution plating method on starch-casein agar (SCA), which was incubated at 30 °C for 14 days.

Jiangella muralis 15-Je-017^T (Kämpfer et al. 2011) was isolated from the cellar wall of a house colonized with moulds by using agar plate containing ISP-3 medium and incubated at 28 °C for 2 weeks.

Haloactinopolyspora alba YIM 93246^T (Tang et al. 2011) was isolated from a hypersaline soil sample, after 3 week incubation at 37 °C on cellulose-casein multi-salt (CCMS) medium described by Tang et al. (2008).

Maintenance

Members of this family do not require special procedures for maintenance and medium and long-term storage. These should be stored at room or preferably refrigerator temperature. Generally, strains are maintained on isolation medium as agar slants 4 °C for a few days. GTY (Tang et al. 2010) agar slants for *Haloactinopolyspora alba* contained 15 % NaCl (w/v).

Medium-term maintenance is in 20 % (v/v) glycerol suspensions at −80 °C.

Long-term preservation is by lyophilization or in liquid nitrogen.

Ecology

As the habitats of the members of this family are very diverse: *Jiangella gansuensis* YIM 002^T was isolated from a desert soil sample, *Jiangella alba* strain YIM 61503^T was isolated from stem samples of *Maytenus austroyunnanensis* collected from a tropical rainforest, *Jiangella alkaliphila* D8-87^T was isolated from a soil of a natural cave, *Jiangella muralis* 15-Je-017^T was isolated from the cellar wall of a house colonized with moulds, while *Haloactinopolyspora alba* YIM 93246^T was isolated from a hypersaline soil sample collected from a salt lake.

Actually, as judged from the few reports on other strains affiliated to the two genera, the isolation source is much broader. Internet search on *Jiangella* reveals the presence of names of species which have no standing in taxonomy as they have never validly published: "*Jiangella ginsengisoli*" (Im and Lee 2006, unpublished) isolated from a ginseng field in Korea was related to *Jiangella gansuensis* (98 % similarity, accession no AB271058). A *Jiangella* strain related to *Jiangella gansuensis* by BLAST analysis (97 % similarity, accession no EU741189) was isolated from water of Costa Rica in Pacific and Caribbean (Solano et al. 2008). A *Jiangella* strain related to *Jiangella gansuensis* by BLAST analysis (98 % similarity, accession no GU574118) was isolated from mould-colonized water-damaged building material (Schafer et al. 2010, unpublished). A *Jiangella* strain related to *Jiangella gansuensis* by BLAST analysis (98 % similarity, accession no EU910884) was isolated from a hypersaline soil sample in Hami Lake (Cao et al. 2008, unpublished). A *Jiangella* strain related to *Jiangella alkaliphila* by BLAST analysis (99 % similarity, accession no JX035894) was isolated from animal feces (Tang et al. 2012, unpublished). The NCBI taxonomy browser lists several additional unnamed strains or clones affiliated to *Jiangella*, e.g., from an insect herbivore, USA (accession number HM559049), mould-colonized water-damaged building material, Germany (GU574028), simulated low-level-radioactive-waste site, USA (GQ263071), saline-alkali soil, China (JF727732), marine sediments in the Bay of Cadiz, Spain(GQ249574), and aliphatic hydrocarbon-contaminated soil, France (FM209114).

Application

The only evidence that any strain of the two genera is involved in application originates from a study by Qin et al. (2009a) involving a strain of *Jiangella* (YIM 61503 for antimicrobial activity). This strain inhibited growth of *Bacillus subtilis*, and did no inhibit growth of *Candida albicans, Staphylococcus aureus*, and *Pseudomonas aeruginosa*. Screening showed lack of presence of PKS-I, PKS-II, and NRPS functional genes.

25 The Families *Jonesiaceae*, *Ruaniaceae*, and *Bogoriellaceae*

Erko Stackebrandt
Leibniz Institute DSMZ-German Collection of Microorganisms and Cell Cultures, Braunschweig, Germany

Abstract
All three families are members of the order *Micrococcales* (Busse 2012). As such they are Gram-positive, not acid-fast, do not form endospores, and do not contain mycolic acids in their cell wall. *Jonesiacea* is a monogeneric family and contains two species, *J. denitrificans* and *J. quinhaiensis*. *Ruaniaceae* encompasses two monospecific genera, *Ruania* and *Haloactinobacterium*, while *Bogoriella* embraces the monospecific genus *Bogoriella* and *Georgenia* for which six species have been described. Phylogenetic neighbors are the families *Bogoriellaceae, Ruaniaceae, Beutenbergiaceae*, and *Actinomycetaceae*. The rationale for treating these three neighboring genera in one chapter but omitting *Actinomycetaceae* is the fact that the latter family contains seven genera with more than 50 species, deserving a chapter on its own. Except for *Jonesia denitrificans*, a former member of the genus *Listeria*, hardly any information is available for other species of these families besides their original description.

Taxonomy: Historical and Current

Short Description of the Families and Their Genera

The family descriptions are mainly based upon phylogenetic position and the presence of 16S rRNA sequence signatures. Differentiating, predominantly chemotaxonomic properties, are indicated in ❯ *Table 25.1*. The phylogenetic closeness of all members of the order *Micrococcales* together with the species richness of this order explains why branching points of lineages at almost any rank are rarely supported by high bootstrap values, hence without statistic significance. The consequence is that the addition of novel taxa will lead to rearrangements of lineages, most likely be followed by future reclassification of taxa, predominantly at the level of families.

[a]Schumann et al. 2004; [b]*Ruania* (Gu et al. 2007); [c]*Haloactinobacterium* (Tang et al. 2010a); [d]*Bogoriella* (Groth et al. 1997); [e]*Georgenia* (Altenburger et al. 2002); [f]Schaal et al. (2006); [g]*Beutenbergia* (Groth et al. 1999); [h]*Salana* (von Wintzingerode et al. 2001); [i]*Serinibacter* (Hamada et al. 2009a); [j]*Miniimonas* (Ue et al. 2011).

The family contains the type genus *Ruania* (Gu et al. 2007) and the genus *Haloactinobacterium* (Tang et al. 2010a). The two type species share 96.2 % 16S rRNA gene sequence similarity. Discriminating properties for these two genera are indicated in Tables 25.1, 25.3, and 25.4.

Bogoriellaceae Stackebrandt and Schumann 2000, 1283[VP] emend. Zhi, Li and Stackebrandt 2009, 597 [VP] emend. Hamada, Iino, Tamura, Iwami, Harayama and Suzuki 2009, 2813.

Bo.go.ri'.el'la. M. L. dim. fem. n. *Bogoriella*, named after Lake Bogoria in Kenya, the place from which isolate HKI0088[T] originated.

The 16S rRNA gene signatures consists of: 144–178 (U-G), 258–268 (G-C), 280 (C), 293–304 (G-U), 379–384 (C-G), 479 (U), 586–755 (C-G), 589–650 (Y-R), 602–636 (C-G), 668–738 (A-U), 1003–1038 (G-C), 1027–1034 (C-G), 1409–1491 (C-G), 1414–1486 (C-G) (Hamada et al. 2009a).

The family accommodates the genera *Bogoriella* (Groth et al. 1997) and *Georgenia* (Altenburger et al. 2002). The phylogenetic distance between the two genera is about 94.2 % 16S rRNA gene sequence similarity.

Phylogenetic Structure of the Family and Its Genera

The phylogenetic tree (Fig. 25.1) indicates that none of the three families are sister clades. 16S rRNA gene sequence dendrograms published in the original genus and species descriptions do not reveal a coherent picture of the as the number and selection of reference organisms vary. The phylogenetic closeness of the two genera of *Bogoriellaceae* was confirmed in the last five species descriptions of *Georgenia* and in the description of *Haloactinobacterium album* (Tang et al. 2010a). In the publications of Tang et al. (2010a, b), the family *Beutenbergiaceae* branched closer to *Ruaniae* than to *Bogoriellaceae*, while *Jonesia denitrificans* branched deeply in the tree of the order *Micrococcales*; the latter branching is also shown in the studies of Groth et al. (1997), Li et al. (2007), and Kämpfer et al. (2010). In the description of *Ruania* (Gu et al. 2007) *R. albidiflava* branches next to members of *Georgenia* and *Bogoriella*, while *Beutenbergiellaceae* spp. branched more deeply. Neither *Ruania albidiflava* nor members of *Jonesia* were included in the

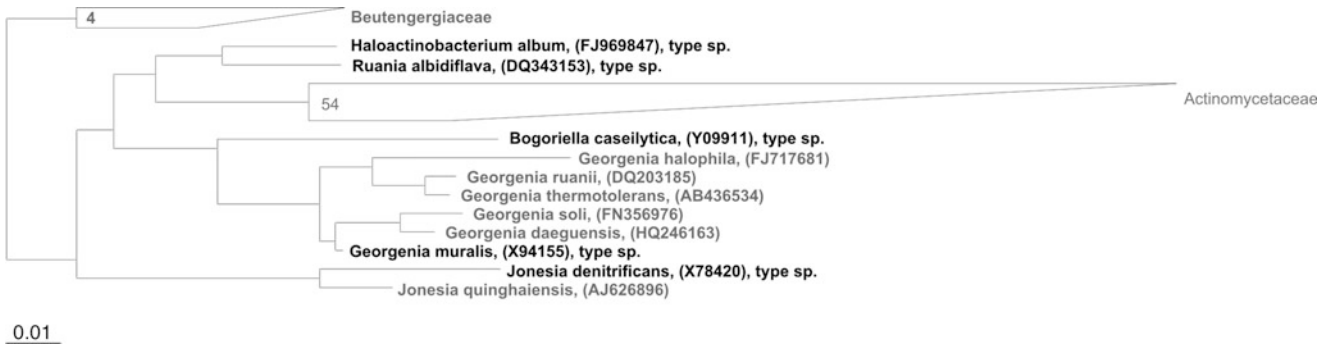

Fig. 25.1

Maximum likelihood genealogy reconstruction based on the RAxML algorithm (Stamatakis 2006) of the sequences of all members of the families *Jonesiaceae, Ruaniaceae, and Bogoriellaceae* present in the LTP_106 (Yarza et al. 2010). The tree was reconstructed by using a subset of sequences representative of close relative genera to stabilize the tree topology. In addition, a 40 % conservational filter for the whole bacterial domain was used to remove hypervariable positions. Number in triangle denotes number of taxa included. The *bar* indicates 5 % sequence divergence

description of *Georgenia thermotolerans* (Hamada et al. 2009b) and of *G. daeguensis* Woo et al (2012) while *Ruania albidiflava* was not a closely related neighboring species of *Bogoriellaceae* in the study of Kämpfer et al. (2010) and Tang et al. (2010b). None of the publications included any member of *Actinomycetaceae*.

The family *Jonesiaceae* was created by Stackebrandt et al. (1997) on the basis of phylogenetic position and the presence of a unique set of 16S rRNA gene sequence signature nucleotides. Based on a modification of this set, due to newly described actinobacterial species and the availability of their 16SrRNA gene sequences, the description of *Jonesiaceae* was emended (Zhi et al. 2009). The family *Ruaniaceae* was described in 2010 (Tang et al. 2010a) after the finding that the genera *Ruania* (Gu et al. 2007) and *Haloactinobacterium* (Tang et al. 2010a) form a separate line of descent among the order *Micrococcales*. The family *Bogoriellaceae* was established for the genus *Bogoriella* by Stackebrandt and Schumann (2000), based upon a unique set of signature nucleotides of the genus *Bogoriella*. The genus *Georgenia* (Altenburger et al. 2002) was added to the emended family by Hamada et al. (2009a) on the basis of phylogenetic position and an emended set of signature nucleotides. Families containing more than a single genus are not coherent with respect to peptidoglycan type, polar lipids, or major fatty acids (*Table 25.1*). *Haloactinobacterium* (*Ruaniaceae*) and most *Georgenia* species (*Bogoriellaceae*) share the same L-Lys-L-Glu peptidoglycan type. *Jonesiaceae* differs from *Ruaniaceae* and *Bogoriellaceae* in menaquinone type and lower mol% G+C of DNA.

Jonesia denitrificans was originally classified as *Listeria denitrificans* (Prevot 1961). Results from morphological, biochemical, serological, chemical, and nucleic acid studies, however, indicated that *L. denitrificans* is not a member of the genus *Listeria* (Chatelain and Second 1976; Welshimer and Meredith 1971; Jones 1975; Stuart and Welshimer 1973, 1974; Wilkinson and Jones 1975, 1977; Collins et al. 1983; Fiedler and Seger 1983; Fiedler et al. 1984) but more closely related to coryneform bacteria. Relatedness to *Oerskovia*, *Renibacterium*, and *Arthrobacter* was excluded on the basis of individual chemotaxonomic properties (see Seeliger and Jones 1986). 16S rRNA oligonucleotide analysis then separated *Listeria denitrificans* CIP 55134^T from the other members of *Listeria*, leading to the description *Jonesia denitrificans* (Rocourt et al. 1987). Similarities in the DNA mol% G+C content, peptidoglycan structure, lipid pattern, isoprenoid quinone, and the 16S rRNA similarities supported the taxonomic placement of *J. denitrificans* within the phylum Actinobacteria. Changes in the phylogenetic affiliation of the genus *Jonesia, which included the transfer of Jonesia into Cellulomonadaceae* (Stackebrandt and Prauser 1991) and its exclusion from this family (Rainey et al. 1995) have been summarized by Stackebrandt (2012). In some published phylogenetic dendrograms *Jonesia* species appear to be related to the family *Dermabacteraceae* (Stackebrandt et al. 1997), and more distantly, to *Brevibacteriaceae*. *Jonesia* species differ from members of *Dermabacter* and *Brachybacterium* in peptidoglycan composition, but they share fully unsaturated menaquinones and similar composition in fatty acids and polar lipids; these features, however, are also frequently found in other members of *Micrococcales*. A remote relationship between *Jonesia* (*Listeria*) *denitrificans* and *Brachybacterium faecium* had been observed earlier in a numerical phenetic study (Jones 1975).

Molecular Analyses

The phylogenetic dendrogram of *Georgenia* type strains indicates the presence of two sister clades. One clade is composed of *G. soli* and *G. daeguensis* which share 98.8 % 16S rRNA gene sequence similarity with *G. muralis* branching slightly deeper (~97.5 % similarity). The second clade groups *G. ruanii* and

G. thermotolerans (99 % similarity) with G. *halophila* branching more deep (~96.5 % similarity). The two clades share ~96.2 % similarity.

DNA-DNA hybridization (DDH) studies have been performed on several *Georgenia* type strains, most extensively among *G. daeguensis* 2C6-43^T and the other five type strains of the genus. The phylogenetic neighbors strain 2C6-43^T and *G. soli* DSM 21838^T, sharing 98.8 % 16S rRNA gene sequence similarity, exhibit 40.5 % DDH similarity, while the other type strains show DDH values below 30 % (Woo et al. 2012). Additional DDH values are available for the neighboring species *G. thermotolerans* TT02-04^T and *G. ruanii* NBRC 103883^T, sharing 99.0 % 16S rRNA gene sequence similarity (45–47 % DDH similarity) and for strain TT02-04^T and *G. muralis* (7–10 % DDH similarity) (Hamada et al. 2009b), as well as for G. *ruanii* YIM 004 T and *G. muralis* DSM 14418 T (18 %) (Li et al. 2007). No DDH studies were done for other *Georgenia* species nor for members of *Jonesiaceae* and *Ruaniaceae* as the 16S rRNA gene sequence similarities among the type strains of the respective genera were below the threshold value of 97 %, indicative of separate genomospecies (Stackebrandt and Goebel 1994).

The only study including DNA fingerprinting method was that of Altenburger et al. (2002) who performed ERIC-, REP-, and BOX PBR on the type strain and two additional strains of *Georgenia muralis* to confirm their membership to the same species. Neither riboprinting, ribotyping, nor MALDI-TOF analyses is available for any member of these three families.

Genome Analyses

Jonesia denitrificans DSM 20603^T is the only strain of the three families for which the full genome sequence has been generated (INSDC ID CP001706) (Pukall et al. 2009). The single replicon genome, analyzed in the course of the *Genomic Encyclopedia of Bacteria and Archaea* project, is 2,749,646 bp long with a 58.42 % GC content. This value is only slightly higher than those determined by T_m and nuclease method performed on purified DNA (56–58 mol%, ❯ *Table 25.1*). Extrachromosomal elements were absent. Besides 47 pseudogenes, 2,629 genes have been predicted of which 2,558 were protein coding genes, and 71 were RNA genes. The majority of the genes (68.3 %) were assigned a putative function, 69.45 % of the genes were assigned to clusters of orthologous groups (COGs), while the remaining ones are annotated as hypothetical proteins. The distribution of genes into COGs functional categories indicate that the highest number of genes is involved in carbohydrate transport and metabolism (210; 8.2 %), followed by genes coding for amino acid transport and metabolism (162; 6.3 %) and transcription (160; 6.3 %); 23 genes (0.9 %) were found to code for secondary metabolites biosynthesis, transport, and catabolism. A detailed listing of COG categories is given by Pukall et al. (2009).

The sequences of the five 16S rRNA gene copies in the genome of strain DSM 20603^T are identical but differ by eight nucleotides from the published 16S rRNA gene sequence of the same strain deposited as ×78420. This sequence has also been used as a reference by Tang et al. (2010a) and in the Living tree Project which has been the basis for the tree shown in ❯ *Fig. 25.1*. Other publications used the sequence X83811 of *J. denitrificans* (Schumann et al. 2004; Tang et al. 2010b; Li et al. 2007). Whether about 0.5–0.8 % sequence difference (depending upon the 16S rRNA gene fragment analyzed) observed between these two sequences actually influences some of the discrepancies seen in the branching of *J. denitrificans*, as indicated above, needs to be evaluated.

Phages

No phages have been described to lyze strains of Jonesia, 16 *Listeria* phages isolated from environmental sources and from lysogenic *Listeria* strains were active on strains of *L. monocytogenes, L. seeligeri, L. innocua, L. ivanovii*, and *L. welshimeri* but not on those of *L. murrayi, L. grayi* (united under *M. grayi* [Rocourt et al. 1992]), or *Jonesia* (formerly *Listeria*) *denitrificans* (Loessner and Busse 1990).

Phenotypic Analyses

Jonesia Rocourt et al. 1987, 268^{VP}.

Jones'i.a L.fem. n. *Jonesia* of Jones, honoring Dorothy Jones, a British microbiologist.

Nonsporing rods showing branched Y- and club-like forms. Irregular, branching rods may occur in one species. Gram-positive, but many cells, especially in older cultures, are readily decolorized. Filamentous and coccoid cells may also occur in older cultures. Motile or nonmotile. Colonies on nutrient agar are 0.5–1.5 mm in diameter (24–48 h), convex, smooth, grayish, and translucid to opaque, becoming yellowish in 10–20 days. Colonies of may show rhizoid appearance (4 mm diameter). Catalase-positive, oxidase-negative. Chemotaxonomic properties are indicated in ❯ *Table 25.1*. Cell wall contains teichoic acid of the poly(ribitol phosphate) type (only *J. denitrificans* investigated). No lipoteichoic acid. Acid production from a wide range of mono- and polysaccharides.

The mol% G+C of DNA is 56–58.

The type species is *Jonesia denitrificans* Prevot 1961^{AL}. The type strain is CIP 55.134^T.

The two type strains *J. denitrificans* DSM 20603^T and *J. quinhaiensis* DSM 1570^T share 96.6 % 16S rRNA gene sequence similarity. According to API 50 CHE substrate panel, the type strains of both species utilize: glycerol, L-arabinose, D-xylose, galactose, D-glucose, D-fructose, D-mannose, arbutine, aesculin, salicine, cellobiose, maltose, lactose, saccharose, trehalose, amidon, glycogen, ß-gentiobiose, D-turanose, and 5-ceto-gluconate. According to the Biolog GP2 substrate panel, the following substrates were utilized in addition: dextrin, glycerol, maltotriose, D-psicose, D-ribose, adenosine, 2'-deoxyadenosin. Additional metabolic properties are indicated in ❯ *Table 25.2* (modified from Schumann et al. 2004) and ❯ *Table 25.3*.

Table 25.2
Differentiating cultural and physiological differences between *Jonesia denitrificans* DSM 20603^T and *J. quinghaiensis* DSM 15701^T (Data from Schumann et al. 2004)

Differentiating properties	*J. denitrificans* DSM 20603^{T1}	*J. quinghaiensis* DSM 15701^{T1}
Morphology	Coccoid to irregular rods, (0.3–0.5 × 2–3 μm) Filamentous forms may develop.	Rod shaped (0.5 × 1.5–2 μm)
Staining	Gram-positive, older cells may be Gram-negative	Gram-positive
Motility	+, peritrichous flagella	–
Optimal growth temperature	~30 °C.	20–30 °C

+, positive; –, negative; w, weakly positive

In addition, *J. denitrificans* has the following properties: Temperature limits of growth 10–40 °C. Cells do not survive heating at 60 °C for 30 min. Grow in 5 % but not 10 % (w/v) NaCl. Catalase-positive. Oxidase-negative. Facultatively anaerobic. Acid but no gas produced from melibiose, starch, and dextrin. Weak acid production from melezitose. No acid produced from L-fucose, D-arabinose, sorbose, L-xylose, methyl β-xyloside, rhamnose, erythritol, inositol, dulcitol, sorbitol, a-methyl-d-glucoside, a-methyl-d-mannoside, *N*-acetylglucosamine, inulin, d-raffinose, xylitol, d-fucose, d-arabitol, l-arabitol, gluconate, 2-ketogluconate, and melibiose, (API50CH). Extracellular enzymes hydrolyze DNA, RNA, cellulose, and starch but not gelatin, chitin, casein, lecithin (egg yolk), xanthine, tyrosine, Tween 20, or Tween 80; slight hydrolysis of Tweens 40 and 60 takes place after 7 d. Phosphatase, sulfatase, and urease are not produced. Esculin is hydrolyzed. Sodium hippurate is not hydrolyzed or only weakly hydrolyzed (H_2SO_4 method) after 10 d. Acid produced in litmus milk. Nitrates are reduced to nitrites. H2S-negative. Indole-negative. Galactosamine is a diagnostic whole-cell sugar.

Jonesia quinghaiensis is in addition characterized by an optimal pH of 7–9; optimal salt concentration is 2.0–7.5 % (w/v) NaCl.

Source: mud of a soda lake in Qinghai, a Western province of China. The type strain is QH3A7^T.

Ruania Gu et al. 2007, 811.^{VP}

Ru.an'i.a. N. L. n. *Ruania* named after Ji-Sheng Ruan, a Chinese microbiologist.

Gram-positive, aerobic, mesophilic, moderately halotolerant, non-acid-fast, nonmotile and non-spore-forming cocci. No rod-coccus cycle observed. Chemotaxonomic properties are indicated in *Table 25.1*. The genus contains a single species, *Ruania albidiflava*, the type strain is 3-6^T.

Cells are 0.5–0.8 μm in diameter. Colonies are convex and moist, with a pale yellow color. Growth optimum at 28° C. pH range for growth is of 5.5–12.5 with an optimum at pH 6.5–10.5. Can tolerate up to 10 % (w/v) NaCl. Catalase-positive, oxidase-negative. Indole and Voges-Proskauer reactions are negative. H_2S is not produced. Potato starch is decomposed, but adenine, casein, aesculin, gelatin, hippurate, hypoxanthine, tyrosine, urea, and xanthine are not. Acids are produced from salicin, D-ribose, methyl β-D-xylopyranoside, D-fructose, aesculin, D-maltose, D-xylose, and L-fucose, but not from L-xylose, L-sorbose, dulcitol, inositol, D-sorbitol, methyl α-D-mannopyranoside, methyl α-D-glucopyranoside, amygdalin, D-lactose, sucrose, D-trehalose, inulin, D-melezitose, D-raffinose, starch, glycogen, xylitol, gentiobiose, D-fucose, DL-arabitol, 2-ketogluconate. Additional reactions are listed in *Table 25.3*. Utilizes the following substrates as sole carbon sources: acetate, D-lactose, D-melezitose, L-alanine, L-cysteine, L-leucine, L-methionine, L-proline, methyl a-D-glucoside, oxalate, D-fructose, D-glucose, D-glutamic acid, D-maltose, D-ribose, D-sorbitol, D-trehalose, glycerol, L-arginine, L-fucose, and sucrose. The following substrates are not utilized: citrate, D-cellobiose, D-galactose, D-inulin, D-lactulose, D-mannitol, D-mannose, D-raffinose, D-rhamnose, D-sorbose, D-xylose, dulcitol, erythritol, glycogen, inositol, L-arabinose, L-leucinamide, L-ornithine, L-phenylalanine, L-tyrosine, L-valine, malate, malonate, nicotinamide, salicin, and succinate.

In the API ZYM assay, tests are positive for cystine arylamidase, a-fucosidase, lipase (C8), acid phosphatase, β-galactosidase, b-glucosidase, N-acetyl-β-glucosaminidase, and a-mannosidase, but negative for esterase (C4), lipase (C14), trypsin, chymotrypsin, and b-glucuronidase (see also *Table 25.4*).

Whole-cell sugars are galactose and glucose.

[a]Schumann et al. 2004; [b]Gu et al. 2007; [c]Tang et al. 2010a

The type species is *Ruania albidiflava.*

Haloactinobacterium Tang, Zhi, Wang, Wu, Lee, Kim, Lou, Xu and Li 2010, 2118.[VP]

Ha.lo.ac.ti.no.bac.te'ri.um. Gr. n. hals, halos salt; Gr. n. actis, actinos a ray; L. neut n.bacterium a rod; N.L. neut. n. *Haloactinobacterium* a halophilic actinobacterium.

Cells are aerobic, Gram-positive, nonmotile, and moderately halophilic short rods (0.3–0.4 × 0.6–0.7 μm). No rod-coccus life cycle. The chemotaxonomic properties are indicated in ❯ *Table 25.1*.

The genus contains a single species *Haloactinobacterium album*, the type strain is YIM39906[T].

In addition to properties indicated in ❯ *Tables 25.1*, ❯ *25.3*, and ❯ *25.4*, the species is characterized as follows: Colonies are creamy white, circular, smooth, opaque and non-pigmented on GTY agar supplemented with 10 % NaCl. Grows at 10–40 °C (optimum 37 °C), at pH 6.0–10.0 (optimum pH 7.0–8.0), and with 2–16 % (w/v) NaCl (optimum 7–10 % NaCl). Catalase-positive and oxidase-negative. Voges-Proskauer tests are negative. Cellulose and aesculin are hydrolyzed, but gelatin, casein, dextrin, starch, DNA, chitin, urea, and Tweens 20, 40, 60, and 80 are not. H_2S production, melanin, and indole are negative. With API ZYM, positive for esterase lipase (C8), cystine arylamidase, β-galactosidase, β-glucosidase, α-mannosidase, and N-acetyl-β-glucosaminidase, but negative for lipase (C14), trypsin α-chymotrypsin, naphthol-AS-BI-phosphohydrolase, and β-glucuronidase. With GP2 MicroPlates, oxidizes L-arabinose, D-fructose, L-fucose, D-galactose, a-D-glucose, maltose, D-psicose, D-ribose, sucrose, D-xylose, methyl β-D-galactoside, pyruvic acid, pyruvic acid methylester, DL-α-glycerol phosphate, D,L-lactic acid, acetic acid, glycerol, and amygdalin.

Produces acid (see also ❯ *Table 25.4*) from maltose, D-mannose, L-rhamnose, D-ribose, D-xylose, methyl β-D-xylopyranoside, aesculin, and salicin, but not from D-fucose, gentiobiose, lactose, melezitose, melibiose, raffinose, L-sorbose, starch, sucrose, trehalose, L-xylose, DL-arabitol, dulcitol, inositol, D-mannitol, D-sorbitol, xylitol, glycogen, inulin, methyl α-D-mannopyranoside, methyl a-glucopyranoside, potassium 5-ketogluconate, or potassium 2-ketogluconate.

Bogoriella Groth et al. 1997, 793.[VP]

Bo.go.ri.el'la.M. L. dim. fem. n. *Bogoriella*, named after Lake Bogoria in Kenya, the place from which isolate HKI 0088 T originated.

Cells are nonmotile, irregular, and rod shaped or coccoid and occur singly, in pairs, or in small irregular clusters. Aerobic

Table 25.4
Physiological characteristics of *Ruania albidiflava* 3-6^T and *Haloactinobacterium album* YIM 93306^T. Both type strains produce acids (API 50CHE) from D-xylose, D-fructose galactose, aesculin, maltose, lactose, sucrose, trehalose, starch, glycogen β-gentiobiose, salicin and utilize (Biolog GP2 substrate panel) dextrin, glycerol, maltotriose, D-psicose, D-ribose, and adenosine-2′-deoxyadenosine, other compounds used are listed in Table 25.3. or microaerophilic. Very poor growth can occur under anaerobic conditions. Catalase-positive and oxidase-negative. Chemotaxonomic properties are indicated in Tables 25.1 and 25.5.

The genus contains a single species, *Bogoriella caseilytica*. The type strain HKI 0088^T.

Cells are 0.5 to 0.8 by 1.0 to 2.5 µm. A few cells may be filamentous and up to 10 µm long. Colonies are round, smooth, slightly convex, glistening, and 1–3 mm in diameter. The colony color varies from pale yellow to intense yellow. Alkaliphilic. Optimal growth occurs at pH 9–10 and at 28–37 °C. NaCl tolerant. Aerobic or microaerophilic. In addition to the metabolic properties indicated in Tables 25.5, the species produces acids from D-cellobiose, dextrin, D-fructose, D-galactose, D-glucose, D-glucitol, glycerol, inulin, lactose, maltose, D-raffinose, D-ribose, salicin, sucrose, potato starch, trehalose, and D-xylose. Aconitate, benzoate, citrate, formate, succinate, and tartrate are not utilized as carbon sources. Starch, esculin, casein, and gelatin are hydrolyzed while urea, hippurate, adenine, hypoxanthine, xanthine, tyrosine, and Tween 80 are not decomposed or hydrolyzed. Hydrogen sulfide is produced; indole is not produced. Methyl red and Voges-Proskauer reactions are negative.

Altenburger et al. 2002, 880^{VP}, emend Li et al. 2007, 1426.

Ge.or.gen'i.a. suff.-ia to denote a locality; N.L. fem. n. *Georgenia* referring to the village St. Georgen in Styria, where the type strain was isolated.

Cells are nonmotile, exhibiting a rod-coccus cycle. Rods and cocci occur singly or in small clusters. Cocci are 1 µm in diameter, rods are 2 µm in length and 1 µm in width. Growth occurs under both aerobic and anaerobic conditions. Oxidase- and catalase-positive. Chemotaxonomic properties are indicated in Tables 25.1 and 25.5. In addition, a low content of polyamines is present in the type species which are spermidine and spermine as major polyamines.

The type species is *Georgenia muralis*, the type strain is 1A-C^T. Type strains of the other species are indicated in Table 25.5.

Phenotypic tests on type strains included a variety of different determination methods, such as a non-commercial microtiter plate system for carbon source utilization, sugar fermentation, and qualitative enzymes tests (Kämpfer et al. 1991) for *G. muralis* (Altenburger et al. 2002) and *G. soli* (Kämpfer et al. 2010); API ZYM, API Coryne, API 20 E, and API 50CH systems (bioMérieux) for *G. thermotolerans* (Hamada et al. 2009b) and *G. halophila* (Tang et al. 2010b); API ID32 GN and API 20NE for *G. daeguensis* (Woo et al. 2012); and, in addition to API ID32 GN, another system for *G. ruanii* (Hangzhou Tianhe Microorganism Reagent tubes) (Li et al. 2007). Reactions determined for the same strain in different studies agree by and large when the same methods were applied (Altenburger et al. 2002 and Kämpfer et al. 2010), but differed significantly when the same strain tested by a different method than the originally applied method (see Kämpfer et al. 2010 versus Hamada et al. 2009b). As the same method was used to characterize all available 6 type strains of *Georgenia* (Woo et al. 2012), the results of this study are included here to show

Table 25.5

Differential metabolic and chemotaxonomic characteristics of type strains of *Georgenia* (*G*; modified *Table 1* of Woo et al. 2012) and *Bogoriella* (*B.*, Groth et al. 1997). In substrate assimilation tests, all strains showed identical biochemical characteristics except those indicated here. For a detailed listing, see Woo et al. (2012)

[a]*Georgenia* type strains were analyzed by API GN and API 20NE, while the type strain of *Bogoriella* was analyzed by Biolog GP

[b]no interpeptide bridge structure was determined, proposed was L-Lys-L-Glu

[c]Different proportions of fatty acids were reported in the original descriptions of type strains by Kämpfer et al.(2010), Altenburger et al. (2002), Hamada et al. (2009b), Li et al. (2007), and Tang et al. (2010b)

differentiating properties among the type strains (*Table 25.5*) and the reader is referred to the original studies for obtaining information on additional tests of individual type strains. All strains of *Georgenia* are positive for esculin hydrolysis and p-nitrophenyl-β-D-galactopyranoside but negative for arginine dihydrolase, urease, indole production and glucose acidification. In addition to the information indicated in *Table 25.5*, all type strains utilize glucose, sucrose, maltose, gluconate, and glycogen

for growth but not L-histidine, L-serine, L-proline, D-sorbitol, inositol, caprate, adipate, citrate, phenyl-acetate, Na-malonate, lactate, propionate, valerate, trisodium citrate, and 4-hydroxybenzoate (Woo et al. 2012).

Isolation, Enrichment, and Maintenance Procedures

Isolation and Enrichment

Jonesia denitrificans CIP 55.134^T was isolated from cooked ox blood (Sohier et al. 1948), but the natural habitat of the organism is not known. It grows well on tryptic soy broth agar (TSBA, Difco, containing 1.5 % Difco agar) and on tryptose blood agar base to which 1 % glucose is added. *Jonesia qinghaiensis* QH3A7^T (Schumann et al. 2004) was isolated from a mud sample of a soda lake (ca. pH 9.0) in the west of China. Isolation was done at 28° C by dilution plating on Bacto marine broth agar (MBA), pH value 7.2.

Ruania albidiflava 3-6^T (Gu et al. 2007) originate from a cotton field farmland soil sample, Shandong Province, China. A 1-g soil sample was suspended in 10-ml sterile distilled water and mixed thoroughly by shaking overnight at room temperature. The soil-water suspension was serially diluted and spread onto yeast extract-starch agar (Riken-Japan Collection of Microorganisms medium no. 42) plates, followed by incubation for 1 week under humid conditions at 28 °C.

Haloactinobacterium album YIM 93306^T (Tang et al. 2010a) was isolated from a soil sample collected from salt Lake Qijiaojing Xinjiang province, northwest China after 3 weeks incubation at 37 °C on glucose-tryptone-yeast (GTY) agar containing (g per liter) glucose 1, tryptone 0.5, yeast extract 2, $CaCl_2$ 1, NaCl 100, and agar15, [final pH not adjusted] supplemented with 10 % (w/v) NaCl. NaCl was sterilized separately before being added to the medium.

Bogoriella caseilytica HKI0088^T (Groth et al. 1997) was isolated from a soda soil sample, near lake Bogoria, in the Kenian-Tanzanian Rift Valley by dilution plating on a medium containing (g per liter) glucose 10.0, peptone (Difco) 5.0, yeast extract (Difco) 5.0, KH_2PO 1.0, $MgSO_4 \cdot 7H_2O$ 0.2, NaCl 40.0, Na_2CO_3 10.0, and agar 20.0 (pH 9.6). The NaCl and Na_2C0_3 were autoclaved separately and were added to the organic compounds at 60 °C before the agar medium was poured.

G. daeguensis 2C6-43^T (Woo et al. 2012) originate from an activated sludge sample, Korea, that was initially incubated with 50 ppm (0.39 mM) of 4-Chlorphenole and then diluted serially in 0.85 % saline solution. Aliquots of each serial dilution were spread on R2A agar and incubated at 30 °C for 14 days. The isolate was routinely cultured at 30 °C on R2A agar containing (g per liter) glucose 0.5, soluble starch 0.5, casein hydrolysate 0.5, yeast extract 0.5, peptone 0.5, MgSO4 · 7H2O 0.05, KH2PO4 0.3, and agar 15 (7.2 prior to autoclaving).

G. ruanii YIM 004^T (Li et al. 2007) was isolated from a forest-soil sample collected from Lijiang, Yunnan Province, China, after 2-week incubation at 28 °C on ISP 2 agar (Shirling and Gottlieb 1966).

G. halophila YIM 93316^T (Tang et al. 2010b) was isolated from soil of the same area from which *Haloactinobacterium album* has been recovered (Qijiaojing Lake, Xinjiang, China) after 3 weeks of incubation at 37 °C on the same medium that was also used for the isolation of *H. album* (final pH 7.5).

G. soli CC-NMPT-T3^T (Kämpfer et al. 2010) was isolated from iron-ore-contaminated soil near New Mangalore Port, Karnataka, India, on nutrient agar (Oxoid).

G. muralis 1A-C^T (Altenburger et al. 2002) was recovered from a medieval wall painting in the church of St Georgen, Styria, Austria, as described by Altenburger et al. (1996). Approximately 1-g material was collected in a sterile tube. The homogenized samples were suspended in sterile saline with 0.001 % Tween 80 and shaken continuously for 1 h; 0.1 ml of appropriate dilutions was transferred to casein mineral medium agar plates containing (g per liter) K_2HPO_4 0.6, Na_2HPO_4 $2H_2O$ 0.5, $MgS0_4 \cdot 7H_2O$ 0.05, $MgCl_2 \cdot 7H$,O 0.1, KNO_3 0.2, $FeCl_3 \cdot 6H_2O$ 0.01, casein 0.8, yeast extract 0.4 (pH 7.0) plus 2 % sucrose.

G. thermotolerans TT02 -04^T (Hamada et al. 2009b) was isolated from a forest-soil sample in Iriomote island, Japan, using the selective SDS/yeast extract pretreatment of soil which was mixed with a solution containing yeast extract (YE) 6 % and sodium dodecyl sulfate (SDS) 0.05 %, at 40 °C for 20 min (Hayakawa and Nonomura 1987). The slurry was subsequently diluted with water and the sample was allowed to incubate for a few week on humic acid-vitamin (HV) agar plates containing nalidixic acid 20 mg/L. Humic acid-vitamin medium contains (per liter) humic acid 1 g, Na_2PO_4 0.5 g, KCL 1.7 g, $MgSO_4 \cdot 7H_2O$ 50 mg, $FeSO_4 \cdot 7H_2O$ 10 mg, $CaCO_3$ 10 mg, agar 10. Before adding, humic acids are dissolved in 10 mo of 0.2 N NaOH. The other components are dissolved in distilled water and the pH is adjusted to 7.2, then autoclaved; 1 ml of the vitamin stock solution is added by sterile filtration (Hayakawa and Nonomura 1989).

Maintenance

Members of this family do not require special procedures for maintenance and medium and long-term storage. Facultative anaerobic strains may be preserved for some months by stab inoculation in nutrient agar (Tryptose Agar for *J. denitrificans*, or other similar media) in screw-capped vials. These should be stored at room or, preferably refrigerator temperature. Generally strains are maintained on isolation medium as agar slants at 4 °C for a few days. GTY agar slants for G. halophila contained 10 % NaCl (w/v).

Medium-term maintenance is in 20 % (v/v) glycerol suspensions at −20 °C or at −70 °C.

Long-term preservation is by lyophilization or in liquid nitrogen.

Ecology

As the habitat of most species of the five genera is only known for mainly the type strain, information on the ecological niche and on ecological function of members of the three families is lacking. As for other members of the order *Micrococcales*, soil appears to be the natural environment for several species to thrive: Two type strains were isolated from forest soil, two other strains from halophilic soil. On the other hand, the isolation source cooked ox blood, activated sludge, or a medieval wall painting may point toward wind or water-borne random niche occupation and unknown functions. Actually, as judged from the few reports on other strains affiliated to the five genera, the isolation source is broader. Internet search on *Georgenia* reveals the presence of names of species which have no standing in taxonomy as they have never validly published: Chen, C., and Li, W.-J. "Georgenia deserti sp. nov. isolated from a desert soil in Egypt" and "Georgenia ferrireducens" Pukhova, N.Y., Pukhov, D.E., Poltaraus, A.B., and Rodionova, T.A. "*Georgenia ferrireducens* sp. nov., a novel Fe(III) reducing actinobacterium". Strain HM06-11, found in drilling draining fluid of a deep subsurface sample, was related to *Georgenia muralis* 3A-1 (Mayhew et al. 2008). Another strain related to *Georgenia muralis* by BLAST analysis (100 % similarity, accession no AB094466) was isolated from sub-seafloor sediment of the sea of Okhotsk (Inagaki et al. 2003). A *Georgenia* strain with high similarity to sequences of as-yet uncultured *Georgenia* strains and to *G. desertii* (98 % similarity, accession no DQ203185) was cultivated from oral squamous cell carcinoma tissue removed from a 96-year-old female patient (Hooper et al. 2006). Airway specimen analysis from acute exacerbations of chronic obstructive pulmonary disease (Huang et al. 2010) by 16S rRNA phylochip analyses resulted in the detection many actinobacteria including a single *Georgenia* signal with relationship to *G. muralis* 3A-1. The NCBI taxonomy browser lists several additional unnamed strains and clones affiliated to *Georgenia*, e.g., from the halophilic Lunar Lake, India (accession number FN995635), activated sludge, Japan (AB211016), Taklamaka desert, China (EF01725), Phoenix spacecraft associated surfaces (EU977822), and the marine environment (JF346459).

Information on additional strains of the families *Jonesiaceae* and *Ruaniaceae* is sparse. A single GenBank entry is found for an uncultured *Ruania* strain (accession number HQ646261) detected in a denitrifying sulfide removal process. A single clone remotely related to *Jonesia* spp. (accession number DQ 788537) was found in a biofilm of a recirculation aquaculture system effluent (Schneider et al. 2007).

Pathogenicity and Clinical Significance

Due to its original classification as a member of *Listeria*, *Jonesia denitrificans* is classified as a biosafety level group 2 organism. It is β-hemolysis negative and CAMP test against *Staphylococcus aureus* and *Rhodococcus equi* is also negative. It is serologically distinct from *Listeria* spp. and from *Erysipelothrix* spp. (Welshimer and Meredith 1971; Wilkinson and Jones 1975). It is pathogenic to rats and mice when injected intraperitoneally but does not cause conjunctivitis when instilled into the eyes of rabbits and guinea pigs. The finding of some strains of *Georgenia* in clinical material of human should not be used elevate their biosafety level as long as their direct involvement in pathogenicity has been proven.

J. denitrificans is sensitive by agar diffusion method to penicillin, streptomycin, chloramphenicol, aureomycin, terramycin, erythromycin, tetracycline, bacitracin, novobiocin, oleandomycin, kanamycin, vancomycin, colomycin, polymyxin B, and nitrofurantoin but resistant to sulfonamide, neomycin, and nalidixic acid.

Ruania albidoflava cells are susceptible to ampicillin (10 mg), chloramphenicol (30 mg), ciprofloxacin (5 mg), erythromycin (15 mg), gentamicin (10 mg), kanamycin (30 mg), neomycin (30 mg), polymyxin B (300 IU), rifampicin (15 mg), and streptomycin (10 mg). Not susceptible to nitrofurantoin (300 mg) or oxacillin (1 mg).

Bogoriella caseilytica cells are susceptible to ampicillin, chloramphenicol, ciprofloxacin, erythromycin, gentamicin, kanamycin, lincomycin, neomycin, oxacillin, oxytetracycline, penicillin G, polymyxin B, rifampin, and streptomycin. Cells are resistant to nitrofuran and sulfonamid.

Georgenia ruanii ells are susceptible to penicillin G, vancomycin, polymyxin B erythromycin, terramycin, aureomycin, tetracycline, streptomycin, novobiocin, gentamicin, and chloramphenicol. Cells are resistant to oleandomycin and nalidixic acid.

No information on antibiotic sensitivity and resistance is available for *J. quinghaiensis, Haloactinobacterium album, Georgenia muralis, G. thermotolerans, G. soli, G. daeguensis*, and *G. halophila.*

Application

The only evidence that any strain of the three families is involved in application originates from a study by Sianidis et al. (2005) involving a strain of *Jonesia* (DSM14140 with restricted distribution). This strain has been used in the large-scale production of a xyloglucanase (Xeg, family 74 glycoside hydrolases). Xeg was overexpressed in *Streptomyces lividans* TK24 and is the longest heterologous polypeptide shown to be secreted from *S. lividans.*

26 The Suborder *Kineosporiineae*

Tomohiko Tamura · Ken-Ichiro Suzuki
Biological Resource Center (NBRC), National Institute of Technology and Evaluation (NITE), Kisarazu-shi, Chiba, Japan

Abstract
Kineosporiaceae is only one family within the order "*Kineosporiales,*" which includes the genera *Angustibacter*, *Kineococcus*, *Kineosporia*, *Pseudokineococcus*, and *Quadrisphaera* at this writing.

Members of the genera *Angustibacter*, *Kineococcus*, *Pseudokineococcus*, and *Quadrisphaera* are characterized by formation of cocci to rods, *meso*-diaminopimelic acid as a cell wall diamino acid, saturated, iso-branched methyl and anteiso branched methyl fatty acid as the cellular fatty acid. The members of the genus *Kineosporia* are characterized by formation of spores on substrate hypha by the intermediary of sporophores, *meso*- and LL-diaminopimelic acid as a cell wall diamino acid, saturated, unsaturated, and 10 methyl branched methyl fatty acid as the cellular fatty acid.

Members of this family are found in soil, desert sand, coast sediment, shield cell facility, aerobic granule, air sample, roof tile, sphagnum, leaf, fallen leaf, plant litter, root, on stem of plant.

Taxonomy, Historical and Current

Short Description of the Families

The family description is based mainly on phylogenetic positions and patterns of 16S rRNA gene sequence signatures.

Kineosporiaceae Zhi, Li and Stackebrandt 2009, 596^{VP}

Ki'ne.o.spo.ri.a'ce.ae. N.L. fem. n. *Kineosporia* type genus of the family; -aceae ending to denote a family; N.L. fem. pl. n. *Kineosporiaceae* the *Kineosporia* family (Zhi et al. 2009).

Phylogenetically, a member of the order "*Frankiales*" (Ludwig et al. 2012), phylum Actinobacteria.

The family contains the genera *Angustibacter* (Tamura et al. 2010; Kim et al. 2013; Lee 2013), *Kineococcus* (Yokota et al. 1993), *Kineosporia* (Pagani and Parenti 1978; Itoh et al. 1989; Kudo et al. 1998), *Pseudokineococcus* (Jurado et al. 2011), and *Quadrisphaera* (Maszenan et al. 2005).

Substrate hypha may occur. Motile or nonmotile. Cross-linkage of peptidoglycan is by the A type; diagnostic diamino acids include *meso*-diaminopimelic acid or *meso*- and LL- diaminopimelic acid. Each peptidoglycan is directly linked without interpeptide bridges, and the muramic acid in peptidoglycan is *N*-acetylated. The cellular fatty acids are a complex mixture of straight-chain saturated, monounsaturated, and iso- and anteiso-methyl-branched acids. Predominant fatty acid is C16:0 and C18:1 for *Kineosporia*, anteiso-C15:0 for *Kineococcus*, *Pseudokineococcus*, and *Quadrisphaera*, and iso-C17:0, iso-C15:0, C16:0, iso-C16:0, anteiso-C15:0, anteiso-C17:0, and/or C16:1 for *Angustibacter*. Menaquinone MK-9(H_4), MK-9(H_2), or MK-8(H_2) is the predominant isoprenoid quinone. The pattern of 16S rRNA signatures consists of nucleotides at positions 127:234 (A–U), 142:221 (C–U), 598:640

E. Rosenberg et al. (eds.), *The Prokaryotes – Actinobacteria*, DOI 10.1007/978-3-642-30138-4_179,

Table 26.1
Diagnostic properties of the genera *Kineosporia*, *Angustibacter*, *Kineococcus*, *Pseudokineococcus* and *Quadrisphaera Fodinicola* belonging in the family *Kineosporiaceae* (Jurado et al. 2011, amended)

Characteristic	*Kineosporia*	*Angustibacter*	*Kineococcus*	*Pseudokineococcus*	*Quadrisphaera*
Cell morphology	Single spores borne at tips of substrate hyphae and spore clusters on a sporophore	Irregular rods and cocci	Cocci in tetrad arrangements	Cocci in pairs, tetrads and clusters	Cocci in tetrad arrangements
Motility	Motile	Motile or Non-motile	Motile or non-motile	Motile	Non-motile
Cell-wall diamino acid(s)	meso- and LL-A2pm	meso-A2pm	meso-A2pm	meso-A2pm	meso-A2pm

Predominant menaquinone	MK-9(H4)	MK-9(H4)	MK-9(H2)	MK-9(H2)	MK-8(H2)
Polar lipids	PC, DPG, PI, PIM	DPG, PG, PI, PIM	DPG, PG, GL	DPG, PG, PL, GL, PGL, PI	DPG, PG, PI
Characteristic sugars	Gal, Man, Rib	Gal, Rib	Gal, Ara	Rib, Rha, Gal, Ara	ND
DNA G+C content (mol%)	69–71	71–74	73–77	77	75

Data from Tamura et al. (2010), Lee (2006) and Jurado et al. (2011)
A2pm 2,6-diaminopimelic acid, *A* anteiso-methyl-branched, *I* iso-methyl-branched, *M* 9- 10-methyl-branched, *S* straight-chain saturated, *U* monounsaturated, *DPG* diphosphatidylglycerol, *GL* unknown glycolipid, *PC* phosphatidylcholine, *PG* phosphatidylglycerol, *PI* phosphatidylinositol, *PIM* phosphatidylinositol mannosides, *PL* unknown phospholipids, *PGL* unknown phosphoglycolipid, *Ara* arabinose, *Gal* galactose, *Man* mannose, *Rha* rhamnose, *Rib* ribose, *ND* no data

(U–G), 840:846 (A–C), 845 (A), 986:1218 (A–U), 1163:1173 (G–U), 1164:1172 (G–C), and 1165:1171 (G–A). Predominant polar lipids include diphosphatidylglycerol, phosphatidylglycerol, phosphatidylinositol, phosphatidylinositolmannosides, phosphatidylcholine, and several phosphoglycolipids, phospholipids, and glycolipids. Phosphatidylethanolamine is absent. Mycolic acids and teichoic acids are absent. Galactose, as a diagnostic whole-cell sugar, is present. G+C values are in the DNA range between 69 and 77 mol%. The family *Kineosporiaceae* was proposed by Zhi et al. (2009); the genera *Kineococcus, Kineosporia, and Quadrisphaera* are assigned to this family. Diagnostic properties of the genera *Kineosporia*, *Angustibacter Kineococcus, Pseudokineococcus, and Quadrisphaera* are shown in ❯ *Tables 26.1* and ❯ *26.2*.

Phylogenetic Structure of the Family and Its Genera

The members of the family *Kineosporiaceae* form a cluster in the tree of the NJ method based on the 16S rRNA gene sequences, while those of ML the method indicate that the genus *Angustibacter* is placed outside the family. Consequently, within the family, the five genera formed separate lineages in the NJ tree and, except the genus *Angustibacter*, in the ML tree (❯ *Figs. 26.1* and ❯ *26.2*).

Molecular Analyses

DNA-DNA Hybridization Studies

DNA-DNA hybridization (DDH) studies have been performed on *Kineosporiaceae* strains by Kudo et al. (1998) to separate five species including the type species. Sakiyama et al. (2009) confirmed the homogeneity and independency of three strains of *Kineosporia babensis* by DDH. DDH was carried out between the type strain of *Kineosporia mesophila* and those of the five species of the genus and showed 59–34 % relatedness (Li et al. 2009b). DDH relatedness has been reported between type strains of *Angustibacter aerolatus* and *Angustibacter luteus* (42–47 %; Kim et al. 2013); between type strains of *Angustibacter peucedani* and *Angustibacter luteus* (22.3 ± 0.9 %; Lee 2013); between type strains of *Kineococcus gynurae* and type strains of *Kineococcus aurantiacus* and *Kineococcus radiotolerans* (25 % and 39.4 %, respectively; Duangmal et al. 2008);

Table 26.2

Differentiating cultural features between type strains of *Kineosporia* (Li et al. 2009, amended)

Characteristic	*Kineosporia aurantiaca*	*Kineosporia babensis*	*Kineosporia mesophila*	*Kineosporia mikuniensis*	*Kineosporia rhamnosa*	*Kineosporia rhizophila*	*Kineosporia succinea*

All strains were positive for hydrolysis of urea and starch and for utilization of L-arabinose, cellobiose, D-fructose, D-galactose, glucose, maltose, D-mannitol and L-rhamnose. All strains were negative for decomposition of adenine, hypoxanthine and xanthine. + positive, – negative. [a]One of three strains tolerates up to 3 %

between type strains of *Kineococcus glutinatus* and *Kineococcus xinjiangensis* (41.6 ± 1.8 %; Nie et al. 2012); and between type strains of *Pseudokineococcus lusitanus* and *Kineococcus marinus* (46.6 ± 0.8 %; Jurado et al. 2011).

Genome Analyses

The whole genome sequence of the type strain of *Kineococcus radiotolerans* SRS30216 (GOLD ID Gc00615)

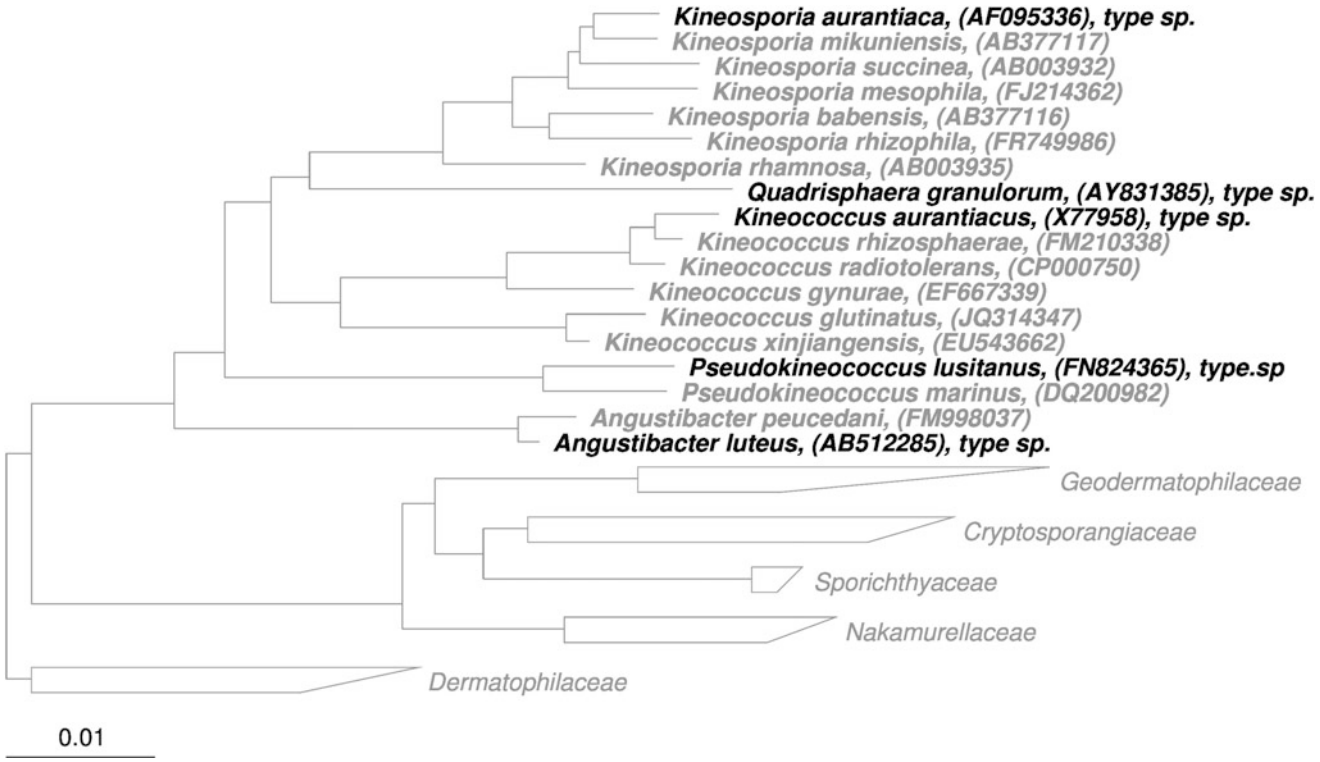

Fig. 26.1

Phylogenetic reconstruction of the family *Kineosporiaceae* based on 16S rRNA and created using the neighbor-joining algorithm with the Jukes-Cantor correction. The sequence datasets and alignments were used according to the All-Species Living Tree Project (LTP) database (Yarza et al. 2010; http://www.arb-silva.de/projects/living-tree). The tree topology was stabilized with the use of a representative set of nearly 750 high quality type strain sequences proportionally distributed among the different bacterial and archaeal phyla. In addition, a 40 % maximum frequency filter was applied in order to remove hypervariable positions and potentially misplaced bases from the alignment. Scale bar indicates estimated sequence divergence

has been released. The genome of the type strain of *Kineococcus radiotolerans* contains 4,957 kbp, 4,785 open reading frames (orfs), and a mol% G+C content of 74 %.

Phages

No phages have been observed to lyse strains of *Angustibacter*, *Kineococcus*, *Kineosporia*, *Pseudokineococcus*, and *Quadrisphaera*.

Phenotypic Analyses

Kineosporia Pagani and Parenti 1978, 289^{AL}, Emend. Kudo Matsushima Itoh Sasaki and Suzuki 1998

Ki.ne.o.sporia. Gr. n. kinesis, motion; N.L. fem. n. spora (from Gr. fem. n. spora, a seed), a spore; N.L. fem. n. *Kineosporia*, an organism that has motile spores.

Aerobic, Gram-positive, and nonacid fast. Colonies on agar medium lack aerial mycelia, form central projections with radiating vegetative hyphae, and are occasionally accompanied by bunches of spore clusters in the agar. Mature colonies have a gelatinous matrix, which confers a glossy appearance. Spores, which are spherical to ovoid or pyriform with a long axis of 1–2 μm, are catenated around the central projection or are located singly or aggregately at the tips of hyphae. The spores are motile with polar tufts of flagella.

The peptidoglycan contains both LL- and *meso*-DAP; the ratio in the cells from submerged culture containing both mycelia and spores is dependent on strains. *meso*-DAP is generally predominant in the cells of spore fraction (Kudo et al. 1998). The content of glycine is smaller in the spore fraction (Itoh et al. 1989). The whole cells contain galactose, glucose, mannose, and ribose, but the content of mannose is negligible in the spore fraction. In addition, rhamnose and 3-O-methylrhamnose are present in the cells of *Kineopsoria rhamnosa*. Phosphatidylcholine is a diagnostic phospholipid, and MK-9(II,III-H4) is present as a main menaquinone component. The cellular fatty acid profile mainly contains 16:0, 18:1, and 10Me 18:0 and lacks iso/anteiso branched fatty acids. 2-Hydroxy fatty acids are also present in some species. Lipid compositions are not significantly different in the whole cultured organism and the spore fraction. Mycolic acids are absent.

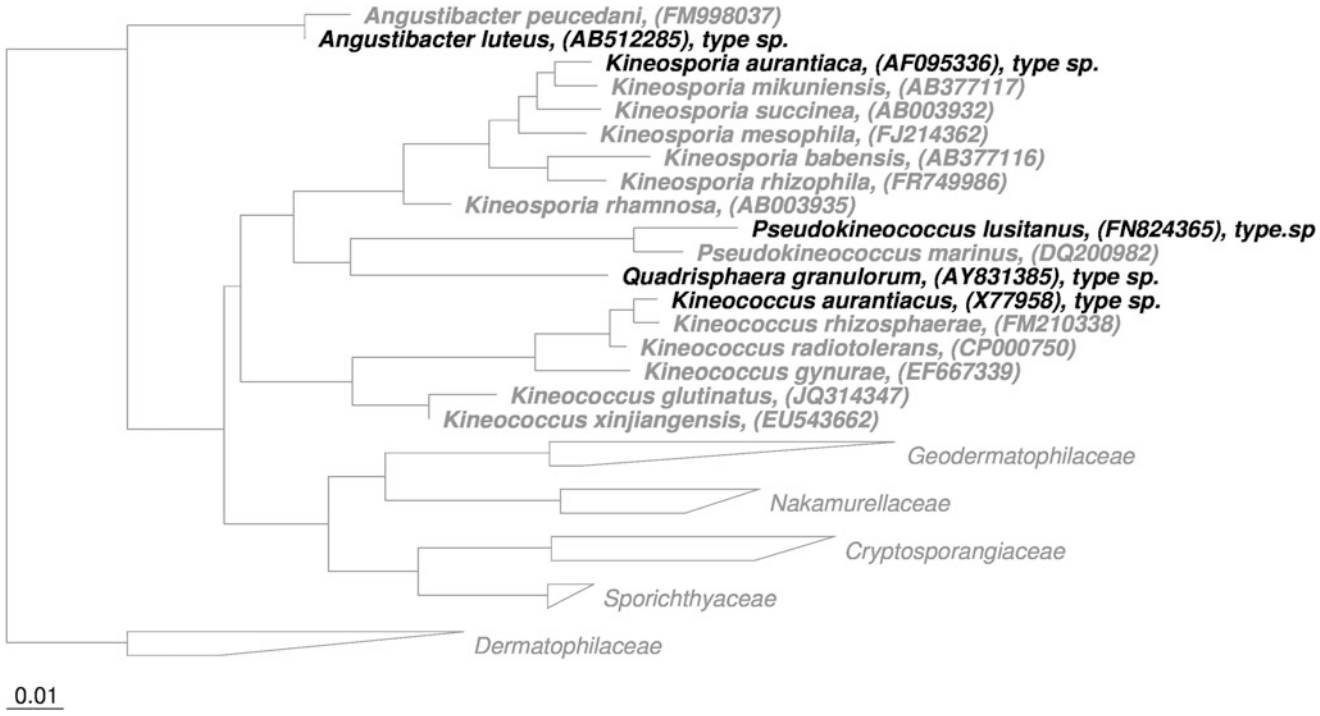

Fig. 26.2

Phylogenetic reconstruction of the family *Kineosporiaceae* based on 16S rRNA and created using the maximum likelihood algorithm RAxML (Stamatakis 2006). The sequence datasets and alignments were used according to the All-Species Living Tree Project (LTP) database (Yarza et al. 2010; http://www.arb-silva.de/projects/living-tree). Representative sequences from closely related taxa were used as outgroups. In addition, a 40 % maximum frequency filter was applied in order to remove hypervariable positions and potentially misplaced bases from the alignment. Scale bar indicates estimated sequence divergence

The mol% G+C content ranges from 68.3 to 70.8.

The type species is *Kineococcus aurantiaca* Pagani and Parenti 1978. Type strain is ATCC 29727 = DSM 43858 = NBRC 14067 = JCM 3230 = NRRL B-16913 = VKM Ac-702.

Angustibacter Tamura Ishida Otoguro Yamamura Hayakawa and Suzuki 2010, 2441^{VP}, Emend. Lee 2013[1]

An.gu.sti.bac'ter. L. adj. angustus narrow; N.L. masc. n. bacter a rod; N.L. masc. n. *Angustibacter* narrow bacterium (Table 26.3).

Gram-positive, non-spore-forming cocci to rods. Variable in motility and catalase. Aerobic or facultatively anaerobic. The peptidoglycan is of the A type (A1γ sensu; Schleifer and Kandler 1972) containing *meso*-diaminopimelic acid, alanine, and glutamic acid. Cell-wall sugars are galactose, glucose, and ribose. Mycolic acids are absent. The major menaquinone is MK-9(H4). The phospholipids comprise diphosphatidylglycerol, phosphatidylglycerol, phosphatidylinositol, and phosphatidylinositol mannoside. The cellular fatty acids are of the complex mixture of straight-chain saturated, monounsaturated, and iso- and anteiso-methyl-branched acids, and the composition is variable in species. Anteiso-C15:0, iso-C15:0, C16:0, iso-C16:0, and summed feature 9 (including iso-C17:1ω9c and/or C16:0 10-methyl) are predominating.

The mol% G + C content ranges from 70.9 to 73.6, and the type strain of the type species is 71 mol%.

The type species is *Angustibacter luteus* Tamura et al. 2010. Type strain is TT07R-79 = NBRC 105387 = KACC 14249 = JCM 17683.

Kineococcus Yokota Tamura Nishii and Hasegawa 1993, 52^{VP}

Ki.ne.o.coc'cus. Gr. n. kinesis, motion; N.L. masc. n. coccus (from Gr. masc. n. kokkos, a grain, seed), coccus; N.L. masc. n. *Kineococcus*, a motile coccus (Table 26.4).

Cells are Gram-positive, spherical, and 1.0–1.5 μm in diameter and occur in pairs, in tetrads, or in clusters. Motile with tufts of flagella. Endospores are not formed. Colonies are circular and rough and may be cream-colored to mange. Strictly aerobic. Catalase- and urease-positive. Oxidase-negative.

[1] The genus description was emended to contain motile, aerobic, and/or catalase-negative species by Kim et al. (2013) and Lee (2013) separately.

Data from Kim et al. (2013), Lee (2013), Tamura et al. (2010)

Strains are positive for aesculin hydrolysis and β-galactosidase (API 20NE), enzyme activation of alkaline phosphatase, acid phosphatase, esterase lipase (C8), valine arylamidase, leucine arylamidase, α-galactosidase, β-galactosidase, α-glucosidase and β-glucosidase (API ZYM), and acid production from D-glucose, aesculin ferric citrate, cellobiose, sucrose, raffinose, glycogen and melibiose (API 50CH). Both strains are negative for nitrate reduction, indole production, glucose fermentation, arginine dihydrolase and urease (API 20NE), utilization of malic acid, trisodium citrate, phenylacetic acid, itaconic acid, suberic acid, sodium malonate, lactic acid, L-alanine, 3-hydroxybutyric acid, L-serine, D-mannitol, L-fucose, D-sorbitol, propionic acid, capric acid, L-histidine, potassium 2-ketogluconate and 4-hydroxybenzoic acid (API 20NE and API 32GN), enzyme activation of lipase (C14), trypsin, α-chymotrypsin, β-glucuronidase, *N*-acetyl-β-glucosaminidase, α-mannosidase and α-fucosidase (API ZYM), and acid production from glycerol, erythritol, D-arabinose, D-adonitol, methyl β-D-xylopyranoside, L-sorbose, dulcitol, inositol, D-mannitol, D-sorbitol, methyl α-D-mannopyranoside, methyl α-D-glucopyranoside, *N*-acetylglucosamine, amygdalin, arbutin, salicin, inulin, melezitose, xylitol, turanose, D-tagatose, L-fucose, D-arabitol, L-arabitol, potassium gluconate, potassium 2-ketogluconate and potassium 5-ketogluconate (API 50CH). + Positive, *w* weakly positive, − negative, *nd* not determined

The cells do not reduce nitrate to nitrite. Acid is produced from glucose and some other sugars. Esculin is hydrolyzed. Starch, gelatine, and casein are not hydrolyzed. The optimum growth temperature is 27 °C.

The cell-wall peptidoglycan contains *meso*-DAP, alanine, and glutamic acid. The major menaquinone is MK-9(H2). Mycolic acid is not present. The major cellular fatty acid is anteiso-C15:0. Diphosphatidylglycerol, phosphatidylglycerol, and unidentified glycolipids are present as polar lipids.

The mol% G+C content of the type strain of the type species is 74 mol%.

The type species is *Kineococcus aurantiacus* Yokota et al. 1993. Type strain is RA 333 = ATCC 51238 = CIP 105426 = DSM 7487 = IFO (now NBRC) 15268 = JCM 10180 = VKM Ac-1947.

Pseudokineococcus Jurado Laiz Ortiz-Martinez Groth and Saiz-Jimenez 2011, 2515[VP]

Pseu.do.ki.ne.o.coc'cus. Gr. adj. pseudês false; NL. masc. n. *kineococcus* a bacterial genus name; N.L. masc. n. *Pseudokineococcus* the false *Kineococcus* (Table 26.5).

Cells are spherical and 1.0–1.5 μm in diameter and occur in pairs, in tetrads, or in clusters. Cells are motile and have tufts of flagella. Endospores are not formed. Gram-positive. Colonies are circular, rough, and orange-colored. Strictly aerobic. Catalase-positive and oxidase-negative. Do not reduce nitrate to nitrite. Acid is produced from glucose and some other sugars. Aesculin is hydrolyzed. The diagnostic diamino acid of the peptidoglycan is *meso*-diaminopimelic acid. The major menaquinone is MK-9(H2). Mycolic acids are

not present. The characteristic phospholipid of the genus is phosphatidylglycerol. Diphosphatidylglycerol and phosphatidylinositol may be present. The major cellular fatty acid is anteiso-C15:0.

The mol% G + C content of the type strain of the type species is 77 mol%.

The type species is *Pseudokineococcus lusitanus* Jurado et al. 2011. Type strain is T2A-S27 = CECT 7306 = DSM 23768 = LMG 24148.

Kineococcus marinus (Lee 2006) was transferred to the genus *Pseudokineococcus* by Jurado et al. (2011).

Quadrisphaera Maszenan Tay Schumann Jiang and Tay 2005, 1771[VP]

Qua.dri.sphae'ra. L. pref. numer. adj. quadr- four; L. fem. n. sphaera a ball, globe, sphere; N.L. fem. n. *Quadrisphaera* four-fold balls, coccus in tetrad.

Gram-positive, non-spore-forming cocci, 1 · 2–3 · 0 μm in diameter, occurring in tetrad arrangement, fitting the morphological description of tetrad-forming organisms. MK-8(H2) is the predominant menaquinone. The major cellular fatty acid is anteiso-C15:0.

The mol% G+C content of the type strain of the type species is 75 mol%.

The type species is *Quadrisphaera granulorum* Maszenan et al. 2005 (*Table 26.6*). Type strain is AG019 = ATCC BAA-1104 = DSM 44889 = JCM 16010.

Isolation, Enrichment, and Maintenance Procedures

Kineosporia aurantiaca was isolated from soil at St. Rphael, France, by cultivating on Czapek-glucose agar and incubating at 30 °C (Pagani and Parenti 1978). Strains of this species were also isolated from plant samples in Japan (Kudo et al. 1998).

+ positive, − negative, (+) weakly positive, +/− variable, *ND* not determined

Strains of *Kineosporia mikuniensis, Kineosporia rhizophila, Kineosporia rhamnosa*, and *Kineosporia succinea* were isolated from plant samples such as leaves of cat-tail (*Typha latifolia*), fallen leaves, root of galingale (*Cyperus microria*), and sphagnum in Japan. The collected samples were dried at 28 °C for at least 1 week and were ground with a blender after adding sterile water. The suspension was incorporated into an agar medium containing 0.2 g yeast extract (Difco) 50 mg cycloheximide, 50 mg nystatin, and 15 g agar in 1,000 ml distilled water (pH not adjusted) and poured to petridishes for incubation at 28 °C for more than 2 weeks. Colonies were picked up with a sterile needle under a stereomicroscope and transferred to yeast extract-starch agar (2 g yeast extract, 10 g soluble starch, and 15 g agar in 1,000 ml). In addition to the four species, two strains of *Kineosporia aurantiaca* were also isolated (Kudo et al. 1998).

Kineosporia babensis was isolated from plant litter collected from the mountainside at Ba Be National Park, Bac Kan Province, in northern Vietnam. The samples were dried at room temperature for 5–7 days and treated with rehydration-centrifugation method (Hayakawa et al. 2000) and inoculated on humic acid-vitamin agar (Hayakawa and Nonomura 1987) containing nalidixic acid (20 mg/l) and kabicidin (0.75 mg/l).

Kineosporia mesophila was isolated from a surface-sterilized stem sample of *Tripterygium wilfordii* from Yunnan province, southwest China. The procedure was according to that of Coombs and Franco (2003) followed by Li et al. (2009).

Angustibacter luteus was isolated by using the yeast extract-SDS method (Hayakawa and Nonomura 1989) from broad-leaf forest soil at Rishiri Island, Hokkaido, Japan. The type strain was picked up on HV medium (Hayakawa and Nonomura 1987) containing 20 mg/L nalidixic acid and 50 mg/L cycloheximide after incubating at 28 °C for 2 weeks. Subcultivation of the isolate was conducted in yeast extract-malt extract agar (ISP-2 medium: Shirling and Gottlieb 1966) containing 4 g/L yeast extract, 10 g/L malt extract, 4 g/L glucose, and 20 g/L agar (pH 7.3), yeast extract–soluble starch (YS) agar containing 2 g/L yeast extract, 10 g/L soluble starch, and 15 g agar (pH 7.3), and NBRC medium 802 (Code No. 398-01671; Wako Pure Chemical Ind., Ltd., Osaka, Japan) containing 10 g/L Polypepton (Wako), 2 g/L yeast extract, 1 g/L $MgSO_4 \cdot 7H_2O$, 15 g/L agar (pH 7.0).

Angustibacter aerolatus was isolated from an air sample in Jeju Island, Republic of Korea. Type strain was isolated under aerobic conditions on an R2A (Difco) agar plate containing 0.5 g/L Bacto yeast extract (Difco), 0.5 g/L Bacto proteose peptone No. 3 (Difco), 0.5 g/L Bacto casamino acids (Difco), 0.5 g/L glucose, 0.5 g/L soluble starch, 0.3 g/L Sodium pyruvate, 0.3 g/L K_2HPO_4, 0.05 g/L $MgSO_4 \cdot 7H_2O$, 15 g/L agar (pH 7.2+/−0.2). The strain was purified and maintained on R2A agar plates.

Angustibacter peucedani was isolated from soil adhering to a root of a wild plant (*Pseucedanum japonicum* Thumb) collected in Mara Island, Jeju, Republic of Kore*a*. Soil samples were diluted by consecutive tenfold dilutions with sterile distilled water, and aliquots (100 ml) of the dilutions were transferred onto starch–casein agar medium containing 10 g/L soluble starch, 0.3 g/L casein, 2 g/L KNO_3, 2 g/L NaCl, 2 g/L KH_2PO_4, 0.02/L g $CaCO_3$, 0.05/L g $MgSO_4$. $7H_2O$, 0.01 g/L $FeSO_4 \cdot 7H_2O$, 18 g/L agar (pH 7.2). The agar plates were incubated for 6 weeks at 30 °C, and a tiny, orange colony was subcultured on ISP-2 medium.

Kineococcus aurantiacus was isolated from soil obtained from Indore region of India by the dilution plate method on a medium containing 10 g/L soluble starch, 1 g/L casein, 0.05 % K, HPO, and 1.5 % agar (pH 7.0–7.5) supplemented with 25 μg/ml nalidixic acid, 12.5 μg/ml kanamycin, 5.0 μg/ml cefsulodin, and 6.25 μg/ml kabicidin. Type strain was isolated from soil obtained from Indore region of India. Subcultivation of the strain was conducted in ISP-2 medium.

Kineococcus gynurae was isolated from the roots of a Thai medicinal plant, *Gynura pseudochina* (L.) DC. var. *hispida* Thwaites, Bangkok, Thailand, by using starch casein agar (Küster and Williams 1964) supplemented with antibacterial and antifungal agents (nalidixic acid and ketokonazole). The plates were incubated at room temperature for 14 days. One colony was isolated and purified on glucose yeast extract (GYE) agar containing 10 g/L glucose, 10 g/L yeast extract, and 15 g/L agar (pH 7.0). Subcultivation of the strain was conducted in GYE agar.

Kineococcus glutinatus was isolated from a soil sample collected from a dry-hot river valley in Dongchuan county, Yunnan Province, southwest China. Soil samples dissolved in sterilized water were shaken at 28 °C with 200 rpm for 1 h. The soil suspension was serially diluted to 10^{-2} fold, and 200 μL of the 10^{-2} dilution was spread on GTY medium (Tang et al. 2008) supplemented with nalidixic acid (25 mg/L) and nystatin (50 mg/L). Growth was observed after incubation at 28 °C for 2 weeks. Pure cultures of strain were obtained by repeated incubating on ISP 2 medium.

Kineococcus radiotolerans was isolated from a shielded cell facility in the Savannah River Technology Center at the Savannah River Site, in Aiken, South Carolina, USA. The radiation level of the sampling site was 0.18–3.5 Gyh^{-1}, and all the isolation procedures were carried out in the shielded cells with mechanical manipulation. The entire swab wiped the surface of the working area was placed in 10 ml PTYG nutrient solution (1 % glucose, 0.5 % yeast extract, 0.5 % tryptone, 0.5 % peptone, 0.006 % $MgSO_47H_2O$, 0.0006 % $CaCl_2$, pH 10.7) in a 15 ml centrifuge tube. The alkaline pH of the medium due to the nature of the samples (Phillips et al. 2002).

Kineococcus rhizosphaerae was isolated from rhizosphere soil of a cliff-associated plant (*Peucedanum japonicum* Thunb.) on Mara Island, Jeju, Republic of Korea. Soil samples serially diluted with sterile distilled water and transferred onto plates of starch-casein agar. Colonies were cultivated at 30 °C for 14 days (Lee 2009).

Kineococcus xinjiangensis was isolated from desert sand in Xinjiang Province, China. Medium used for isolation was ten-fold-diluted tryptic soy broth (Difco) (Liu et al. 2009).

Quadrisphaera granulorum was isolated from aerobic granules. The aerobic granules were cultivated in a laboratory-scale sequencing batch reactor as described by Dulekgurgen et al. (2003), with synthetic wastewater containing acetate as the sole carbon source (Moy et al. 2002). Granule samples were harvested 4 weeks after reactor start-up and were disrupted at 2,500 r.p.m. for 3 min with a Mini Beadbeater (Biospec Products). Microscopic observations of these granules revealed that the microbial community was dominated by coccoid cells that clustered mostly in tetrads. These coccoid cells were retrieved from the disintegrated biomass using a Skerman micromanipulator (Skerman 1968) and transferred to GS agar (Williams and Unz 1985) plates for incubation at 25 °C (Williams and Unz 1985). Colonies arising from micromanipulated cells were transferred several times to GS agar plates to obtain pure cultures; culture purity was confirmed microscopically by examining cells from single colonies.

***Pseudokineococcus* lusitanus** (Jurado et al. 2011) was isolated from a roof tile in Oportp, Portugal, on Tryptose Soy Agar (TSA) (Oxoid) after 4 weeks at 28 °C.

Pseudokineococcus marinus was isolated from a sediment sample of the coast of Jeju, Republic of Korea. Beach sediment samples were taken at a depth of 1 m below the surface and placed directly into sterilized 50 ml Falcon tubes. For bacterial isolation, each sediment sample (1 g) was placed into a sterile plastic tube containing 9 ml sterile distilled water, which was then mixed in a tube rotator for 30 min at moderate speed. Aliquots (100 ml) of the serial diluent of the samples were transferred onto SC-SW agar plates containing 10 g/L soluble starch, 0.3 g/L casein, 2 g/L KNO_3, 2 g/L NaCl, 0.02 g/L $CaCO_3$, 18 g/L agar, 0.05 g/L $MgSO_4.7H_2O$, and 0.01 g/L $FeSO_4.7H_2O$ in a 60 : 40 mixture of natural seawater and distilled water supplemented with 60 % (v/v) sterilized natural seawater. The plates were incubated at 30 °C for 14 days, and colonies were subcultured on YE-SW medium containing 4 g/L yeast extract, 10 g/L malt extract, 4 g/L glucose, and 18 g/L agar in a 60 : 40 mixture of natural seawater and distilled water.

Members of the family *Kineosporiaceae* grow in complex liquid or on solidified media, such as ISP-2 medium, Bennett's agar containing 1 g/L yeast extract, 1 g/L beef extract, 2 g/L NZ amine, 10 g/L glucose, and 20 g/L agar (pH 7.3), YS agar and yeast extract-glucose broth containing 10 g/L yeast extract, and 10 g/L glucose. Members of these families do not require special procedures for maintenance or preservation. Cultures can be maintained by serial transfers onto the appropriate solid media. Growth on agar slants can be maintained at 4 °C for over 1 month. Medium-term preservation is in 12–15 % (v/v) glycerol suspensions at −80 °C. Long-term preservation of

liquid cultures supplemented with 12–15 % (v/v) glycerol or 7 % (v/v) dimethylsulfoxide is recommended in the vapor phase of liquid nitrogen (−150 °C). Freeze-drying and L-drying methods can be also applied for long-term storage.

Ecology

Members of the family *Kineosporiaceae* were isolated from soils, broad-leaf forest soil, an air sample, soil adhering to a root of a wild plant (*Pseucedanum japonicum* Thumb), the roots of a Thai medicinal plant, *Gynura pseudochina* (L.) DC. var. *hispida* Thwaites, soil collected from dry-hot river valley, sediment sample of the coast, shielded cell facility, rhizosphere soil of a cliff associated plant (*Peucedanum japonicum* Thunb.), desert sand, plant litter, surface-sterilized stem sample of *Tripterygium wilfordii*, fallen leaves, root of galingale (*Cyperus microiria*), sphagnum, leaves of cat-tail (*Typha latifolia*), aerobic granules, roof tile.

Pathogenicity and Clinical Relevance

Pathogenicity has not been reported for any members of the family *Kineosporiaceae*.

Application

There have been several reports regarding the special use of members of the family *Kineosporiaceae*.

Abstract
The family *Micrococcaceae* is well-defined family within the order *Actinomycetales*. Members of the family are defined by a wide range of morphological and chemotaxonomic properties, such as polar lipids, fatty acids, amino acids of peptidoglycan, and whole-cell sugars which are used for the delineation of genera and species. All genera of the family *Micrococcaceae* are characterized by the occurrence of L-lysine as diagnostic diamino acid of the type A peptidoglycan and predominance of *iso*- and *anteiso*-branched cellular fatty acids but differ markedly in the structures of their interpeptide bridges and in the composition of their respiratory quinones predominantly with 7–10 isoprenoid units in the side chain, which are either completely unsaturated, dihydrogenated, or a combination of both. Polar lipid profiles usually contain phosphatidylglycerol, diphosphatidylglycerol, phosphatidylinositol, and unknown glycolipid(s). Genera affiliated with this family are *Acaricomes*, *Arthrobacter*, *Auritidibacter*, *Citricoccus*, *Enteractinococcus*, *Kocuria*, *Micrococcus*, *Nesterenkonia*, *Renibacterium*, *Rothia*, *Sinomonas*, *Yaniella*, and *Zhihengliuella*. Members of the family are mainly found in mammalian skin, clinical specimen, blood cultures, and in various soil samples as well as marine

Taxonomy, Historical and Current

Short Description of the Family

Mic.ro.co.cca'.ce.ae. M.L. fem. n *Micrococcus*, type genus of the family; suff. *-aceae*, ending to denote a family; N.L. fem. pl. n. *Micrococcaceae*, the *Micrococcus* family. Spherical or elliptical usually aerobic eubacteria that produce yellow or orange or red pigment.

The family *Micrococcaceae* proposed by Pribram (1929) was later reorganized and emended by Stackebrandt et al. (1997) exclusively based on signature nucleotides in the 16S rRNA gene sequences. At that time, in addition to the type genus *Micrococcus*, the genera *Arthrobacter* (Conn and Dimmick 1947), *Kocuria* (Koch et al. 1995), *Nesterenkonia* (Stackebrandt et al. 1995), *Renibacterium* (Sanders and Fryer 1980), *Rothia* (Georg and Brown 1967), and *Stomatococcus* (Bergan and Kocur 1982) were placed into this family. The single species of the latter genus, *Stomatococcus mucilaginosus*, was reclassified as *Rothia mucilaginosa* (Collins et al. 2000). Subsequently, seven additional genera were assigned to the family including *Citricoccus* (Altenburger et al. 2002), *Acaricomes* (Pukall et al. 2006), *Zhihengliuella* (Zhang et al. 2007), *Yaniella* (Li et al. 2008a), *Sinomonas* (Zhou et al. 2009), *Auritidibacter* (Yassin et al. 2011), and *Enteractinococcus* (Cao et al. 2012) that have also been incorporated into the family *Micrococcaceae*. Genera of this family share the characteristics of the order *Micrococcales*. Gram stain positive. Morphological forms vary from cocci to short slender, irregular rod coccobacilli with varying sizes, which may show primary branching; short filaments and coccoid forms may occur in late exponential phase cultures; or vegetative mycelia with the oldest parts of the mycelium fragment into sections of different sizes and more or less irregular shape and fragmentation may continue to yield rodlike cells in appearance and arrangement. Aerial mycelium is not formed. Species mostly are nonmotile. Aerobic to facultatively anaerobic, producing acid from a variety of carbohydrates. Cross-linkage of the peptidoglycan is of A type with a lysine diamino acid. Interpeptide bridges contain either aspartic acid or glutamic acid. The prominent fatty acids are $C_{15:0}$ anteiso, $C_{15:0}$ iso, or $C_{15:0}$ anteiso and $C_{17:0}$ anteiso. Predominant menaquinones are MK-7, MK-8, MK-9, and MK-10 isoprenoid quinone. The polyamines of the representatives of the family examined thus far, including species of the genera *Micrococcus*, *Kocuria*, *Arthrobacter*, and *Citricoccus* (Altenburger et al. 1997, 2002; Gvozdiak et al. 1998; Hamana 1994), are mainly spermidine, often with moderate amounts of spermine. Representatives of the family are characterized by a pattern of 16S rRNA gene sequence signature nucleotides at positions 41:401 (G-C), 45–396 (U-G), 69–99 (A-U), 144–178 (C-G), 140–223 (R-U), 142–221 (C-G), 157–164 (G-U), 248–276 (C-G), 258–268 (A-U), 293–304 (G-U), 379–384 (C-G), 407–435 (A-U), 502–543 (R-Y), 586–755 (C-G), 589–650 (C-G), 591–648 (U-A), 610 (G), 602–636 (C-G), 615–625 (G-C), 839:847 (A-U), 863 (U), 1133–1141 (A-U), 1244–1293 (C-G), 1254–1283 (G-C), 1263–1272 (A-U), 1310–1327 (R-Y), and 1414–1486 (C-G) (Zhi et al. 2009). Polar lipid profiles usually contain phosphatidylglycerol, diphosphatidylglycerol, phosphatidylinositol, and unknown glycolipid(s). Usually found in soil, rhizosphere, solar salt, fish, blood cultures and mammalian skin. The genomic G+C content value varies from 57.7 to 76.0 mol% (*Table 27.1*). Regardless of the complex phylogeny, the *Micrococcaceae* is well defined in rRNA gene trees. It includes all the genera that were classified within this family in the previous road map except for *Stomatococcus*, which has since been reclassified to the genus *Rothia* (Collins et al. 2000; Garrity et al. 2005). In addition, six genera have been added, including *Acaricomes*, *Yaniella*, *Zhihengliuella*, and the recently described three genera *Sinomonas* (Zhou et al. 2009), *Auritidibacter* (Yassin et al. 2011), and *Enteractinococcus* (Cao et al. 2012).

Phylogenetic Structure of the Family and Its Genera

According to the phylogenetic branching of actinobacterial type strains in the RaxML 16S rRNA gene tree of the Living Tree Project (Yarza et al. 2008, 2010), the family is moderately related to the families *Brevibacteriaceae* and *Dermabacteraceae*. A phylogenetically broad group containing *Microbacteriaceae*, *Actinomycetaceae*, and several other less species-rich families appear as a sister clade of these families (*Fig. 27.1*).

The genus *Micrococcus* forms a subclade within the family that is closely related to the genus *Citricoccus*. This relationship is supported by similarities in the cell-wall composition, major fatty acids, and polar lipids, although significant differences are present in the menaquinone composition (Busse 2012a). The genus *Micrococcus* comprises the type species *Micrococcus luteus* and five closely related species *Micrococcus antarcticus*, *M. endophyticus*, *M. flavus*, *M. lylae*, and *M. yunnanensis*. In rRNA gene trees, the monospecific genus *Acaricomes* (type species *Acaricomes phytoseiuli*) is closely related to *Arthrobacter sanguinis* within the large radiation of *Arthrobacter* species (dealt in separate chapter on "*Arthrobacter*"). However, chemotaxonomic data which might support this relationship are not available, and it remains unproven (Busse 2012a). The rRNA gene tree of the genus *Arthrobacter* is complex with many short branches and multifurcations that are difficult to resolve. Moreover, the genera *Acaricomes*, *Renibacterium*, and *Zhihengliuella* appear within the radiation that includes the type species *Arthrobacter globiformis*, making the genus *Arthrobacter* paraphyletic. Reclassification of many *Arthrobacter* species may be necessary in the future to reduce the diversity of the genus.

Table 27.1

Chemotaxonomic characteristics of genera of the family *Micrococcaceae*

Genera	Characteristic				
	Quinone system	Peptidoglycan interpeptide bridge	Major fatty acids	Major polar lipids	DNA G+C content (mol%)
Acaricomes[a]	MK-10(H2), MMK-10(H2)	L-Lys–L-Ala	$C_{15:0}$ anteiso and $C_{17:0}$ anteiso	DPG, PG, PI	57.7
Auritidibacter[b]	MK-10	L-Lys–Gly–L-Glu	iso-$C_{15:0}$ and anteiso-$C_{17:0}$	DPG, PG, PI. GL	59.7
Citricoccus[c]	MK-9(H2), MK-7(H2) MK-8(H2)	Lys–Gly–Glu	$C_{15:0}$ anteiso or $C_{15:0}$ anteiso and $C_{17:0}$ anteiso	DPG, PG, PI, GL, PL, UL	63.8–68.0
Kocuria[d]	MK-7(H2) or MK-8(H2) or MK-7(H2), MK-8(H2) or MK-8(H2), MK-9(H2), MK-7(H2) or MK-8(H2), MK-9(H2)	L-Lys–L-Ala3–4	$C_{15:0}$ anteiso	DPG, PG,PI	60.0–75.3
Micrococcus[e]	MK-8, MK-8(H2) or MK-8(H2) or MK-7(H2), MK-8(H2)	L-Lys–peptide subunit or L-Lys–D-Asp	$C_{15:0}$ anteiso or $C_{15:0}$ anteiso and $C_{15:0}$ iso	PG, DPG, PI, GL	66.4–75.5
Nesterenkonia[f]	MK-8, MK-9, MK-7	Lys–Gly–Glu, Lys–Glu, or Lys–Gly–Asp	$C_{15:0}$ anteiso, $C_{17:0}$ anteiso, $C_{16:0}$ iso	DPG, PG, PI, PL, GL	64–72
Renibacterium[g]	MK-9, MK-10	Lys–Ala–Glym	$C_{15:0}$ anteiso, $C_{17:0}$ anteiso	DPG, GL	52–54
Rothia[h]	MK-7 or MK-7, MK-6(H2)	Lys–Ala3, Lys–Ala, Lys–Ser, Lys–Gly, or Lys–Gly–Ala	$C_{15:0}$ anteiso, $C_{17:0}$ anteiso, $C_{16:0}$ iso, $C_{16:0}$	DPG, PG	49–60
Sinomonas[i]	MK-9(H_2), MK-8(H_2)	L-Lys–L-Ala3	$C_{15:0}$ anteiso, $C_{15:0}$ iso, $C_{17:0}$ anteiso	DPG, PG, PI, PME	71
Yaniella[j]	MK-8 and MK-9 or MK-8	L-Lys–Gly–L-Glu	$C_{15:0}$ anteiso,$C_{15:0}$ iso, or $C_{15:0}$ anteiso	DPG, PG, PL, GL	53–58
Zhihengliuella[k]	MK-9, MK-10	L-Ala–L-Glu	$C_{15:0}$ anteiso, $C_{15:0}$ iso, $C_{17:0}$ anteiso	DPG, PI, PG, PL, GL(s)	66.5–70.3
Enteractinococcus[l]	MK-7, MK-8	L-Lys–Gly–L-Glu	$C_{15:0}$ iso, $C_{15:0}$ anteiso, $C_{16:0}$ iso	DPG, PG, PI, PIM, DMDG, GL	56.2–61.6

In addition, some species are more closely affiliated with type species of other genera in the family *Micrococcaceae* and should be reclassified on those grounds. A combination of rRNA gene sequence similarity and chemotaxonomic features has been used to further classify *Arthrobacter* species into four "rRNA clusters," five "subclades," and two "groups" (Busse 2012). The rRNA clusters comprise species with similar chemotaxonomic features and high rRNA gene sequence similarity that do not form a discrete clade in the phylogenetic trees. In rRNA gene trees, this latter group is affiliated with the clade containing the genera

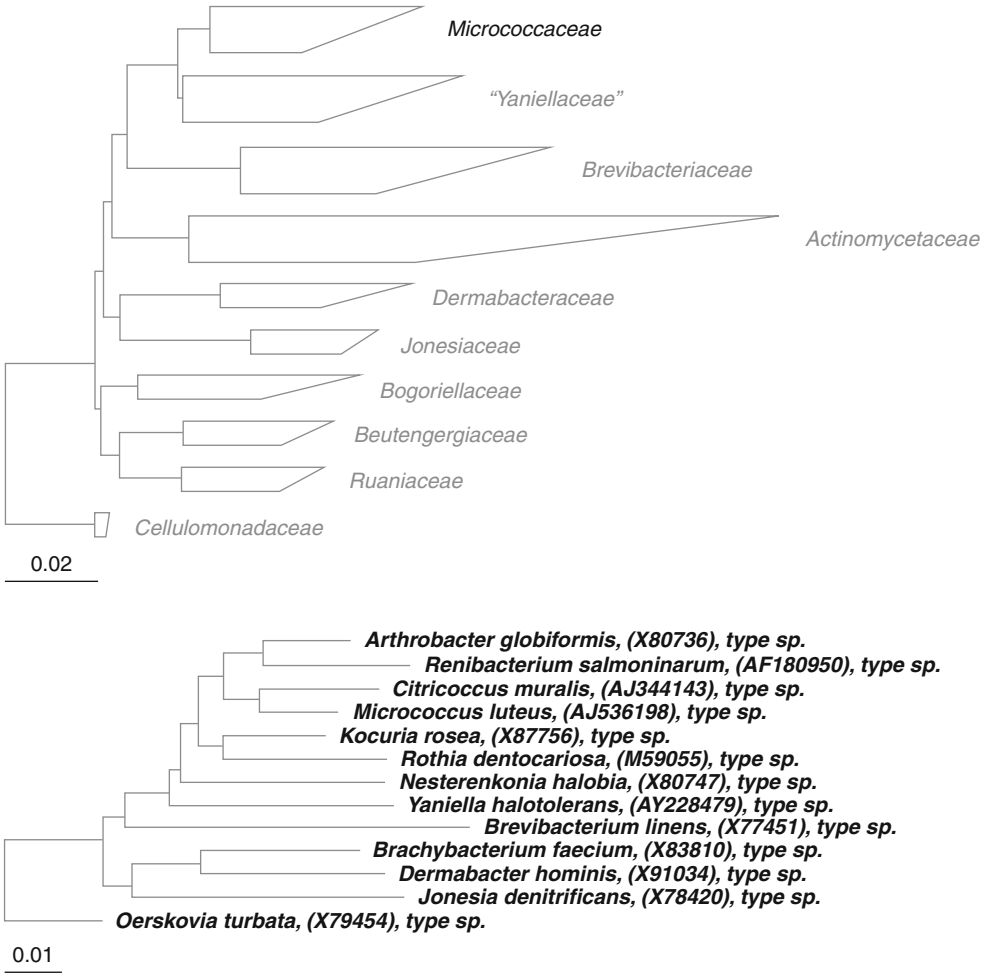

Fig. 27.1
Maximum likelihood genealogy reconstruction based on the RAxML algorithm (Stamatakis 2006) of the sequences of all members of the family *Micrococcaceae* present in the LTP_106 (Yarza et al. 2010). The number in triangle denotes the number of taxa included. The bar indicates 5 % sequence divergence (Stamatakis et al. 2005)

Nesterenkonia, *Sinomonas*, and *Yaniella*. Possibly, they represent a novel genus within this clade (Heyrman et al. 2005). The genus *Citricoccus* is closely related to the genus *Micrococcus* in rRNA gene trees. It comprises the type species *Citricoccus muralis* and the closely related species *Citricoccus alkalitolerans*, *C. parietis*, and *C. zhacaiensis*. The genus *Kocuria* represents one of the deepest lineages in the family *Micrococcaceae*. The genus comprises four clades. The first contains the type species *Kocuria rosea* as well as *Kocuria aegyptia*, *K. flava*, *K. himachalensis*, *K. polaris*, and *K. turfanensis*. The second clade is closely related and comprises *Kocuria halotolerans*, *K. koreensis*, and *K. kristinae* as well as the genus *Rothia*. The third clade includes only *Kocuria palustris*. The last clade appears as the deepest lineage in the family and comprises *Kocuria atrinae*, *K. carniphila*, *K. gwangalliensis*, *K. marina*, *K. rhizophila*, and *K. varians*. However, the biological significance of these clades is not currently supported by chemotaxonomic or other evidences, so their importance is not yet certain. The genus *Nesterenkonia* is in a clade containing the genera *Sinomonas* and *Yaniella* and the *Arthrobacter* species *Arthrobacter albus* and *A. cumminsii*. The genus contains two subclades. The first comprises the type species *Nesterenkonia halobia* and *Nesterenkonia aethiopica*, *N. alba*, N. *flava*, *N. halophila*, *N. lacusekhoensis*, and *N. xinjiangensis*. The second, closely related subclade comprises *Nesterenkonia halotolerans*, *N. jeotgali*, *N. lutea*, and *N. sandarakina*. Although the chemotaxonomic and physiological properties of the two clades are very similar, only members of this second subclade possess peptidoglycan containing L-Lys–Gly–D-Asp (Stackebrandt 2011). In the first subclade, the peptidoglycan contains L-Lys–Gly–D-Glu or L-Lys–D-Glu. The monospecific genus *Renibacterium* (type species *Renibacterium salmoninarum*) is related to *Arthrobacter russicus* and *Arthrobacter* Subclade IV, which includes *Arthrobacter psychrolactophilus*, *A. stackebrandtii*, and *A. psychrochitiniphilus*. Differences in the menaquinone and peptidoglycan composition of *Renibacterium* and the *Arthrobacter* species do not provide support for this affiliation, although it is possible that *Renibacterium* was derived from an

Arthrobacter ancestor by changes in these and other characters. The genus *Rothia* includes a well-defined clade composed of the type species *Rothia dentocariosa* and *Rothia aeria*, *R. amarae*, *R. mucilaginosa*, *R. nasimurium*, and *R. terrae*. These taxa are also related to some species of *Kocuria*. The genus *Sinomonas* comprises the type species *Sinomonas flava* and *Sinomonas atrocyanea*. In rRNA gene trees, it is affiliated with the clade containing the genera *Nesterenkonia*, *Yaniella*, and the *Arthrobacter* group 2 species *Arthrobacter albus* and *A. cumminsii*. The genus *Yaniella* contains the type species *Yaniella halotolerans* and *Yaniella flava*. Although originally classified in its own family (Li et al. 2008a), the rRNA gene trees calculated here suggest it is closely related to *Nesterenkonia*, *Sinomonas*, and *Arthrobacter* group 2 species *Arthrobacter albus* and *A. cumminsii*. This conclusion is consistent with similarities in cell-wall, menaquinone, and phospholipid compositions (Yassin et al. 2011). However, the DNA G+C content is quite different, 53–58 mol% in *Yaniella* and 64–72 mol% in *Nesterenkonia*. The genus *Zhihengliuella* comprises the type species *Zhihengliuella halotolerans* and *Zhihengliuella alba* and is closely related to the subclades of *Arthrobacter*. Presumably, this relationship reflects the heterogeneity of the genus *Arthrobacter* rather than the need for reclassification of the genus *Zhihengliuella*, and apart from this, two more genera have been validly published like *Auritidibacter and Enteractinococcus* where *Auritidibacter* has one species and *Enteractinococcus* has two valid species: *Enteractinococcus coprophilus* and another reclassified species from *Yaniella fodinae* to *Enteractinococcus fodinae*.

Molecular Analyses

DNA–DNA Hybridization Studies

A description of all *Citricoccus* species includes results of DNA–DNA hybridization (DDH) studies, and a few species only were found to be closely related, e.g., *C. alkalitolerans* and *C. muralis* (56 %; Li et al. 2005b) and a cluster comprising *C. parietis* (35–63 %; Schäfer et al. 2010) and *C. zhacaiensis* 39–54 % (Meng et al. 2010). Type strains of the *Kocuria* species based on DDH results revealed similarity values below 70 %, indicative of separate genomospecies. DDH values are moderately high values ranging between 31 % and 71 % similarity like *K. rhizophila* (31 %) with *K. palustris*, whereas others related to *Kocuria* shows 37–46 % (Kovács et al. 1999). *K. polaris*, *K. rosea*, *K. flava*, *K. aegyptia*, and *K. turfanensis* are close neighbors, as strains of these species share between 64 % and 75 % DNA similarity (Reddy et al. 2003; Zhou et al. 2008). DDH relatedness of *Micrococcus* species was reported in the range of 27–65 %, e.g., *M. antarcticus*, *M. luteus*, and *M. lylae* with 40 % similarity (Liu et al. 2000), *M. flavus* (36–55 %, Liu et al. 2007), *M. endophyticus* (27–54.2 %, Chen et al. 2009), *M. yunnanensis* (27–65.4 %, Zhao et al. 2009), and *M. terreus* (39–57.5 %, Zhang et al. 2010). DDH reassociation values for *Nesterenkonia* species were of 11–66 %. For example, *N. halotolerans* with strains *N. sandarakina* and *N. lutea* showed 43.3 % and 39.1 %, respectively, and between the *N. sandarakina* and *N. lutea* was 45.2 %. DDH results of *N. aethiopica* with the closest phylogenetic affiliation, i.e., *N. halobia*, *N. lacusekhoensis*, and *N. xinjiangensis*, showed between 35.7 % and 63.7 %. While DDH relatedness between strain *N. jeotgali* and other type strains of *Nesterenkonia* species showed value of 11–53 % (Stackebrandt et al. 1995; Collins et al. 2002; Li et al. 2004b, 2005a), *N. flava* with 14–66 % relatedness to its closest phylogenetic neighbor (Luo et al. 2008). *N. alba* revealed 35–60.7 % relatedness with other species (Luo et al. 2009). *Rothia* species revealed the DDH relatedness between *Rothia aeria* and *R. dentocariosa* genomovar II was 100 %, whereas they showed only 34.1 and 21.2 % relatedness with their related neighbor's like *R. mucilaginosa* and *R. dentocariosa* (Li et al. 2004c). *R. terrae* and its closest phylogenetic neighbors showed 15–21 % DDH relatedness (Chou et al. 2008). Species of *Sinomonas* have moderate DDH relatedness, e.g., *S. flava* and *S. atrocyanea* (52.2 %, Zhou et al. 2009). *Zhihengliuella* species also showed moderate level of DDH relatedness between strains *Z. alba* and *Z. halotolerans* (41.4 %, Tang et al. 2009a).

Riboprinting and Ribotyping

The study including DNA fingerprinting method was that of Yoon et al. (2006) who performed combined rep-PCR fingerprints generated by REP, BOX, and $(GTG)_5$ PCR primers. The cutoff point for the recognition of clades was set at 30 % similarity (*Fig. 27.2*) on the type strains of *Nesterenkonia* species to confirm their membership to the genus. As the number of bands is low, the phylogenetic significance is restricted, and the resulting dendrogram of ribopatterns bears no similarity with the 16S rRNA gene dendrogram. At the intraspecies level, the patterns may vary significantly, and the ribopattern of the type strain does not necessarily characterize additional strains of the species (Yoon et al. 2006). RiboPrint analysis in *Kocuria* species by the RiboPrint robot (Qualicon, DuPont) indicates that a unique pattern defines each type strain (*Fig. 27.3*). As the number of bands is low, the phylogenetic significance is restricted, and the resulting dendrogram of ribopatterns bears no similarity with the 16S rRNA gene dendrogram (Busse 2012). Neither riboprinting nor ribotyping analyses are available for any member of other genera in the *Micrococcaceae* family. At the intraspecies level, the patterns may vary significantly, and the ribopattern of the type strain has limited significance taxonomically.

Fourier-Transform Infrared (FT-IR) Spectroscopy

The method and its taxonomic application were described in detail by Oberreuter et al. (2002). The method is particularly valuable for the differentiation of related species from similar ecological niches, which display almost identical phenotypic traits in terms of traditional physiological and biochemical criteria and similar (identical) colony colors. It should be noted that spectral similarities of strains do not necessarily correspond to their

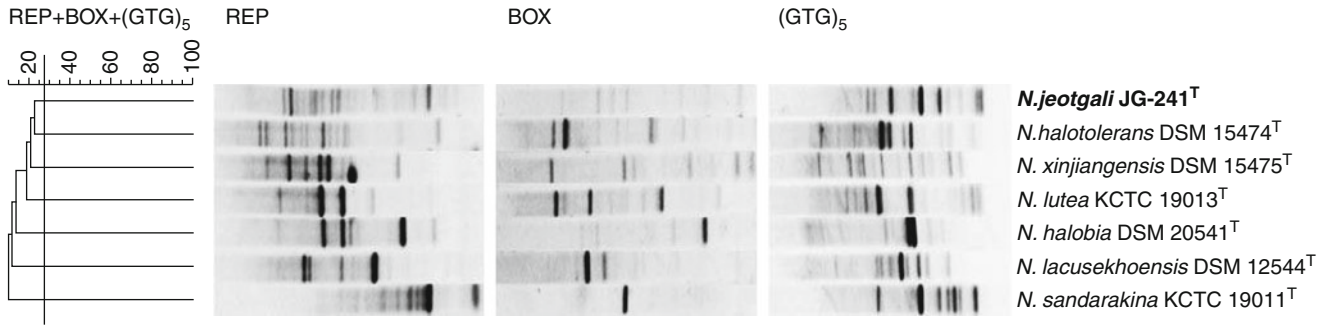

Fig. 27.2

Consensus dendrogram showing relationships among *Nesterenkonia* in the *Micrococcaceae* family based on similarity values derived by using the Jaccard correlation coefficient and the UPGMA algorithm in an analysis of the combined rep-PCR fingerprints generated by REP, BOX, and $(GTG)_5$ PCR primers. The cutoff point for the recognition of clades was set at 30 % similarity

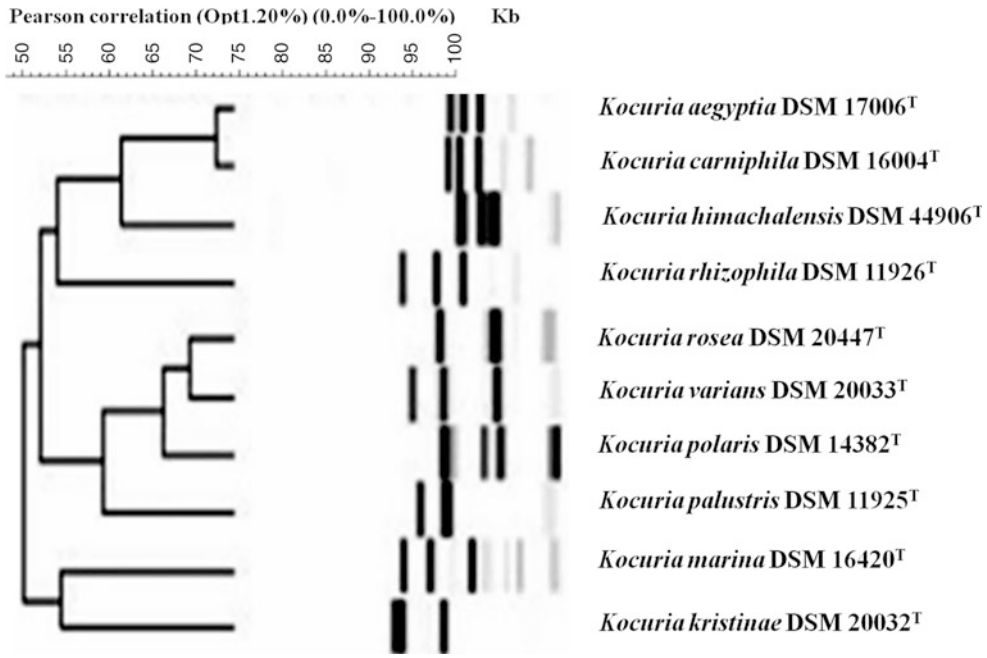

Fig. 27.3

Normalized *Eco*RI RiboPrint profiles (Qualicon, DuPont) of *Kocuria* species of *Micrococcaceae* family and a dendrogram of band pattern relatedness as generated by using BioNumerics software (Applied Maths, Kortrijk, Belgium)

phylogenetic relationships (Kümmerle et al. 1998; Oberreuter et al. 2002). The method has been tested on many representatives of the suborder *Micrococcineae* (Oberreuter et al. 2002).

Matrix-Assisted Laser Desorption/Ionization Time-of-Flight Mass Spectrometry (MALDI/TOF)

MALDI/TOF mass spectrometry is a rapid and efficient identification method for intact whole bacteria (Holland et al. 1996, 1999) which has been proven to aid medical diagnostics and risk assessment. This technique may cover a broad taxonomic range depending on the instrument conditions chosen, from the genus level up to the authentication of strains. Although reports on the application of MALDI/TOF mass spectrometry for members of the suborder *Micrococcineae* (Vargha et al. 2006) are still rare, this fast method has turned out to be of great taxonomic importance when compared with gene sequence phylogenies (Stackebrandt et al. 2005), and its application as a tool for characterization and differentiation at the species level is highly encouraged.

Genome Analyses

The genomes of five members of this family have been sequenced to date, namely, *Arthrobacter aurescens* TC1 and *Arthrobacter* sp. strain FB24, *Kocuria rhizophila*, and *Renibacterium*

salmoninarum (Mongodin et al. 2006; Kim et al. 2011). Sequencing and annotation of the genome analysis of strain *K. rhizophila* DC2201 (NBRC 103217, Hiromi et al. 2008) revealed a single circular chromosome (2,697,540 bp; G+C content of 71.16 %) containing 2,357 predicted protein-coding genes. Most of the predicted proteins (87.7 %) were orthologous to actinobacterial proteins, and the genome showed fairly good conservation of synteny with taxonomically related actinobacterial genomes. On the other hand, the genome seems to encode much smaller numbers of proteins necessary for secondary metabolism (one each of non-ribosomal peptide synthetase and type III polyketide synthase), transcriptional regulation, and lateral gene transfer, reflecting the small genome size. The presence of probable metabolic pathways for the transformation of phenolic compounds generated from the decomposition of plant materials and the presence of a large number of genes associated with membrane transport, particularly amino acid transporters and drug efflux pumps, may contribute to the organism's utilization of root exudates, as well as the tolerance to various organic compounds.

Renibacterium salmoninarum is the causative agent of bacterial kidney disease and a significant threat to healthy and sustainable production of salmonid fish worldwide. The complete genome of *R. salmoninarum* ATCC 33209 was sequenced (Wiens et al. 2008) and shown to be a 3,155,250-bp circular chromosome that is predicted to contain 3,507 open-reading frames (ORFs). A total of 80 copies of three different insertion sequence elements are interspersed throughout the genome. Approximately 21 % of the predicted ORFs have been inactivated via frameshifts, point mutations, insertion sequences, and putative deletions. The *R. salmoninarum* genome has extended regions of synteny to the *Arthrobacter* sp. strain FB24 and *Arthrobacter aurescens* TC1 genomes, but it is approximately 1.9 Mb smaller than both *Arthrobacter* genomes and has a lower G+C content, suggesting that significant genome reduction has occurred since divergence from the last common ancestor. A limited set of putative virulence factors appear to have been acquired via horizontal transmission after divergence of the species; these factors include capsular polysaccharides, heme sequestration molecules, and the major secreted cell surface antigen p57 (also known as major soluble antigen). Examination of the genome revealed a number of ORFs homologous to antibiotic resistance genes, including genes encoding β-lactamases, efflux proteins, macrolide glycosyltransferases, and rRNA methyltransferases. The genome sequence provides new insights into *R. salmoninarum* evolution and may facilitate identification of chemotherapeutic targets and vaccine candidates that can be used for prevention and treatment of infections in cultured salmonids.

Micrococcus luteus (NCTC2665, "Fleming strain") has one of the smallest genomes of free-living actinobacteria sequenced to date, comprising a single circular chromosome of 2,501,097 bp (G+C content, 73 %) predicted to encode 2,403 proteins (Young et al. 2010). The genome shows extensive synteny with that of the closely related organism, *Kocuria rhizophila*, from which it was taxonomically separated relatively. Despite its small size, the genome harbors 73 insertion sequence (IS) elements, almost all of which are closely related to elements found in other actinobacteria. An IS element is inserted into the *rrs* gene of one of only two *rrn* operons found in *M. luteus*. The genome encodes only four sigma factors and 14 response regulators, a finding indicative of adaptation to a rather strict ecological niche (mammalian skin). The high sensitivity of *M. luteus* to β-lactam antibiotics may result from the presence of a reduced set of penicillin-binding proteins and the absence of a *wblC* gene, which plays an important role in the antibiotic resistance in other actinobacteria. Consistent with the restricted range of compounds it can use as a sole source of carbon for energy and growth, *M. luteus* has a minimal complement of genes concerned with carbohydrate transport and metabolism. It has very few genes associated with secondary metabolism. In contrast to most other actinobacteria, *M. luteus* encodes only one resuscitation-promoting factor (Rpf) required for emergence from dormancy, and its complement of other dormancy-related proteins is also much reduced. *M. luteus* is capable of long-chain alkene biosynthesis, which is of interest for advanced biofuel production; a three-gene cluster essential for this metabolism has been identified in the genome.

Draft genome sequence of *Citricoccus* strain CH26A genome was submitted recently (Hayano-Kanashiro et al. 2011). A total of 826,643 reads were generated and assembled de novo with the Newbler assembler, v. 2.5, yielding 67 contigs with an *N*50 of 121 kb and the largest contig of 299.376 kb. Size of the *Citricoccus* CH26A genome is 3.7 Mb, with a mean GC content of 70.96 %. Gene prediction and annotation carried out further and identified 3,030 coding sequences, grouped into 23 categories. Genome-scale metabolic reconstruction (GSMR) of central metabolic pathways using an actinomycete-focused metabolic database analysis showed the presence of all genes for the glycolytic and pentose phosphate pathways, as well as those for the biosynthesis of amino acids and nucleotides.

The sequencing of draft genome of *K. atrinae* C3-8 produced 2,116,953 reads with an average length of 123 bases covering 261 Mb (Nam et al. 2012). The sequence reads were assembled into 221 contigs (>1 kb in size; 246 contigs greater than 500 bases) with approximately 82-fold coverage. The draft genome of *K. atrinae* C3-8 is 3.19 Mbp long with a G+C content of 63.8 %. Single copies of the 5S, 16S, and 23S rRNAs and 45 tRNAs were identified using RNAmmer 1.2 (Lagesen et al. 2007) and tRNA scan-SE (Lowe and Eddy 1997), respectively. A total of 3,959 predicted protein-coding sequences were annotated (Aziz et al. 2008). Of the predicted protein-coding genes, 1,243 (31.4 %) were assigned as encoding hypothetical proteins. These included 497 genes related to carbohydrate metabolism. A total of 205 genes were related to protein metabolism. A single gene for histidinol phosphate phosphatase (EC 3.3.3.15), which catalyzes the biosynthesis of histidine, was identified. Eight genes were related to molybdopterin synthesis. A more detailed analysis of this genome will provide useful information related to the application of microorganisms in the food industry.

Genome sequencing of *Nesterenkonia* sp. strain F was performed (Sarikhan et al. 2011) and obtained a total of 201,320 random reads, covering a total of 44,347,672 bp. The approximate coverage of *Nesterenkonia* sp. strain F genome was 16-fold. The sequence reads were assembled into 138 contigs. The G+C content of the draft genome was 71.5 %, similar to that previously reported by Stackebrandt et al. (1995). The sum of the sizes of the 138 large contigs in *Nesterenkonia* sp. strain F is 2,812,133 bp. The draft genome contained 2,484 genes, with 1,794 nonhypothetical and 690 hypothetical protein-coding sequences and 50 structural RNAs. Analysis of annotated genome sequence of *Nesterenkonia* sp. strain F revealed the presence of genes involved in production of α-amylases, including maltodextrin glucosidase and alpha-glucosidase. In addition, the genes encoding proteins involved in resistance to heavy metals and toxic compounds, including copper homeostasis, cobalt–zinc–cadmium resistance, arsenic resistance, and β-lactamase, were identified. These results show the genetic potential of the *Nesterenkonia* sp. strain to adapt to extreme lifestyles. Furthermore, the genome comprises clustered regularly interspaced short palindromic repeats (CRISPR), which constitutes an effective mechanism against foreign genetic elements as an adaptive immune system. The CRISPR-associated helicase Cas3, the RecB family exonuclease Cas4b, and the CRISPR-associated protein Cas1 have been detected. The *Nesterenkonia* sp. strain has also glycolysis and gluconeogenesis systems, a pentose phosphate pathway, and a tricarboxylic acid cycle. It contains genes for response to osmotic and oxidative stresses, in addition to heat shock, cold shock, and detoxification systems, and also the genes involved in ammonia assimilation and nitrate and nitrite ammonification, which are very attractive for bioremediation studies.

Phages

The set of phages proposed to be specific of the genus *Micrococcus* (Sozzi et al. 1973) are phages N1 (ATCC 4698-B1), N4 (ATCC 4698-B2), N8 (ATCC 4698-B3), and N3 (ATCC 4698 B4) for host *Micrococcus luteus* ATCC 4698.

Phenotypic Analyses

Micrococcus Cohn (1872), 151[AL] Emend. Stackebrandt, Koch, Gvozdiak, Schumann (1995), 682 Emend. Wieser, Denner, Kämpfer, Schumann, Tindall, Steiner, Vybiral, Lubitz, Maszenan, Patel, Seviour, Radax, and Busse (2002), 635

Mi.cro.coć cus. Gr. adj. *mikros* small, little; N.L. masc. n. *coccus* (from Gr. masc. n. *kokkos* grain, seed) coccus; N.L. masc. n. *Micrococcus* small coccus.

Members of the genus share the *Micrococcaceae*-specific signature nucleotides at positions 293–304, 610, 598, 615–625, 1025–1036, 1026–1035, 1265–1270, and 1278 of the 16S rRNA gene sequence (*E. coli* numbering) and lack the signature nucleotides at positions 640, 839–847, and 859 (Stackebrandt et al. 1997).

Cells are spherical and nonmotile. Endospores are not formed. Gram stain positive, aerobic, and yellow colored. Chemoorganotrophic; metabolism is strictly respiratory. Catalase and oxidase positive, mesophilic, and non-halophilic. The peptidoglycan contains L-lysine as the diagnostic diamino acid. The peptidoglycan type is either A2, with the interpeptide bridge consisting of a stem peptide, or A4α both with lysine as the diagnostic diamino acid (Wieser et al. 2002). The predominant menaquinones are either MK-8 and MK-8(H2) or MK-8(H2) or MK-7(H2) and MK-8(H2). The cytochromes are *aa*3, *b*557, *b*567, and *d*626; cytochromes *c*550, *c*551, *b*563, *b*564, and *b*567 may be present. Polar lipids are phosphatidylglycerol, diphosphatidylglycerol, phosphatidylinositol, an unknown glycolipid, and an unknown ninhydrin-negative phospholipid. The cellular fatty acids are iso- and anteiso-branched fatty acids, with $C_{15:0}$ anteiso and $C_{15:0}$ iso predominating. The major aliphatic hydrocarbons (br-Δ-C) are C27 to C29. Mycolic acids and teichoic acids are absent; teichoic acids may be present. Mannosamine-uronic acid may be present as an amino sugar in the cell-wall polysaccharide. D-Arabinose, *p*-arbutin, D-cellobiose, D-galactose, D-melibiose, D-ribose, and salicin are not assimilated. Members of the genus share the *Micrococcaceae*-specific signature nucleotides at positions 293:304, 610, 598, 615:625, 1025:1036, 1026:1035, 1265:1270, and 1278 of the 16S rRNA gene sequence (*Escherichia coli* numbering) and lack the signature nucleotides at positions 640, 839:847, and 859 (Stackebrandt et al. 1997).

The genus *Micrococcus* is the type genus of the order *Micrococcales* Prévot 1940 and the family *Micrococcaceae* Pribram 1929. Former members of the genus including *Micrococcus varians*, *M. kristinae*, *M. roseus*, *M. agilis*, *M. sedentarius*, *M. nishinomiyaensis*, and *M. halobius* have been reclassified in other genera based on their distinct phylogenetic positions and differences in the quinone systems, interpeptide bridges of the peptidoglycans, and fatty acids (Koch et al. 1995; Stackebrandt et al. 1995). *Micrococcus varians*, *M. kristinae*, and *M. roseus* were reclassified as species of the genus *Kocuria*. *Micrococcus agilis* was transferred to the genus *Arthrobacter*. *Micrococcus sedentarius*, *Micrococcus nishinomiyaensis*, and *Micrococcus halobius* were proposed as species of the genera *Kytococcus*, *Dermacoccus*, and *Nesterenkonia*, respectively.

The genus *Micrococcus* (Cohn 1872) was emended after taxonomic dissection resulting from phylogenetic and chemotaxonomic analyses (Stackebrandt et al. 1995). *M. luteus* can be divided into three biovars that are distinguished by several chemotaxonomic and biochemical traits: biovar I, represented by *M. luteus* DSM 20030[T]; biovar II, represented by strains D7 (DSM 14234); and biovar III, represented by strain Ballarat (DSM 14235). On the basis of the results, emended descriptions of the genus *Micrococcus* and *M. luteus* into three biovars are as follows: biovar I, represented by *M. luteus* DSM 20030[T]

[peptidoglycan type A2, predominant quinones MK-8 and MK-8(H_2)]; biovar II, represented by strains D7, 3, 6, 7, 13C2, 38, 83, and 118 [peptidoglycan type A2, predominant quinone MK-8(H_2)]; and biovar III, represented by strain Ballarat [peptidoglycan type A4*a*, predominant quinone MK-8(H_2)]. Consequently selected physiological and biochemical properties appear to remain suitable for differentiating between *M. luteus* and *M. lylae* strains (Table 27.2).

The genus now consists of seven species, *Micrococcus luteus* (the type species of the genus), *M. lylae*, *M. antarcticus*, *M. endophyticus*, *M. yunnanensis*, *M. flavus*, and *M. terreus*. The type strains of the species are separated from each other at 97.8–99.8 % 16S rRNA gene sequence similarities. DNA G+C content (mol%): 69–76. The chemotaxonomic properties and other detailed characteristics of all the species are given in Table 27.3.

Kocuria Stackebrandt, Koch, Gvozdiak, and Schumann (1995), 690^{VP}

Ko.cu'ri.a. N.L. fem. n. *Kocuria*, named after Miroslav Kocur, a Slovakian microbiologist for his pioneering studies on Gram-stain-positive cocci.

The genus Kocuria was first proposed by Stackebrandt et al. (1995) on the basis of a detailed phylogenetic and chemotaxonomic analysis of the genus *Micrococcus* (Stackebrandt et al. 1995). This leaded further to the description of *Dermacoccus*, *Kocuria*, *Kytococcus*, and *Nesterenkonia*. The latter three genera are members of the family *Micrococcaceae*, order *Micrococcales*, within the emended order *Actinomycetales* (Buchanan 1917) (Stackebrandt et al. 1997). The new genus *Kocuria* embraced three former *Micrococcus* species, i.e., *Kocuria rosea* (*Micrococcus roseus* Flügge 1886), *Kocuria varians* (*Micrococcus varians* Migula 1900), and *Kocuria kristinae* (*Micrococcus kristinae* Kloos et al. 1974). Based upon 16S rRNA gene sequence similarities, *Kocuria* species appear to be equidistantly related to members of *Arthrobacter* and *Rothia*, but the bootstrap values of the deeply branching lineages within this family are low, thus without statistical significance. The genus currently comprises 17 recognized species and *Kocuria rosea* as a type species (*Micrococcus roseus* Flügge 1886 183^{AL}).

Species of the genus *Kocuria* are closely related among themselves and form four intrageneric lineages. The 16S rRNA gene sequence similarities indicate the presence of two strain clusters and two individual lineages. The branching order is supported by bootstrap values of higher than 70 % (in *Bergey's Manual of Systematic Bacteriology*, Vol. 5, p. 626). Members of these two clusters share higher than 98 % similarities among each other, while the four lineages are separated from each other by similarities of 95.5–97.5 %. The clustering of strains within each of the two clusters is correlated neither with similarities at the phenotypic level nor with the habitats from which they were isolated. However, *Eco*RI-based RiboPrint analysis by the RiboPrint robot (Qualicon, DuPont) using some members of Kocuria could not clearly differentiate between each species or any clue regarding two clusters.

Cells are coccoid, Gram positive, catalase positive, nonhalophilic (except *K. halotolerans*), mesophilic, nonencapsulated, non-endospore forming, and nonmotile. Strains are chemoorganotrophic, and metabolism is strictly respiratory. Most of them are aerobic; however, the strains of one species are slightly facultatively anaerobic. The cell-wall peptidoglycan type is A3a (L-Lys–L-Ala3–4); however, mycolic acids and teichoic acids are absent. Menaquinones are hydrogenated; the predominant menaquinones are MK-7(H2), MK-8, or MK-9(H2), either alone or in combination. Polar lipids include diphosphatidylglycerol and phosphatidylglycerol; phosphatidylinositol is present in one species. The major fatty acid is C15:0 anteiso. *DNA G+C content* (mol%): 66–75.

Kocuria species resemble each other in the majority of chemotaxonomic properties and differ from each other mostly in quantitative composition of these markers. The peptidoglycan is characterized by the presence of lysine in position 3 of the peptide subunit. The interpeptide bridge consists of 3 or 4 L-alanine residues, thus defined as the A3a variation (Schleifer and Kandler 1972). The isoprenoid quinones are hydrogenated menaquinones MK-8(H_2), MK-9(H_2), and MK-7(H_2), occurring either as a single component or in combination with each other. The major fatty acid is $C_{15:0}$ anteiso (>50 % of total), but $C_{15:0}$ iso and $C_{16:1}$ represent about 10 % each of the total. The base composition of DNA spans a rather broad range (60–75 mol%), which may be due to the different methods used for quantitation. At the interspecies level, a range of 9 % and 6 % has been determined for *Kocuria rosea* and *Kocuria varians* species, respectively, for which more than the type strain is available for investigation. The extreme values were determined for the recently described type strains of *Kocuria marina* (60 mol%) and *Kocuria himachalensis* (75.3 mol%). Chemotaxonomic characteristics have been discussed in Table 27.4.

Growth temperatures and salt tolerance parameters considerably vary. Most *Kocuria* strains grow between 20 °C and 37 °C. Strains like *Kocuria aegyptia* can grow at up to 40 °C, and *Kocuria marina* even up to 43 °C. Only the type strains of *Kocuria polaris* and *Kocuria marina* are able to grow at 5 °C. The strains of *Kocuria polaris* and *Kocuria palustris are unable to* grow and divide at 37 °C. Similarly, most strains tolerate 5 % NaCl, but only one strain tolerates 15 % NaCl. The optimal pH range required for growth may be broad (i.e., 5–12 for *Kocuria aegyptia* and 7–12 for *Kocuria polaris*) or narrow, usually slightly alkaliphilic. Main peculiar property is that all species produce acids from one or more carbohydrates which make them distinct from other authenticated members of *Micrococcus*. Majority strains do not degrade starch and DNA. Gelatinase, esterase, and lipase can be variably utilized by few species.

DNA–DNA hybridization experiments are conducted between various pairs of type strains, ultimately most of which

Data from Wieser et al. (2002), + Positive, – negative, (+) weakly positive, *y* yellow, *w* white

share lower than 98.8 % 16S rRNA similarities. Interestingly, in each case, the corresponding DNA–DNA reassociation values were lower than 60 %. Even at a 16 rRNA gene sequence similarity of 99.8 % (*Kocuria polaris* vs. *Kocuria rosea*), the corresponding DNA reassociation value was as low as 71 %. These data clearly indicate a threshold level of 98.8 % 16S rRNA gene sequence similarity is essential to be included as a member in *Kocuria*.

Citricoccus Altenburger, Kämpfer, Schumann, Steiner, Lubitz, and Busse (2002), 2099[VP]

Ci.tri.coc'cus. L. n. *citrus* lemon, citron or citrus, an African tree; N.L. masc. n. *coccus* a sphere; N.L. masc.n. *Citricoccus* lemon-yellow-pigmented coccus.

The genus *Citricoccus* (belonging to the family *Micrococcineae* within the class *Actinobacteria*) was proposed by Altenburger et al. (2002). Presently, the genus contains four validly described strains: *C. muralis*, *C. alkalitolerans*, *C. parietis*, and *C. zhacaiensis* which were isolated from a medieval wall painting, a desert soil in Egypt, a mold-infected wall, and a wastewater bioreactor, respectively (Altenburger et al. 2002; Li et al. 2005b; Schäfer et al. 2010; Meng et al. 2010). Recently, *Citricoccus nitrophenolicus* was isolated from wastewater treatment plant; however, strains described as DSM 23311 and CCUG 59571 are not cited in the species description. The genus *Citricoccus* comprises a type species *Citricoccus muralis*, and all strains belonging to the genus are nonpathogenic in nature.

Although the type strains of *C. muralis* and *C. alkalitolerans* share more than 99.5 % 16S rRNA gene sequence similarity, the DNA–DNA relatedness value between them (56 %; Li et al. 2005b) was lower than the threshold value of 70 % for species delineation (Wayne et al. 1987). Interestingly, phenotypic differences were also noteworthy in a sense that type strain of *C. alkalitolerans* being alkalitolerant with optimum growth at pH 8.0–9.0, while that of *C. muralis* prefers neutral environments. Similar case can also be seen in case of C. zhacaiensis, where 16S rRNA gene similarity was 98.9 % and 98.8 % with *C. alkalitolerans* and *C. muralis* and DNA–DNA hybridization values were 54 % and 39 %, respectively (Meng et al. 2010). Differences in the isolation sources, closer similarity with respect to 16S rRNA similarity, and differences in DNA–DNA hybridization have been correlated with phenotypic, chemotaxonomic, and biochemical attributes by each strain in a particular habitat as summarized in *Table 27.5*.

The bacteria are Gram-stain-positive cocci, occurring singly, in short chains, or in clusters, about 1 mm in diameter; cells are nonmotile, non-spore forming, and aerobic. Oxidase-negative and catalase-positive characteristics. The members of the genus are Gram-positive cocci and have the following chemotaxonomic characteristics: MK-9(H_2) as the predominant menaquinone, along with moderate amounts of MK-7(H_2) and MK-8(H_2), is also present. Polar lipids are diphosphatidylglycerol, phosphatidylglycerol, phosphatidylinositol, four unknown glycolipids, two unknown phospholipids, and an unknown lipid. Recently, Nielson et al. (2005) proposed an emended description of the genus *Citricoccus* Altenburger et al. (2002) as correct, except that either MK-9 or MK-8 may be the predominant menaquinones. While spermidine is a predominant polyamine, anteiso-$C_{15:0}$, anteiso-$C_{17:0}$, iso-$C_{16:0}$, and iso-$C_{15:0}$ are the major fatty acids (Altenburger et al. 2002; Li et al. 2005b; Meng et al. 2010).

Renibacterium, Sanders and Fryer (1980), 501[VP]

Re.ni.bac.te¢ri.um. L. pl. n. *renes* the kidneys; L. neut. n. *bacterium* rod; N.L. neut. n. *Renibacterium* kidney bacterium.

Members belong to *Renibacterium* genus mainly known as kidney disease bacterium, the causative agent of bacterial kidney disease in salmonid fishes. The initial isolation report was found in two independent cases in the 1930s, bacterial kidney disease (corynebacterial kidney disease, salmonid kidney disease; also known as Dee disease) reported from Atlantic salmon. In another report, similar disease was first reported in the United States in brook trout (*Salvelinus fontinalis*) and brown trout (*Salmo trutta*) from a hatchery (Belding and Merriii 1935). Bacteria in both case reports a small, Gram-positive diplobacillus that did not grow on any available media was reported. After this report, these bacteria are commonly found in salmonid populations from parts of Europe, Canada, the United States, Japan, and Iceland; however, host of pathogenesis is restricted to only salmonid fishes.

Furthermore, attempts were made to culture and identify causal agent bacteria of kidney disease on the basis of its morphological appearance, as a species of *Corynebacterium* by Ordal and Earp (1956). After that, Smith in 1964 isolated the same bacteria and concluded that Dee disease of *sal*monids in Scotland and bacterial kidney disease were caused by the same bacterium. After this report, since these two findings, no further studies on the classification of the kidney disease bacterium (KDB) have been reported till date due to fastidious nature and slow growth rate of bacteria.

The generic classification of KDB within the coryneform group of bacteria is questioned and further complicated by the various taxonomic issues encountered with this diverse group (Rogosa et al. 1974). Prior to the description of *Renibacterium*, the organism was linked with *Brevibacterium* (Smith 1964), *Corynebacterium* (Sanders et al. 1978), *Lactobacillus* (Vladik et al. 1974), *Listeria* (Bullock et al. 1975), and *Rickettsia* (Snieszko and Griffin 1955). By 16S rRNA sequence-based cataloging, *Renibacterium salmoninarum* was assumed to comprise a member of the actinomycete subdivision, being related to *Arthrobacter*, *Brevibacterium*, *Cellulomonas*, *Jonesia*, *Micrococcus*, *Promicromonospora*, *Stomatococcus*, and *Terrabacter* (Gutenberger et al. 1991; Stackebrandt et al. 1988). This was supported by Grayson et al. (2000), linking *Renibacterium* to the high-G+C group of the actinobacteria, notably *Arthrobacter*, on the basis of rRNA gene sequence comparisons (Grayson et al. 2000). The organism has been included in the family *Micrococcaceae* (Stackebrandt and Schumann 2000) with low genetic diversity (Starliper 1996). Presently, *Renibacterium* has only one type strain and same as a type species.

Short rods or coccobacilli, 0.3–1.0 × 1.0–1.5 mm, usually occur in pairs (diplococcobacilli) and short chains. Gram stain positive, nonencapsulated, nonmotile, and non-endospore forming. Aerobic, slow-growing bacterium; temperature for optimum growth 15–18 °C; no growth at 37 °C. Cysteine required for growth. Growth enhanced by addition of blood, serum (especially fetal calf serum), or charcoal to media. No acid production from sugars. Catalase positive. The cell-wall peptidoglycan contains D-alanine, D-glutamic acid, glycine, and lysine as the diamino acid. Cell-wall sugars include galactose, rhamnose, *N*-acetylglucosamine, and *N*-acetylfucosamine. No mycolic acids are present. The major fatty acid is 12-methyltetradecanoic acid ($C_{15.0}$) with 14-methylhexadecanoic acid ($C_{17:0}$ anteiso) also present in significant amounts. The major respiratory quinines are unsaturated menaquinones with nine isoprene units. Based on some biochemical, phenotypic, and chemotaxonomic properties, *Renibacterium* differs from other genera in *Micrococcaceae* family as described in *Table 27.6*.

Rothia Georg and Brown (1967), 68[AL] Brian Austin (Updated from Gerencser and Bowden 1986)

Roth'i.a. N.L. fem. n. *Rothia* named for Genevieve D. Roth, who performed basic studies with these organisms (Gerencser and Bowden 1986).

Historically, the genus was classified within the family *Actinomycetaceae* because of morphological similarities (Schaal 1992). Later in 1997, Stackebrandt and co-workers transferred the genus to the family *Micrococcaceae* based on phylogenetic evidences. The genus currently harbors six species with *Rothia dentocariosa* as the type species.

Cells are Gram positive, nonmotile, non-acid-fast, endospore negative, catalase positive, and oxidase negative. Aerobic to microaerophilic with poor growth under obligately anaerobic conditions. Cells occur in different shapes that include cocci, diphtheroid, filamentous, and mycelial with mostly in a diameter of about 1 μm. Mixtures of the above morphologies are also a common occurrence. Mycelial forms may fragment into bacillary or coccoid forms. Growth in solid media occurs mostly in the form of filaments, whereas broth cultures usually appear coccoid in cell morphology. The chemotaxonomic properties and other detailed characteristics of all the species are given in *Table 27.1*. Young colonies are usually creamy, white, and smooth, while mature colonies are rough, dry, folded, and convex adhering to the agar medium with difficulty in picking them. However, in some cases, old colonies may also be round, convex, and smooth surfaced, reflecting a bacillary or coccoid micromorphology (Daneshvar et al. 2004).

The optimum temperature for growth is 30–37 °C. Generally nonhemolytic except for the type species wherein some strains show hemolysis on rabbit blood (Daneshvar et al. 2004). Positive for nitrate reduction, VP test (except *R. nasimurium*), and gelatin and aesculin hydrolysis but not for casein, starch, and urea. A variety of sugars are fermented for acid production, and lactic acid is the main product of this metabolism together with acetic acid and small amounts of succinic acid (Daneshvar et al. 2004). Generally, acid is produced from fructose, D-glucose, glycerol, maltose, and sucrose. Details of some other biochemical tests are given in *Table 27.1*. Negative for indole production. In the Biolog GP2 system, all species are positive for oxidation of the three substrates, α-D-glucose, D-psicose, and glycerol, and negative for α-cyclodextrin, β-cyclodextrin, inulin, mannan, *N*-acetyl-D-glucosamine, *N*-acetyl-β-D-mannosamine, amygdalin, L-arabinose, D-arabitol, D-cellobiose, D-galactose, D-galacturonic acid, gentiobiose, *m*-inositol, α-D-lactose, lactulose, D-mannitol, D-melibiose, α-methyl-D-galactoside, β-methyl-D-galactoside, α-methyl-D-mannoside, D-raffinose, L-rhamnose, sedoheptulosan, D-sorbitol, stachyose, D-tagatose, xylitol, D-xylose, *p*-hydroxyphenylacetic acid, α-ketoglutaric acid, lactamide, D-malic acid, *N*-acetyl-L-glutamic acid, D-alanine, L-alanine, glycyl-L-glutamic acid, L-pyroglutamic acid, adenosine, 2′-deoxyadenosine, inosine, thymidine, adenosine-5′-monophosphate, thymidine-5′-monophosphate, D-fructose-6-phosphate, α-D-glucose-6-phosphate, α-D-glucose-1-phosphate, and DL-α-glycerol phosphate.

The chemotaxonomic properties of the genus that are important for species description include fatty acids, menaquinone composition, polar lipids, and cell-wall amino acids. The most predominant fatty acid is anteiso-$C_{15:0}$ (>50 %), whereas iso-$C_{16:0}$ and anteiso-$C_{17:0}$ occur in variable amounts in different species (5–20 %). The major menaquinone is MK-7. The peptidoglycan is of the A3α type with L-Lys and D-Ala occurring at positions 3 and 4 of the peptide subunit, respectively. The interpeptide bridge generally consists of L-ala residues except in *R. mucilaginosa* where L-ala is partially replaced by L-ser. The diagnostic polar lipids of the genus are

phosphatidylglycerol and diphosphatidylglycerol. Some other lipids such as phosphatidylinositol and unknown phospholipids and glycolipids may also be present in minor quantities as in the case of *R. amarae* and *R. terrae*, respectively. These characteristics are summarized in Table 27.7. The G+C content of the genus ranges from 53.7 % to 59.0 % (Chou et al. 2008; Austin 2012).

Zhihengliuella Zhang, Schumann, Yu, Liu, Zhang, Xu, Stackebrandt, Jiang, and Li (2007), 1018^{VP} Emend. Tang, Wang, Chen, Lou, Cao, Xu, and Li (2009), 2029

Zhi.heng.li.u.el¢la. N.L. fem. dim. n. *Zhihengliuella* named after Zhi-Heng Liu (1940–), a Chinese microbiologist who devotes himself to the study of actinomycete taxonomy.

The genus *Zhihengliuella* was established by Zhang and his colleagues in 2007. The species was isolated from a saline soil sample in China. The genus was placed within the family *Micrococcaceae* and revealed 16S rRNA gene sequence similarities of 93.5–96.4 % to members of the family. Interestingly, the genus shows close proximity to certain species of the *Arthrobacter nicotianae* group (sensu Keddie et al. 1986), e.g., *Arthrobacter nicotianae*, *A. protophormiae*, *A. uratoxydans*, *A. rhombi*, *A. bergerei*, and *A. arilaitensis* in possessing A4α peptidoglycan with the interpeptide bridge Ala-Glu and the menaquinones MK-9 and MK-10. However, this close relationship based on chemotaxonomic properties is not supported by 16S rRNA-based phylogeny (Busse 2012). The genus currently encompasses four species *Z. halotolerans* (Zhang et al. 2007), *Z. alba* (Tang et al. 2009a), *Z. salsuginis* (Chen et al. 2010), and *Z. aestuarii* (Baik et al. 2011) with *Z. halotolerans* as the type species of the genus. The species *Z. salsuginis* is however not a validly published name.

The cells are Gram positive, strictly aerobic, nonmotile, and coccoid to ovoid to rods measuring 0.5–1.0 × 0.8–2.0 μm in size or 0.6–0.9 μm in diameter. Cells of *Z. salsuginis* occur in pairs, tetrads, and clusters (Chen et al. 2010). Colonies are pale yellow or white in color, circular, convex, and with entire margins and 1–3 mm in diameter. All the species described till date are catalase positive, oxidase negative, mesophilic with a growth temperature range of 4–45 °C and an optimum of 25–30 °C, slightly alkaliphilic with pH optimum of 7.5–9.0, and moderately halotolerant with growth at NaCl concentrations of 0–25 % with optimum at 5–10 %. However, the presence of NaCl is not a mandatory requirement for growth. Negative for nitrate reduction, H_2S production, MR-VP test, indole production, and urea hydrolysis. All species (except *Z. aestuarii*) produce acid from D-fructose, D-glucose, maltose, L-rhamnose, D-ribose, starch, sucrose, and D-xylose but not from dulcitol, D-galactose, inulin, melibiose, and melezitose (Chen et al. 2010). All species assimilate D-glucose and maltose and (except *Z. aestuarii*) also utilize sucrose, glycerol, gluconate, and L-glutamic acid. Negative for (except *Z. aestuarii*) utilization of acetamide, adonitol, L-arginine, butyrate, citrate, formate, fumarate, D-galactose, L-glycine, glycogen, histidine, hydroxy-L-proline, inulin, L-isoleucine, L-leucine, malate, malonate, melezitose, L-methionine, L-proline, propionate, L-rhamnose, succinate, L-valine, and D-xylose. Other characteristics are given in Table 27.8.

In addition to the above morphological and biochemical characteristics, chemotaxonomic properties like peptidoglycan structure, cell-wall sugars, fatty acids, and menaquinone system are important biomarkers for description of species within the genus. The cell-wall type is A4α (L-Lys–L-Ala–L-Glu). The most important parameter is the occurrence of cell-wall sugar tyvelose which differentiates this genus from other members of the family *Micrococcaceae*. MK-9 and MK-10 are the major menaquinones with any one of them being predominating depending upon the species. Major polar lipids are diphosphatidylglycerol, phosphatidylglycerol, and phosphatidylinositol. Anteiso-$C_{15:0}$ is the major fatty acid. G+C content ranges from 59.1 to 70.3 which is quite wide keeping in mind that there are just four species within the genus currently. All the characteristics are given in detail in Table 27.2. The species seem to grow optimally at NaCl concentrations of 2–10 % (Baik et al. 2011). However, the strains are not obligately halophilic determined by their ability to grow at 0 % NaCl concentration and are probably halotolerant since they tolerate up to 25 % salt concentration (Baik et al 2011).

Yaniella (Li, Chen, Xu, Zhang, Schumann, Tang, Xu, and Jiang 2004a; Li, Zhi, and Euzéby (2008b), 526^{VP}) (Illegitimate Homotypic Synonym: *Yania* Li, Chen, Xu, Zhang, Schumann, Tang, Xu, and Jiang 2004a, 529)

Ya.ni.el'la. N.L. fem. dim. n. *Yaniella* named after Sun-Chu Yan (1912–1994), a Chinese microbiologist who devoted his life to the study of actinomycete taxonomy and antibiotics.

The genus *Yaniella* was proposed by Li et al. in 2004a originally as *Yania*. The genus was later emended by description of one more species with proposal of a new family *Yaniellaceae* (Li et al. 2005c). The family was proposed based on some unique 16S rDNA signature nucleotides, compared to other families of the order *Micrococcales*, such as 140–223 (A–G), 142–221 (C–A), 615–625 (G–U), 839–874 (A–A), and 1134–1140 (A–U) (Li et al. 2004a, 2005c). However, Yassin et al (2011) based on observations by Zhi et al (2009) concluded that the family *Yaniellaceae* should no longer be retained and transferred the genus to the family *Micrococcaceae*. The name *Yania* has been replaced by the name *Yaniella* because of the precedence of the genus name *Yania* in zoological descriptions (Li et al. 2008a). The genus currently encompasses two species *Yaniella halotolerans* (Li et al. 2004a) and *Y. flava* (Li et al. 2005c) with the former as the type species. One additional species *Y. fodinae* proposed (Dhanjal et al. 2011) was recently reclassified as member of another genus *Enteroactinococcus* (Cao et al. 2012).

Cells are Gram positive, nonmotile, aerobic, non-spore formers with a coccoid or oval morphology, and about

(+), weakly positive *DPG* diphosphatidylglycerol, *PG* phosphatidylglycerol, *PI* phosphatidylinositol; *PC* phosphatidylcholine, *Tyv* tyvelose, *Glu* glucose, *Man* mannose

0.4–0.7 μm in diameter and occur singly or in clusters. Colonies are yellow in color, circular, lubricious, and opaque. Catalase positive and oxidase negative. Both species are moderately halophilic or halotolerant and negative for MR-VP, melanin production, H_2S and indole production, Tweens 20 and 80, casein, and starch hydrolysis. Positive for lysine decarboxylase, arginine dihydrolase and lipase activity. Negative for ornithine decarboxylase, L-aspartic arylamidase, α-galactosidase activities and growth on cellulose. Substrates acetamide, fructose, galactose, glucose, maltose, mannose, and salicin are utilized for growth, whereas adonitol, arabinose, arabitol, inositol, mannitol, and sorbitol are not. The type species *Y. halotolerans* YIM 70085^T grows within a temperature range of 10–40 °C, with optimum being 28–30 °C. Data for temperature range and optimum is not available for *Y. flava*. The range of pH for growth is 6.0–9.0 and optimum is 7.0–8.0 for both species. The presence of salts (especially KCl) seems to enhance the growth of both species. Optimal KCl concentration for growth is 10–15 %. Other differential physiological and metabolic characteristics of both species are given in *Table 27.3*. The cell-wall peptidoglycan is of the A4α type (L-Lys–Gly–L-Glu) with L-glutamic acid and glycine present in the interpeptide bridge. The major fatty acids are anteiso-$C_{15:0}$ and iso-$C_{15:0}$ or anteiso-$C_{15:0}$. MK-8 or MK-8 and MK-9 are the major menaquinones. The polar lipids consist of diphosphatidylglycerol, phosphatidylglycerol, unknown phospholipid, and glycolipid. The other properties are listed in *Table 27.9*. The G+C content of genomic DNA ranges from 53.5 to 57.9.

Acaricomes Pukall, Schumann, Schutte, Gols, and Dicke (2006), 465^{VP}

A.ca.ri.co¢mes. N.L. masc. pl. n. acarithe mites; L. masc. n. comes companion; N.L. masc. n. *Acaricomes* companion of mites.

The genus *Acaricomes* was established by Pukall et al. in 2006 and was isolated from diseased, surface-sterilized specimens of the predatory mite *Phytoseiulus persimilis* Athias-Henriot. The genus was placed within the family *Micrococcaceae* and revealed 16S rRNA gene sequence similarities of 94.0–94.8 % to members of the family. Cells are aerobic, mesophilic, Gram positive, non-spore-forming rods, catalase positive, and oxidase negative. A rod–coccus life cycle is absent. The optimum pH for growth is pH 6·0–8·0. The peptidoglycan type is A3α L-lys–L-Ala_3. The predominant menaquinone is the partially saturated menaquinone MK-10(H_2) with one of the ten isoprene units hydrogenated; in addition, MMK-10(H_2) is detectable. The major fatty acids determined are anteiso-$C_{15:0}$ (12-methyltetradecanoic acid) and anteiso-$C_{17:0}$ (14-methylhexadecanoic acid). The major polar lipids are phosphatidylglycerol, diphosphatidylglycerol, and phosphatidylinositol. The G+C mol% is of is 57.7 determine by HPLC.

The genus contains a single species, *Acaricomes phytoseiuli*. The type strain DSM 14247^T.

Cells are 0.5–0.8 × 1–1.5 μm in size. Colonies on TSA are circular, convex, 1–2 mm in diameter, and colored yellowish. Growth occurs at 15–30 °C with an optimum of 25 °C. Grows at pH 6.0–9.5. The following substrates are utilized: dextrin, α-D-glucose, α-D-fructose, maltose, maltotriose, D-mannose, sucrose, turanose, L-glutamic acid, and glucose 1-phosphate. The following substrates are not utilized: α- and β-cyclodextrin; glycogen; inulin; mannan; Tween 40; *N*-acetyl-D-glucosamine; *N*-acetyl-D-mannosamine; amygdalin: L-arabinose; D-arabitol; arbutin; D-cellobiose; L-fucose; D-galactose; D-galacturonic acid; gentiobiose; D-gluconic acid; *myo*-inositol; α-D-lactose; lactulose; D-mannitol; D-melezitose; D-melibiose; methyl-α-D-galactoside; methyl-β-D-galactoside; 3-methyl glucose; methyl-α-glucoside; methyl-β-D-glucoside; methyl α-D-mannoside; D-psicose; D-raffinose; L-rhamnose; D-ribose; salicin; sedoheptulosan; D-sorbitol; stachyose; D-tagatose; D-trehalose; xylitol; D-xylose; acetic acid; α-, β-, and γ-hydroxybutyric acid; *p*-hydroxyphenylacetic acid; α-ketovaleric acid; lactamide; D-lactic acid methyl ester; L-lactic acid; D-malic acid; methylpyruvate; monomethyl succinate; propionic acid; pyruvic acid; succinamic acid; succinic acid; *N*-acetyl-L-glutamic acid; L-alaninamide; D-alanine; L-alanyl glycine; glycyl-L-glutamic acid; L-serine; putrescine; 2,3-butanediol;

glycerol; adenosine; 2′-deoxyadenosine; inosine; thymidine; uridine; adenosine 5′-monophosphate; thymidine 5′-monophosphate; uridine 5′-monophosphate; fructose 6-phosphate; and DL-α-glycerol phosphate. Cell-wall sugars are galactose and glucose.

Auritidibacter Yassin, Hupfer, Siering, Klenk, and Schumann (2011), 228^{VP}

Au.ri.ti.di.bac'ter. L. n. auris, -is the ear; L. suff. -itis, -itidis, suffix used for inflammation; N.L. masc. n. bacter a rod; N.L. masc. n. *Auritidibacter* rod-shaped bacterium causing inflammation of the ear, also referring to the source of isolation.

The genus *Auritidibacter* was proposed by Yassin et al. (2011) with less than 95 % sequence similarity related to members of the family *Micrococcaceae*.

Cells are aerobic, Gram positive, motile, and non-spore forming and have a rod–coccus life cycle where the cells were cocci in the stationary growth phase, were rods in 11-h-old cultures, were predominantly short rods or oval-shaped after 60 h, and had a coccoid shape again after 108 h. Catalase positive and grows at 10–37 °C. Peptidoglycan type is A4α (L-Lys–Gly–L-Glu), MK-10 as the predominant menaquinone and long-chain cellular fatty acids of straight-chain and branched-chain saturated types (with iso-$C_{15:0}$ and anteiso-$C_{17:0}$ predominating). The major polar lipids included diphosphatidylglycerol, phosphatidylglycerol, and phosphatidylinositol in addition to unknown glycolipids. The DNA G+C content was 59.7 mol%. The pattern of the 16S rRNA gene signature nucleotides consists of nucleotides at positions 400 (U), 671 (U), 986 (U), 987 (G), 1120 (U), and 1408 (G). The pattern of signature nucleotides must be considered tentative and should be updated as the number of sequences in this lineage increases. The genus contains a single species *Auritidibacter ignavus*; the type strain is IMMIB L-1656^T.

The species has the following characteristics – cell size: cocci are 0.3–1 mm in diameter. Rods are 0.4–0.5 mm wide and 2.1–2.5 mm long. Colonies are cream colored and smooth and have an entire margin. Growth occurs on BHI agar, DST agar, Columbia agar supplemented with 5 % sheep's blood, and TSA agar. CAMP reaction is negative with *S. aureus*. Tolerates up to 12 % NaCl. Grows at pH 7.4–9.0 (optimum at pH 9.0) but not at pH 4–6. Nitrate reduction is negative. Acetoin production is positive. Hydrolyzes DNA and starch (3 days of incubation). Tyrosine is weakly hydrolyzed. The following substrates are not hydrolyzed: adenine, casein, elastin, aesculin, gelatin, guanine, hippurate, hypoxanthine, keratin, testosterone,

xanthine, and urea. Acetate, adipate, adonitol, L-arabinose, isoamyl alcohol, 2,3-butanediol, cellobiose, citrate, meso-erythritol, D-galactose, D-glucose, D-gluconate, m-hydroxybenzoate, p-hydroxybenzoate, myo-inositol, L-lactate, lactose, maltose, D-mannitol, melezitose, 1,2-propanediol, raffinose, L-rhamnose, D-sorbitol, sucrose, trehalose, and D-xylose are not assimilated. Acetamide, L-alanine, gelatin, L-proline, and L-serine are not utilized as simultaneous sources of carbon and nitrogen. Activity is detected for alkaline phosphatase, ester lipase C8, naphthol-AS-BI-phosphohydrolase, α-glucosidase, and pyrazinamidase. No activity is detected for acid phosphatase, arginine dihydrolase, esterase C4, β-glucosidase, α-galactosidase, β-galactosidase, β-glucuronidase, *N*-acetyl-β-glucosaminidase, lipase C14, α-mannosidase, α-fucosidase, α-chymotrypsin, trypsin, cystine arylamidase, leucine arylamidase, pyrrolidonyl arylamidase, and valine arylamidase.

Nesterenkonia Stackebrandt, Koch, Gvozdiak, and Schumann (1995), 689^{VP} Emend. Collins, Lawson, Labrenz, Tindall, Weiss, and Hirsch (2002) Emend. Li, Chen, Kim, Zhang, Park, Lee, Xu, and Jiang (2005)

Ne.ste.ren.ko¢ni.a. N.L. fem. n. Nesterenkonia honoring olga nesterenko, a Ukrainian microbiologist.

Taxonomic dissection of the genus *Micrococcus* by Stackebrand et al. in 1995 led to propose new genus *Nesterenkonia* with the type strain *Nesterenkonia halobia* (DSM 20541^T) for the strain *Micrococcus halobius* sp. *n* (Onishi and Kamekura 1972). The genus currently encompasses *Nesterenkonia lacusekhoensis* (Collins et al. 2002), *Nesterenkonia xinjiangensis* (Li et al. 2004a), *Nesterenkonia halotolerans* (Li et al. 2004), *Nesterenkonia lutea* (Li et al. 2005a), *Nesterenkonia sandarakina* (Li et al. 2005a), *Nesterenkonia jeotgali* (Yoon et al. 2006), *Nesterenkonia aethiopica* (Delgado et al. 2006), *Nesterenkonia alba* (Luo et al. 2009), *Nesterenkonia flava* (Luo et al. 2008), and *Nesterenkonia halophila* (Li et al. 2008b).

Cells are Gram positive, aerobic, mesophilic, nonencapsulated, moderately halophilic or halotolerant, motile or nonmotile, and non-spore forming which may consist of short rods, sometimes showing branching, or of cocci. Some species are alkaliphilic or alkalitolerant. Chemoorganotrophic; metabolism is strictly respiratory. They are catalase positive, and cell wall does not contain mycolic acid. The major cellular fatty acids are iso- and anteiso-branched fatty acids, with anteiso-$C_{15:0}$ and anteiso-$C_{17:0}$ and iso-$C_{16:0}$ predominating. Major phospholipids are diphosphatidylglycerol, phosphatidylglycerol, and phosphatidylinositol. Menaquinones are present, MK-7, MK-8, and MK-9 predominating. Peptidoglycan is of the A4α type (L-lys–gly–L-Glu, L-lys–L-glu, or lys–gly–D-Asp). The G+C content of the DNA is 64–72 mol%.

Chemotaxonomic and phenotypic properties which differentiate among the *Nesterenkonia* species are indicated in Table 27.10.

Sinomonas Zhou, Wei, Wang, and Lai (2009), 259^{VP} Emend. Zhou, Chen, Zhang, Wang, and Xu (2012), 764

Sinomonas (Si.no.mo'nas. M.L. n. Sina China; L. fem. n. monas a unit, monad; N.L. fem. n. *Sinomonas* a monad from China).

The genus *Sinomonas* (type species *Sinomonas flava*) was first proposed by Zhou et al. (2009) with the description of the newly isolated strain *S. flava* CW 108^T and the reclassification of *Arthrobacter atrocyaneus* as *Sinomonas atrocyanea* (type strain DSM 20127^T) (Zhou et al. 2009; Kuhn and Starr 1960). Shortly after the description of the genus *Sinomonas* was published, two novel species *Arthrobacter echigonensis* and *Arthrobacter albidus* were proposed (Ding et al. 2009), but strains of these species showed high 16S rRNA gene sequence similarity values (>98 %) with strains of *S. flava* and *S. atrocyanea* and low 16S rRNA gene sequence similarity (less than 95.2 %) to all other members of the related genera *Citricoccus*, *Micrococcus*, *Zhihengliuella*, *Arthrobacter*, *Kocuria*, *Rothia*, *Yaniella*, *Acaricomes*, and *Renibacterium* within the family *Micrococcaceae*.

Sinomonas flava species was isolated from a saline soil sample in China. It showed high 16S rRNA gene sequence similarity to *Arthrobacter atrocyaneus* DSM 20127^T. Furthermore, *Arthrobacter atrocyaneus* displayed well-differentiated morphological and physiological characteristics. The two strains were separated from other members of the *Micrococcaceae* by colony color or obvious growth on PYES (Wieser et al. 2002), YDC (Kuhn and Starr 1960) and TYB (containing 0.3 % yeast extract, 0.2 % beef extract, 0.6 % tryptone, 0.3 % NaCl, and 0.001 % $FeCl_3$) media at 41 °C. Both strains shared the same 16S rRNA gene signature nucleotides, and most signature nucleotides of the two strains match those of the family *Micrococcaceae* (Stackebrandt et al. 1997), except at positions 640, 839, 847, 1025, 1036, and 1278 (*E. coli* numbering), where the nucleotides U, A, U, U, C, G, and U were replaced by G, C, G, C, U, C, and C, respectively. Based on the signature nucleotide, results supported the placement of the two isolates in a new genus. The name *Sinomonas flava* genus novel and *Arthrobacter atrocyaneus* DSM 20127^T is reclassified as *Sinomonas atrocyanea* comb. nov. (Zhou et al. 2009). Recent studies carried out by Zhou et al. (2012) proposed one more new species *Sinomonas soli* and also reclassified the species *A. echigonensis* and *A. albidus* as members of the genus *Sinomonas* as *Sinomonas echigonensis* comb. nov. and *Sinomonas albida* comb. nov., respectively, and emended the description of the genus Sinomonas. The genus currently encompasses five species *S. flava*, *S. atrocyanea* (Zhou et al. 2009), *Sinomonas soli*, *Sinomonas echigonensis*, and *Sinomonas albida*, respectively (Zhou et al. 2012). All five species formed a deep separate lineage within the family *Micrococcaceae*.

Cells stain Gram positive or variable and are aerobic, mesophilic rods (or show a rod–coccus cycle) and nonmotile, bent rods (0.5–0.9 × 1.7–4.5 μm). Weak catalase activity is present and oxidase activity is absent. Colonies are circular, convex, and pale yellow colored after 2 days cultivation

Symbols: + positive, – negative, w weak reaction, and nd not determined. Abbreviation: *Asp* aspartic acid, *Gly* glycine, *Glu* glutamic acid, *Lys* lysine, *DPG* diphosphatidylglycerol, *PG* phosphatidylglycerol *PI* phosphatidylinositol, and *GL* unidentified glycolipids(s)

at 30–37 °C on TYB, YDC, or PYES media. Growth occurs at 15–42 °C (optimum 30–37 °C) and pH 5.0–9.0 (optimum pH 6.0–8.0). No dark-blue pigment is produced on YDC agar at 30 °C. Growth occurs with 0–3 % NaCl, but does not occur with 4 % NaCl. Displays the following results in API 20NE tests: Tween 80 is hydrolyzed, but casein, starch, and tyrosine are not hydrolyzed; urease, β-galactosidase, and lipase activities are present; arginine dihydrolase, tryptophan decarboxylase, ornithine decarboxylase, and lysine decarboxylase activities are absent; nitrate is reduced and nitrite is not reduced; citrate is not utilized and gelatin is not hydrolyzed; H_2S is not produced; the Voges–Proskauer test is positive; and indole is negative. Displays the following results in API 50CHB tests: aesculin, cellobiose, erythrito1, D-fructose, D-glucose, glycerol, inositol, 2-ketogluconate, maltose, D-mannose, mannitol, melezitose, methyl-b-D-xyloside, D-ribose, sorbitol, sucrose, and turanose are utilized as sole carbon sources. *N*-acetylglucosamine, D-adonitol, amygdalin, D- and L-arabitol, D- and L-arabinose, arbutin, dulcitol, D- and L-fucose, D-galactose, gentiobiose, gluconate, glycogen, inulin, 5-ketogluconate, D-lactose, D-lyxose, melibiose, methyl-a-D-glucoside, methyl-α-D-mannoside, raffinose, L-rhamnose, salicin, L-sorbose, starch, D-tagatose, trehalose, xylitol, and D- and L-xylose are not utilized. The major fatty acids are ai-$C_{15:0}$, i-$C_{15:0}$, and ai-$C_{17:0}$. The respiratory quinone system consists of MK-9(H_2) and MK-8(H_2) in a molar ratio of about 7:1. Polar lipids consist of diphosphatidylglycerol, phosphatidylglycerol, and phosphatidylinositol and a minor amount of phosphatidylmonomethylethanolamine. The peptidoglycan type is A3α, and cell-wall sugars are galactose, mannose, ribose, and glucose. The DNA G+C content is 66.9–71.8 mol%. All the characteristics are given in detail in *Table 27.11*.

Enteractinococcus Cao, Yi, Jin, Han, He, Li, Huang, and Xue (2012), 2710

Enteractinococcus (En.ter.ac.ti.no.coc'cus. Gr. n enteron intestine; Gr. n. actis actinos a ray; N.L. masc. n. coccus a grain or berry; N.L. masc. n. *Enteractinococcus* intestinal and ray coccus).

The genus *Enteractinococcus* was very recently established by Cao et al. in 2012, isolated from *Panthera tigris* amoyensis faeces Wild Animal Park, China. The genus was placed within the family *Micrococcaceae*. The genus shows close proximity to species of the *Yaniella* with 16S rRNA gene sequence similarities of 95.9–96.2 %. Currently, the genus comprises two validly proposed species *Enteractinococcus coprophilus* and another one was reclassified species from *Yaniella fodinae* (Dhanjal et al. 2011) to *Enteractinococcus fodinae* (Cao et al. 2012).

Cells are nonmotile coccoids that occur singly or in clusters. Catalase positive; negative for production of H_2S and starch and gelatin hydrolysis. Major cellular fatty acids are iso-$C_{15:0}$ and anteiso-$C_{15:0}$. The cell-wall peptidoglycan is of type A4a (L-Lys–Gly–L-Glu). The quinone system comprises menaquinones MK-7 and MK-8. Major polar lipids are DPG, PG, and DMDG. The DNA G+C content is 56.2–61.6 mol%.

In addition, cells were not shown; the rod–coccus cell cycle as observed in the members of the genera *Arthrobacter*, *Auritidibacter*, and *Sinomonas*. The menaquinones were different from those in all genera of the family *Micrococcaceae*. The polar lipid profile, namely, DPG, PG, PI, PIM, DMDG, and unknown phospholipids, was very different from all genera of the family *Micrococcaceae*. Colonies are orange yellow. Growth occurs at 10–37 °C and at pH 7.0–11.0. Optimum growth occurs at 28 °C and pH 8.0. Tolerates up to 11 %, 15 %, and 11 % (w/v) NaCl, KCl, and $MgCl_2.6H_2O$, respectively. Oxidase negative. Positive for nitrate reduction, but negative for gelatinase, cellulose, and starch hydrolysis, milk coagulation and peptonization, and H_2S and urease production. Utilizes acetic acid, acetoacetic acid, L-aspartic acid, D-aspartic acid, D-arabitol, L-arginine, a-hydroxybutyric acid, b-hydroxy-DL-butyric acid, c-aminobutyric acid, citric acid, D-fructose, D-fucose, L-fucose, D-fructose 6-phosphate, methyl-b-D-glucoside, glycerol, a-D-glucose, D-glucose-6-phosphate, D-gluconic acid, D-glucuronic acid, L-glutamic acid, *N*-acetyl-D-glucosamine, α-ketoglutaric acid, inosine, L-galactonic acid lactone, L-lactic acid, D-mannitol, D-mannose, D-malic acid, L-malic acid, mucic acid, *N*-acetyl-neuraminic acid, propionic acid, L-pyroglutamic acid, pectin, glycyl-L-proline, quinic acid, raffinose, L-rhamnose, D-sorbitol, bromosuccinic acid, L-sorbose, D-saccharic acid, sodium butyrate, sodium lactate, L-serine, D-serine, sucrose, D-salicin, D-sorbitol, Tween 40, xylitol, and D-xylose, but not L-arabinose, L-alanine, α-ketobutyric acid, cellobiose, dextrin, dulcitol, D-lactic acid methyl ester, formic acid, fusidic acid, D-galactose, *N*-acetyl-D-galactosamine, 3-methyl glucose, gelatin, gentiobiose, D-galacturonic acid, glucuronamide, L-histidine, myo-inositol, α-lactose, maltose, melibiose, *N*-acetyl-β-D-mannosamine, methylpyruvate, p-hydroxyphenylacetic acid, stachyose, trehalose, or turanose. The cell-wall peptidoglycan is of A4a type (L-Lys–Gly–L-Glu). Whole-cell sugars contain mannose, galactose, rhamnose, glucose, and ribose. The main fatty acids are iso-$C_{15:0}$, anteiso-$C_{15:0}$, and iso-$C_{16:0}$, with lesser amounts of anteiso-$C_{17:0}$, iso-$C_{14:0}$, iso-$C_{15:1}$ G, iso-$C_{17:0}$, $C_{16:0}$, anteiso-$C_{15:1}$ A, iso-$C_{13:0}$, iso-$C_{16:1}$ G, $C_{14:0}$, and $C_{14:1}$ω5c. The DNA G+C content of the type strain is 56.2 mol%. All the characteristics are given in detail in *Table 27.12*.

Isolation, Enrichment, and Maintenance

Members of the family *Micrococcaceae* grow on a wide range of media as isolation procedures for *Micrococcus* species do not exhibit any special growth requirements. Common media containing yeast extract and peptone and a pH close to 7.0 are suitable for isolation. Specific isolation of *Micrococcus antarcticus* and *Micrococcus yunnanensis* may be done at 4 °C. To suppress growth of staphylococci, the medium for isolation of *Micrococcus luteus* should be supplemented with 0.03 % (w/v) furazolidone (Baker 1984) and 10 % (w/v) NaCl

Data from Zhou et al. (2009, 2012), Ding et al. (2009)

+ positive, – negative, (+) weakly positive. All strains are negative for citrate utilization, gelatin liquefaction, H_2S production, indole, tryptophan deaminase, ornithine decarboxylase, lysine decarboxylase. All are positive for β-galactosidase

(Wieser et al. 2002) and incubated at 45 °C. *Micrococcus* cultures may be lyophilized or stored as a glycerol culture at −80 °C by common procedures used for many bacteria. Storage on agar slants at 4 °C for several weeks and as a glycerol suspension in 20 % concentration (v/v) or lyophilized forms for several years.

Different methods are available by which *Kocuria* sp. can be cultured from variety of samples and sources. The use of P-agar is recommended for the isolation of strains from mammalian skin of Kloos and Musselwhite (1975) and of Kloos et al. (1976) using P-agar (Naylor and Burgi 1956), and also supplementation of media with cycloheximide (50 mg/ml; Kloos et al. 1976) or 7 % NaCl (Schleifer et al. 1981) was suggested in order to prevent fungal and bacterial contaminant growth. Strains of *Kocuria varians* and *Kocuria kristinae* have been isolated on *Corynebacterium* agar. Some *Kocuria* strains may be isolated from soil or sand as described by Prauser et al. (1997) in which a diluted soil suspension in phosphate buffer is mixed with solubilized organic agar medium with agar content reduced to 0.6 % (w/v) like a semisolid medium at 48 °C. *Kocuria polaris* was isolated from Antarctic bacterial medium (ABM) (Reddy et al. 2003). *Kocuria himachalensis* was obtained on tryptone soy broth (Oxoid CM 129). *Kocuria marina* was isolated on Bacto marine broth (Difco 2216). *Kocuria aegyptia* was recovered on a medium containing (g/l^{-1}) glucose, 10.0; peptone, 5.0; yeast extract, 5.0; KH_2PO_4, 1.0; $MgSO_4 \cdot 7H_2O$, 0.2; Na_2CO_3, 10.0; and agar, 15, pH 10–10.5 (Li et al. 2006).

Data for all strains taken from Dhanjal et al. (2011) and Cao et al. (2012)

Diphosphatidylglycerol (*DPG*), phosphatidylglycerol (*PG*), phosphatidylinositol (*PI*), phosphatidylinositol mannosides (*PIM*), dimannosyl diacylglycerol (*DMDG*), an unknown glycolipid (*GL*)

Recently, *K. salsicia*, *K. atrinae*, and *K. koreensis* have been isolated on marine agar 2216 (MA, BBL) (Park et al. 2010; Yun et al. 2011), whereas *K. halotolerans* was isolated on modified ISP 5 medium (Tang et al. 2009b), and *K. gwangalliensis* was isolated on nutrient agar medium (Difco) and was maintained on PPES-II medium (Seo et al. 2009). Except *K. kristinae* (optimum temperature at 37 °C), all other representatives of the genus grow optimally at 28–30 °C. Strains can be stored for some weeks as slant cultures at 4 °C and as 20 % (w/v) glycerol suspensions at −20 °C and at −80 °C or for long-term preservation by lyophilization in skim milk and in liquid nitrogen at −196 °C.

There is no report of specific growth requirement for the members of *Citricoccus*; hence, no specific isolation medium has been defined. However, good growth occurs on PYES agar (Altenburger et al. 2002), R2A agar, TS agar (Oxoid), and, a very low at nutrient medium, CasMM agar (Altenburger et al. 1996) at 10–28 °C. Moderate growth occurs at 4 °C and 37 °C, but no growth is observed at 40 °C. Strain like *C. parietalis* (Schäfer et al. 2010) can be maintained on organic medium M79 and preserved at 28 °C by mixing in a 1:1 ratio of well-grown cultures in organic medium M79 broth with glycerol preservation medium (Salser 1978), containing (w/v) 1.26 % K_2HPO_4, 0.36 % KH_2PO_4, 0.01 % $MgSO_4$. H_2O, 0.09 % sodium citrate, 0.18 % $(NH_4)_2SO_4$, and 8.8 % glycerol. Stock cultures of the isolates in liquid M79 supplemented with 5 % DMSO were additionally maintained in the vapor phase of liquid nitrogen. The strains of *C. zhacaiensis* can be maintained in ZC medium (g/l^{-1}) 10.0 g NaCl, 1.0 g KCl, 2.0 g $MgCl_2$. $6H_2O$, 2.0 g casamino acids (Difco, Becton Dickinson), and 5.0 g Bacto yeast extract (Becton Dickinson), pH 7.5 (Meng et al. 2010). Similar enrichment, isolation, and testing media for different parameters like auxotrophy are also studied using various media (Nielsen et al. 2011). *Citricoccus* cultures can be lyophilized or stored in 21 % glycerol at −80 °C.

For isolation of *Renibacterium* species, diseased kidney tissue specimens of fish can be streaked or plated on Mueller–Hinton medium supplemented with 0.1 % (w/v) L-cysteine hydrochloride (Wolf and Dunbar 1959); kidney disease medium (KDM-2) containing 1.0 % (w/v) peptone, 0.05 % (w/v) yeast extract, 0.1 % (w/v) L-cysteine hydrochloride, and 1.5 % (w/v) agar, at pH 6.5, sterilized at 121 °C for 15 min, and cooled to 45 °C, and then 20 % (v/v) sterile fetal calf serum added (Evelyn 1977); selective kidney disease medium (SKDM) containing 1.0 % (w/v) tryptone, 0.05 % (w/v) yeast extract, 0.005 % (w/v) cycloheximide, and 1.0 % (w/v) agar, at pH 6.8, sterilized at 121 °C for 15 min, and cooled to 50 °C, and then sterile fetal calf serum added to 10 % (v/v); filter-sterilized solutions containing L-cysteine hydrochloride (0.1 % w/v), D-cycloserine (0.00125 % w/v), polymyxin B sulfate (0.0025 % w/v), and oxolinic acid (0.00025 % w/v) (Austin et al. 1983); or charcoal agar containing 1.0 % (w/v) peptone, 0.05 % (w/v) yeast extract, 0.1 % (w/v) L-cysteine hydrochloride, 0.1 % (w/v) activated charcoal, and 1.5 % (w/v) agar, at pH 6.8, sterilized at 121 °C for 15 min (the charcoal may be placed in dialysis tubing prior to sterilization to obtain a clear broth medium) as suggested by Daly and Stevenson (1985). *Renibacterium* cultures may be lyophilized by common storage used for many bacteria. Broth cultures supplemented with 15–20 % (v/v) glycerol as cryopreservation agent may be frozen at −70 °C, and their viability is maintained for longer periods.

The various species of *Rothia* described thus far do not seem to be isolated in any specific medium. It appears that species can be isolated in undefined media containing complex nutrients like tryptone, yeast, or beef extract. Strains belonging to the genus have been isolated on diverse media such as blood agar, Luria broth, and humic acid vitamin agar (Hayakawa and Nonomura 1987). In fact some species such as *R. terrae* and *R. amarae* have been maintained in nutrient agar and trypticase soy agar, respectively (Fan et al. 2002; Chou et al. 2008). Cultures can be preserved at −80 °C as a glycerol suspension in 20 % concentration (v/v), TSA, or blood agar slants at 4 °C or lyophilized (Fan et al. 2002; Chou et al. 2008).

As detailed in the above section, marine agar supplemented with NaCl seems to be a good axenic medium for isolation of *Zhihengliuella* species from saline soil samples. Cultures are routinely maintained on marine agar slants at 4 °C and as 20 % (w/v) glycerol suspensions at −20 or −80 °C. *Z. alba* can also be maintained on modified ISP 5 medium containing 5 % NaCl at 4 °C. Cells of *Z. salsuginis* can also be maintained by lyophilization at 4 °C.

Species of the *Yaniella* genus, *Y. halotolerans*, and *Y. flava* have been isolated on ISP 5 media (g/l^{-1}) 1.0, asparagine; 10.0, glycerol; 1.0, K_2HPO_4; 1.0 ml trace salts solution; and 20.0, agar (Shirling and Gottlieb 1966) and SGA agar (7.5 g casamino acids, 10.0 g yeast extract, 20.0 g $MgSO_4 \cdot 7H_2O$, 3.0 g sodium citrate, 2.0 g KCl, 1.0 ml trace salts solution, and 15.0 g agar per 1,000 ml distilled water, pH 7.5–7.6; Al-Tai and Ruan 1994), respectively, by dilution plating of saline soil samples. Both the media were supplemented with 15–20 % KCl which appears to be necessary for isolation. The trace salts solution for both strains consisted of 0.1 g $FeSO_4 \cdot 7\ H_2O$, 0.1 g $MnCl_2 \cdot 4H_2O$, and 0.1 g $ZnSO_4 \cdot 7H_2O$ per 1,000 ml distilled water, pH 7.0–7.4. Both species were isolated by incubation at 28 °C for 2 weeks. Cells can be maintained on potato agar or ISP 5 agar slants containing 10 % KCl (w/v) at 4 °C or as glycerol suspension (20 % v/v) at −20 °C.

Species of the genus *Sinomonas* were isolated on PYES (Wieser et al. 2002), YDC (Kuhn and Starr 1960), and TYB (containing 0.3 % yeast extract, 0.2 % beef extract, 0.6 % tryptone, 0.3 % NaCl, and 0.001 % $FeCl_3$) media at 41 °C from surface and polluted forest soil. Strains were routinely cultivated using TYB and PYES media at 30 °C. The pure culture was preserved in 25 % (v/v) glycerol at −80 °C, and strains can also be maintained by lyophilization at 4 °C.

Acaricomes phytoseiuli may be isolated from its host (the predator mite *Phytoseiulus persimilis*) after surface sterilization on Luria–Bertani agar and incubation for 1 week at 25 °C under aerobic conditions (Pukall et al. 2006). No information is available concerning maintenance of *Acaricomes phytoseiuli*. Similarly, *Auritidibacter ignavus* IMMIB L-1656^T (Yassin et al. 2011) was isolated from an ear swab of a 28-year-old man with

fulminant otitis externa by plating on Columbia agar supplemented with 5 % sheep's blood (BD). No information is available concerning maintenance of *Acaricomes phytoseiuli* CSC^T and *Auritidibacter ignavus* IMMIB L-1656^T.

Species of the genera *Nesterenkonia* were isolated from different habitats like *Nesterenkonia aethiopica* DSM 17733^T (Delgado et al. 2006) isolated from a soiled feather sample collected on the shore of Lake Abjata in Ethiopia (7° 60′ N 38° 62′ E), growing in complex YP medium (Mota et al. 1997) at 37 °C, with shaking at 200 r.p.m. *Nesterenkonia alba* CAAS 252^T (Luo et al. 2008, 2009) was isolated from the black liquor treatment system of a cotton pulp mill in Wuhan, China, using the standard dilution plating method. The carboxymethylcellulose sodium salt medium (CMC; containing l^{-1} peptone, 10 g; yeast extract, 10 g; NaCl, 5 g; carboxymethylcellulose sodium salt, 10 g; KH_2PO_4, 1 g, pH 10, adjusted with NaOH) was used for isolation, and these plates were incubated at 42 °C. *Nesterenkonia flava* CAAS 251^T (Luo et al. 2008, 2009) was isolated from paper-mill effluent collected in Wuhan, China, using Luria–Bertani (LB) medium at 37 °C at pH 10.0. *Nesterenkonia halobia* (Onishi and Kamekura. 1972) was isolated from unrefined solar salt of unknown origin obtained from Noda, Japan, in complex medium (Sehgal and Gibbons 1960) and nutrient broth containing 1 M NaCl. *Nesterenkonia halophila* YIM 70179^T (Li et al. 2008b) was isolated from a saline soil sample collected from Xinjiang Province, northwest China, by using the dilution plating method. For isolation, MSG medium supplemented with 25 % KCl (w/v) was used. The MSG medium was modified from S-G medium (Sehgal and Gibbons 1960) and contained (per liter distilled water) 7.5 g casamino acids, 10.0 g yeast extract, 3.0 g trisodium citrate, 2.0 g NaCl, 2.0 g $MgCl_2 . 6H_2O$, 1.0 g $MgSO_4 . 7H_2O$, 0.05 g $FeSO_4 . 7H_2O$, and 0.2 mg $MnSO_4 . 7H_2O$ (pH 9.0). Sterilized saturated NaOH was used to adjust the pH. Plates were incubated at 28 °C for 2 weeks. *Nesterenkonia halotolerans* YIM 70084^T and *Nesterenkonia xinjiangensis* YIM 70097^T (Li et al. 2004b) were isolated from hypersaline soil samples from Xinjiang Province, western China, using a modified glycerol/asparagine agar (ISP 5) medium (Shirling and Gottlieb 1966) supplemented with 15 % (w/v) $MgCl_2 . 6H_2O$ and KCl, respectively. The isolation plates were incubated at 28 °C for 2 weeks. *Nesterenkonia jeotgali* JG-241^T (Yoon et al. 2006) was isolated from jeotgal, a traditional Korean fermented seafood, by the usual dilution plating technique on marine agar 2216 (MA; Difco) at 30 °C. *Nesterenkonia lacusekhoensis* IFAMEL-30^T (Collins et al. 2002) was isolated from a 23 m deep water sample of Ekho Lake (a hypersaline, meromictic, and heliothermal lake in the ice-free Vestfold Hills, East Antarctica) by means of a Kemmerer sampler. For isolation, PYGV medium (Staley 1968) agar prepared with Ekho Lake water of 10 % salinity was used. The sample was spread directly onto these plates and incubated at 15 °C in the dark. *Nesterenkonia lutea* YIM 70081^T (Li et al. 2005a) was isolated from a saline soil sample from China using a modified glycerol/asparagine agar medium (ISP 5) (Shirling and Gottlieb 1966) supplemented with 15 % (w/v) $MgCl_2 . 6H_2O$. Isolation plates were incubated at 28 °C for 2 weeks. *Nesterenkonia sandarakina* YIM 70009^T (Li et al. 2005a) was isolated from a soil sample collected from the eastern desert of Egypt using modified medium A (supplemented with 15 % NaCl, w/v, pH 10 · 0–10 · 5), as described previously (Hozzein et al. 2004). Isolation plates were incubated at 28 °C for 2 weeks.

Nesterenkonia alba CAAS 252^T and *Nesterenkonia flava* CAAS 251^T were subcultured and maintained on peptone yeast extract agar (PYA; containing l^{-1} peptone, 8.0 g; yeast extract, 3.0 g; K_2HPO_4, 1.0 g; EDTA, 3.5 mg; $ZnSO_4.7H_2O$, 3.0 mg; $FeSO_4 . 7H_2O$, 3.0 mg; $MnSO_4 . H_2O$, 2.0 mg; $CuSO_4 . 5H_2O$, 1.0 mg; H_3BO_3, 1.0 mg; agar, 15.0 g; $NaHCO_3/NaCO_3$, 0.1 mol, pH 10.0) and Luria–Bertani (LB) plates at 42 °C (for strain CAAS 252^T) or at 40 °C (for strain CAAS 251^T).

Nesterenkonia halophila YIM 70179^T strain YIM 70179^T was maintained on MSG agar slants that contained 10 % KCl (w/v) at 4 °C and as glycerol suspensions (20 %, v/v) at −20 °C. *Nesterenkonia halotolerans* YIM 70084^T and *Nesterenkonia xinjiangensis* YIM 70097^T were cultivated and maintained on medium containing 0.1 % (w/v) asparagine, 1 % glycerol, 0.1 % $K_2HPO_4.3H_2O$, 0.5 % yeast extract, 10 % $MgCl_2.6H_2O$ (for strain YIM 70084^T), or 10 % KCl (for YIM 70097^T). The pH was adjusted to 7.2 with 1 M NaOH. *Nesterenkonia lutea* YIM 70081^T and *Nesterenkonia sandarakina* YIM 70009^T were cultivated and maintained on modified TSA medium containing 5–10 % $MgCl_2 . 6H_2O$ (w/v), pH 7.0–8.0 for strain YIM 70081^T, or 5–10 % NaCl (w/v), pH 8.0–9.0 for strain YIM 70009^T. *Nesterenkonia lacusekhoensis* IFAM EL-30^T is maintained on the modified PYGV medium described above, while *Nesterenkonia halobia* DSM 20541^T is maintained on modified Corynebacterium agar (DSM medium 53 containing 6 % NaCl) (catalogue of strains, DSMZ 2001). All strains can also be stored on medium ISP 5, containing the recommended salt (NaCl or KCl) concentration or in the Microbank system (BioLab Diagnostics, Richmond Hill, ON, Canada). For medium-term maintenance, 20 % (v/v) glycerol suspensions at −20 °C or at −70 °C were recommended, and for long-term preservation, lyophilization in liquid nitrogen was recommended.

Strains of *Enteractinococcus* were isolated on trypticase soy agar (TSA; HiMedia) and mycose-proline agar (5 g mycose, 1 g proline, 1 g $(NH_4)_2SO_4$, 1 g NaCl, 2 g $CaCl_2$, 1 g K_2HPO_4, 1 g $MgSO_4 . 7H_2O$, 3.7 mg vitamin mixture (Hayakawa and Nonomura 1987), 20 g agar, pH 7.2) supplemented with chloramine (50 mg l^{-1}) after incubation at 28 °C for 21 days. The strain was maintained on trypticase soy agar (TSA; Difco) slants at 4 °C and as 20 % (v/v) glycerol suspensions at −20 °C.

Habitat and Ecology

Members of the *Micrococcaceae* family have been isolated from various habitats, including activated sludge, medieval wall painting, meat, human and other mammal skin, marine sediment, freshwater, desert soil, cyanobacterial mat, plants, seafood, saline soil, and oral cavity from which the original cultures were isolated (Stackebrandt et al. 1995; Rainey et al. 1997; Kovács et al. 1999; Altenburger et al. 2002; Reddy

et al. 2003; Kim et al. 2004; Li et al. 2005a, b, c, 2006; Tvrzová et al. 2005; Mayilraj et al. 2006; Zhou et al. 2008; Seo et al. 2009; Tang et al. 2009; Meng et al. 2010; Park et al. 2010; Schäfer et al. 2010; Yun et al. 2011).

Optimal growth temperature reflects the natural habitat of some *Micrococcus* species. *Micrococcus antarcticus* isolated from Antarctica grows best at 16.8 °C, *Micrococcus flavus* isolated from activated sludge grows best at 31 °C, and *Micrococcus luteus* and *Micrococcus lylae* both isolated from human and other mammal skin exhibit optimal growth at 37 °C. Kloos and Musselwhite (1975) showed that *Micrococcus luteus* is the predominant organism isolated from skin of the head, legs, and arms, whereas *Micrococcus lylae* is only occasionally isolated from skin but most frequently during the colder seasons. The association of *Micrococcus luteus* with humans is also indicated by the higher frequency of recovery from airborne bacteria collected in the "Museo Correr" in Venice, Italy, during visiting hours (Camuffo et al. 1999; Wieser et al. 2002). *Micrococcus luteus* and more rarely *Micrococcus lylae* can be also isolated from different foodstuffs. During the production of cassava fish among others, *Micrococcus luteus* can be isolated early in the fermentation process (Anihouvi et al. 2007). *Micrococcus luteus* has been isolated in moderate amounts from "androlla" (a Spanish dry-fermented sausage; García Fontán et al. 2007) and detected during ripening of Camembert cheese (Addis et al. 2001) and in goat cheese (Prado et al. 2001). Micrococci are the only Gram-stain-positive bacteria which can be isolated from ice-stored fish, and strains of *Micrococcus luteus* were shown to make up almost 20 % of totally recovered strains from this source (Lakshmanan et al. 2002a). *Micrococcus endophyticus* and *Micrococcus yunnanensis* were isolated from plant tissue and root, respectively (Chen et al. 2009; Zhao et al. 2009), whereas *Micrococcus terreus* and *Micrococcus flavus* were isolated from forest soil and activated sludge (Liu et al. 2007; Zhang et al. 2010).

Type strains of species originate from various habitats, including meat (*Kocuria carniphila*, *Kocuria varians*, and *Kocuria Kristina*); mammalian skin (*Kocuria kristinae*, *Kocuria varians*); marine sediment (*Kocuria marina*) and freshwater (*Kocuria rosea*, *Kocuria varians*); cold (*Kocuria himachalensis*), temperate (*Kocuria rosea*), and desert (*Kocuria aegyptia*) soils; cyanobacterial mat (*Kocuria polaris*); phyllosphere (*Kocuria palustris*); seafood (*K. salsicia*, *K. atrinae*, *K. koreensis*); air (*K. flava* and *K. turfanensis*); seawater (*K. gwangalliensis*); and the saline soil (*K. halotolerans*) (Stackebrandt et al. 1995; Rainey et al. 1997; Kovács et al. 1999; Reddy et al. 2003; Kim et al. 2004; Tvrzová et al. 2005; Mayilraj et al. 2006; Li et al. 2006; Zhou et al. 2008; Seo et al. 2009; Tang et al. 2009b; Park et al. 2010; Yun et al. 2011).

Presently, the *Citricoccus* genus contains four validly described strains: *C. muralis* were isolated from a fragment of a stalactite in Jourmon Cave (Gifu Prefecture, Japan), from deep-sea sediment from the Western Mediterranean Sea (Fritz 2000), and from subsea floor sediment in the southwestern part of the Sea of Okhotsk (Inagaki et al. 2003). In addition, Tiago et al. (2004) found *Citricoccus*-like organisms in nonsaline, alkaline environments. *C. alkalitolerans*, *C. parietis*, and *C. zhacaiensis* were isolated from a medieval wall painting, a desert soil in Egypt, a mold-infected wall, and a wastewater bioreactor, respectively (Altenburger et al. 2002; Li et al. 2005b; Schäfer et al. 2010; Meng et al. 2010). Recently, *Citricoccus nitrophenolicus* was isolated from wastewater treatment plant. *Renibacterium salmoninarum* is the only species in the genus *Renibacterium* which was isolated from diseased fish by using diseased kidney tissue.

The type species of the genus *Rothia* were isolated from oral cavity of humans where it is believed to be a common inhabitant (Georg and Brown 1967). In a later report, Daneshvar et al. (2004) reported isolation of eight strains of *R. dentocariosa* from various clinical samples such as throat, blood, urine, mammaries, sputum, and bronchus. These investigators also transferred the species *Stomatococcus mucilaginosus* to the genus *Rothia* as *R. mucilaginosa* comb. nov. The species *R. mucilaginosa* is a regular inhabitant of the human mouth and upper respiratory tract. It has also been found in bronchial secretions and blood cultures (Bergan and Kocur 1982). This *R. nasimurium* as the name indicates was isolated from the nose of a healthy mouse (Collins et al. 2000). *R. amarae* was isolated from a sludge suspension sample collected from a water sewer in China (Fan et al. 2002). *R. aeria* was isolated from air samples from the Russian space station Mir and was described together with a novel *Arthrobacter* and *Rhodococcus* sp. (Li et al. 2004c). In a previous study by Kawamura et al. (2001), these Gram-positive isolates were suspected to be opportunistic pathogens for immunocompromised astronauts. *R. terrae* was isolated from a wasteland soil in Taiwan (Chou et al. 2008). Type species for *Acaricomes* genus *Acaricomes phytoseiuli* has been isolated from the diseased predator mite *Phytoseiulus persimilis* Athias-Henriot (Pukall et al. 2006).

The organism was originally isolated from unrefined solar salt. Recently, more species have been added to the genus *Nesterenkonia*, isolated from various sources like hypersaline *Nesterenkonia lacusekhoensis* for strains from alkaline olive oil extraction waste (Collins et al. 2002; Ntougias et al. 2006), to *Nesterenkonia halobia* for strains from decomposing rhizomes of the reed *Phragmites australis* (Borsodi et al. 2005) and a strain from alkaline water of Lake Abijata, Ethiopia (Martins et al. 2001), and to *N. halotolerans* and *N. xinjiangensis* for a strain from an alkaline groundwater environment (Tiago et al. 2004; Li et al. 2004b). *N. sandarakina*, *N. lutea* (Li et al. 2005a), and *N. aethiopica* (Delgado et al. 2006) were isolated from hypersaline soils, while *N. jeotgali* (Yoon et al. 2006) was isolated from jeotgali, a traditional Korean fermented seafood. Many research studies on microbial diversity on such ecosystems have reported the occurrence of strains belonging to this genera: extreme alkali-saline soil (Shi et al. 2012), hypersaline high Arctic spring channel (Lay et al. 2012), and saline lake of Sovata, Romania (Borsodi et al. 2010). *N. halobia* is the most thoroughly studied species. In all, 150 taxonomic properties of six strains, isolated from ponds of a saltern located in Huelva, Spain (Ventosa et al. 1998), were studied (Mota et al. 1997).

Acaricomes phytoseiuli CSC^T was isolated from an infected mite *Phytoseiulus persimilis* (Pukall et al. 2006), and *Auritidibacter ignavus* IMMIB L-1656^T was isolated from a 28-year-old man with fulminant otitis (Yassin et al. 2011). So far, the genera *Acaricomes* and *Auritidibacter* are only represented by a single strain of a single species. Hence, their habitat and ecology are not well understood and in future addition of strains will increase the knowledge regarding these aspects.

Zhihengliuella halotolerans the type species of the genus was isolated from a saline soil sample collected from Qinghai Province, northwest China (Zhang et al. 2007). The second reported species *Z. alba* was also recovered from a saline soil sample in China. The other two species *Z. salsuginis* and the recently described *Z. aestuarii* were isolated from a salt brine and tidal flat sediment, respectively (Tang et al. 2009a; Chen et al. 2010; Baik et al. 2011).

The two type species of the genus *Yaniella*, *Y. halotolerans* and *Y. flava*, have been isolated from saline soil samples of the Xinjiang and Qinghai Provinces, respectively, of China (Li et al. 2004, 2005). One additional species *Y. fodinae* proposed (Dhanjal et al. 2011) was recently reclassified as member of another genus *Enteroactinococcus* (Cao et al. 2012) which was isolated from coal mine and *Panthera tigris* amoyensis faeces. It therefore appears that saline environments may be the best place to look for these species but their specific habitat and ecological roles are not possible to discuss due to dearth of data on this aspect. Probably isolation of more strains within the genus will shed some light on this issue.

Sinomonas flava type strain of the genus *Sinomonas* was isolated from a surface layer of forest soil in Anhui Province. Then reclassified strain *Sinomonas echigonensis* was isolated as a contaminant on a plate of Sabouraud's glucose agar. Recently proposed novel species *Sinomonas soil* was isolated from a polluted forest soil sample in Anhui Province, China. *Arthrobacter echigonensis* and *Arthrobacter albidus* (Ding et al. 2009) were reclassified as *Sinomonas echigonensis* and *Sinomonas albida* which were basically isolated from a filtration substrate made from trass, a volcanic rock on NY medium.

Type species of *Enteractinococcus* genus were isolated from soil sample of coal mine in India and from suspension inoculum (suspended in 0.85 % NaCl solution) of tiger feces collected from Wild Animal Park in China.

Pathogenicity and Clinical Significance

Strains of *Micrococcus* spp. are widespread in nature and are frequently found as normal skin flora in humans and other mammals. *Micrococcus* strains such as *M. luteus* have been isolated associated with catheter-related bacteremia in patients undergoing hemodialysis or leukemia treatment and in patients with pneumonia, endocarditis, intracranial abscesses, continuous ambulatory dialysis peritonitis, septic arthritis, and meningitis. Since *Kocuria* spp. were contained in the genus *Micrococcus* prior to 1995, some of the early reports documenting the roles of *Micrococcus* strains in human infections may be attributable to *Kocuria* spp. There are only a few reports dealing with micrococci related to human infections. However, *Micrococcus luteus* in particular can be considered an opportunistic pathogen. Strains of this species were identified as causative agents of septic shock (Albertson et al. 1978); meningitis (Fosse et al. 1985); septic arthritis (Wharton et al. 1986); endocarditis (Dürst et al. 1991; Glupczynski et al. 1986; Seifert et al. 1995); infections associated with indwelling lines, continuous ambulatory peritoneal dialysis, or a ventriculoperitoneal shunt (Magee et al. 1990); intracranial suppuration (Selladurai et al. 1993); bacteremia (Peces et al. 1997; von Eiff et al. 1996); chronic cutaneous infections in HIV-positive patients (Smith et al. 1999); and catheter infection (Oudiz et al. 2004). Another threat to human health is the ability of *Micrococcus luteus* to produce cadaverine in food through the action of lysine decarboxylase (Lakshmanan et al. 2002b). Cadaverine itself has little toxicity, but it potentiates the toxicity of histamine in food by inhibiting histamine-metabolizing enzymes such as diamine oxidase and histamine *N*-methyltransferase (Taylor and Sumer 1986).

Members belonging to the genus *Kocuria* are the part of commensal microbes on human skin, mucous membranes, the oral cavity, and outer ear canal (Frank et al. 2003; Szczerba 2003b; Szczerba and Krzeminski 2002) and were detected in indoor environments and in bacterial contaminations of airplanes (Gorny and Dutkiewicz 2002; McManus and Kelley 2005). *Kocuria rosea* and *Kocuria kristinae* were reported to cause catheter-related bacteremia in patients with severe underlying diseases (Altuntas et al. 2004; Basaglia et al. 2002); *Kocuria kristinae* infection has been reported to be associated and antibiotically treated with acute cholecystitis (Ma et al. 2005). Amoxicillin with clavulanic acid, doxycycline, ceftriaxone, cefuroxime, or amikacin (Szczerba 2003a) have been recommended to cope up with infections. For diagnosis of such infections, phenotypic-based identification methods are available, but sometimes they are misleading (Ben-Ami et al. 2003). Recently, DNA-based molecular techniques involving a combination of 16S rRNA gene amplification and subsequent single-strand conformation polymorphisms (SSCP) of the variable region V3 and a combination of community-level physiological profiling and rRNA restriction analysis (ARDRA) were used to determine the change in microbial populations in goat milk (Callon et al. 2007; Borsodi et al. 2007).

Renibacterium belongs to hallmark of kidney disease bacteria (KDB), and first two cases were reported from salmonid fishes, which are the only hosts known for the infection and etiology. By intraperitoneal injection into Chinook salmon, the mortality was observed in first ever in vivo studies reported by Ordal and Earp (1956). Later, Murray et al. (1992) induced disease in same Chinook salmon animal model by immersing them in 10^4–10^6 cells/ml for 15–30 min and by cohabitation of healthy with other experimentally infected fish. After this noteworthy observation, various studies proved that pathogen becomes internalized in non-phagocytic cells (González et al. 1999) and macrophages that produce virulence factors (McIntosh et al. 1997); within phagocytic cells, the pathogen divides slowly and survives for >10 days (Gutenberger et al. 1997); respiratory burst products

generated by macrophages kill renibacteria (Campos-Pérez et al. 1997; Hardie et al. 1996). Various genetic answers came from colonization and infection causes, i.e., soluble cell surface p57 protein is responsible for agglutination of salmonid leukocytes (Senson and Stevenson 1999; Wiens et al. 1999) and the presence of proteases (Sakai et al. 1989) and hemolysins (Grayson et al. 1995a, 2001) in extracellular products (ECPs) with the mode of action reflecting inhibition of the respiratory burst but not phagocytic activity in spleen phagocytes (Densmore et al. 1998). Several virulence factors like hydrophobicity and auto-aggregation (Bruno 1988), an iron acquisition mechanism (Grayson et al. 1995b), respond to infection by the production of stress factors, including plasma cortisol and lactate, and reduced levels of plasma glucose (Mesa et al. 1999); a 70-kDa stress protein (HSP70) that has been recognized in diseased coho salmon (Forsyth et al. 1997) has been linked with severity of infection. Routine serological diagnostic methods include co-agglutination (Kimura and Yoshimizu 1981), Western blots (Lovely et al. 1994), the fluorescent antibody test, and the enzyme-linked immunosorbent assay (Griffiths et al. 1996, 1991; Jansson et al. 1996; Kozinska and Pekala 2005; O'Connor and Hoffnagle 2007; Pascho et al. 1998) that have also been suggested along with somewhat cross-reactivity. The polymerase chain reaction (PCR) targeting a 320-bp fragment of a 57-kDa protein (p57 antigen; Pascho et al. 1998), nested reverse transcriptase PCR (C.ook and Lynch 1999), quantitative PCR (Powell et al. 2005), real-time PCR, sequencing of the 16S rRNA gene (Konigsson et al. 2005), and terminal restriction fragment length polymorphism (Nilsson and Strom 2002) are specific and sensitive for testing purpose.

Out of the six species of *Rothia* described so far, three strains, *R. dentocariosa*, *R. mucilaginosa*, and *R. aeria*, have been isolated from humans, from oral cavity, mouth, and upper respiratory tract and blood, synovial fluid, and sputum, respectively. These species are now established as opportunistic pathogens especially in children and immunocompromised individuals. *R. dentocariosa* and *R. mucilaginosa* have been isolated from infections in patients diagnosed with a medical condition that results in lowered immune responses such as cancers, AIDS, transplantations, or surgery (Austin 2012). *R. dentocariosa* has been frequently associated with endocarditis in patients with periodontal disease and recovered from children with eye infections and tonsillitis (Austin 2012). Daneshvar et al (2004) had reported charcoal-black-pigmented colonies of *R. dentocariosa* isolated from the female genitourinary tract. *R. mucilaginosa* has been mainly associated with meningitis in immunocompromised patients with cancers or those who receive stem cell transplantations (Austin 2012). The species is also an etiological agent for bacteremia in patients with leukemia, pneumonia, and AIDS (Austin 2012). Recently, *R. aeria* has been established as a causative agent of sepsis in a female neonate (Monju et al. 2009) and an 88-year-old woman diagnosed with rheumatoid arthritis (Verrall et al. 2010). In both cases, the patients had a history of dental infection, thus implicating the oral cavity as the source of pathogen. The species was also associated with a case of acute bronchitis in a 66-year-old man with rheumatoid arthritis (Michon et al. 2010). In both cases of adults, immunosuppressive therapy was administered to the patients due to arthritis, and it is speculated that this resulted in the normal bacterial inhabitant of the mouth to become a pathogen. Except these three cases, there has been till date no other report of pathogenesis regarding *R. aeria*. Antimicrobial MICs determined using the broth microdilution method in accordance with National Committee for Clinical Laboratory Standards (NCCLS) revealed that the *R. dentocariosa* strains were susceptible to cefepime, cefotaxime, ceftriaxone, chloramphenicol, levofloxacin, penicillin, tetracycline, and vancomycin (Daneshvar et al. 2004). *R. mucilaginosa* is sensitive to bacitracin, ampicillin, chloramphenicol, erythromycin, fusidic acid, lincomycin, neomycin, novobiocin, oleandomycin, oxytetracycline, and penicillin G. Usually sensitive to sulfonamide and streptomycin (Bergan and Kocur 1982). *R. terrae* is sensitive by disc diffusion method to the following antibiotics: ampicillin, chloramphenicol, erythromycin, penicillin G, rifampicin, novobiocin, streptomycin, and tetracycline. It is resistant to gentamicin, kanamycin, and nalidixic acid (Chou et al. 2008). Based on Clinical and Laboratory Standards Institute interpretative criteria for staphylococci, *R. aeria* is sensitive to most of the antibiotics like penicillin, ampicillin, erythromycin, clindamycin, gentamicin, vancomycin, amoxicillin, and cefotaxime and is resistant to ofloxacin (Monju et al. 2009; Verrall et al. 2010; Michon et al. 2010). For the rest of the three species, *R. aeria*, *R. amarae*, and *R. nasimurium*, no data on antibiogram is available.

Acaricomes phytoseiuli is assumed to be the causative agent of the "non-responding syndrome" in *Phytoseiulus persimilis* (Schütte et al. 1998; Dicke et al. 2000; Bjørnson and Schütte 2003). *Auritidibacter ignavus* can cause fulminant obits externa in humans, but no information is available concerning the pathogenic potential for humans and clinical importance. The cells were sensitive to the following antimicrobial agents (mg per disc): ampicillin (10), cefazolin (30), clindamycin (2), oxacillin (5), penicillin (10), and vancomycin (30).

No pathogenic role has been reported for other members of the *Micrococcaceae* family like *Citricoccus*, *Nesterenkonia*, *Yaniella*, *Sinomonas*, *Zhihengliuella*, and *Enteractinococcus*.

Applications

Micrococci, like many other representatives of the *Actinobacteria*, can be catabolically versatile, with the ability to utilize a wide range of unusual substrates, such as pyridine, herbicides, chlorinated biphenyls, and oil. They are likely involved in detoxification or biodegradation of many other environmental pollutants. Other *Micrococcus* isolates produce various useful products, such as long-chain (C21–C34) aliphatic hydrocarbons for lubricating oils. *Micrococcus* species has potential role in bioremediation and in its importance in biotechnology. In the former sphere, it combines two properties essential to dealing with toxic wastes: the ability to degrade toxic organic pollutants and tolerance to metals (Sandrin and Maier 2003).

Often found in contaminated soils, oil spills, and sludge, *M. luteus* can degrade hydrocarbons and olefinic compounds (Zhuang et al. 2003), use biphenyl as a carbon source, and degrade phthalates (Eaton 1982). It harbors a plasmid capable of degrading malathion and chlorpyrifos (Guha et al. 1997). A whole repertoire of functions which deal with metals have been found in *M. luteus*. It carries out biosorption of strontium (Faison et al. 1990) and to a lesser degree lead, nickel, and zinc (Lo et al. 2001). The organism was utilized in a filtration system bound to gelatin beads for the biosorption of strontium. Since strontium is an end product of uranium decay, this could be a major component of atomic energy waste management. There is special interest in its ability to bind gold (Levchenko et al. 2001). Interesting variants of *M. luteus* have been isolated from gold deposits in Russia, which are able to precipitate gold by concentrating and crystallizing it on their surface. It has been suggested that these properties could be used for gold adsorption and concentration from low-abundance ores and depleted deposits (Marakushev 1991).

In the chemical and pharmaceutical industries, *M. luteus* may be exploited for its capability in isoprene synthetic reactions. This is the cornerstone of sterol, carotenoid, rubber, and fatty acid synthesis, and *M. luteus* has been the platform for isolation of important enzymes in this most basic processes, including the cis-prenyltransferase gene, whose gene product carries out the condensation of isopentenyl phosphate with allelic diphosphate (Oh et al. 2000). This is an essential step in the biosynthesis of terpenes, major components of a number of commercial products. The membranes of *M. luteus* are rich in enzymes that catalyze the synthesis of prenyl pyrophosphates at chain lengths between 15 and 45 carbon atoms (Saito and Ogura 1981). A number of interesting biological issues are also inherent in the study of *Micrococcus*, including dormancy without spore formation, resuscitation from dormancy, and the significance of tetrad formation. Although capable of survival under stress conditions, such as low temperature and starvation, *M. luteus* does not form spores as survival structures, usually thought of as a prerequisite for long-term survival in some other bacteria like Bacilli and Actinomycetes. This capability to survive for long periods in extreme environments may well explain their repeated isolation from within fossilized amber (Greenblatt et al. 2004). Of special recent interest is the elucidation of the resuscitation-promoting factor (Rpf) described in *Micrococcus luteus* (Mukamolova et al. 2002). This was the founder member of a family of secreted transglycosylase-like proteins that can resuscitate bacteria from a dormant state (Kell and Young 2000; Cohen-Gonsaud et al. 2005; Mukamolova et al. 2006). *M. luteus* Rpf can improve the cultivability of other high-G+C organisms with a low plating efficiency manyfold. Rpf has many important implications for the detection and culturing of these organisms, a number of which are important human pathogens (e.g., *Mycobacterium tuberculosis*). Genes similar to *rpf* have a widespread distribution throughout the actinobacteria, and most organisms, including *M. tuberculosis*, contain multiple gene homologues. *M. luteus* is very unusual in containing only a single, apparently essential *rpf*-like gene, which makes *M. luteus* the organism of choice for further work on the mechanism of restoration of cultivability. The tetrad of *Micrococcus luteus* may share with that of *Deinococcus radiodurans* a special function in DNA repair (Englander et al. 2004). Comparative genomics should, therefore, also provide clues to understanding developmental physiology and morphology in actinobacteria. The ability to adapt to oligotrophic environments and tolerate toxic metals and organic compounds may also relate to these morphological alterations. Finally, *M. luteus* (formerly *Micrococcus lysodeikticus*) is of historical interest in microbiology and medicine, since it played a prominent part in Fleming's discovery of lysozyme, to which it shows exquisite sensitivity (Fleming 1922). Some species of *Micrococcus* carry out biosorption of Sr (Faison et al. 1990). Indeed, these species belong to a group of bacterial strains that are particularly well adapted to environments contaminated with elevated levels of toxic metals and that are potentially useful for bioremediation applications (Young et al. 2010, and references therein). The genus *Micrococcus* now includes seven species, with one of the smallest actinobacterial genomes sequenced to date; *M. luteus* possesses unusual abilities to remediate co-contaminated sites with organic and metal pollutants through a whole repertoire of functions which deal with these pollutants (Sandrin and Maier 2003; Young et al. 2010). In addition, *M. luteus* can degrade hydrocarbons and olefinic compounds (Zhuang et al. 2003), use biphenyl as a carbon source, and metabolize dibutylphthalate by a pathway which has at least five regulatory units (Eaton 1982). As mentioned earlier, *Micrococcus luteus* has important biotechnology applications, especially in the chemical and pharmaceutical industries. *M. luteus* may be potentially exploited for its capability in isoprene and terpene synthetic reactions. *M. luteus* has been the platform for isolation of the cis-prenyltransferase gene (a *Rer2* gene homolog first found in *S. cerevisiae*). *cis*-Prenyltransferase catalyzes the sequential condensation of isopentenyl diphosphate with allylic diphosphate to synthesize polyprenyl diphosphates that play vital roles in cellular activity. Even earlier studies have shown that the membranes of *M. luteus* are rich in enzymes that catalyze the synthesis of prenyl pyrophosphates (small molecules required to make compounds such as cholesterol, carotene, and alkylamines) (Saito and Ogura 1981). Prenyl pyrophosphates are currently being looked at as possible nonpeptide antigens that stimulate certain T-cells as vaccines to prevent human infections and to treat cancer. Their activation requires their exposure to small phosphorus containing antigens in the family of prenyl pyrophosphates and their related biosynthetic precursors such as isopentenyl pyrophosphate (IPP) and dimethylallyl pyrophosphate (DMAPP), which are naturally occurring metabolites in *Micrococcus luteus* as well as several microbial pathogens. Various prenyl pyrophosphate and diphosphonate compounds are being tested to find new vaccine candidates and thus invite the potential use of isoprenoid-pyrophosphonates as specific immunoregulatory molecules (Zgani et al. 2004). The invention discloses an application of a strain of *Micrococcus antarcticus* in low-temperature sewage disposal, *Micrococcus antarcticus* applied in low-temperature sewage disposal. At lower

temperature (10–15 °C) *Micrococcus antarcticus* efficiently removes BOD, COD, egg white, fat, and the starch in sewage, has very high application value in biological processing which low temperature sewage/wastewater (such as sewage).

Polycyclic aromatic hydrocarbons degrading activity in *Kocuria* species have been reported. Harwati et al. (2007) first time reported degradation of components of Arabian light crude oil by *Kocuria rosea* and *Kocuria aegyptia*. Nazina et al. (2002) isolated a strain *Kocuria erythromyxa* (*K. rosea* according to reclassification) from an oil field. Rauch et al. (2006) isolated *Kocuria rhizophila* from aviation fuel tank. Tumaikina et al. (2008) isolated *K. rosea* from the pondweed surface that grew on agar medium with crude oil as carbon source. Mariano et al. (2008) isolated *Kocuria palustris* from soil of a petrol pump and first time reported degradation of commercial diesel oil by *K. palustris*. Similarly, biodegradation of methyl-*tert*-butyl ether by *Kocuria* sp. has been reported by Lalević et al (2012), and 6-aminohexanoate oligomer hydrolases from the alkaliphilic *Kocuria* species have been reported (Yasuhira et al. 2007). Bacteriocin in food biopreservation is represented by variacin produced from *Kocuria varians* to control the growth of *B. cereus* in chilled dairy products (O'Mahony et al. 2001).

Potential xylanolytic actinomycete strain was reported (Kocuria RM1) from the extremely alkaline bauxite residue obtained from National Aluminum Company Ltd., Damanjodi, India (Krishna et al. 2008). Karn et al. (2011) investigated the PCP degradation activity in Kocuria which degraded 58.64 % of PCP from the sludge within 2 weeks of treatment. These results highlight the potential of these bacteria to be used in bioremediation of high-strength PCP contaminated pulp and paper-mill sludge. Lignin peroxidase enzymes from *Kocuria rosea* MTCC 1532 have been studied by Parshetti et al. (2010, 2012) and tested for its ability to decolorize different groups of dyes. And novel alkali-stable, cellulase-free xylanase from *Kocuria* sp. Mn22 has been investigated by Li et al. (2009).

Some species such as *Nesterenkonia halobia* have been shown to produce industrially relevant enzymes such as amylases (Sánchez-Porro et al. 2003), while other species secrete unique serine proteases (Yang et al. 2007). However, no detailed studies have yet been performed on the production of hydrolytic enzymes from this genus. Therefore, Lucretia et al. (2009) describe the isolation of hydrolase-producing bacteria from evaporator ponds at Sua Pan in Botswana, with more emphasis on the production of xylanase by a newly isolated *Nesterenkonia* species.

Hong et al. (2010) first time described the cloning and expression of a family 11 xylanase, Xyn11NX, from the genus *Nesterenkonia*. This xylanase had high sequence homology to the xylanases from Actinomycetes but showed much broader pH adaptability and higher thermostability. Good pH adaptability and thermal stability, cellulase-free natures, and less complex hydrolysis products make it promising for various applications in many industries, especially in pulp and paper industry. Nel et al. (2011) reported the nitrilase superfamily with amidase activity derived from a novel psychrophilic strain of the genus *Nesterenkonia*, isolated from Antarctica Dry Valley soils. Cold-active amidases have yet to find commercial application, but there remains substantial interest in the applications of cold-active enzymes. The focus of such interest is in industrial sectors where low-temperature processing is beneficial, most commonly in the food and beverage industry and in some chemical biotransformations.

Zamakhchari et al. (2011) investigated the specific microorganisms in mixed dental plaque that display potent gluten-degrading activity from *Rothia* genus. The most efficient cleaving strains were identified as *Rothia mucilaginosa* and *Rothia aeria*. In gliadin pretreatment with mammalian digestive enzymes, gliadins (and by inference glutens) serve as a good substrate for *Rothia*-associated bacterial enzymes and are rapidly cleaved. Importantly, major immunogenic epitopes that play a key role in celiac disease are also targeted by *Rothia* enzymes. These findings suggest that *Rothia* bacteria may contribute to the digestive processing of immunogenic gluten proteins. Gluten-degrading microorganisms in the gastrointestinal tract may play a hitherto unappreciated role in the digestion/detoxification of dietary gluten. They open promising new avenues in the search for novel therapies to neutralize the deleterious effects of gluten in patients with celiac disease. Furthermore, to exploit these bacteria or their enzymes is highly attractive, since they belong to the normal flora of the upper gastrointestinal tract. Patent No US20120230976 A1 disclosed are glutamine endopeptidase enzymes from *Rothia* sp. bacteria that are naturally associated with the oral cavity, formulations comprising the glutamine endopeptidase enzymes and the use thereof for the treatment, prevention of allergic reaction, and diagnosis of gluten allergy-related diseases such as celiac sprue, gluten allergy, and/or dermatitis herpetiformis. While the human digestive enzyme system lacks the capacity to cleave immunogenic gluten, such activities are naturally present in the oral microbial enzyme repertoire. The identified bacteria may be exploited for physiological degradation of harmful gluten peptides (Helmerhorst and Oppenheim 2012).

Nelly et al. (2004) isolated a new strain of *Renibacterium salmoninarum* with the capacity to grow on and degrade *n*-hexadecane and at the same time to produce surface-active compounds. And this is the first report of *Renibacterium salmoninarum* strain that produces the two typical for *Pseudomonas aeruginosa* rhamnolipids. There are several reports of pathogenic bacteria that were found to produce biosurfactants (Burd and Ward 1996; Iglewski 1989). The exact role of biosurfactants is not clear – maybe they assist the colonization of host tissues or participate in increasing the bioavailability and degradation of hydrophobic organic contaminants by the host bacteria (Finnerty 1994; Rosenberg 1986; Rouse et al. 1994). Hence, these organisms may play an important role in the natural degradation of hydrocarbon contaminants in the environment and have potential use in accelerated bioremediation processes.

Nielsen and Ingvorsen (2012) reported a Gram-positive bacterium *Citricoccus nitrophenolicus* (strain PNP1T, DSM 23311^T, CCUG 59571^T) isolated from a wastewater treatment plant was capable of effectively degrading p-nitrophenol (pNP)

as a source of carbon, nitrogen, and energy for growth strain also degraded 4-chlorophenol, phenol, and salicylate. pNP was degraded at pH values between 6.8 and 10.0 and at temperatures between 15 °C and 32 °C. Therefore, it is a potential candidate for use in subsequent bioremediation of this breakdown product at the Breakwater 42 waste dump following alkaline hydrolysis and solubilization of the original contaminants in the aquifer. An antitumor activity has been reported by Nataliya et al. (2011) from a novel actinobacterium; *Citricoccus* strain KMM 3890 was isolated from a sediment sample from the Sakhalin shallow environment. In addition to its hemolytic activity, strain exhibited inhibitory activity against Gram-positive bacteria. It was found that the marine isolate *Citricoccus* sp. KMM 3890 produced large amount of the compound, which was isolated and structurally characterized as known cyclic siderophore nocardamine on the basis of combined spectral analyses. Nocardamine showed inhibitory effects to colony formation of T-47D, SK-Mel-5, SK-Mel-28, and PRMI-7951 tumor cell lines. This study can be considered as the first report on marine isolate of the genus *Citricoccus* producing nocardamine with antitumor activity.

Abstract
Since the last edition of *The Prokaryotes*, most microorganisms grouped in the chapter "The genus *Actinoplanes* and Related Genera" have been formally classified in the family *Micromonosporaceae*, order *Micromonosporales*, phylum Actinobacteria. According to the phylogenetic branching of the RaxML 16S rRNA gene tree, the members of the family represented by all type strains form well-defined clades and are related to members of the families *Glycomicetaceae* and *Jiangellaceae*. The family currently harbors 27 genera and includes microorganisms characterized by three types of sporulating structures, namely, single spores, spore chains, and sporangia which are borne directly on the substrate hyphae. Spores may be nonmotile or motile with tufts of polar flagella. They are aerobic, non-acid fast and mesophilic microorganisms. Many strains produce carotenoid mycelial pigments, giving the

E. Rosenberg et al. (eds.), *The Prokaryotes – Actinobacteria*, DOI 10.1007/978-3-642-30138-4_196,

colonies an orange to red appearance; however blue-green, brown, or purple pigments are also produced.

Most members of the family *Micromonosporaceae* are characterized by a cell-wall type chemotype II. The wall peptidoglycan contains *meso*- and/or 3-hydroxy-diaminopimelic acid and is of the A1α type; L-lysine may also be found as a diagnostic amino acid. Except for Pilimelia especies which contain acetate, the first aino acid of the peptide chain is glycine in all members of the family. Whole-organism hydrolysates are rich in arabinose, xylose, and galactose, with variable amounts of other sugars. The organisms produce complex mixtures of saturated, iso-, and anteiso-fatty acids. Phosphatidylethanolamine is the diagnostic phospholipid (phospholipid type II).

Micromonosporaceae strains have been isolated from diverse habitats including soil, sediments, fresh and marine water, rhizosphere, and plant tissues. Many species degrade chitin, cellulose, lignin, and pectin, and these microorganisms play an important role in the turnover of organic plant material. In addition, many strains produce useful secondary metabolites and enzymes. They have important applications in industry, biotechnology, and agriculture.

Taxonomy: Historical and Current

Short Description of the Family

Mi.cro.mo.no.spo.ra.ce'a.e. N. L. fem. n. *Micromonospora* type genus of the family; suff.-*aceae* ending to denote a family; N. L. fem. pl. n. *Micromonosporaceae* the *Micromonospora* family.

The family *Micromonosporaceae* is a member of the order *Micromonosporales* (Genilloud 2012) in the phylum Actinobacteria. The genus *Micromonospora* (Ørskov 1923) is the type genus of the family which at time of writing includes 27 phylogenetically closely related genera (http://www.bacterio.cict.fr) that can be distinguished using a combination of chemotaxonomic, morphological, and phylogenetic characteristics.

Members of the family *Micromonosporaceae* stain Gram-positive and form non-fragmenting, branched, and septate substrate hyphae; aerial mycelium is absent or scanty. Microorganisms in this taxon are characterized by three types of sporulating structures, namely, single spores, spore chains, and sporangia which are borne directly on the substrate hyphae. Spores may be nonmotile or motile with tufts of polar flagella. These bacteria are aerobic, non-acid fast, and mesophilic. Colonies on agar media are flat to elevated with smooth or wrinkled surfaces and show a large variety of pigments. Many strains produce carotenoid mycelial pigments giving the colonies an orange to red appearance; however blue-green, brown, or purple pigments may also be produced. The wall peptidoglycan contains *meso*- and/or 3-hydroxy-diaminopimelic acid and is of the A1α type; L-lysine may also be found as a diagnostic amino acid. Except for Pilimelia especies which contain acetate, the first aino acid of the peptide chain is glycine in all members of the family. Whole-organism hydrolysates are rich in arabinose, xylose, and galactose, with variable amounts of other sugars. The organisms produce complex mixtures of saturated, iso-, and anteiso-fatty acids. Phosphatidylethanolamine is the diagnostic phospholipid (phospholipid type II) but diphosphatidylglycerol, phosphatidylglycerol, and phosphatidylinositol are also found as major components. Mycolic acids are absent. Menaquinone profiles are heterogeneous and may include all types of the MK-9 and MK-10 series. A family-specific pattern of the 16S rRNA gene sequence signatures was defined at positions 127 : 234 (A–U), 209 (G), 534 (G), 831 : 855 (U–G), 832 : 854 (G–Y), 833 : 853 (U–G), 840 : 846 (Y–G), 845 (G), 955 : 1225 (A–U), 986 : 1219 (U–A), and 987 : 1218 (G–C) based on 17 genera described at that time (Zhi et al. 2009).

Microorganisms classified in the family *Micromonosporaceae* have been isolated from diverse habitats including soil, sediments, fresh and marine water, rhizosphere, and plant tissues (Kawamoto 1989; Zhao et al. 2004; Valdés et al. 2005; Maldonado et al. 2005a; Trujillo et al. 2007; de Menezes et al. 2008; García et al. 2010; Carro et al. 2012; Genilloud 2012).

Molecular Analyses

Phylogenetic Structure of the Family and Its Genera

As currently defined, the family *Micromonosporaceae* Krasil'nikov 1938, emend. Zhi et al. 2009 with the type genus *Micromonospora* (Ørskov 1923) is the only member of the order "*Micromonosporales*," class *Actinobacteria* (Stackebrandt et al. 1997; Genilloud 2012). In addition to the genus *Micromonospora*, at present the family includes the following genera: *Actinocatenispora* (Seo and Lee 2009); *Actinoplanes* (Couch 1950; emended by Stackebrandt and Kroppenstedt 1987), *Allocatelliglobosispora* (Lee and Lee 2011), *Asanoa* (Lee and Hah 2002), *Catellatospora* (Asano and Kawamoto 1986; emended by Lee and Hah 2002; emended by Ara et al. 2008a), *Catelliglobosispora* (Ara et al. 2008a), *Catenuloplanes* (Yokota et al. 1993), *Couchioplanes* (Tamura et al. 1994), *Dactylosporangium* (Thiemann et al. 1967), *Hamadaea* (Ara et al. 2008a), *Jishengella* (Xie et al. 2011b), *Krasilnikovia* (Ara and Kudo 2007a), *Longispora* (Matsumoto et al. 2003), *Luedemanella* (Ara and Kudo 2007b), *Phytohabitans* (Inahashi et al. 2010), *Phytomonospora* (Li et al. 2011), *Pilimelia* (Kane 1966), *Planosporangium* (Wiese et al. 2008), *Plantactinospora* (Qin et al. 2009), *Polymorphospora* (Tamura et al. 2006), *Pseudosporangium* (Ara et al. 2008b), *Rugosimonospora* (Monciardini et al. 2009), *Salinispora* (Maldonado et al. 2005a), *Spirilliplanes* (Tamura et al. 1997), *Verrucosispora* (Rheims et al. 1998), and *Virgisporangium* (Tamura et al. 2001).

According to the phylogenetic branching of the 16S rRNA gene tree, the 27 genera represented by the type species form, in general, well-defined clades; however, the genera *Phytomonospora* and *Actinocatenispora* cluster together and form a long branched cluster which is recovered outside the *Micromonosporaceae* main group (*Fig. 28.1*).

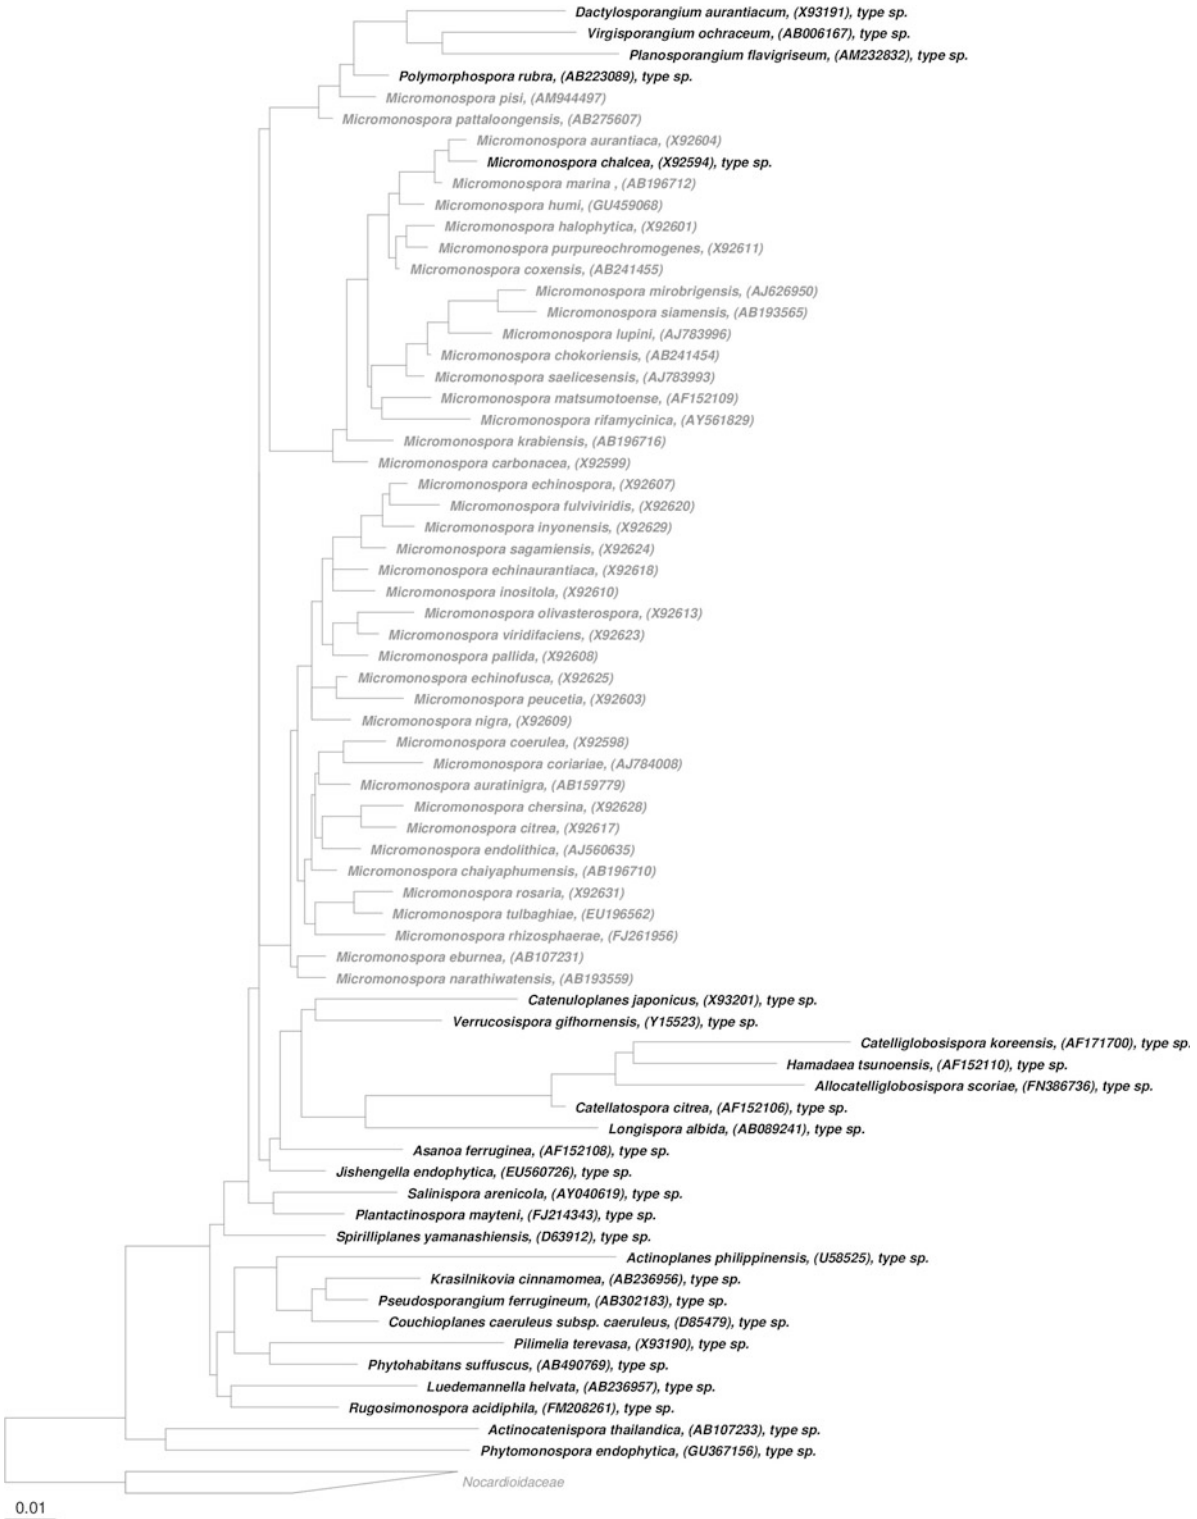

Fig. 28.1

Phylogenetic reconstruction of the family/*Micromonosporaceae*/based on 16S rRNA and created using the maximum likelihood algorithm RAxML (Stamatakis 2006). The sequence dataset and alignment were used according to the All-Species Living Tree Project (LTP) database (Yarza et al. 2010; http://www.arb-silva.de/projects/living-tree <http://www.arb-silva.de/projects/living-tree>). Representative sequences from closely related taxa were used as outgroups. In addition, a 40 % maximum frequency filter was applied in order to remove hypervariable positions and potentially misplaced bases from the alignment. *Scale bar* indicates estimated sequence divergence

The family *Micromonosporaceae* is moderately related to members of the families *Glycomicetaceae* and *Jiangellaceae*. Interestingly, when representatives of the family *Glycomicetaceae* (the genera *Glycomyces* and *Stackebrandtia*) are included in the same phylogenetic analyses, these taxa show a close relationship with the genus *Phytomonospora* (tree not shown). The three genera share several chemotaxonomic markers including a type II cell wall which contains *meso*-diaminopimelic acid. However, differences in the phospholipid type and menaquinone composition do exist. Before the genus *Phytomospora* was formally described, Ludwig et al. (2012) already pointed the close relationship between the genus *Actinocatenispora* and the members of the family *Glycomycetaceae*. In the previous edition of this volume, the genus *Glycomyces* was included with the "Actinoplanetes" taxa, due to their chemotaxonomic similarities; however, it was made clear that its position in this group was exceptional (Vobis 2006).

The largest group in ❯ *Fig. 28.1* corresponds to the *Micromonospora* species which share 16S rRNA gene sequence similarity values of 95.8–99.5 %. Clearly, the genus *Micromonospora* is polyphyletic. The type strains divide in two clades which in turn form smaller subclusters; the relative positions of the species are generally conserved in the overall topology of other phylogenetic trees constructed with different methods (Carro et al. 2012; Xie et al. 2012b). In the case of the species *Micromonospora pisi* and *Micromonospora pattaloongensis*, the type strains form separate lines of descent which relate to Pol*ymorphospora rubra*. The relationship of these strains was pointed out in recent studies including an MLSA analysis of the genus *Micromonospora* based on 5 genes: 16S rRNA, gyrB, rpoB, atpD, and recA where *P. rubra* was also included (Carro et al. 2012). The main differences between the genera *Micromonospora* and *Polymorphospora* are found in the whole cell-wall sugar composition and fatty acid type. However, García et al. (2010) reported different whole-cell sugar and fatty acid compositions when *P. rubra* TT 97-42^T was reanalyzed in a comparative study that also included *M. pisi* and *M. pattaloongensis*. Further investigation will be necessary to determine whether *P. rubra* TT 97-42^T is sufficiently different to warrant representing a genus distinct from *Micromonospora*.

The *Actinoplanes* species form the second largest group in the family tree. The genus does not represent a monophyletic taxon and also forms several clades (not shown). The species *A. globisporus* has the deepest branch and shows a similarity of 94.1 % with the species *Actinoplanes auranticolor* and up to 96.9 % with the rest of the species. Nevertheless, the phylogenetic position of *A. globosisporus* within the *Actinoplanes* clade is supported by different tree making algorithms. The genera *Krasilnikovia*, *Pseudosporangium*, and *Couchioplanes* are the nearest relatives.

The remaining members of the family (with 1–12 species at the time of writing) all form independent coherent clusters albeit not always monophyletic. Nevertheless, the distribution of genus-specific properties and signature nucleotides that define the genera correlate with the phylogenetic distinctness of each genus. Furthermore, it should be noted that 11 of the current taxa represented on the tree are monospecific genera; therefore, it is expected that the topology of the current tree will change as new representative species of these genera are added.

Molecular Analyses

DNA-DNA Hybridization Studies

DNA-DNA hybridization (DDH) studies have been carried out in many descriptions of new taxa included in the family *Micromonosporaceae*. In general, where studies have been carried out, DNA-DNA reassociation values are rather low compared to their corresponding 16S rRNA gene sequence similarity values.

In the genus *Micromonospora*, the highest DNA-DNA reassociation value, 61.3 %, has been reported between *M. inyonensis* and *M. sagamiensis;* these strains share a 16S rRNA sequence similarity value of 99.4 % (Kroppenstedt et al. 2005). Similar results were also observed between *M. chersina* and *M. endolithica* (33.5 %; Hirsch et al. 2004), *M. aurantiaca* and *M. chalcea* (44 %; Kasai et al. 2000), *M. echinospora* and *M. sagamiensis* (52 %), *M. citrea* and *M. echinofusca* (53 %), *M. echinaurantiaca* and *M. viridifaciens* (53 %) (Kroppenstedt et al. 2005). In all cases, 16S rRNA sequence similarities are >99.1 %.

Recently, Carro et al. (2012) reported a good correlation between DDH and MLSA studies. These authors propose that genomic species within the genus *Micromonospora* could be defined as groups of strains that share >98.5 % similarity in the concatenated nucleotide sequences of gyrB, recA, atpD, rpoB, and 16S rRNA genes.

Many descriptions of *Actinoplanes* species have also included DDH studies to determine the genomic status of the taxa described. In general, DNA-DNA hybridization values are moderately low; however, unlike *Micromonospora* species, the correlation between DDH values and 16S rRNA gene sequence similarities is not clear. The DNA-DNA reassociation value reported for the species *Actinoplanes auranticolor* and *Actinoplanes lobatus* is 41.5 % (Wink et al. 2006), while *Actinoplanes toevensis* and *Actinoplanes tereljensis* have a DDH value of 42.2 % (Ara et al. 2010). These two strain pairs have a 16S rRNA gene sequence similarity >99 %. Interestingly, *A. toevensis* shares a higher DNA-DNA hybridization value (46.7 %) with *A. durhamensis* while these species share a sequence similarity of 97.0 % (Ara et al. 2010). The latter species also appears to be closely related with *A. tereljensis* (56.3 %, Ara et al. 2010).

Unfortunately, DDH studies have not been carried out for various *Actinoplanes* strains that show a 16S rRNA gene sequence similarity higher than 99.5 %. This is the case for *A. campanulatus* and *A. capillaceus*, (16S sequence similarity 99.8 %), or *A. auranticolor* and *A. lobatus* (99.7 %). Likewise, *Actinoplanes humidus* and *Actinoplanes consettensis* (100 % sequence similarity) have not been included

in DNA-DNA hybridization studies to confirm that they are indeed different genomic species. Although the two representative type strains are distinguishable by the reduction of nitrate (Goodfellow et al. 1990), DNA-DNA hybridization studies may be required to confirm that they are genomically defined species.

Six of the twelve *Dactylosporangium* species descriptions have included DNA-DNA comparative studies. The overall 16S rRNA gene sequence similarity between all species ranges from 97.1 % to 99.7 %. Moderately high DNA-DNA values were reported for the species *Dactylosporangium luteum*, *Dactylosporangium luridum*, and *Dactylosporangium salmoneum* and their respective closest phylogenetic neighbors (Kim et al. 2010). Specifically, *Dactylosporangium luteum* was compared against *D. aurantiacum*, *D. luridum*, *D. matsuzakiense*, *D. salmoneum*, and *D. vinaceum*; values reported ranged from 42 % to 53 %. *Dactylosporangium luridum* was tested against *D. aurantiacum* (59 %), *D. matsuzakiense* (61 %), *D. salmoneum* (60 %), and *D. vinaceum* (61 %). DDH values ranging from 52 % to 60 % were reported between *Dactylosporangium salmoneum* and *D. aurantiacum*, *D. matsuzakiense* and *D. vinaceum*. Levels of DNA-DNA relatedness between the above-mentioned strains were established by measuring the divergence between the thermal denaturation midpoints of homologous and heterologous DNA following the procedure developed by Gonzalez and Saiz-Jiménez (2005).

The initial renaturation method (De Ley et al. 1970; Huß et al. 1983) was used to obtain DNA relatedness values between *Dactylosporangium darangshiense* and its closest relatives *D. fulvum* (12.2–14.8 %) and *D. roseum* (2.5–3.6 %); the type strains share 16S rRNA gene sequence similarities of 99.0–99.1 % (Seo and Lee 2010).

Dactylosporangium maewongense was compared against the species *D. aurantiacum*, *D. fulvum, D. matsuzakiense, D. roseum, D. thailandense*, and *D. vinaceum* showing homology values between 9.6 % and 32 % (Chiaraphongphon et al. 2010). DDH studies are also available for *Dactylosporangium tropicum* and its neighboring species *D. matsuzakiense*, *D. salmoneum*, and *D. vinaceum* with values ranging from 20.6 to 38.8 (Thawai et al. 2011). In both studies, the microplate method of Ezaki et al. (1989) was used.

Although *Dactylosporangium roseum* and *D. fulvum* share the highest 16S rRNA gene sequence similarity (99.7 %), DNA-DNA hybridization studies have not been carried out between the corresponding type strains of these species. These microorganisms described by Shomura et al. (1985, 1986) can be differentiated by several phenotypic features including the production of coremia by *D. fulvum*, the reverse color of the substrate mycelium which is pink in *D. roseum* and yellow in *D. fulvum*. In addition, the strains show different reactions to gelatin liquefaction, starch hydrolysis, and tolerance to NaCl (Shomura et al. 1986).

Yokota et al. (1993) performed DNA-DNA hybridization studies for 13 actinomycete strains and proposed to divide them into six DNA-DNA homology groups. These genomic groups were also supported by quantitative fatty acid data; however, no other phenotypic characteristics that differentiated the six DNA homology groups were found at that time (Yokota et al. 1993). Therefore, these authors refrained from describing six species in the new genus *Catenuloplanes* and only proposed one, *Catenuloplanes japonicus*; Tamura et al. (1995) later completed the studies on these strains and proposed five additional species: *Catenuloplanes niger, Catenuloplanes indicus, Catenuloplanes atrovinosus, Catenuloplanes castaneus*, and *Catenuloplanes nepalensis*. The overall DDH values among the six species range from 24 % to 56 %. DNA-DNA relatedness studies were applied to support the reclassification of "*Planopolyspora crispa*" in the genus *Catenuloplanes* as *Catenuloplanes crispus*. The values as determined by the method of Ezaki et al. (1989) between *Catenuloplanes crispus* and the remaining six species ranged from 28 % to 59 % (Kudo et al. 1999).

All five *Catellatospora* species have been defined using DNA-DNA homology studies; the values reported are 16–58 % (Lee et al. 2000; Ara and Kudo 2006). The 16S rRNA gene sequence similarity between the species is 95–99.7 %.

Asanoa ferruginea and *Asanoa ishikariensis* which were formerly classified in the genus *Catellatospora* share a 16S rRNA gene sequence similarity of 99.2 %; however, a DNA-DNA hybridization value of 41 % clearly differentiated between the two species (Lee and Hah 2002). In addition, the recently described species *Asanoa siamensis* which shares a 16S rRNA gene sequence similarities of 98.5–99.5 % with *Asanoa hainanensis* (99.5 %), *Asanoa iriomotensis* (99.0 %), *Asanoa ishikariensis* (98.9 %),and *Asanoa ferruginea* (98.5 %) share low DDH values with these species (19–31 %) (Niemhom et al. 2012).

Most of the corresponding species in the genera *Actinocatenispora*, *Couchioplanes*, *Luedemannella*, *Planosporangium*, *Plantactinospora*, *Rugosimonospora*, *Salinispora*, *Verrucosispora*, and *Virgisporangium* have been defined on the basis of DNA-DNA hybridization studies. Specific values between strain *Actinocatenispora rupis* CS5-AC17^T and the other two species were 6.1–7.1 % (*A. thailandica* DSM 44816^T) and 21.5–27.6 % (*A. sera* NRRL B-24477^T) (Seo and Lee 2009). The two subspecies of *Couchiplanes caeruleus* show a value of 52 % (Tamura et al. 1994). A DDH value of 50 % was reported for the type strains *Luedemannella helvata* and *L. flava* (Ara and Kudo 2007b). The level of DNA-DNA relatedness between the strains *Planosporangium mesophilum* YIM 48875^T and *P. flavigriseum* YIM 46034^T is 45.5 %. The type strain *Plantactinospora mayteni* YIM 111 61359^T exhibits values of 42.7 % and 24.7 % with *P. siamensis* CM2-8^T (formerly classified as *Actinaurispora siamensis*) and *P. endophytica* YIM 68255^T respectively. *P. mayteni* YIM 61359^T and *A. siamensis* CM2-8^T share 97.8 % 16S rRNA gene sequence similarity (Zhu et al. 2011). Overall genome similarity between *Rugosimonospora acidiphila* Delta1^T and *R. afrinaca* Delta3^T was reported to be <10 % (Monciardini et al. 2009). The two obligate marine *Salinispora* species, *S. arenicola* and *S. tropica*, have a DNA-DNA relatedness value of 44.9 % (Maldonado et al. 2005a). The four species assigned to the genus *Verrucosispora* exhibit DDH values above 35 %.

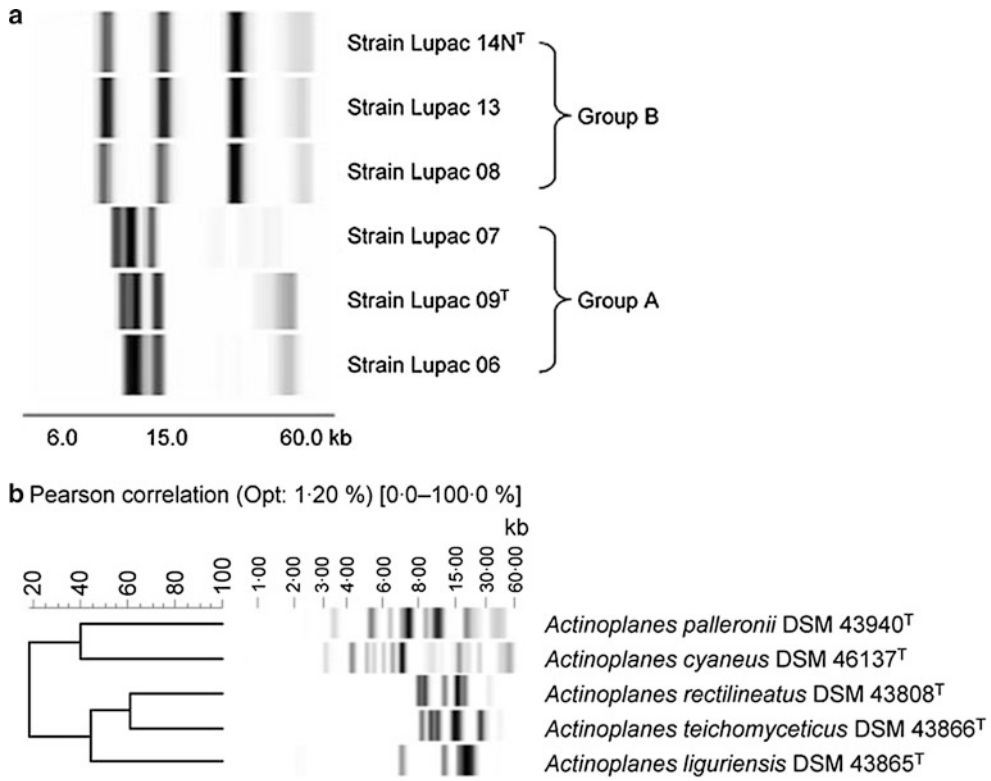

Fig. 28.2
(a) Riboprint patterns of *Micromonospora lupini* (Group B) and *Micromonospora saelicesensis* (Group A) generated with the restriction enzyme PvuII. (b) Diversity of normalized PvuII ribotype patterns found within several members of the genus *Actinoplanes* and their phylogenetic neighbors

Namely, *V. gifhornensis* shows values of 38.2 %, 42 %, and 53 % with *V. lutea*, *V. sediminis*, and *V. maris*, respectively. DNA-DNA relatedness between *V. lutea* and *V. sediminis* is reported to be 53 % (Dai et al. 2010; Goodfellow et al. 2012). 16S rRNA gene sequence similarities between the four type strains are 98.7–99.7 %. The description of the species *Virgisporangium ochraceum* (3 strains) and *V. aurantiacum* (1 strain) included overall genomic comparative studies for the four strains. The DDH values between the three strains classified as *V. ochraceum* ranged from 40 % to 60 %, 16S rRNA gene sequence similarities between these strains is 99.7–99.9 %. The values between the three *V. ochraceum* strains YU655-43^T, YU793-41, and YU794-41 and *V. aurantiacum* YU438-5^T was 12–20 % (Tamura et al. 2001). The comparison of *Virgisporangium aliadipatigenens* IR20-55^T against *V. ochraceum* NBRC 16418^T and *V. aurantiacum* NBRC 16421^T yielded values of 6–21 % (Otoguro et al. 2010).

In the case of *Longispora albida* and *Longispora fulva*, DDH studies were not carried out based on the argument that a low 16S rRNA gene sequence similarity (96.4 %) was shared by the two type strains. Since the 16S rRNA gene sequence similarities between the three species (and two subspecies) of the genus *Pilimelia* is 96.1–98.6 %, DNA-DNA hybridization studies have not been carried out. Given that at this point the genera *Allocatelliglobosispora*, *Catelliglobosispora*, *Hamadaea*, *Jishengella*, *Krasilnikovia*, *Phytohabitans*, *Phytomonospora*, *Polymorphospora*, *Pseudosporangium*, and *Spirilliplanes* contain single species descriptions, no DDH studies have been performed.

Riboprinting and Ribotyping

Only a few members of the family *Micromonosporaceae* have been included in riboprinting or ribotyping analyses. As mentioned by Stakcebrandt and Schumann (see chapter family *Cellulomonadaceae*), the automated riboprinting RiboPrint® system works with entire rrn operons and flanking DNA regions, while the ribotype approach works with PCR amplified 16S rRNA genes which are then subjected to restrictions and one-dimensional gel electrophoresis.

Several taxonomic studies have applied riboprinting for the characterization of members of the family *Micromonosporaceae*, mainly for the characterization of *Micromonospora* and *Actinoplanes* strains (Kroppenstedt et al. 2005; Wink et al. 2006; Trujillo et al. 2007). In all studies, *PvuII* was used as the restriction enzyme for cutting the genomic DNA. In the *Micromonospora* studies, riboprint profiles were obtained from six strains to demonstrate that they belonged to two different species (Fig. 28.2a) (Trujillo et al. 2007), while Kroppenstedt

Table 28.1

ND not determined

et al. (2005) produced distinct patterns for 23 *Micromonospora* type strains analyzed. In a similar way, specific profiles were obtained for each one of the *Actinoplanes* species analyzed (*Fig. 28.2b*) (Wink et al. 2006).

MALDI-TOF

Rapid identification of bacteria can be performed by whole-cell matrix-assisted laser desorption ionization-time of flight (MALDI-TOF) methodology. The identification process is based on fingerprinting analyses of ribosomal proteins and other abundant basic proteins. Ribosomal proteins represent about 20 % of the protein mass and about 3 % of the total cellular mass, and as they are specific to individual species, they are ideal to be used as biomarkers (Liyanage and Lay 2006; Uhlik et al. 2011). So far, this technique has only been applied to analyze eight *Micromonospora* type strains (Kroppenstedt et al. 2005). In this study, the strains were analyzed over a mass (m = z) range of 2,000–20,000 and compared to new isolated strains. The number of peaks of significant intensity ranged between 14 (*Micromonospora olivasterospora* DSM 43868^T) and 43 (*M. echinaurantiaca* DSM 43904^T). MALDI-TOF mass spectroscopy of whole cells confirmed the discrete taxonomic entity of each of the test strains and type strains of described species. Mass similarity values for repeated analyses of individual strains ranged above 70 %. In contrast, mass similarities determined between strains were significantly lower, ranging from 0 % to 42 %. The full potential of the MALDI-TOF spectrometric method for identification and authenticity of *Micromonospora* species, and other members of the family *Micromonosporaceae*, still needs to be investigated.

Genome Comparison

The chromosome topology of *Micromonosporaceae* was first determined by Pulse Field Gel Electrophoresis (PFGE) for the strains *Actinoplanes philippinensis* DSM 43019^T and *Micromonospora chalcea* DSM 43026^T. Both strains were shown to contain chromosomes with genome sizes of 8.8 and 7.7 Mb, respectively, and both chromosomes were suggested to be linear (Redenbach et al. 2000). This preliminary information has been gradually enriched after the completion of full genome sequences from a reduced number of strains of the family *Micromonosporaceae*. At present, genome comparison is currently possible for several strains of the genera *Actinoplanes*, *Micromonospora*, *Salinispora*, and *Verrucosispora*. These genome sequences have shown that members of the family present large circular chromosomes ranging from 5.1 to 9.2 Mb (*Table 28.1*). First annotations have revealed that extended regions in these genomes are devoted to secondary metabolism, and to adaptation and colonization of the environment. The first *Micromonospora* genome to be publicly available corresponds to the type strain *Micromonospora aurantiaca* ATCC 27029^T, containing a circular chromosome of 7.03 Mb with 72.8 % GC content. The genome presents 6.361 protein-coding genes, 9 rRNA genes, and 52 tRNA genes, and 6.222 proteins have been predicted, including proteins related to secondary metabolism and several hydrolytic enzymes such as xylanases and amylases that may play a role in their life cycle and the colonization in the environment (Genbank accession no. CP002162.1). The second *Micromonospora* full genome sequence published corresponds to the strain *Micromonospora lupini* Lupac 08, a strain isolated from the root nodules of *Lupinus angustifolius*, with 7.32 Mb and a GC content of 71.96 % (Alonso-Vega et al. 2012). The annotation of this sequence has revealed 7,054 protein-coding genes, 10 rRNA genes and 77 tRNA genes (GenBank accession no. CAIE01000001). Preliminary data obtained from the genome sequence of *M. lupini* Lupac 08 indicate, as in the case of *M. aurantiaca*, that it contains a significant number of genes involved in secondary metabolism as well as genes encoding hydrolytic enzymes such as cellulases, amylases, xylanases, and pectinases. A third *Micromonospora* full genome sequence corresponding to the non-characterized strain of *Micromonospora* sp. L5 isolated from the roots of *Casuarina equisetifolia* in Mexico has been recently made available. The circular genome with 6.96 Mb and 72.8 % GC content has

been shown to contain 6,326 genes coding for 6,150 proteins, 9 rRNAs, and 53 tRNAs (GenBank accession no. CP002399).

The genomes of members of the genus *Actinoplanes* have only been studied for two industrial strains, the strain *Actinoplanes missouriensis* 431 (ATCC 14538, NBRC 102363) (Yamamura et al. 2012), an industrial strain producing xylose isomerase and glucose isomerase, two enzymes used in the production of high-fructose corn syrup (Yamamura et al. 2012) and the strain *Actinoplanes* sp. SE50/110, the producer of the α-glucosidase inhibitor acarbose (Schwientek et al. 2012). The genome of *A. missouriensis* 431 is a circular chromosome of 8.77 Mb with 70.8 % GC content that contains 8.203 genes coding for 8,124 proteins, 18 rRNAs, and 58 tRNAs. The genome sequence of the strain *Actinoplanes* sp. SE50/110 has been recently published (GenBank Accession No. CP003170) as a circular chromosome of 9.24 MB with 71.3 % GC content coding for 8,247 proteins, 18 rRNAs, and 97 tRNAs. Two additional *Actinoplanes* species are currently being sequenced although no completed data are still available: the strain *Actinoplanes friuliensis* DSM 7358^T, the producer strain of the lipopeptide antibiotics friulimicins, and the type strain *Actinoplanes globisporus* DSM 43857^T.

In the case of the obligate marine genus *Salinispora*, full genome sequences are available for both formally described species, Salinispora arenicola CNS-205 (GenBank accession No. CP000850) and Salinispora tropica CNB-440^T (GenBank accession No. CP000667). The genome sequence of both strains revealed circular chromosomes of 5.79 and 5.18 Mb, respectively, with a GC content of 69.5 %. The difference in the genome sizes is translated in the number of 5,172 and 4,654 genes coding for 4,917 and 4,536 predicted proteins. In the case of *S. tropica* CNB-440^T, the producer of the proteasome inhibitor salinosporamide A, almost 9.9 % of its genome is dedicated to natural product assembly with as many as 17 secondary metabolic biosynthesis gene clusters predicted to be involved in siderophore, melanin, polyketide, non-ribosomal peptide, terpenoid, and aminocyclitol production (Udwary et al. 2007). A comparative genomic analysis has revealed a large paralogous family of genes encoding polymorphic membrane proteins of the type V autotransporters, proposed to represent an adaptation to life in low nutrient environments (Penn et al. 2009). More recently, the presence of candidate marine adaptation genes has been proposed in both *Salinispora* genome sequences, *S. arenicola* CNS-205 and *S. tropica* CNB-440^T (Penn and Jensen 2012). In the case of the proposed third species "*Salinispora pacifica*" CNT-133, the partial full genome sequence has revealed so far a smaller genome (4.38 Mb) of similar GC content (69.8 %).

The strain *Verrucosispora maris* AB-18-032^T was isolated from a deep marine sediment sample collected from the Sea of Japan and produces the abyssomicins, natural-product inhibitors of the *para*-aminobenzoic acid biosynthetic pathway, and the antitumoral proximicin A, a furan analogue of netropsin. This strain is the first member of this genus to be sequenced (Roh et al. 2011). It has been shown to contain a circular chromosome of 6.67 Mb with a GC content of 70.9 % and a circular plasmid of 0.58 Mb with a GC content of 70.3 %. The chromosome has 5,947 protein-coding sequences, 51 tRNA genes, and 9 rRNA genes, whereas the plasmid contains 55 coding genes.

Additional full genome sequencing projects are currently in progress as part of a large international full genome sequence project, for the type species *Longispora albida* DSM 44784^T and Catelliglobosispora koreensis DSM 44566^T.

Current genome analysis has been limited to a reduced number of strains but has provided the first insights into the enormous metabolic diversity, adaptation capabilities, and biosynthetic potential of the members of this family that are still largely underexplored. The generation of new genome sequences, an activity currently in expansion, will open new avenues to explore the topology and organization of these genomes across different members of the family *Micromonosporaceae*.

Phages

Several *Micromonospora*-specific actinophages have been reported, including the lytic phages φUW21 and φUW51 (Kikuchi and Perlman 1977, 1978), the temperate phage MPφWR-1 (Tilley et al. 1990), and phages with undetermined infection cycles and specificities (Caso et al. 1990). Several other lytic *Micromonospora* phages have been used to screen for the presence of restriction enzymes (Meyertons et al. 1987). Phage pMLP1 was found to be present in "*Micromonospora carbonacea* var. *africana*" ATCC 39149 as a replicative form as well as an integrative form and plasmid derivatives containing the site-specific *att*/*int* functions of pMLP1 were found to be able to integrate genes into the chromosome (Alexander et al. 2003). None of the *Micromonospora* phages, however, have been developed into a gene cloning vector. Li et al. (2004) described a temperate phage, φHAU8, that is capable of infecting and transfecting *Micromonospora* sp. strain 40027, a producer of fortimicin A, which exhibits potent, broad-spectrum antibacterial activity against Gram-positive and Gram-negative bacteria both in vitro and in vivo (Ma et al. 1986). These authors developed φHAU8 into a phasmid that functions as a λ-cosmid vector in *Escherichia coli* and as a phage in *Micromonospora* sp. strain 40027. A *Micromonospora*-specific phage isolated from soils of Tropical Rain Forests of Northern Queensland was reported to cross inter-genus boundaries and lysed several *Actinoplanes* and *Couchioplanes* strains (Kurtböke et al. 1998).

Crystalline phage particles have been detected in the cytoplasm of the substrate hyphae of a *Dactylosporangium thailandense* strain; the phage showed poor lytic activity and did not infect other actinomycetes (Higgins and Lechevalier 1969).

Phages infecting the industrially important *Actinoplanes* strain SN223 were isolated from soil samples collected at the shores of inland waters in Germany. The genome sizes range from 53 to 58 kb. Preliminary analyses revealed G+C contents

comparable with the G/C bias of the host. Electron microscopy of three selected viruses displayed no obvious morphological differences, the phage heads being icosahedral and their tails non-contractible. Two of the phages (φAsp2, φAsp3.1) characterized in more detail are capable of provoking putative pseudolysogenic growth of the host bacterium. The carrier state for φAsp2, in which cells are tightly packed with viruses, was demonstrated by electron microscopy. The latter phage is apparently widely distributed, as it was isolated from regions which are distantly located, i.e., more than 600 km apart from each other (Jarling et al. 2004a). Phage φAsp2 has a circularly permutated chromosome that consists of 58,638 bp; its G/C-bias of 70.39 % resembles the host's G+C content (71–73 % within the genus) (Jarling et al. 2004b).

Phenotypic Analyses

Since the last edition of *The Prokaryotes*, most taxa included in the chapter "*Actinoplanes*, and related genera" have been formally grouped in the family *Micromonosporaceae*. At present, the family includes 27 genera, of which the type genus *Micromonospora* is the largest with 48 validly published species at the time of writing. The main morphologic and chemotaxonomic features of members in the family *Micromonosporaceae* are listed in ❯ *Table 28.2*.

Micromonospora Ørskov 1923, 321[AL] Emend. Kasai et al. 2000

Mi.cro.mo.no.spo'ra. Gr. adj. *mikros*, small; Gr. adj. *monos*, single, solitary; Gr. fem. n. *spora*, a seed and in biology a spore; N.L. fem. n. *Micromonospora*, small, single-spored (organism).

Typically, Micromonosporae colonies on agar media are light orange, orange, red, brown, or purple. In many old cultures a green-black, brown-black, or black mucous mass of spores becomes apparent (❯ *Fig. 28.3c*). Good to moderate growth is observed on several ISP media including ISP 3, ISP 4, ISP 5, and ISP 6 agars (Shirling and Gottlieb 1966). Abundant growth is usually obtained on ISP 2, modified Bennett's (Wakisaka et al. 1982), and SA1 agars (Trujillo et al. 2005). Colonies are raised and folded with areas of different colors, and soluble pigments may also be formed (3A). The upper mycelial layers may burst open (❯ *Fig. 28.3b*, *d*) Well-developed, branched, substrate mycelium (0.2–06 µm diameter) is produced while aerial mycelium is usually absent or scanty.

The formation of single spores is the main morphological characteristic of the genus *Micromonospora*; however, spores are often produced in dense clusters on the surface or completely embedded in the substrate (❯ *Fig. 28.3e*). The spores are nonmotile, and spherical to oval in shape, with a diameter of 0.7–1.5 µm. The spore surface ornamentation of Micromonosporae may be smooth, warty, or blunt-spiny as in the case of *M. saelicesesis*, *M. rosaria*, and *M. echinospora* respectively.

Compared to *Streptomyces*, *Micromonospora* spores are quite resistant. Viable spores of *Micromonospora* were recorded from sediments deposited at least 100 years before (Cross and Attwell 1974). Populations of *Micromonospora* species, accompanied by other actinomycetes, have also been frequently found in streams, rivers and lakes (Rowbotham and Cross 1977; Al-Diwany and Cross 1978; de Menezes et al. 2008). Their spores are hydrophilic and wettable and can easily be removed from soil by the passage of water (Ruddick and Williams 1972). The spores withstand ultrasonication, moist heat treatment (20 min at 60 °C), and dry heat up to 75 °C, and they are resistant to various chemical solutions such as acetone (Kawamoto et al. 1982), dimethylformamide, formamide, *tert*-butyl alcohol, and phenol (Hayakawa et al. 1991b). However, they are sensitive to acidic pH (Kawamoto 1989).

Micromonosporae stain Gram-positive, are non-acid fast, chemo-organotrophic and usually grow between 20 °C and 45 °C. NaCl tolerance ranges from 1.5 % to 5 % (w/v). *Micromonospora* strains do not grow below pH 5.0 or above pH 9.5.Most strains are aerobic, but some may grow under microaerophilic conditions (Goodfellow and Williams 1983). Although strictly anaerobic *Micromonospora* strains isolated from the intestinal tract of termites (Hungate 1946) and from the rumen of sheep (Maluszy'nska and Janota-Bassalik 1974) have also been reported, these isolates need to be properly identified to clarify their affiliation to the genus *Micromonospora*.

Micromonospora species are well known for their ability to degrade complex polysaccharides such as cellulose, chitin, and lignin (McCarthy and Broda 1984; Kawamoto 1989; Jendrossek et al. 1997). In particular, cellulose is frequently utilized as substrate (Jensen 1930; Sandrak 1977; Kawamoto 1989). *Micromonospora* strains isolated from fresh water lakes in the United Kingdom were reported to degrade cellulose (de Menezes et al. 2008). Furthermore, these *Micromonospora* populations were also shown to be important members of the active bacterial population in these freshwater lakes, particularly colonizing cellulosic substrates at the lake sediment (de Menezes et al. 2012). The genome sequence of *Micromonospora lupini* Lupac 08 isolated from a nitrogen-fixing nodule of the legume *Lupinus angustifolius* was recently sequenced (Alonso-Vega et al. 2012). Information derived from the genomic data indicated that this strain contains a significant number of genes encoding hydrolytic enzymes such as cellulases, amylases, xylanases, and pectinases that may have a role in the colonization process. Cellulose and xylan degradation was recently confirmed in the laboratory (Trujillo, unpublished results). Selected phenotypic characteristics of the genus *Micromonospora* are given in ❯ *Table 28.3*.

Carbohydrates, amino acids, and organic acids are used as carbon sources by Micromonosporae strains. However, various authors have reported that carbohydrate utilization patterns are affected by the basal medium and this may be an explanation for discrepancies between results when studies are performed on different media (Kawamoto 1989). Carro (2009) carried out carbon source utilization studies for 35 *Micromonospora* type

[b]According to Lechevalier et al. (1981)

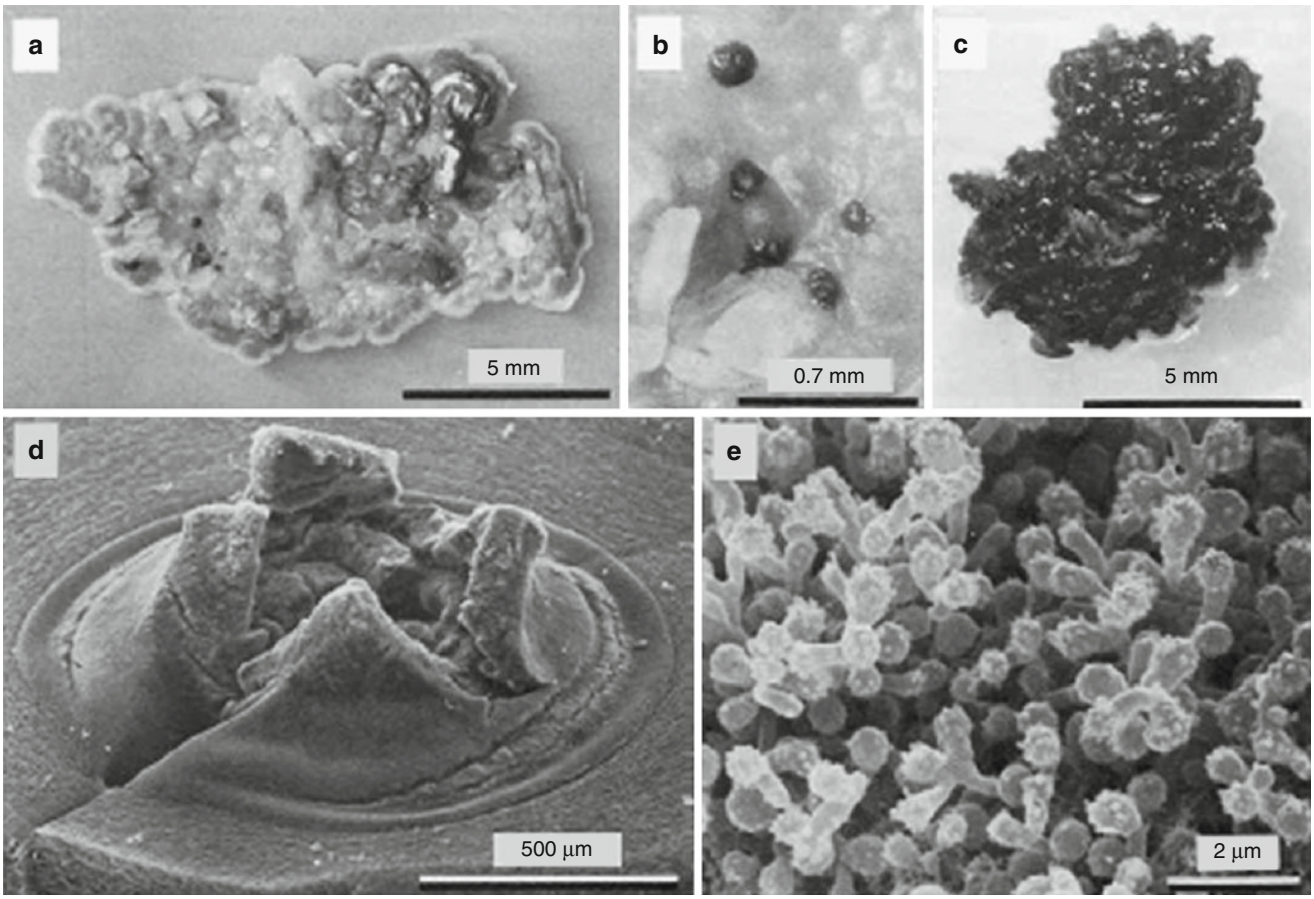

Fig. 28.3

Morphological features of the genus *Micromonospora*. (a) Raised and folded colony with areas of different colors (DM). (b) Clusters of dark spore masses (DM). (c) Colony completely covered by a mucoid, black mass of spores (DM). (d) Crosswise-burst colony exposing the spore-forming substrate mycelium (SEM). (e) Cluster of spores formed on short side-branches of substrate hyphae; surface of the spores is covered with blunt spines (SEM). *DM* dissecting microscope, *SEM* scanning electron microscope

strains using Stevenson's carbon-free medium (Stevenson 1967) as basal medium. These results are consolidated in *Table 28.4*. As expected, all strains utilized glucose, while 80–85 % of the strains utilized arabinose, cellobiose, galactose, mannose, and starch. Arginine, fructose, maltose, raffinose, and saccharose were used by 70–75 % of the strains. On the other hand, none of the strains were able to utilize galacturonic acid, glutaric acid, propionic acid, histidine, *meso*-erythritol, sorbitol, tyrosine, trehalose, xylitol, and xylose. Discrepancies between Carro's results and those published previously for carbohydrate assimilation were observed, confirming earlier observations on the effect of the basal medium on these substrates (Kawamoto et al. 1983; Kawamoto 1989; Genilloud 2012). Inorganic ammonium salts and acidic and basic amino acids are better nitrogen sources than nitrate salts (Kawamoto 1989).

According to the classification scheme of Lechevalier and Lechevalier (1970a), the genus *Micromonospora* is characterized by a cell-wall type II. Glycine and *meso*-diaminopimelic acid (A_2pm) and/or 3-hydroxy-diaminopimelic acid are the characteristic amino acids of the peptidoglycan. The primary structure of the peptidoglycan was described by Kawamoto et al. (1981); glycine, rather than L-alanine, is linked to muramic acid and *meso*-diaminopimelic acid or its hydroxylated derivative is directly cross-linked to the D-alanine of an adjacent peptide subunit. Muramic acid is *N*-glycosylated. The presence of 3-OH-DAP is only found in certain species including *M. carbonacea*, *M. echinospora*, *M. halophytica*, *M. inositola*, *M. matsumotoense*, *M. olivasterospora*, and *M. rosaria*. Deviations from the typical wall chemotype II is found in some *Micromonospora* species, which also contain LL-diaminopimelic acid (Kawamoto et al. 1981). The characteristic whole-cell sugar pattern of *Micromonospora* strains is pattern D, as defined by Lechevalier and Lechevalier (1970b). Xylose and arabinose are the characteristic sugars in *Micromonospora* species; however, the latter sugar is not reported for the species *M. mirobrigensis*, *M. echinofusca*, *M. fulviviridis*, *M. sagamiensis*, or *M. viridifaciens* (Kroppenstedt et al. 2005; Trujillo et al. 2005). In addition, glucose, galactose, mannose, and rhamnose can also be found. Characteristic phospholipids include

All data from Carro (2009), except where indicated

+ positive, – negative, *w* weak, *nd* not determined

[a]Data from Kroppenstedt et al. (2005), Thawai et al. (2007), Jongrungruangchok et al. (2008a, b), Kirby and Meyers (2010), Tanasupawat et al. (2010), Xie et al. (2012b), Songsumanus et al. (2011), Wang et al. (2011), Supong et al. (2012), Everest and Meyers (2012), Zhang et al. (2012)

diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylinositol, and phosphatidylinositol mannosides, a phospholipid type PII (Lechevalier et al. 1977). The main fatty acids are *iso*- and *anteiso*-branched fatty acids. Saturated and unsaturated fatty acids present in *Micromonospora* strains include anteiso-$C_{15:0}$, anteiso-$C_{17:0}$, iso-$C_{16:0}$, iso-$C_{15:0}$, and iso-$C_{17:0}$ acids. Unsaturated or 10-methyl fatty acids may be found in certain strains, but not mycolic acids nor cyclic fatty acids (Kroppenstedt and Kutzner 1976; Dassain et al. 1983). The menaquinone composition of members of the genus *Micromonospora* is complex and heterogeneous; strains can be divided into three groups based on the predominant menaquinone. The two major groups encompass species that have menaquinones with either nine (MK-9) or ten isoprene units (MK-10); the exception, *M. pallida*, has menaquinones with 12 units (MK-12) (Collins et al. 1984; Kawamoto 1989; Tomita et al. 1992; Hirsch et al. 2004, Thawai et al. 2004b, 2005b; Kroppenstedt et al. 2005; Trujillo et al. 2005).

Actinocatenispora Thawai et al. 2006, Emend. Seo and Lee 2009

Ac.ti.no.ca.te.ni.spo′ra. Gr. n. *aktis -inos*, ray; L. n. *catena*, chain; Gr. fem. n. *spora*, seed, and in biology a spore; N.L. fem. n. *Actinocatenispora*, spore chain-producing ray (fungus).

Actinocatenispora strains produce well-developed substrate mycelia on ISP 2 agar, oatmeal agar (ISP 3), and peptone-yeast extract-iron agar (Thawai et al. 2006; Matsumoto et al. 2007; Seo and Lee 2009). The color of the substrate mycelium ranges from pale yellow to orange. White aerial mycelium may also be produced by the species *A. rupis* (Seo and Lee 2009). Spore chains which may consist of up to 20 spores are borne on the aerial mycelium or produced directly from the vegetative mycelium. The spores are cylindrical (0.3–0.4 × 0.5–1.0 μm in size), smooth, and nonmotile. The genus currently harbors three species, *A. thailandica*, the type species, *A. rupis* and *A. sera*.

All Actinocatenisporae strains stain Gram-positive, are aerobic, and usually grow best between 18 °C and 37 °C. Only *A. rupis* grows at 42 °C. They are heterotrophic microorganisms capable of using a diverse array of sugars as carbon sources; however, important differences are found in their assimilation profiles and only D-*glucose* is reported to be used by all species (*Table 28.5*) (Thawai et al. 2006; Matsumoto et al. 2007; Seo and Lee 2009). *Actinocatenispora rupis* and *A. sera* are also capable of metabolizing adonitol, while differences between the three species are found in the assimilation of D-arabinose, glycerol, cellobiose, dextran, galactose, *myo*-inositol, lactose, maltose, D-mannitol, D-mannose, D-melibiose, D-raffinose, L-rhamnose, salicin, xylitol, and xylose.

Various chemotaxonomic markers have been defined in the genus *Actinocatenispora*. The whole-cell sugars arabinose and xylose have been detected in all strains, while the presence of galactose, glucose, mannose, rhamnose, and ribose varies. The cell wall contains glutamic acid, glycine, alanine, and *meso*-diaminopimelic acid. The fatty acid profile includes saturated, unsaturated, and branched fatty acids of which i-$C_{15:0}$, i-$C_{16:0}$, i-$C_{17:0}$, ai-$C_{17:0}$ are the major components (type 3b, Kroppenstedt 1985). The predominant menaquinone is MK-9(H_4), but MK-9 (H_6) and MK-9(H_8) are present in some strains (Seo and Lee 2009). The diagnostic polar lipid in all *Actinocatenispora* strains is phosphatidylethanolamine, but the overall profiles may also contain diphosphatidylglycerol, phosphatidylinositol, phosphatidylinositol mannosides, phosphatidylglycerol, and several unidentified ninhydrin-negative phospholipids (Thawai et al. 2006; Matsumoto et al. 2007; Seo and Lee 2009). Selected phenotypic and chemotaxonomic characters are given in *Table 28.5*.

Actinoplanes Couch 1950, 244[AL] Emend. Stackebrandt and Kroppenstedt 1988

Ac.ti.no.pla'nes. Gr. n. *aktis -inos*, ray, beam; Gr. masc. n. *planes*, a wanderer, roamer; N.L. masc. n. *Actinoplanes* literally, a ray wanderer; intended to signify an actinomycete with swimming spores.

The genus *Actinoplanes* is the second largest group in the family *Micromonosporaceae* and currently holds 30 validly published species. Strains grow well on various complex media such as peptone-Czapek agar (Bland and Couch 1981), Bennett's agar (Waksman 1961), and various ISP media (Shirling and Gottlieb 1966). Actipolanetes form compact colonies up to about 3 cm in diameter after 4–6 weeks of incubation (*Fig. 28.4a*, *c*). These colonies are usually elevated and convoluted, and frequently have protuberances in the center (*Fig. 28.4a*). *Actinoplanes* strains are typically orange to bright orange due to the production of carotenoid pigments (Szaniszlo 1968), but colonies may also be black, brown, cream, green, purple, red, rusty brown, or yellow (Parenti and Coronelli 1979; Vobis 1987; Palleroni 1989).

Actinoplanes species produce a branched and septated substrate mycelium (0.2–1.0 μm in diameter). Although fragmentation of the substrate mycelium is not a common feature, it has been observed in the species *Actinoplanes couchii* when cultured on DSMZ medium 65 (Kämpfer et al. 2007). Aerial mycelium is usually absent or only rudimentarily developed. The unusual presence of aerial hyphae is characteristic for *A. couchii*, *A. ferrugineus*, *A. linguriensis*, *A. rectilineatus*, and *A. teichomyceticus* (Palleroni 1989; Wink et al. 2006). Colonies can be covered with a whitish bloom, if abundant sporangia are produced on the surface of the substrate mycelium (*Fig. 28.4b*, *d*). In general, sporangia develop directly on the surface of a colony (*Fig. 28.4d–f*). In *A. minutisporangius*, they are also submerged (Ruan et al. 1986). Frequently, the sporangia arise terminally from "palisade" hyphae, which are thicker in diameter and vertically oriented (Bland and Couch 1981). Inside the sporangia, the spores are arranged in coils (*Fig. 28.4g*); but in *A. rectilineatus*, they run in parallel rows (Lechevalier and Lechevalier 1975). If the

sporangial envelopes are very thin and transient, individual sporangia may be attached (*Fig. 28.4e*). The shape of the sporangia ranges from globose, subglobose, oval, umbelliform, cylindrical, or lobate to irregular. The average size of a sporangium is from 4 to 25 µm in diameter. Extreme dimensions of sporangia exist in *A. minutisporangius*, with 2 µm as a minimum (Ruan et al. 1986) and 47 µm as a maximum (G. Vobis, unpublished observations).

The spores of *Actinoplanes* are globose or subglobose to short bacilliform and possess a tuft of flagella. *Actinoplanes missouriensis* NBRC 102363 flagellated spores were recently characterized (Uchida et al. 2011). The average swimming speed of the motile spores was 135 µm/s and belongs to the fastest group among bacterial swimming species so far studied. The number of flagella in this strain ranged from 10 to 19 on an average. The flagella grow from one side of the spore rather than around it, as seen for peritrichous flagella, indicating that the spore has polar flagella despite its round cell body (Uchida et al. 2011). Although it is not common for cocci to retain polar flagella in eubacterial species, this organization has been observed in archaeal species, such as *Methanococcus voltae*, in which more than 80 flagella grow from one side of the cell body (Bardy et al. 2002).

Spores of *Actinoplanes brasiliensis* retain their motility for more than one day in liquid mineral medium with glucose (Palleroni 1983). The zoospores of *Actinoplanes* exhibit chemotactic properties. In *A. brasiliensis*, Palleroni (1976) found bromide and chloride ions acting as attractants at a relatively high concentration (0.1 M). Addition of methionine stimulated this chemotactic effect, suggesting that protein methylation may be involved (Palleroni 1983). Not all species of *Actinoplanes* are attracted by halides. Spores of *A. missouriensis* were attracted to fungal conidia, chlamydospores, sclerotia, and to exudates (Arora 1986). Several sugars had the same function. An extract of cattle horn meal can be more attractive to the spores than chloride ions (G. Vobis, unpublished observations). Phototactic effects could not be observed, but an apparent microaerophilic behavior was seen in *A. brasiliensis* (Palleroni 1976). In baiting experiments simulating an aquatic microhabitat, pollen or hair is exposed to the surface of water. The zoospores, once released from the submerged sporangia, are able to swim to the surface, fasten to the natural substrates,

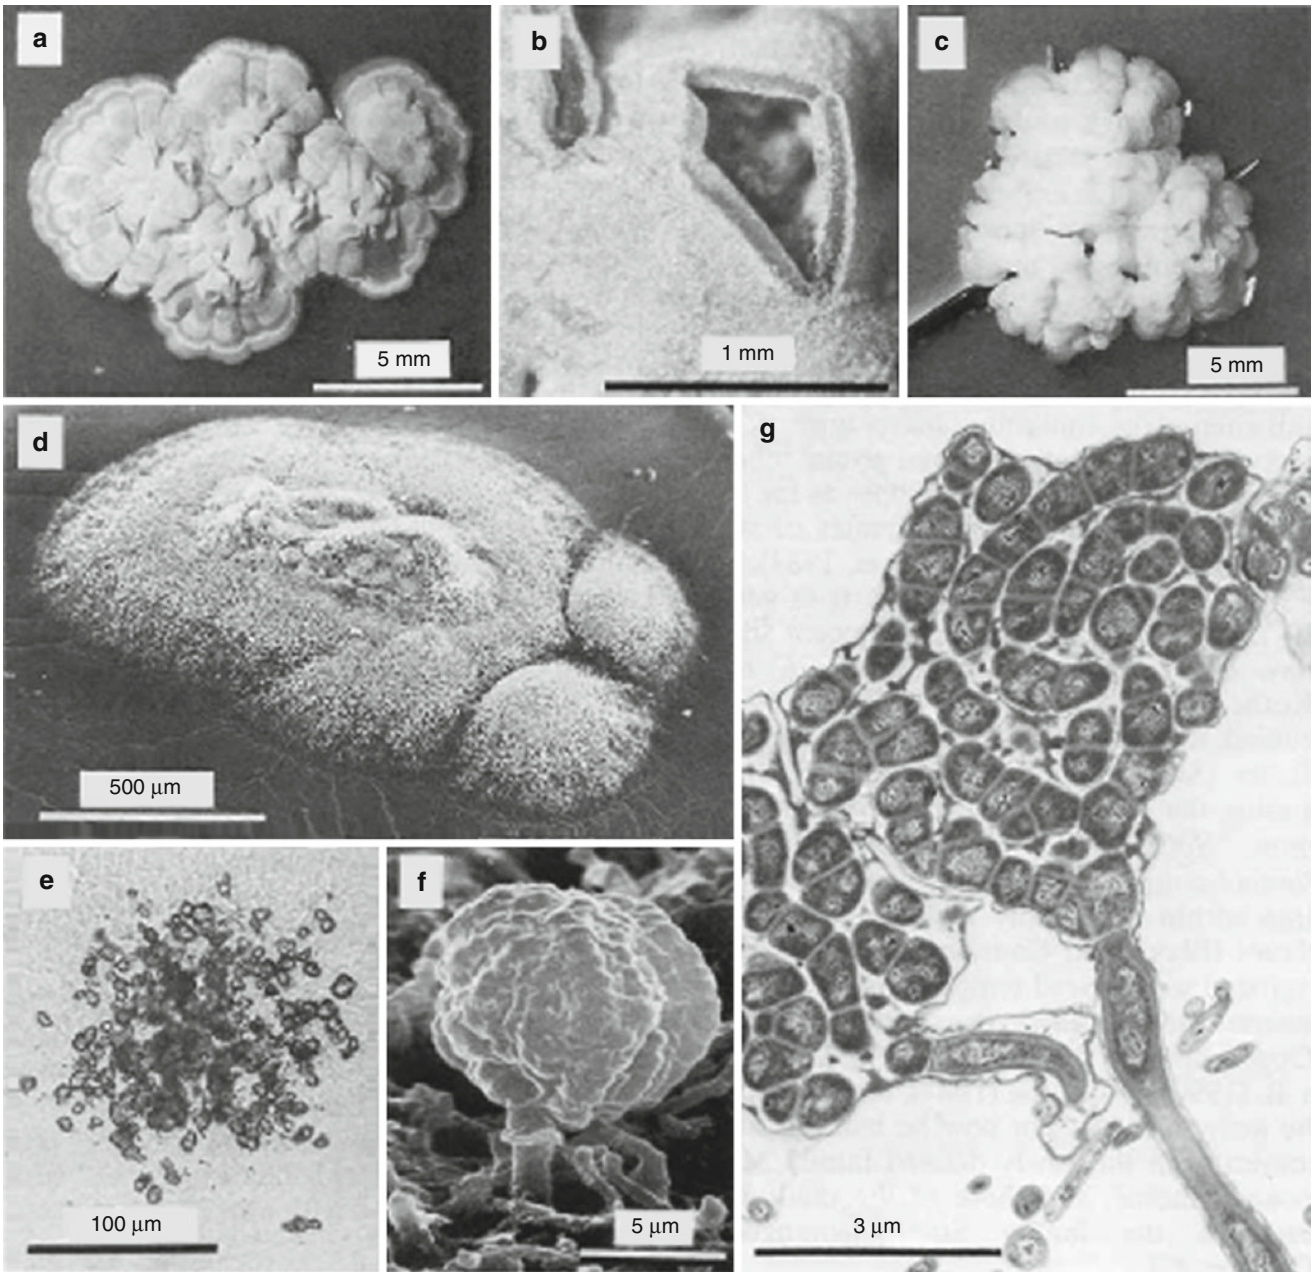

Fig. 28.4
Features of the genus *Actinoplanes*. (a) Colony with rough surface; marginal areas divided into radial and concentric sections, dissecting microscope (*DM*). (b) Burst substrate mycelium covered with a mass of sporangia (DM). (c) Elevated colony with squamules; smooth surface without sporangia (DM). (d) Flat colony with abundant sporangia visible on the substrate mycelium, scanning electron microscope (*SEM*). (e) Irregularly shaped sporangia on agar medium, light microscope (*LM*). (f) Globose sporangium at the tip of a palisade hypha (SEM). (g) Section of a sporangium with coiled chains of spores (*TEM*) (G from Kothe 1987; with permission). *DM* dissecting microscope, *LM* light microscope, *SEM* scanning electron microscope, *TEM* transmission electron microscope

germinate, and colonize them within several days (Couch 1963; Vobis 1984). This may be a result of aerotactic and chemotactic behavior of the spores (Cross 1986). Although the chemotactic response is used effectively in the isolation method of Palleroni (1980), the exact physiological explanation is not yet known.

Green, yellow, or brown soluble pigments are produced by several *Actinoplanes* species. In addition, a cherry-red pigment is characteristic of *Actinoplanes italicus* (Beretta 1973) and a soluble blue pigment, found in *Actinoplanes cyaneus*, has been identified as a celocomycin-actinorodine molecule (Terekhova et al. 1977). Melanoid pigments are also produced by *Actinoplanes digitatis* (Couch 1963).

Actinoplanetes stain Gram-positive, are non-acid fast and aerobic with an oxidative metabolism. The growth temperature

ranges from 10 °C to 35 °C, but the species *A. deccanensis* can grow at 45 °C (Parenti and Coronelli 1979). No growth is observed below 4 °C or above 50 °C. The pH growth range is 6.0–8.0, but several species have been reported to grow in acid (pH 4.0) or alkaline conditions (pH 10.0) (Kothe 1987). Physiological tests such as degradation, hydrolysis, coagulation, peptonization, or liquefaction of various compounds have been carried out for many *Actinoplanes* species (Table 28.6). Thus, casein, chitin, gelatin, lecithin, DNA, and RNA are decomposed by most species. The plant polymer pectin is decomposed by most species, but contradictory results have been reported for the degradation of cellulose (Schäfer 1973; Goodfellow et al. 1990; Solans and Vobis 2003). In addition, hemicellulose can be degraded and lignocellulose can be used as a substrate by several strains (Solans and Vobis 2003). Enzymatic activities for the species *A. liguriensis, A. palleroni, A. rectilenatus, A. regularis, and A. teichomyceticus* have been determined using the API test systems API 20E and API ZYM (Wink et al. 2006). Furthermore, the species *A. couchii*, *A. italicus*, and *A. rectilienatus* have been tested for enzymatic activities based on chromogenic substrates (Kämpfer et al. 2007; Vobis et al. 2012).

Actinoplanes species are capable of assimilating a large variety of substrates as carbon sources including carbohydrates, amino acids, and organic acids. Unfortunately, not all type strains have been tested for the same compounds and it is not easy to make a comparison of their assimilation profiles (Table 28.6). Nevertheless, glucose is utilized by all species, although apparently *A. cyaneus* has never been tested (Vobis and Kämpfer 2012). L-arabinose and D-fructose are used by most species, but contradicting results are reported for *A. liguriensis* (Palleroni 1989; Wink et al. 2006), *A. digitatis* (Vobis and Kothe 1989), and *A. palleroni* (Goodfellow et al. 1990; Wink et al. 2006). In a similar way, D-galactose, D-maltose, D-mannose, D-rhamnose, and D-xylose are used by most species tested (Table 28.6).

According to the classification scheme of Lechevalier and Lechevalier (1970b), the members of the genus *Actinoplanes* are characterized by cell-wall chemotype II. Glycine and *meso*-diaminopimelic acid (A2pm) and/or 3-hydroxy-diaminopimelic acid are the amino acids characteristic of the peptidoglycan. The primary structure of the peptidoglycan was described by Kawamoto et al. (1981). Glycine, rather than L-alanine, is linked to muramic acid, and *meso*-diaminopimelic acid or its hydroxylated derivative is directly cross-linked to the D-alanine of an adjacent peptide subunit: muramic acid is *N*-glycosylated. The *N*-glycolyl muramic acid is a characteristic unique to the genera with cell-wall type II and is found in many *Actinoplanes* and "*Ampullariella*" species (Stackebrandt and Kroppenstedt 1987). It can be easily identified by a colorimetric method (Uchida and Aida 1977).

Actinoplanes species have wall chemotype II and the sugar pattern D (Lechevalier and Lechevalier 1970a) whereby the pentoses xylose and arabinose are the characteristic sugars. Other sugars that may be present are arabinose, galactose, glucose, and mannose. Galactose has not been detected in *Actinoplanes regularis*, *Actinoplanes campanulatus*, or *Actinoplanes digitatis* (Stackebrandt and Kroppenstedt 1987). The phospholipid profile corresponds to type II (Lechevalier et al. 1977; 1981) and is characterized by the presence of phosphatidylethanolamine as diagnostic phospholipid; nevertheless, this phospholipid is not present in *A. regularis* (Stackebrandt and Kroppenstedt 1987). Other lipids that may be present include phosphatidylinositol, phosphatidylinositol mannoside, and phosphatidylglycerol. A hydrophilic glycolipid and other uncharacterized lipids and glycolipids have also been reported for the species *A. couchii* (Kämpfer et al. 2007) and *A. humidus* (Goodfellow et al. 1990).

The genus *Actinoplanes* contains menaquinones with 9–10 tetrahydrogenated isoprene side chains, MK-9(H_4) and MK-10(H_4), and fit into the type 3b of the classification scheme of Kroppenstedt (1985). Minor amounts of MK-9(H_2) and MK-9(H_6) are found in the species *A. auranticolor*, *A. couchii*, *A. derwentensis*, *A. humidus*, *A. palleroni*, and *A. utahensis* (Stackebrandt and Kroppenstedt 1987; Goodfellow et al. 1990; Kämpfer et al. 2007). Minor proportions of MK-9(H_8) can also be found (Goodfellow et al. 1990b; Kämpfer et al. 2007). Smaller amounts of MK-10(H_2) and traces of MK-10(H_6) are characteristic for *Actinoplanes couchii* (Kämpfer et al. 2007). The additional presence of MK-7(H_4, H_6, H_8) and MK-8(H_2, H_4, H_6, H_8) has been reported in various species including *A. consettensis*, *A. derwentensis*, *A. humidus*, *A. lobatus*, and *A. palleroni* where they may occur in minor amounts (Goodfellow et al. 1990).

Complex mixtures of straight-chain, branched-chain, and unsaturated fatty acids are found in *Actinoplanes* species (Goodfellow et al. 1990; Sun et al. 2009; Ara et al. 2010). Although the amount varies significantly between the strains analyzed, in general, the major fatty acids (>10 %) include $C_{15:0}$, $C_{16:0}$, $C_{17:0}$, $C_{18:0}$, iso-$C_{15:0}$, anteiso-$C_{15:0}$, iso-$C_{16:0}$, anteiso- $C_{17:0}$, $C_{17:0}\omega9c$, $C_{17:1}\omega8c$ (Stackebrandt and Kroppenstedt 1987; Matsumoto et al. 2000; Wink et al. 2006; Kämpfer et al. 2007; Sun et al. 2009; Ara et al. 2010). No fatty acid data are available for *Actinoplanes cyaneus* and *Actinoplanes digitatis*.

Asanoa Lee and Hah 2002 Emend. Xu et al. 2011

As.a.no′a. N.L. fem. n. *Asanoa*, named after Kozo Asano, the Japanese microbiologist who made the original description of the genus *Catellatospora*.

The genus *Asanoa* was proposed to accommodate two strains previously classified in the genus *Catellatospora* and subsequently reclassified as *Asanoa ferruginea* and *Asanoa ishikariensis* (Lee and Hah 2002). Since then, three additional species have been described, namely, *Asanoa iriomotensis*, *Asanoa hainanensis*, and *Asanoa siamensis* (Tamura and Sakane 2005; Xu et al. 2011; Niemhom et al. 2012). Colony color on ISP 3 agar may be orange-red, bright orange, yellow-green, and olive. Members of this taxon

Data from Thiemann (1969), Schäfer (1973), Kothe (1987), Palleroni et al. (1989), Vobis and Kothe (1989), Goodfellow et al. (1990), Matsumoto et al. (2000), Kämpfer et al. (2007), Wink et al. (2006), Tamura et al. (2011), Vobis et al. (2012)

+ positive, – negative, *v* variable, *w* weak, *nd* not determined

produce branched non-fragmented vegetative hyphae (0.3–0.4 µm in diameter), but a true aerial mycelium is not formed. Spore chains are borne on the tip of short sporophores arising directly from the agar surface; tap-water agar, glycerol/calcium malate agar, or HV agar are the recommended media to induce sporulation (Tamura and Sakane 2005; Xu et al. 2011). *Asanoa siamensis* produces a strong red-orange soluble pigment on ISP 2 agar (Niemhom et al. 2012).

Asanoa species stain Gram-positive, are nonmotile and aerobic. Best growth occurs between 20 °C and 30 °C but not below 15 or above 40 °C. Nitrate is reduced to nitrite by *A. hainanensis*, weakly reduced by *A. siamensis* but not reduced by any of the remaining species. The pH range for growth of *Asanoa* strains ranges from 6 to 9, but *A. siamensis* can grow at pH 12 (Niemhom et al. 2012). All members of the taxon are heterotrophic with an oxidative metabolism.

All *Asanoa* strains assimilate D-galactose, D-glucose, melibiose, and L-rhamnose. Utilization of the following substrates varies among the five species: D-arabinose, L-arabinose, D-cellobiose, dextran, dulcitol, D-fructose, D-lactose, maltose, D-mannose, mannitol, methyl α-D-glucoside, D-raffinose, D-ribose, salicin, starch, sucrose, D-trehalose, and D-xylose. Inulin, L-sorbose, D-melezitose, methanol, meso-erythritol, D-sorbitol, and D-xylitol do not appear to serve as carbon sources; however, not all species have been tested (Table 28.7).

The chemotaxonomic characteristics of *Asanoa* strains include the presence of *meso*-diaminopimelic acid and 3-hydroxy-diaminopimelic acid as diaminoacids. The acyl type of the cell wall is glycolyl. The whole-cell sugars found in all *Asanoa* species are glucose, mannose, and xylose, while the presence of arabinose, galactose, rhamnose, and ribose is variable. The predominant menaquinones in *A. ferruginea*, *A. ishikariensis*, and *A. iriomotensis* are MK-10(H_6, H_8). In the case of *A. hainanensis* the presence of MK-9(H_4, H_6, H_8) was reported (Xu et al. 2011). Except for *Asanoa hainanensis* which contains a phospholipid type IV with phosphatidylethanolamine, phosphatidylinositol mannosides, and phospholipids of unknown structure containing glucosamine, all species exhibit a phospholipid type PII pattern comprised of diphosphatidylinositol mannoside, diphosphatidylglycerol, phosphatidylinositol, and phosphatidylethanolamine. An unknown phospholipid is also reported for *Asanoa ferruginea* and *A. ishikariensis* (Lee and Hah 2002). The fatty acid profile is characterized by significant amounts of anteiso-$C_{15:0}$, anteiso-$C_{17:0}$, iso-$C_{15:0}$, $C_{17:0}$, and iso-$C_{16:0}$ (Table 28.7).

Catellatospora Asano and Kawamoto 1986 Emended. Lee and Hah 2002 Emended. Ara et al. 2008a

Ca.tell.a.to.spo′ra. L. n. *catella*, a small chain; Gr. fem. n. *spora*, a seed and in biology a spore; N.L. fem. n. *Catellatospora*, (organism forming) small chain of spores.

The genus *Catellatospora* was described by Asano and Kawamoto (1986) for aerobic, Gram-staining positive, mesophilic strains that produce short chains of nonmotile spores borne directly on the substrate mycelium. There are currently five recognized species in the genus, namely, *C. citrea* the type species, *C. bangladeshensis*, *C. chokoriensis*, *C. coxensis*, and *C. methionotrophica*. *Catellatospora* strains produce well-developed branched, non-fragmenting, vegetative hyphae (0.3–0.6 µm in diameter). Straight to flexuous chains composed of about 5–30 spores are borne on the substrate mycelium, singly or in clusters. Colonies may be waxy and leathery and lack aerial mycelium (Fig. 28.5). Catellatosporae grow well on complex media such as ISP 2, ISP 3 agar (Shirling and Gottlieb 1966), Bennett's (Waksman 1950), and Hickey-Tresner agar (Hickey and Tresner 1952). Colonies show different shades of yellow depending on the culture medium while diffusible pigments have not been observed. All strains are positive for catalase.

Catellatospora strains are able to assimilate a wide range of carbohydrates as carbon sources. All species use D-galactose, glucose, lactose, sucrose, trehalose, and D-xylose. Most species utilize glycerol, maltose, L-rhamnose, and salicin (Asano and Kawamoto 1986; Ara and Kudo 2006). Other carbon sources utilized are given in Table 28.8.

Catellatospora citrea has been studied for its capacity to produce several enzymes. The type strain showed good activity for esterase lipase (C8), leucine arylamidase, trypsin, chymotrypsin, β-galactosidase, α-glucosidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, and α-mannosidase. It is resistant to novobiocin (20 µg/ml) and crystal violet (0.0001 %, w/v) (Asano and Kawamoto 1986). As reported by Asano and Kawamoto (1988), most of the metabolic characteristics of *C. citrea* and *C. methionotrophica* are similar except for the absolute requirement for methionine by the latter species. In addition, *C. methionotrophica* is sensitive to novobiocin (50 µg/ml).

The five *Catellatospora* species show a very homogeneous chemotaxonomic profile. All species include *meso*-diaminopimelic and 3-hydroxy-diaminopimelic acids and a glycosylated peptidoglycan in their cell walls. Their fatty acid profile includes saturated straight-chain, saturated branched, and unsaturated fatty acids, the major components are iso-$C_{15:0}$, iso-$C_{16:0}$, $C_{17:0}$, and $C_{17:1}\omega8c$. The polar lipid pattern of all strains includes phosphatidylethanolamine, diphosphatidylglycerol, phosphatidylinositol, and phopstidylinositol mannosides except for *C. citrea* where phosphatidylglycerol is present but not diphosphatidylglycerol. The major menaquinone is MK-9 (H_4) but MK-9(H_2, H_6, H_8) are also found. *Catellatospora citrea* also contains MK-8 (H_4, H_6, H_8). The major differences in the chemotaxonomic profiles of *Catellatospora* strains are found in the whole-cell sugars present. Arabinose and xylose are reported for all species. Galactose, ribose, mannose, and glucose are found in all species except *C. citrea*, and rhamnose has been detected only in *C. bangladeshensis*, *C. chokoriensis*, and *C. coxensis* (Asano and Kawamoto 1988; Lee and hah 2002; Ara and Kudo 2006).

Catenuloplanes Yokota et al. 1993 Emend. Kudo et al. 1999

Ca.te.nul.o.plan′es. L. fem. n. *catenula*, a short chain; Gr. masc. n. *planes*, a wanderer; N.L. masc. n. *Catenuloplanes*, a short chain wanderer; intended to signify a motile short chain.

The genus *Catenuloplanes* was proposed by Yokota et al. (1993) to accommodate strains of arthrospore-bearing actinobacteria isolated from soils in Japan, India and Nepal. This taxon currently harbors seven recognized species (Table 28.9). *Catenuloplanes* strains stain Gram-positive, are non-acid fast, and are strict aerobic filamentous microorganisms. A non-fragmenting light yellow to orange substrate mycelium is formed on different complex media, but the formation of a monopodial or dichotomously branched aerial mycelium is scant or absent (Yokota et al. 1993). If produced, spores chains are aggregated into clusters resembling flowers or sporochia, which are compact and flat at the center of the colony but filamentous toward the edge. The short chains on the aerial mycelium are arranged in spirals of one to two turns (hooked or less frequently flexuous). The spore chains may be covered by outer sheaths (Petrolini et al. 1993; Kudo et al. 1999). The spores are rod shaped, straight, or curved (0.6–0.8 by 2–4 μm), have a smooth surface, and motile by peritrichous flagella. Strains show good growth on yeast extract-malt extract agar, inorganic salts-starch agar, starch agar Czapek-sucrose agar, and glucose-asparagine agar (Shirling and Gottlieb 1966). Several diffusible pigments are produced on some of these media (Table 28.9). The optimal temperature range for growth of all species is 21–28 °C.

Members of the genus *Catenuloplanes* have an oxidative metabolism. The degradation of several chemical organic compounds has been determined for all strains; a selection of these tests is presented in Table 28.9. All strains decompose casein, aesculin, and urea, while the degradation of elastin and testosterone is useful for differentiating between the seven species. In a similar way, *Catenuloplanes* strains are able to use a wide range of carbohydrates and organic acids as carbon sources (Table 28.9). All species use L-arabinose, D-cellobiose, D-fructose, D-galactose, D-glucose, glycerol, *myo*-inositol, D-lactose, maltose, D-mannitol, D-mannose, L-rhamnose, salicin, starch, sucrose, D-trehalose, and D-xylose. In addition, all strains produce acid from L-arabinose, D-fructose, D-galactose, D-glucose, *myo*-inositol, L-rhamnose, sucrose, and D-xylose. The organic acids fumarate, L-malate, and succinate serve as carbon sources for all strains, unlike benzoate, citrate, mucate, oxalate, and L-tartrate which are not assimilated by any of the present known species. Other physiological characteristics include the coagulation and peptonization of milk, liquefaction of gelatin, and sensitivity to novobiocin and kanamycin (20 μg/ml). On the other hand, hydrogen sulfide is not produced, and nitrate is not reduced to nitrite.

From the chemotaxonomic point of view, *Catenuloplanes* species are a highly homogeneous taxon. The cell walls are of type VI according to the classification of Lechevalier and Lechevalier (1970a) and contain glutamate, serine, glycine,

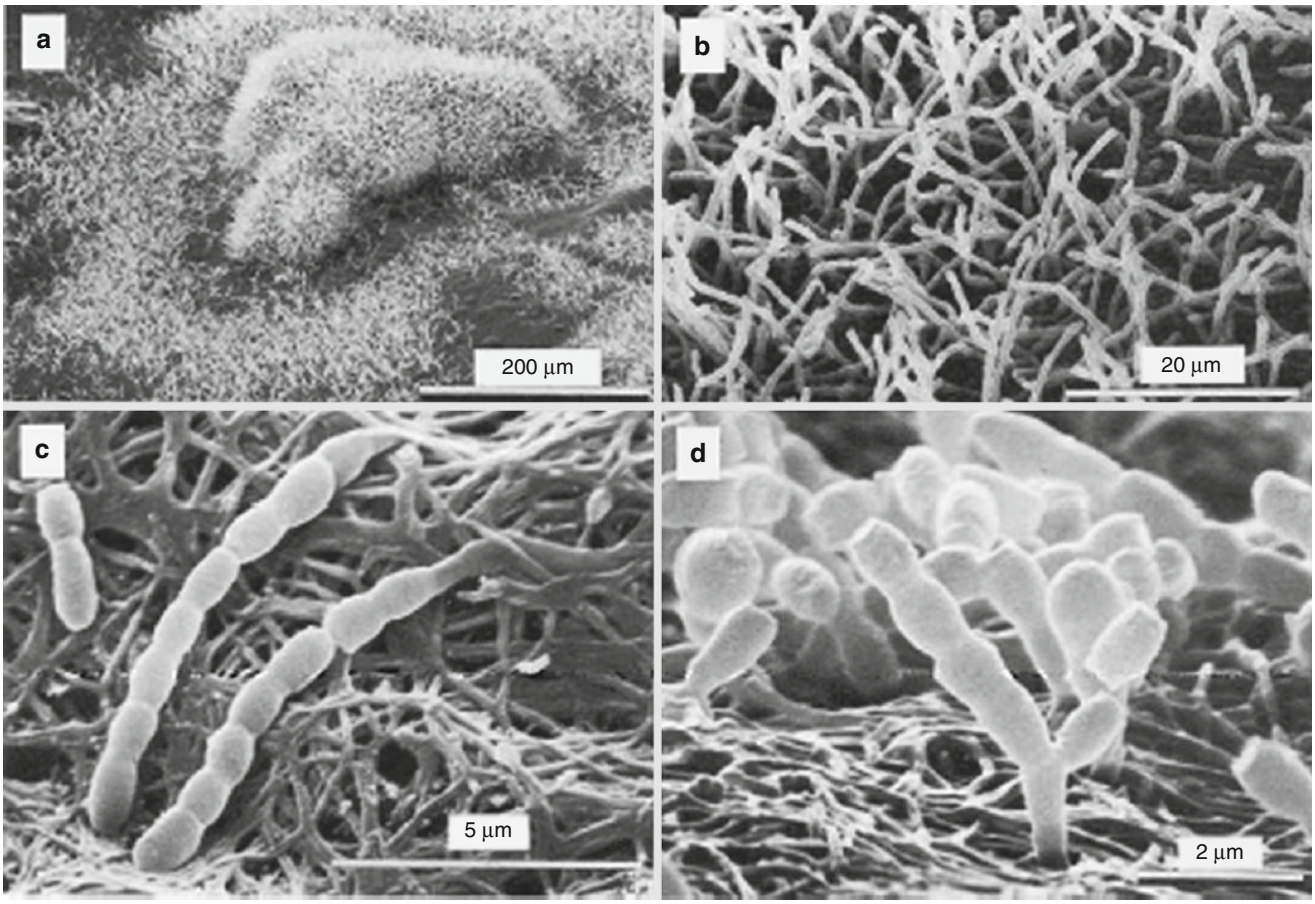

Fig. 28.5
Morphological features of the genus *Catellatospora*. (a) A sporulating colony. (b) Spore-forming hyphae on the surface of agar medium. (c) Short spore chains emerging from substrate hyphae. (d) Branched spore chains on rudimentary sporophores containing cylindrical to ovoid spores. (All SEMs). *SEM* scanning electron microscope

alanine, and lysine in addition to small amounts of ornithine. The configuration of the amino acids present suggests that the peptidoglycan is of type Aα3 (Schleifer and Kandler 1972; Yokota et al. 1993). The whole cell-wall sugars present in all strains are xylose, mannose, ribose, and glucose, while the sugars rhamnose, arabinose, and galactose have only been detected in some species (*Table 28.9*). The cellular fatty acid composition of Catenuloplanetes shows a mixture of saturated and branched fatty acids which include hexadecanoic acid ($C_{16:0}$), octadecanoic acid ($C_{18:0}$), octadecenoic acid ($C_{18:1}$), and 14-methylhexadecanoic acids (anteiso-$C_{17:0}$) as major components. Hexadecenoic acid ($C_{16:1}$), heptadecanoic acid ($C_{17:0}$), and 14-methylpentadecanoic acid (iso-$_{16:0}$) may also be present in smaller amounts (Kudo et al. 1999; Yokota et al. 1993). The polar lipid profile has been determined for the type strains *C. japonicus* N381-16^T, *C. crispus* JCM 9312^T, and *C. niger* N406-14^T, all strains contain phosphatidylcholine as the diagnostic phospholipid (Yokota et al. 1993; Kudo et al. 1999) which corresponds to the type III (Lechevalier et al. 1977). Other phospholipids found in these strains are given in *Table 28.9*. All species contain MK-10 and MK-11 (H_2, H_4, H_6) as part of their menaquinone profile; in addition, the presence of MK-10 with different degrees of hydrogenation (H_2, H_4, H_6 and H_8) varies among the strains.

Dactylosporangium Thiemann et al. 1967

Dac.ty.lo.spo.ran′gi.um. Gr. n. *daktulos*, finger; Gr. n. *spora*, a seed, and in biology a spore; Gr. neut. n. *angeion* (Latin transliteration *angium*), vessel; N.L. neut. n. *Dactylosporangium* an organism with finger-shaped, spore-containing vessels (sporangia).

The genus *Dactylosporangium* proposed by Thiemann et al. (1967) currently harbors 12 validly described species (*Table 28.10*). All *Dactylosporangium* strains stain Gram-positive, are non-acid fast, and produce motile zoospores. The non-septate substrate mycelium (0.5–1.0 µm in diameter) is irregularly branched and does not separate into fragments either in solid or liquid cultures. A true aerial mycelium is not produced; however, some species such as *D. fulvum* produce a rudimentary aerial mycelium on ISP 3 and ISP 4 agar (Shomura et al. 1986).

Two completely different types of spores can be formed in *Dactylosporangium* strains: motile spores inside sporangia and nonmotile spores or globose bodies, which are borne singly on the substrate hyphae. The sporangia sit directly on the substrate hyphae, either singly or in bundles (Fig. 28.6a, b). They are finger-shaped or clafiform, containing only one row of no more than four spores (Fig. 28.6c). The sporangiospores (0.4–1.3 × 0.5–1.8 µm) have an oblong, ellipsoidal, ovoid, or slightly pyriform shape and are sometimes still connected while swimming by means of a polarly inserted tuft of flagella. The nonmotile, globose bodies (1.7–2.8 µm in diameter) exhibit a typical phase-brightness (Fig. 28.6d). They arise terminally on short side-branches of the substrate hyphae (Fig. 28.6e). Amorphous material can be deposited outside the spore wall (Fig. 28.6f). The cytoplasm includes crystalline proteins and structured bodies (Sharples and Williams 1974). The formation of globose bodies has been observed in most species except in *D. matsukiense*, *D. roseum*, *D. thailandense*, and *D. vinaceum*. The development of sporangia depends on the agar media used to cultivate *Dactylosporangiaceae* strains; its production can be promoted by soil agar, calcium malate agar, and inorganic salts-starch agar (Thiemann et al. 1967; Shomura et al. 1986).

Colonies of *Dactylosporangium* are compact, tough, and somewhat leathery. The substrate mycelium color ranges from pale yellow-orange to deep orange or wine color (Table 28.10). Abundant to moderate growth is obtained for most species on the following media: inorganic salts-starch agar, oatmeal agar (ISP 3), tyrosine agar, tryptone-yeast extract agar, and yeast extract-malt extract agar. On the other hand, poor to moderate growth is reported for glycerol-asparagine agar and peptone-yeast extract-iron agar (Kim et al. 2010). Soluble pigments are produced by several species when grown on various of the above media: For instance, on oatmeal agar, *D. vinaceum* produces a wine to purple black pigment, *D. thailandense*, a light brown to brown, and *D. matsuzakiense*, a light brownish pink pigment.

Dactylosporangium strains are strict aerobic and mesophilic. Their optimum growth temperature range is found between 25 °C and 37 °C; however, the species *D. aurantiacum*, *D. luteum*, *D. matsuzakiense*, and *D. thailandense* are reported to grow at 15 °C (Kim et al. 2010). Best growth develops at pH 6.0–7.0; however, *D. ludirum*, *D. matsuzakiense*, *D. roseum*, *D. salmoneum*, and *D. thailandense* are able to grow at pH 4. On the other hand, *D. luteum*, *D. fulvum*, *D. salmoneum*, and *D. thailandense* grow at pH 10.

The importance of using the same basal medium for carbon utilization studies has been pointed out by different authors for members of the family *Micromonosporaceae* (Kawamoto et al. 1983; Kawamoto 1989; Genilloud 2012). Kim et al. (2010) were successful using the same basal medium to study nine of the twelve *Dactylosporangium* species. In the case of the remaining species, *D. darangshiense*, *D. maewongense*, and *D. tropicum*, ISP 9 agar (Shirling and Gottlieb 1966) was used to test the carbon substrates. All species assimilate glucose, and 75–85 % of the strains utilize cellobiose, D-mannitol, raffinose, starch, trehalose, and D-xylose. Several organic acids have also been included in carbon source tests. In this case, the species *D. luridum*, *D. fulvum*, *D. salmoneum*, and *D. thailandense* showed the ability to use most of the substrates tested. Species carbon assimilation profiles for tested substrates are given in Table 28.10.

The ability to degrade various polymers has been studied for many *Dactylosporangium* strains. Most species degrade aesculin and xylan; other degradation activities for a range of substrates are presented in Table 28.10. In addition, most strains are catalase positive, produce hydrogen sulfide, reduce nitrate to nitrite, and tolerate NaCl up to 3 %. Antibiotic resistance (µg/ml) has been recorded for most species for ciprofloxacin (2), clindamycin (8), and lincomycin (8) (Kim et al. 2010). In general, Dactylosporangiae are sensitive to streptomycin (4 µg/ml) except for *D. fulvum*.

(e) Globose spores on the surface of substrate mycelium (SEM). (f) Section of a globose spore with paracrystalline inclusion bodies and perispherical deposits (TEM) (c–f from Vobis 1987; with permission). *LM* light microscope, *PC* phase contrast, *SEM* scanning electron microscope, *TEM* transmission electron microscope

Several chemotaxonomic markers have been determined for all *Dactylosporangium* type strains representing the 12 species. They contain the diaminopimelic acid isomers 3-hydroxy- (3-OH) and *meso*- in their cell-wall peptidoglycan except for *D. darangshiense*, *D. tropicum*, and *D. matsuzakiense* which contain *meso*- and 3-OH respectively. All species also contain the diagnostic whole-cell sugars rhamnose and xylose apart from *D. tropicum* which only contain xylose. Other sugars present may include galactose, glucose, mannose, rhamnose, and ribose (*Table 28.10*). Thus, the chemical composition of the cell walls conforms to chemotype II and sugar pattern D (Lechevalier and Lechevalier 1970a). The fatty acid composition of *Dactylosporangium* strains includes a complex mixture of saturated, unsaturated, branched, and methyl-branched fatty acids (Kim et al. 2010; Seo and Lee 2010). Major components (≥5 %) are iso-$C_{16:0}$, iso-$C_{15:0}$, and anteiso-$C_{17:0}$. The composition of the isoprenoid quinones is characterized by the possession of menaquinones with nine isoprene units (MK-9), whereas isoprenologues with ten units (MK-10) are absent. MK-9(H_2) and MK-9(H_4) are present in minor amounts, and MK-9(H_6) and MK-9 occupy predominant positions (Collins et al. 1984; Goodfellow et al. 1990; Ruan et al. 1998; Kim et al. 2010). The presence of MK-9(H_4), MK-9(H_6) and MK-9(H_8) indicates that *Dactylosporangium* belongs to the menaquinone type 4b of the classification scheme of Kroppenstedt (1985).

Longispora Matsumoto et al. 2003 Emend. Shiratori-Takano et al. 2011

Lon.gi.spo′ra. L. adj. *longus*, long; Gr. fem. n. *spora*, a seed and in biology a spore; N.L. fem. n. *Longispora*, long spore.

The genus *Longispora* with the species *Longispora albida* and *Longispora fulva* was proposed by Matsumoto et al. (2003). The two strains included in this taxon stain Gram-positive, are non-acid fast, aerobic, and nonmotile. Good growth is observed on yeast extract-malt extract agar, oatmeal agar, and nutrient agar; however, *L. albida* shows better growth when agar is substituted for gellan gum (Matsumoto et al. 2003). The colony color ranges from light yellow to gray-greenish olive and have a leathery texture. A branched, non-fragmenting substrate mycelium is produced. The aerial hyphae carry long spore chains (>20 spores) that arise from the tip of short sporophores that branch from the substrate hyphae. The spores are cylindrical (0.4–0.5 × 1.0–1.4 μm), nonmotile, and have a smooth surface.

Longispora strains are strict aerobic and mesophilic, the two existing types strains do not grow above 40 °C; their tolerance to NaCl is 1.5 % (w/v) and is variable with respect to nitrate reduction activities. The strains showed a low activity profile when tested for their potential to degrade several polymers including plant components such as cellulose, starch, and xylan (Table 28.11). Similarly, the ability of the two species to assimilate various substrates as carbon sources was low (Matsumoto et al. 2003; Shiratori-Takano et al. 2011). Only glucose was used by both type strains, while *myo*-inositol, sucrose, and xylose are assimilated by *L. fulva* (Table 28.11).

Chemotaxonomic studies have been included in the characterization of *L. albida* and *L. fluva*. The cell-wall peptidoglycan contains *meso*-diaminopimelic acid, glycine, and alanine and conforms to type A1γ (Schleifer and Kandler 1972). The whole-cell sugars present in both strains are galactose and xylose, while arabinose, rhamnose, galactose, mannose, and ribose are variable. The main menaquinones are MK-10(H_4) and MK-10(H_6), but MK-10(H_8) is also found in both strains in minor amounts. The diagnostic phospholipid of the genus is phosphatidylethanolamine. The predominant cellular fatty acid components are heptadecenoic ($C_{17:1}$), 14-methylpentadecanoic (i-$C_{16:0}$), and octadecenoic ($C_{18:1}$) acids. A summary of their chemotaxonomic properties is given in Table 28.11.

Luedemannella Ara and Kudo 2007b

Lue.de.mann.ella. N.L. fem. dim. n. *Luedemannella*, referring to G. M. Luedemann, a Russian actinomycetologist who contributed to the taxonomy of the family *Micromonosporaceae*.

The genus *Luedemannella* with two species, *Luedemanella helvata* and *L. flava* groups microorganisms which stain Gram-positive, are non-acid fast and aerobic. Good growth is observed on several complex media including Bennett's and ISP 2 agars, on these media, the color of the colonies ranges from

light yellow to orange (Ara and Kudo 2007b). A non-fragmenting, branched substrate mycelium is produced by *Luedemannella* strains, but the presence of aerial mycelium has not been observed. Nonmotile spores (0.2–0.4 µm) are produced in spherical-shaped sporangia (3.0–5.0 µm) which hold several spores. The shape of the spores is spherical to oval with a smooth surface (Ara and Kudo 2007b).

Luedemannella strains are strictly aerobic and mesophilic microorganisms, their temperature range for growth is 20–30 °C; however *L. helvata* is capable of growing at 37 °C; the pH range for growth is 5–9. In addition, *L. helvata* can grow in the presence of 2 % NaCl. Ara and Kudo (2007b) tested the ability of *L. helvata* and *L. flava* to use a large variety of carbohydrates as carbon sources. In general, *L. flava* was capable of utilizing more substrates although for some of them, a weak reaction was recorded (see *Table 28.12*). Both species utilize L-arabinose, glucose, lactose, maltose, sucrose, trehalose, and xylose.

The chemotaxonomic characteristics of the genus *Luedemannella* conform to those found within the family *Micromonosporaceae* (Ara and Kudo 2007b). The cell-wall peptidoglycan contains *meso*-diaminopimelic acid and glucose, mannose, xylose, galactose, mannose, rhamnose, ribose, and arabinose as the whole-cell sugars, indicating a whole-cell sugar pattern D (Lechevalier and Lechevalier 1970a). The menaquinone composition includes MK-9(H_6), and MK-9(H_4) as predominant menaquinones and small amounts of MK-9(H_2) and MK-9(H_8). Branched iso- and anteiso-, saturated, unsaturated, and branched fatty acids are the main components (fatty acid type 2d, Kroppenstedt 1985). The polar lipid profile comprises phosphatidylethanolamine, diphosphatidylglycerol, phosphatidylglycerol, phosphatidylinositol, and phosphatidylinositol mannosides. A summary of these characteristics is found in *Table 28.12*.

Pilimelia Kane 1966 344[AL]

Pi.li.mel'i.a. L. n. *pilus*, a hair; Gr. fem. n. *melia*, *Melia*, a nymph loved by the river god *Inachus*; N.L. fem. n. *Pilimelia*, an aquatic organism growing on hair substrate.

The current species in the genus *Pilimelia* are *P. terevasa*, *P. anulata*, and *P. columellifera* with two subspecies. *Pilimelia* strains form small, compact colonies, which are about 5 mm in diameter after 4 weeks of incubation. Growth is supported by keratinic substances like hair (*Fig. 28.7a*) and cattle horn meal (Vobis 1984). Growth is successful only on complex media that include 50 % diluted skim milk agar (Gordon and Smith 1955), casamino acids-peptone-Czapek agar and nutrient-sugar agar (Henssen and Schäfer 1971), peptone-yeast extract-iron agar (Shirling and Gottlieb 1966), oatmeal-yeast extract agar (Vobis et al. 1986), and yeast extract-starch agar (Emerson 1958).

Pilimelia strains produce branched, septate, substrate hyphae (0.2–0.8 µm in diameter), but aerial mycelium is not developed. The sporangia are developed directly on the surface

of agar medium or on natural substrates (Fig. 28.7b). They are globose, ovoid, pyriform, campanulate, or cylindrical and approximately 10–15 µm in size. In some strains, each sporangium contains up to a thousand spores (Fig. 28.7f), which are rod-like to reniform. The spores can vary from 0.3 to 1.5 µm in length, and are equipped with a laterally inserted tuft of flagella. Nonmotile spores are also produced. Nutrient-poor media with addition of natural keratinic substances promote the production of sporangia. If sporangia are dipped into water, numerous flagellated spores are released, leaving behind the sporangial envelope (Vobis 1984). The wind may act as a vehicle for spore transport over long distances. On reaching natural keratinic substances, e.g., hair of mammals, they colonize the new substrate to produce mycelium and sporangia within 14 d (Vobis 1989a). The life cycle of *Pilimelia* can be considered as "aeroaquatic" (Vobis 1987).

The three *Pilimelia* species show differential morphological and colonial characters. *P. terevasa* has spherical to campanulate sporangia with parallel rows of abundantly branches spore chains. The colonies have a soft consistency and are yellow to yellow-gray. *Pilimelia anulata* has cylindrical sporangia (Fig. 28.7e), the top segment of the sporangiophore is expanded to form a small ring-like structure (Fig. 28.7d). The mycelium has a yellowish color and is soft and pasty. In contrast, the colonies of *P. columellifera* are very solid and spherical to pyriform sporangia are produced, with the spore chains inside arranged in swirls (Vobis 1984). The sporangiophores are unseptate and reach into the lumen of the sporangium, where they are visible as small columns. The substrate mycelium of *P. columellifera* is either golden-yellow to orange or colorless to pale brownish in the subspecies *pallida* (Vobis et al. 1986).

All species of *Pilimelia* are aerobic, mesophilic, and stain Gram-positive. Growth at 10–35 °C has been reported, although growth was also observed at 42 °C (Schäfer 1973). The optimum pH for growth is 7.0; however, strains can also grow between pH 5.0 and 7.8. The physiology of *Pilimelia* strains is not well understood, carbon source substrates have not been clearly identified as strains studied neither utilized the various carbon sources tested (Vobis 1986), nor individual or combinations of purified amino acids (Kane Hanton 1974). Four *Pilimelia* strains isolated from rhizosphere of *Discaria trinervis* were not able to degrade plant polymers such as starch, cellulose, hemicellulose, pectin, or lignin when tested in the laboratory (Solans and Vobis 2003) (Table 28.13). Pilimeliae are able to colonize keratinic substrates like hair of mammalia or snake skin (Karling 1954; Gaertner 1955; Tribe and Abu El-Souod 1979). Although they can aggressively attack the scleroproteins of animals, they are not known as dermatophytes.

The diaminoacid *meso*-diaminopimelic acid is present in the cell-wall peptidoglycan of *Pilimelia* strains, where glycine is also found. Arabinose and xylose are the whole-cell sugars present in all strains, conforming to the sugar pattern D as many other genera in the family *Micromonosporaceae*. Phosphatidylethanolamine and phosphatidylcholine are the characteristic polar lipids in the genus, corresponding to the type II (Lechevalier et al. 1977). The main menaquinones found in *Pilimelia* strains are MK-9(H_2) and MK-9(H_4). As for the fatty acid profile, these microorganisms contain high amounts of i-$C_{15:0}$, i-$C_{15:1}$, and $C_{17:1}$. A summary of the chemotaxonomic features is given in Table 28.13.

Planosporangium Wiese et al. 2008

Pla.no.spo.ran′gi.um. Gr. n. *planes*, a wanderer; N.L. neut. n. *sporangium*, sporangium, spore case; N.L. neut. n. *Planosporangium*, wandering sporangium, referring to the production of sporangia with motile spores.

The genus *Planosporangium* with the species *P. flavigriseum* and *P. mesophilum* accommodates aerobic actinobacteria with branched hyphae, that stain Gram-positive, and have motile or nonmotile spores. *Planosporangium* strains grow well on ISP 2 and ISP 3 agars; however, only the type strain of *P. flavigriseum* shows good growth on potato dextrose-agar (PDA), but it does not grow on nutrient agar (Wiese et al. 2008; Cao et al. 2011). The texture of the colonies is tough and wrinkled. The substrate mycelium (0.6–0.7 µm) is extensively branched with pale gray, orange-yellow, orange or pale gray-olive color, depending on media and culture conditions but diffusible pigments are not formed. The surface of spores is smooth. White aerial mycelium is formed after three (*P. mesophilum*) and nine (*P. flavigrseum*) weeks of growth. Globose spores (0.5–1.5 µm) arising from the tips of short sporophores have been observed in both *Planosporangium* species. In addition, *P. flavigresum* produces motile spores inside finger-like sporangia. Each sporangium contains a single row of three or more straight or slightly curved rod-shaped and motile spores with a single flagellum (Wiese et al. 2008).

As indicated by the species name, *P. mesophilum* grows within the range of 28–30 °C. *P. flavogriseum* grows at 28 °C; however, growth studies at other temperatures have not been carried out. A low enzymatic activity profile was reported for both type strains when tested against several substrates including starch, gelatin, urea, and others (see Table 28.14). Common carbon sources utilized by both species include glucose, maltose, mannose, and D-xylose. A variable result was obtained with other sugar substrates tested; in general, *P. flavogriseum* shows a wider assimilation profile than *P. mesophilum* (Table 28.14).

The cell-wall peptidoglycan of *Planosporangium* strains contains *meso*-diaminopimelic acid. On the other hand, the composition of the cell-wall sugars is quite different in both species. Arabinose and xylose are reported for *P. flavigriseum*, while mannose, ribose, glucose, and galactose were detected in *P. mesophilum*. Phosphatidylethanolamine is the major phospholipid found in both type strains, and the menaquinone MK-9(H_4) is also a common component. Differences in the

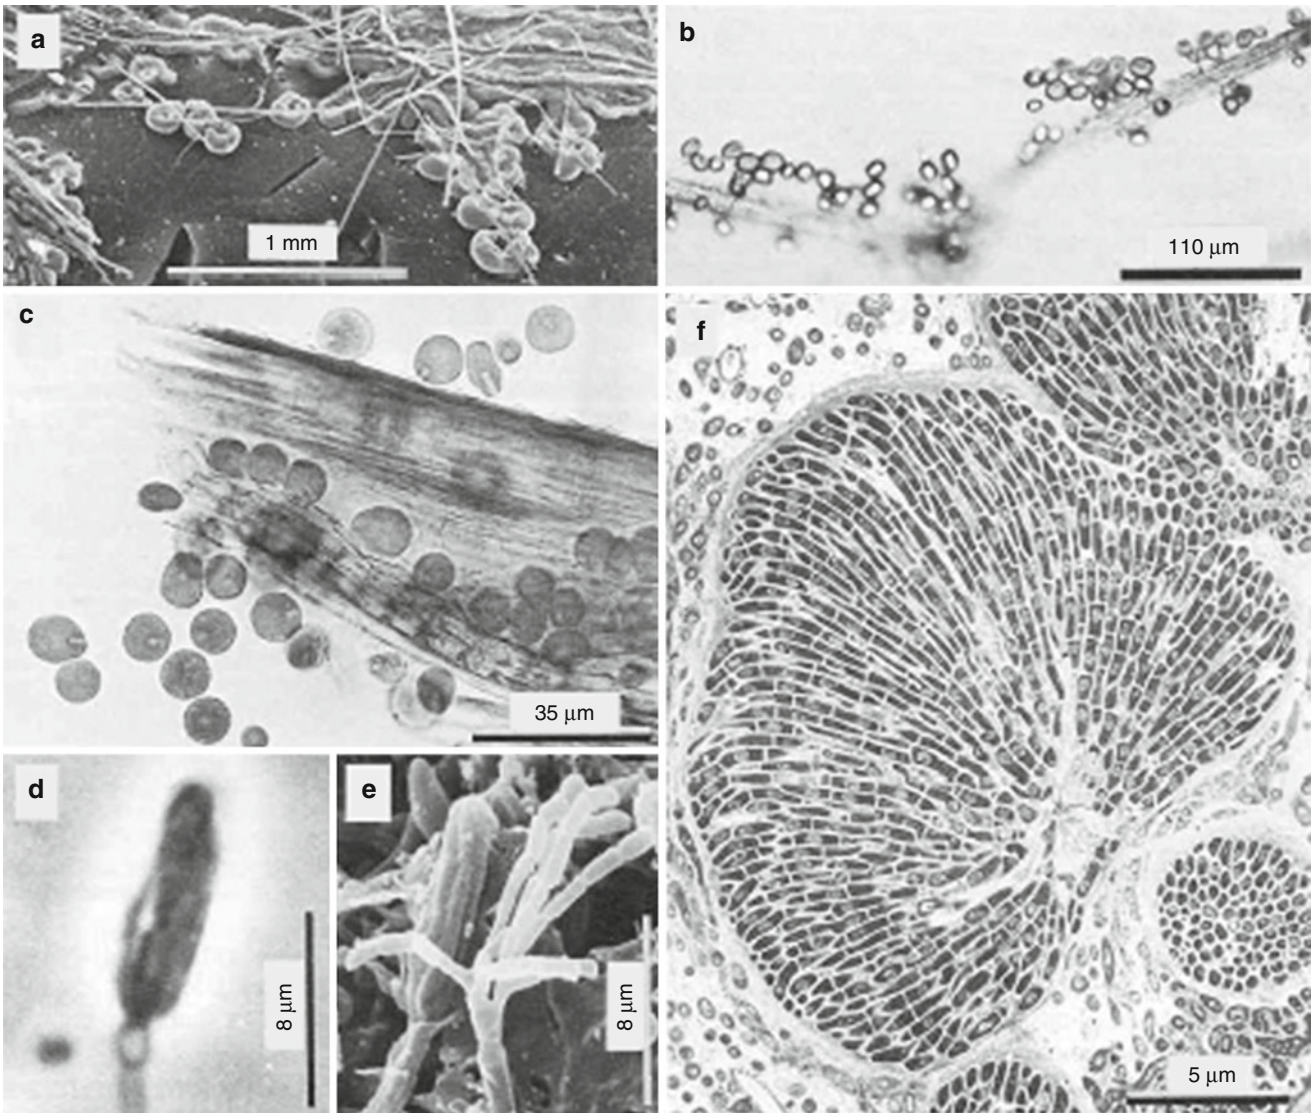

Fig. 28.7

Morphological features of the genus *Pilimelia*. (a) Compact, small colonies on agar medium; hairs added as natural substrate (SEM). (b) Bundles of sporangia formed on hair (LM). (c) Globose to pyriform sporangia with internal columella; structure of the colonized part of the hair was destroyed (LM). (d) Cylindrical sporangium with an annulus at the base (PC). (e) Penicillate conidiophore with bacilliform conidia; the sporangium behind it has parallel-arranged sporogeneous hyphae (SEM). overall menaquinone composition are given in *Table 28.14*. The major fatty acids are anteiso- and iso-branched such as i-$C_{15:0}$, i-$C_{16:0}$, ai-$C_{17:0}$, and $C_{17:1}\omega 8c$.

Plantactinospora Qin et al. 2009

Plan.tac.ti.no.spo′ra. L. n. *planta*, a plant; Gr. n. *actis actinos*, a ray; Gr. fem. n. *spora*, a seed, and in biology a spore; N.L. fem. n. *Plantactinospora*, pertaining to a spore-forming actinomycete isolated from plant tissues.

The genus *Plantactinospora* harbors three species, *P. mayteni*, the type species (Qin et al. 2009), *P. endophytica*, and *P. siamensis* which was previously classified as *Actinaurispora siamensis* (Zhu et al. 2012). *Plantactinospora* strains stain Gram-positive and are non-acid fast. Good growth of all strains is obtained on ISP 2 agar; in this medium, the color of the colonies is orange-yellow to red-brown and a light yellow pigment is produced by *P. siamensis*. White aerial mycelium is sparsely produced. Other media tested for growth can be found in the description of the different species (Qin et al. 2009; Thawai et al. 2010; Zhu et al. 2012). The growth of the colonies is raised and folded.

+ positive, – negative, *w* weak, *nd* not determined
m-DAP *meso*-diaminopimelic acid
Ara arabinose, *Xyl* xylose
PE phosphatidylethanolamine, *PC* phosphatidylcholine

The cells form extensively branched substrate mycelia (0.16–0.23 µm in diameter), which carry smooth or rough surfaced, nonmotile spores (0.63–1.10 µm); these are borne singly or in clusters.

Plantactinospora strains are strict aerobic, and mesophilic. The temperature growth range is 4–45 °C with an optimum of 20–37 °C. The pH range for growth of *P. endophytica* is 5–10, while that of the other two species is more restricted and it ranges from 5 to 8. Tolerance to NaCl is found within the range 2–3 %. The production of catalase and oxidase, nitrate reduction, and production of hydrogen sulfide is variable. Differences between the three species are also found in their ability to degrade several substrates including Tween 20, Tween 40, and Tween 80 (Table 28.15). Cellobiose, D-fructose, glucose, L-rhamnose, and D-xylose are used by all strains as a source of carbon and energy. Additionally, *P. mayteni* and *P. siamensis* utilize D-galactose, inositol, lactose, and mannitol, while *P. endophytica* does not use these substrates as carbon and energy sources. Other physiological results can be found in Table 28.15.

The chemotaxonomic profiles of all three *Plantactinospora* type strains have been determined. In general, their profiles are highly homogeneous, but small differences are found at the level of polar lipids and menaquinone composition. All strains contain *meso*-DAP in their cell-wall peptidoglycan and the whole-cell sugar pattern is D with arabinose, galactose, glucose, mannose, xylose, and rhamnose. The major fatty acids are iso-$C_{15:0}$, anteiso-$C_{17:0}$, iso-$C_{16:0}$, and anteiso-$C_{15:0}$. All strains contain a phospholipid type II pattern with phosphatidylethanolamine as the diagnostic polar lipid; however, several unknown lipids are reported for *P. mayteni* and *P. endophytica*. The menaquinone composition includes a complex mixture of MK-9 and MK-10 menaquinones with different degrees of hydrogenation. The composition of each species is given in Table 28.15.

Rugosimonospora Monciardini et al. 2009

Ru.go′si.mo.no.spo′ra. L. adj. *rugosus*, rugose, wrinkled; Gr. adj. *monos*, single; Gr. fem. n. *spora*, a seed and, in bacteriology, a spore; N.L. fem. n. *Rugosimonospora*, a bacterium forming single, rugose spores.

The genus *Rugosimonospora* is represented by the species *R. acidophila* and *R. africana* (Monciardini et al. 2009), and the two type strains were isolated from soil samples collected in Italy and Cameroon, respectively. The microorganisms stain Gram-positive, are non-acid fast and aerobic. Good to abundant growth is observed on several ISP media especially on ISP 2 and ISP 7 agars. The color of the colonies on the above media ranges from colorless to yellow to orange, and green sporulation spots may be observed. Pink to red-brown soluble pigments are produced on tyrosine-containing media. Extensive, non-fragmenting substrate mycelium is formed and single spores arise from the hyphae. The spores are spherical (0.7–0.8 μm in diameter), nonmotile, and have a rugose surface (Table 28.16).

Rugosimonospora strains have and oxidative metabolism. They are mesophilic bacteria that grow between 15 °C and 37 °C with an optimum of 22–28 °C. Best growth is obtained at slightly acidic pH values of 5–6. *Rugosimonospora africana* is tolerant to 1 % NaCl but not *R. acidophila*. Both species hydrolyze casein, gelatin, starch, and tyrosine but do not reduce nitrate. Glycerol, mannose, and xylose are readily used as carbon sources by both *Rugosimonospora* species, while L-arabinose, fructose, inositol, raffinose, and rhamnose are weakly used (Table 28.16) (Monciardini et al. 2009).

The following chemotaxonomic markers are found in both *Rugosimonospora* species. The diaminopimelic acid isomer present in the peptidoglycan is 3-hydroxy-diaminopimelic acid. The whole-cell sugars are galactose, arabinose, and xylose. Differences in fatty acid, menaquinone, and polar lipid composition were reported by Monciardini et al. (2009) as follows: Polar lipids detected in *R. acidiphila* were phosphatidylglycerol, diphosphatidylglycerol, phosphatidylinositol, phosphatidylethanolamine, and an unknown phospholipid, while *R. africana* contains several unknown phospholipids in addition to the above-mentioned phospholipids. The common menaquinones found in

DPG diphosphatidylglycerol, *PE* phosphatidylethanolamine, *PI* phosphatidylinositol, *PIMs* phosphatidylinositol mannosides

both *Rugosimonospora* species are MK-9(H_8) and MK-9(H_6); in addition, *R. acidiphila* contains MK-9(H_4). The most striking difference is found in the fatty acid profiles of both species. While both strains contain iso-$C_{16:0}$ and anteiso-$C_{17:0}$ in high amounts (>17 %), cyclohexyl $C_{17:0}$ is reported as the major component of *R. acidiphila* (>25 %). The presence of cyclohexyl $C_{17:0}$ was always detected as the major component found under different culture conditions, while it was never detected in *R. africana* (Monciardini et al. 2009). Cyclohexyl $C_{17:0}$ has been reported in major amounts in

some representatives of the family *Microbacteriaceae* (Suzuki and Komagata 1983; Aizawa et al. 2007; Qiu et al. 2007; Vaz-Moreira et al. 2008), but not in the family *Micromonosporaceae*.

Salinispora Maldonado et al. 2005a

Sa.li.ni.spo′ra. L. adj. *salinus*, saline; Gr. fem. n. *spora*, a seed and, in bacteriology, a spore; N.L. fem. n. *salinispora*, a spore-forming bacterium originating from a saline habitat, indicating the marine habitat of the organism.

The genus *Salinispora* encompasses a group of microorganisms isolated from tropical and subtropical marine sediments (Jensen et al. 1991). The genus currently harbors two species, *S. tropica* and *S. arenicola*. Salinisporae stain Gram-positive, are non-acid fast and nonmotile. *Salinispora* strains grow well on complex media such as ISP 2 and M4 (Jensen et al. 1991); however, media must be prepared with seawater or be supplemented with sodium. Mincer et al. (2002) reported that *Salinispora* strains did not grow when sodium salts were replaced with equimolar concentrations of potassium salts, suggesting a specific sodium ion requirement. Nevertheless, growth is reported at low sodium concentrations (5 mM) if the medium is supplemented with sufficient concentrations of the appropriate non-sodium salts (Kim et al. 2005; Tsueng and Lam 2008a). Cells may lyse if the osmotic strength of the growth medium is not sufficiently high.

Colonies are tough, leathery, and adhere to the agar surface. The color of the colonies ranges from pale to bright orange to brown. Dark brown to black, bright orange, or pink diffusible pigments are frequently produced. These actinobacteria form extensively branched, non-fragmenting substrate hyphae (0.25–0.5 μm in diameter) that carry single or clusters of smooth-surfaced spores (0.8–3.8 μm), which may be sessile or borne on short sporophores. Aerial mycelium is not produced.

+ positive, –negative, *w* weak, *nd* not determined
meso-DAP *meso*-diaminopimelic acid, *Ara* arabinose, *Gal* galactose, *Xyl* xylose, *DPG* diphosphatidylglycerol, *PG* phosphatidylglycerol, *PE* phosphatidylethanolamine, *PI* phosphatidylinositol

Salinispora strains are strict aerobic, chemo-organotrophic, and mesophilic; good growth is observed at 10–30 °C and pH 7–12. Both species degrade arbutin, casein, elastin, gelatin, and starch but not cellulose, chitin, tributyrin, or xylan (Table 28.17). The following carbon sources are assimilated by both species: cellobiose, α-lactose, melezitose, and starch. Fructose, mannose, ribose, sorbose, or xylose is not utilized. Additional carbon sources are given in Table 28.7. *Salinispora arenicola* is resistant to rifampicin (25 μg/ml), but *S. tropica* is sensitive.

The diaminopimelic isomer found in the cell-wall peptidoglycan of *Salinispora* strains is *meso*-diaminopimelic acid and the whole-cell sugars are arabinose, galactose, and xylose. The phospholipid profile corresponds to type II (Lechevalier et al. 1977, 1981) and is characterized by the presence of diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylglycerol, and phosphatidylinositol. The major menaquinone detected in both *Salinispora* species is MK-9(H_4). The fatty acid composition includes a complex mixture of saturated, iso-, and anteiso-fatty acids such as iso-$C_{15:0}$, iso-$C_{16:0}$, iso-$C_{18:0}$, $C_{17:0}$, 10-methyl-$C_{18:0}$.

Salinisporae are important producers of secondary metabolites with potential pharmacological application (see section "Application" in this chapter).

Verrucosispora Rheims et al. 1998

Ver.ru'co.si.spo.ra. L. fem. n. *verruca* wart; Gr. n. *spora* a seed; M.L. fem. n. *Verrucosispora* an organism with warty spores).

The genus *Verrucosispora* currently comprises four species, *V. gifhornensis* the type species (Rheims et al. 1998), *V. lutea* (Liao et al. 2009), *V. maris* (Goodfellow et al. 2012), and *V. sediminis* (Dai et al. 2010), the type strains of which have been isolated from a peat bog, a mangrove sediment, and deep-sea sediments, respectively. Cells stain Gram-positive, are non-acid fast and nonmotile. Morphologically, the genus is characterized by branching hyphae which form a well-developed substrate mycelium, absent or sparse aerial mycelium is

produced and spores with smooth, warty, or hairy surfaces which are borne singly, in pairs, or clusters. All *Verrucosispora* strains show good growth on ISP 1, ISP 2, ISP 3, and ISP 4 agar media, and only moderate to poor growth on ISP 5 and ISP 6 agars. Light orange, orange, or even dark brown-orange are the usual colony colors of *Verrucosispora* strains. An orange diffusible pigment is produced by *V. gifhornensis* on several ISP media (Rheims et al. 1998).

Verrucosisporae are aerobic microorganisms that grow at 20–45 °C, at pH values of 3.5–10, and have an oxidative metabolism. Variation is found in their ability to reduce nitrate, to produce hydrogen sulfide, and the degradation of various polymers including aesculin, arbutin, and elastin (Table 28.18). *Verrucosispora lutea* and *V. sediminis* are able to grow in media supplemented with 5 % NaCl (w/v).

A diverse variety of carbohydrates have been tested as carbon and energy sources for all *Verrucosispora* type strains, assimilation results for each one of the four species are given in Table 28.18. As expected, all strains utilize glucose. In addition, *V. maris* is able to use organic acids and alcohols as carbon sources (Goodfellow et al. 2012). Furthermore, L-histidine is used as a carbon and nitrogen source by all species except *V. lutea*. Several amino acids, including L-alanine, L-phenylalanine, L-arginine, L-glutamic acid, L-histidine, L-methionine, L-serine, and L-valine, have also been tested as nitrogen sources (Table 28.18).

The chemotaxonomic characteristics of the genus *Verrucosispora* coincide with others found within the family *Micromonosporaceae*. The presence of *meso*-diaminopimelic acid is the diaminoacid isomer found in the peptidoglycan. The whole-cell sugar hydrolysates of *V. gifhornis* and *V. maris* contain mannose and xylose, but *V. lutea* has xylose and glucose, while *V. sediminis* has glucose, mannose, glucose, and glucosamine. Phosphatidylethanolamine is the diagnostic phospholipid (type II, Lechevalier et al. 1977, 1981); in addition, diphosphatidylglycerol and phosphatidylinositol mannoside are also found in all strains. Differences in the polar lipid profile of the four type strains are given in Table 28.18. The main menaquinone detected in *Verrucosisporae* strains is MK-9(H_4), but minor amounts of MK-9(H_6), MK-10(H_4), MK-9(H_2), and MK-9(H_{10}) may also be found (Table 28.18). The fatty acids i-$C_{16:0}$, i-$C_{15:0}$, and ai-$C_{17:0}$ are the main components of the species *V. gifhornesis*, *V. lutea*, and *V. sediminis*. The fatty acid profile of the type strain of *V. maris* has not been determined.

Virgisporangium Corrig. Tamura et al. 2001 Emend. Otoguro et al. 2010

Vir.go.spo.ran′gi.um. L. n. *virga*, a slender green branch, rod; N.L. neut. n. *sporangium* (from Gr. n. *spora*, a seed and in biology a spore; Gr. n. *angeion*, vessel), sporangium (spore-containing vessel); N.L. neut. n. *Virgosporangium*, an organism with rod-shaped sporangia (spore-containing vessels).

The genus *Virgisporangium* includes the species *V. ochraceum*, *V. aurantiacum*, and V. *aliadipatigenens*, isolated from different soil samples collected in Japan (Tamura et al. 2001; Otoguro et al. 2010). These bacteria stain Gram-positive, are non-acid fast and aerobic. Moderate to good growth is obtained on ISP 2, ISP 3, and ISP 7 agar media. The color of the vegetative mycelium is yellow to orange, and soluble pigments are produced by all species on ISP 7 agar. *V. ochraceum* and *V. aliadipatigenens* produce a light brown pigment, while *V. aurantiacum* produces a red-orange to brown pigment. *Virgisporangium* strains produce branching, non-fragmented hyphae, and slender sporangia are formed on short sporangiophores on the substrate mycelium. Each sporangium typically contains a single row of six or more spores which are oval or short rods (0.6–0.9 by 0.8–1.5 μm) and are motile.

Virgisporangium strains grow at 15–37 °C and are heterotrophic microorganisms with an oxidative metabolism. Nitrate is reduced by all species; however, it is strain variable in the case of *V. aliadipatigenens*. The latter species is also able to assimilate calcium malate. Starch is degraded by all strains while gelatin is not.

Several carbon sources are used by all *Virgisporangium* species and include L-arabinose, D-fructose, glucose, glycerol, maltose, mannose, and xylose. Other carbon sources utilized are found in Table 28.19. Several enzymatic activities have been determined using the API ZYM system (Otoguro et al. 2010). All species produce alkaline phosphatase; other activities are given in Table 28.19.

The cell-wall of *Virgisporangium* strains contains glutamic acid, glycine, alanine, and the diagnostic diaminoacid 3-hydroxy-diaminopimelic acid. The whole-cell sugars 3-*O*-methylmannose, rhamnose, mannose, glucose, arabinose, xylose, and galactose are found in *V. ochraceum* and *V. aurantiacum*, but the sugars rhamnose and arabinose are lacking in *V. aliadipatigenens*. The phospholipid type of *Virgisporangium*, like many other genera in the family *Micromonosporaceae*, is type II (Lechevalier et al. 1981) with phosphatidylethanolamine as the diagnostic phospholipid. The major menaquinones are MK-10(H_4) and MK-10(H_6). The major fatty acids are iso-$C_{16:0}$, and anteiso-$C_{17:0}$ or *cis* 9-$C_{17:1}$ and $C_{17:0}$.

Monospecific Genera

The family *Micromonosporaceae* contains 11 monospecific genera which are listed below. Selected morphological characteristics are summarized in Table 28.20.

Allocatelliglobosispora Lee and Lee 2011

Al.lo.ca.tel′li.glo.bo.si.spo′ra. Gr. adj. *allos*, another, the other; N.L. fem. n. *Catelliglobosispora*, a bacterial generic name; N.L. fem. n. *Allocatelliglobosispora*, the other *Catelliglobosispora*, an organism that is phylogenetically close to *Catelliglobosispora* but chemotaxonomically distinct.

***Pseudosporangium* Ara et al. 2008b**

Pseu.do.spo.ran′gi.um. Gr. adj. *pseudes* false; Gr. n. *spora* seed; Gr. neut. n. *angeion* a vessel; N.L. neut. n. *Pseudosporangium* false sporangium.

***Spirilliplanes* Tamura et al. 1997**

Spi.ril.li.plan′es. N.L. dim. neut. n. *spirillum*, a small spiral; Gr. masc. n. *planes*, a wanderer; N.L. fem. (*sic*) n. *Spirilliplanes*, an organism with wandering cells, in spirals.

The genus *Couchioplanes* was first described by Tamura in 1994 to accommodate a group of actinomycetes exhibiting motile arthrospores that included two strains producing characteristic blue mycelia and previously described as *Actinoplanes caeruleus* and "*Actinoplanes azureus*" as well as a new soil isolate. All these organisms form spore chains and aerial mycelia aggregating into clusters resembling sporangia and they are characterized by the presence of L-Lysine instead of *meso*-diaminopimelic acid in the cell wall, clearly differing from previously described members of other genera with motile arthrospores. The three strains were included in the new species *Couchioplanes caeruleus*, where two subspecies were identified, *Couchioplanes caeruleus* subsp. *caeruleus* IFO 13939^T and *Couchioplanes caeruleus* subsp. *azureus* IFO 13993^T on the basis of their differences in the production of soluble pigments, growth in the presence of 2 % NaCl, and the utilization of rhamnose and mannitol as carbon sources (Tamura et al. 1994).

A second taxon that produces zoospores is the genus *Spirilliplanes* described by Tamura in 1997 and clearly distinguished from other motile actinomycetes in the wall chemotype, as well as menaquinone and fatty acid content. In this genus, zoospores are produced in chains of very narrow and coiled sporogeneous hyphae that aggregate and often appear to be sporangium-like structures, but are not true sporangia and spores are not enclosed in a sporangial wall. The genus differs from other actinomycetes genera with a chemotype II wall (glycine and meso-diaminopimelic acid) and is clearly distinguishable from the genera that produce motile spores by the absence of arabinose as whole-cell sugar. The type strain is *Spirilliplanes yamanashiensis* IFO 15828^T.

The genera *Catelliglobosispora* and *Hamadaea* were proposed to accommodate two species originally classified as *Catellatospora koreensis* and *Catellatospora tsunoense* (Ara et al. 2008a). The strains were shown to form by phylogenetic analysis a distinct clade within the family *Micromonosporaceae*, also supported by differences in the chemotaxonomic markers when compared to other members of the genus *Catellatospora*. The type species *Catelliglobosispora koreensis* DSM 44566^T produces straight, short chains of nonmotile spores borne directly on the substrate mycelium and abundant globose bodies, similar to those observed in the species *Hamadaea tsunoensis* and *Allocatelliglobosispora scoriae*, but not observed in other *Catellatospora* species. The three strains can be clearly distinguished by their chemotaxonomic composition (Ara et al. 2008a). The type strain *Hamadaea tsunoensis* DSM 44101^T produces well-developed branched mycelium and can be distinguished physiologically from *Catelliglobosispora koreensis* by the differential utilization of carbon sources and other growth requirements (Ara et al. 2008a). The genus *Allocatelliglobosispora* was established to accommodate a strain isolated from volcanic ashes collected in the Republic of Korea (Lee and Lee 2011). The type species *Allocatelliglobosispora scoriae* DSM 45362^T develops short chains of nonmotile spores singly or in clusters, together with globose bodies. Phylogenetic analysis based on 16S rRNA genes sequences relate remotely this genus to the genera *Catellatospora*, *Catelliglobosispor*a and *Hamadea*.

The genus *Polymorphospora* was described by Tamura et al. (2006) to accommodate new isolates of the family *Micromonosporaceae* obtained from Japanese soils surrounding mangrove roots and characterized by a strong reddish pigmentation of the mycelium and the formation of short and nonmotile spore chains. These strains were shown to form a distinct monophyletic clade and could be distinguished from other *Micromonosporaceae* by their chemotaxonomic and morphological characteristics. The type species is *Polymorphospora rubra* DSM 44947^T.

Three different genera associated to endophytic actinomycetes have been described within the family

Table 28.20
Morphological characteristics of monospecific genera

Genus	Sporulation	Spore surface	Spore motility	Sporangia	Substrate mycelium color	Soluble pigment
Allocatelliglobosispora	*Short spore chains from substrate mycelium*	nd	No	Globose bodies	Light brown to brown	Brown on ISP3 and oatmeal nitrate agar
Catelliglobosispora	*Strait short spore chains from substrate mycelium*	Smooth	No	Globose bodies	Cream to light yellow	No
Couchioplanes	*Spore chains in branched aerial mycelia*	Smooth	Yes	Pseudosporangia	Yellowish orange to blue	Yellow to pale brownish on peptone-yeast extract-iron agar
Hamadaea	*Strait short spore chains from substrate mycelium*	Smooth	No	Globose bodies	Pale yellow to bright marigold	No
Jishengella	Single spores on substrate mycelium	Warty	No	No	Vivid orange to dull orange	No
Krasilnikovia	*Long chains, coiled and aggregated from substrate mycelium*	Smooth	No	Globose pseudosporangia on substrate mycelium	Light yellow to cinnamon	No
Phytohabitans	*Long chains, > 10 spores*	Smooth	No	No	Pale orange to pale brown	No
Phytomonospora	Single spores on substrate mycelium	Smooth	No	No	Light yellow to yellowish brown	No
Polymorphospora	Short spore chains	nd	No	No	Red to reddish-orange	No
Pseudosporangium	*Spore chains*	Smooth	No	Pseudosporangia	Rusty to clove brown	No
Spirilliplanes	Spore chains in spirals; aggregated coiled sporogeneous hyphae	Smooth	Yes	No	Yellow to orange	Brownish pigment in tyrosine agar

Data for reference genera from Tamura et al. (1994, 1997, 2006), Ara and Kudo (2007), Ara et al. (2008a, b), Inahashi et al. (2010), Lee and Lee (2011), Xie et al. (2011b)
nd not determined

Micromonosporaceae: the genera *Phytohabitans*, *Phytomonospora*, and *Jishengella*. The genus *Phytohabitans* was described by Inahashi et al. (2010) for a new endophytic actinomycete isolated from the roots of a variety of orchid collected in Japan and producing long chains of nonmotile spores. The type strain *Phytohabitans sulfuscus* DSM 45306^T showed sequence similarity with the genera *Catenuloplanes* and *Asanoa* in the phylogenetic analysis, but could be distinguished by the different menaquinone composition, the characteristic whole-cell sugars, and the fatty acid and phospholipid profile (Inahashi et al. 2010). The genus *Jishengella* was described for another endophytic actinomycete isolated from the roots of *Acanthus illicifolius* in China, producing extensively branched substrate mycelium, carrying uneven warty-surfaced and nonmotile spores born singly on the substrate mycelium, and with similar morphology to strains of the genus *Verrucosispora* (Xie et al. 2012a). The type strain is *Jishengella endophytica* DSM 45430^T. The genus *Phytomonospora* is the most recently described monospecific genus for a novel endophytic actinomycete isolated from the roots of *Artemisia annua* L. in Yunnan, China. The strain *Phytomonospora endophytica* DSM 45386^T produces single nonmotile spores borne directly on the vegetative mycelium and can be distinguished from other single-spored *Micromonosporaceae* by its distinct phylogenetic position and its physiological and chemotaxonomic characteristics, especially the predominant menaquinone, characteristic whole-cell sugars, and fatty acids and polar lipid profiles (Li et al. 2011).

Two genera have been described for isolates forming irregular pseudosporangia on substrate mycelia. The genera *Krasilnikovia* and *Pseudosporangium* were described respectively by Ara and Kudo (2007a) and Ara et al. (2008b), to accommodate two strains isolated from sandy soils from Bangladesh. Both strains form spherical pseudosporangial structures that develop singly and are formed directly from aggregated spore chains on the substrate mycelia. Spores in spore chains are nonmotile and present an oval or reniform morphology in the case of *Krasilnikovia*. The type species, *Krasilnikovia cinnamoneae* JCM 13252^T, is clearly distinguishable on the basis of morphological, physiological, chemotaxonomic, and phylogenetic analyses from the closest genera *Couchioplanes* and *Actinoplanes*. The genus *Pseudosporangium* produces many small, nonmotile, spherical, smooth-surfaced spores in chains and forms irregular pseudosporangia on the sparse aerial mycelium by the aggregation of spore chains and individual spores. The type strain is *Pseudosporangium ferrugineum* is JCM14710^T.

Isolation, Enrichment, and Maintenance Procedures

Isolation and Enrichment

Without applying selective procedures, it is difficult to isolate members of family *Micromonosporaceae* from soil or other natural substrates. Although they are mesophilic and aerobic organisms, the growth rate of their colonies is often very slow, and on routine actinomycete isolation plates, the fast-growing streptomycetes can overrun them before they have developed conspicuous mycelia. Special pretreatments of the freshly collected samples enhance the number of *Micromonosporaceae* strains and reduce the non-desirable concomitant microorganisms, these methods include heating soil suspensions at 70 °C for 10–30 min (Rowbotham and Cross 1977; Sandrak 1977), 50 °C for 1 h (Monciardini et al. 2009) and dry heating of soil samples at 120 °C for 60 min (Shearer 1987). The pretreatment of soil suspensions with ammonia or dry heating for 1 h subsequent treatment with chlorine for 10–30 min (Burman et al. 1969; Willoughby 1969a) or with 1.5 % (w/v) phenol have been shown to be highly effective isolation methods (Hayakawa et al. 1991b; Wang et al. 2011). Dilution and heat shock treatments and stamping methods have been effective for the isolation of *Micromonospora* and *Salinispora* strains from sediments (Mincer et al. 2002; Magarvey et al. 2004).

The addition of humic acid activates the germination of spores (Hayakawa and Nonomura 1987a), and media with low nutrient concentration favor the growth of *Micromonospora* (Rowbotham and Cross 1977). To avoid growth of fungi on the isolation plates, cycloheximide (50 μg/ml) and/or nystatin (100 units/ml) can be added to the isolation media (Rowbotham and Cross 1977). The selection effect can be enhanced by the addition of antibiotics like gentamicin (Ivanitskaia et al. 1978); nalidixic acid; novobiocin (Sveshnikova et al. 1976); and tunicamycin (Wakisaka et al. 1982; Nonomura and Hayakawa 1988). Other chemicals such as the antifungal reagent Benlate (Matsumoto et al. 2007) or potassium bichromate (Xu et al. 2011) have been employed for the isolation of novel *Micromonosporaceae* strains.

Useful isolation media include Actinomycete isolation agar, pH 8.2 (Difco), arginine-glycerol-salts agar (Hunter et al. 1984), arginine-vitamin agar, cellulose-asparagine agar (Goodfellow and Haynes 1984), colloidal chitin agar (Hsu and Lockwood 1975), glucose–asparagine–vitamin agar (Takahashi et al. 1996), humic acid-vitamins agar (Hayakawa and Nonomura 1987a), Kodoka's cellulose benzoate agar (Sandrak 1977), M3 agar (Rowbotham and Cross 1977), mannitol-rifampicin agar (Kämpfer et al. 2007), raffinose–histidine medium (Williams et al. 1984), yeast extract-mannitol agar (Vincent 1970), starch-casein-nitrate agar supplemented with B vitamins (Shearer 1987), and 1/10 ATCC 172 agar (Xie et al. 2012b).

The differing behavior of the spores permits the use of two isolation methods: (1) direct isolation on selective agar media for genera having nonmotile spores and (2) techniques using spore motility to specifically enrich the sporangiate members. Obviously, strains belonging to one group can appear also on the isolation plates intended for the others.

The isolation plates and the enrichment cultures are usually incubated at 22–28 °C. Because of the very slow growth rate of *Micromonosporaceae* strains, the incubation time has to be extended up to 10 weeks in some cases (Goodfellow and Haynes 1984). The use of a dissecting microscope is recommended to select the colonies grown on the isolation plates. The mycelia can be picked up and transferred with toothpicks or with a thin metal needle.

In agreement with the wide distribution of *Micromonosporaceae* strains in nature, samples from various habitats have proved to be favorable sources of inoculum: soil, sediment, mud, water, plant material, and invertebrates. The above-mentioned isolation methods are applied according to the characteristics of different samples.

Isolation from Water

The freshly collected water samples should be stored at 4 °C until processed. If necessary, the spores can be concentrated from a relatively large volume of water either by the membrane filtration technique (Burman et al. 1969) or by centrifugation (Okami and Okazaki 1978). To reduce the number of the concomitant vegetative bacterial cells, a pretreatment either with mild heating or chemical substances is recommended. For the heat treatment procedure, 2 ml of the water sample is placed in a glass tube which is sealed and heated in a water bath. Various periods of incubation and temperatures have been used: 6 min at 55 °C (Rowbotham and Cross 1977), 10 min at 70 °C (Cross 1981a), or 60 min at 44 °C (Burman et al. 1969). An alternative pretreatment with chlorine was suggested by

Burman et al. (1969) and Willoughby (1969b): The samples are first treated with 4 mg/l ammonia, followed by 2 mg/l chlorine (added as 1 ml of a hypochlorite solution containing 200 mg/l of available chlorine). Samples are allowed to stand for 10–30 min; then the chlorine is neutralized with sodium thiosulfate. The correct amount has to be calculated from titration of a blank sample.

After brief mixing of the pretreated samples (either heat or chlorine), spreading can be carried out immediately with 0.2 ml of the sample on each agar plate (Rowbotham and Cross 1977). If necessary, dilutions can be made, either with sterile buffer (0.5 M KH_2PO_4 adjusted with NaOH to pH 7.2; Hsu and Lockwood 1975) or with quarter-strength Ringer's solution containing gelatin (0.01 % w/v; pH 7.0; Rowbotham and Cross 1977). The inoculated plates are incubated at 28 °C or 30 °C for 3–4 weeks. Direct plating of water samples on isolation agar led to the discovery of *Micromonospora mirobrigensis* WA201^T: 100 µl of pond water was plated directly on soil extract agar (SEA) at pH 6.5. SEA plates were incubated for 2 weeks at 28 °C in the dark (Trujillo et al. 2005). A significant number of Micromonospora strains isolated from the water column, sediment, and cellulose baits placed in freshwater lakes were recovered (de Menezes et al. 2008).

Isolation from Soil and Sediments from Freshwater and Marine Habitats

Soil-Dilution-Plate Techniques Soil samples, marine sediments, or mud from lakes and rivers are air-dried at room temperature and then ground in a mortar (Shearer 1987). About 1 g of the sample is added to 10 ml of saline solution. The suspension is mixed (vortex mixer) for 1 min and diluted in series with a sterile salt solution. The salt solution proposed by Wakisaka et al. (1982) contains 0.01 % $MgSO_4 \cdot 7H_2O$ and 0.002 % Tween, from which air is eliminated by use of a vacuum desiccator for about 30 min. Instead of a salt solution, sterile water can also be used for suspension and serial dilutions (Hayakawa and Nonomura 1987a). Ultrasonic processing (Matsumoto et al. 2007) or Ribolisation with the FastPrep-Instrument for 2 s at a speed of 4.0 m/s (Xie et al. 2012b) is helpful for dispersing of soil particles. Petri dishes are prepared one day before plating and incubated at 37 °C overnight to eliminate films of moisture on the agar surface (Shearer 1987). An inoculum (0.1 ml) of the proper dilution is placed on each plate and spread with a sterile glass rod. Plates are incubated at 28–30 °C for 4–5 weeks.

Cellulose-decomposing micromonosporae can be isolated from soil adjacent to the roots of wheat and maize according to the method of Sandrak (1977). One milliliter of soil suspension is mixed with 0.67-g sterile cellulose powder (as used for thin-layer chromatography) and 2 ml of liquid Kadota's benzoate medium (Sandrak 1977). The mixture is spread on plates with Kadota's benzoate agar. The cellulose layer is allowed to dry before the plates are incubated for 25–30 days at 28 °C (Cross 1981b). For *Micromonospora* species from marine sediments, Goodfellow and Haynes (1984) incubated the isolation plates at 18 °C for 10 weeks (duplicates at 4 °C for 6 months).

Heat or chlorine treatment, as described for water samples, can also be used with soil and sediment dilutions (Cross 1981b). An alkaline pretreatment method is suggested by Wakisaka et al. (1982): One milliliter of the diluent is mixed with 9 ml of 0.01 N NaOH. After standing for 5–10 min, the mixture is neutralized with 0.1 N HCl to pH 6–7 (with cooling) before serial dilution and plating. Nonomura and Hayakawa (1988) treated the soil-water suspension with 1.5 % phenol at 30 °C for 30 min.

The routine plating technique has been successfully applied for the isolation of strains of the genera *Allocatelliglobosispora, Catellatospora, Dactylosporangium, Krasilnikovia, Longispora, Luedemannella Micromonospora* and *Verrucosispora.*

Dry Heat Technique A procedure which involved dry heating of soil samples at extreme temperatures was originally developed by Nonomura and Ohara (1969) for the isolation of *Microbispora* and *Streptosporangium* species. Shearer (1987) demonstrated that this technique is also useful for the isolation of *Dactylosporangium* and *Micromonospora* strains. The samples are first air-dried at room temperature and ground in a mortar. Then they are heated in a drying oven at 120 °C for 60 min. One gram of the heat-treated soil is added to 10 ml of saline solution and then processed as described for the routine dilution-plating technique. Inoculated plates are incubated at 28 °C for 4–5 weeks. Arginine-vitamin agar, humic acid-vitamins agar (Hayakawa and Nonomura 1987a), and starch-casein-nitrate agar with B vitamins are used as selective media (Shearer 1987). *Spirilliplanes yashamaniensis* was isolated by this pretreatment (Tamura et al. 1997).

Stamping Technique The stamp technique was used successfully in the study of actinomycete populations of salt marsh ecosystems (Hunter et al. 1984). Depending on the moisture content, the samples of soil or mud are air-dried in Petri dishes for several days at room temperature. Two methods of further pretreatment were suggested by Hunter-Cevera et al. (1986): (1) the dried samples are ground with a pestle in a mortar and heated for 2 h at 60–65 °C, and (2) dried samples are mixed with powdered chitin (1: 1) and incubated for 2–3 weeks at 26 °C.

The pretreated and ground samples are stamped onto the isolation plates using the following procedure: A small circular sponge (Dispo culture plug, 16 mm; Scientific Products) is pressed into the powdered sample and removed. The excess small crumbs are shaken off. A stack of a dozen plates with various different alternating selective media is then inoculated by successively "stamping" (lightly touching) the sponge to the agar surface 10 times in a circle around the perimeter and three times in the middle of each plate (Hunter et al. 1984). Continuously stamping with the same plug yields the desired dilution effect. Plates are incubated at 26–28 °C for 2 weeks. Arginine-glycerol salts agar, starch-casein-nitrate agar, and thin pablum agar were recommended as the selective media for the isolation of *Micromonospora* strains (Hunter-Cevera et al. 1986).

The stamping method was used by Mincer et al. (2002) for the isolation of Salinisporae strains. In this case, 10 ml of wet

sediment was aseptically placed into a sterile aluminum dish, dried (ca. 24 h) in a laminar flow hood, ground lightly with a pestle, pressed into a sterile foam plug (14 mm in diameter), and inoculated onto agar media by stamping eight or nine times in a circular fashion, giving a serial dilution effect.

Isolation from Plant Material

Surface sterilization should be carried out before isolation from plant material. A special wash technique was employed by Willoughby (1968, 1969a) for the investigation of actinomycete populations on decomposing leaf litter. The leaves are collected at a fairly early stage of the decomposition. Small pieces of approximately 3 cm^2 are cut out, and each piece is transferred to a 100-ml conical flask containing 25 ml of sterile-filtered lake water. After 2 min of agitation on a rotary shaker, small aliquots of the leaf-washing liquid are either incorporated into molten agar (0.5 ml/plate) or spread onto the surface of agar, 0.2 ml for each plate, using a right-angled glass rod. The plates are incubated at 25 °C for 3–5 weeks (Willoughby 1968). The most successful isolation medium for strains of *Actinoplanes* and *Micromonospora* was colloidal chitin agar with cycloheximide as the antifungal agent. Ethanol and sodium hypochlorite are commonly used as sterilization agents. Mercury chloride (2.5 % w/v) has been used for root nodule surface sterilization (Trujillo et al. 2007). After sterilization, the nodules are homogenized using a glass rod and plated onto yeast-mannitol agar.

Endophytic *Micromonospora* strains have been recovered from surface-sterilized wheat roots. The roots were excised and subjected to a three-step surface sterilization procedure: a 60-s wash in 99 % ethanol, followed by a 6-min wash in 3.125 % NaOCl, a 30-s wash in 99 % ethanol, and a final rinse in sterile reverse osmosis-treated (RO) water. The surface-sterilized roots were then aseptically sectioned into 1-cm fragments and distributed onto the isolation media, followed by incubation at 27 °C for up to 4 weeks (Coombs and Franco 2003). Surface-sterilized nitrogen-fixing legume nodules have been shown to be extremely rich reservoirs for the isolation of novel *Micromonospora* strains (Trujillo et al. 2006, 2007, 2010; García et al. 2010; Carro et al. 2012). Several *Plantactinospora* strains have also been isolated from plant and root materials (Qin et al. 2009; Zhu et al. 2011).

Special Isolation Methods Using Motile Spores

The following very selective isolation methods are used when dormant sporangia are present in the substrate to be tested. The sporangia can release actively swimming spores when submerged in water. The individual spores must be motile for many hours and must show positive chemotaxis to specific chemical substances. Once fastened to a natural or cultural substrate, they must be able to germinate and form new mycelia and, for use of the baiting technique, produce a new generation of sporangia.

Baiting Technique The baiting technique is the classical isolation method for *Actinoplanes*, which made possible the first discovery of actinomycetes with motile spores (Couch 1949). Although other powerful techniques are available, baiting is still the only way to isolate keratinophilic *Pilimelia* strains.

The sample (0.5–1.0 g) is placed in a small, sterilized Petri dish (3 or 4 cm in diameter) or in a chamber of a multi-well microtiter plate, which is then half flooded with sterile demineralized water. After cautiously stirring, the particles settle to the bottom. Natural baits are exposed singly or in combination on the surface of the water: pollen of *Pinus*, *Liquidambar*, or *Sparganium*, boiled *Paspalum* grass leaves, hair of mammalian (human, dog, deer, cattle, white mice, etc.), or bits of snake skin (Couch 1949, 1954; Karling 1954; Gaertner 1955; Kane 1966; Schäfer 1973; Tribe and Abu El-Souod 1979; Makkar and Cross 1982; Hayakawa et al. 1991d). A ring of parafilm can be used to ensure the baits do not stick to the wall of the Petri dish (Hayakawa 2003). The baits must be presterilized, depending on their consistency, either chemically with ethanol or propylene dioxide or by autoclaving (Gaertner 1955; Schäfer 1973; Makkar and Cross 1982). The baiting enrichment cultures are closed and stored undisturbed at room temperature for several weeks. The water level can be regulated by addition of sterile distilled water. The examination for actinoplanetes can begin after one week with a dissecting microscope using 100× magnification and horizontal lighting (Bland and Couch 1981). Further examination after 3–4 weeks is recommended for keratinophilic organisms (Schäfer 1973).

Sporangia of actinoplanetes are recognizable as glistening beads on the air-exposed sides of the baits. Such baits are then removed carefully from the water and transferred to a 3 % agar plate (Bland and Couch 1981). Individual sporangia are separated from the bait and rolled several centimeters over the surface of agar, using a thin-pointed tungsten needle, which has a tip curved like a hockey stick. In this way, contaminants are removed from the sporangial surface. Cleaned sporangia can be transferred either directly or together with a small, cut-out agar block onto a Petri dish with suitable agar medium. Media for isolation from pollen and grass leaves include Czapek sucrose agar, peptone-Czapek agar (Bland and Couch 1981), half-concentrated casamino acids-peptone-Czapek agar (Schäfer 1973), or Emerson's yeast extract-starch agar (Emerson 1958). Sporangia from keratinic baits should be transferred to highly diluted skim milk-cattle horn-meal agar (Vobis 1984).

The colonies originating from the individual sporangia are visible with the naked eye after 1–4 weeks of incubation and can partly be used as the inoculum for the new strain on slant cultures. The other part of the mycelium can be transferred onto sporulation agar for morphological identification.

Dehydration-Rehydration This technique utilizes the ability of the sporangia to withstand desiccation and to release motile spores when they are subsequently in contact with water. Besides soil samples, it is also applicable to leaf litter, decaying plant material from aquatic habitats, organic debris, etc. (Makkar and Cross 1982).

The samples are dried at 28–30 °C for 7 days. For rehydration, 0.5 g of soil or corresponding substrate is mixed with 50 ml of sterile tap water in a 150-ml beaker or Erlenmeyer flask, which is covered with sterile aluminum foil (Vettermann and Prauser 1979; Shearer 1987). The suspension is incubated at 20–30 °C for about 1 h. During the first 30 min, the vessel can be shaken at irregular intervals. After that, the particles should be permitted to settle. From the supernatant, 0.5–1.0 ml are removed with a sterile pipette and spread onto agar plates (Shearer 1987). If it is necessary, dilutions can be prepared from the inoculation fluid (Makkar and Cross 1982).

Rehydration and Centrifugation Method An enrichment method incorporating differential centrifugation after rehydration was developed by Hayakawa et al. (2000). Samples are rehydrated with 10 mM phosphate buffer containing 10 % soil extract at 30 °C for 90 min. The liquid enriched with zoospores is centrifuged at 1,500×*g* for 20 min. Portions of the supernatant are then plated on humic acid-vitamin agar supplemented with nalidixic acid and trimethoprim or cycloheximide. The centrifugation procedure specifically eliminates strains of *Streptomyces* and other nonmotile actinomycetes (Hayakawa 2003). Using this method, several *Actinoplanes* strains have been obtained (Ara et al. 2010; Yamamura et al. 2012).

Chemotactic Method The spores of *Actinoplanes* exhibit an apparently microaerophilic reaction and are attracted to chloride and bromide ions (Palleroni 1976). Therefore, a chemotactic method can be used to isolate these strains. An essential part of this technique is a simple isolation chamber, a sterilizable plastic block (80 × 40 × 12 mm) with two circular holes (9-mm deep and 24 mm in diameter) whose centers are 32 mm apart. They are connected by a channel that is 2-mm wide and 3-mm deep (Palleroni 1980). One gram of a soil sample is divided into two equal parts and then placed in each compartment. Sterile water is added nearly to the rim and stirred cautiously. After incubation for 1 h at 30 °C, the spores are released from the sporangia and move freely in the water. Using a sterilized tweezer, a sterile 1-µl glass capillary about 32-mm long is filled with 0.01 M phosphate buffer (pH 7.0) containing 0.01 M KCl and placed in the channel. The capillary must be submerged, connecting the two suspensions. After incubation at 30 °C for 1 h more, the attracted spores are concentrated in the lumen of the capillary, which is then removed and washed from the outside with a jet of sterile water. The contents of the capillary are blown into 1-ml sterile water or buffer. Portions of the dilution are taken with a sterile pipette and spread onto carefully dried agar plates. The plates are then incubated at 28 °C. Starch-casein sulfate agar is recommended as the isolation medium (Palleroni 1980). Although colonies can be selected after 4 days, slowly growing actinomycetes may only be detectable after 3 weeks.

An alternative chemotactic method which employed the capillary technique of Palleroni (1980), but using g-collidine or vanillin (100 mM) as chemoattractants, (Hayakawa et al. 1991c) was used for the isolation of *Dactylosporangium* and *Virgisporangium*, using humic acid agar (Tamura et al. 2001; Hayakawa 2003).

Moist Incubation Technique This method is suitable for the direct detection of actinoplanetes on natural substrate. Although the ability to produce motile spores obviously plays no role, *Actinoplanes* strains can be readily enriched (Willoughby 1968). Portions of decaying leaves or other biological substrates, freshly collected from the field, are washed with sterile water to remove adhering detritus. They are placed in prepared Petri dishes, the bottoms of which have been covered with very moist filter paper or layers of cellulose before autoclaving. The Petri dishes, working as moist chambers, are sealed and incubated for about 4 weeks at 25 °C. Examination with both dissecting and light microscopes is necessary to identify the sporangia of the actinoplanetes (Willoughby 1969a).

Enrichment and Isolation Procedures of *Dactylosporangium*

More recently, Hayakawa (2003) summarized his own valuable experiences of isolating rare actinomycetes. To isolate selectively high numbers of *Dactylosporangium* strains from soil, combinations of several techniques are recommended. At first, the soil samples are dried slowly at room temperature for a week, sieved, and ground slightly in a mortar (Nonomura and Ohara 1969). After that, the samples can be pretreated physically with dry heat (120 °C) for 1 h, followed by treatment with the chemical germicide BC (0.01 or 0.03 %), exposed for 30 min at 30 °C (Hayakawa et al. 1991a). Especially in the latter case, the globose bodies (aleuriospores) function as the surviving units.

The enrichment procedures profit by the release of zoospores from the sporangia in an aqueous environment. One possibility is an improved chemotactic method employing the capillary technique of Palleroni (1980), but using g-collidine or vanillin (100 mM) as chemoattractant instead of the traditional 0.01 M KCl (Hayakawa et al. 1991c). A further enrichment method named "rehydration and centrifugation" was developed by Hayakawa and colleagues (2000). The samples are flooded with 10 mM phosphate buffer containing 1 % soil extract at 30 °C for 90 min. The fluid is centrifuged at 1,500×*g* for 20 min and the supernatant, containing actively swimming zoospores, is used for plating. The isolation medium used was humic acid-vitamin agar (Hayakawa and Nonomura 1987a, 1987b) supplemented with nalidixic acid (20 mg/l) (Nonomura and Hayakawa 1988; Hayakawa et al. 1991a; 1995). An alternative source for isolation of *Dactylosporangium* was demonstrated by Okazaki (2003) using leaves as the substrate. Freshly picked leaves were cut into several pieces, rinsed with sterile water, and soaked in 70 % ethanol for 1 min. They are then washed once more with sterile water, soaked in 1 % NaClO for 3 min, and rinsed again with sterile water. After these treatments, the leaf pieces were incubated on 0.8 % water agar for several weeks. A culture-independent, nested PCR procedure based on

genus-specific oligonucleotide primers was used to detect the presence of members of the genus *Dactylosporangium* in several environmental samples. This information was used to develop a reliable strategy for the selective isolation and characterization of dactylosporangiae using several selective media supplemented with antifungal antibiotics and either gentamicin or oxytetracycline (Kim et al. 2011).

Maintenance procedures Sporulated cultures can be maintained for months on agar slopes or sealed plates at 4 °C. Long-term storage can be achieved by lyophilization, by liquid drying, or by maintaining spores or liquid seed cultures in 10–15 % glycerol at −80 °C (Wellington and Williams 1978). Lyophilization of spores or hyphal suspensions in 10 % skim milk + 1 % monosodium glutamate and L-drying in 0.01 M potassium phosphate buffer (pH 7.0) containing 3 % monosodium glutamate (Sakane and Kuroshima 1997) are also recommended for long-term preservation.

Ecology

Habitat

Members of family *Micromonosporaceae* are widely distributed in soil and aquatic environments. Different kinds of wet soils or sediments are their main habitats and include peat swamps (Thawai et al. 2004, 2005a, b; Songsumanus et al. 2011) and soils close to waterfalls (Ara and Kudo 2006; Kämpfer et al. 2007). They also appear in different plant rhizospheres (Tamura et al. 2005; Wang et al. 2011; Xu et al. 2011), and cliff soils (Seo and Lee 2009). There is evidence that mangrove environments also contain high populations of members of the family *Micromonosporaceae* (Eccleston et al. 2008; Hong et al. 2009). This is well illustrated by the isolation of *Asanoa* (Tamura and Sakane 2005; Xu et al. 2011), *Micromonospora* (Huang et al. 2008; Thawai et al. 2008; Wang et al. 2011; Songsumanus et al. 2012; Xie et al. 2012a), *Verrucosispora* (Liao et al. 2009; Xi et al. 2011; Xie et al. 2012b), *Polymorphospora* (Tamura et al. 2006), and *Jishengella* (Xie et al. 2011b). It is also believed that marine environments contain large populations of *Micromonospora* spp. (Maldonado et al. 2005b; Eccleston et al. 2008). Furthermore, uncultured actinomycetes related to the genera *Actinoplanes, Micromonospora*, and *Salinispora* were revealed by a DGGE analysis of 16S rRNA gene fragments from river water samples (Yoshida et al. 2008). Plant materials, especially nitrogen-fixing nodules (Trujillo et al. 2006, 2007, 2010; Carro et al. 2012) and roots, are also common habitats for *Micromonosporaceae* strains (Qin et al. 2009; Inahashi et al. 2010; Kirby and Meyers 2010; Li et al. 2011; Xie et al. 2012b; Zhu et al. 2012).

Specific primers to detect members of the family *Micromonosporaceae* including the genera *Dactylosporangium* (Monciardini et al. 2002; Kim et al. 2011), *Micromonospora* (Qiu et al. 2008), and *Verrucosispora* (Xie et al. 2012a) have been designed and employed in culture-independent surveys for diverse environmental samples. A new PCR primer system for the selective identification of actinobacteria was recently developed and used for the analysis of several environmental samples and building materials (Schäfer et al. 2010). In this study, the genera *Actinocatenispora* (2.1 %), *Dactylosporangium* (13.5 %), *Micromonospora* (1.0 %), *Polymorphospora* (18.8 %), and *Verrucosispora* (1.0 %) were detected from a compost sample clone library, while a sequence of *Actinoplanes*, representing 1 % of the total clone library was detected in plaster. In addition, the genera *Actinoplanes Pilimelia* and *Polymorphospora* were found in a bioaerosol of a compost plant. A pair of family-specific PCR primers for *Micromonosporaceae* was designed and employed for the clone library analysis of 16 soil samples collected at 4 mangrove sites in China. The results revealed that one third of the reported genera including *Actinoplanes, Asanoa, Jishengella, Krasilnikovia, Micromonospora, Plantactinospora, Polymorphospora, Pseudosporangium, Rugosimonospora*, and *Verrucosispora* belonged to the target family; of these, the genera *Micromonospora, Rugosimonospora, Plantactinospora*, and *Verrucosispora* were detected in all four sampling sites, suggesting their wide distribution (K Hong's group, unpublished data).

A BLAST search to detect other habitats where members of the family *Micromonosporaceae* have been detected using both dependent and independent culture methods includes anthracene-contaminated soils, coal beds, banana plantations, ants, urban aerosols, marine sponges, semi-arid lead-zinc mines, and permafrost soils (Brodie et al. 2006, 2007; unpublished sequence accession numbers: DQ125928; DQ129567; EF612364; GU002091; HQ336732; HQ864100; JF417727; JQ427735; JX1333365;). These examples reflect the wide distribution of *Micromonosporaceae* strains in many diverse habitats.

In the following paragraphs, we describe in more detail the ecology of the genera *Micromonospora, Actinoplanes, Dactylosporangium, Pilimelia, Salinispora, and Verrucosispora*, given their importance in several biological processes and application within the family. The habitat of members of monospecific genera where only the type strain is available must be considered tentative.

Micromonospora Micromonosporae have been isolated from diverse habitats including soil, water, and marine sediments (Kawamoto 1989; Zhao et al. 2004; Maldonado et al. 2005b; de Menezes et al. 2008). Micromonosporas are very common in alkaline and neutral soils (Jensen 1930; Vobis 2006), and although many strains have been shown to be sensitive to acid pH (Kawamoto 1989), they have been isolated from acid soils (Zenova et al. 2004). However, their predominant incidence seems to be in aquatic ecosystems, including both freshwater and marine habitats (Cross 1981a; Goodfellow and Haynes 1984). Since they decompose chitin, cellulose, and lignin of lake sediments, they might play an important role in lacustrine ecology (Erikson 1941).

The presence of *Micromonospora* in lake systems has been shown by investigations in many countries and was comprehensively reviewed by Cross (1981a, b).

Besides streptomycetes and nocardioforms, micromonosporas were the predominant actinomycetes in the bottom sediments of Blelham Tarn, UK, with numbers increasing from littoral to profundal mud samples (Willoughby 1969b). This dominance was even more striking in deeper mud layers, as could be shown in studies of other lakes of the English Lake District (Johnston and Cross 1976; de Menezes et al. 2008). Similar observations were made by Fernandez (1984) at a thermal lake, Lake Héviz, in Hungary. Compared with the surface of the mud, the number of micromonosporas increased twofold at a depth of 20 cm, whereas the number of streptomycetes decreased significantly in the same layer. Under those conditions, the spores of *Micromonospora* seem to be more resistant than the propagules of *Streptomyces* and nocardioform actinomycetes. This could be confirmed in investigations on the longevity of actinomycete spores in deep mud cores. Viable spores of *Micromonospora* were recorded from sediments deposited at least 100 years before (Cross and Attwell 1974). Their tolerance to low oxygen tensions suggests that micromonosporae may grow under the microaerophilic conditions found in alluvial soils, floodplain meadows, and wet soils of river ecosystems (Goodfellow and Williams 1983; Vobis 2006; Zenova and Zviagintsev 2002), plant litter, lichens, roots, and organic soil horizons (Zenova et al. 1994; González et al. 2005).

Micromonospora species have been isolated from many different marine habitats, ranging from coastal regions to deep-sea sediments. Abundant micromonosporas were found in salt marsh ecosystems in New Jersey (USA), with seasonal fluctuations in quantity (Hunter et al. 1981). In a study at the San Francisco Bay (USA) National Wildlife Refuge, Hunter et al. (1984) showed that micromonosporas occur more frequently in rhizospheric soils of seashore plants than in mud samples obtained from plant-free areas. Watson and Williams (1974) studied the actinomycetes in a coastal sand belt near Formby, Lancashire (UK). In sea water and beach strand, the *Micromonospora* strains predominated. They grew well on freshwater media and most of them tolerated seawater salinity. Okazaki and Okami (1972) isolated micromonosporaes from littoral muds and from samples collected in shallow sea areas of the Pacific Ocean, occurring more frequently at the bottom than in the sea water. Relative numbers of *Micromonospora* species increased with the depth, while an opposite trend was seen for *Streptomyces* species during investigation on rare actinomycetes of shallow water sediments of the Trondheim fjord, Norway (Bredholdt et al. 2007). Weyland (1969, 1981) found that the micromonosporas predominated in the deep-sea sediments, and his results were confirmed by Goodfellow and Haynes (1984). Furthermore, some Micromonosporae were recovered from marine sediments of over 3,000 m depth (K Hong's group, unpublished data), or detected by culture-independent methods (Stach et al. 2003). Some authors suggest that the actinomycetes are a part of the indigenous marine microflora, able to grow in seawater and its sediments (Okami and Okazaki 1978; Weyland 1981; Jensen et al. 1991; Takizawa et al. 1993; Mincer et al. 2002; Magarvey et al. 2004). Active mycelial growth was demonstrated in sand particles (Jensen et al. 2005). Using cellulose baits, de Menezes et al. (2008) demonstrated that the proportion of hyphal fragments to spores of Micromonosporae was higher in the baits closer to the surface and decreased with depth, and inferred that the organisms spores are germinated when the growth condition is available and not likely as washed in from the surrounding soil.

Micromonosporae strains have also been isolated from different plant materials. They have been described as colonizing the roots of *Casuarina* and *Triticum* species (Coombs and Franco 2003; Valdés et al. 2005). A *Micromonospora* isolate was also described from surface-sterilized wheat root tissue and culture-independent methods have identified clones of endophytic actinobacteria most closely related to *M. endolithica* and *M. peucetia* in wheat roots, suggesting the presence of a large diversity of *Micromonospora* species in plants (Conn and Franco 2004). Surface-sterilized nitrogen-fixing legume root nodules of *Lupinus angistifolius*, *Pisum sativum*, and other legumes have been shown to be extremely rich reservoirs for the isolation of novel *Micromonospora* strains (Trujillo et al. 2007, 2010; García et al. 2010; Carro et al. 2012). A collection of >2,500 strains is kept in our laboratory (Trujillo, unpublished results).

Actinoplanes Actinoplanetes are widely distributed in soil throughout the world (Couch 1963; Schäfer 1973; Parenti and Coronelli 1979). They occur in all types of soil, arid desert areas (Makkar and Cross 1982), sand dune systems close to seashores (Palleroni 1976), and subtropical and tropical regions. Schäfer (1973) isolated *Actinoplanes* strains from 56 % of soil samples investigated; Nonomura and Takagi (1977) isolated strains from 75 % soil samples collected from Japan; and Vobis (1987) isolated strains from 65 % of Argentina samples.

In general, the sporangiate actinoplanetes can be considered as normal inhabitants of soil and leaf litter (Cross 1981b), although they can also be isolated directly from lake or river water (Willoughby 1969b, 1971). A frequent drying and wetting of the substrates increases their occurrence. Favored habitats are edges of ponds, drainage ditches, and barnyards (Shearer 1987). Sediments of rivers are also a good source for the isolation of *Actinoplanes* strains (Goodfellow et al. 1990). In a large-scale investigation of the distribution of the actinoplanetes in soil in Japan, Nonomura and Takagi (1977) demonstrated a correlation between their abundance, the type of soil, its pH value, and the content of organic matter. Relatively few actinoplanetes occurred in soils with pH 4.0–5.0 and abundant organic matter content. Their number increased with lower humus content and a pH value between 6.4 and 7.2. Soils with a permanent high content of water (e.g., paddy rice fields) have no advantage compared with cultivated fields, which are dry for longer periods.

Strains of *Actinoplanes* can also colonize plant or animal debris (Cross 1981b; Makkar and Cross 1982). They occur frequently on twigs submerged in streams (Willoughby 1971), muddy dead leaves that are caught and dried on branches of overhanging trees (Cross 1981b), and on allochthonous leaf litter cast up on the shores of lakes (Willoughby 1969b).

The function of actinoplanetes in soil ecosystems is not well known. With a behavior of typical saprophytic microorganisms, abilities to degrade any kind of biological material may be possible. Chitin has been used as a carbon source for the isolation of strains by Makkar and Cross (1982). However, chitin is not easily degraded and growth may be very slow; thus, in some cases, the aim for using a chitin medium for isolation is to inhibit or decrease the growth of other microorganisms (Willoughby 1968). Degradation tests using chitin from insects and fungi (Schäfer 1973) did not agree with the positive results of Goodfellow et al. (1990) who used the basal medium of Gordon (1967) supplemented with 0.5 % (w/v) chitin.

Since *Actinoplanes* strains exhibit good growth on xylose and arabinose, it is possible that they play a role in decomposing plant origin sugars (Parenti and Coronelli 1979). A study of saprophytic actinomycetes associated with the root system of the actinorhizal plant *Discaria* revealed that all 27 isolated *Actinoplanes* strains could degrade starch, cellulose, and pectin; nine of the isolates were capable of decomposing hemicellulose and/or colonized preferably the thin sections of dead wood (Solans and Vobis 2003). The most active *Actinoplanes* strains, BCRU-ME 3, promoted *Frankia* symbiosis of *Discaria trinervis* and *Sinorhizobium meliloti*//*Medicago sativa* symbiosis (Solans 2007; Solans et al. 2009).

Dactylosporangium Members of the genus *Dactylosporangium* are distributed worldwide. They have been found in diverse types of soil, including cultivated fields, forest, and pasture soils (Hayakawa et al. 1991c; Vobis 2006). These include soil samples from Italy (Thiemann 1970a), Japan (Shomura et al. 1983a, b, 1985, 1986), Thailand (Thiemann 1970a, b; Chiaraphongphon et al. 2010), and UK (Kim et al. 2010). Other strains have been found from soil of an uncultivated field of grass in Colombia (Shearer 1987), and from soil samples collected in tropical and subtropical regions in Yunnan, China (Xu et al. 1996). Isolates have also been reported from soil samples collected in Zambia (Africa), Lüneburger Heide (Germany), and the National park Taman Negawa (Malaysia) (G. Vobis and J.M. Wink, unpublished results).

Thiemann et al. (1967) isolated 33 strains of *Dactylosporangium* from different soil samples collected in Thailand, Brazil, and Argentina. In another study, 140 *Dactylosporangium* isolates were obtained from 454 soil samples collected from various parts of the world (Thiemann 1970a). The soil types included sandy as well as loamy soils. No correlation could be established between the type of soil, its pH (4.0–9.0), and the incidence of *Dactylosporangium*. Hayakawa and Nonomura (1987a) obtained isolates from soil samples from vegetable and corn fields with pH ranging from 5.4 to 6.1, collected in different Prefectures (Nagano, Mie, Gunma, and Iwate) in Japan. Field soils seem to be the most fruitful sources for isolating *Dactylosporangium* strains, together with other diverse rare actinomycete taxa, but they were also isolated frequently from mountainous forest soils. Field, mountain grass-land, and rice paddy with soil of pH 6.0–7.0, organic matter content <5 %, and immature brown humic acid <0.8 (D log K) are the characteristic soil habitats of *Dactylosporangium* (Hayakawa 2003).

Only a few sources other than soil were successfully tested as natural substrates inhabited by *Dactylosporangium* or simply utilized as intermediate locations by its resistant structures like the globose bodies. Johnston and Cross (1976) isolated strains from the surface muds of two lakes of the English Lake District in Great Britain. *Dactylosporangium* strains were also found on plant debris (Lechevalier 1981). Leaf litter in marsh water in New Jersey (USA) was used as substrate to isolate the antibiotic dactylocycline-producing strain SC 14051. More recently, Okazaki (2003) reported an antibiotic-producing strain, *Dactylosporangium aurantiacum*, isolated from fresh plant leaves of *Cucubalus* sp.

A culture-independent, nested PCR procedure based on genus-specific oligonucleotide primers detected the presence of members of the genus *Dactylosporangium* in 14 out of 21 diverse environmental samples. This information was then used to isolate Dactylosporangiae using a selective isolation procedure. Presumptive *Dactylosporanigum* strains were isolated from 13 of the 14 environmental samples found to contain members of the genus *Dactylosporangium* in the culture-independent studies. It is interesting that many of the isolates were recovered from acidic soils, notably those isolated from the hay meadow soil (pH 5.5) and from the agricultural soils from Kuala Lumpur (pH 5.7) and Srinagar (pH 5.5) (Kim et al. 2011).

Pilimelia These strains are able to colonize keratinic substrates like hair of mammalia or snake skin (Karling 1954; Gaertner 1955; Tribe and Abu El-Souod 1979). Although they can aggressively attack the scleroproteins of animals, they are not known as dermatophytes. They are distributed worldwide and occur statistically in about one of every five soil samples (Schäfer 1973; Vobis et al. 1986). Using the baiting technique, Karling (1954) had found them in soil cultures first from New York City (USA), and later from various parts of the Amazon Valley in Brazil, as well as from Indiana, Iowa, Louisiana, New Jersey, and Virginia (USA). Sixteen percent of soil samples from the African continent were positive for the presence of *Pilimelia* (Gaertner 1955). Schäfer (1973) discovered sporangia of this genus in enrichment cultures in 22 % (96 out of 427) soil samples collected from different geographical regions of the world. Strains presumptively identified as *Pilimelia terevasa* and *Pilimelia columellifera* have been reported to be widely distributed in diverse soils from England (Tribe and Abu El-Souod 1979). Thirty four *Pilimelia*-like isolates could be recovered from 8 out of 32 soil samples from the arid environment of the Mojave Desert along the California–Nevada border using the baiting technique (Garrity et al. 1996). Although it appears that *Pilimelia* may be abundant in nature, they are very difficult to isolate and cultivate (Schäfer 1973; Vobis et al. 1986).

Salinispora Over 1,000 *Salinispora* strains have been isolated from sediments collected from the subtropical Atlantic,

the Red Sea, and the Sea of Cortez, suggesting a pan-tropical distribution. The maximum depth of successful isolation of this genus is 1,100 m (Mincer et al. 2002). Though the genus is broadly distributed in tropical and subtropical sediments (Jensen and Mafnas 2006), the three *Salinispora* species known (including "*S. pacifica*" not validly published) show distinct biogeographical patterns. *S. tropica* appears to have a restricted distribution and it is limited to the Caribbean Sea. Salinispora *arenicola* has the broadest distribution and has been recovered from all sites in which the genus has been reported. "*S. pacifica*" has an intermediate distribution, and is yet to be cultured from the Caribbean (Jensen and Mafnas 2006). A culture-independent method was used to detect *Salinispora* in environmental DNA from different depths of marine sediments collected in Bahamas in different years. No new species level diversity was detected, and 97 % of the 105 strains examined by restriction fragment length polymorphism belonged to one phylotype (*S. arenicola*) (Mincer et al. 2002). *Salinisporae* have also been reported from a marine sponge (Kim et al. 2005).

This genus has been claimed to be an obligate marine actinomycete, and all strains tested required seawater indicating a high level of marine adaptation (Mincer et al. 2002; Maldonado et al. 2005b). Although the comparative genomic analysis explained their adaptation in marine environments (Penn and Jensen 2012), good growth of *S. tropica* strains CNB440, CNB476, and NPS21184 was detected in both agar and liquid media containing the potassium-chloride-based salt formulation with sodium concentration of 5.0 mM (Tsueng and Lam 2008a, b; 2010).

Verrucosispora The type species of *Verrucosispora* was first isolated from a samples taken from a peat bog near Gifhorn, Lower Saxony, Germany (10°33′E, 52°30′N). Samples were taken from a depth of 20–40 cm after removal of the top peat layer. Later, two strains isolated from marine sediments were found to produce novel compounds and showed promising antibacterial and anticancer activities (Bister et al. 2004; Fiedler et al. 2008); this finding promoted the interest of looking for more *Verrucosisporae* from marine environments (Maldonado et al. 2009). Thus, Verrucosisporae appear to be natural inhabitants of marine environments, deep-sea sediments, and mangrove samples. They also occur in surface-sterilized roots of the mangrove plant *Acanthus illicifolius* (K Hong's group, unpublished data).

Pathogenicity: Clinical Relevance

At present, it appears that none of the members classified in the family *Micromonosporaceae* have been reported as pathogens or have any clinical relevance. Although *Pilimelia* strains can aggressively attack the scleroproteins of animals, they are not known as dermatophytes.

Application

Many members of the *Micromonosporaceae* produce useful secondary metabolites and enzymes. They have important applications in industry, biotechnology, and agriculture. For example, gentamicin (Weinstein et al. 1963a, b; Kumar et al. 2008) and vitamin B 12 (Florent and Ninet 1979) is produced by *Micromonospora* strains. *Actinoplanes* sp. SE50/110 is known as the wild type producer of the alpha-glucosidase inhibitor acarbose, a potent drug used worldwide in the treatment of type-2 diabetes mellitus (Wehmeier and Piepersberg 2004; Schwientek et al. 2012). Applications which have been established already or might be used commercially in the future are described below.

Antibiotics

In 2012, the number of known antibiotic compounds produced by all the actinomycetes together amounted to about 13,700 (Bérdy 2012), and the proportion produced by members of the family *Micromonosporaceae* (mainly *Micromonospora*, *Actinoplanes*, and *Dactylosporangium*) increased from less than 1 % in 1966 up to 10 % in 2005 (Lechevalier and Lechevalier 1967; Bérdy 2005). As can be seen in *Table 28.21*, genera in the family *Micronomosporaceae* cover nearly all of the chemical groups of antibiotics that are produced by the genus *Streptomyces*. But they complement one another, only the β-lactam antibiotics seem to be absent.

Micromonospora Among the antibiotics produced by the family *Micromonosporaceae*, those of *Micromonospora* occupy the most important commercial position (Crueger and Crueger 1982). An intensive screening of *Micromonospora* species as sources for new antibiotics began in 1963 with the discovery of gentamicin (Weinstein et al. 1963a). Over 740 different antibiotics have been described (Bérdy 2005). Aminoglycosides of *Micromonospora* show antibiotic effect against both Gram-positive and Gram-negative bacteria and have been introduced into clinical practice. The gentamicins C1, C1a, and C2 are produced by *M. purpurea* and *M. echinospora* and exhibit excellent activity against *Staphylococcus aureus* and species of *Pseudomonas* and *Proteus*. Because of their nephrotoxicity, they are used in human therapy only for severe infections (Wagman and Weinstein 1980; Crueger and Crueger 1982; Kumar et al. 2008). Sisomycin and fortimicins, derived from *M. inyonensis* and *M. olivoasterospora*, respectively, have a similar spectrum of effectivity as gentamicin and can be used against gentamicin-resistant organisms (Wagman and Weinstein 1980).

The range of chemical structures produced by micromonosporae is quite large (*Table 28.21*). Examples include the aminoglycosides, represented by gentamicin, sisomicin, and verdamicin; the antibiotics G-52, G-418, and JI-20; mannosidostreptomycin; kanamycin; neomycin B (antibiotic 460); sagamicin (gentamicin C2b);

Table 28.21

Table modified from Vobis (2006)

AG aminoglycoside, *ML* macrolide, *AML* ansamacrolide, *BLA* β-lactam, *PEP* peptide, *GP* glycopeptides, *ANC* anthracycline, *TC* tetracycline, *NUC* nucleotide, *POL* polyene, *QN* quinine, + production

paromamine fortimicins; and antibiotics 66–40 and SF 1854 (Nara et al. 1977; Wagman and Weinstein 1980). The macrolides comprise megalomycins, rosaramicin, juvenimicins, the M-4365 complex, erythromycins, and antibiotic XK 41-B-2. Examples for ansamacrolides (ansamycins) are halomicins, rifamycins, and compound 32656. Bottromycin, microsporonin, the 70591 complex, and actinomycin should be cited as representatives of the peptide antibiotics. Other miscellaneous antibiotics isolated from *Micromonospora* species include the oligosaccharides everninomycin and antlermicin, the nucleosides PA-1322 and XK-101–2, and the quinone PA-2046 (Wagman and Weinstein 1980).

Other compounds include arisostatins A and B (Furumai et al. 2000); ziracin oligosaccharides (Chu et al. 2002); anthraquinones lupacidins A, B, and C (Igarashi et al. 2007, 2011b); maklamicin (Igarashi et al. 2011a); and lipopeptide FW523-3 (Xie et al. 2011a). Most of the above compounds produced by micromonosporae showed antimicrobial and anticancer cell activities.

Actinoplanes More than 248 antibiotics are known from *Actinoplanes* species (Bérdy 2005), including chemical groups of peptides, glycopeptides, anthracyclines, nucleosides, polyenes, and quinones (Okami and Hotta 1988; Vobis 1992) (*Table 28.21*). The polypeptides generally exhibit activity against Gram-positive bacteria, such as the acidic peptide 41.012, an agent active against mycobacteria (Celmer et al. 1977). The antibiotics A-10947, A-7413, taitomycin, and gardimicin are sulfur-containing polypeptides; the latter two are also active against anaerobic bacteria (Parenti and Coronelli 1979; Yaginuma et al. 1979). The cyclic polypeptides A/287 and mycoplanecin show growth-promoting and antituberculosis effects, respectively (Hamill and Stark 1974; Nakajima et al. 1983).

The proline antimetabolite L-acetidine-2-carboxylic acid was isolated from *A. ferrugineus*. This amino acid has not been found in any other prokaryote and has only been found in eukaryotes (Palleroni 1979). *A. teichomyceticus* produces the glycopeptide teicoplanin (formerly called teichomycin A2), which is composed of six factors. It belongs to the vancomycin family (Malabarba et al. 1984). The same strain also produces a phosphorus-containing glycolipid (teichomycin A1). Both carbohydrate antibiotics are active against Gram-positive bacteria (Parenti et al. 1978). Some amino-acid derivatives are of clinical relevance, e.g., teicoplanin, a glycopeptide from *A. teichomyceticus* ATCC 31121^T (Bardone et al. 1978), actaplanin, a glycopeptide from *A. missouriensis* ATCC 23342 (Debono et al. 1984), and ramoplanin, a glycolipodepsipeptide from *Actinoplanes* sp. ATCC 33076 (Ciabatti and Cavalleri 1989).

Some metabolites belonging to various other chemical groups are also found in strains of *Actinoplanes*. The polycyclic xanthones actinoplanone A and B were found to be potent cytotoxins in in vitro assays with Hela cells (Kobayashi et al. 1988). Chuangxinmycin, composed of a unique bicyclic system formed of an indole nucleus fused to a thiopyran residue, is clinically effective in cases of septicemia and urinary and biliary infections caused by *Escherichia coli* (Parenti and Coronelli 1979). The antibiotic A/15104 Y is a chlorophenol derivative, active against bacteria and fungi. It represents the first example of a halogenated pyrrole from actinomycetes; the other biological sources have been sponges and pseudomonads (Cavalleri et al. 1978). A well-studied example of the antifungal polyenic macrolides is the antibiotic 67–121 (Sch16656). It is a complex of four polyene heptaenes produced by *A. caeruleus* (Horan and Brodsky 1986). It is also produced by *A. azureus*, a strain which also produces the plauracins (Parenti and Coronelli 1979). Purpuromycin is a naphthoquinone antibiotic of the rubromycin type, effective against bacteria and fungi (Coronelli et al. 1974). The neplanecins are nucleosides produced by another *A. regularis* strain. They are antitumor antibiotics with additional activities against phytopathogenic fungi (Yaginuma et al. 1981). Viriplanin is an anthracyclic antibiotic isolated from *A. regularis*, which shows activities against herpes simplex viruses (Hütter et al. 1986). Integramycin is an alkaloid that inhibits HIV-1 integrase produced by

Actinoplanes sp. ATCC202188 (Singh et al. 2002). A cyclic peptide, philipimycin, with strong antibacterial activities against Gram-positive bacteria is produced by *A. philippinensis* MA7347 (Zhang et al. 2008).

Dactylosporangium Pyridomycin is an antimycobacterial antibiotic produced by the type strain of *Dactylosporangium fulvum* SF 2113^T (Shomura et al. 1986). At present, more than 58 antibiotics are known from *Dactylosporangium* strains (Bérdy 2005), belonging to several chemical divisions (Table 28.21). As with *Micromonospora*, the major antibiotics seem to be aminoglycosides. Dactimicin is produced by *D. matsuzakiense* and *D. vinaceum* (Shomura et al. 1980, 1983b). It is a member of the pseudosaccharide group of antibiotics, is active against a wide variety of bacteria, including resistant strains with aminoglycoside-modifying enzymes (Omoto et al. 1987). The closely related aminoglycosides gentamicin, sisomicin, fortimicin, and antibiotic G-367 were also isolated from products of *D. thailandense* strain G-367. Aminoglycosides of the fortimicin antibiotic group are produced by *D. matsuzakiense* ATCC 31570^T (Dairi et al. 1992), and by the *Dactylosporangium* strain G 308. Another carbohydrate antibiotic is known from *D. roseum*, namely, the orthosomycine complex SF-2107 (Shomura et al. 1985). All the above-mentioned antibiotics are generally active against Gram-positive and Gram-negative bacteria.

Capreomycin, a polypeptide compound previously known from *Streptomyces capreolus*, was also isolated from "*D. variesporium*." It is of primary interest for its use as an antituberculosis agent (Tomita et al. 1977). The tetracycline antibiotic compound Sch34164 (Patel et al. 1987) and the macrolide tiacumicin (Hochlowski et al. 1986) have been isolated from other *Dactylosporangium* species. Dactylocyclines A and B, produced by strain SC 14051, have tested positive against tetracycline-resistant bacteria (Tymiak et al. 1993). Tiacumicins, a complex of 18-membered macrolide antibiotics, are metabolites produced by strain AB718C-41, described as *D. aurantiacum* subsp. "hamendensis" (Theriault et al. 1987). Tiacumicins B and C present positive results against diarrhea-associated bacterium *Clostridium difficile* in vitro and in vivo tests (Swanson et al. 1991). Strain SF-2253 produces L-threo-b–hydroxyaspartic acid, an antibiotic useful against a wide spectrum of microorganisms. This amino acid is also an inhibitor of glutamate uptake, frequently used in neurological studies (Alexander et al. 1997). All these examples suggest that the capacity for producing antibiotic metabolites in this genus may be very large.

Salinispora Salinisporae are best known for their production of secondary metabolites including the highly selective proteasome inhibitor salinosporamide A (Feling et al. 2003), which is currently undergoing clinical trials for the treatment of cancer (Fenical et al. 2009). Members of the genus *Salinispora* have proven to be a particularly rich source of new chemical structures. Many distinct structural types have been characterized from this genus, including the hybrid PKS-NRPS salinosporamides A, B, and C (Feling et al. 2003; Williams et al. 2005); the modified enediyne sporolide polyketides A and B (Buchanan et al. 2005; McGlinchey et al. 2008); the novel polyene macrolactam salinilactam A (Udwary et al. 2007); the compounds known as arenicolides (Williams et al. 2007); the depsipeptide arenamides (Asolkar et al. 2009, 2010); the polyketide rifamycin, the cyclic heptapeptide cyclomarin A, the indolocarbazole staurosporine (Fenical and Jensen 2006) and their derivatives saliniketal (Williams et al. 2007) and cyclomarazine (Schultz et al. 2008) from *S. arenicola* CNS-205. In addition, the antitumor antibiotic lomaivitacin (He et al. 2001), the cyanosporasides A and B (Oh et al. 2006), and four new compounds of new polyketides, salinipyrones A and B and pacificanones A and B, are produced by "*S. pacifica*" strains CNS103 and CNS-237, respectively. The 16S rRNA gene sequence of the two "*S. pacifica*" strains differs by only three nucleotide positions, but the chemical screening by LC-MS analysis indicated that their secondary metabolite profiles are very different.

Based on the analysis of two genome sequences of *S. tropica* CNB-440 and *S. arenicola* CNS-205, secondary metabolism is the major functionally annotated class of metabolic genes that differentiates the two species (Penn et al. 2009, 2012). This is supported by the observation that secondary metabolite production occurs in species-specific patterns with *Salinispora arenicola* strains producing rifamycins and staurosporines while *Salinispora tropica* strains produce salinosporamides and sporolides (Jensen et al. 2007).

Verrucosispora *Verrucosispora* is another genus from marine environment that has attracted considerable interest as they produce new bioactive compounds, exemplified by the discovery of the polycyclic polyketides, abyssomicins A to H from *V. maris* AB-18-032 (Bister et al. 2004; Keller et al. 2007; Goodfellow et al. 2012), the aminofuran antibiotics, proximicins A to C from *Verrucosispora* strain MG-37 (Fiedler et al. 2008), and the diterpenes, gifhornenolones A and B from *V. gifhornensis* (Shirai et al. 2010). Abyssomicin C is active against methicillin-resistant *Staphylococcus aureus* (MRSA) and vancomycin-intermediate/resistant *Staphylococcus aureus* (VRSA) by inhibiting the *para*-aminobenzoic acid pathway that therefore inhibits folic acid biosynthesis at an early stage (Riedlinger et al. 2004). Proximicins show strong cytostatic effect on various human tumor cell lines (Fiedler et al. 2008). The whole genome sequence of *V. maris* AB-18-032^T revealed 23 biosynthetic gene clusters that encode the known or predicted secondary metabolites (Roh et al. 2011).

Inhibitors of α-Glucosidase as Pharmaceutical Drugs

In the course of screening for inhibitors of amylases and other mammalian intestinal carbohydrate-splitting enzymes, strains of *Actinoplanes* exhibited higher amounts of activity than did those of *Streptomyces* and *Streptosporangium*

(Frommer et al. 1979). Applied orally together with food carbohydrates like starch and other oligosaccharides, these glycoside hydrolase inhibitors slow down oligosaccharide decomposition and reduce or avoid postprandial hyperglycemia and hyperinsulinemia of type IV. Therefore, they may be useful to treat metabolic illnesses such as diabetes mellitus, adipositas, and hyperlipoproteinemia (Truscheit et al. 1981; Creutzfeldt 1988).

Pseudo-oligosaccharides with an essential core consisting of an unsaturated cyclitol and 4-amino-4, 6-dideoxyglucose are the most important group of α-glucosidase inhibitors. In culture filtrates of *Actinoplanes* strain SE 50, a very effective pseudotetrasaccharide with the generic name "acarbose" was found. This low-molecular-weight compound is stabile to acid, alkali, and heat treatment and exhibits pronounced inhibition of sucrase, maltase, and amylase (Truscheit et al. 1981). Since 1990, the large-scale fermentation has been performed in industrial production of acarbose (Wehmeier and Piepersberg 2004). The complete genome sequence of *Actinoplanes* sp. SE50/110 was just published recently. The 9.2 Mb genome consists of one circular chromosome. Besides the already published acarbose biosynthetic gene cluster sequence, several new gene clusters of non-ribosomal peptide, polyketide, and their hybrids were identified (Schwientek et al. 2012).

Enzymes

Xylose isomerase can be obtained from strains of *Actinoplanes* and *Micromonospora* (Crueger and Crueger 1982; Peczyńska-Czoch and Mordarski 1988). The glucose isomerase converts D-glucose into D-fructose and is used commercially in the starch industry to obtain high-fructose corn syrup (Aunstrup et al. 1979). Starting from about 95 % glucose syrup, a twice sweeter fructose syrup is produced which is usually composed of 53 % of D-glucose, 42 % of D-fructose, and 5 % of oligosaccharides (Crueger and Crueger 1982).

Actinoplanes missouriensis strain ATCC 14538 produces an intracellular, soluble glucose isomerase with a molecular weight of about 80,000 Da. The optimal pH of the enzyme is 7.0 at temperatures between 60 °C and 65 °C. A requirement for cobalt ions for optimal activity is eliminated if the proper amount of magnesium ions is used (Gong et al. 1980). The xylose isomerase of *Ampullariella* strain ATCC 31354 (transferred later to *Actinoplanes*) exhibits superior thermostability and activity over a wide range of conditions. However, the strain itself is difficult to use as a production organism, which makes it desirable to clone and express its enzyme in a more convenient microorganism (Saari et al. 1987).

An extracellular enzyme system capable of lysing cells of various yeast species was produced by *Micromonospora chalcea* when grown on a defined medium containing laminarin as the sole carbon source. β (1 → 3) glucanase and protease were the most prominent hydrolytic activities present in the culture supernatants. The system also displayed weak chitinase and β (1 → 6) glucanase activities while devoid of mannanase activity (Gacto et al. 2000).

The genome analysis results showed that *Micromonospora* strains L5 and Lupac 08, isolated from *C. equisetifolia* and *Lupinus angustifolius* nitrogen-fixing nodules, respectively, have cellulase and xylanase, pectin and chitin activities (Hirsch and Valdés 2010; Alonso-Vega et al. 2012).

Application in Agriculture

Reports of hyperparasitism by actinoplanetes on parasitic *Peronosporales* and *Saprolegniales* demonstrate a possible biological control of serious diseases of economic plants (Lechevalier 1988). The oospores of pink rot-causing *Phytophthora megasperma* var. *sojae* or f. sp. *glycinea* can be parasitized by certain strains of *Actinoplanes* and *Micromonospora* (Sneh et al. 1977). The hyphae of *Actinoplanes missouriensis* penetrate the walls of the oogonia and the oospores without forming appressoria or haustoria or changing the morphological and internal structures of the oospores (Sutherland et al. 1984). In greenhouse experiments, the root rot of soybeans caused by *Phytophthora* could be reduced by *Actinoplanes missouriensis*, *A. utahensis*, and *Micromonospora* sp. (Filinow and Lockwood 1985). A number of studies have already implicated *Micromonospora* and other actinomycetes as biocontrol agents in the protection of carrot (El-Tarabily et al. 1997), wheat (Coombs and Franco 2003) Chinese cabbage (Lee et al. 2008), and cucumber (El-Tarabily et al. 2009).

Conn et al. (2008) demonstrated that *Micromonospora* and other endophytic actinobacteria were able to suppress a number of pathogens, both in vitro and *in planta*, through the activation of key genes in the systemic acquired resistance or the jasmonate/ethylene pathways in *Arabidopsis thaliana*. Antibiotic and cellulase production is another way to inhibit plant pathogens (Shomura et al. 1983a; El-Tarabily et al. 1996; Ismet et al. 2004). An isolate from mangrove rhizosphere soil in West Malaysia, *Micromonospora* sp. M39, produces metabolites including 2, 3-dihydroxybenzoic acid, phenylacetic acid, and the antibiotics cervinomycin A1 and A2 that are effective against the rice blast pathogen *Pyricularia oryza* MPO 292 (Ismet et al. 2004). Large *Micromonospora* populations have been isolated from nitrogen-fixing nodules of legume and non-legume plants (Valdés et al. 2005; Trujillo et al. 2010). These studies suggest that the genus *Micromonospora* maintains a close interaction with these plants.

Furthermore, the presence of this microorganism does not appear to be restricted to a single legume plant species, and has been isolated from at least 20 different legume plant species (Trujillo et al. 2006, 2007, 2010; García et al. 2010; Carro et al. 2012). The potential ecological role played by this actinobacterium in both actinorhizal and legume root nodules is yet to be unraveled.

The acidic substance SF 2185 is an antibiotic against plant pathogens, particularly the causal organisms of cucumber downy mildew and rice blast. The producing strain SF-2185 was identified as *D. aurantiacum* subsp. "gifuense"

(Matsumoto et al. 1985). *D. aurantiacum* strain SANK 61299 produces the plant growth inhibitors streptol, A-79197-2 (disaccharide of streptol), and A-79197-3 (trisaccharide of streptol), which inhibit the germination of *Brassica rapa*. The depsipeptide antibiotics plauracin A 17002 and A2315 belong to the virginiamycin group, composed of a mixture of macrocyclic lactones and depsipeptides. They can be used for growth promotion in chicken, swine, and ruminants (Hamill and Stark 1975; Parenti and Coronelli 1979). "*D. salmoneum*" produces the polyether antibiotic compound 44,161, which is useful for the control of coccidiosis in poultry and improving feed efficiency in ruminants (Celmer et al. 1978). The compound 44161 is identical to nigerimicin, which is also known as a herbicidal agent (Heisey and Putnam 1990). Members of *Dactylosporangium* produce the streptol moieties that are important for herbicidal activity (Kizuka et al. 2002).

Degradation and Remediation

The production of hydrolytic enzymes allows *Micromonospora* species to play an active role in the degradation of organic matter in their natural habitats. Most *Micromonospora* species probably degrade biopolymers (Erikson 1941), and they can even attack lignin complexes (McCarthy and Broda 1984). Many of the salt marsh isolates of Hunter et al. (1981) were active in the decomposition of chitin and cellulose. In particular, cellulose is frequently utilized as substrate (Jensen 1930; Sandrak 1977; Kawamoto 1989; de Menezes et al. 2008). The cellulose studied from "*Micromonospora melanosporea*" was found to be more heat stable than those of the fungus *Trichoderma*, but less stable than the enzymes of thermophilic actinomycetes. The principal sugar released by *Micromonospora* cellulase from ball-milled bagasse and filter paper was cellobiose (Van Zyl 1985). *Micromonospora* strains isolated from the water column, sediment, and cellulose baits placed in freshwater lakes were shown to be able to degrade cellulose in lake water without any addition of nutrients (de Menezes et al. 2008, 2012). *Micromonospora* together with other three genera were able to efficiently degrade rice straw pieces in minimal medium, causing significant weight loss between 50 % and 61 %. Application of this knowledge may improve the management of waste rice straw (Abdulla and El-Shatoury 2007).

Several members of the family *Micromonosporaceae* (e.g., *Actinoplanes*, *Micromonospora*, and *Dactylosporangium*) were found to degrade rubber and use it as a sole carbon source. An endo-cleavage mechanism of degradation was indicated by the molecular mass reduction (Jendrossek et al. 1997; Rose and Steinbüchel 2005). *Micromonospora aurantiaca* strain W2b was found to be a weaker rubber decomposer that did not grow adhesively but formed clear zones around its colonies after cultivation on natural rubber dispersed in mineral agar (Linos et al. 2000). This activity may also have potential biotechnological applications.

29 The Family *Mycobacteriaceae*

Stephen Lory
Department of Microbiology and Immunobiology, Harvard Medical School, Boston, MA, USA

Abstract
In this chapter, the medically-important species of the family of *Mycobacteriacea*, with a single genus, *Mycobacterium*, will be briefly discussed.

The family of *Mycobacteriaceae* contains the single genus *Mycobacterium* with over 150 species (Fig. 29.1). They are broadly distributed in various natural environments, and with several notable exceptions, they do not appear in parasitic or disease associations. This genus also includes *Mycobacerium tuberculosis*, currently responsible for serious bacterial infections of humans in many parts of the world, with millions of deaths annually. Other *Mycobacterium* species can cause a variety of infections as well; for example, worldwide, there are over quarter million new cases of leprosy, a debilitating disease caused by *Mycobacterium leprae*. A number of mycobacterial saprophytes have been shown to cause opportunistic infections in immunocompromised individuals, and many are pathogens of animals.

Mycobacteriaceae are obligate aerobic organisms; they do not take up stain well in the Gram-staining procedure but are considered Gram-positive based on the structure and composition of their cell envelope. They are acid fast when the Ziehl-Neelsen stain is applied and appear as rods in chains or as individual cells. Growth requirements vary from simple media containing carbon, nitrogen, and energy sources to more substantially supplemented media, primarily with molecules involved in iron acquisition or certain vitamins. Some extreme examples such as *Mycobacterium leprae* cannot be cultured on laboratory media at all. Most other species can utilize sugars, simple alcohols, and acids as well as complex organic molecules such as aromatic or aliphatic hydrocarbons. They possess a full electron transport chain, and under hypoxic conditions, electron acceptors other than oxygen can be used, most commonly nitrate or fumarate. The various *Mycobacterium* species exhibit a great variation of growth rates, with doubling times ranging from a few hours to days. Although they can grow on simple media, their growth improves significantly when rich sources of lipids and fatty acids are included, and egg yolk is usually included in media to stimulate growth. These growth differences are used occasionally to categorize mycobacteria into fast- and slow-growing groups, and this division is in general supported by phylogenetic clustering based on molecular markers such as 16S rRNA genes or whole genome sequence comparisons. Overall, pathogenic *Mycobacteriaceae* grow slowly on most laboratory media while the nonpathogenic strains belong to the fast growth group (Cook et al. 2009).

One of the key features of the physiology of *Mycobacterium* species is the presence of a thick, relatively impermeable cell wall consisting of various lipids attached to peptidoglycan, the most prominent of which are differentially substituted forms of mycolic acid. The mycolic acids are highly hydrophobic because of their abundance and the size of the fatty acid chains ranging between 60 and 100 carbons in length. It is this structure that renders mycobacteria largely impermeable, and although they are Gram-positive, the outer layer of the cell wall encloses a compartment analogous to the periplasm of Gram-negative bacteria.

Owing to its medical importance, the most extensively studied *Mycobacterium* species is the obligate human pathogen *M. tuberculosis*, the causative agent of the disease tuberculosis. The bacteria are transmitted from infected individuals by aerosol in droplets following sneezing or coughing. Once inhaled, the mycobacteria reach the alveoli of the lung and are phagocytized by alveolar macrophages frequently resulting in their elimination. However, in a fraction of infected individuals, *M. tuberculosis* are not killed by the macrophages, and instead, they replicate within these immune cells. The infected macrophages are often killed; the bacteria are released and infect other macrophages. *M. tuberculosis* can spread within the lung and cause pulmonary tuberculosis. The bacteria can also enter the blood stream through damaged vessels and disseminate to various organs where they can replicate and cause tuberculosis-like diseases in bones and joints, kidneys, and intestinal tract and reinfect the lung. In the majority of infected individuals, the bacteria are restricted to a small area of the lung; the infected cells are walled off and form a small granuloma (an aggregate of cells and fibrous material). This is called the latent infection, and the majority of the *M. tuberculosis* cells are confined, and some even lose viability. However, in ca. 10 % of individuals with latent tuberculosis, the dormant bacteria can be reactivated often years after the initial exposure and lead to active tuberculosis.

Several other *Mycobacterium* species are phylogenetically closely related to *M. tuberculosis*; they are responsible for primary human infections or they can be transmitted from infected animals. Together, these are often referred to as "*M. tuberculosis* complex" and include, in addition to *M. tuberculosis*, *Mycobacterium africanum*, *Mycobacterium bovis*, *Mycobacterium microti*, *Mycobacterium caprae*, and *Mycobacterium pinipedii*. The genetic and therefore physiological closeness of this group is highlighted by the efficacy of a vaccine derived from *M. bovis* (*M. bovis* BCG) in protecting against human infections by *M. tuberculosis*.

M. africanum causes tuberculosis exclusively in West Africa or in emigrants from this region of the world. It is a true opportunistic pathogen capable of infecting individuals with compromised defenses including the elderly, those with an

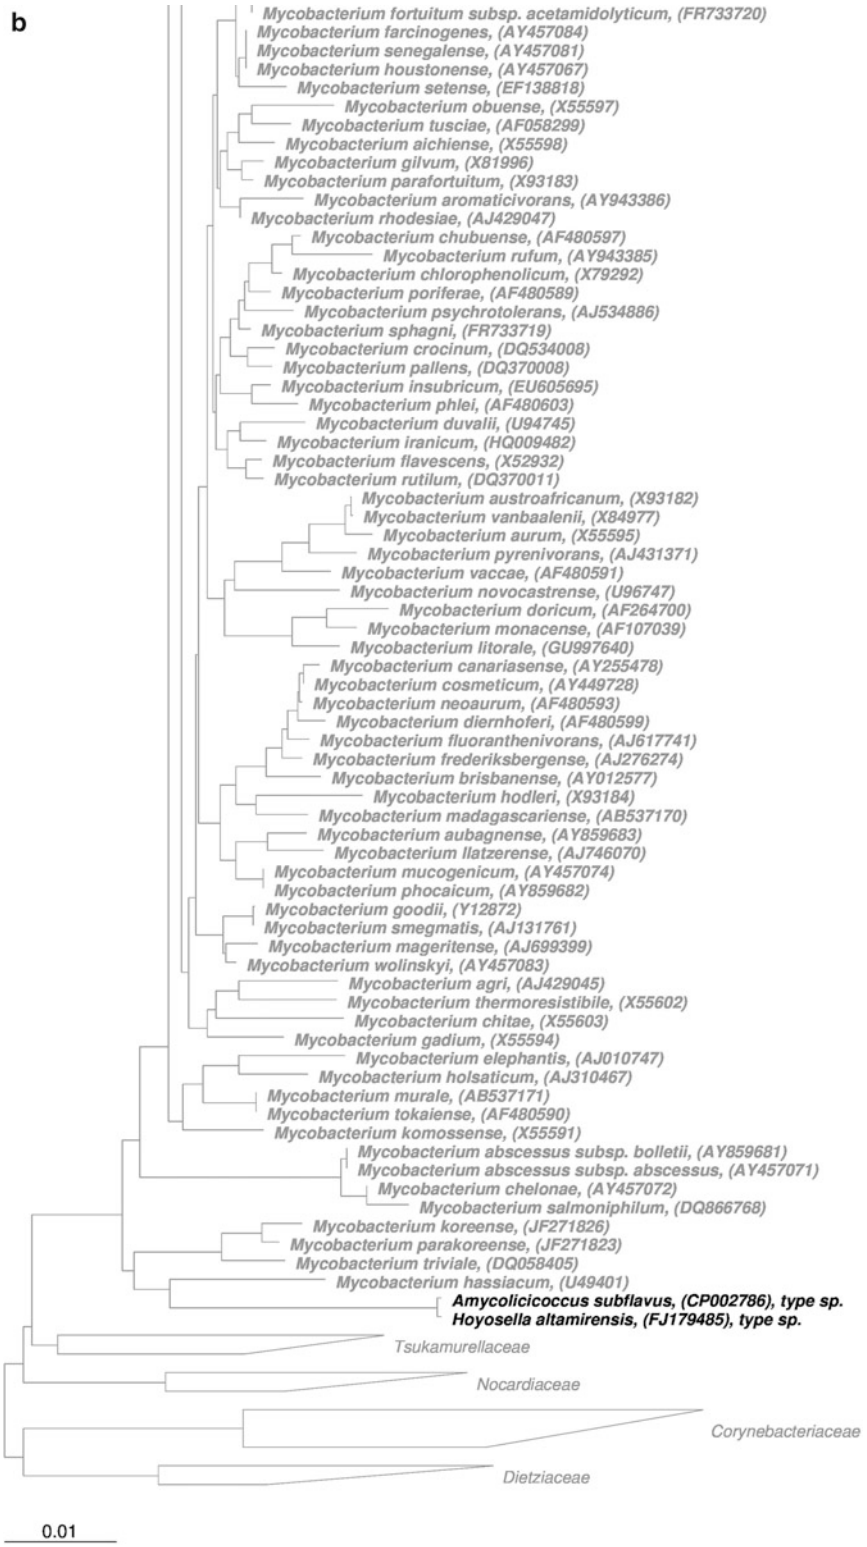

Fig. 29.1

Phylogenetic reconstruction of the family *Mycobacteriaceae* based on 16S rRNA and created using the neighbor-joining algorithm with the Jukes-Cantor correction. (a and b) Overlap in order to follow through the whole topology. The sequence datasets and alignments were used according to the All-Species Living Tree Project (LTP) database (Yarza et al. 2010; http://www.arb-silva.de/projects/living-tree). The tree topology was stabilized with the use of a representative set of nearly 750 high quality type strain sequences proportionally distributed among the different bacterial and archaeal phyla. In addition, a 40 % maximum frequency filter was applied in order to remove hypervariable positions and potentially misplaced bases from the alignment. Scale bar indicates estimated sequence divergence

HIV infection, or suffering from malnutrition. Patients with an *M. africanum* infection present the classical pulmonary and extrapulmonary symptoms of tuberculosis. *M. bovis* can infect domestic animals (cattle, goats, and pigs) and occasionally wild animals such as bison, deer, and elk. Cattle are the most common animal hosts for *M. bovis*, where it causes a disease called bovine tuberculosis. Animals with active diseases usually transmit the bacteria between each other by aerosol; on the other hand, zoonotic transmission to humans can take place by any one of several routes including inhalation and consumption of or direct contact with the flesh or milk of the infected animals. Bovine tuberculosis is similar to tuberculosis in humans with a major lung involvement and potential dissemination into organs. In humans, *M. bovis* infection by the respiratory route follows a similar course as the disease caused by *M. tuberculosis* including an ability to establish a latent form of the disease. Ingestion of infected animal products usually leads to a disease that remains localized in the intestinal tract and lymphatic tissues. Small wild rodents and farm animals are the primary reservoirs of *M. microti*, and they can occasionally infect humans. One common route is via cats that serve as intermediary hosts. The symptoms in humans are those of classical pulmonary tuberculosis. Similar disease is caused by the opportunistic pathogen *M. canettii*; it is endemic in Eastern Africa, and the mode of transmission remains unknown. *M. pinnipedii* has been isolated from seals, where it caused tuberculosis-like lung lesions. Transmission to animal handlers, but without symptoms of the disease, was detected using serological methods,

Mycobacterium leprae is responsible for leprosy (Hansen's disease), an infection of the skin, the subcutaneous tissue with a major involvement of the peripheral nervous system, leading to the loss of sensation, while the infection of the eyes can result in blindness (Britton and Lockwood 2004). Nerve damage can result in disfigurement and loss of limbs. Leprosy is a chronic infection with a long latent period of several years. The slow progression of the disease makes it difficult to trace the mode of transmission. Air droplets from patients with the disease are the most likely sources of new infections. *M. leprae* is one of the few *Mycobacterium* species that has not been cultured in any laboratory medium necessitating passage via animal hosts, usually in footpads of mice or in armadillos. The doubling time in these animals is approximately 2 weeks. For the laboratory identification of the infecting organisms, direct microscopic observations of samples from the skin or various lesions showing acid-fast rod-shaped bacteria, together with the classical symptoms of leprosy, provide the definitive evidence for the confirmation of leprosy. A new form of leprosy was recently identified in Central America; it is caused by *Mycobacterium lepromatosis*, a species closely related to *M. leprae*. Since neither organism can be cultured and appears identical microscopically, they can be differentiated from each other only by polymerase chain reaction–based species-specific assays of DNA obtained from infected lesions.

The remaining *Mycobacterium* species with a disease-causing potential are frequently called nontuberculous mycobacteria. These mycobacteria represent a heterogeneous group of broadly distributed environmental organisms, and a substantial number have been implicated in infections of immunocompromised individuals (Esteban et al. 2012). Four closely related organisms referred to as *M. avium* complex are commonly found in fresh- and saltwater and occasionally in animals (Rindi and Garzelli 2014). *Mycobacterium avium* Subsp. *hominissuis* causes lung and soft tissue infections in immunodeficient individuals such as those with AIDS; the *Mycobacterium avium* Subsp. *avium* infects chickens, where it can cause avian tuberculosis; *Mycobacterium avium* Subsp. *Paratuberculosis* causes in ruminants Johne's disease, a chronic progressive enteritis, and *Mycobacterium avium* Subsp. *silvaticum* is responsible for a tuberculosis-like disease in pigeons. In humans, they can cause initially a respiratory disease and subsequently a disseminated infection most commonly in patients with HIV infections. There is little information regarding the mode of acquisition of these organisms; however, person-to-person transmission is very unlikely.

Sporadic infections of humans by *Mycobacterium kansassi*, *Mycobacterium malmoense*, *Mycobacterium simiae*, *Mycobacterium szulgai*, and *Mycobacterium xenopi* can be responsible for a respiratory disease in both immunocompetent and immunocompromised individuals. *Mycobacterium abscessus*, *Mycobacterium chelonae*, *Mycobacterium haemophilum*, *Mycobacterium ulcerans*, and *Mycobacterium marinum* cause skin and soft tissue infections.

The availability of the genome sequences of a large number of *Mycobacterium* species greatly increased our understanding of genetic changes that took place during the evolution and environmental adaptation of this group of organisms (Behr 2013). Moreover, comparing sequence variations including the location of single-nucleotide changes in the same genes in different species and strains within individual species allows for a reconstruction of the evolutionary history of various mycobacteria. It is now recognized that the progenitor of current virulent *M. tuberculosis* originated from environmental mycobacteria, most likely a strain of *M. canettii* in East Africa (Supply et al. 2013). Its genome and that of early *M. tuberculosis* ancestors was assembled through multiple horizontal gene transfer events. Following adaptation to latency, it reemerged, and at the time of animal domestication, it adapted to these new hosts as *M. bovis*. On its evolutionary path towards becoming a specialized pathogen with a limited host range, *M. tuberculosis* has undergone a significant genome reduction leading to a highly conserved genetic makeup within 4 megabase chromosomes with ca. 4,000 genes and a relatively low level of genetic variation at the nucleotide level. In contrast, other mycobacteria like *M. marinum* have assembled large mosaic genomes providing them an ability to survive in a broad range of environments including human hosts, where they can produce a tuberculosis-like disease.

A more dramatic reductive genome occurred in *M. leprae* with a massive loss of genes through the deletion or accumulation of inactivating mutations giving rise to pseudogenes (Singh and Cole 2011). Nearly half of *M. leprae* genes are nonfunctional due to mutations, and some are completely

or partially deleted. Another remnant of active reduction of the genome is the presence of large numbers of related insertion sequences and repetitive genetic elements dispersed in the chromosome; these can facilitate the deletion of large blocks of DNA or a rearrangement of groups of genes by homologous or site-specific recombination. The direct consequence of these massive genetic changes is greatly restricted metabolic capabilities and the confinement of this organism to a limited number of hosts.

30 The Family *Nakamurellaceae*

Kwang Kyu Kim · Jung-Sook Lee
Korean Collection for Type Cultures, Biological Resource Center, Korea Research Institute of Bioscience and Biotechnology, Daejeon, Republic of Korea

Abstract
Nakamurellaceae, a family within the order "*Frankiales*," originally comprised the three monospecific genera, *Nakamurella*, *Humicoccus*, and *Saxeibacter*. Very recently, with the description of a novel taxon (*Nakamurella panacisegetis*) within *Nakamurellaceae*, the genera *Humicoccus* and *Saxeibacter* were united with the genus *Nakamurella* on the basis of high levels of 16S rRNA and *rpoB* gene sequence similarity, together with a robust phylogenetic relationship, and the overall chemotaxonomic similarity. Consequently, *Nakamurellaceae* is a monogeneric family and contains four species, *Nakamurella multipartita*, *Nakamurella flavida* (formerly *Humicoccus flavidus*), *Nakamurella lactea* (formerly *Saxeibacter lacteus*), and *N. panacisegetis*. Members of the family *Nakamurellaceae* are mainly found in soil, but they have been isolated from activated sludge, a rock, glacier sediment, and a plant root as well. This chapter is a modified and updated version of previous family descriptions (Tao et al. Int J Syst Evol Microbiol 54: 999–1000, 2004; Zhi et al. Int J Syst Evol Microbiol 59:589–608, 2009).

Taxonomy: Historical and Current

Short Description of the Family

Na.ka.mu.rel.la'ce.ae. N.L. fem. n. *Nakamurella* type genus of the family; *-aceae* ending to denote a family; N.L. fem. pl. n. *Nakamurellaceae* the *Nakamurella* family. The description is an emended version of the descriptions given by Tao et al. (2004) and Zhi et al. (2009).

Phylogenetically a member of the order "*Frankiales*" (Normand and Benson 2012), class *Actinobacteria*, phylum Actinobacteria. The pattern of 16S rRNA signatures consists of nucleotides at positions 195 (G), 196 (C), 841 (C), 952:1229 (C-G), 955:1225 (A-U), 986:1219 (A-U), 1059:1198 (U-A), and 1308:1329 (U-A) (Stackebrandt et al. 1997; Zhi et al. 2009). The family contains only the type genus *Nakamurella* (Tao et al. 2004; emended by Kim et al. 2012).

The family description is based upon the phylogenetic position and the presence of 16S rRNA sequence signatures. Phenotypic properties that differentiate *Nakamurellaceae* from the nearest neighboring families are summarized in ❯ *Table 30.1*.

Phylogenetic Structure of the Family and Its Genera

According to the phylogenetic branching of actinobacterial type strains in the RAxML 16S rRNA gene tree of the Living Tree Project (Yarza et al. 2010; Release LTPs108), the family is moderately related to the families *Cryptosporangiaceae*, *Sporichthyaceae*, and *Geodermatophilaceae* of the order "*Frankiales*." The reduced tree (❯ *Fig. 30.1*) also shows that the family *Nakamurellaceae* is closely related to the three families, the latter being a sister clade. However, *Nakamurellaceae* is clearly distinguished from the neighboring families in that it contains a menaquinone with eight isoprene units as its major quinone component and does form neither hyphae nor spores (❯ *Table 30.1*). Until now, a couple of studies have indicated that the six families of the order "*Frankiales*" do not form a coherent phylogenetic lineage, and the taxonomy of this order needs to be emended (Normand 2006; Gao and Gupta 2012; Ludwig et al. 2012). According to the publication by Zhi et al. (2009), the

Maximum-likelihood genealogy reconstruction based on the RAxML algorithm (Stamatakis 2006) of the sequences of all members of the family *Nakamurellaceae*. The tree was reconstructed by using a subset of sequences representative of close relative genera to stabilize the tree topology. In addition, a 40 % conservational filter for the whole bacterial domain was used to remove hypervariable positions. The *bar* indicates 1 % sequence divergence

families *Frankiaceae* (including the type of the order) and *Acidothermaceae* branched independently of the families *Nakamurellaceae*, *Cryptosporangiaceae*, *Sporichthyaceae*, and *Geodermatophilaceae* in the maximum-parsimony tree and furthermore, *Nakamurellaceae* branched independently of the other families of the order "*Frankiales*" in the maximum-likelihood tree. Therefore, the affiliation of the family *Nakamurellaceae* into the order "*Frankiales*" remains uncertain.

The family *Microsphaeraceae* was created by Stackebrandt et al. (1997) to accommodate a single genus and species, *Microsphaera multipartita* (Yoshimi et al. 1996), on the basis of phylogenetic position and the presence of a unique set of 16S rRNA sequence signatures. Later, the name *Microsphaera* was proven to be illegitimate because of precedence of the fungal genus *Microsphaera* (Wallr.) (Léveillé 1851), and accordingly, the genus and family names were replaced by *Nakamurella* and *Nakamurellaceae*, respectively (Tao et al. 2004). Originally, *Nakamurella multipartita* (formerly *Microsphaera multipartita*) was a strictly aerobic, Gram-positive, nonmotile, non-spore-forming, coccus-shaped actinobacterium (Yoshimi et al. 1996). The chemotaxonomic markers characteristic of the genus *Nakamurella* were MK-8(H_4) as the predominant menaquinone; $C_{15:0}$ iso, $C_{16:0}$ iso, and $C_{18:1}$ as the major fatty acids; and *meso*-diaminopimelic acid in the cell-wall peptidoglycan (Yoshimi et al. 1996). Later, the genus *Humicoccus* was described in *Nakamurellaceae*, this was distinguished from the genus *Nakamurella* by the differences in predominant menaquinones, major fatty acids, and whole-cell sugars (Yoon et al. 2007), and more recently, the genus *Saxeibacter* was reported to be another deep-rooted member of this group and characterized by some unique features with respect to cell morphology, colony pigmentation, and fatty acid and polar lipid profiles (Lee et al. 2008). Subsequently, the description of *Nakamurellaceae* was emended due to the newly described genera and the availability of their 16S rRNA gene sequences (Zhi et al. 2009).

Very recently, the taxonomic reevaluation of the genera *Nakamurella*, *Humicoccus*, and *Saxeibacter* was carried out during the description of a novel taxon that occupies an intermediate position within the family *Nakamurellaceae* (Kim et al. 2012). It revealed that the three genera of *Nakamurellaceae* are related to each other at the genus level, considering high levels of 16S rRNA and *rpoB* gene sequence similarity and the overall chemotaxonomic similarity. Accordingly, the genera *Humicoccus* and *Saxeibacter* were united with the genus *Nakamurella* having a priority, and as such, the novel taxon was assigned to the genus *Nakamurella* with the name *Nakamurella panacisegetis* (Kim et al. 2012). At that time, the description of the genus *Nakamurella* was emended, but the emendation of the family was not done. Currently, *Nakamurellaceae* is a monogeneric family containing four species, *N. multipartita*, *Nakamurella flavida* (formerly *Humicoccus flavidus*), *Nakamurella lactea* (formerly *Saxeibacter lacteus*), and *N. panacisegetis*, which form a robust phylogenetic relationship, irrespective of algorithms applied to the set of 16S rRNA gene sequences (Kim et al. 2012).

Molecular Analyses

The phylogenetic dendrogram (Fig. 30.1) of *Nakamurellaceae* species indicates the presence of one sister clade. The clade is composed of *N. flavida* and *N. panacisegetis*. *N. lactea* branches more deeply, and the outermost species is *N. multipartita*. According to the maximum-likelihood tree showing relationships between all representative members of the order "*Frankiales*" (Kim et al. 2012), *N. flavida* and *N. lactea* form a sister clade that shares 97.4 % 16S rRNA gene sequence similarity with *N. panacisegetis* branching more deeply (~97.0 % similarity). *N. multipartita* also occupies the outermost position and shows ~96.4 % similarity to the other *Nakamurella* species. Next, the type strains of *Nakamurellaceae* species show ~94.2 % similarity to *Sporichthya* type strains and ~93.8 % similarity to *Blastococcus* type strains. The dendrogram based on complete *rpoB* gene sequences also shows a robust phylogenetic relationship between *Nakamurellaceae* species, in which *N. panacisegetis* and *N. flavida* form a deep-rooted clade and *N. lactea* branches most deeply (Kim et al. unpublished). *rpoB* gene sequence similarity between the type strains of *Nakamurellaceae* species is 85.8–89.2 % (Kim et al. 2012), which is slightly higher than the 85.5 % cutoff value for genus delineation (Adékambi et al. 2008).

DNA-DNA hybridization (DDH) study on *Nakamurellaceae* has been performed only by Kim et al. (2012). During the description of the genus *Humicoccus*, *N. flavida* (*H. flavidus*) strain DS-52^T and the type strain of *N. multipartita* shared 96.5 % 16S rRNA gene sequence similarity, which was below the 97 % threshold value indicative of separate genomospecies (Stackebrandt and Goebel 1994). Therefore, no DDH study was done. During the description of the genus *Saxeibacter*, *N. lactea* (*S. lacteus*) strain DLS-10^T shared 97.1 % 16S rRNA gene sequence similarity with the type strain of *N. flavida* (*H. flavidus*). However, due to the significant phenotypic differences between them, DDH study was not done. According to the results of Kim et al. (2012), *N. panacisegetis* P4-7^T shows 8–15 % relatedness to *N. multipartita* KCTC 19567^T, *N. flavida* KCTC 19127^T, and *N. lactea* KCTC 19285^T, and *N. flavida* KCTC 19127^T shows 11–26 % relatedness to *N. multipartita* KCTC 19567^T and *N. lactea* KCTC 19285^T.

The only study including a DNA fingerprinting method was that of Kim et al. (2012), in which random amplified polymorphic DNA (RAPD) analysis was performed using the Ready-To-Go RAPD Analysis Beads (GE Healthcare), and genomic fingerprints of the type strains of *Nakamurellaceae* species generated with two RAPD analysis primers confirmed their separate species status. Neither riboprinting nor MALDI-TOF analysis is available for any member of the family *Nakamurellaceae*.

Genome Analysis

Nakamurella multipartita DSM 44233^T is the only strain of the family *Nakamurellaceae* for which the full genome sequence has been generated (INSDC ID CP001737) (Tice et al. 2010).

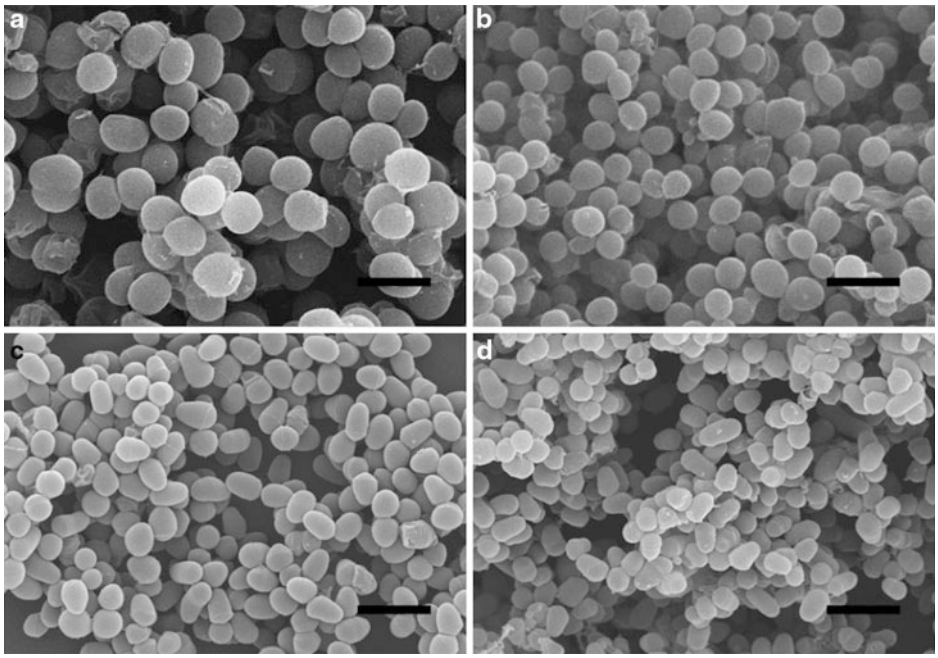

Fig. 30.2
Scanning electron micrographs of cells of *N. multipartita* KCTC 19567^T (a), *N. flavida* KCTC 19127^T (b), *N. lactea* KCTC 19285^T (c), and *N. panacisegetis* P4-7^T (d). Bars, 2 μm.

The single replicon genome, a part of the *Genomic Encyclopedia of Bacteria and Archaea* project, is 6,060,298-bp long with a G + C content of 70.92 mol%. This DNA G + C value is higher or slightly higher than those determined by the HPLC method; 67.5 mol% from Yoshimi et al. (1996) and 70.2 mol% from Kim et al. (2012). Extrachromosomal elements were absent. Besides 175 pseudogenes, 5,471 genes have been predicted of which 5,415 were protein-coding genes, and 56 were RNA genes. The majority of the genes (66.5 %) were assigned a putative function, 67.14 % of the genes were assigned to clusters of orthologous groups (COGs), while the remaining ones were annotated as hypothetical proteins. The distribution of genes into COG functional categories indicates that the highest number of genes is involved in transcription (400; 9.1 %), followed by genes coding for carbohydrate transport and metabolism (341; 8.3 %) and amino acid transport and metabolism (334; 8.1 %). A detailed listing of COG categories is given by Tice et al. (2010).

The sequences of the two 16S rRNA gene copies in the genome of strain DSM 44233^T are identical but differ by three nucleotides (one N and two gaps) from the published 16S rRNA gene sequence of the same strain (Y-104^T) deposited as D50066. The former sequence was used as a reference by Kim et al. (2012), and the latter was used at the time of the original description of *N. multipartita* (Yoshimi et al. 1996). The sequence Y08541 of *N. multipartita* JCM 9343^T has been used in the Living Tree Project that is the basis for the tree shown in *Fig. 30.1* and other publications (Yoon et al. 2007; Lee et al. 2008).

Recently, a genome-based study on phylogenetic framework and molecular signatures for the main clades of the phylum Actinobacteria has been performed (Gao and Gupta 2012). The phylogenetic tree based upon concatenated sequences for 35 conserved proteins indicates that *N. multipartita*, a part of the order "*Frankiales*," forms an outgroup of the "*Pseudonocardiales*" clade, and a clade consisting of *N. multipartita* and "*Pseudonocardiales*" species is also strongly supported (100 % bootstrap value). However, other "*Frankiales*" species (i.e., *Frankia alni*, unclassified *Frankia* spp., *Acidothermus cellulolyticus*, and *Geodermatophilus obscurus*) do not branch with *N. multipartita*, which is in agreement with the 16S rRNA gene-based phylogeny shown in the maximum-likelihood tree by Zhi et al. (2009).

Phenotypic Analyses

The main features of members of *Nakamurellaceae* are listed in *Table 30.1*.

Nakamurella Tao, Yue, Chen and Chen 2004, 999^{VP}, Emend. Kim, Lee and Lee 2012, 294

Na.ka.mu.rel'la. M.L. dimin. ending *-ella*; N.L. fem. n. *Nakamurella* to honor the Japanese microbiologist Professor Kazunori Nakamura

Cells are strictly aerobic, Gram-positive, nonmotile, non-spore-forming, cocci or short rods (*Fig. 30.2*). A cell-wall-like structure occurs in the middle of cells (*Fig. 30.3*). Colonies on nutrient agar are 0.5–1.0 mm in diameter (within 4 days), circular, convex, smooth, and translucent to opaque. Catalase-positive. Oxidase-negative. The optimum growth temperature

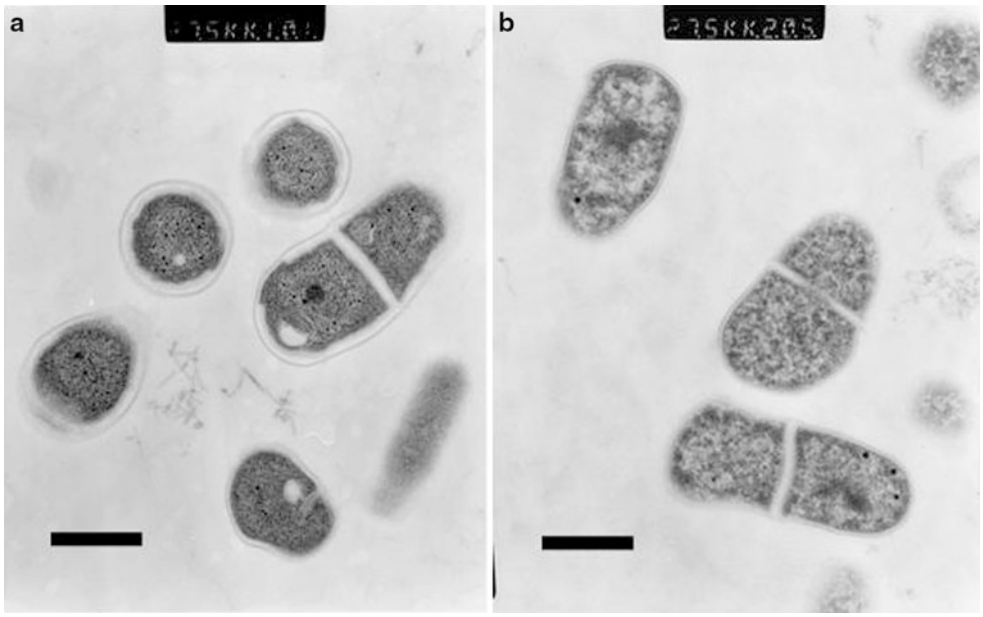

Fig. 30.3
Transmission electron micrographs of thin sections of *N. lactea* KCTC 19285^T (a) and *N. panacisegetis* P4-7^T (b) showing a cell-wall-like structure in the middle of cells. Bars, 0.5 μm

is 25 °C. The optimum pH is 6.0–7.0. NaCl tolerance range is variable. Indole and H_2S are not produced. The methyl red and Voges-Proskauer tests are negative. Hydrolyzes aesculin and gelatin, but not casein, hypoxanthine, Tweens 20 and 80, tyrosine, or xanthine. Negative for arginine dihydrolase, lysine decarboxylase, ornithine decarboxylase, and phenylalanine deaminase. On egg yolk agar, lecithinase activity is absent. Utilizes D-arabitol, D-cellobiose, D-fructose, D-galactose, D-glucose, lactose, D-maltose, D-mannitol, D-mannose, L-rhamnose, salicin, starch, sucrose, D-trehalose, and D-turanose as sole sources of carbon and energy, but not L-arginine, citrate, itaconate, L-lysine, malonate, or suberate. Acid is not produced from dulcitol, D-galactose, lactose, D-mannitol, L-rhamnose, salicin, or D-sorbitol. According to API ZYM test results, esterase lipase (C8), leucine arylamidase, acid phosphatase, and α-glucosidase are present, but alkaline phosphatase, lipase (C14), trypsin, α-chymotrypsin, β-glucuronidase, and α-fucosidase are absent. The cell-wall peptidoglycan contains *meso*-diaminopimelic acid. The whole-cell sugars are glucose, mannose, ribose, and rhamnose; additional sugars, galactose, and xylose, may be present. The acyl type of the peptidoglycan is acetyl. The major quinone is MK-8(H_4). The major fatty acids are branched-chain saturated ($C_{15:0}$ iso, $C_{16:0}$ iso, $C_{15:0}$ ante and $C_{17:0}$ ante), and straight-chain saturated ($C_{16:0}$ and $C_{17:0}$) or unsaturated ($C_{18:1}$ ω9c). Mycolic acids are not present. The diagnostic polar lipids are diphosphatidylglycerol (DPG), phosphatidylethanolamine (PE), phosphatidylinositol (PI), an unidentified aminophospholipid (APL), an unidentified phosphoglycolipid (PGL1), and an unidentified lipid (UL1). Additional phenotypic characteristics are listed in *Table 30.2*. The DNA G + C content is 67.5–74.3 mol%.

The type species is *Nakamurella multipartita*.

Isolation, Enrichment, and Maintenance Procedures

Isolation and Enrichment

N. multipartita Y-104^T was isolated from activated sludge acclimated with sugar-containing synthetic wastewater under aerobic conditions (Yoshimi et al. 1996). Activated sludge was cultured aerobically in a fed batch reactor system with synthetic wastewater containing (per liter) glucose 0.75 g, peptone 0.03 g, yeast extract 0.03, $(NH_4)_2SO_4$ 0.1 g, and KH_2PO_4 0.07 g. After 90 days acclimation, strain Y-104^T was isolated from the sludge by the dilution plate method with GPY agar containing (per liter) glucose 1.0 g, peptone 0.5 g, yeast extract 0.5 g, KH_2PO_4 0.1 g, $(NH_4)_2SO_4$ 0.1 g, and $MgSO_4 \cdot 7H_2O$ 0.1 g (pH 7.0) incubated at 25 °C for 20 days.

N. flavida (*H. flavidus*) DS-52^T was isolated from soil samples collected in Dokdo, Korea, using the standard dilution plating technique at 25 °C on tenfold diluted nutrient agar (Difco) (Yoon et al. 2007).

N. lactea (*S. lacteus*) DLS-10^T was isolated from a rock sample collected from the peak of Darangshi Oreum (a small mountain 300 m above sea level) in Jeju, Korea (Lee et al. 2008). Rock samples (1 g) were ground to powder using a pestle and suspended in 10-ml sterilized, distilled water. Aliquots of serial dilutions of the sample were transferred to starch-casein agar containing (per liter) soluble starch 10 g, casein 0.3 g, KNO_3 2 g, NaCl 2 g, KH_2PO_4 2 g, $CaCO_3$ 0.02 g, $MgSO_4 \cdot 7H_2O$ 0.05 g, $FeSO_4 \cdot 7H_2O$ 0.01 g, and agar 18 g (pH 7.2). Subsequently, strain DLS-10^T was isolated after 7 days incubation at 30 °C.

N. multipartita P4-7^T was isolated from soil of a ginseng field located in Geumsan County, Korea (Kim et al. 2012).

A soil sample collected from a ginseng field was diluted serially in sterile distilled water, and samples of each serial dilution were spread on one-tenth-strength nutrient agar. Subsequently, strain P4-7^T was isolated after 4 weeks incubation at 25 °C.

Maintenance

Members of this family do not require special procedures for maintenance and medium- and long-term storage. Generally, strains are maintained on isolation medium as agar slants at room temperature or at 4 °C for a week. *N. multipartita* may be maintained for a month on GPY agar slants.

Medium-term maintenance is in 20 % (v/v) glycerol suspensions at −20 °C or at −70 °C. Long-term preservation is by lyophilization or in liquid nitrogen.

Ecology

The habitat of all *Nakamurellaceae* species is only known for the type strain. As for other members of the order "*Frankiales*," soil appears to be the natural environment for two species to thrive: one type strain was isolated soil of Dokdo (the easternmost island of Korea) and the other strain from soil of a ginseng field. On the other hand, the isolation source activated sludge or a mountain rock may indicate random niche occupation of water or soil-origin organisms. The publications or sequence

depositions on *Nakamurella*-related strains, on which intensive taxonomic studies have yet to be done, may provide more diverse isolation information. Antarctic bacterium 3C6, closely related to *N. panacisegetis* (99 % 16S rRNA gene sequence similarity), was isolated from the glacier sediment of Antarctica (García-Echauri et al. 2011). *Saxeibacter* sp. R-36686 and *Frankineae* bacterium MI-1.2 V7, moderately related to *N. lactea* (98 % and 97 % similarity, respectively), and Actinobacterium R-36375, related to *N. flavida* (95 % similarity), were isolated from soil samples of Antarctica and the Subantarctic island (Peeters et al. 2011; Sanyika et al. 2012). *Actinomycetales* bacterium Gsoil 972 (DNA accession no. AB245399) isolated from soil of a ginseng field was closely related to *N. lactea* (almost 100 % similarity). *Nakamurella* sp. I10A-02501 (JX273663) and *Nakamurella* sp. I10A-02502 (JX273664) isolated from a plant root were related to *N. multipartita* (96 % similarity for each). The NCBI taxonomy browser lists several additional bacterial clones affiliated to *Nakamurellaceae*, e.g., from biofilm reactor, USA (EF125941), freshwater sediment, Chile (EF632902), coal bed, China (JF417732), permafrost and meadow soil, China (JQ978619, HQ645167 and HQ864131), rice phyllosphere, Philippines (HE589887 and HE589890), midgut homogenate of humus-feeding larva, Germany (AJ576407), and giant panda feces, China (JF920386).

Pathogenicity: Clinical Relevance

Until now, no clinical studies on the pathogenicity of *Nakamurellaceae* species have been reported and no strains have been isolated from the clinical specimen. However, according to the studies on diversity and dynamics of bacterial community in indoor environments (Rintala et al. 2008; Täubel et al. 2009) and on temporal shifts in the skin microbiome (Kong et al. 2012), six bacterial clones were found to be affiliated to *Nakamurellaceae* in the former two studies and 22 bacterial clones for the latter. This means that some members of *Nakamurellaceae* are closely associated with human environments.

N. multipartita is sensitive by agar diffusion method to amikacin (30 μg), bacitracin (10 U), chloramphenicol (30 μg), ciprofloxacin (5 μg), doxycycline (30 μg), erythromycin (15 μg), kanamycin (30 μg), neomycin (30 μg), rifampin (5 μg), streptomycin (10 μg), tetracycline (30 μg), trimethoprim (5 μg) and vancomycin (30 μg) but resistant to ampicillin (10 μg), aztreonam (30 μg), carbenicillin (100 μg), ceftazidime (30 μg), cephalothin (30 μg), gentamicin (10 μg), nalidixic acid (30 μg), novobiocin (30 μg), oxacillin (1 μg), penicillin (10 U), and polymyxin B (300 U) (Kim et al. 2012).

N. flavida is sensitive to amikacin (30 μg), ampicillin (10 μg), bacitracin (10 U), chloramphenicol (30 μg), ciprofloxacin (5 μg), doxycycline (30 μg), erythromycin (15 μg), gentamicin (10 μg), kanamycin (30 μg), neomycin (30 μg), novobiocin (30 μg), polymyxin B (300 U), rifampin (5 μg), streptomycin (10 μg), tetracycline (30 μg), trimethoprim (5 μg) and vancomycin (30 μg) but resistant to aztreonam (30 μg), carbenicillin (100 μg), ceftazidime (30 μg), cephalothin (30 μg), nalidixic acid (30 μg), oxacillin (1 μg), and penicillin (10 U) (Kim et al. 2012).

N. lactea is sensitive to amikacin (30 μg), ampicillin (10 μg), bacitracin (10 U), carbenicillin (100 μg), chloramphenicol (30 μg), ciprofloxacin (5 μg), doxycycline (30 μg), erythromycin (15 μg), gentamicin (10 μg), kanamycin (30 μg), neomycin (30 μg), polymyxin B (300 U), streptomycin (10 μg) and vancomycin (30 μg) but resistant to aztreonam (30 μg), ceftazidime (30 μg), cephalothin (30 μg), nalidixic acid (30 μg), oxacillin (1 μg), novobiocin (30 μg), penicillin (10 U), rifampin (5 μg), tetracycline (30 μg), and trimethoprim (5 μg) (Kim et al. 2012).

N. panacisegetis is sensitive to amikacin (30 μg), bacitracin (10 U), chloramphenicol (30 μg), ciprofloxacin (5 μg), doxycycline (30 μg), erythromycin (15 μg), gentamicin (10 μg), kanamycin (30 μg), neomycin (30 μg), novobiocin (30 μg), polymyxin B (300 U), rifampin (5 μg), streptomycin (10 μg), tetracycline (30 μg) and vancomycin (30 μg) but resistant to ampicillin (10 μg), aztreonam (30 μg), carbenicillin (100 μg), ceftazidime (30 μg), cephalothin (30 μg), nalidixic acid (30 μg), oxacillin (1 μg), penicillin (10 U), and trimethoprim (5 μg) (Kim et al. 2012).

Application

The only evidence that any strain of the family may be involved in application originates from a study by Yoshimi et al. (1996) with *N. multipartita* Y-104^T. This strain can take up a number of sugars and accumulate large amounts of polysaccharide in its cells in the absence of nitrogen and phosphate sources. This ability may play an important role in the competition among various bacteria to take up limiting substrates in activated sludge processes and the rapid decrease of reserve polysaccharide levels in activated sludge treating carbohydrate wastes.

31 The Class *Nitriliruptoria*

Erko Stackebrandt[1] · *Linda G. Otten*[2]
[1]Leibniz Institute DSMZ-German Collection of Microorganisms and Cell Cultures, Braunschweig, Germany
[2]Biocatalysis Group, Department of Biotechnology, Delft University of Technology, Delft, The Netherlands

Abstract
The *Nitriliruptoria* line of descent is one of the deeply branching actinobacterial lineages, containing the orders *Nitriliruptorales* and *Euzebyales*. Each of them is defined by a single family, genus, and species, respectively: within *Nitriliruptoraceae*, it is the genus *Nitriliruptor* with *Nitriliruptor alkaliphilus* (Sorokin et al. 2009) and within *Euzebyaceae*, it is *Euzebya* with *Euzebya tangerina* (Kurahashi et al. 2010). The higher classification as a subclass *Nitriliruptoridae*, and recently as a class *Nitriliruptoria*, followed the description of *Euzebya tangerina* and the notion that *Nitriliruptorales* and *Euzebyales* are phylogenetic neighbors, sharing a common origin. *Nitriliruptor alkaliphilus* has been isolated from soda lake sediments of the Kulunda Steppe (Altai, Russia). The Gram-positive type strain ANL-iso2^T is the only known alkaliphilic bacterium to degrade isobutyronitrile [iBN, (CH3)2CHCN] and utilizes it as a sole source of energy, carbon, and nitrogen. Biodegradation is via the nitrile hydratase/amidase system. *Euzebya tangerina* was isolated from abdominal epidermidis of a sea cucumber, *Holothuria edulis*. In addition to the type strains, the lineage contains several unclassified isolates and hitherto uncultured strains from sources different to those of the type strains.

Taxonomy: Historical and Current

Short Description of Higher Taxa

The descriptions of order and family (Sorokin et al. 2009), and subclass (Kurahashi et al. 2010) and class (Ludwig et al. 2012), and is based solely on one and two strains, respectively, and they likely need to be emended with more taxa described. The definition of the class *Nitriliruptoria* is based solely on its phylogenetic position. Morphological, cultural, and chemotaxonomic properties differentiating the two genera of this class from each other and from neighboring genera are shown in ❯ *Table 31.2*.

Nitriliruptoridae Kurahashi, Fukunaga, Sakiyama, Harayama, Yokota 2010, 2318^{VP}

Ni.tri.li.rup.to.ri'da.e. N.L. masc. n. *Nitriliruptor* type genus of the type order of the subclass; suff. -idae, ending to denote a subclass; N.L. fem. pl. n. Nitriliruptoridae the *Nitriliruptor* subclass.

The description is the same as that for the genus *Nitriliruptor*. Separation of these organisms into a class is justified by their distinct lineage within the phylum Actinobacteria based on 16S rRNA gene sequences. The pattern of 16S rRNA gene sequence signature nucleotides of members of the class is as for the family *Nitriliruptoraceae*. The class contains the type order *Nitriliruptorales* and the order *Euzebyales*.

Nitriliruptorales Sorokin, van Pelt, Tourova, Evtushenko 2009, 252^{VP}

Ni.tri.li.rup.to.ra'les N.L.masc.n. *Nitriliruptor* type genus of the family -ales ending to denote an order; N.L. fem. pl. n. *Nitriliruptorales* the order of the type genus *Nitriliruptor*. The description is the same as that for the genus *Nitriliruptoraceae*. The pattern of 16S rRNA gene sequence signature nucleotides of members of the subclass is as for the type family *Nitriliruptoraceae*. *Nitriliruptor* is the type genus.

E. Rosenberg et al. (eds.), *The Prokaryotes – Actinobacteria*, DOI 10.1007/978-3-642-30138-4_197,

Euzebyales Kurahashi, Fukunaga, Sakiyama, Harayama, Yokota 2010, 2318[VP]

Eu.ze.by'a.les. N.L. fem. n. *Euzebya* type genus of the family; -ales, ending to denote an order; N.L. fem. pl. n. *Euzebyales* the order of the genus *Euzebya*. The description is the same as that for the genus *Euzebyaceae*. The pattern of 16S rRNA gene sequence signature nucleotides of members of the order is as for the family *Euzebyaceae*. *Euzebya* is the type genus.

Nitriliruptoraceae Sorokin, van Pelt, Tourova, Evtushenko 2009, 251[VP]

Ni.tri.li.rup.to.ra'ce.ae. N.L. masc. n. *Nitriliruptor* type genus of the family; -aceae ending to denote a family; N.L. fem. pl. n. *Nitriliruptoraceae* the family of the genus *Nitriliruptor*.

The description is the same as that for the genus Nitriliruptor. The pattern of 16S rRNA gene signature nucleotides and nucleotide pairs of members of the family consists of: 47–396 (G–C), 232 (S), 241–285 (G–C), 291–309 (U–A), 294–303 (A–U), 295–302 (G–C), 361 (A), 443–491 (G–C), 890 (C), 1165–1171 (U–A), 1311–1326 (A–U). The type genus is *Nitriliruptor*.

Euzebyaceae Kurahashi, Fukunaga, Sakiyama, Harayama, Yokota 2010, 2318[VP]

Eu.ze.by.a.ce'ae. N.L. fem. n. *Euzebya* type genus of the family; -aceae ending to denote a family; N.L. fem. pl. n. Euzebyaceae the family of the genus *Euzebya*.

The description is the same as that for the genus *Euzebya*. The pattern of 16S rRNA gene sequence signature nucleotides and nucleotide pairs of members of the family consists of 101 (G), 211 (C), 346 (G), 427 (U), 579 : 762 (U–C), 589 : 650 (U–A), 612 : 628 (U–A), 614 : 626 (A–U), 841 : 845 (A–U), 986 : 1219 (A–U), 1002 : 1038 (G–U), 1031 (G), 1075 : 1082 (C–G). The type genus *Euzebya*.

Phylogenetic Structure of the Families and Their Genera

The previous higher classification as a subclass *Nitriliruptoridae* followed the description of *Euzebya tangerina* and the notion that *Nitriliruptorales* and *Euzebyales* are phylogenetic neighbors, sharing a common origin. More recently, with the publication of *Bergey's Manual of Systematic Bacteriology*, Vol. 5: The Actinobacteria (Ludwig et al. 2012) and the elevation of the order *Actinomycetales* to the class level (*Actinobacteria*), the subclass "Nitriliruptoridae" was consequently also elevated to the rank of a class, together with other deeply rooting lineages such as "Acidimicrobiia," "Coriobacteriia," "Rubrobacteria," and "Thermoleophili." As depicted in ❯ *Fig. 31.1* the *Nitriliruptor* lineage is phylogenetically remotely related to a clade embracing *Acidimicrobiaceae*, *Iamia*, *Ilumatobacter*, and *Candidatus* "Microthrix parvicella" (not shown) as well as other deeply rooting actinobacterial classes. This is in accordance with the topology depicted by Kurahashi et al. (2010).

The type strain of *Nitriliruptor alkaliphilus* is phylogenetically related to several as-yet uncultured actinobacteria. The number of such taxa has increased significantly since the original description of *N. alkaliphilus*. More than 50 records with at least 91 % and higher BLAST similarity values are recorded when the 16S rRNA gene sequence of *N. alkaliphilus* (EF422408) is run against the public database. Clone sequences from the top scoring entries (93–95 %) have been retrieved from soils contaminated with anthracene (Castro-Silva et al., unpublished [e.g., HM438005], ultramafic rocks in the Leka ophiolite complex (Central Norway) (JN003088), soil from the Mars Desert Research Station (Utah, USA) (HQ910264), highly alkaline saline soil from Lake Texcoco (Mexico) (Valenzuela-Encinas et al. 2008), soda lake sediment from Lake Xiarinur (Inner Mongolia) (GU083674). Especially the latter two alkaline sites as well as the locations mentioned by Sorokin et al. (2007) allows the conclusion that members related to *Nitriliruptor alkaliphilus* thrive in alkaline environments, e.g., asphalt seep and pits (Kim and Crowley 2007), Mono Lake (Humayoun et al. 2003), or Wadi an Natrun, Egypt (Mesbah et al. 2007).

A similar situation is seen with the type strain of *Euzebya*. Since the original description of the type species in 2010, dozens of novel environmental clone sequences deposited in public nucleic acid databases are found to be related, remotely though, to *E. tangerina* above BLAST cutoff values of 91 %. Interestingly and not expected from the significant differences in metabolism described for *N. alkaliphilus* and *E. tangerina*, several clone sequences found in the same environment, such as the highly alkaline saline soil from Lake Texcoco (Mexico) (Serna et al., unpublished) and soils contaminated with anthracene (Castro-Silva et al., unpublished [e.g., JQ426201], Dendooven and Vazquez-Nunez, unpublished [e.g., HM438033]), were related to both species. Horath and Bachhofen (2009) detected remotely related *Euzebya* clone sequences in dolomite rocks in the central Alps.

Though the two type strains have been isolated from very different environments, the frequent isolation from the same of genomic material from strains moderately related to these two taxa indicates that at the higher taxonomic rank, species may share more genomic similarities than described for the two type strains.

Genome Comparison

The genome of *Nitriliruptor alkaliphilus* was recently sequenced (Otten, L. G. and Muyzer, G. unpublished) and annotated using the RAST annotation server (Aziz et al. 2008). Although the sequencing did not result in the assembly of a single contig, the total amount of 5,262,836 sequenced base-pairs within the 1825 contigs is very similar to the expected value of 5.2 Mbps, as measured by Pulse Field Electrophoresis. Furthermore, the

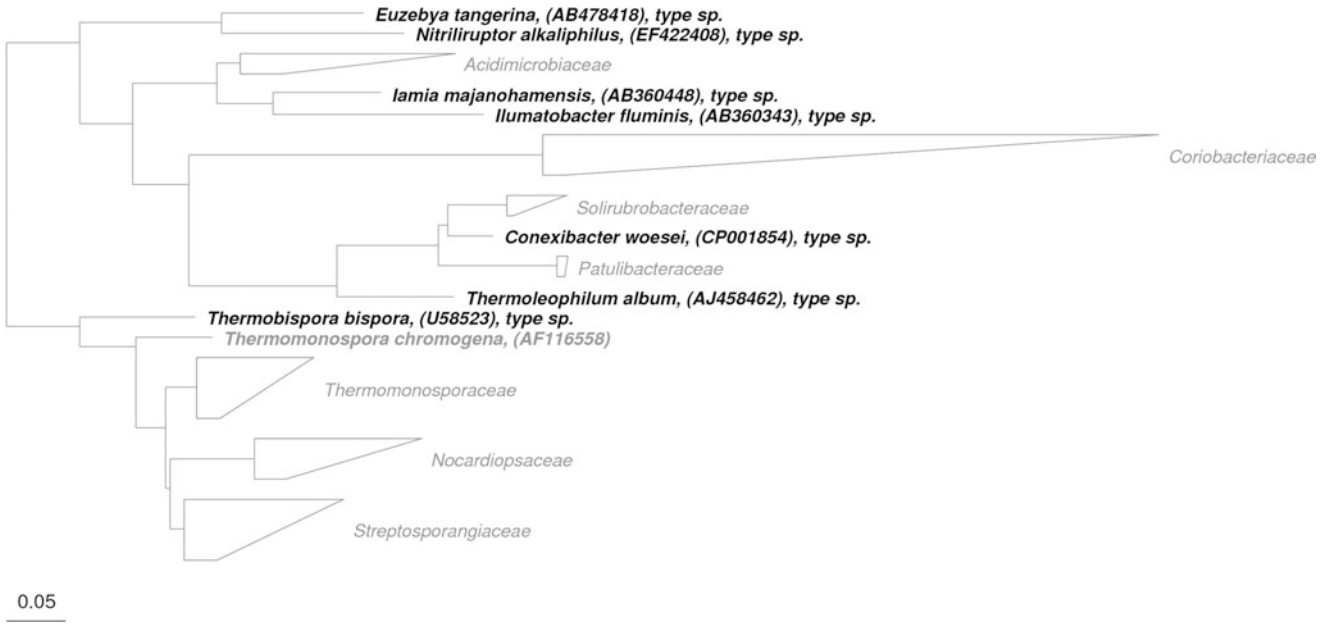

Fig. 31.1

Maximum likelihood genealogy reconstruction based on the RAxML algorithm (Stamatakis 2006) of the sequences of all type strains present in the LTP_106 (Yarza et al. 2010). The tree was reconstructed by using a subset of sequences representative of closely and moderately related taxa to stabilize the tree topology. In addition, a 40 % conservational filter for the whole bacterial domain was used to remove hypervariable positions. The bar indicates 1 % sequence divergence

amount of annotated genes is quite similar to the amount assigned in the genome of *Thermomonospora curvata* DSM 43183, which is an Actinobacterium with a similar total genome size (5.56 Mbps). This means that although the contigs were not merged to one genome read, most genes will be present in the annotation. Since this genome is the only genome sequenced in this order, it cannot be compared within the order. Therefore, we compared genome features to related organisms in the *Actinobacteria* class, namely, *Thermomonospora curvata* DSM 43183 (Chertkov et al. 2011), *Rhodococcus jostii* RHA1 (McLeod et al. 2006), and *Acidothermus cellulolyticus* 11B (Barabote et al. 2009) (*Table 31.1*).

The most important difference between *N. alkaliphilus* and the other organisms is the amount of genes coding for membrane transport systems (5 % of the total annotated genes compared to 1.5 % on average in the others). There are at least 2 full multi-subunit cation antiporters, probably Na+ / H+ antiporters (subunits A to G) and an MhnB-related cluster. All ion pumps are situated in very close clusters next to each other. The abundance of so many ion transporters is easily explained by the fact that this organism was isolated from an alkaline soda lake, where there is a lot of salt and pH stress (Sorokin et al. 2007).

Furthermore, there are relatively many genes related to fatty acid, lipid, and isoprenoid syntheses. Most of these genes are part of the fatty acid biosynthesis system FASII or fatty acid metabolism cluster. There are however no genes annotated in the "glycerolipid and glycerophospholipid metabolism" subsystem. The cell wall does however contain glycerol phosphates and phosphodiesters (Sorokin et al. 2009). It is therefore likely that several genes have been mis-annotated, but it also might point to the fact that this organism is using a somewhat different enzyme system to prepare its cell wall. May be the cell wall components are slightly different from other bacteria, to sustain growth in such a hostile environment.

Strangely enough, the amount of genes in the stress response subsystem is relatively low. This might mean that this organism has either different stress response systems than comparable organisms, or it saves energy by not responding to a lot of different stresses, which could have evolved in this environment because of the energetic benefits.

The amount of genes producing carbohydrates seems to be elevated compared to the other organisms, but the amount is similar to genes in the amino acids and derivatives cluster, like in *R. jostii* and *A. cellulolyticus*, which means that this elevation is probably not meaningful. On the other hand, genes in the virulence, disease, and defense and miscellaneous category are much lower. We expect this to stem from the fact that the genome was not assembled to one contig and from the different genetic makeup of these enzymes, thereby missing some genes in the annotation or placing it in a subsystem (73 % of the annotated genes are not in a subsystem). This latter reason is also valid for RNA metabolism, since there are potentially 51 RNAs, which is less than *T. curvata* (68) and *R. jostii* (64), but similar to *A. cellulolyticus* (49), so one would expect the same amount of genes for the production of RNA. The subsystems protein

metabolism and cofactors, vitamins, prosthetic groups, and pigments are both slightly decreased, which might mean that there are less enzymes with cofactors available, which could have a broader substrate range, or again the difference in gene makeup of this organism prevents enzymes from being annotated correctly by a computer program. To explore these differences in gene amounts, annotation and assignment to certain subsystems should be manually checked. Also, the whole organism or separate genes can be tested for a lot of different enzymatic steps.

There is a putative cobalt uptake protein, but no uptake proteins for nickel are annotated. This cobalt uptake protein is totally different from other organisms, which could point to another function than supplying cobalt for cobalamin-dependent enzymes. One of the options is that this cobalt uptake might be important for the NHase found in this organism. The organism was isolated by using isobutyronitrile as the carbon, energy, and nitrogen source (Sorokin et al. 2009). NHase and amidase activity was established (Sorokin et al. 2007), and the NHase genes were found in the usual setting, together with an amidase and a chaperone. From the sequence, it is clear that the NHase is a cobalt enzyme, which was already expected from the substrate specificity and stability of the enzyme. Furthermore, there are 3 nitrilases assigned, which

together with the NHase-amidase cluster can account for the excellent growth on so many different nitriles as sole carbon and nitrogen source.

Phenotypic Analyses

Nitriliruptor alkaliphilus and *Euzebya tangerina* are Gram-positive, catalase- and oxidase-positive, nonmotile rods, sharing the same peptidoglycan type (A1γ) and a similar DNA base composition. They slightly differ from each other in fatty acid composition and in the composition of whole cell sugars (Table 31.2). Most significantly, *N. alkaliphilus* ANL-iso2^T differs from *E. tangerina* F10^T in its alkaliphily and in the metabolism of a wide range of nitriles. It should, however, be noted that strain F10^T has not been investigated in this respect and the observation that as yet-uncultured strains of both species thrive in the same and in similar environments may indicate that the metabolism of the species *E. tangerina* may be more versatile than described.

Nitriliruptor Sorokin et al. 2009, 251^{VP}

Ni.tri.li.rup'tor. N.L. n. *nitrilum* nitrile, nitrile group; L. masc. n. *ruptor* breaker; N.L. masc. n. *nitriliruptor* nitrile-breaker.

In addition to the properties listed in Table 31.2: utilizes short-chain organic acids, amides, and aliphatic nitriles as energy and carbon source. Alkaliphilic and moderately salt-tolerant. The type species is *Nitriliruptor alkaliphilus*.

In addition to the properties given for the genus, the description of the type strain description is based on that given by Sorokin et al. (2009): Cells are 0.4 × 1.5–3.0 μm in size, occurring singly or in pairs under most conditions. When grown on glucose and yeast extract, chain formation was observed. Colonies are colorless, flat, and spreading. Able to grow on propionitrile (C_3), butyronitrile (C_4), isobutyronitrile (C_4), valeronitrile (C_5), and capronitrile (C_6) as carbon and energy source. No growth on acetonitrile (C_2). Growth on nitriles is biphasic, with fast initial hydrolysis of nitriles to the corresponding amides, carboxylic acids, and ammonia and slow further utilization of these products, resulting in biomass growth: Products of isobutyronitrile conversion are isobutyroamide, isobutyrate, and ammonium. Able to metabolize, without growth, a large spectrum of aliphatic and some aromatic nitriles via the nitrile hydratase/amidase enzyme system. Growth on acetate, propionate, pyruvate, butyrate, isobutyrate, valerate, succinate, malate, citrate and fumarate, glucose, maltose, fructose, arabinose, mannose, sucrose, α-trehalose, melezitose, inositol, cellobiose and glycerol and complex organic substrates such as yeast extract and peptone. Gelatin is hydrolyzed while starch, casein, cellulose, chitin, pectin, and xylane are not hydrolyzed. The presence of an anionic carbohydrate-containing polymer(s) in the cell wall is indicated by the presence of glycerol phosphates, phosphodiesters, and an unidentified amino sugar.

The type strain ANL-iso2^T (=DSM 45188^T = NCCB 100119^T = UNIQEM U239^T) was isolated from soda lake sediments of the Kulunda Steppe (Altai, Russia).

Euzebya Kurahashi et al. 2010, 2318^{VP}

Eu.ze'by.a. N.L. fem. n. *Euzebya* named for Jean Paul Marie Euzeby, a French microbiologist.

Properties given for the genus are indicated in Table 31.2. Phosphatidylglycerol is the polar lipid; contains in addition several unidentified glycolipids and glycophospholipids.

The type species is *Euzebya tangerina*.

In addition to the properties given for the genus, the description of the type strain description is based on that given by Kurahashi et al. (2010): Cells are approximately 0.6–0.8 × 1.5–6.0 μm. Colonies on MA plates are pulvinate with entire edge, tangerine in color, nearly opaque, displaying a hard texture after 5 weeks of incubation at 25 °C. Reduction of nitrate to nitrite and of nitrite to N_2. Positive for hydrolysis of gelatin and urea, production of acetoin, and assimilation of L-arabinose and melibiose. Negative for β-galactosidase, arginine dihydrolase, lysine decarboxylase, ornithine decarboxylase, tryptophan deaminase, utilization of citrate, production of H_2S and indole, assimilation of amygdalin, D-glucose, inositol, D-mannose, rhamnose, sucrose and sorbitol.

The type strain is F10^T (=NBRC 105439^T = KCTC 19736^T), isolated from the ventral epidermis of the sea cucumber *Holothuria edulis* at Aka Island, Okinawa, Japan.

Isolation, Enrichment, and Maintenance Procedures

Nitriliruptor alkaliphilus ANL-iso2^T was isolated from an iBN enrichment of a mixed sediment sample, consisting of 10 samples from Kulunda Steppe (southwestern Siberia, Altai, Russia). The mineral medium used for enrichment and maintenance (Sorokin et al. 2007) is the same used by the German Collection for Microorganisms and Cell Cultures for routine maintenance (http://www.dsmz.de/microorganisms/medium/pdf/DSMZ_Medium1105.pdf).

For enrichment (Sorokin et al. 2007), liquid culture was incubated on a rotary shaker at 100 rpm and 28 °C. At ammonia concentration of 2 mM, the culture was transferred into a new medium at a 1:100 dilution and after several transfers, the culture from a maximal positive dilution (10^{-11}) was plated onto solid medium, either by surface spreading or by the agar-shake technique. After 30 days incubation in closed jars, separate colonies were placed into 5-mL liquid medium with appropriate substrates at a 5–20 mM concentration in 30-mL serum bottles closed with rubber septa.

In the case of the solid medium, iBN is added after the medium is cooled down to 50 °C. Growth of pure cultures is performed in 250-mL closed serum bottles with 50-mL liquid on a rotary shaker at 100–150 rpm and 30 °C.

Table 31.2

Major cultural and chemotaxonomic properties differentiating the type strains of type species of the classes *Nitriliruptoria* and related taxa. All type strains are oxidase Gram-positive and non-endospore-forming rods (no data are available for oxidase reaction by strain YM22-133^T)

Long-term storage in the DSMZ occurs as vacuum-dried culture.

Euzebya tangerina F10^T was isolated from the abdominal epidermis of a sea cucumber, *Holothuria edulis* (Kurahashi et al. 2010) which had been collected off the coast of Aka Island, Okinawa prefecture, Japan, at a depth of 6 m. The holothurian specimen was washed several times with sterile sea water, the epidermis homogenized and diluted serially to a ratio of 1:10 in sterile sea water (Kurahashi and Yokota 2004). A 0.1-mL aliquot of the dilution was spread onto SN medium (http://www-cyanosite.bio.purdue.edu/media/table/SN.html) and incubated at 25 °C for about 5 weeks. Subcultivation of strain F10^T was carried out on marine agar 2216 (MA; Becton Dickinson) at 20 °C. Stock cultures can be

maintained in marine broth 2216 (Becton Dickinson) with 5 % DMSO at −80 °C. The strain can be lyophilized. Rehydration medium is per liter: 5-g peptone, 3-g yeast extract, 1-g $MgSO_4 \cdot 7H_2O$, pH 7.0

Application

Biocatalysis for Added-Value Products

Nitriles are organic compounds widely used in industry as intermediates and building blocks in organic synthesis, as well as organic solvents. Nitrile-hydrolyzing enzymes are used as a green alternative to the heterogeneous copper catalyst process performed at temperatures over 100 °C. They can be used to produce a wide spectrum of higher value carboxylic amides and acids from the nitrile intermediates under relatively mild conditions (van Pelt et al. 2008b; Prasad and Bhalla 2010). The ability of *Nitriliruptor alkaliphilus* ANL-iso2^T to metabolize a wide range of nitriles offers a great potential for organic synthesis, especially as this actinobacterium is the first alkaliphilic and moderately salt-tolerant representative of nitrile-degrading microorganisms (Sorokin et al. 2009). In addition to hydrolysis of C3 to C6 nitriles, resting cells pre-grown in the presence if iBN, were able to metabolize a much wider range of industrially important nitriles, suggesting that this strain offers a useful potential for the sustainable production of chemicals with high commercial value.

The cobalt-containing nitrile hydratase of strain ANL-iso2^T has been purified, and its activity and enantioselectivity tested on a wide range of chiral and achiral nitriles (van Pelt et al. 2011). As compared to the activity of the hydratase against hexane-nitrile, the enzyme is active against 2-chloro-2-phenylacetonitrile (69 % as compared to hexane-nitrile), benzonitrile (60 %), and phenylpropionitrile (28 %), but converted only the latter chemical enantioselectively, with preference for the (S)-enantiomer. Although little activity was detected for 2-(4-nitrophenyl) propane-nitrile (7 μmol min^{-1} mg^{-1}) and naproxen-nitrile (17 μmol min^{-1} mg^{-1}), very high enantioselectivity was seen, resulting in the latter case in the amide precursor of the active enantiomer of the pain reliever naproxen.

Although high activity (and enantioselectivity) is important for industrial use of biocatalysts, the enzyme also has to be stable under harsh conditions. The nitrile hydratase of strain ANL-iso2^T was immobilized as a cross-linked enzyme aggregate (CLEA) and appeared to be highly stable under various conditions (van Pelt et al. 2008a). The CLEA could be reused in more than 35 cycles without losing any activity, which makes it a very good candidate for commercial use. Furthermore, the enzyme was shown to work very well in a bi-enzymatic cascade reaction in order to make the amide directly from the aldehyde and cyanide (van Pelt et al. 2009). Even at a pH of 4.5, which is necessary to keep the hydrocyanation reaction enantioselective, the enzyme was still active and the substrate was fully converted by both enzymes. In summary, the nitrile hydratase of *Nitriliruptor alkaliphilus* ANL-iso2^T is a very versatile and stable biocatalyst, which can be used for the hydration of various nitriles under a broad range of pHs, even though it was isolated from an alkaliphilic host.

Bioremediation

As indicated by Sorokin (2009), the enzymic makeup of *Nitriliruptor alkaliphilus* ANL-iso2^T to metabolize a wide range of nitriles also offers great capability for environmental biotechnology. This strain, either alone or as part of a consortium, is able to metabolize such a wide range of industrially important nitriles, that it could be useful for the bioremediation of polluted environments. While iBN hydrolysis of strain ANL-iso2^T to isobutyroamide, which is the first product of iBN hydrolysis in the nitrile hydratase/amidase pathway, is accompanied with little biomass growth, isobutyroamide is rapidly scavenged in a haloalkaliphilic consortium by a novel member of the gamma-proteobacterial genus *Marinospirillum*, *strain* ANL-isoa (Sorokin et al. 2007), also isolated from the same lake sediments. A consortium like this could be used to purify high pH waste streams from nitrile-manufacturing sites, although also neutral pH waste streams can be resolved as the nitrile hydratase is >90 % active between pH 7 and 11.5, and still has useful activities at pH 4–11.5.

32 The Family *Nocardiaceae*

Michael Goodfellow
School of Biology, University of Newcastle, Newcastle upon Tyne, UK

Abstract
The family *Nocardiaceae*, a member of the order *Corynebacteriales*, encompasses eight phylogenetically closely related genera, that can be distinguished using a combination of chemotaxonomic, morphological, and physiological criteria. The genus "*Prescottella*" and, its constituent species, "*Prescotella equi*" (formerly *Rhodococcus equi*) have still to be validated though their taxonomic integrity is supported by genotypic and phenotypic data, including results from comparative genomic analyses. *Nocardiaceae* strains are widely distributed in aquatic and terrestrial habitats, notably soil and as constituents of foam and mixed liquors in activated sludge wastewater treatment plants. In general, members of the family are considered to have a saprophytic lifestyle though it is becoming increasingly evident that they should be seen as opportunistic pathogens when isolated from clinical material. Some *Nocardia* species are causal agents of two serious diseases, nocardiosis and actinomycetoma. These and other infections are probably underreported due to the lack of reliable selective isolation and identification procedures. "*Prescottella equi*" is a facultative intracellular pathogen that causes severe suppurative bronchopneumonia in foals, while *Rhodococcus fascians* is a soil-borne pathogen that induces the formation of differentiated galls in many herbaceous plants. The application of comparative genomic, genetic, and molecular biological studies show that *Gordonia*, *Nocardia*, and *Rhodococcus* strains exhibit remarkable metabolic diversity that can be exploited for a broad range of biotechnological purposes. It is also evident that these genera are grossly underspeciated.

Taxonomy: Historical and Current

Short Description of the Family

No. car. di. a. ce' a.e. N.L. fem. n. *Nocardia* type genus of the family, suff. *–aceae* ending to denote a family N.L. fem. pl. n. *Nocardiaceae* the *Nocardia* family.

The family *Nocardiaceae* is a member of the order *Corynebacteriales* (Goodfellow and Jones 2012) in the phylum Actinobacteria. The genus *Nocardia* (Trevisan 1889) is the type genus of the family which at the time of writing includes eight phylogenetically closely related genera (http://www.bacterio.cict.fr) that can be distinguished using a combination of chemotaxonomic, morphological, and phylogenetic characteristics.

Members of the family *Nocardiaceae* stain Gram-positive to Gram-variable and are typically acid-alcohol fast to

E. Rosenberg et al. (eds.), *The Prokaryotes – Actinobacteria*, DOI 10.1007/978-3-642-30138-4_404,

Phylogenetic reconstruction of the family *Nocardiaceae* based on 16S rRNA and created using the neighbor-joining algorithm with the Jukes-Cantor correction. The sequence dataset and alignment were used according to the All-Species Living Tree Project (LTP) database (Yarza et al. 2010; http://www.arb-silva.de/projects/living-tree). Scale bar indicates estimated sequence divergence

partially acid-alcohol-fast at some stage of the growth cycle. They are aerobic, nonmotile, mesophilic, chemo-organotrophs with an oxidative metabolism. Some strains form an extensively branched substrate mycelium that fragments into coccoid- and rod-shaped elements, others are coccoid or rod-like or have a rod-coccus/rod-coccus-mycelium growth cycle. Colonies may be smooth to rough, convex, irregular and show a range of colors, including beige, brown, buff, orange, pink, red, and yellow. The wall peptidoglycan contains *meso*-diaminopimelic acid and is of the A1γ type. Whole-organism hydrolysates are rich in arabinose and galactose, with variable amounts of other sugars. Muramic acid moieties are *N*-glycolated. Phosphatidylethanolamine is the diagnostic phospholipid though diphosphatidylglycerol, phosphatidylinositol, and phosphatidylinositol mannosides are also found as major components. Cells contain major proportions of straight-chain, saturated, unsaturated, and 10-methyloctadecanoic (tuberculostearic) fatty acids though the latter is only found in trace amounts in some strains. Mycolic acids have 30–77 carbon atoms and up to six double bonds. The fatty acids released on pyrolysis gas chromatography of mycolic acid methyl esters have 12–20 carbon atoms. Menaquinone composition is variable. A family-specific pattern of 16S rRNA gene sequence signatures is found at positions 250 (U), 316:337 (C–G), 418:425 (C–G), 580:761 (U–A), 559–639 (C–G), 662–743 (C–G), 987–1218 (G–C), and 1000–1040 (A–U). The DNA G+C content ranges from 63 to 73 mol%.

Microorganisms classified in the family *Nocardiaceae* have been isolated from diverse habitats, notably soil, coniferous litter, herbivorous dung, freshwater and marine sediments, and wastewater systems (Goodfellow and Williams 1983; Colquhoun et al. 1998; Seviour and Nielsen 2010; Golinska et al. 2013). Some species cause diseases in animals, including humans, a few are plant pathogens (Goethals et al. 2001; Brown-Elliott et al. 2006; Fahal 2006; Goodfellow and Maldonado 2012; van de Sande 2014; van de Sande et al. 2014a, b).

Molecular Analyses

Phylogenetic Structure of the Family and Its Genera

As currently defined, the family *Nocardiaceae* (Castellani and Chalmers 1919), emended by Zhi et al. (2009) with the type genus *Nocardia* (Trevisan 1889) is one of eight genera classified in the order *Corynebacteriales*, class *Actinobacteria* (Stackebrandt et al. 1997). In addition to the genus *Nocardia*, the family currently includes the following taxa: *Gordonia* (Tsukamura 1971) emended by Stackebrandt et al. (1988); *Millisia* (Soddell et al. 2006a); "*Prescottella*" (Jones et al. 2013a). *Rhodococcus* (Zopf 1891) emended Goodfellow et al. (1998a); *Skermania* (Chun et al. 1997), *Smaragdicoccus* (Adachi et al. 2007), and *Williamsia* (Kämpfer et al. 1999). The inferred phylogenetic relationships between these taxa are shown in *Fig. 32.1*.

Until recently, membership of the family *Nocardiaceae* was restricted to the genera *Nocardia* and *Rhodococcus* (Rainey et al. 1995; Stackebrandt et al. 1997; Garrity et al. 2005), but was later extended to include the genera *Gordonia*, *Millisia*, *Skermania*, and *Williamsia* mainly on the basis of taxon-specific signatures in 16S rRNA genes (Zhi et al. 2009). This classification is recognized here albeit with the addition of the genera "*Prescottella*"

(Jones et al. 2013a) and *Smaragdicoccous* (Adachi et al. 2007). A case can be made for the continued recognition of the family *Gordoniaceae* (Stackebrandt et al. 1997) to include not only the type genus but also the genera *Millisia*, *Skermania*, and *Williamsia*, as these taxa have been found to form a branch in the *Corynebacteriales* 16S rRNA gene tree (Goodfellow et al. 2012). Consequently, the current assignment of genera to the family *Nocardiaceae*, like earlier ones, should be seen as a staging post to improved classifications in the future.

The genus *Nocardia* currently contains 84 validly published species which form the largest clade in the *Nocardiaceae* 16S rRNA gene tree (Fig. 32.2). This well-defined monophyletic clade is most closely related to the genera "*Prescottella*," *Rhodococcus*, and *Smaragdicoccus*. It is apparent from the tree that *Nocardia* species fall into several multimembered subclades, one of which includes *N. asteroides*, the type species, and *N. abscessus*, *N. asiatica*, *N. cyriacigeorgica*, *N. farcinica*, *N. higoensis*, *N. neocaldonensis*, *N. puris*, *N. shimofusensis*, and *N. thailandica*, all but two of which were isolated from clinical material. Similarly, a subclade toward the foot of the tree encompasses *N. aciditolerans*, *N. africana*, *N. aobensis*, *N. cerradoensis*, *N. elegans*, *N. kruczakiae*, *N. mikami*, *N. vaccinii*, *N. veterana*, and *N. vermiculata*. This taxon includes the two most closely related *Nocardia* species, *N. kruczakiae* and *N. veterana*, the type strains of which share a 16S rRNA gene sequence similarity of 99.8 % (Conville et al. 2006). The importance of using high quality 16S rRNA gene sequences to distinguish between closely related *Nocardia* species was underlined by Roth et al. (2003).

The key causal agents of the diseases actinomycetoma and nocardiosis, namely *N. asteroides*, *N. cyriacigeorgica*, *N. brasiliensis*, *N. nova*, and *N. otitidiscaviarum*, are scattered throughout the nocardial tree though the final member of this group, *N. brasiliensis*, belongs to the *N. asteroides* subclade. Similarly, the fish pathogens, *N. salmonicida* and *N. seriola*, are in different subclades as is *N. crassostreae*, the oyster pathogen. *Nocardia jiangxiensis* and *N. miyunensis* form a distinct phyletic line which is well separated from the third aciditolerant species, *N. aciditolerans*, an organism that is common in spruce litter (pH 3.8–4.9; Golinska et al. 2013).

There is evidence that the Sec A1 protein, which is involved in the export of proteins across bacterial membranes (Schmidt and Kiser 1999), may provide a reliable way of distinguishing between members of closely related *Nocardia* species. Thus, sequence analysis and alignment of a 468 bp region of the *Sec A1* gene gives higher resolution between *Nocardia* species than corresponding 16S rRNA gene sequence data (Conville et al. 2006). These workers showed that the sequence similarity of type and reference nocardiae to their closest phylogenetic neighbors was in the range 85.0–98.7 % for the *Sec A1* gene compared with 94.4–99.8 % for corresponding 16S rRNA gene sequences. The type strains of *N. kruczakiae* and *N. veterana*, for instance, gave sequence diversities with the *Sec A1* and 16S rRNA genes of 91.9 % and 99.8 %, respectively.

The genus *Gordonia* (formerly "*Gordona*") was proposed by Tsukamura (1971), became a synonym of the genus *Rhodococcus* (Goodfellow and Alderson 1977), and was revived by Stackebrandt et al. (1988) based on 16S rRNA sequence data. At present, the genus comprises 32 validly published species which form a distinct lineage in the 16S rRNA gene tree (Fig. 32.3). It can be seen from the tree that *Gordonia* species fall into a number of loosely defined subclades with many short branches though *G. kroppenstedtii* forms a distinct independent branch at the periphery of the tree. However, greater resolution is found between *Gordonia* species based on *gyr B* gene sequence analysis (Shen et al. 2006a). Shen and his colleagues also found that gordoniae have much lower interspecies *gyr B* substitution rates than *Corynebacterium*, *Nocardia*, and *Rhodococcus* strains.

The phylogenetic relationships between validly published *Rhodococcus* species are shown in Fig. 32.4. The species cluster into several lineages, a result which is in good agreement with previous studies (Rainey et al. 1995; McMinn et al. 2000; Jones and Goodfellow 2012); the taxonomic status of some of these lineages is supported by 16S rRNA and high bootstrap values and 16S rRNA gene signatures (Goodfellow et al. 1998a; Gürtler et al. 2004; Zhao et al. 2012; Jones et al. 2013b). Nevertheless, the taxonomic implications of rhodococcal lineages remain unclear though it has been mooted that some of them, notably the *R. erythropolis* and *R. rhodochrous* subclades, might merit generic status (Goodfellow et al. 1998a; Gürtler et al. 2004; McMinn et al. 2004, Jones and Goodfellow 2012). It is also interesting that *R. cerastii*, *R. fascians*, *R. kyotensis*, and *R. yunnanensis* form an independent lineage loosely associated with the *R. erythropolis* subclade. Similarly, *R. rhodnii* forms a distinct branch in the rhodococcal tree just beyond the periphery of the *R. rhodochrous* subclade. Finally, *R. corynebacteroides*, *R. kroppenstedtii*, *R. triatomae*, and *R. trifolii* form a somewhat diffuse subclade; *R. canchipurensis* also belongs to this taxon (Nimaichand et al. 2013).

The genus *Williamsia*, the remaining multimembered taxon, forms a monophyletic clade within the evolutionary radiation encompassed by the family *Nocardiaceae* (Fig. 32.5). The eight validly published species fall into two subclades that encompass strains with short branches. The two most closely related strains, *W. marianensis* and *W. muralis*, share a 99.5 % 16S rRNA gene similarity, but were isolated from markedly different environments, namely, sediment collected from the Challenger Deep of the Mariana Trench and from non-water-damaged building material, respectively (Kämpfer et al. 1999; Pathom-aree et al. 2006).

The remaining genera classified in the family *Nocardiaceae* are monospecific. Three of them, *Millisia brevis*, *Skermania piniformis*, and *Smaragdicoccus niigatensis*, form markedly independent lineages (Fig. 32.6). The fourth, "*Prescottella equi*," is the causal agent of equine pneumonia and has had a tortuous taxonomic history. Until recently, this organism sat uneasily within the genus *Rhodococcus*, as *R. equi*, as it was not clear from 16S rRNA gene sequence analyses whether it should be seen as a genus in its own right (Ruimy et al. 1995; McMinn et al. 2000; Gürtler et al. 2004; Gürtler and Seviour 2010) or as a taxon more closely related to the genus *Nocardia* than to other members of the genus *Rhodococcus* (Ruimy et al. 1994, 1995;

Goodfellow et al. 1998a; Matsuyama et al. 2003; Yoon et al. 2000a). This Gordonian knot was severed when Jones et al. (2013b) proposed that *R. equi* be reclassified as "*Prescottia equi*." This binomial was subsequently replaced by "*Prescotella equi*" when the name *Prescottia* was found to be illegitimate as it had previously been used for a plant genus belonging to the family *Orchidaceae* (Jones et al. 2013a). The genus name "*Prescottella*" and its constituent species "*P. equi*"

have still to be validated, but will be used throughout this chapter as comparative genomic analyses show that members of this taxon are closely related to one another, but distantly related to the remaining *Rhodococcus* strains and to *N. brasiliensis* (Sangal et al. 2014). The taxonomic status of *R. kunmingensis* needs to be clarified as this organism forms a loose branch in the *Nocardiaceae* gene tree with *P. equi* (*Fig. 32.1*), as found by Jones et al. (2013b). *Smaragdicoccus niigatensis* is loosely associated with this lineage.

Molecular Analyses

DNA:DNA Hybridization Studies

It is laborious and time-consuming to establish DNA:DNA hybridization (DDH) values; hence, where possible, it is advisable to avoid doing DDH measurements. Stackebrandt and Goebel (1994) recommended that if two strains shared 16S rRNA gene sequence similarities at or below a 97 % threshold, it was not necessary to undertake DDH determinations to prove that they belonged to the same species. This threshold was subsequently raised to 98.7–99 % based, as before, on an empirical dataset compiled from the taxonomic literature (Stackebrandt and Ebers 2006). Using real-world 16S rRNA gene sequence and DDH data, Meier-Kolthoff et al. (2013) have concluded, using a regression model, that a threshold of 99 % is a reasonable cut-off point at which DDH experiments are no longer required to show that strains belong to the same species. This means that many of the DDH experiments carried out on members of the family *Nocardiaceae* could have been avoided without a significant risk of strains being misclassified.

DNA:DNA hybridization assays have been used extensively to delineate *Gordonia*, *Nocardia*, *Rhodococcus*, and *Williamsia* species. In general, such studies have shown that DNA:DNA relatedness values are low when compared with corresponding 16S rRNA gene similarities. This has proved to be particularly so in studies designed to clarify relationships between closely related nocardiae. The type strains of *N. kruczakiae* and *N. veterana*, for instance, share a 16S rRNA gene similarity of 99.8 % and a DNA:DNA homology of 55 ± 8.5 (Conville and Witebsky 2005), a relatedness value below the universally recognized 70 % cut-off point for the delineation of bacterial species (Wayne et al. 1987). In contrast, DDH studies showed that representatives of aciditolerant nocardiae which shared 16S rRNA gene similarity values between 99.4 % and 99.8 % belonged to the same genomic species (Golinska et al. 2013). These results suggest that the relationship between

Scale bar indicates estimated sequence divergence

N. cummidelens and *N. soli* needs to revisited, given their position in the *Nocardia* tree (*Fig. 32.2*).

DDH assays have been especially useful in clarifying relationships between clinically significant isolates assigned to the *N. asteroides* complex, as exemplified in the recognition of *N. abscessus* (Yassin et al. 2000), *N. anaemiae* (Kageyama et al. 2005a), *N. araoensis* (Kageyama et al. 2004a), *N. concava* (Kageyama et al. 2005b) *N. cyriacigeorgica* (Yassin et al. 2001a), *N. exalbica* (Iida et al. 2006), *N. higoensis* (Kageyama et al. 2004b), and *N. niigatensis* (Kageyama et al. 2004c). Similarly, DHH studies provided valuable data for the classification of strains assigned to the *N. transvalensis* 16S rRNA gene clade as *N. blacklockiae* and *N. wallacei* (Conville et al. 2008) and for the establishment of *N. mexicana* (Rodrigues-Nava et al. 2004) and *N. pseudobrasiliensis* (Ruimy et al. 1996) for strains previously classified as *N. brasiliensis*. DDH studies have also been pivotal in the classification of nocardiae isolated from diverse habitats, as seen by the recognition of *N. artemsiae* (Zhao et al. 2012), *N. endophytica* (Xing et al. 2011), *N. goodfellowii* (Sazak et al. 2012), *N. iowensis* (Lamm et al. 2009), *N. jiangxiensis* (Cui et al. 2005), *N. rhamnosiphila* (Everest et al. 2011), *N. takedensis* (Yamamura et al. 2005), and *N. xishanensis* (Zhang et al. 2004).

It is evident from DDH studies that all *Gordonia* species form well-delineated genomic species (Goodfellow et al. 2012), including those which have high 16S rRNA gene similarity values. The type strains of *G. aichiensis* and *S. sputi*, for instance, share a 16S rRNA gene similarity of 99.7 %, but have a DNA:DNA relatedness value of only 38–40 % 3(Klatte et al. 1994b; Goodfellow et al. 1998a). Similarly, relatively high DDH similarities have been recorded between *G. alkaliphila* and *G. hirsuta* (Cha and Cha 2013), *G. caeni* and *G. hirsuta* (Srinivasan et al. 2012), *G. humi* and *G. amarae* (Kämpfer et al. 2011a), and *G. neofelifaecis* (Liu et al. 2011a) and *G. sihwensis* (Kim et al. 2003). In addition, DNA:DNA relatedness data provided strong support for the proposal that *G. nitida* (Yoon et al. 2000a) be recognized as a later synonym of *G. alkalivorans* (Arenskőtter et al. 2005).

Some *Rhodococcus* species, notably ones classified in the *R. erythropolis* subclade, share high 16S rRNA gene sequence similarities, but relatively low DNA:DNA relatedness values (Zhang et al. 2005; Ghosh et al. 2006; Xu et al. 2007; Li et al. 2008; Wang et al. 2010; Kämpfer et al. 2013b). The type strain of *R. jialingiae*, for example, is closely related to the type strains of *R. baikonurensis* (99.8 % 16S rRNA gene sequence similarity), *R. erythropolis* (99.1 %), *R. globerula* (98.3 %), and *R. quinshengii* (98.8 %), but the corresponding DDH values are low at 19.3 %, 18.6 %, 10.6 %, and 27.7 %, respectively (Wang et al. 2010). Similar results have been reported for species assigned to the *R. rhodochrous* subclade (Goodfellow et al. 2004; Jones et al. 2004; Zhao et al. 2012) and to the heterogeneous subclade that encompasses *R. canchipurensis*, *R. corynebacteroides*, *R. kroppenstedtii*, *R. triatomae*, and *R. trifolii* (Mayilraj et al. 2006; Kämpfer et al. 2013b; Nimaichand et al. 2013); the type strains of *R. aetherivorans* and *R. ruber*, for example, have a 16S rRNA gene sequence similarity of 99.6 % and 46 % DNA relatedness (Goodfellow et al. 2004). The type strains of *R. corynebacteroides* and *R. kroppenstedtii* show 62 % DNA:DNA relatedness (Mayilraj et al. 2006), a value previously

incorrectly attributed to *R. kroppenstedtii* and "*P. equi*" (Jones and Goodfellow 2012). It is also clear from DNA:DNA pairing and associated data that the *Rhodococcus* strain RHA1 (McLeod et al. 2006) is a *bona fide* member of the species, *R. jostii* (Jones et al. 2013c).

DNA:DNA relatedness studies were not carried out between the type strains of *W. deligens*, *W. faeni*, and *W. serinedens* and their nearest phylogenetic nerighbors, given low 16S rRNA gene sequence similarities (Yassin and Hupfer 2006; Yassin et al. 2007; Jones et al. 2010). Indeed, several of the DDH assays that were carried out between the type strains of novel *Williamsia* species could have been safely omitted, given the 16S rRNA gene sequence threshold recommended by Meier-Kolthoff et al. 2013). The type strains of the two most closely related species, *W. marianensis* and *W. maris*, share a 99.5 % 16S rRNA gene sequence similarity and 11 % DNA:DNA relatedness (Pathom-aree et al. 2006). Similarly, *W. limnetica* DSM 45521^T, a relatively close relative of *W. marianensis* DSM 44944^T and *W. muralis* DSM 44343^T, shares DDH values with the latter of 18.8 % and 22.4 %, respectively (Sazak and Sahin 2012). Further, the type strain of *W. phyllosphaerae* has a DDH similarity of 29.4 % with *W. maris* DSM 44693^T, its phylogenetic neighbor (Kämpfer et al. 2011b); the corresponding value between the type strains of *W. maris* and *W. muralis* was recorded as 23 % (Stach et al. 2004).

"*Prescotella equi*" NCTC 1621^T shares low levels of DNA:DNA similarity with representative strains of *G. rubripertincta* (8–10 %), *R. coprophilus* (10–16 %), *R. rhodochrous* (7–18 %), and *R. ruber* (9–20 %) (Mordarski et al. 1980, 1981). In contrast, a somewhat higher DNA:DNA relatedness value, 34 ± 10 %, was reported between the type strains of *R. kunmingensis* and "*P. equi*" which form a loose clade in the *Nocardiaceae* 16S rRNA gene tree (➔ *Fig. 32.1*). The type strains of *M. brevis*, *S. piniformis*, and *S. niigatensis*, the only species classified in the genera *Millisia*, *Skermania* and *Smaragdicoccus* respectively, have such low levels of 16S rRNA gene similarities to their nearest neighbors, namely, species of *Gordonia* (93.7–95.7 %), *Nocardia*, and *Rhodococcus* (94.5–95.7), and *Nocardia* (94.5–95.0 %), respectively, that it was not necessary to carry out DNA:DNA relatedness studies.

Phages

Our scant knowledge about *Nocardiaceae* phages is surprising, given their potential as biocontrol agents (Petrovski et al. 2011a, b) and as key drivers of bacterial niche adaptation and evolution (Chanchaya et al. 2003; Comeau and Krisch 2005). Bradley and his colleagues studied the growth and characteristics of nocardiophages (Bradley and Ritzi 1967; Brownell et al. 1967) and showed that they could be used to distinguish between actinomycete genera (Bradley and Anderson 1958; Bradley et al. 1961). Following Bradley's lead, extensive phage host range studies were undertaken by Prauser and coworkers (Prauser and Falta 1968; Prauser and Momirova 1970; Prauser 1976, 1981) who found that actinophages, including those active against *Nocardia* and related organisms (nocardiophages), only showed activity on hosts with the same wall chemotype (as described by Lechevalier and Lechevalier 1970). The close relationship between the genera *Nocardia* and *Rhodococcus* was underpinned by actinophage susceptibility patterns (Prauser 1981), a result underlined and extended in more recent studies (Thomas et al. 2002; Petrovski et al. 2011a, d).

Phages that infect *Nocardia* species have received little attention though ones active against *N. asteroides* (Andrzejewski and Pietkiewicz 1972; Pulverer et al. 1975; Andrzejewski et al. 1978; Petrovski et al. 2011b), *N. brasiliensis* (Pulverer et al. 1974; Petrovski et al. 2013a), *N. carnea* (Williams et al. 1980; Petrovski et al. 2013a), *N. nova* (Petrovski et al. 2013b), and *N. otitidiscaviarum* (Prauser 1981) have been reported. A phage isolated from a *N. asteroides* strain was found to have a non-contractible tail and a head, the shape of an icosahedron (Andrzejewski and Müller 1975). Putative prophages have been detected in the whole-genome sequence of *N. farcinica* IMF 10152 (Ishikawa et al. 2004).

Phages targeting *Rhodococcus* strains have received more attention than those propagated in *Nocardia* species. In early studies, phages active against rhodococci were used extensively as genetic markers in mating experiments involving strains labeled "*N. canicruria*" and "*N. erythropolis*." Some of these phages, such as φC and φEC, were examined in growth and characterization experiments (Brownell et al. 1967, 1980; Brownell and Denniston 1984; Brownell and Crockett 1971). However, while a limited number of *Rhodococcus* phages have been characterized, relatively little was known until recently about *Rhodococcus* phage genomics, as exemplified by studies on *Rhodococcus* bacteriophages RGL3 and RER2 (Petrovski et al. 2011a, 2013a).

Phages RGL3 and RER2, which lyse *Rhodococcus* and *Nocardia* species, have novel genomes of 46.5 and 48.0 kb, respectively, and share a modular genome organization, as seen in other sequenced *Siphoviridae* phage genomes (Petrovski et al. 2013a). Interestingly the genomes of these phages do not share any similarity with other *Nocardia* or *Rhodococcus* phages, but are related to *Mycobacterium* phages. Other polyvalent phages active against rhodococci were isolated from four different activated sludge plants and one of them, phage RRH1, was shown to have the smallest recorded *Siphoviridae* genome (14.2 kb) with only 20 genes (Petrovski et al. 2011d).

"*Prescotella equi*" phages isolated from soil have been the subject of characterization, genomic and functional analyses. Summer et al. (2011) sequenced the genomes of four such phages and found that they had features characteristic of mycobacteriophages, including the prevalent long-tailed morphology and the presence of genes encoding Lys B-like mycolate-hydrolyzing lysis proteins. Twenty-seven "*P. equi*" phages were isolated from geographically separated locations by Salifu et al. (2013a) who divided them into 16 distinct groups based on host range, genomic restriction patterns, and virion protein profiles. Most of the phages were *Siphoviridae*, but one

group belonged to the *Myoviridae*, the first nonmycobacterial actinomycete phage assigned to this family. A comprehensive genomic and proteomic analysis of one of the phages assigned to this unique group had a circular chromosome and an average GC content (67.7 mol%) similar to that of its host, "*P. equi*" NCIMB 10027 (Salifu et al. 2013b). Petrovski et al. (2013b) isolated a novel *Siphoviridae* phage, REQ1, with a genome size of 51.3 bp. The lytic ability of this phage was assessed against 65 different actinobacterial strains (Petrovski et al. 2011c), but it was only active on a single strain, "*P. equi*" Requ 28.

There are grounds for believing that "*P. equi*" phage may be of value in reducing "*P. equi*" populations in environments where foals are susceptible to infection (Summer et al. 2011; Petrovski et al. 2013b; Salifu et al. 2013a). In a similar vein, Shibayama and Dabbs (2011) found that phage YF1, which they propagated on "*P. equi*" ATCC 14887, encoded multiple inhibitory products which might contribute to antibacterial drug discovery by providing new antibacterial targets.

Gordonia is the only one of the remaining genera classified in the family *Nocardiaceae* that contains strains used to propagate phage. Polyvalent *Gordonia* phage GTE2, a member of the family *Siphovirdiae*, has a characteristic icosahedral head encompassing a double-stranded DNA linear genome (45.5 kb) with 10 bp 3′-protruding ends, and is a candidate for the biocontrol of *Gordonia*—*Rhodococcus*—and *Nocardia*—stabilized foams in activated sludge plants (Petrovski et al. 2011a). Petrovski et al. (2012) described two phages, GRU1 and GTE5, originally isolated from activated sludge by Thomas et al. (2002) that targeted *G. rubripertincta* and *G. terrae*, respectively. These phages were shown to be closely related members of the family *Siphoviridae*, possessed similar-sized icosahedral heads that encompassed double-stranded DNA (~65 kb) though only phage GRU1 propagated in a strain of *N. nova*. The two phages reduced or eliminated foam formation by their host cells under laboratory conditions and hence quality as prospective components of cocktails of lytic phages designed to reduce populations of foam generating mycolic acid–containing actinomycetes below the threshold required for stable foam formation in activated sludge plants (Thomas et al. 2002; Withey et al. 2005; Petrovski et al. 2011c). Similarly, *Tsukamurella* phage TPA2, an important member of the activated sludge phage metapopulation, targets a wide range of *Tsukamurella* species and hence may be useful for the biocontrol of *Tsukamurella* stabilized foams (Petrovski et al. 2011e).

Plasmids

Plasmids have been detected in pathogenic strains of *Nocardia* (Provost et al. 1996; Ishikawa et al. 2004), including *N. asteroides* (Kasweck et al. 1981, 1982; Kasweck and Little 1982), in *Gordonia* strains (Brőker et al. 2004; Indest et al. 2010), in "*P. equi*" (Vásquez-Boland et al. 2010; Giguere et al. 1999, 2011), but are especially common in *Rhodococcus* species (Gürtler et al. 2004; Larkin et al. 2010).

Provost and his colleagues (1996) found a statistically significant correlation between the localization of cutaneous infections and the virulence of plasmid-bearing nocardiae, but were not able to relate the presence of plasmids to specific phenotypic traits. Two circular plasmids, pNF1 and pNF2, were detected in a *N. farcinica* strain (Ishikawa et al. 2004). Xia et al. (2006) sequenced a small circular plasmid, PXT 107, from *Nocardia* strain 107 and showed that it consisted of 4335 base pairs (bp) and encoded a replication palindromic (Rep) protein and six hypothetic proteins. They also found that the *E. coli–Nocardia* shuttle vector pHA Q22, which includes the rep gene of PXT 107, propagated in *Nocardia*, but not in *Streptomyces*. Descriptions of other native plasmids in *Nocardia* include pN 1100 (Liu et al. 2000), p C1 (Shen et al. 2006c), and PYS1, a cryptic, broad-host range plasmid from *N. aobensis* IFM 10795 (Shibayama et al. 2011). *Nocardia*-derived plasmids are being used increasingly as cloning vectors, as outlined by Luo et al. (2013a). A *Rhodococcus*, *Gordonia–E. coli* shuttle vector (Kalscheuer et al. 1999) was found to replicate in *Nocardia* (Luo et al. 2013b).

Plasmids have been isolated and characterized from a few *Gordonia* strains, including the type strain of *G. bronchialis* (see NCBI Genome Database). A native 101-kbp megaplasmid, pkB1, isolated from *G. westfalicia* KbI, encodes genes essential for cadmium resistance and rubber degradation (Brőker et al. 2004). Subsequently, Brőker and his colleagues (2008) constructed mobilized *E.coli–Gordonia* shuttle vectors based on the origin of replication of megaplasmid pkBI and showed that it could be transferred from the *G. westfalicia* strain to related bacteria such as *G. polyisoprenivorans*. Indest et al. (2010) characterized megaplasmid pGKT2 from *Gordonia* sp. strain KTR9 that contains flavodoxin reductase genes (XpIB) which are involved in the degradation of hexahydro-1,3,5-trinitro-1,3,5 triazine (Hexogen); these genes were upregulated nearly fourfold when the strain was grown in the presence of Hexogen, but were repressed by various inorganic nitrogen sources.

The many different types of plasmids found in *Rhodococcus* strains range from small cryptic, closed circular plasmids to large linear ones (Larkin et al. 1998, 2005, 2010; van der Geize and Dijkhuizen 2004; Matsui et al. 2007; Letek et al. 2008). Many rhodococcal cells contain circular and linear plasmids, as exemplified by *R. rhodochrous* strain B-276 which has four circular cryptic and four linear megapasmids (Saeki 1998; Saeki et al. 1999). Similarly, *R. erythropolis* PR4, an alkane-degrading strain, contains one linear and two circular plasmids (Sekine et al. 2006). The innumerable small circular plasmids that have been detailed in rhodococci, include plasmids pKA 22 (4,969 bp) and pKTL1 (100 bp) that encode haloalkane-degrading genes (Kulakova et al. 1995), and a 150 bp plasmid in *R. erythropolis* strain IGTS 8 which encodes genes involved in desulfurization of organosulfur compounds (Denis-Larose et al. 1997). Other circular plasmids code for diphenyl metabolism (Masai et al. 1997), chloroalkane degradation (Kulakova et al. 1995), 2-methylalanine metabolism (Schreiner et al. 1991), and propene degradation (Matsui et al. 2007). Some cryptic plasmids have mobilization functions (Yang et al. 2007a).

A distinctive feature of many studies on rhodococci is that large linear plasmids are associated with the presence of catabolic genes. Thus, *R. jostii* strain RHA1 (Jones et al. 2013c), the most effective degrader of polychlorinated biphenyls, contains three large linear plasmids, pRHL1 (1,100 kb), pRHL2 (450 kb), and pRHL3 (330 kb) (McLeod et al. 2006). Other large linear rhodococcal plasmids encode genes for the catabolism of alkylbenzene (Kim et al. 2002), naphthalene (Uz et al. 2000; Kulakov et al. 2005), toluene (O'Brien et al. 2002; Priefert et al. 2004), trichloroethene (Saeki et al. 1999), and chloroaromatic compounds (Konig et al. 2004). Such plasmids are often conjugative and have conjugative genes and functions (Yang et al. 2007b).

Other functions coded by linear plasmids include hydrogen autotrophy in *R. opacus* (Kalkus et al. 1990, 1993), plant virulence genes in *R. fascians* (Crespi et al. 1992; Depuydt et al. 2009a, b), and isopropyl metabolism in *R. erythropolis* (Masai et al. 1995). Sequences and genome annotations have been generated for some linear plasmids, including pBD2 from *R. erythropolis* (Strecker et al. 2003), pREC1 and p REL2 from *R. erythropolis* PR4 (Sekine et al. 2006), and pRHL3 from *R. jostii* strain RHA1 (Warren et al. 2004). Rhodococcal plasmids have been used as vectors for the expression of recombinant proteins (Nakashima and Tamura 2004a, b) and for the development of shuttle vectors (Kostichka et al. 2008; Lessard et al. 2004; Mangan et al. 2005).

Plasmids associated with pathogenicity determinants in "*P. equi*" have been characterized extensively (Prescott 1991; Takai et al. 1991a; Tkachuk-Saad and Prescott 1991; Ribeiro et al. 2005; Vásquez-Boland et al. 2010). These large, circular plasmids encode *vap* genes that are involved in the pathogenicity of horses (*vap A*) and pigs (*vap B*). Several variants of the *vap A* plasmid have been determined based on restriction fragment length polymorphisms (Takao et al. 1999; Ribeiro et al. 2005). A simple PCR assay is available to distinguish between *vap A* and *vap B* plasmid types (Oldfield et al. 2004). There is evidence that vap genes evolved in plasmid-encoded pathogenicity islands (Letek et al. 2008). These workers also noted that "*P. equi*" virulence factors are representative of a new family of actinobacterial plasmids that combine plasmid-specific insertions with a conserved backbone structure linked to plasmid maintenance and transfer.

Molecular Identification and Typing

Reliable methods are available to assign unknown *Nocardiaceae* isolates to the genus level (Goodfellow and Jones 2012), but accurate identification to species remains problematic even for clinically significant strains. The difficulties associated with accurate identification of unknown nocardiae based on biochemical, chemical, morphological, and physiological criteria led to the introduction of molecular diagnostic tools, notably to distinguish between species of pathogenic *Nocardia* (Laurent et al. 1996; Isik and Goodfellow 2002; Gürtler et al. 2004; Goodfellow and Maldonado 2012; van de Sande et al. 2014a, b). PCR-restriction pattern analysis of a 441-bp fragment of the 65-kDA host shock protein (*hsp 65*) was used to differentiate between individual *Nocardia* species (Steingrübe et al. 1995, 1997; Wilson et al. 1998; Rodrigues-Nava et al. 2006). Sequence-based approaches such as those based on 16S rRNA gene polymorphisms have also been used for this purpose (Mellmann et al. 2003; Cloud et al. 2004; Patel et al. 2004; Conville et al. 2006). Molecular methods can also be used to directly detect nocardiae in clinical material (Couble et al. 2005; Marchandin et al. 2006).

Approaches such as those outlined above, while of value, have led to the misidentification of both clinically and environmentally significant nocardiae when used to distinguish between a broad range of *Nocardia* species (Conville et al. 2000; Pottumarthy et al. 2003; Rodrigues-Nova et al. 2006). This problem is compounded by the fact that the genus *Nocardia* is underspeciated (Wang et al. 1999; Orchard and Goodfellow 1980; Roth et al. 2003) and includes important pathogenic species, such as *N. asteroides*, *N. farcinica*, and *N. nova*, that are heterogeneous (Goodfellow and Maldonado 2012). Consequently, for accurate identification, unknown nocardiae need to be compared with their nearest phylogenetic neighbors using appropriate diagnostic procedures.

Molecular-based approaches have been used to distinguish between *Gordonia* and *Rhodococcus* species. Clinically significant gordoniae have been assigned to species based on PCR-restriction enzyme analysis of the 439-bp Telenti fragment of the 65 *hsp* gene (Patel et al. 2004), while primers targeted at species-specific 16S rRNA gene signatures have been shown to distinguish between some *Rhodococcus* species (Bell et al. 1999). Primers have also been used to detect a unique 700-bp fragment of "*P. equi*" chromosomal DNA (Arriaga et al. 2002). This organism can also be detected using a PCR assay that targets the choE gene (Ladrón et al. 2003).

At one time, serological and skin testing for cutaneous hypersensitivity were used for early diagnosis of nocardial infections in animals and humans (Pier et al. 1968; Pier and Fichtner 1971, 1981; Magnusson 1976; Angeles and Sugar 1987; Boiron and Provost 1990a; Boiron and Stynen 1992; Boiron et al. 1993). In general, these approaches have fallen from grace, partly because of their low sensitivity and lack of specificity, but also due to the introduction of diagnostic molecular procedures. However, the enzyme-linked immunosorbent assay (ELISA) introduced for the serological diagnosis of *N. brasiliensis* was useful in cases of mycetoma where the identification of the causal agent in culture was not possible (Salinas-Carmona et al. 1993).

Typing methods have been used to establish the infection source and mode of transmission of clinically significant *Nocardiaceae* species, especially with respect to hospital-acquired nocardial infections (Schaal and Lee 1992; McNeil and Brown 1994; Brown-Elliott et al. 2006). Thus, an outbreak of nocardiosis among immunocompromised patients in a renal unit was attributed to a specific *N. asteroides* serotype (Stevens et al. 1981). Clinically relevant *N. asteroides* strains have been

Table 32.1

Comparison of the general features of the complete genomes of strains classified in the family *Nocardiaceae*

Strains	Chromosomal topology	No. of plasmids (topology)	Total genome size (Mb)	Average GC%	No. of genes	No. of proteins	rrn operons	tRNA genes
Gordonia bronchialis Strain 3410^T	Circular	1 (Circular)	5.29	67.1	4,984	4,696	2	49
Nocardia brasiliensis Strain HUJEG-1	Circular	–	9.44	68.0	8,474	8,414	3	51
Nocardia cyriacigeorgica Strain GUH-2	Circular	–	6.19	68.4	5,560	5,477	3	49
Nocardia farcinica Strain IFM 10152	Circular	2 (Circular)	6.29	70.7	5,998	5,934	3	53
"*Prescotella equi*" ATCC 33707	Circular	–	5.26	68.8	5,105	5,030	5	52
Rhodococcus erythropolis Strain PR4	Circular	1 (Linear), 2 (Circular)	6.90	62.3	6,511	6,437	5	54
Rhodoccous jostii Strain RHA1	Linear	3 (Linear)	9.70	67.0	9,221	9,145	4	50
Rhodococcus opacus Strain B4	Linear	2 (Linear), 3 (Circular)	8.83	67.6	8,259	8,197	4	49

Note:
1. The virulence plasmid of *P. equi* ATCC 33707 was not included
2. The details were obtained from NCBI Genome Database (http://www.ncbi.nlm.nih.gov/genome)

typed using plasmid (Jonsson et al. 1986), restriction fragment length polymorphisms (Patterson et al. 1992), pulsed field gel electrophoresis, and randomly amplified polymorphic DNA PCR (Louie et al. 1997). Pulsed field gel electrophoresis was used to show that a *N. farcinica* strain was responsible for postoperative wound infections in a hospital surgical ward in Germany (Blümel et al. 1998). Studies on herds of dairy cattle where cases of mastitis were evident showed that the causal *N. asteroides* strains were usually of the same serotype, implying animal-to-animal transmission (Pier and Fichtner 1981).

Molecular epidemiological studies on "*P. equi*" have revealed considerable heterogeneity in the genotype of clinical and fecal strains isolated from foals, horses, and their immediate environment (Soedarmanto et al. 1997; Morton et al. 2001; Cohen et al. 2003; Venner et al. 2007). Bolton and his colleagues (2010) examined *rep*-PCR amplicons, in an automated microfluidics format, to type virulent "*P. equi*" isolates from a single foal and found that the animal was infected with multiple strains of the pathogen. A simple PCR typing system for "*P. equi*" based on three virulent plasmids demonstrated that there was an association between specific plasmid types and animal hosts (Ocampo-Sosa et al. 2007).

Genome Comparisons

Only eight full genome sequences are available for members of the family *Nocardiaceae* (Table 32.1). However, 25 *Nocardia*, 17 *Rhodococcus*, and 1 *Smaragdicoccus niigatensis* draft sequences have been published by the NCBI Genome Database (http://www.ncbi.nlm.nih.gov/genome) with the promise of many more to come (Luo et al. 2013a).

Complete genome sequences are available for three strains of *Nocardia*: *N. brasiliensis* HUJEG-1 (Vera-Cabrera et al. 2012), *N. cyriacigeorgica* (Zoropogui et al. 2012), and *N. farcinica* IFM 10152 (Ishikawa et al. 2004). All three organisms have circular chromosomes though the one for *N. brasiliensis* is considerably larger than those for the other two strains (Table 32.1). The complete genome of *N. farcinica* IFM 10152, an organism that was isolated from the bronchus of a 68-year-old male Japanese patient, consists of a single, circular chromosome (6.01 Mb) with a mean GC content of 70.8 mol% and two plasmids, pNF1 (184,027 bp) and p NF2 (87,093 bp), with mean G+C contents of 67.2 % and 68.4 %, respectively. This chromosome contains many candidate genes for multidrug resistance, secondary metabolism, and virulence, whereas plasmids pNF2 and pNF1 encode 90 and 160 predicted protein-coding genes, respectively. Analysis of paralogous protein families indicates that the organism has the capacity to live as a saprophyte in the soil ecosystem and as a pathogen in animal tissue.

It is also apparent from the complete genomes of the *N. brasiliensis* and *N. cyriacigeorgica* strains that they have the capacity to follow both saprophytic and pathogenic modes of life (Vera-Cabrera et al. 2013; Zoropogui et al. 2012). The *N. brasiliensis* strain has been used widely in antimicrobial and immunological assays (Salinas-Carmona and Rocha-Pizaña 2011;

Salinas-Carmona et al. 2011; Trevino-Villareal et al. 2012). The complete genome of this organism contains many catabolic and lipid biosynthetic genes, orthologs for virulence factors, and gene clusters for the synthesis of bioactive compounds, including antibiotics, polyketides, and terpenes (Vera-Cabrera et al. 2012, 2013). Virulence factors, such as lipases, phosphatases, and proteases, were also found. An *in silico* analysis of the genome sequence indicated that the organism had acquired diverse genes by horizontal gene transfer from other members of the soil ecosystem.

The *N. cyriacigeorgica* (formerly *N. asteroides*) strain was isolated from a fatal human infection (Beaman and Maslam 1977) and subsequently used extensively for studying nocardial infection (Beaman 1981; Beaman and Beaman 1994, 2000). The whole genome of this organism includes candidate genes similar to those found in the complete genomes of *M. tuberculosis* H37Rv^T and *N. farcinica* IFM 10152 (Cole et al. 1998; Ishikawa et al. 2004). The genes included 6 complete *myc* loci which code for mammalian cell entry, a 385-kDa—antigen protein family and 19 lipoproteins (Zoropogui et al. 2012). In addition, two superoxide dismutases and three catalase genes were found to be similar to genes involved in macrophage resistance in *Nocardia* (Beaman et al. 1985).

A complete genome is available for *G. bronchialis* strain 3410^T (Ivanova et al. 2010) and a draft one for *G. neofelifaeces* NRRL B-51395^T (Ge et al. 2011). The general features of the genome of the *G. bronchialis* strain are shown in *Table 32.1*. Nearly 67 % of the protein-coding genes of this organism were given a predicted function, 5.5 % for lipid transport and metabolism, and 4.2 % for metabolite biosynthesis, transport, and metabolism. The *G. neofelifaecis* strain was isolated from the feces of a clouded leopard (*Neofilis nebulosa*) and shown to transform cholesterol to androsta-1,4-diene-3,17-dione by side chain cleavage (Liu et al. 2011a, b). The draft genome (4.25 Mb) includes 46 genes for tRNA, 5 rRNA loci, and, as predicted, several gene clusters for cholesterol degradation.

Complete genome sequences have been generated for *R. jostii* strain RHA 1 (McLeod et al. 2006), *R. erythropolis* strain PR4, and *R. opacus* strain B4 though published reports on the latter two organisms are awaited. However, all three organisms have similar genomic features though the *R. erythropolis* has a circular chromosome (*Table 32.1*). The *R. jostii* strain, an isolate from lindane-contaminated soil (Seto et al. 1995), is particularly well known for its ability to transform polychlorinated biphenyls. This organism has a large genome (9.70 Mb) composed of a linear chromosome and three linear plasmids. The genome contains many catabolic genes which squares with the remarkable catabolic versatility of the strain. The predicted protein-coding genes are not only rich in ligases and oxygenases, but also in nonribosomal peptide synthase genes that are indicative of an extensive secondary metabolism. The organism was considered to have evolved to simultaneously metabolize plant-derived compounds in oxygen-rich habitats.

Draft genomes are available for several industrially significant rhodococci, as exemplified by *R. erythropolis* sp. strain Xp (Tao et al. 2011), *R. pyridinivorans* strain AK37 (Kriszt et al. 2012), *Rhodococcus* sp. strain R04 (Yang et al. 2011), and *Rhodococcus* sp. strain P14 (Zhang et al. 2012). The genome of the *R. erythropolis* strain (7.2 Mb), a soil isolate shown to be effective in deep desulfurization of petroleum soils (Yu et al. 2006), contained several genes considered relevant to the degradation of dibenzothiophene. Similarly, the genome sequence of *R. pyridinivorans* strain AK37, a pyridine-degrading bacterium isolated from industrial wastewater in Korea (Yoon et al. 2000c), contained genes that encoded for at least six different pathways for monocyclic aromatic hydrocarbon degradation; key enzymes for alkane and biphenyl degradation were also identified. *Rhodococcus* strain R04, an isolate from contaminated soil, degrades polychlorinated biphenyls (PGB) through both ring cleavage and dechlorination, and has a large genome (9.12 Mb). The genome contains many genes that are potentially involved in xenobiotic metabolism, including four extradiol dioxygenase genes (*bpHC*) and two hydrolase genes (*bhpD*) involved in PCB degradation. Finally, the draft genome sequence of *Rhodococcus* sp. strain P14, an isolate from oil-contaminated sediment that mineralizes polycyclic hydrocarbons with three to five rings, contained nearly 1,000 genes predicted to be involved in biodegradation of xenobiotics.

To date, the smallest complete genome found in *Nocardiaceae* strains is that of "*P. equi*" 103S, a protolypic clinical isolate (Letek et al. 2010). It can be seen from *Table 32.1* that the 5.0 Mb "*P. equi*" genome is significantly smaller than those of the three *Rhodococcus* strains; it lacks extensive catabolic and secondary metabolism genes and displays unique adaptations for host colonization. Letek and his colleagues provided evidence that the relatively small size of the "*P. equi*" genome was not a consequence of reductive evolution, as in the *M. leprae* genome (Cole et al. 2001), but was due to gene expansion in the rhodococcal strains.

Phenotypic Markers

Since the last edition of *The Prokaryotes*, the family *Nocardiaceae* has expanded to include the genera *Gordonia*, *Millisia*, "*Prescotella*," *Skermania*, *Smaragdicoccus*, and *Williamsia*. *Nocardia*, the type genus, encompasses 84 validly published species, including the type species *N. asteroides*. The key chemical and morphological properties of the genera classified in the family *Nocardiaceae* are shown in *Table 32.2*.

Nocardia Trevisan 1889^{AL}

No. card' ia. N.L. fem. n. *Nocardia* named after Edmond Nocard (1850–1903), a French veterinarian who first isolated members of this taxon.

Nocardia is the oldest name in current use for an aerobic actinobacterial genus. Strains grow well on most standard media, as exemplified by brain-heart infusion (Difco), glycerol-asparagine (ISP 5; Shirling and Gőttlieb 1996), glucose-yeast extract (Gordon and Mihm 1962), modified

Examples of abbreviations: MK-8 (H_4, ω cyclo), hexahydrogenated menaquinone with eight isoprene units where the two end units are cyclized; SQA and SQB, smaragdiquinones A and B
Abbreviations: *ND* not determined, *S* saturated, *T* tuberculostearic acid, (*T*) trace amounts of tuberculostearic acid, *U* unsaturated

Bennett's (Jones 1949), modified Sauton's (Mordarska et al. 1972), Sabouraud glucose and yeast extract-malt extract (ISP 2; Shirling and Gottlieb 1966) agars, as well as on Middlebrook media (Lorian 1968) and Mueller-Hinton 11 medium supplemented with glucose (Kageyama et al. 2004a, b, c, d, e, f, g, h). Media should be incubated at 25–37 °C for up to 3 weeks. Aciditolerant nocardiae belonging to *N. aciditolerans*, *N. jiangxiensis*, and *N. miyunensis* grow well on media adjusted to pH 5.5 (Cui et al. 2005; Golinska et al. 2013). Colonies may be smooth to granular and irregular, wrinkled, or heaped. Most strains synthesize carotenoid-like pigments which import various shades of brown, orange, pink, red, or yellow colors to colonies growing on solid culture media. Brown or yellowish diffusible pigments may be produced.

The only constant morphological characteristic of nocardiae is their capacity to produce filamentous branched cells which fragment into irregular coccoid and rod-like elements. Aerial hyphae are almost invariable formed though at times they may only be visible microscopically. The growth and stability of aerial and substrate mycelia are influenced by cultivation conditions (Locci 1976; Williams et al. 1976; Beaman and Beaman 1994). Developmental morphological studies undertaken by Locci (1976) on *N. asteroides* and *N. farcinica* strains demonstrated the value of scanning electron microscopy in elucidating the intricate growth cycles of these organisms.

Short-to-long chains of well-to-poorly differentiated spores may be detected occasionally on aerial hyphae and, more rarely, on aerial and substrate mycelia. Short chains of spores are formed on the aerial mycelia of *N. aobensis* (Kageyama et al. 2004d), *N. artemisiae* (Zhao et al. 2011), *N. asiatica* (Kageyama et al. 2004e), *N. callitridis* (Kaewkla and Franco 2010), *N. inohanensis* (Kageyama et al. 2004c), *N. niigatensis* (Kageyama et al. 2004c), and *N. takedensis* (Yamamura et al. 2005). *Nocardia beijingensis* and *N. brevicatena* form spores on aerial and substrate mycelia (Lechevalier et al. 1961; Wang et al. 2001).

Nocardiae are Gram-positive to Gram-variable and are acid-alcohol-fast positive at some stages of the growth cycle. Most strains grow between 20 °C and 40 °C, optimally ~28 °C, and in pH range 5–10, optimally ~pH 7.0. However, some species, such as *N. acidivorans*, *N. harenae*, *J. jejunensis*, and *S. spelucae*, grow at 10 °C and others, like *N. arthritidis*, *N. brasiliensis*, *N. ignorata*, *N. jinanensis*, *N. kruczakiae*, and *N. otitidiscaviarum*, grow well at 45 °C. All members of the genus are heterotrophic with an oxidative metabolism. A generation time of 5.5 h has been reported for *N. asteroides* and *N. brasiliensis* strains (Beadles et al. 1980). Some strains reach stationary phase within 3–7 days, others grow more slowly.

Nocardiae do not have specific growth requirements. Most strains grow on media containing casein, meat or yeast extract, and simple nitrogen sources, including amino acids and nitrate. They degrade complex polysaccharides and can assimilate diverse carbon compounds, including glucose, acetate, and propionate (Goodfellow 1971; Kämpfer et al. 2004; Golinska et al. 2013; Luo et al. 2013a). However, additional comparative data are needed before their biochemical, degradative, and carbon assimilation profiles are known as representatives of many species of *Nocardia*, including type strains, have still to be examined (Goodfellow and Maldonado 2012). This problem is compounded by the fact that many properties attributed to nocardiae in the early literature (Arai et al. 1988; Cain 1981; Peczyńska-Czoch and Mordarski 1988; Finnerty 1992; Tárnok 1976) were acquired from strains now classified in the genera *Amycolatopsis*, *Gordonia*, and *Rhodococcus* (Goodfellow and Jones 2012; Goodfellow and Maldonado 2013; Goodfellow et al. 2012; Tan and Goodfellow 2012). Biochemical and degradative profiles and sole carbon utilization patterns of *Nocardia* species are shown in *Table 32.3*. However, recent studies show that authenticated representatives of the genus exhibit a high degree of metabolic activity (Goodfellow and Maldonado 2012; Luo et al. 2013a), as shown by their ability to synthesize novel bioactive products (Schneider et al. 2009; El-Gendy et al. 2008; Lamm et al. 2009) and degrade complex organic compounds (Berekaa 2006; Le et al. 2010).

The cell envelopes of nocardiae contain a pronounced peptidoglycan layer, sugars and lipids, notably mycolic acids (Michel and Bordet 1976; Minnikin 1982, 1993). Ester bonds connect mycolic acids to an arabinogalactan layer which is attached to the peptidoglycan. The outer mycolic acid layer is analogous to the outer membrane of Gram-negative bacteria. The latter contain channel-forming proteins, the porins, that allow the passage of solutes through the outer membrane. Little is known about the molecular basis of nocardial cell wall permeability though porins have been detected in the mycolic acid layers of *N. asteroides* and *N. farcinica* strains (Riess et al. 1998, 1999).

Nocardia species have cell walls that contain major amounts of *meso*-diaminopimelic acid, arabinose, and galactose (Michel and Bordet 1976; Goodfellow et al. 1999), that is, they have a wall chemotype IV sensu Lechevalier and Lechevalier (1970), an A1γ peptidoglycan (Schleifer and Kandler 1972) and *N*-glycolyl muramic acid (Uchida and Aida 1979a, b; Uchida and Seino 1997; Uchida et al. 1999). They contain diphosphatidylglycerol, phophatidylethanolamine (taxonomically significant nitrogenous phospholipid), phosphatidylinositol, and phosphatidylinositol mannosides as major polar lipids and thereby have a phospholipid type II pattern (Lechevalier et al. 1977, 1981) albeit with a variable distribution of phosphatidylglycerol (Minnikin et al. 1977; Kämpfer et al. 2004). The predominant respiratory quinone is hexahydrogenated menaquinone with eight isoprene units in which the two terminal ones are cyclized (Collins et al. 1987; Howarth et al. 1986); minor components detected in some species include MK-8(H_2), MK-8(H_4), and MK-9 (Rodrigues-Nava et al. 2004, 2007; Yamamura et al. 2007; Ezeoka et al. 2013; Sazak et al. 2012). Nocardiae contain characteristic lipid soluble iron-binding compounds, the nocobactins (Ratledge and Patel 1976), while the G+C content of their genomic DNA falls within the range 63–73 mol%. Nocardiae typically contain major amounts of straight-chain saturated, unsaturated, and tuberculostearic fatty acids, that is, they have a type II fatty acid profile sensu Kroppenstedt (1985). Most strains have qualitatively similar fatty acid profiles though some closely related species can be distinguished by

qualitative differences in fatty acid composition (Kageyama et al. 2004a, b, c; Kämpfer et al. 2007; Lamm et al. 2009; Kaewkla and Franco 2010).

The most characteristic components of the walls of nocardiae are the mycolic acids (Minnikin and Goodfellow 1976, 1980; Minnikin 1982, 1993). Mycolic acids with between 44 and 64 carbon atoms and up to 4 double bonds have been detected in several species, including *N. amikacinitolerans* (Ezeoke et al. 2011), *N. asteroides* (Bordet et al. 1965), *N. brasiliensis* (Lanéelle and Asselineau 1970), *N. farcinica* (Yano et al. 1990), *N. niwae* (Moser et al. 2011), *N. otitidis-caviarum* (Alshamaony et al. 1976), and *N. seriolae* (Kudo et al. 1988). *Nocardia asteroides* can adapt to temperature changes by altering wall mycolic acid composition (Tomiyasu 1982). The fatty acid esters released on pyrolysis gas chromatography of mycolic acid methyl esters contain 12–18 carbon atoms (Minnikin and Goodfellow 1976, 1980). Two lipid spots, one corresponding to mycolic acids (Rf value ~ 0.47) and the other to nonhydroxylated fatty acids (Rf value ~ 0.9), are usually detected by one-dimensional thin-layer-chromatography of nocardial whole-organism hydrolysates (Minnikin et al. 1975; Yassin and Brenner 2005; Yassin et al. 2001b). However, a second mycolic acid has been reported in some species, as exemplified by *N. abscessus* (Yassin et al. 2000), *N. asiatica* (Kageyama et al. 2004e), *N. beijingensis* (Wang et al. 2001), and *N. exalbida* (Iida et al. 2006).

Gordonia (Tsukamura 1971) Stackebrandt, Smida and Collins 1988, 345[VP]

Gor.do' ni. a. N.L. fem. n. *Gordonia*, named after Ruth E. Gordon, a celebrated bacterial systematist.

Gordonia strains grow well on standard media used to cultivate actinomycetes, such as modified Bennett's (Jones 1949), modified Sauton's (Mordarska et al. 1972), R2A (Oxoid), and tryptone-soy (Oxoid) agars. Colony morphology ranges from circular, convex, shiny, and smooth colonies with entire edges to rough, matt and folded ones with irregular edges. Most colonies are 2–10 mm in diameter, have a soft texture, and may be cream, beige, yellow or tan through to apricot, orange, pink, or red. Diffusible pigments are not produced. The type strains of *G. alkanivorans* and *G. westfalica* form smooth and rough colonies (Kummer et al. 1999; Linos et al. 2002). Glycosylated peptidoglycolipids influence the colony morphology of *G. hydrophobica* (Moorman et al. 1997).

Gordoniae tend to form short rods and cocci which may occur singly, in pairs, in small groups, as V-shaped elements, or as short chains. Some species have a typical rod-coccus life cycle, whereby cells in early growth phase are rods and those in exponential phase are cocci (Kummer et al. 1999). Other species form elementary branched hyphae which fragment into rod and coccoid-like forms, as shown by *G. alkanivorans* (Kummer et al. 1999), *G. lacunae* (Le Roes et al. 2008), *G. polyisoprenivorans* (Linos et al. 1999), and *G. soli* (Shen et al. 2006b). *Gordonia amarae* strains form moderately branching, substrate hyphae that grow into agar media and do not fragment in undisturbed culture (Lechevalier and Lechevalier 1974). *Gordonia defluvii* shows acute-angled and right-angled branching (Soddell et al. 2006b) which is reminiscent of the right-angled branching pattern of *G. amarae* (Lechevalier and Lechevalier 1974; Klatte et al. 1994) and the "pine-tree-like" morphology of *S. piniformis* (Blackall et al. 1989; Chun et al. 1997). *Gordonia amarae* and *G. defluvii* strains form microscopically visible aerial hyphae (Lechevalier and Lechevalier 1974; Soddell et al. 2006b).

Gordonia strains are Gram-positive to Gram-variable and usually partially acid-alcohol-fast. In general, they grow at 10–37 °C, optimally ~ 28 °C, but do not grow at either 5 °C or 45 °C. The pH growth range is 5–11, and optimally ~ pH 7.0. *Gordonia alkaliphila* grows from pH 6 to 11 and optimally at pH 9 (Cha and Cha 2013). Gordoniae grow well in the absence of NaCl, but can grow in the presence of 4 %, w/v NaCl. All members of the genus are heterotrophic with an oxidative metabolism.

Gordonia species do not have any specific growth requirements, but do show remarkable metabolic activity (Arenskőtter et al. 2004). They are biochemically active, degrade complex polysaccharides, and use diverse compounds as sole carbon sources (*Tables 32.4* and *32.5*). Currently, a broad comparison of their phenotypic features is not possible as the type strains of several species have not been examined for such properties. However, it is known that gordoniae can cleave diverse 7-amino-4-methylcoumarin and 4-methylumbelliferone conjugated fluorogenic substrates (Goodfellow et al. 1991). Enzymatic profiles of some species, including *G. alkanivorans* (Cha and Cha 2013), *G. soli* (Shen et al. 2006b), and *G. caeni* (Srinivasan et al. 2012), have been determined using API-ZYM kits.

The metabolic activity of *Gordonia* strains rivals that of rhodococci, as witnessed by their ability to break down environmental pollutants and xenobiotics, and by their capacity to transform or synthesize organic compounds of biotechnological interest (Drzyzga 2012). Thus, cholesterol is metabolized by *G. cholesterolivorans* (Drzyzga et al. 2009, 2011), nitriles by *G. namibiensis* (Brandão et al. 2001), phenol by *G. kroppenstedtii* (Kim et al. 2009), hydrocarbons such as liquid paraffin by *G. paraffinivorans* (Xue et al. 2003), natural rubber substrates by *G. polyisoprenivorans* (Linos et al. 1999) and *G. westfalica* (Linos et al. 2002), and pyrene by a *Gordonia* strain (Xu et al. 2011). Xenobiotic compounds that are metabolized include alkanes by *G. alkanivorans* (Kummer et al. 1999), dibenzothiophene by *G. amicalis* (Kim et al. 2000), and benzothiophene by *G. desulfuricans* (Kim et al. 1999). Other unusual compounds metabolized by gordoniae include butyl benzyl phthalates (Chaterjee and Dutta 2003), fluroanthene (Britto et al. 2000) and hazardous nitro-compounds, such as hexahydro-1,3,5-trinitro-1,3,5-triazine (Hexogen), an explosive that is difficult to degrade (Gorontzy et al. 1994; Thompson et al. 2005). Specific anabolic capabilities include the ability of *G. alkanivorans* to produce exopolysaccharides (Ta-Chen et al. 2008) and *Gordonia* strains to synthesize biosurfactants (Franzetti et al. 2009) and steroids (Schneider et al. 2008).

Adapted from Srinivarsan et al. (2013)
+ positive, *w* weak positive, – negative

Whole-cell hydrolysates of gordoniae contain *meso*-diaminopimelic acid as the sole diamino acid in the peptidoglycan and arabinose and galactose as characteristic whole-cell sugars (wall chemotype IV, according to Lechevalier and Lechevalier 1970). They have a A1γ peptidoglycan (Schleifer and Kandler 1972), *N*-glycolyl muramic acid moieties (Uchida and Aida 1979a; Uchida and Seino 1997; Srinivasan et al. 2012), and typically contain diphosphatidylglycerol, phosphatidylethanolamine (taxonomically significant phospholipid), phosphatidylinositol, and phosphatidylinositol mannosides as major components (Minnikin et al. 1977), which equates to a phospholipid pattern type II after Lechevalier et al. (1977, 1981); additional components detected in some species include unidentified aminophospholipids, glycolipids, phosphoglycolipids, and phospholipids (Xue et al. 2003; Cha and Cha 2013). Dihydrogenated menaquinones with nine isoprene units (MK-9 [H_2]) are the predominant isoprenologue (Alshamaony et al. 1976; Collins et al. 1977, 1985); minor components, such as MK-7 (H_2) and MK-8 (H_2), have been detected in some species (Kummer et al. 1999; Kämpfer et al. 2011a, 2013a). *Gordonia effusa* is unusual as it contains major amounts of MK-9 [H_4) and MK-9 [H_8) with a smaller proportion of MK-9 [H_4) (Kageyama et al. 2006).

In general, *Gordonia* species contain similar mixtures of straight-chain saturated, unsaturated, and tuberculostearic acids (type II fatty acid pattern sensu Kroppenstedt (1985) though species-specific patterns and intraspecific differences have been reported (Klatte et al. 1994; Kim et al. 2003; Drzyzga et al. 2009; Liu et al. 2011). The mycolic acids of gordoniae have 46–70 carbon atoms with up to 4 double bonds (Alshamaony et al. 1976; Kageyama et al. 2006); the fatty acids released on pyrolysis gas chromatography of mycolic acid methyl esters have 12–16 carbon atoms (Minnikin and Goodfellow 1976, 1980). *Gordonia amarae* strains isolated from activated sludge foam contain shorter chain and more fully saturated mycolic acids than those derived from analyses of *Gordonia* type strains (Stratton et al. 1999). One-dimensional TLC of gordonial whole-organism hydrolysates yields two lipid spots, one corresponding to mycolic acids (Rf value ~ 0.5) and the other to monohydroxylated fatty acids (Rf ~ 0.9). A lipoglycan structurally related to mycobacterial lipoarabinomannan has been detected in *G. rubripertincta* (sic) (Flaherty and Sutcliffe 1999).

Rhodococcus (Zopf 1891) emend. Goodfellow, Alderson and Chun 1998a

Rho. do. coc' cus. Gr. N. rhodon, the rose; N.L. masc. n. coccus (from Gr. masc. n. kokkos, grain, seed) coccus; N.L. masc. n. *Rhodococcus*, a red coccus.

Rhodococcus strains grow well on media such as glucose-yeast extract (Gordon and Mihm 1962), trypticase soy (Oxoid) and yeast extract-malt extract (ISP 2, Shirling and Gottlieb 1966) agars and on modified Bennett's agar supplemented with thiamine (Mordarska et al. 1972). *Rhodococcus marinonascens* requires seawater for growth, grows well at 5 °C and optimally at about 20 °C (Helmke and Weyland 1984). Colonies may be rough, smooth, or mucoid and pigmented buff; cream, orange, red, or yellow; and most have a soft texture. Colony pigmentation may be enhanced by exposure to light (Rowbotham and Cross 1977a).

Rhodococci show a remarkable cellular heterogeneity, but do not exhibit any distinctive morphological features other than the ability of some species to form hyphae that fragment into rods and/or cocci (Locci 1976, 1981; Williams et al. 1976; Helmke and Weyland 1984; Locci and Sharples 1984; Apajalahti et al. 1986). The growth cycle starts with a coccus or short rod stage, and this is usually followed by a series of more or less complex morphological developments. Cocci may differentiate into short rods, branched filaments, or in the most differentiated form into extensively branched hyphae. The next generation of cocci and short rods is formed by fragmentation of the rods, filaments, and branched hyphae. The timing of the fragmentation process is influenced by the growth conditions (Williams et al. 1976). *Rhodococci* do not usually form aerial hyphae; an exception is *R. coprophilus* which produces feeble aerial hyphae (Locci and Sharples 1984). The time taken to complete the growth cycle ranges from 24 h in relatively undifferentiated forms, such as *R. erythropolis*, to several days for those like *R. coprophilus* which show pronounced morphological differentiation (Locci et al. 1982).

Rhodococcus strains are Gram-positive to Gram-variable and are usually partially acid-alcohol-fast at some stage of the growth cycle. In general, they grow from 15 °C to 40 °C, optimally ~ 30 °C, from pH 5.0 to 10.0 with an optimum ~ pH 7.0; they also grow in the presence of 5 %, w/v NaCl. *Rhodococcus cerastii* and *R. trifolii* grow at 50 °C (Kämpfer et al. 2013b). In contrast, *R. marinonascens* does not grow at temperatures above 28 °C (Helmke and Weyland 1984). *Rhodococci* are heterotrophic, with an oxidative type of metabolism.

Rhodococci use a broad range of compounds as sole carbon compounds, as shown by species assigned or associated with the *R. corynebacteroides*, *R. erythropolis*, and *R. rhodochrous* 16S rRNA clades (*Tables 32.6–32.8*). More to the point, they show an astonishing catabolic versatility that has been the subject both of broadly based reviews (Bell et al. 1998, Gürtler et al. 2004, van der Geize and Dijkhuizen 2004; De Carvalho and da Fonseca 2005; Larkin et al. 2006; Alvarez 2010a; Yam et al. 2010), as well as to ones that concentrate on their capacity to produce industrially important enzymes (Bunch 1998; Beard and Page 1998; Hughes et al. 1998; Martínková et al. 2010; Ma 2010) or to turnover environmental pollutants, including xenobiotics (Warhurst and Fewson 1994; Larkin et al. 2005; Kuyukina and Ivshina 2010). Their metabolic versatility is mainly due to the presence of large linear plasmids and multiple homologs of enzymes in catabolic pathways (van der Geize and Dijkhuizen 2004; Larkin et al. 2005, 2010; McLeod et al. 2006).

The metabolic versatility of *Rhodococcus* strains can be illustrated by the ability of *R. aetherivorans* to metabolize methyl t-butyl ether (Goodfellow et al. 2004), *R. bakonurensis* to break down diesel oil (Li et al. 2006), *R. erythropolis* to desulphuranize

benzothiophene and dibenzothiophene (Oldfield et al. 1997, 1998), *R. koreensis* to utilize 2,4-dinitrophenol (Yoon et al. 2000a), and *R. zopfii* to degrade natural estrogens (Yoshimoto et al. 2004) while *R. qinghengii* metabolizes carbendiazine, a commonly used benzimidazole fungicide (Xu et al. 2007) which damages the liver and endocrine system and has mutagenic and teratogenic effects on animals at low concentrations (Mazellier et al. 2003). In addition, alkyl ether (Kim et al. 2007), dibenzofuran (Aly et al. 2008), methyl-*s*-trizones (Fujii et al. 2007), nitrophenol (Ghosh et al. 2007), polychlorinated bipheyl (PCB) (Leigh et al. 2006), and xylene (Taki et al. 2007) are degraded by strains provisionally classified by Gűrtler and Seviour (2010) as *R. ruber*, *R. pyridinivorans*, *R. jostii*, *R. imtechensis*, *R.wratislaviensis*, and *R. opacus*, respectively. Several genetic tools have been developed to realize the metabolic potential of *Rhodococci* (Finnerty 1992; Larkin et al. 1998), including *E. coli–Rhodococcus* shuttle vectors (Shao et al. 1995; De Mot et al. 1997; Mangan et al. 2005; Matsui et al. 2006, 2007). In addition, cloned and characterized amidase and nitrile hydratase genes from *Rhodococci* have been expressed in *E. coli* (Ikehata et al. 1989; Hashimoto et al. 1991; Kobayashi et al. 1991).

Rhodococci have an A1γ peptidoglycan in which the muramic acid residues of the glycan strands are *N*-glycolated (Schleifer and Kandler 1972; Uchida and Seino 1997). Cells typically contain diphosphatidylglycerol, phosphatidylethanolamine (taxonomically significant phospholipid), phosphatidylinositol, and phosphatidylinositol mannosides as major phospholipids (type II pattern after Lechevalier et al. 1977, 1981); fatty acids rich in straight-chain saturated, monounsaturated, and branched-chain components (fatty acid type 1b after Kroppenstedt 1985); and dihydrogenated menaquinones with eight isoprene units as the predominant isoprenologue (Collins et al. 1985). Mycolic acids have 28–54 carbons with up to 4 double bonds, while fatty acids released on pyrolysis gas chromatography of mycolic acid methyl esters have 12–16 carbon acids (Alshamaony et al. 1976); Minnikin and Goodfellow 1980; Sutcliffe 1998). Selective ion monitoring gas-chromatography-mass spectrometric analysis gives a much more detailed profile of mycolic acid composition than gas-chromatography-mass spectrometry, as exemplified by a *R. rhodochrous* strain in which the mycolic acids were assigned to 60 subgroups based on α- and β-mycolic acid chain lengths and degrees of unsaturation (Stratton et al. 1999). These workers also noted that mycolic acid composition was sensitive to growth conditions.

The most recent model of the cell wall organization of *Rhodococci* is that proposed by Sutcliffe et al. (2010). The rhodococcal cell wall is dominated by mycolic acids that are covalently linked to the peptidoglycan-arabinogalactan complex and which form an outer permeability barrier. In line with this, channel-forming proteins have been extracted from whole-cells of *R. corynebacteroides* and *R. erythropolis* strains (Lichtinger et al. 2000, Riess and Benz 2000). Other non-covalently associated components found in cell envelopes of *Rhodococci* include free lipids, lipoproteins, and polysaccharides (Sutcliffe et al. 2010). A lipoarabinomannan (LAM)-like lipoglycan of a *R. ruber* strain was shown to have a truncated structure in which the lipomannan core was directly substituted with *t*-arabinofuranose residues (Gibson et al. 2003). LAM-like

lipoglycans have been detected in the type strain of *R. rhodnii* (Flaherty et al. 1996). In addition, the cell walls of *R. corynebacteroides*, *R. erythropolis*, *R. rhodochrous*, and *R. ruber* and *R. wratislaviensis* are a rich source of structurally diverse lipids, including glycolipids, lipopeptides, and glycolipopeptides (Sutcliffe et al. 2010).

Williamsia et al. 1999, Kämpfer, Andersson, Rainey, Kroppenstedt and Salkinoja-Salonen 1999[VP]

Wil. li. am' si. a. N.L. fem n. Williamsia named to honor Stanley Thomas Williams (1937–2004), a British microbiologist, for his numerous contributions to the taxonomy and ecology of actinomycetes.

The genus *Williamsia* currently encompasses eight validly published species which grow well on complex media such as Brain-Heart Infusion (BBL), glucose-yeast extract (Gordon and Mihm 1962), modified Bennett's (Jones 1949), nutrient (Bacto), R2A (BBL), and yeast extract-malt extrat (Shirling and Gottlieb 1966) agars. Colonies tend to be smooth, entire, and slightly convex, 1–3 mm in diameter and have a soft texture. Some strains produce yellow colonies but in the main orange to red colonies are formed.

Williamsia strains are Gram-positive, non-acid-alcohol-fast, nonmotile actinomycetes which form short rods and/or coccoid elements. Most strains grow from 20 °C to 37 °C, optimally ∼ 28 °C, and at or around pH 7.0. However, *W. faeni* and *W. maris* grow at 10–30 °C, but not at 37 °C (Stach et al. 2004; Jones et al. 2010). The cellular morphology of *W. muralis* is unusual as transmission electron microscopy reveals that the surface of cells is covered by fimbrial-like structures (Kämpfer et al. 1999). Similar structures have been detected in *R. percolatus* (Briglia et al. 1996). All members of the genus are heterotrophic with an oxidative metabolism. A broad range of compounds are used as sole carbon sources (*Table 32.9*).

Williamsiae typically contain *meso*-diaminopimelic acid, arabinose, and galactose in whole-organism hydrolysates (wall chemotype IV after Lechevalier and Lechevalier 1970); major amounts of straight-chain saturated, unsaturated, and tuberculostearic acids; phosphatidylethanolamine (taxonomically significant component), diphosphatidylglycerol, phosphatidylglycerol, and phosphatidylinositol as major components (phospholipid type II sensu Lechevalier et al. 1977, 1981) and mycolic acids with 50–58 carbon atoms (Kämpfer et al. 1999; Sazak and Sahin 2012). The fatty acid methyl esters released on pyrolysis gas chromatography of mycolic acid methyl esters of the type strain of *W. serinedens* have 16 and 18 carbon atoms (Yassin et al. 2007).

Williamsia strains show considerable variation in cellular fatty acid profiles and to a lesser degree in isoprenoid quinone composition. Most contain major amounts of palmitic ($C_{16:0}$), hexadecenoic ($C_{16:1}$), oleic ($C_{18:1}$), and tuberculostearic (10-methyl $C_{18:0}$) acids (Pathom-aree et al. 2006; Jones et al. 2010), that is, they have a fatty acid type 1b pattern sensu Kroppenstedt (1985). *Williamsia muralis* has a similar fatty acid profile albeit with minor amounts of $C_{16:1}$ *cis*9 (Kämpfer et al. 1999). In addition, *W. deligens* contains a minor amount of $C_{16:1}$, but shows a significant presence (40 %) of C_{20} saturated and unsaturated fatty acids (Yassin and Hupfer 2006). All but one of the *Williamsia* type strains contain dihydrogenated menaquinones either as the sole isoprenologue, as in the case of *W. faeni*, *W. marianensis*, or with minor amounts of MK-7 (H_2) and/or MK-8 (H_2), as with *W. serinedens* and *W. phyllosphaerae*. The exception, *W. limnetica*, has MK-8 (H_2) as the major component albeit with sizeable proportions of MK-7 (H_2) and MK-9 (H_2) (Sazak and Sahin 2012).

Monospecific Genera

Millisia Soddell, Stainsby, Eales, Kroppenstedt, Seviour and Goodfellow 2006a[VP]

Mil. li.' si.a. N.L. fem. n. named after Nancy F. Mills, a celebrated microbiologist who promoted wastewater microbiology in Australia.

Key features of the four monospecific genera classified in the family *Nocardiaceae* are considered here.

The history of the genus *Millisia* began when Soddell and Seviour (1994) isolated two unusual actinomycetes from an Australian wastewater treatment plant that showed rudimentary right-angled branching and salmon-pink filamentous colonies. Additional studies based on numerical taxonomic and 16S rRNA gene sequence data indicated that the isolates might merit generic status (Soddell and Seviour 1998). Subsequent work undertaken by Soddell et al. (2006a) underpinned this point as they were able to show that the two isolates could be distinguished from members of other mycolic acid-containing taxa using a combination of genotypic and phenotypic data. Soddell and his colleagues considered that the type species, *Millisia brevis*, was most closed related to the genera *Gordonia* and *Skermania*.

It is now apparent that the genus *Millisia* forms a deep branch in the *Nocardiaceae* 16S rRNA gene tree in which it shows a loose association with the genus *Skermania* (*Fig. 32.1*). Soddell and his colleagues (2006a) showed that the type strain of *M. brevis* can be distinguished from representatives of the genus *Skermania* and other mycolic acid-containing genera as it synthesized a high proportion of oleic acid ($C_{18:1}$; 26.3 %) and a low proportion of tuberculostearic acid (3 %). Further, thin-layer chromatographic analysis showed that the *M. brevis* type strain gave a mycolic acid spot with a similar Rf value to those of representatives of the genera *Gordonia* and *Rhodococcus*. Additionally, Curie-point pyrolysis mass spectrometric analysis showed that the type strain of *M. brevis* was clearly separated from representatives of other mycolic acid–containing genera. An actinomycete associated with a deep-water marine invertebrate has been found to share an identical partial 16S rRNA gene sequence with *M. brevis* strain J81^T (Sfanos et al. 2005).

"*Prescottella*" Jones, Sutcliffe and Goodfellow 2013a

Pres. cot. tel'la. N.L. fem dim. n. *Prescotella*, named after John Prescott to celebrate his many contributions to unraveling the pathogenicity of *Rhodococcus equi*.

The genus "*Prescottella*" with the species "*Prescottella equi*" was proposed by Jones et al. (2013a) to replace the illegitimate name "*Prescottia*" Jones et al. (2013b) and the illegitimate combination *Prescottia equi* (Jones et al. 2013b). Following an extensive polyphasic taxonomy study, these names had been proposed to provide a new home for an old pathogen, namely, *R. equi* (formerly *Corynebacterium equi*). This organism, an important pathogen of foals, had been a somewhat atypical member of each of these taxa (Barton and Hughes 1980; Rainey et al. 1995; Gürtler and Seviour 2010).

"*Prescottella equi*" strains are Gram-positive, acid-alcohol fast, pleomorphic actinomycetes. In smears, cells tend to show clumping or palisade configurations or L- or V-shaped elements though a rod-coccus life cycle may be exhibited. Smears from liquid cultures may exhibit branching filaments with swollen ends. The organism grows well from 5 °C to 40 °C, optimally ~ 30 °C, on standard media used to cultivate gordoniae and rhodococci. Smooth, shiny, orange to red colonies with entire margins are formed on glucose-yeast extract agar. Some strains produce copious amounts of slime which may fall onto the covers of inverted Petri dishes during incubation. Strains of "*P. equi*" are metabolically active; they use a broad range of sole carbon sources, degrade complex polysaccharides, and show considerable enzymatic activity (Jones et al. 2013b).

The chemotaxonomic properties of "*P. equi*" are similar to those of members of the genus *Rhodococcus* (Barton et al. 1989;

Jones et al. 2013b). Strains have whole-organism hydrolysates rich in *meso*-diaminopimelic acid, arabinose, and galactose (wall chemotype IV according to Lechevalier and Lechevalier; 1970), an A1γ peptidoglycan (Schleifer and Kandler 1972) and *N*-glycolated muramic acid moieties (Uchida and Seino 1997). They typically contain dihydrogenated menaquinones with eight isoprene units as the predominant isoprenologue (Collins et al. 1977; Barton et al. 1989) and have qualitatively similar fatty acids composed of straight-chain saturated, monounsaturated, and 10-methyl-branched fatty acids (Collins et al. 1982a; Barton et al. 1989), significant numbers of strains synthesize the carbon 16 version of 10-methyloctadecanoic acid (Jones et al. 2013b). Polar lipid patterns contain major amounts of diphosphatidylglycerol and phosphatidylethanolamine (taxonomically significant component), less intensive spots corresponding to phosphatidylglycerol, phosphatidylinositol, and mono- and diacylated phosphatidylinositol diamannosides, characteristic polar glycolipids, and a less polar trehalose mycolate (Barton et al. 1989). This polar lipid pattern is distinctive as it serves to distinguish "*P. equi*" from *Corynebacterium* and *Rhodococcus* strains (Minnikin et al. 1978, 1980). The mycolic acids of "*R. equi*" have 28–50 carbon atoms and up to four double bonds, the fatty acids released on pyrolysis gas chromatography of mycolic acid methyl esters have 12–16 carbon atoms (Collins et al. 1982b; Barton et al. 1989).

Skermania, Chun, Blackall, Kang, Hah and Goodfellow 1997, 129[VP]

Sker. man. i.a. N.L. n. Skermania named after Victor Bruce Darlington Skerman (1921–1993), a celebrated Australian bacterial systematist.

The genus *Skermania* was proposed by Chun et al. (1999) for actinomycetes that had initially been described as pine-tree-like Organisms due to their distinctive tree-like micromorphology (Blackall et al. 1988). Subsequently, somewhat tentatively, Blackall and her colleagues (1989) assigned members of this taxon to the genus *Nocardia*, as *Nocardia pinensis*, mainly on chemotaxonomic and biological evidence while highlighting that they showed atypical nocardial features, such as the presence of unusual mycolic acids, a characteristic antibiotic sensitivity pattern, and a relatively slow growth rate. *Skermania piniformis* forms a deep-rooted branch in the *Nocardiaceae* 16S rRNA gene tree showing a loose, albeit distant relationship to *Millisia brevis* (Fig. 32.1), another organism isolated from activated sludge foam from sewage treatment plants. There is evidence that the genus may be underspeciated (Soddell and Seviour 1994).

Skermaniae grow on glycerol-asparagine agar (ISP 5; Shirling and Gottlieb 1966), SMAS medium (BBL) enriched with 1 % (v/v) horse serum (Soddell and Seviour 1994), as well as on tryptone-yeast extract-glucose (TYG), yeast extract, and yeast extract-glucose agars (Blackall et al. 1989; Soddell and Seviour 1998). Like mycobacteria, they grow best on media containing glycerol as a carbon source and asparagine as a nitrogen source. TYG agar supports the growth of orange, opaque, circular colonies that are 1–2 mm in diameter (Blackall et al. 1989). Colonies have a pasty texture, are difficult to emulsify and culture, and while they appear dry and friable macroscopically, they are moist and shiny when examined microscopically. Whole colonies tend to remain intact when taken from the surface of agar media. Macroscopically visible colonies are evident in slightly turbid TRG broth. On solid TRG medium, strains may take 10–21 days to produce colonies that are about 1–2 mm in diameter with growth rates being variable (Blackall et al. 1989).

Skermania strains produce an extensive substrate mycelium that does not fragment in undisturbed culture. Secondary branching is rare or absent. The branch angles of skermaniae are acute, not right-angled as in *G. amarae*. Branches near the apex are shorter than those further away, while the septate mycelia taper after branch points. Short branched and unbranched aerial hyphae are visible microscopically. Phase bright spherical regions can be detected at terminal and intercalary positions in microcolonies.

Skermaniae are Gram-positive and non-acid-fast. Filaments from activated sludge plants and from culture media contain intracellular sudanophilic and polyphosphate inclusions. The maximum and minimum growth temperatures are 31 °C and 15 °C, respectively. Growth is not enhanced in an atmosphere containing 5 % CO_2. Eales et al. (2006) found that skermaniae did not behave as strict aerobes in foam, as expected from pure culture studies (Chun et al. 1997). Indeed, they are facultative aerobes capable of anaerobic nitrate respiration as substrates are taken up under anoxic (NO_3) conditions. Eales and her colleagues also pointed out that an ability to take up a substrate in the absence of oxygen does not necessarily mean that an organism can grow in the absence of oxygen. The metabolic activity of *S. piniformis* strains is evident from their ability to cleave diverse 7-amino-4-methylcoumarin and 4-methylumbelliferone conjugated substrates (Chun et al. 1997) and their capacity to grow on diverse compounds as sole carbon sources (Soddell and Seviour 1996). These workers also found that skermaniae produced more biomass and grow faster on hydrophilic substrates, like oils, than on hydrophobic substrates, such as glucose.

Skermaniae show a range of chemotaxonomic properties found in other genera classified in the family *Nocardiaceae* (Blackall et al. 1989). They have a wall chemotype IV, an A1γ peptidoglycan, *N*-glycolated muramic acid residues, diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylinositol, and phosphatidylinositol mannosides as major phospholipids, predominant amounts of hexahydrogenated menaquinones with eight isoprene units with the last two cyclized (MK-8 [H_4, ω cycl]), large proportions of straight-chain saturated, unsaturated, and 10-methyloctadecanoic fatty acids and mycolic acids with 58–64 carbon atoms, 2–6 double bonds, and monounsaturated side chains, while fatty acids released on pyrolysis gas chromatography of mycolic acid methyl esters

have 16–20 carbon atoms. *Skermania* strains are especially rich in hexadecanoic ($C_{16:0}$), hexadecanoic ($C_{16:1}$), octadecanoic, and 10-methyloctadecanoic acids.

Smaradicoccus Adachi, Katsula, Matsunda, Peng, Misawa, Shizuri, Kroppenstedt, Yokota and Kasai 2007[VP]

Sma. rag. di'coc'cus. L.n. smaragdus malachite, N.L. masc. n. coccus (from Gr. masc. n. kokkus) grain; N.L. masc. n. *Smaragdicoccus malachite* (−colored) coccus.

The type strain of the type species of the genus *Smaragdicoccus* was isolated from a petroleum-contaminated soil by enrichment culture (Adachi et al. 2007). *Smaragdicoccus niigatensis* forms a deep-rooted branch in the *Nocardiaceae* 16S rRNA gene tree and shows a loose association with "*P. equi*" (Fig. 32.1). The type and only strain is Gram-positive, nonmotile, forms coccoid cells (0.86-µm in diameter), but not spores. On W-medium (Peng et al. 2003), malachite green-like, round colonies, 1–3 mm in diameter, are formed after 7 days at 25 °C in a hexadecane-saturated atmosphere. The organism also grows at 4–37 °C, but not at 45 °C, on 1/10 trypticase soy agar (Difco). It grows at 30 °C on yeast extract-malt extract and peptone-yeast extract-iron agars (ISP media 2 and 6; Shirling and Gottlieb 1966). Fructose glucose, hexadecane, and sodium-*n*-butyrate are utilized after 14 days at 30 °C, and sucrose following a month's incubation; better growth was observed when the W-medium was supplemented with 0.1 % than with 1.0 % (w/v) of the carbon source. Esterase (C4), esterase lipase (C8), lipase (C4), leucine arylamidase, and naphthol-AS-BI phosphohydrolase activities have been detected using API ZYM kits.

Smaragdicoccus niigatensis exhibits several chemical markers typical of the family *Nocardiaceae*. It has a wall chemotype IV, an A1γ peptidoglycan, *N*-glycolated muramic acid, diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylinositol, and phosphatidylinositol mannoside as major phospholipids and straight-chain saturated and unsaturated fatty acids though 10-methyl-branched components, if present, are in trace amounts. The mycolic acids have 43–49 carbon atoms. In contrast, *S. niigatensis* has an unusual menaquinone profile that consists of two components, namely, MK-8 (H_4, ω-methylenecyclyl) and MK-8 (H_4, diacyl). The earlier component has the same UV and MS/MS profiles as MK-8 (H_4 cycl) which is characteristic of *Nocardia* (Howarth et al. 1986; Collins et al. 1987) and *Skermania* (Blackall et al. 1989).

Isolation, Enrichment, and Maintenance Procedures

Selective Isolation and Enrichment

It is difficult to isolate *Nocardiaceae* strains from clinical and environmental samples by using standard methods as isolation plates tend to be overrun by fast-growing bacteria. Consequently, as with other actinomycetes, a plethora of selective isolation procedures have been recommended for the isolation of *Nocardia* and related mycolic acid–containing genera from samples taken from clinical and environmental sources (Goodfellow 2010; Tiwari and Gupta 2012a). In general, the most effective isolation strategies are those designed to select specific fractions of *Nocardiaceae* communities based on their biological properties and distribution patterns in aquatic and terrestrial ecosystems (Rowbotham and Cross 1977b; Seviour et al. 2010; Golinska et al. 2012). Nevertheless, most procedures used to isolate *Nocardia* and related genera involve the detachment of vegetative cells and mycelial fragments (propagules) bound to particulate matter, chemical and/or physical pretreatment of substrates, choice of selective media, fine-tuning of cultural conditions, and finally the recognition of target organisms using taxon-specific identification procedures.

Physicochemical bonds between propagules and particulate matter influence the recovery of actinomycetes from samples taken from natural habitats. Standard methods used to detach propagules from organic matter, sediment, and soil particles, such as shaking in water and weak buffers (e.g., 1/4 strength Ringer's solution) although widely used, are not particularly effective (Hopkins et al. 1991a). In contrast, the dispersion and differential centrifugation (DDC) technique, a multistage procedure introduced by Hopkins et al. (1991b), combines several physicochemical treatments shown to be effective in increasing the yield of actinomycetes from natural habitats when compared with reciprocal shaking methods (MacNaughton and O'Donnell 1994; Atalan et al. 2000; Sembiring et al. 2000; Maldonado et al. 2005). Soil suspensions prepared using the DDC procedure when plated onto an acidified medium led to the isolation of the type strains of *N. jiangxiensis* and *N. myunensis* (Cui et al. 2005).

Several pretreatment regimes have been used to selectively isolate *Nocardia*, *Rhodococcus*, and related strains from environmental samples. Propagules of these and other actinomycetes tend to be more resistant to desiccation and heat than cells of vegetative bacteria; hence, simply heating or drying soil or sediment samples reduces the number of Gram-negative bacteria able to grow on selective isolation plates (Labeda and Shearer 1991; Goodfellow 2010). The type strains of *N. acidivorans* and *N. tenerifensis*, for instance, were isolated from soil samples that had been held at 100 °C prior to plating-out soil suspensions onto isolation media (Kämpfer et al. 2004, 2007). Similarly, a *N. rhamnosiphila* strain was isolated from a soil sample that had been heated at 100 °C for an hour before inoculating soil dilutions onto Czapek Solution agar (Everest et al. 2011).

Several *Nocardia* species have been isolated from soil, water, and deteriorating rubber rings following pretreatment of 10^{-1} preparations at 55 °C for 6 min (Orchard and Goodfellow 1974; Orchard et al. 1977; Maldonado et al. 2000). This heat pretreatment regime also led to the isolation of the type strain of *G. sinesedis* from a soil sample (Maldonado et al. 2003) and to

the recovery of many *R. coprophilus* strains from aquatic and terrestrial environmental samples (Rowbotham and Cross 1977b). Sucrose gradient centrifugation has been used to selectively isolate *Nocardia* spp., including *N. takedensis*, from soil (Yamamura et al. 2003, 2005).

Nocardiaceae strains are generally isolated by plating pretreated or non-pretreated suspensions of clinical or environmental samples onto nutritionally rich empirically formulated media. The lack of accepted, taxon-specific isolation procedures helps explain why so little is known about the occurrence, distribution, numbers, and activities of constituent members of the family *Nocardiaceae* in natural habitats. The somewhat haphazard approaches to the isolation of members of the family also go someway to explain why so many *Nocardiaceae* species are based on descriptions of single isolates.

Nocardia. Early procedures used to selectively isolate nocardiae were based on their ability to grow on hydrocarbons as sole carbon sources (Cross et al. 1976; Tárnok 1976; Nesterenko et al. 1978a), as exemplified by the paraffin baiting technique (Sőhngen 1913). Modifications of this technique have been used occasionally to isolate *Nocardia* strains from clinical material (Ashdown 1990) and soil (Portaels 1976; Schaal and Bickenbach 1978; Khan et al. 1997; Rodriguez-Nava et al. 2007). However, it is now general practice to isolate nocardiae from either pretreated or non-pretreated substrates by plating-out serial dilutions onto either general purpose or selective media supplemented with antifungal antibiotics (e.g., actidione and/or nystatin at 50 μg mL^{-1}). Inoculated plates are incubated at 20–37 °C under aerobic conditions.

High numbers of nocardiae have been isolated, using the heat pretreatment regime described above, by plating-out serial dilutions of substrates onto Diagnostic Sensitivity Agar supplemented with various combinations of tetracycline and antifungal antibiotics (Orchard and Goodfellow 1974; Orchard et al. 1977; Maldonado et al. 2000). Similarly, many aciditolerant nocardiae have been isolated by inoculating serial dilutions of litter and acidic soil from a spruce forest onto starch-casein medium with agar or gellan gum as gelling agents; the media were supplemented with antifungal antibiotics and adjusted to pH5.5 with IN HC l (Golinska et al. 2012). In each case, *Nocardia* colonies growing on the isolation media were recognized by their cream colored substrate mycelia and abundant, translucent white aerial hyphae. Numerous nocardiae have been detected by plating dilutions of sediment, soil, and water samples onto chitin, glycerol-asparagine, and starch-casein agars (Jiang and Xu 1996; Xu et al. 1996).

Single and small numbers of nocardial colonies have been isolated from soil and sand using general purpose media with and without antibacterial antibiotics, as exemplified by the isolation of *N. acidivorans* on mannitol-rifampicin agar (Kämpfer et al. 2007), *N. altamirensis* on tryptone-soy agar (Jurado et al. 2008), *N. beijingensis* on glucose-asparagine agar (Wang et al. 2001), *N. caishijiensis* on Bennett's agar (Zhang et al. 2003), *N. cerradoensis* on R5 agar (Alburquerque-Barros et al. 2003), *N. goodfellowii* and *N. thraciensis* on Gauze's No. 2 agar supplemented with nalidixic acid (Sazak et al. 2012), *N. grenadensis* on soil extract agar (Kämpfer et al. 2012), *N. jinanensis* on modified Sauton's agar (Sun et al. 2009), *N. lijiangensis* on HV agar (Xue et al. 2003), and *N. neocaledonensis* on oatmeal agar (Saintpierre-Bonaccio et al. 2004). In addition, nocardiae have been isolated on nutrient-rich media inoculated with surface-sterilized plant material, as shown by the growth of *N. artemisiae* and *N. endophytica* on sodium propionate-asparagine-salts agar (Xing et al. 2011; Zhao et al. 2011) and *N. callitridis* on VL10 agar supplemented with nalidixic acid and a cocktail of amino acids (Kaewkla and Franco 2010).

Standard nutrient-rich media used in clinical settings have led to the isolation of novel pathogenic nocardiae from clinical specimens, as witnessed by the recovery of *N. ninae* on blood agar Laurent et al. (2007) and *N. anaemiae*, *N. aobensis*, *N. arthritidis*, and *N. vermiculata* (Kageyama et al. 2004f) on Muller-Hinton 11 medium supplemented with glucose and glycerol (Kageyama et al. 2004a, e, 2005a). Other media formulations recommended for the isolation of clinically significant nocardiae include brain-heart infusion agar (Schaal 1977), Sabouraud's glucose agar supplemented with chloramphenicol (Ajello and Roberts 1981), and paraffin agar (Shawar et al. 1990). Pathogenic nocardiae have been isolated from clinical material using robust selective isolation procedures. Hamid et al. (2001), for instance, isolated strains of a new pathogen, *N. africana*, by treating sputa of patients with pulmonary disease using the digestion-decontamination procedure of Roberts et al. (1991) and then plating-out the digested products onto Lowenstein Jensen slopes.

Gordonia. In general, the approaches used to isolate gordoniae depend upon whether the target organisms are of clinical, biotechnological, or environmental interest. Gordoniae, including *G. amarae* and *G. defluvii*, are common in foaming-activated sludge plants where they present a possible health hazard (de los Reyes et al. 1998a, b; Seviour and Nielsen 2010). Large numbers of putatively novel *Gordonia* spp. have been isolated by inoculating dilutions of activated sludge foam onto glucose-yeast extract agar and incubating plates at 30 °C for 14 days (Goodfellow et al. 1996, 1998b). Gordoniae are easy to recognize on isolation plates as they present as large, rough, grayish-pink dry colonies. Suitable media for the isolation of the ubiquitous *G. amarae* include Czapek's agar supplemented with yeast extract (Higgins and Lechevalier 1969) and glycerol agar (Gordon and Smith 1953). Similarly, *G. caeni* was isolated from a sludge sample taken from a sewage disposal plant by plating dilutions onto R2A agar (Srinivasan et al. 2012). In contrast, *G. defluvii* strains have been recovered from activated sludge foam by micromanipulation, as described by Soddell and Seviour (1998).

Enrichment culture is the favored approach to isolate gordoniae of biotechnological interest from environmental samples, as exemplified by the selective isolation of *G. amicalis* (Kim et al. 2000), *G. cholesterolivorans* (Drzyzga et al. 2009), *G. desulfuricans* (Kim et al. 1999), *G. kroppenstedtii* (Kim et al. 2009), *G. namibiensis* (Brandão et al. 2001), *G. neofelisfaecis* (Liu et al. 2011), and *G. paraffinivorans* (Xue et al. 2003).

In contrast, soil suspensions inoculated onto nutrient-rich media led to the isolation of *G. lacunae* (le Roes et al. 2008) and *G. shandongensis* (Luo et al. 2007).

Although most gordoniae have been isolated from environmental sources, they are being reported increasingly in clinical settings where they should be seen as potential opportunistic human pathogens (Lal et al. 2010; Johnson et al. 2011). The methods used to isolate clinically significant gordoniae are rarely given in case reports though it seems likely that standard procedures will apply. *Gordonia otitidis*, for example, was isolated on blood agar plates that had been incubated at 37 °C for 7 days (Iida et al. 2004). Clinically significant gordoniae have been isolated using procedures designed to detect pathogenic mycobacteria (Tsukamura 1971; Gil-Sande et al. 2006).

Rhodococcus. *Rhodococci* have been isolated from diverse habitats by enrichment culture and by plating pretreated and non-pretreated substrates onto nutrient-rich media such as Czapek's agar (Higgins and Lechevalier 1969), glycerol agar (Gordon and Smith 1953), and glycerol-asparagine agar (Shirling and Gottlieb 1966). In contrast, taxonomically novel *Rhodococci* were isolated from Pacific Ocean sediments by Colquhoun et al. (1998) using a nutritionally poor medium, M3 agar, formulated by Rowbotham and Cross (1977b). *Rhodococci* from activated sludge have been isolated by micromanipulation (Soddell et al. 1992).

Specific fractions of rhodococcal communities present in aquatic and terrestrial habitats have been isolated by plating suspensions of environmental samples onto diverse rich nutrient media. Thus, *R. canchipurensis* was isolated from a limestone deposit on starch-casein agar (Nimaichand et al. 2013), *R. imtechensis* from pesticide-contaminated soil using tryptic soy agar (Ghosh et al. 2006), *R. jostii* from human skeletal remains using peptone-yeast extract agar (Takeuchi et al. 2002), and *R. maanshanensis* from soil using modified Sauton's agar (Zhang et al. 2002). In contrast, use of a mineral salts medium supplemented with alkanes was used to isolate "*R. luteus*" (a subjective synonym of *R. fascians*; Klatte et al. 1994) from soil and the skin of carp (Nesterenko et al. 1982). The obligate marine species, *R. marinonascens*, was isolated by plating dilutions of marine sediments onto rich media supplemented with seawater and incubating for up to 12 weeks (Weyland 1969; Helmke and Weyland 1984). The endophyte *R. artemisiae* was isolated by inoculating extensively pretreated plant suspensions onto propionate-asparagine-salt agar supplemented with sodium chloride and nalidixic acid (Zhao et al. 2012). The type strains of *R. cerastii* and *R. trifolii* were obtained from the leaf surface of *Trifolium repens* after growth for 14 days on M125 medium (Kämpfer et al. 2013b).

Rhodococci of potential biotechnological value have been isolated from environmental samples using selective enrichment procedures, as exemplified by the recovery of the *R. aetherivorans* from methyl *t*-butyl enrichments of petrochemical sludge from a chemical effluent plant (Salanitro et al. 1994; Goodfellow et al. 2004). Similarly, *R. erythropolis* was isolated from the discharge of an industrial site polluted with haloalkanes using a defined growth medium supplemented with 1-chlorobutane as the sole source of carbon and nitrogen (Sallis et al. 1990). Selective enrichment of industrial wastewaters using mineral salts media supplemented with 2,4-dinitrophenol, and pyridine led to the isolation of *R. koreensis* (Yoon et al. 2000b) and *R. pyridinivorans* (Yoon et al. 2000c), respectively. Novel and presumptively novel *Rhodococcus* spp. have been isolated from contaminated soil (Xu et al. 2007).

"***Prescottella***." Several selective media have been used to isolate "*P. equi*" from clinical and environmental sources (Makrai et al. 2005; Muscatello et al. 2007). One such formulation, NANAT medium, which consists of a tryptone-soy broth, yeast extract agar base supplemented with nalidixic acid, novobiocin, and potassium tellurite, has been used to good effect (Woolcock et al. 1979; Mutimer and Woolcock 1980; Muscatello et al. 2007). "*Prescotella equi*" has also been isolated from soil using TANT broth, a selective enrichment medium that contains actidione, nalidixic acid, penicillin, and potassium tellurite, prior to subculturing onto Tinsdale (Oxoid) agar containing actidione and M3 agar supplemented with potassium tellurite (Barton and Hughes 1981). Colonies of "*P. equi*" are evident on these selective media after 4 to 5 days incubation at 30 °C. Another selective isolation medium, based on a Mueller-Hinton base supplemented with ceftazdine and novobiocin, was developed by von Graevenitz and Punter-Streit (1995). A modified version of this medium gave significantly higher yields of "*P. equi*" from soil compared with NANAT agar (Muscatello et al. 2007).

Skermania. A micromanipulatory technique (Skerman 1968) has been used extensively to isolate skermaniae from activated sludge foam and mixed liquors of wastewater treatment plants in Australia (Blackall et al. 1989; Soddell and Seviour 1998; Seviour and Nielsen 2010). The first successful isolation of *S. piniformis* was achieved by Blackhall and her colleagues who used a Skerman micromanipulator to pick up and transfer acute-angled, branching filaments from activated sludge samples onto either yeast extract-glucose agar or tryptone-yeast extract agar plates which were incubated at several temperatures. Visible colonies of *S. piniformis* (1–2 mm in diameter) grew on the isolation media within 10–21 days.

Smaragdicoccus and Williamsia. Better procedures are needed to establish the numbers, distribution, and diversity of *Smaragdicoccus* and *Williamsia* strains in natural habitats. The sole strain of *S. niigatensis* was isolated from petroleum-contaminated soil by enrichment culture using hexadecane as the sole carbon source (Adachi et al. 2007). Single representatives of *Williamsia* species have been isolated from several habitats using standard isolation media with and without antibacterial antibiotics. *Williamsia maris* and *W. marianensis* were isolated from marine sediments using M3 agar and raffinose-histidine agar supplemented with antifungal antibiotics (Stach et al. 2004; Pathom-aree et al. 2006) and *W. limnetica* from a freshwater sediment on starch-casein agar containing antifungal antibiotics and rifampicin (Sazak and Sahin 2012). Similarly, the type strain of *W. faeni* was isolated

from suspensions of a hay meadow soil plated onto Gauze medium 2 supplemented with antifungal antibiotics, nalidixic acid, and novobiocin and incubated at 30 °C for 21 days (Jones et al. 2010).

Maintenance Procedures

Standard methods can be used for short- and long-term storage. Short-term preservation of cultures can be achieved by serial transfer onto media such as modified Bennett's (Jones 1949) and glucose-yeast extract (Gordon and Mihm 1962) agar slopes with storage between transfers at 4 °C. Lyophilization, preservation in liquid nitrogen, and frozen glycerol suspensions can be used for long-term storage. For lyophilization, propagules are suspended in a suitable fluid such as glucose serum or skimmed milk plus glucose (each at 7.5 %, v/v). For preservation in liquid nitrogen, organisms are grown on a suitable medium in small tubes and when sufficient growth is visible, the tubes are sealed with cotton wool plugs dipped in liquid paraffin wax, and then stored in a liquid nitrogen vessel. Glycerol suspensions are prepared by scraping growth from inoculated agar plates and making heavy suspensions in aqueous glycerol (3 mL) held in small vials which are stored at −20 °C (Wellington and Williams 1978). Frozen glycerol suspensions can be used as a long-term means of preservation and as a quick source of inoculum. Working inocula are prepared by thawing suspensions at room temperature and, after use, they are promptly frozen and stored again at −20 °C.

Ecology

Members of the genera *Nocardia*, *Gordonia* and *Rhodococcus* are common in aquatic and terrestrial habitats where they are considered to have a role in organic matter turnover and in the degradation of xenobiotics (Cross et al. 1976; Goodfellow and Williams 1983; Larkin et al. 2010; Luo et al. 2013a). The most comprehensive ecological studies on these and other mycolic acid–containing actinomycetes, notably skermaniae, have been focused on their presence, abundance, and activities in activated sludge wastewater treatment plants (Soddell and Seviour 1990; de los Reyes et al. 2002; Seviour et al. 2008; Seviour and Nielsen 2010). However, nocardiae are best known as causal agents of mycetoma and nocardiosis (McNeil and Brown 1994; Goodfellow 1992,1996; 1998; Brown-Elliott et al. 2006; Goodfellow and Maldonado 2012; van de Sande et al. 2013) though gordoniae and *Rhodococci* are being recognized increasingly as opportunistic pathogens of humans (Jones and Goodfellow 2012; Goodfellow et al. 2012; Drzyzga 2012). It is also becoming increasingly apparent that "*P. equi*" is an agent of human disease (Jones and Goodfellow 2012) though this organism is best known as a serious pathogen of foals (Barton and Hughes 1980; Prescott 1991; Vásquez-Boland et al. 2010).

The ecology, pathogenicity, and biotechnological applications of the genera *Nocardia*, *Gordonia*, *Rhodococcus*, and "*Prescotella*" will be considered further. However, little more can be said about the genus *Williamsia* as so few strains have been assigned to this taxon and even less about the genera *Millisia* and *Smaragdicoccus* as these taxa are currently represented by two and a single strain, respectively.

Nocardia. Nocardiae are widely distributed in diverse natural habitats (Cross et al. 1976; Goodfellow and Williams 1983; Goodfellow and Maldonado 2012). Some strains have been found to form endophytic associations with plants (Kaewkla and Franco 2011; Xing et al. 2011; Zhao et al. 2011) and others form mutualistic associations with blood-sucking insects (Cross et al. 1976; Xu et al. 1996; Yamamura et al. 2003b). However, their primary habitat seems to be soil as large populations (up to 1.4×10^5 colony forming units per gram of soil) have been reported for temperate and tropical soils (Orchard et al. 1977; Xu et al. 1996). In addition, many nocardiae have been detected in litter and soil from a spruce forest in County Durham, UK (Golinska et al. 2012), from sediment and water samples from freshwater lakes in Yunnan Province in Southwest China (Jiang and Xu 1985, 1996), from soil amended with either sewage effluent or dried sludge (Orchard et al. 1977; Orchard 1979, 1981), and from oil-contaminated soil (Khan et al. 1997).

Relatively little is known about the functional roles of nocardiae in natural habitats though there is evidence that they are involved in organic matter turnover (Orchard 1979, 1981). They have been implicated in the biodeterioration of natural rubber joints in water and sewage pipes (Hutchinson et al. 1979; Hookey 1984) and in foam formation in activated sludge plants (Soddell and Seviour 1990; Seviour and Nielsen 2010) though it would seem that their role in this latter respect has been overplayed (Soddell et al. 1992; Stainsby et al. 2002). The unfolding metabolic activity of nocardiae isolated from environmental sources is in sync with a saprophytic lifestyle (Goodfellow and Maldonado 2012; Luo et al. 2013a), as shown by the ability of *N. nova* and *N. takedensis* strains to degrade natural rubber and microbial gutta percha (Warneke et al. 2007; Luo et al. 2013b).

Improved nocardial systematics has been the motive force behind the rapid increase in the number of *Nocardia* species isolated from environmental sources (Goodfellow and Maldonado 2012). Novel species recovered from aquatic and littoral habitats include *N. grenadensis* from Caribbean Sea sand (Kämpfer et al. 2012), *N. harenae* from beach sand (Seo and Lee 2006), and *N. takedensis* from activated sludge scum (Yamamura et al. 2005). Similarly, novel taxa derived from terrestrial habitats include *N. aciditolerans* from litter and soil horizons of a spruce forest (Golinska et al. 2012), *N. altamirensis* from a cave soil (Jurado et al. 2008), *N. artemsiae* from a surface-sterilized stem of *Artemesia annua* (Zhao et al. 2011), *N. callitritis* from a surface-sterilized root of a native Australian pine tree (Kaewkla and Franco 2010), *N. endophytica* from a healthy stem of *Jatropha curcas* (Xing et al. 2011), *N. goodfellowii* and *N. thraciensis* from Turkish soils (Sazak and Sahin 2012), and *N. neocaledoniensis* from a brown hypermagnesian ultramafic soil (Saintpierre-Bonaccio et al. 2004). Studies such as these provide a useful insight into the

distribution and species diversity of nocardiae, but are of limited ecological value as species descriptions tend to be based on single isolates.

Gordonia. Interest in the biotechnological potential of gordoniae and improvements in their systematics has led to a substantial increase in the number of validly published *Gordonia* species (Arenskőtter et al. 2004; McLeod et al. 2006; Drzyzga 2012; Goodfellow et al. 2012). Expressions of this taxonomic trend include the recognition of *G. alkaliphila* from a tidal flat sediment (Cha and Cha 2013), *G. caeni* and *G. cholesterolivorans* from sewage sludge (Drzyzga et al. 2009; Srinivasan et al. 2012), *G. defluvii* from activated sludge foam (Soddell et al. 2006b), *G. humi* from soil (Kämpfer et al. 2011a), *G. lacunae* from an estuarine sand sample (le Roes et al. 2008), and *G. neofelisfaecis* from fresh feces of a clouded leopard (Liu et al. 2011a).

Gordoniae are widely distributed in aquatic and terrestrial ecosystems and have been found in especially high numbers in foaming-activated sludge plants across the world (Soddell and Seviour 1990; Goodfellow et al. 1996, 1998b; Lechevalier and Lechevalier 1974; Soddell et al. 1992), but it is now apparent that taxonomically diverse mycolic-acid-containing actinomycetes are implicated in this process (Petrovski et al. 2011c), including *G. defluvii* (Soddell et al. 2006b), *M. brevis* (Soddell et al. 2006a) and *S. piniformis* (Chun et al. 1997). The outer mycolic acid layer of the walls of such actinomycetes is considered to render cells sufficiently hydrophobic that they accumulate on the surfaces of aeration tanks in wastewater treatment plants (Seviour and Nielsen 2010).

Gordonia amarae is used as the model organism to establish relationships between foaming and numbers of mycolic acid-containing actinomycetes in activated sludge plants. To this end, oligonucleotide hybridization studies were used to identify and quantify *G. amarae* and related foam-inducing actinomycetes (de los Reyes et al. 1997, 1998a, b, c, Oerther et al. 1999; Iwahori et al. 2001); a cause-effect relationship was eventually reported between foaming and levels of *G. amarae* cells (de los Reyes and Raskin 2002). Similarly, Davenport et al. (2000) reported a relationship between foaming and the concentration of mycolic acid–containing actinomycetes in a mixed activated sludge reactor using a quantitative fluorescent in situ hybridization (FISH) procedure. However, ecophysiological studies on *G. amarae* cast doubt on the relationship between filament numbers determined using FISH and incidents of foaming (Carr et al. 2006). Indeed, laboratory-based foaming tests carried out on diverse mycolic acid–containing actinomycetes indicated that stable foam formation required three components: air bubbles, surfactants, and hydrophobic cells (Petrovski et al. 2011c). It was also shown that the ability to generate foam depended on a threshold cell number which varied between individual strains and was reduced markedly in the presence of surfactant. These data challenge the concept that a universal threshold is applicable to all mycolic acid–containing actinomycetes involved in foaming. To complicate matters further, differences in substrate utilization patterns of FISH probed *G. amarae* have been established in samples taken from different activated sludge plants (Kragelund et al. 2007). It has been shown that *G. amarae* causes foaming problems when biosurfactants are synthesized in the presence of hexadecane (Pagilla et al. 2002).

The remarkable metabolic versatility shown by gordoniae suggests that they are involved in the degradation of recalcitrant organic compounds in water and soil though ecophysiological studies are needed to determine whether this is so. However, *Gordonia* strains are known for their capacity to survive near-starvation conditions (Warhurst and Fewson 1994) and to metabolize toxic environmental pollutants, as well as natural and synthetic isoprene rubber (Arenskőtter et al. 2004; Drzyzga 2012).

Rhodococcus. Relatively little is known about the numbers, distribution, and roles of *Rhodococci* in natural habitats though they are common in soil and in freshwater and marine sediments (Goodfellow and Williams 1983; Jiang and Xu 1996; Colquhoun et al. 1998) and have been isolated from the gut contents of blood-sucking arthropods with which they form mutualistic associations (Cross et al. 1976; Goodfellow and Aubert 1980; Yassin 2005). An extensive ecological study was carried out on *R. coprophilus* by Rowbotham and Cross (1977b) who found that this organism grew on herbivorous dung and was present in high numbers in grazed pastures, and in streams, rivers, and lake muds that received run-off from dairy farms. Al-Diwany and Cross (1978) found a significant correlation between the numbers of fecal streptococci and *R. coprophilus* in polluted water and suggested that the latter might be used as an indicator of farm animal effluent, a view that was to be shared by others (Mara and Oragui 1981; Oragui and Mara 1985).

Relatively little is known about the ecology of other *Rhodococcus* species though *R. erythropolis*, *R. rhodochrous*, and *R. ruber* seem to be common in soil (Goodfellow and Williams 1983) and in activated sludge foam (Lemmer and Kroppenstedt 1984; Sezgin et al. 1988). *Rhodococcus gordoniae*, *R. intechensis*, and *R. quinshengii* were isolated from contaminated landsites (Jones et al. 2004; Ghosh et al. 2006; Xu et al. 2007), *R. koreensis* and *R. pyridinivorans* from industrial wastewater (Yoon et al. 2000a, c), and *R. coprophilus* from both aquatic and terrestrial habitats (Rowbotham and Cross 1977a, b). Other rhodococcal species have been isolated from more rarified habitats, as exemplified by the isolation of *R. artemisiae* from the medicinal plant *Artemesia annua* (Zhou et al. 2012), *R. baikonurensis* from the MIR space station (Li et al. 2004), *R. cerastii* from *Trfolium repens* (Kämpfer et al. 2013b), *R. josti* from a medieval grave (Takeuchi et al. 2002), and *R. trialomae* from a blood-sucking insect belonging to the genus *Triatomae* (Yassin 2005). *Rhodococci* involved in foam formation in activated sludge plants (Lemmer and Kroppenstedt 1984; Mori et al. 1998; Sezgin et al. 1988; Lemmer et al. 1998; Stainsby et al. 2002) have received little attention from either ecophysiological or taxonomic perspectives. However, representatives of several rhodococcal species produce stable foam under laboratory conditions though on the cessation of aeration, the foam films proved to be unstable (Petrovski et al. 2011c). Strains identified as *R. coprophilus*, *R. erythropolis*, *R. rhodochrous*, and *R. ruber* have been isolated from activated sludge foam

(Lemmer and Kroppenstedt 1984; Sezgin et al. 1988). Davenport et al. (1998) designed two genus-specific 16S rRNA oligonucleotide gene probes and used them to detect *Rhodococci* in samples of activated sludge foam using confocal laser scanning microscopy.

"***Prescotella***". Members of this monospecific genus are best known as facultative intracellular multihost pathogens (Letek et al. 2010; Vásquez-Boland et al. 2010). However, the natural environment of "*P. equi*" is soil, notably ones enriched with fecal material from domestic and wild animals (Barton and Hughes 1980; Prescott 1991; Takai et al. 1986, 2006). It is possible that the organism contributes to foaming in activated sludge plants as under laboratory conditions, two "*P. equi*" strains were found to produce stable foams (Petrovski et al. 2011c). Additional studies are needed to unravel the biology of "*P. equi*" in the environment.

Skermania. Skermaniae are associated with foaming-activated sludge plants in Australia (Blackall et al. 1988, 1989; Seviour et al. 1990; Soddell and Seviour 1994, 1998) and other parts of the world (de los Reyes et al. 2002; Eales et al. 2005; Soddell and Seviour 1990; Soddell et al. 1993). It is not known whether the organism is more widely distributed in the environment as all strains to date have been isolated from foam and mixed liquor systems by micromanipulation of pine-tree-like organisms (PTLOs; alias *S. piniformis*) onto rich nutrient media followed by incubation for up to 3 weeks. There is also evidence that *S. piniformis* has a slow growth rate in activated sludge (de los Reyes et al. 2002).

PTLOs have been the subject of several ecophysiological studies based on the use of in situ techniques, notably fluorescent in situ hybridization/microautoradiography (FISH/MAR) studies (Seviour et al. 2008). Using this latter procedure, Eales et al. (2005) found that PTLOs were highly selective in their substrate utilization in foams as out of eight substrates, they only assimilated oleic acid; this compound was metabolized both aerobically and anaerobically though uptake was low under anoxic conditions with nitrate and nitrite as oxygen accepters. Eales and her colleagues showed that a high proportion of the PTLOs were metabolically inactive in the foam. Most exhibited low respiratory activity as detected using the redox dye CTC and low intensity signals from FISH probing with 16S rRNA targeted probes. They also found a strong correlation between the accumulation of polyhydroxyalkanoates in filaments and the intensity of their fluorescent FISH signals.

Pathogenicity

Members of the family *Nocardiaceae* other than some *Nocardia* species and "*P. equi*" are usually considered to have a saprophytic lifestyle. However, it is becoming increasingly evident that mycolic acid–containing bacteria per se should be seen as potential opportunistic pathogens of humans (Koerner et al. 2009; Drzyzga 2012; Jones and Goodfellow 2012). Consequently, unusual *Nocardiaceae* strains isolated in diagnostic microbiological units should not be summarily dismissed as being of little consequence. However, within the family, pathogens have only been detected, to date, in the genera *Nocardia*, *Gordonia*, *Rhodococcus*, and "*Prescotella*."

Nocardia. Strains belonging to this genus are being reported with increasing frequency from clinical material, notably from specimens taken from immunocompromised patients (Poonwan et al. 1995, 2005; Boiron et al. 1998; Farina et al. 2001, 2007; Pintado et al. 2002; Saubolle and Sussland 2006; Serrano et al. 2007; Cargill et al. 2010). In this context, nocardiae are known best as causal agents of suppurative and granulomatous diseases of humans and animals, notably mycetoma and nocardiosis (Boiron et al. 1993; Beaman and Beaman 1994; McNeil and Brown 1994; Goodfellow 1996, 1998; Brown-Elliott et al. 2006; Goodfellow and Maldonado 2012; Luo et al. 2013a; van de Sande et al. 2013a).

Mycetoma, a major health problem in many tropical and subtropical regions, is caused by aerobic, filamentous actinomycetes (actinomycetoma) and by fungi (eumycetoma). It is an infection of subcutaneous tissue that is characterized by large tumor-like swellings mainly located at the extremities (Schaal and Beaman 1984; Fahal 2004, 2006; Brown-Elliott et al. 2006). The disease is mainly confined to tropical and subtropical areas, in Mexico, Senegal, and Sudan, though its true incidence and prevalence are not known (van de Sande 2013). Such gaps in our knowledge about mycetoma may now be addressed with greater vigor as the disease has been added to the World Health Organisation's list of Tropical Neglected Diseases (van der Sande et al. 2013a, b).

About 60 % of human mycetoma is caused by actinomycetes (Vera-Cabrera et al. 2004), mainly by *N. asteroides*, *N. brasiliensis*, *N. otitidiscaviarium*, and *N. transvalensis* (Buot et al. 1987; Beaman and Beaman 1994; Mirza and Campbell et al. 1996; Lum and Vadmal 2003; Fahal 2004). *Nocardia brasiliensis*, the major causal agent, is responsible for the vast majority of cases in Mexico (Lopez-Martinez et al. 1992). Other *Nocardia* species, such as *N. africana*, *N. mexicana*, and *N. veterana*, have been reported to cause human mycetoma (Hamid et al. 2001; Kano et al. 2002; Rodrigues-Nava et al. 2004). Mycetoma has been simulated in a mouse model (Gonzalez-Ochoa 1973; Zlotnik and Buckley 1980; Salinas-Carmona et al. 2011) that has been used to study host-parasite relationships (Ortiz-Ortiz et al. 1984; Zlotnik 2007).

Nocardiosis, unlike actinomycetoma, has a worldwide distribution. It tends to develop as an opportunistic infection that complicates primary diseases, such as leukemia, lymphoma, and other neoplasms (McNeil and Brown 1994; Brown-Elliott et al. 2006), other predisposing factors include steroid therapy, chronic bronchopulmonary disease, organ transplantations, and acquired immunodeficiency syndrome (Poonwan et al. 1995; Choucino et al. 1996; Gallant and Ko 1996; Patel and Paya 1997; Diego et al. 2005). Immunocompetent hosts can be infected usually after traumatic inoculation into skin (Beaman and Beaman 1994; Maraki et al. 2004). Accurate diagnosis and treatment of the disease still depends on the isolation and identification of the causal organism (Brown-Elliott et al. 2006; Goodfellow and Maldonado 2012). Many in vitro antibiotic

sensitivity assays have been carried out on *Nocardia* strains (Goodfellow and Orchard 1974; Wallace et al. 1983; Boiron and Provost 1988, 1990b; Vera-Cabrera et al. 2004), some of which have influenced antibiotic regimes recommended for treating nocardial infections (Brown-Elliott et al. 2006; Minero et al. 2009; Wilson 2012; van de Sande et al. 2013b).

Clinically human cases of nocardiosis can be described as skin infections (cutaneous, subcutaneous and lymphocutaneous), pulmonary and extrapulmonary, and systemic infections (Schaal and Beaman 1984; Schaal 1998). Cutaneous and lymphocutaneous infections are usually due to *N. asteroides*, *N. brasiliensis*, *N. farcinica*, and *N. transvalensis*, and pulmonary and systemic infections to these taxa together with *N. africana*, *N. mikami*, *N. nivae*, *N. pseudobrasiliensis* and *N. veterana* (Torres et al. 2000; Hamid et al. 2001; Farina et al. 2001, 2007; Conville et al. 2003; Pottumarthy et al. 2003; Jannat-Khah et al. 2010; Moser et al. 2011). In Thailand, the most prevalent agents of nocardiosis were found to be *N. beijingensis*, *N. cyriacigeorgica*, and *N. farcinica* (Poonwan et al. 2005). Nocardiae isolated from abscesses include *N. abscessus* (Yassin et al. 2000), *N. niigatensis* (Kageyama et al. 2004c), *N. nova* (Hamdad et al. 2007), *N. puris* (Yassin et al. 2003), and *N. yamanashensis* (Kageyama et al. 2004c).

Initially, nocardiosis was seen to be a late presenting, community-acquired infection, but it is now known that it is a transmissible disease (Young et al. 1971; Cox and Hughes 1975; Exmelin et al. 1996). Nosocomial infections caused by *N. asteroides* have been reported from liver (Sahathevan et al. 1991) and renal transplant (Houang et al. 1980; Baddour et al. 1986) units. Similarly, *N. farcinica* was found to be responsible for postoperative wound infections in patients undergoing vascular surgery (Schaal 1991). This organism is a particularly serious and versatile pathogen which can cause cerebral, cutaneous, and pulmonary abscesses (Schaal and Lee 1992; Kageyama et al. 2001; Hitti and Wolff 2005; Farina et al. 2007).

Nocardiae cause infections other than mycetoma and nocardiosis. Nocardial infections have been recorded in HIV patients (Kim et al. 1991; Javaly et al. 1992; Poonwan et al. 1995) and, more specifically, as the cause of brain abscesses (Barnaud et al. 2005; Hashimoto et al. 2008), endocarditis (Watson et al. 2001; Cargill et al. 2010), keratitis (Lalitha et al. 2006, 2012), and pleural emphysema (Maraki et al. 2006). It can be concluded that nocardiae are not only widespread in natural habitats but also in clinical settings where they can cause serious, sometimes fatal infections (Martinez et al. 2008; Minero et al. 2009). The recent dramatic increases in the reported frequency in nocardial infections can be attributed to the widespread use of immunosuppressive drugs and to raised clinical and microbiological awareness (Goodfellow 1996, 1998; Poonwan et al. 2005; Brown-Elliott et al. 2006). Mice have been used extensively as the experimental animal to study *Nocardia*-host interactions (Beaman 1973, 1984, 1992, 1993; Beaman and Ogata 1993; Beaman and Beaman 1994, 1998, 2000).

Nocardia strains cause infections in domesticated and wild animals (Beaman and Sugar 1983; Beaman and Beaman 1994; Ramos-Vara et al. 2007). Mastitis can be a serious problem in dairy animals, notably cows (Bushnell et al. 1979; Battig et al. 1990; Stark and Anderson 1990; Da Costa et al. 1999). *Nocardia farcinica* was implicated in an epizootic infection of cattle in Canada (Manninen et al. 1993); this organism is a significant cause of mastitis of goats in Sudan (Maldonado et al. 2004). The most frequently identified nocardial pathogens of animals are *N. asteroides*, *N. brasiliensis*, and *N. otitidiscaviarum*. In addition, *N. africana* has been isolated from a feline mycetoma (Hattori et al. 2003), *N. crassastreae* causes nocardiosis in Pacific oysters (Friedman et al. 1998), and *N. salmonicida* and *N. seriola* are fish pathogens (Kudo et al. 1988; Isik et al. 1999).

The mechanisms involved in nocardial pathogenicity and host immunity to nocardial infections have been extensively studied by Blaine Beaman and his colleagues (Beaman and Moring 1988; Beaman and Beaman 1994, 1998, 2000) who found that virulent strains of *N. asteroides* appeared to be influenced by several interrelating factors, such as the stage in the growth cycle, capacity to inhibit phagosome-lysozyme fusion, to resist oxidative killing mechanisms of phagocytes, and to alter enzymes within phagocytes. However, the factors involved in host resistance to nocardial infections are complex and remain poorly understood. The role of L-forms in nocardial infections also requires further study (Beaman 1992).

Gordonia. Most gordoniae have been isolated from environmental sources, but some have been associated with human infections in immunocompromised and immunocompetent patients from around the time the genus was validly published in 1988 (Richet et al. 1991; Riegel et al. 1991; Drancourt et al. 1997). Gordonial infections are on the increase mainly in immunocompromised patients with underlying health problems, such as those with pulmonary conditions (Drzyzga 2012; Goodfellow et al. 2012). In many cases, infections occur after major surgery and are associated with medical devices, such as heart machines and catheters (Jannat-Khan et al. 2009; Drzyzga 2012). Gordoniae have also been reported to cause abscesses (Drancourt et al. 1994; Werno et al. 2005), cutaneous infections (Zardawi et al. 2004), endocarditis (Lesens et al. 2000; Verma et al. 2006), mycetoma of the hand (Bakker et al. 2004), septicaemia (Kempf et al. 2004), but they are most frequently associated with catheter-related bacteremia (Pham et al. 2004; Blaschke et al. 2007; Renvoice et al. 2009; Lal et al. 2010).

A better understanding of the incidence, epidemiology, and clinical significance of *Gordonia* strains is needed. These aims should be fostered by improvements in gordonial systematics, as exemplified by the recognition of new pathogenic species. *Gordonia aria* was proposed for an organism isolated from the sputum of a patient with bacterial pneumonia (Kageyama et al. 2006), *G. effusa* from a patient with kidney malfunction (Kageyama et al. 2006), and *G. otitidis* from patients with bronchitis and external otitis (Iida et al. 2005). To date, gordoniae have not been associated with infections of animals, apart from a case of mesenteric lymphadenitis in pigs (Tsukamura et al. 1988).

"***Prescotella***." "*Prescotella equi*" is a facultative intracellular pathogen that is best known as a cause of severe suppurative

bronchopneumonia in foals (Barton and Hughes 1980; Prescott 1991; Vásquez-Boland et al. 2010). The prevalence and fatalities of "*P. equi*" pneumonia are high (Takai et al. 1995; Prescott 1991). Infections of animals other than horses are rare though a broad range of domesticated and wild animals are known to have been infected. An increasing number of "*P. equi*" infections are being recorded in cats and dogs (Patel 2002; Takai et al. 2003) and goats (Tkachuk-Saad et al. 1998; Kabongo et al. 2005). The typical expression of "*P. equi*" pneumonia is as a chronic suppurative bronchopneumonia with extensive abscess formation and associated lymphadenitis (Barton and Hughes 1980; Prescott 1991). Foals are typically infected within the first 5 months of birth probably due to the relative immaturity of the immune system in individual foals (Hooper-McGrevy et al. 2001; Chaffin et al. 2004; Darrah et al. 2004). Nearly all strains isolated from infected foals have the virulent 30–90 kB plasmid which encodes the 15–17 kDA protein, Vap A (Takai et al. 1991a, b, 2003). Loss of this plasmid leads to an inability to cause disease in foals (Hondalus and Mosser 1994; Giguere et al. 1999). The variant plasmid encoding Vap B has been identified in non-equine animal hosts (Oldfield et al. 2004; Letek et al. 2010). Strains which lack Vap A and B proteins are relatively common in non-equine isolates (Meijer and Prescott 2004).

The mechanisms involved in "*P. equi*" pathogenicity will only be touched upon here as they have been considered in detail elsewhere (Prescott 1991; Meijer and Prescott 1994; Vásquez-Boland et al. 2010). Once access to the host has been gained, cells of "*Prescotella equi*" are engulfed by macrophages in the lungs. Central to the pathogenicity of the organism is its ability to survive and replicate in alveolar macrophages (Hondalus and Mosser 1994). A key survival mechanism is the active manipulation of the endosomal pathway of the host (Fernandez-Mora et al. 2005; Toyooka et al. 2005). Intracellular proliferation of the pathogen eventually causes the death of macrophages and extensive damage to lung tissue characterized by cavitation and granuloma formation (Luhrmann et al. 2004; Meijer and Prescott 2004). "*Prescottella equi*" is increasingly being seen as a pathogen of immunocompromised humans, particularly those with AIDS (McNeil and Brown 1994; Kedlaya et al. 2001; Weinstock and Brown 2002). The clinical presentation of infections in humans reflects the immune condition of the host and the virulence of the pathogen. Infections range from localized to fatal systemic infections (Nasser and Bizri 2001; Kohl and Tillmanns 2002; Kamboj et al. 2008). The first fatal case of a "*P. equi*" infection in a previously healthy individual was reported by Gabriels et al. (2006).

Rhodococcus. *Rhodococci* are common in the environment but have been rarely implicated as human pathogens, mainly as agents of pulmonary disease in severely immunocompromised individuals (Osoagbaka 1989; McNeil and Brown 1994). *Rhodococcus globerulus* and *R. ruber* have been considered agents of keratitis (Cuello et al. 2002; Lalitha et al. 2006, 2012) and a *Rhodococcus* strain as the cause of osteomyelitis in a healthy immunologically normal young girl (Broughton et al. 1981). There is evidence that *Rhodococci* can cause mycetoma (Severo et al. 1987). It seems likely that the clinical presentation of rhodococcal infections will be influenced by the immune state of the host and the virulence of the pathogen, but at present, there is little information on either of these matters. In contrast, *R. fascians* is a well-known pathogen of numerous plants (Crespi et al. 1992; Veereke et al. 2005; Putnam and Miller 2007).

Rhodococcus fascians is a soil-borne pathogen that induces the formation of differentiated galls in many herbaceous plants (Putnam and Miller 2007). Galls consist of proliferating masses of meristematic tissue covered by very short hypertrophied shoots (shoot hyperplasia) that appear at the crown of infected plants (de O Manes et al. 2001; Goethals et al. 2001). These symptoms are triggered by cytokinins secreted by the colonizing bacteria, these induce a signaling cascade leading to activation of mitotic cell division, prevention of endoreplication, and ectopic expression of meristem-specific KNOX genes (Crespi et al. 1992, 1994; Depuydt et al. 2008, 2009a). The establishment of the disease in *Arabidopsis thaliana* has been studied extensively, notably by using an integrated genomics approach (Depuydt et al. 2009b). The severity of the disease induced by the pathogen is influenced by the route of infection and by the age and type of the plant (Vereeke et al. 2000).

The virulence determinants for the *R. fascians*-plant interaction are located on a linear plasmid, pFiD 188 (Vereecke 1997; Crespi et al. 1992, 1994; Stange et al. 1996; Temmerman et al. 2000). Two bacterial loci, *atl* and *fas*, are needed for complete virulence (Cornelis et al. 2002). The *alt* operon is involved in the biosynthesis of regulatory compounds that are necessary to induce *alt* and *fas* gene expression and are induced during the interaction with the plant (Maes et al. 2001). The *fas* operon encodes proteins, including an isopentenyl transferase which is involved in the biosynthesis of a compound that shows cytokinin activity (Crespi et al. 1992, 1994; Temmerman et al. 2000). It is thought that novel compounds produced by the pathogen disrupt plant hormone balances, eventually leading to disease (Vereeke et al. 2000). Temmerman et al. (2000) isolated an AraC-type regulatory gene, *fasR*, located on the linear plasmid pFi D188, and found that it was required for pathogenicity and *fas* gene expression.

Applications

It is apparent from earlier sections and from recent reviews of the literature that members of the family *Nocardiaceae*, especially *Gordonia*, *Nocardia*, and *Rhodococcus* strains, show extraordinary metabolic diversity that can be exploited for biotechnological applications (Larkin et al. 1998, 2005, 2006; Drzyzga 2012; Luo et al. 2013a), especially given the availability of toolkits for genetic engineering (McLeod et al. 2005; Larkin et al. 2010; Luo et al. 2013a). The increasing interest that is being shown in *Nocardiaceae* strains as a source of commercially significant primary and secondary metabolites and as agents of biodegradation and bioremediation reflects these developments (Drzyzga 2012; Luo et al. 2013a). Applications that have been

established already or which might be commercially useful in the future are considered below.

Biodegradation and Bioremediation

Nocardiaceae strains are common in natural ecosystems where, given their metabolic prowess, they can be expected to have an integral role in the turnover or organic matter and in the degradation of xenobiotic compounds. Indeed, given the ability of gordoniae, nocardiae and rhodococci to grow in polluted habitats makes them serious candidates for the bioremediation of industrially polluted sites and for the management of agricultural and urban waste (Warhurst and Fewson 2010; Larkin et al. 2005, 2010; Kuyukina and Ivshina 2010; Drzyzga 2012; Luo et al. 2013a). *Rhodococci*, for instance, are especially effective at degrading aromatic and aliphatic amides and nitriles and hence are of potential value for waste cleanup where these chemicals are produced (Bunch 1998; Heald et al. 2001; Martínková et al. 2010).

Enzymes

Presently the most important bioactive compounds synthesized by members of the family *Nocardiaceae*, notably by *Rhodococcus* strains, are enzymes (Tarnók 1976; Peczynska-Czoch and Mordarski 1988; Warhurst and Fewson 1994; Alvarez 2010b). Such enzymes are of current or potential use in several areas of biotechnology, such as clinical chemistry, medicinal therapy, and in the manufacturing of fine and bulk chemicals. In general, the value of *Nocardiaceae* strains in the commercial production of enzymes is enhanced by their high yield, cost efficiency, and susceptibility to genetic manipulation.

Nocardia. Members of this taxon are attracting considerable interest in academic and industrial circles as the extent of their metabolic versatility begins to unfold (Goodfellow and Maldonado 2012; Luo et al. 2013a, b). Some strains, notably *N. iowensis* NRRL 5646^T (Lamm et al. 2009), synthesize an extraordinary diversity of biotransforming enzymes that convert natural and synthetic compounds into valuable products such as novel carnosic acid derivatives (Hosny et al. 2002), flavanoids (Maatooq and Rosazza 2005), vanillic acid (Dhar et al. 2007), and 4-vinylphenol (Lee and Rosazza 2004). This organism contains the first nitric oxide synthase system characterized in prokaryotes (Chen and Rosazza 1994, 1995).

Gordonia. The number of compounds of biotechnological significance synthesized by *Gordonia* species is on the rise as the extent of their metabolic capabilities is realized (Arenskőtter et al. 2004; Goodfellow et al. 2012; Drzyzga 2012). Gordoniae are, for instance, a potential source of carotenoid pigments (De Miguel et al. 2000, 2001; Takaichi et al. 2008), novel steroids (Schneider et al. 2008; Liu et al. 2011b) and biosurfactants, including gordonan (Kondo et al. 2000; Drzyzga et al. 2009; Franzetti et al. 2009).

Gordoniae are also of interest given the ability of some strains to remove sulfur from hydrocarbons, notably from fossil fuels (Ma 2010). Most work on biological desulfurization systems use dibenzothiophene (DBT) or benzothiophene as model compounds (Gilbert et al. 1998; Kim et al. 1999, 2000; Matsui et al. 2001a; Santos et al. 2006). The pathway specifically involved in cleaving C-S bonds during metabolic desulfurization has been dubbed the "4S" pathway (Gallagher et al. 1993; Kilbane 2006), as four different molecules are formed during DBT desulfurization (Ma 2010). Sulfur removal mediated by bacteria is seen as a potential alternative to the deep hydrodesulfurized processes used in oil refineries to produce low sulfur fuel oils. *Gordonia* sp. strain CYKS1, the first member of the genus shown to be capable of dibenzothiophene desulfurization (Rhee et al. 1998), was used as a desulfurization catalyst in a two stage process developed by Chang et al. (2001) for the treatment of model and diesel oils, a process that was subsequently optimized (Choi et al. 2003).

Rhodococcus. Rhodococcal enzymes have received the most attention, notably as biocatalysts in industrial processes (Martínková et al. 2010; Ma 2010). In particular, *Rhodococci* have a remarkable capacity to synthesize enzymes that transform nitrile compounds (Beard and Page 1998; Hughes et al. 1998; Martínková et al. 2010). The enzymes involved in this process are the nitrilases, which catalyze the hydration of nitriles to amides (Bunch 1998). Many rhodococcal enzymes are able to convert synthetic nitriles into amides and acids have been found and some of these conversions have been developed commercially. Such biotransformations are an attractive alternative to chemically catalyzed reactions as they proceed at moderate temperatures, at near neutral pH, and yield highly pure products without the formation of undesirable by-products (Beard and Page 1998; Hughes et al. 1998; Martínková et al. 2010). The first successful biocatalyst process involving the production of a commodity chemical was the nitrile hydrolase catalyzed process for the production of acrylamide developed by the Nitto Chemical Industrial Company in collaboration with Kyoto University (Kobayashi et al. 1992).

Currently, the production of acrylamide is carried out by the Mitsubishi Rayon Company using immobilized cells of *R. rhodochrous* strain J1 (Martínková et al. 2010). The versatile nitrile hydratase synthesized by this strain is induced when the culture medium is supplemented with cobalt and crotonamide (Nagasawa et al. 1988, 1993; Nagasawa and Yamada 1990; Yamada and Kobayashi 1996); approximately 30,000 t of acrylamide are produced annually using this process. The same biocatalyst is used for the production of nicotinamide by Lonza AG (Shaw et al. 2003). Nitrilases have been used to manufacture fine chemicals on a small scale, such as 6-hydroxypicolinic acid (Lonza AG; Liese et al. 2000) and (R)-mandelic acid and (R)-3-chloromandelic acid (Mitsubishu Rayon Co., Brady et al. 2004). The application of nitrile biocatalysts for other industrial applications is promising, given encouraging results from laboratory scale experiments (Brady et al. 2004; Martínková et al. 2010).

Rhodococci have been examined extensively to determine their suitability for large-scale removal of sulfur from fossil fuels (Ma 2010). Most attention has been focused on *R. erythropolis* IGTS8, notably on the enzymes and genes involved in the DBT desulfurization pathway (Kilbane and Jackowzki 1992; Oldfield et al. 1997, 1998; Santos et al. 2007). This organism was isolated by Kilbane and Bielaga (1990) and used by Energy Biosystems Corporation in the development of their industrial microbial desulfurization strategy. The "4" pathway for sulfur removal mentioned earlier was first reported in *R. erythropolis* IGTS8 (Gallagher et al. 1993). Several mutants of this strain have been genetically engineered to increase its ability to effect the desulfurization process (Hirasawa et al. 2001; Matsui et al. 2001b; Holland et al. 2003). The influence of operational conditions during batch culture of strain IGTS8 was examined by Del Olmo et al. (2005) who proposed a kinetic model to describe the development of its desulfurization ability during growth. Extensive desulfurization of diesel fuels was achieved by Zhang et al. (2007) using a *R. erythropolis* strain isolated from oil-contaminated soil.

Rhodococcus strains are a potential source of carotenoid pigments (Tao et al. 2004, 2006) and novel bioflocculants and biosurfactants (Lang and Philp 1998; Kuyukina and ivshina (2010). Carotenoids synthesized by *R. erythropolis* have been characterized as 4-keto-γ-carotene and γ-carotene, respectively (Tao et al. 2004). In an additional study, the β-carotene gene (crtU) from *Brevibacterium linens* was expressed in *R. erythropolis* to produce chlorobactene, an asymmetrical aryl carotenoid which has a similar structure to the food colorant isorenieratene (Tao et al. 2006); the former has potential as a colorant that gives a different shade of color than isorenieratene and its hydroxyl derivatives (Dufossé et al. 2001). Rhodococcal biosurfactants are attractive for certain applications due to their biodegradability, low toxicity, and nonionic properties, as well as their pH and temperature stability (Ristau and Wagner 1983; Rapp and Gabriel-Jűrgens 2003). Particular attention has been paid to trehalose mycolates, notably those from *R. erythropolis* and *R. wratislaviensis* strains (Kim et al. 1990; Tuleva et al. 2008; Marques et al. 2009).

Secondary Metabolites

New drugs, notably antibiotics, are urgently needed to control the spread of antibiotic-resistant pathogens and to treat life-threatening diseases such as cancer (Donadio et al. 2010; Goodfellow and Fiedler 2010; Cragg and Newman 2013). Actinomycetes, notably streptomycetes, remain the richest source of novel antibiotics though relatively few of the nearly 14,000 known antibiotic compounds produced by actinomycetes have been derived from members of the family *Nocardiaceae* (Bérdy 2012). However, evidence from whole-genome sequences indicates that *Nocardiaceae* strains have the capacity to produce secondary metabolites (Ishikawa et al. 2004; McLeod et al. 2006; Vera-Cabrera et al. 2013). It is also known that some members of the family *Nocardiaceae*, notably *Nocardia* strains, are a source of novel secondary metabolites (Goodfellow and Maldonado 2012; Tiwari and Gupta 2012b; Luo et al. 2013a).

Nocardia. Several clinically significant *Nocardia* species have been found to produce novel antibiotics (Goodfellow and Maldonado 2012; Luo et al. 2013a). *Nocardia brasiliensis* strains are a particularly rich source of bioactive compounds, as exemplified by the discovery of brasilibactin A, a novel cytotoxic compound (Tsuda et al. 2005), brasilicardins A-D, new immunosuppressive terpenoid antibiotics (Shigemori et al. 1998; Komaki et al. 1989; Komatsu et al. 2004), brasilidine A, a cytotoxic indole alkaloid (Kobayashi et al. 1997), brasilinolides A and B, immunosuppressive macrolides (Shigemori et al. 1996; Komaki et al. 1998; Mikami et al. 2000), benzoquinones A-D, novel benz[a] anthroquinones (Nemoto et al. 1997; Tsuda et al. 1996, 1999) and nocarasins A-C, antibacterial benzenoid antibiotics (Tsuda et al. 1999).

Nocardia strains isolated from natural habitats have also been shown to synthesize novel bioactive compounds, as exemplified by nocadicin A, the first naturally occurring monocyclic β-lactam, from *N. uniformis* subsp. *tsuyamanesis* (Aoki et al. 1976) and tubelactomicin A, a 16-membered macrolide antibiotic isolated from a *Nocardia* strain (Igarashi et al. 2000) that was subsequently identified as *N. vinacea* (Kinoshita et al. 2001). Nocardiae exhibit other interesting biological activities, as shown with respect to the anthraqinone chrysophanol, the first secondary metabolic known to be synthesized in an organism-specific way, namely, through different folding mechanisms (Bringmann et al. 1996). These workers showed that *Nocardia* strain Acta 1057, an isolate from a hay meadow soil, produced chrysophanol through folding mode S, whereas eukaryotes (fungi, insects and plants) used folding mechanism F. A third folding mode, S′, was later found in *Streptomyces* strain AK671 (Bringmann et al. 2009).

New bioactive compounds derived from other clinically significant nocardiae include asterobactin, a siderophore with antitumor activity from *N. asteroides* (Nemoto et al. 2002), a cytotoxic macrolide from *N. otitidiscaviarum* (Mikami et al. 1990), immunosuppressive terpenoids from *N. terpenica* (Tanaka et al. 1997a; Hoshino et al. 2007), nocardiocyclines A and B, anthracyclines from *N. pseudobrasiliensis* (Tanaka et al. 1997b), and transvalecin A, a thiozolidine type antibiotic from *N. transvalensis* (Hoshino et al. 2004a, b). Additional novel compounds produced by *Nocardia* strains include the nocardichelins, siderophores with antitumor activity (Schneider et al. 2007), and the nocanthicins, thiazole peptide antibiotics that inhibit gram-positive bacteria (Leet et al. 2003; Li et al. 2003).

Gordonia. Bendigoles A ∼ C are the first secondary metabolites and first sterols to be isolated from a *Gordoniai strain* (Schneider et al. 2008). They were detected in a culture filtrate extract of "*G. australis*" Acta 2299 by HPLC-diode array analysis and characterized as novel steroids by mass spectrometry and NMR experiments; the strain was isolated from activated sludge foam collected from a Biological Nutrient Removal Plant, near

Bendigo, Victoria, Australia. Bendigole C showed binding affinity to human progesterone and bendigoles A∼C weak androgenic activities.

Rhodococcus. In general, *Rhodococci* have not been seen as a potential source of secondary metabolites though natural products have been detected in crude extracts of *Rhodococcus* strains by low resolution mass spectrometry (Geniloud et al. 2011). It has been suggested that *Rhodococcus* sp. strain RO4, a polychlorinated-biphenyl degrader, may be a source of bioactive steroid compounds (Yang et al. 2011). The discovery that *R. jostii* RHA1 contains 24 nonribosomal peptide synthase genes and seven polyketide synthase genes (McLeod et al. 2008) indicates that *Rhodococci* should not be overlooked in the search for novel bioactive compounds.

33 The Family *Nocardioidaceae*

Erika M. Tóth · Andrea K. Borsodi
Faculty of Science, Institute of Biology, Department of Microbiology, Eötvös Loránd University, Budapest, Hungary

Abstract
Nocardioidaceae, a family within the order *Propionibacteriales* in the Propionibacterinae, embraces the genera *Nocardioides, Marmoricola, Aeromicrobium, Kribbella, Actinopolymorpha, Thermasporomyces*, and *Flindersiella*. Recent analysis of 16S rRNA gene sequences (using different clustering algorithms) shows that the genera which currently belong to the family *Nocardioidaceae* form at least two separate phylogenetic clusters. The two clusters are approximately at the same distance from each other and also from the family *Propionibacteriaceae*. The grouping is strengthened also by morphological and chemotaxonomic features. They are Gram-positive bacteria. Young cultures within the family show different morphologies, ranging from branching vegetative hyphae and pleomorph shapes to irregular rods and coccoid cells. Chemoorganotrophic organisms, having respiratory type of metabolism, are mostly catalase positive. Their cell-wall peptidoglycan contains LL-diaminopimelic acid and glycine as diagnostic amino acid (peptidoglycan A3γ). Their predominant menaquinone component is with partially saturated side chain, consisting 8, 9, or 10 isoprene units. Mycolic acids are absent. Members of the family occur in various environments (soils, aquatic environments, plants, etc.); no medically relevant strains or species have been described within the family till now. Some members of the family are active in degradation of recalcitrant chemicals. This contribution is a modified and updated version of previous family descriptions (Nesterenko et al. 1985, 1990; Stackebrandt et al. 1997; Zhi et al. 2009).

Taxonomy, Historical and Current

Short Description of the Family

No.car.di.o.i.da.ce.a.e. N.L. masc. n. *Nocardioides* type genus of the family; suff.—*aceae* ending to denote a family; N.L. fem. pl. n. *Nocardioidaceae* the *Nocardioides* family.

This description is an emended version given by Zhi et al. (2009).

The family *Nocardioidaceae* originally was described by Nesterenko et al. (1985, 1990) (emended by Stackebrandt et al. 1997 and Zhi et al. 2009). At the beginning the family involved the genus *Nocardioides* (Prauser 1976) with the species *N. albus* (Prauser 1976), *N. luteus* (Prauser 1984a), and *N. simplex* (O'Donnell et al. 1982) and some other related organisms with LL-DAP in their cell wall: *Pimelobacter jensenii* (Suzuki and Komagata 1983) and *Arthrobacter tumescens* (Conn and Dimmick 1947; Jensen 1934). *A. tumescens* later was considered to reclassify as *Pimelobacter tumescens* (Suzuki and Komagata 1983). In the same publication, the authors suggested to rename *P. jensenii* as *Nocardioides jensenii* based on many physiological and chemotaxonomic properties. But the name was not validated, so the genus *Pimelobacter* was kept with three species: *P. simplex*, *P. jensenii*, and *P. tumescens*. In the meanwhile O'Donnell et al. (1982) proposed to reclassify *Arthrobacter simplex* (Lochhead 1957) as *Nocardioides simplex*. (Therefore, in 1985, the species *N. simplex* belonged to this genus).

E. Rosenberg et al. (eds.), *The Prokaryotes – Actinobacteria*, DOI 10.1007/978-3-642-30138-4_193,

Based on taxonomic reconsiderations (including 16S rDNA analysis), *N. albus*, *N. luteus, P. simplex*, and *P. jensenii* were shown to form a common phylogenetic group; meanwhile *P. tumescens* represented a separate line of descent (Collins et al. 1989). Chemotaxonomic data and also phage typing of Prauser (1976; 1984) confirmed the abovementioned data; therefore, *P. jensenii* was transferred to the genus *Nocardioides*, and *P. tumescens* was transferred to a newly developed genus as *Terrabacter tumescens* (Stackebrandt et al. 1997). Simultaneously, Collins and Stackebrandt (1989) described the species *Nocardioides fastidiosa* (which was transferred to the genus *Aeromicrobium* by Tamura and Yokota in 1994). In 1994, *N. plantarum* was also described (Collins et al. 1994). Thus, when Stackebrandt et al. (1997) proposed the emended description of the family *Nocardioidaceae*, it contained the genus *Nocardioides* (with the following five species: *N. albus, N. luteus, N. simplex, N. jensenii*, and *N. plantarum*) and the genus *Aeromicrobium* (with species *A. erythreum* and *A. fastidiosum*).

Genera *Kribbella*, *Marmoricola, Hongia*, *Actinopolymorpha*, *Thermasporomyces*, and *Flindersiella* were added to the family between 1999 and 2011 based on polyphasic studies (Vandamme et al. 1996; Park et al. 1999; Urzí et al. 2000; Lee et al. 2000; Wang et al. 2001; Stackebrandt and Schumann 2006; Yabe et al. 2011; Kaewkla and Franco 2011b). When the taxonomic status of *Hongia koreensis* was reclassified (Sohn et al. 2003) this taxon was transferred to the genus *Kribbella* (Park et al. 1999) as *K. koreensis*.

The genus *Jiangella* (Song et al. 2005) was also assigned to belong to the family *Nocardioidaceae*, but recently it has been transferred to a separated family *Jiangellaceae* in the suborder Jiangellineae (Tang et al. 2011). Two other novel genera *Thermasporomyces* (Yabe et al. 2011) and *Flindersiella* (Kaewkla and Franco 2011b) were also added to this family.

At this time the family *Nocardioidaceae* phylogenetically belongs to the order *Actinomycetales*, in the suborder Propionibacterinae, and contains the genera *Nocardioides* (Nesterenko et al. 1990; Stackebrandt et al. 1997; Zhi et al. 2009), *Aeromicrobium* (Miller et al. 1991), *Kribbella* (Park et al. 1999), *Marmoricola* (Urzí et al. 2000), *Actinopolymorpha* (Wang et al. 2001), *Thermasporomyces* (Yabe et al. 2011), and *Flindersiella* (Kaewkla and Franco 2011b). The type genus of the family is *Nocardioides.* Recently, the suborder Propionibacterinae has been elevated to order rank (Patrick and McDowell 2012).

Gram-staining positive (in old cultures Gram variable staining can also be observed at some genera). Cultures show different morphologies, ranging from branching vegetative hyphae and pleomorph shapes to irregular rods and coccoid cells. Clusters of irregular cells can also be observed at some taxa. In some genera even a morphogenetic rod-coccus cell cycle can be observed, and rods can be motile. Aerial hyphae are produced by members of several genera. Vegetative and aerial hyphae can undergo different degrees of fragmentation resulting to rodlike or coccoid cells (depending also on the organism and growth conditions).

Bacteria are chemoorganotrophic, having a respiratory type of metabolism. Their cell-wall peptidoglycan contains LL-diaminopimelic acid and glycine as diagnostic amino acid (peptidoglycan A3γ). Their predominant menaquinone component is with partially saturated side chain, consisting 8, 9, or 10 isoprene units. Cellular fatty acids and their polar lipid profile differ among genera. Mycolic acids are absent.

The set of 16S rRNA gene sequence signature nucleotides are at positions 328 (C), 407:435 (A-U), 451 (G), 453 (C), 819 (U), 825:875 (G-C), 827 (U), 828 (A), 832:854 (G-G), 833–853 (U-C), and 844 (C).

Phylogenetic Structure of the Family and Its Genera

Recent analysis of 16S rRNA gene sequences (using different clustering algorithms) shows that the genera comprising the current family *Nocardioidaceae* form at least two separate phylogenetic clusters. The two clusters are approximately at the same distance from each other and also from the family *Propionibacteriaceae* (Fig. 33.1a). The grouping is strengthened also by morphological and chemotaxonomic features of the genera involved.

The first cluster of the family includes the genera *Nocardioides, Aeromicrobium*, and *Marmoricola*. Their morphology is relatively simple; motile rods can be often observed. One predominant menaquinone occurs in their profile (with tetra-hydrogenated side chain of 8 or 9 isoprene units), and significant amounts of straight-chain saturated and unsaturated fatty acids can be found in their cells.

The second cluster contains the genera *Kribbella, Actinopolymorpha, Flindersiella*, and *Thermasporomyces*. In these genera more complex cell morphology can be observed and the lack of motile cells is characteristic. Their menaquinone profile is more complex involving longer and more saturated side chains. Their fatty acid profiles are dominated by iso- and anteiso-branched fatty acids and contain only a minor amount of straight-chain components.

Moreover, the two clusters have different genome sizes based on the two available complete genome sequences: the genome size of *Nocardioides* sp. JS614 is 4.99 Mb (Coleman et al. 2011) and that of *Kribbella flavida* DSM 17836 7.58 Mb (Pukall et al. 2010).

Within the family the 16S rRNA gene sequence clustering still clearly defines the main lines, and except of genera *Marmoricola* and *Nocardioides*, the allocation of a novel strain into a certain genus is still achievable based on it. In the case of the latter two genera, the position of some species is doubtful: *Marmoricola bigeumensis* groups together with *Nocardioides mesophilus* and *Nocardioides iriomotensis* (Fig. 33.1b). The affiliation of *M. bigeumensis* in the genus *Marmoricola* is based mainly upon on the 16S rRNA gene clustering (Dastager et al. 2008b) though the type strain has a higher binary similarity (97 %) to *Nocardioides jensenii* than to the type species (*M. aurantiacus*) of the genus *Marmoricola*.

The type species *Marmoricola aurantiacus* and *Nocardioides jensenii* share a 96.4 % 16S rRNA gene sequence similarity. The treeing algorithm places these two organisms to a second lineage containing other species of *Nocardioides*. Based on 16S rRNA gene sequence similarity, several secondary-structure-forming nucleotides that are missing in *Nocardioides* species and the unique combination of phylogenetic characteristics and chemotaxonomic properties resulted in the proposal of the new genus *Marmoricola* (Urzí et al. 2000) with the type species *M. aurantiacus*.

Therefore, allocation of a new species into the genus *Marmoricola* or *Nocardioides* is mainly based upon phylogenetic evidence combined with genus-specific chemotaxonomic properties.

The position of members of the type genus *Nocardioides* (Prauser 1976) should also be reconsidered. At present, the genus contains phylogenetically distant species (the most unrelated species show only 92–93 % 16S rRNA gene sequence similarity to one another) which is often lower than the threshold values delineating many phylogenetically well-defined genera within actinomycete families. Moreover species of the genus *Nocardioides* often show phenotypically different characteristics.

The differences between some *Nocardioides* species in the 16S-23S ITS region and RNase P gene sequence also show low similarity values (often at the level of different genera) (Yoon et al. 1998; Yoon and Park 2000).

The genus *Aeromicrobium* was established by Miller et al. (1991) with the type species *Aeromicrobium erythreum*. Subsequently, *Nocardioides fastidiosa* was transferred to the genus as *Aeromicrobium fastidiosum* (Tamura and Yokota 1994). The description of the genus was emended by Yoon et al. (2005a). Comparative analysis of 16S rRNA gene sequences (◉ *Fig. 33.1a*) shows that the genus *Aeromicrobium* is phylogenetically related to members of the genera *Marmoricola* and *Nocardioides* within the radiation of the family *Nocardioidaceae* (Stackebrandt et al. 1997; Urzí et al. 2000; Yoon et al. 2005a).

The genus *Kribbella* was established by Park et al. (1999) as a result of the reclassification of two strains, "*Nocardioides fulvus*" IFO 14399 (Ruan and Zhang 1979) and *Nocardioides* sp. ATCC 39419 (Matson and Bush 1989), as the type strains of *K. flavida* and *K. sandramycini*, respectively. The type species of the genus *Hongia* (*H. koreensis* described by Lee et al. 2000) was transferred to the genus *Kribbella* by Sohn et al. (2003) as *K. koreensis*. The 17 validly described *Kribbella* species form a monophyletic cluster in the phylogenetic tree (◉ *Fig. 33.1c*) based upon 16S rRNA sequence analysis.

The genus *Actinopolymorpha* was placed in the family *Nocardioidaceae* on the basis of 16S rRNA gene sequence analysis: the type strain of *A. singaporensis* carries all family-specific nucleotide signatures except for a G-C pair at nucleotide positions 370:379 and an A-U pair at position 602:636 instead of a G-U pair. On the other hand, *A. singaporensis* strain IM 7744^{T} possesses a number of properties that distinguish it from all other genera of the family (Wang et al. 2001) and shares low levels of 16S rDNA sequence similarities with the other members.

Thermasporomyces and *Flindersiella* are with type species of *T. composti* (Yabe et al. 2011) and *F. endophytica* (Kaewkla and Franco 2011b), respectively (◉ *Fig. 33.1 b* and *c*).

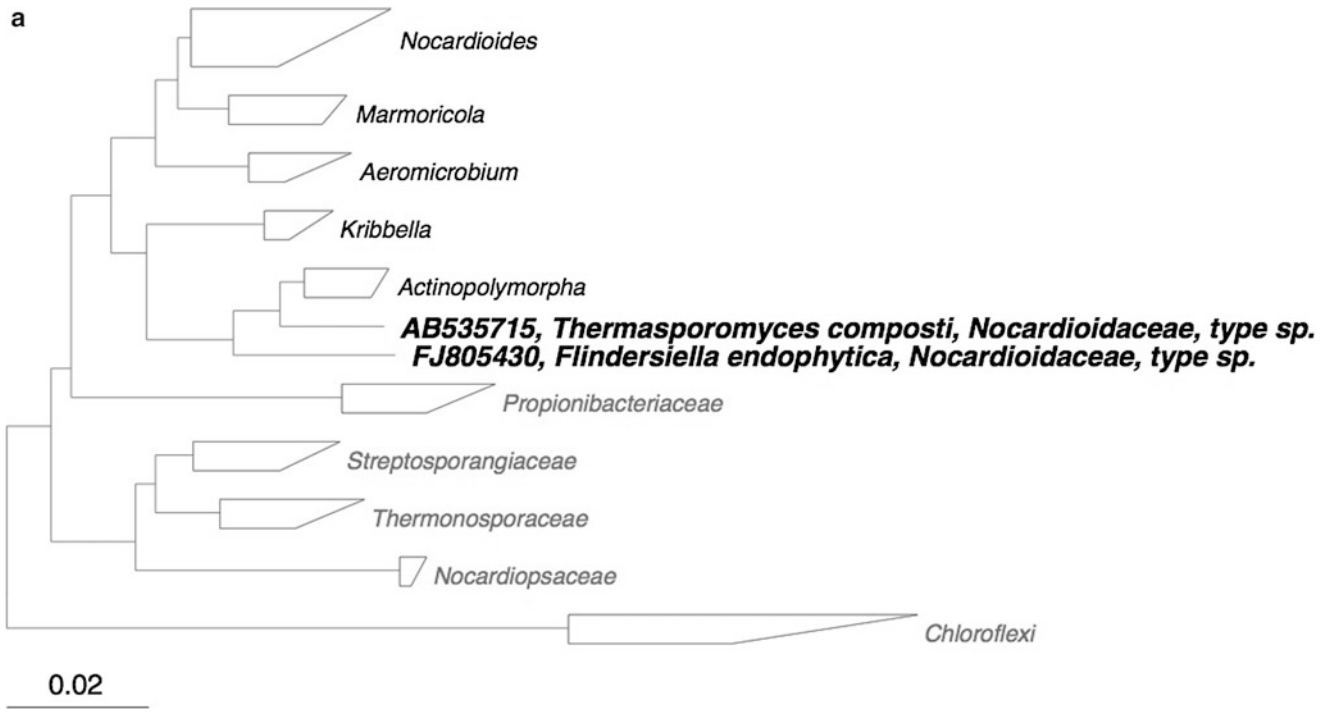

Fig. 33.1 (Continued)

Fig. 33.1 (Continued)

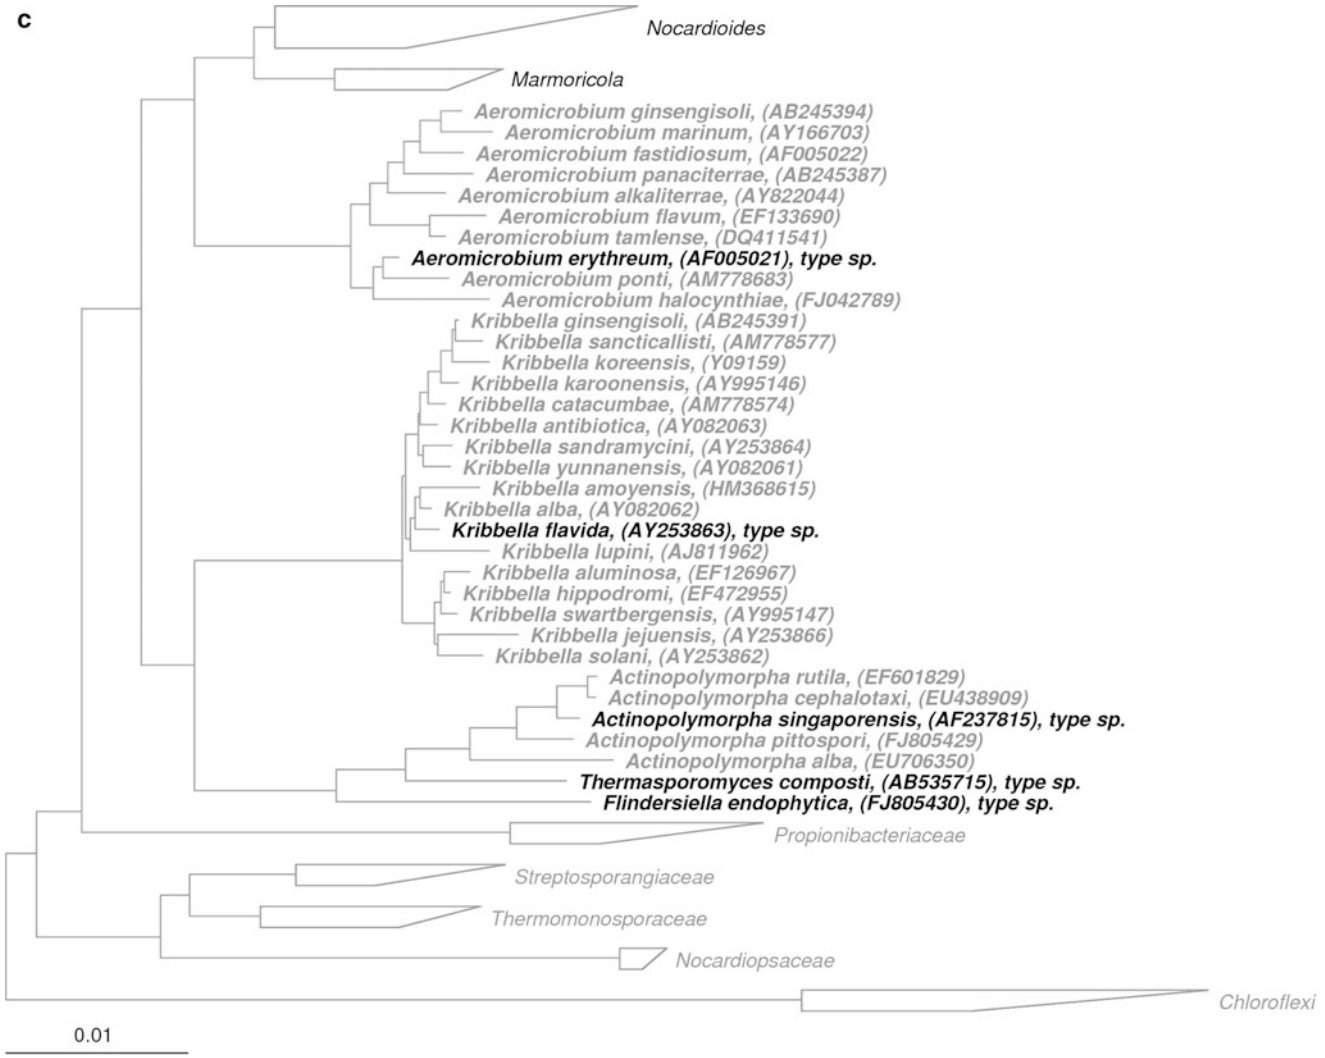

Fig. 33.1

(a–c) Phylogenetic reconstruction of the family *Nocardioidaceae* based on 16S rRNA and created using the neighbor-joining algorithm with the Jukes-Cantor correction. Most sequence datasets and alignments were used according to the All-Species Living Tree Project (*LTP*) database (Yarza et al. 2010; http://www.arb-silva.de/projects/living-tree) except yet not validly published species between question marks, these sequences were imported from the SILVA database (Quast et al. 2013). The tree topology was stabilized with the use of a representative set of nearly 750 high-quality type strain sequences proportionally distributed among the different bacterial and archaeal phyla. In addition, a 50 % maximum frequency filter was applied in order to remove hypervariable positions and potentially misplaced bases from the alignment. Scale bar indicates estimated sequence divergence

Molecular Analyses

DNA-DNA Hybridization Studies

DNA-DNA relatedness was measured between several species within the genera *Nocardioides* (Yoon et al. 1999, 2004, 2005b, 2006b, 2009, 2010; Schippers et al 2005; Park et al. 2008; Lee et al. 2008; 2011; Kubota et al. 2005; Dastager et al. 2009; Zhang et al. 2009; Cui et al. 2009; Yamamura et al. 2011; Alias-Villegas et al. 2012; Liu et al. 2012; Qin et al. 2012), *Aeromicrobium* (Bruns et al. 2003; Yoon et al. 2005a; Lee and Kim 2007; Cui et al. 2007; Kim et al. 2010), *Kribbella* (Li et al. 2004, 2006; Song et al. 2004; Trujillo et al. 2006; Carlsohn et al. 2007; Urzí et al. 2008; Cui et al. 2010; Xu et al. 2012), *Marmoricola* (Lee and Lee 2010; Lee et al. 2011b), and *Actinopolymorpha* (Wang et al. 2008; Cao et al. 2009; Yuan et al. 2010; Kaewkla and Franco 2011a).

All these results show that within the family *Nocardioidaceae*, the DNA-DNA relatedness values (DDH) are below the threshold value of 70 % recommended for definition of bacterial species (Wayne et al. 1987) and the values between the strains of the same species are much above this.

Riboprinting, Ribotyping, and MALDI-TOF MS

Only some members of the genus *Nocardioides* were studied by the automated RiboPrint system (three different strains of *N. hungaricus*, *N. hankookensis*, *N. pyridinolyticus*, and *N. aquiterrae*). These strains were analyzed also by MALDI-TOF (matrix-assisted laser desorption/ionization time-of-flight) mass spectrometric approach. Both methods demonstrated that the strains of the same species are grouped well together, while other species could be well separated showing that within the genera most probably both methods support the result of 16S rRNA gene sequencing (Tóth et al. 2011).

Within the genus *Kribbella*, MALDI-TOF analysis was performed with the type strains of *K. flavida, K. karoonensis, K. koreensis, K. catacumbae* and *K. sancticallisti*, and the results were in agreement with the results of RiboPrint and 16S rRNA gene sequence analysis (Urzí et al. 2008).

RNase P Gene, ITS Multilocus Sequence Analysis

Comparative sequence analysis of ribonuclease P (RNase P) genes was studied by Yoon and Park (2000) with LL-DAP-containing actinomycetes, among them are some members of the genus *Nocardioides* (*N. luteus* KCTC 9575^T, *N. flavus* IFO 14396^T, *N. fulvus* JCM 3335^T, *N. simplex* KCTC 9106^T, *N. nitrophenolicus* KCTC 0457BP^T, *N. plantarum NCIMB* 12834^T, *N. pyridinolyticus* KCTC 0074BP^T, and *N. jensenii* KCTC 9134^T). The mean RNase P gene similarity among the studied strains is approximately 76.6 ± 12.5 %. The topologies of the resultant trees (using different treeing methods) are divergent when compared with the levels of 16S rRNA gene similarities. *N. albus* and *N. luteus* are phylogenetic neighbors with nucleotide similarity of 94 %. The clustering of *N. simplex* and *N. nitrophenolicus* is supported though by low bootstrap values when neighbor-joining and maximum-likelihood methods are used. *N. jensenii*, *N. plantarum*, and *N. pyridinolyticus* form phylogenetic lineages distinct from each species. It is important to mention that the sequence similarity values between more distant *Nocardioides* species are often close to the values between *Nocardioides* species and strains of *Kribbella* or *Aeromicrobium*.

Yoon et al (1998) studied the 16S-23S ITS regions of several *Nocardioides* species. The size of 16S-23S ITS regions varies from 328 (*N. nitrophenolicus*) to 539 bp (*N. albus* group). In few *N. albus* strains (DSM 43874, JCM 5851, JCM 5862) and in *N. simplex* NCIMB 12919, two types of ITS sequences were found (differing in size from 1 to 12 bp). Most probably in these cases, at least two rRNA operons exist in the genome of the strains. The nucleotide similarity of the ITS region between the studied strains ranges from 48.4 % to 84.8 %.

For the multilocus sequence analysis (MLSA) of 16 validly described *Kribbella* species, the following genes were selected: *gyrB* gene (DNA gyrase B subunit), *rpoB* gene (RNA polymerase beta subunit), *recA* gene (recombinase A), *atpD* gene (ATP synthase F1 beta subunit), and *relA* gene (encoding ppGpp synthetase) (Curtis and Meyers 2012). In a previous study, Kirby et al. (2010) demonstrated that the *gyrB*-based genetic distances between *Kribbella*-type strains ranged from 0.0164 to 0.1495, supporting the use of the 0.014 genetic distance value as the threshold for species delineation within this genus. The five-gene concatenated sequence analysis of 4,099 nt revealed that most *Kribbella*-type strains can be distinguished by a genetic distance of >0.04. The MLSA-based tree resulted in a marked improvement in the resolution compared to the 16S rRNA gene tree. By using MLSA, a better understanding of the genus *Kribbella* has been established, and the use of the genes *gyrB, rpoB, recA, relA*, and *atpD* proved to be useful for exploring the phylogenetic relationships within the genus and for determining the closest phylogenetic relatives (Curtis and Meyers 2012).

Genome Comparison

The complete genome of *Nocardioides* sp. strain JS614 has been sequenced (Coleman et al. 2011). Based on the results, the genome (5.3 Mb) consists of a single circular 4,985,871-bp chromosome and one 307,814-bp plasmid (pNOCA01). The average G+C content of the chromosome is 71.65 %, and that of the plasmid is 68.01 %. The chromosome contains 4,645 putative protein-coding genes, 46 tRNAs, and two rRNA operons. The plasmid contains 256 protein-coding genes. In total approximately 69 % of the genome had function predictions.

The genome of the type strain of *Kribbella flavida* IFO 14399^T, DSM 17836 (Park et al. 1999), is 7,579,488 bp long and contains 7,086 protein-coding genes, including 60 RNA genes, and the mol% G+C of DNA is 70.6 % (Pukall et al. 2010). The latter is in agreement with the species description value (Park et al. 1999). The highest number of genes associated with general COG functional categories is found for transcription and carbohydrate transport and metabolism (762 and 636, respectively), followed by amino acid transport and metabolism (397) and energy production and conversion (308).

Phages

Many bacteriophages have been described which multiply in *N. albus*, *N. luteus*, *N. simplex*, and *N. jensenii* but not in any other actinomycete strains (Prauser 1976; 1984; Miller et al. 1991; Williams et al. 1980). The phage sensitivity of *Arthrobacter simplex* and *Arthrobacter jensenii* was rational for the reclassification of the genus *Nocardioides* (Prauser 1976; 1984; Kurtboke and Williams 1991). The following phages cause true lysis and/or clearing effects on strains of all *Nocardioides* ssp. X6 (DSM 49135), X10 (DSM 49104), X24 (DSM 49105). Phages of the following subset cause true lysis and/or clearing effects on strains of the *Nocardioides* sensu stricto species *N. albus*, *N. luteus*, "*N. fulvus*," and "*N. flavus*" X1 (DSM 49101) and X3 (DSM 49102).

Phenotypic Analyses

The main features of members of *Nocardioidaceae* are listed in Table 33.1.

Young cultures within the family show different morphologies, ranging from branching vegetative hyphae and pleomorphic shapes to irregular rods and coccoid cells. Aerial hyphae are produced by members of several genera. Vegetative and aerial hyphae can undergo different degrees of fragmentation resulting in rod-like or coccoid cells (depending also on the organism and growth conditions). Clusters of irregular cells can also be observed in some taxa. Members of the genera *Aeromicrobium* and *Nocardioides* often show a rod-coccus morphogenetic cell cycle, and rods can be motile. Members of the genus *Marmoricola* form coccoid cells. Members of the family are Gram positive (in old cultures Gram variable staining can be also observed at some genera) and are non-acid-fast.

They are chemoorganotrophic, mostly catalase-positive bacteria, having a respiratory type of metabolism. Their cell-wall peptidoglycan contains LL-diaminopimelic acid and glycine as diagnostic amino acid (peptidoglycan A3γ). Their predominant menaquinone components contain partially saturated side chains, consisting 8, 9, or 10 isoprene units. Cellular fatty acids and their polar lipid profile differ among genera (see Table 33.1). Mycolic acids are absent.

Members of the family occur in various environments (see Table 33.2–33.6); no medically relevant strains or species have been described within the family until now.

Nocardioides Prauser (1976)

No.car.di.o.i'des. N.L. fem. n. *Nocardia* name of a genus; L. suff. *-oides* (from Gr. suff. *-eides* from Gr. n. *-eidos*, as form, shape, figure) resembling, similar; N.L. masc. n. *Nocardioides Nocardia*-like, referring to the similarity of life cycles of the type species of this genus and *Nocardia*.

The type strain of *Nocardioides albus* 895-50^T was isolated from soil (Prauser 1976).

In young cultures cells of the genus are often irregular short rods, in some species branched vegetative hyphae can also be observed (*N. albus*, Prauser 1976; *N. luteus*, Prauser 1984). Morphogenetic rod-coccus cycle often occurs in different species. The morphogenetic cycle usually starts with coccoid cells or short rods which develop into rods or short filaments. If mycelia occur, the vegetative and aerial hyphae also undergo various degree of fragmentation. Rod-shaped bacteria may be motile. Colonies can be whitish, creamy, or yellow, rarely orange.

Strains are catalase-positive oxidase variable and grow under aerobic conditions. *Nocardioides* species are chemoorganotrophs and utilize a wide range of carbon and nitrogen sources (see Table 33.2). They may adapt to oligotrophic conditions. Mattes et al. (2005) found that *Nocardioides* sp. JS614 is able to grow even chemolitotrophically.

The majority of *Nocardioides* strains show esterase lipase (C8) activity but are negative for β-glucuronidase, α-fucosidase, and α-mannosidase in API ZYM (bioMérieux) test. Negative test results are observed for H_2S production except for *N. panacisoli* (Cho et al. 2010). The results for Voges-Proskauer test vary between species and experiments. Many species degrade DNA, degradation of cellulose is uncommon, and only few organisms can degrade chitin (Prauser 1976; Tóth et al. 2008) or xylan (Park et al. 2008).

An important characteristic of the *Nocardioides* species is their capability to degrade complex, unusual substrates, including common toxic environmental pollutants and aromatic chemicals (see at applied studies).

Nocardioides species are mostly mesophilic (grow well between 25 °C and 30 °C), but some species grow also at psychrophilic conditions (show growth even at 4 °C). The reported optimal temperature for growth varies among species. Most species of this genus are neutrophilic, but some grow at initial pH values of 5 and/or 12 (see Table 33.2). Most of them are non-halophilic but salt-requiring organisms (mainly isolated from marine and marine-related environments) can also occur (see Table 33.2). These species need usually 0.5–6 % NaCl for their growth.

The cell-wall teichoic acids are present. The predominant menaquinone is MK-8(H_4) containing a tetra-hydrogenated side chain with eight isoprene units. Cellular fatty acids are complex mixtures of saturated and monounsaturated, straight-chain, and iso-, anteiso-, and methyl-branched components; usually 14-methyl pentadecanoic acid (iso C16:0) dominates (see Table 33.2). Polar lipid profile contains different combination of diphosphatidylglycerol, phosphatidylglycerol, phosphatidylinositol, rarely phosphatidylcholine, methyl-phosphatidylinositol, or phosphatidylethanolamine. The polyamine patterns usually contain cadaverine as the predominant component, occasionally with putrescine, spermine, or spermidine (Busse and Schumann 1999; Yamada and Komagata 1972).

The antibiotic sensitivity was studied only on few species within the genus *Nocardioides* (*N. aquiterrae, N. aquaticus, N. caricicola, N. daedukensis, N. dokdonensis, N. fonticola, N. hankookensis, N. insulae, N. pyridinolyticus*, and *N. terrigena*). Except *N. pyridinolyticus*, strains of these species are sensitive for chloramphenicol and streptomycin in different concentrations (Song et al. 2011).

DNA G+C content is 66.6–74.8 mol%.

Marmoricola Urzi et al. (2000), Emend Dastager (2008), Emend Lee and Lee (2010)

Mar.mo.ri'co.la. L. neutr. n. *marmor* marble; L. masc. suffix *–cola* inhabitant of; *Marmoricola* inhabitant of marble.

The type strain *Marmoricola aurantiacus* BC 361^T was isolated from marble (Urzí et al. 2000).

Cells are spherical, occurring singly, in pairs, in tetrads, or in small clusters. No rod-coccus morphogenetic cell cycle occurs.

Symbols and abbreviations: + positive, – negative, *w* weakly positive, *ND* no data available, © conflicting data

Nonmotile, and no endospore formation can be observed. Colonies are yellow or orange pigmented. They can become rough and shaped like craters in old cultures.

Marmoricola species are aerobic, catalase-positive, and oxidase-negative organisms. Strains of all species are positive for aesculin hydrolysis and negative for Voges-Proskauer reaction, urease activity, and indole production. Each utilizes glucose, D-mannitol, and methyl-α-D-glucoside as sole source of carbon but not formate, *meso*-inositol, methyl-α-D-mannoside, or L-sorbose. For other detailed data, see *Table 33.5*.

All members of the genus *Marmoricola* are positive for alkaline phosphatase, esterase lipase (C8), leucine arylamidase, α-glucosidase, and β-glucosidase and negative for lipase (C14), α-galactosidase, β-glucuronidase, N-acetyl-β-glucosaminidase, α-mannosidase, α-fucosidase, arginine dihydrolase, lysine decarboxylase, ornithine decarboxylase, and tryptophane deaminase (Lee and Lee 2010).

Most strains are mesophilic and grow at 20–28 °C; *M. korecus* (Lee et al. 2011a) grows even at 4 °C. They grow in neutrophilic or slightly alkaliphilic conditions (pH range of their growth is 5.1–12.1).

Polar lipid profile contains phosphatidylinositol, phosphatidylglycerol, and diphosphatidylglycerol. Their cellular fatty acid profile consists of straight-chain saturated and mono-unsaturated components (C16:0, C18:1ω9c, C17:1ω8c); in case of *M. aurantiacus* and *M. scoriae* also, TBSA is present. The predominant menaquinone is MK-8(H_4).

DNA G+C content is 71–72 mol%.

Aeromicrobium Miller et al. (1991), Emend Yoon et al. (2005)

Aer.o.mi.cro'bi.um. N. L. noun *Aeromicrobium*, aerobic microbe.

The type strain of *Aeromicrobium erythreum* NRRL B-3381^T was isolated from soil collected in the Lajas Valley near Cabo Rojo, Puerto Rico (Miller et al. 1991).

Cells are Gram positive, non-endospore forming, and mostly nonmotile rods. Irregular rods and coccoid forms are also observed. Branching or mycelial form does not occur. Aerobic, and with the exception of *A. ginsengisoli*, strains are

catalase positive. Except for *A. flavum*, they reduce nitrate to nitrite. All type strains hydrolyze gelatin, utilize trehalose, and produce esterase lipase (C8) but unable to assimilate D-xylitol and negative for cystine arylamidase, α-chymotrypsin, α-galactosidase, β-galactosidase, β-glucuronidase, N-Acetyl-β-glucosaminidase, α-mannosidase, and α-fucosidase. All strains of *Aeromicrobium* species are mesophilic which can grow best at 20–30 °C. *Aeromicrobium* species show growth up to 3–10 % (w/v) NaCl concentration and between pH 5.0 and 8.0. Other selected phenotypic properties are given in ➤ *Table 33.3*.

MK-9(H_4) is the predominant menaquinone. The major components of cellular fatty acids are TBSA (tuberculostearic acid, 10Me-C18:0), C18:1ω9c, and C16:0.

Polar lipids comprise diphosphatidylglycerol, phosphatidylglycerol, phosphatidylinositol, and phosphatidylethanolamine.

DNA G+C content is 65.5–75.9 mol%.

Kribbella Park et al. (1999)

Kribbella (Kribb.el'la. M. L. dim. fem. ending -ella; M.L. fern. n. *Kribbella* arbitrary name formed from the acronym of the Korea Research Institute of Bioscience and Biotechnology, KRIBB, where taxonomic studies of this taxon were performed).

The type strain of *Kribbella flavida* IFO 14399^T was isolated from soil in China and first described as "*Nocardioides fulvus*" by Ruan and Zhang (1979).

Cultures of *Kribbella* produce both vegetative (substrate) and aerial mycelia on many different media (e.g., ISP media, Czapek's agar, nutrient agar) tested that fragment into rod-shaped elements. Cells are nonmotile. The substrate mycelium appears creamy to pale yellow which is generally extensively branched and can penetrate into the agar medium. The aerial mycelium is white or yellow-white. Diffusible pigment production is not observed. Melanin production is variable among the species and depends on the composition of the cultivation medium. Other selected phenotypic properties are displayed in ❯ *Table 33.4*. All strains are Gram positive, aerobic, and catalase positive, but strains of *K. flavida, K. solani, K. jejuensis, K. koreensis*, and *K. sandramycini* show also moderate or weak anaerobic growth (Kirby et al. 2006; Everest and Meyers 2008). Some species are positive for oxidase (*K. flavida, K. sandramycini, K. yunnanensis, K. lupine, K. karoonensis, K. catacumbae, K. sancticallisti* and *K. ginsengisoli*) and/or reduce nitrate (*K. flavida, K. karoonensis, K. swartbergensis, K. hippodromi, K. sancticallisti*, and *K. amoyensis*). D-fructose, D-glucose, glycerol, lactose, maltose, D-mannitol, D-mannose, D-rhamnose, and D-xylose are the most frequently utilized carbon sources. All strains of *Kribbella* species are mesophilic and neutrophilic which can grow best at 20–30 °C on agar media used in the ISP (Shirling and Gottlieb 1966) and at pH values between 6.0 and 8.0. *Kribbella* species are non-halophilic; they show growth up to 2–5 % (w/v) NaCl concentration.

The major menaquinone is MK-9(H_4). Branched-chain fatty acids (e.g., i-C16:0, ai-C15:0, and i-C15:0) are dominant; other fatty acids (e.g., i-C14:0, i-C16:1, i-C17:1, i-C17:1ω9c) occur in lower amounts. The characteristic whole-cell sugars of *Kribbella* species involve ribose, mannose, xylose, galactose, and glucose. Besides phosphatidylcholine present in all species, additional phospholipids are diphosphatidylglycerol, phosphatidylglycerol, and phosphatidylinositol. Some representatives of the genus *Kribbella* contain teichulosonic acid (TULA), a novel type of a glycopolymer with a pseudaminic acid derivative, as the main chain component. In addition, a neutral polysaccharide (mannan) can also be present in varying amounts (Shashkov et al. 2009; Tulskaya et al. 2011).

DNA G+C content is 66.3–71.3 mol%.

Actinopolymorpha Wang et. al (2001)

Ac.ti.no.po.ly.mor'pha. Gr. n. *actis, actinos* a ray; Gr. adj. poly many; Gr. n. *morphus* form, shape; M.L. adj. *Actinopolymorpha* actinomycete of many shapes.

The type strain *Actinopolymorpha singaporensis* IM 7744^T was isolated from a soil in the tropical rainforest of Singapore (Wang et al. 2001).

Members of this genus usually show slow growth on most-tested medium. Irregular cells are in *A. cephalotaxi* (Yuan et al. 2010) which appear to divide through apical and lateral budding and remain attached after division. They often keep in short chains or aggregates in the early stages of their growth. Cells later elongate at different degree and can even swell, forming branched hyphae with uneven thickness.

Salt is often required for their growth; *A. singaporensis* (Wang et al. 2001) tolerates 15 % NaCl concentration. Most species are mesophilic and neutrophiles.

All are catalase positive and able to decompose gelatin, utilize glucose as sole carbon source, and produce acid from arabinose, glucose, and trehalose. All strains are negative for production acid from 1,2-propanediol.

In case of the genus *Actinopolymorpha*, only *A. cephalotaxi, A. rutila*, and *A. alba* were tested for their enzymes in detail (API ZYM). All were positive for esterase (C4), α- and β-glucosidases, and α-mannosidase.

Polar lipid profile contains phosphatidylinositol mannosides, phosphatidylinositol, phosphatidylglycerol, and diphosphatidylglycerol. Their cellular fatty acid profile consists of mainly branched-chain saturated (iC16:0, iC15:0) as major components; in case of *A. pittospori* also iC17:0 and aC17:0 occur. The predominant menaquinone is MK-9(H_6) or/and MK-9(H_4).

DNA G+C content is 67.7–69.6 mol%.

Thermasporomyces Yabe et al. (2011)

Thermasporomyces [Ther.ma.spo.ro.my'ces. Gr. n. *therme* heat; Gr. prefix. a not; Gr. n. spora a seed, and in biology a spore; Gr. masc. n. *mukes* mushroom or other fungus; N.L. masc. n. *Thermasporomyces* the heat (−loving) non-spored fungus].

The type strain of *Thermasporomyces composti* I3^T was isolated from mature compost produced by a field-scale composter (Hazaka system; Hazaka Plant Kogyo Co., Ltd), which is used for the treatment of livestock excreta (Yabe et al. 2011).

Strain I3^T grows well on ISP 3 medium and weakly on ISP 2, 4, and 6 media and nutrient agar. No growth occurs on ISP 1 or ISP 5 media. Strain I3^T develops pale-yellow colonies on ISP 3, pale-yellow-orange colonies on ISP 2, and white colonies on other media. No aerial mycelia or diffusible pigments are observed on any of the media. Strain I3^T forms branched hyphae that fragmented into short chains or aggregates. The fragments are coccoid or short rods. Spores are not observed.

Strain I3^T stained is Gram positive and positive for catalase, oxidase, nitrate reduction, gelatin hydrolysis, milk coagulation,

and peptonization. Casein, carboxymethylcellulose, and xylan are hydrolyzed, while starch, xanthine, and L-tyrosine are not. Raffinose, sorbitol, lactose, cellobiose, and D-arabinose are utilized, but not sodium citrate or sodium succinate. Acid is produced from mannose and maltose, but not from L-rhamnose, sorbitol, inositol, or D-galactose. Enzyme activities detected by API ZYM are alkaline phosphatase, C4 and C8 esterases, leucine arylamidase, α-chymotrypsin, naphthol phosphohydrolase, trypsin, α-galactosidase, α-glucosidase, lipase C14, valine arylamidase, N-acetyl-β-glucosaminidase, and α-mannosidase. Activities not detected by API ZYM are β-galactosidase, β-glucosidase, β-glucuronidase, and α-fucosidase. Growth occurs between 35 °C and 62 °C (optimum 50–55 °C), at pH 5.7–10.0 (optimum pH 7.0) and in the presence of up to 5 % (w/v) NaCl.

The major fatty acids are i-C15:0, ai-C15:0, i-C17:0, and ai-C17:0. The major menaquinones are MK-9(H_4), MK-10(H_4), and MK-11(H_4). Cell-wall sugars are rhamnose and arabinose. The polar lipids consist of ninhydrin-positive phosphoglycolipids, phosphatidylglycerol, diphosphatidylglycerol, and an unknown glycolipid.

DNA G+C content is 69.2 mol%.

Flindersiella Kaewkla and Franco (2011)

Flindersiella (Flin.der.si.el'la. N.L. fem. dim. n. *Flindersiella* named after Flinders University, signifying the site of the host tree from which the type strain originated).

The type strain of *Flindersiella endophytica* EUM 378^T was isolated from surface-sterilized root tissue of a *Eucalyptus microcarpa* tree that grows on the campus of Flinders University, Adelaide, South Australia (Kaewkla and Franco 2011b).

Colony morphology of strain EUM 378^T ranges from smooth to rogues. Colonies are white on ISP 4 and yellowish white on ISP 5, Bennett's media, and NA. They are greyish yellow on ISP 3 and ISP 7 and pale yellow on ISP 2 media. Colonies are olive green on HPDA and change to a bluish purple color after 30 days of growth. The type strain produces a greyish-orange pigment on tyrosine agar. Substrate mycelium develops well on most media, but aerial mycelium is rarely formed. Substrate mycelium is branched with irregular thickness and fragments into short chains or aggregates. Spores are tiny rods on short chains that develop from aerial mycelium. White spores are produced on ISP 3, ISP 4, ISP 7, and HPDA media.

The type strain is aerobic, Gram positive, and catalase positive. Decomposition of gelatin and starch is positive. Acid is produced from adonitol, D-arabinose, cellobiose, fructose, galactose, glucose, maltose, mannitol, mannose, *myo*-inositol, ribose, sorbitol, sucrose, trehalose, xylose, and salicin, but not from 1,2 propanediol and dulcitol. Growth occurs between 15 °C and 37 °C, at pH 5.0 and 10.0 and in the presence of up to 5 % (w/v) NaCl. Optimum growth is achieved at a temperature of 27–37 °C, at pH 6 and 10 and in the presence of <3 % (w/v) NaCl.

The predominant menaquinone is MK-10(H_6). The major fatty acids are i-C16:0, ai-C17:0, and ai-C15:0. Diphosphatidylglycerol and phosphatidylglycerol are the major polar lipids.

DNA G+C content is 68.8 mol%.

Isolation, Enrichment, and Maintenance Procedures

Members of the family *Nocardioidaceae* could be isolated from various sources (see *Table 33.2–33.6*).

Most *Nocardioides* strains have been isolated from diverse terrestric and aquatic environments but also communities associated with plants, animals or humans (*Table 33.2*). To isolate *Nocardioides* species, usually no selective media or enrichment procedures are needed; they generally grow well on different complex media like nutrient agar (Difco), TSA agar (Difco), or YM agar (Difco). Selective enrichment was used from polluted environments in case of *N. pyridinolyticus* (Yoon et al. 1997), *N. aromaticivorans* (Kubota et al. 2005), and *N. oleivorans* (Schippers et al. 2005). For cultivation of *Nocardioides* species, media recommended by the International Streptomyces Project (ISP), furthermore glucose-asparagine agar (Lindenbein 1952) or chitin agar (Prauser 1976), are also adequate. However, organic media with low nutrient concentrations are generally advantageous to isolate diverse *Nocardioides* species from natural habitats. For this reason R2A (Difco), twofold or tenfold diluted R2A agar media, tenfold diluted nutrient agar, and oligotrophic medium PYGV (Staley 1968) have been used. For cultivation of *Nocardioides* from marine ecosystems or hypersaline environments, PYGV medium supplemented with seawater (Lawson et al 2000), marine agar (Difco), or other nutrient media supplemented with seawater or salts in adequate concentrations (Lee 2007b; Choi et al. 2007; Park et al. 2008) were used.

As cells or mycelia of these species are often strongly associated with mineral and organic particles, shaking or other mechanical or chemical desorption of the samples should be performed prior to isolation (Herron and Wellington 1990; Futamata et al. 2004). Endophytic representatives of the genus could be isolated after surface-sterilizing the adequate part of the plant (Coombs and Franco 2003; Qin et al. 2012) on nutrient-poor media, like TWYE (tap water-yeast extract) agar (Crawford et al. 1993), YECD (yeast-extract-casein hydrolysate agar) (Coombs and Franco 2003) or on humic acid-vitamin B (HV) agar (Hayakawa and Nonomura 1987). The incubation conditions of the isolation plates vary according to the natural habitat; usually 25–30 °C is adequate but lower (10–15 °C) or higher (40 °C) temperature values can also be used (Iwabuchi et al. 1998; Lawson et al. 2000; Kim et al. 2008a).

Members of the genus *Marmoricola* were isolated from different environments. *M. aurantiacus* was isolated from a marble statue (Urzí et al. 2000) by dilution plating on Bunt and Rovira medium (Bunt and Rovira 1955) but was also able to grow well even on Leudemann medium (Luedemann 1968).

M. aequoreus was isolated from a deep sandy sediment sample (Lee 2007a). The isolation medium (SC-SW) consisted of 1 % soluble starch, 0.03 % casein, 0.2 % KNO_3, 0.2 % NaCl, 0.002 % $CaCO_3$, 1.8 % agar, 0.005 % $MgSO_4 \times 7H_2O$, and 0.001 % $FeSO_4 \times 7H_2O$ in a 60:40 mixture of natural seawater and distilled water. Later, the strain was maintained on yeast-extract/malt agar medium (Shirling and Gottlieb 1966) prepared in a mixture of seawater and distilled water (YE-SW agar). *M. bigeumensis* was isolated and maintained on one-tenth-strength R2A medium (Reasoner and Geldreich 1985). *M. scoriae* and *M. korecus* were isolated from volcanic habitats on starch-casein agar medium (Lee and Lee 2010). All species can be maintained on R2A medium.

Type strains of the genus *Aeromicrobium* were cultivated on several different culture media which involve TYE medium; marine, nutrient, and R2A agar from the Difco Laboratories; SC-SW and YE-SW agar (Lee and Kim 2007); TGY agar (Brim et al. 2003); and A1 + C medium (Kim et al. 2010). Most *Aeromicrobium* species were maintained on the isolation medium.

Members of the genus *Kribbella* are able to grow on a wide range of culture media. Some species (e.g., *K. flavida, K. sandramycini, K. antibiotica, K. yunnanensis*, and *K. alba*) were isolated on ISP 2 or ISP 5 (International *Streptomyces* Project) media. Among the other species, *K. solani* and *K. jejuensis* were cultivated on GYM (DSMZ 65) medium, *K. lupini* on yeast-extract-mannitol agar (Vincent 1970), *K. karoonensis* on PV8 agar (Tormo et al. 2003), *K. swartbergensis* on MC agar (Nonomura and Ohara 1971), *K. hippodromi* on SM1 agar (Tan et al. 2006), and *K. catacumbae* and *K. sancticallisti* on BRII agar (Urzí et al. 2001). In addition, type strains of *K. koreensis* and *K. aluminosa* were cultured on tap water or water agar (Sohn et al. 2003; Carlsohn et al. 2007), while *K. ginsengisoli* cells grew on modified R2A medium (Cui et al. 2010) reflecting their oligotrophic characteristics. In several cases the selectivity of the isolation medium was provided by adding nalidixic acid or nystatin and cycloheximide antibiotics to the basal medium (Lee et al. 2000; Kirby et al. 2006; Carlsohn et al. 2007; Everest and Meyers 2008). Most *Kribbella* species were maintained on ISP 2 agar.

Members of the genus *Actinopolymorpha* are usually slow-growing microorganisms. They were isolated from soils or rhizosphere or as plant endophyte. Initial isolation was usually performed on special media but later on most of them could be cultivated on ISP media. *A. singaporensis* was isolated on ISP2 medium by Wang et al (2001) after the soil suspension was vigorously shaked in LB medium containing 100 μg ml^{-1} penicillin and streptomycin (in order to kill fast-growing bacteria). *A. rutila* was isolated from a forest soil (Wang et al. 2008) and grew well on ISP media (2, 3, 4, 5), on Czapek's agar plates (Pridham and Lyons 1980), on potato agar, and on nutrient agar medium. *A. alba* (Cao et al. 2009) was isolated from a plant rhizosphere using Gauze 1 agar medium (Gauze et al. 1983) later could be maintained as written in case of *A. rutila*. *A. cephalotaxi* is also a plant rhizosphere bacterium, isolated on a selective medium (L^{-1})—5 g starch, 5 g glycerol, 1 g proline, 1 g $(NH_4)_2SO_4$, 1 g NaCl, 2 g $CaCl_2$, 1 g K_2HPO_4, 1 g $MgSO_4 \times 7H_2O$, 50 mg $K_2Cr_2O_7$, 25 mg aztreonam, and 15.0 g agar—and had a final pH of 7.2. The strain was maintained on ISP 2 agar slants. *A. pittospori* was isolated from a leaf sample of a native apricot tree (Kaewkla and Franco 2011a); after 11 weeks of growth, the crushed leaf tissue was placed on VL70 medium containing a mixture of 17 amino acids (Hudson et al. 1989; Schoenborn et al. 2004).

Thermasporomyces composti was isolated from ISP 3 agar supplemented with 20 mg l^{-1} trimethoprim, 10 mg l^{-1} nalidixic acid, and 20 mg l^{-1} kanamycin (Yabe et al. 2011). During the cultivation, agar plates were incubated at 50 °C for 7 days.

Flindersiella endophytica, isolated from the root of Grey Box, an endemic eucalyptus tree, was cultivated on VL70 medium containing a mixture of 17 amino acids and solidified with 0.8 % gellan gum (Hudson et al. 1989; Schoenborn et al. 2004; Song et al. 2005). Before plating, the root samples were sterilized with 70 % ethanol and 6 % hypochlorite for 5 min each, washed thoroughly with sterile water, and then treated with sterile 10 % $NaHCO_3$ for 10 min before being washed with sterile water. Then, the root tissue was crushed in a sterile mortar.

Cultures of members of the family *Nocardioidaceae* can be maintained in 20 % glycerol suspensions at −20 or −80 °C; for long-term preservation, lyophilization or keeping in liquid nitrogen can be adequate.

Ecology

Habitat

The species of the genus *Nocardioides* occur widespread in natural environments and appear to be ubiquitous microorganisms: they are present in soils and aquatic environments, even at low temperature, deep surface ecosystems, and deserts or in oligotrophic habitats (Boivin-Jahns et al. 1995; Groth et al. 1999; Katayama et al. 2007; Rintala et al. 2008; Zhang et al. 2009; Tóth et al. 2011). Representatives of the genus *Nocardioides* can also occur in polluted soils or wastewaters with toxic, even aromatic compounds (Suzuki and Komagata 1983; Lee et al. 1991, 1994; Rajan et al. 1996; Coleman et al. 2002; Hamamura and Arp 2000; Kubota et al. 2005; Schippers et al. 2005). Bacteria of this genus were also found connected with plants—rhizosphere and roots—some have been reported even as plant endophyte (Coombs and Franco 2003; Song et al. 2011; Qin et al. 2012) or in association with lichens (Li et al. 2007). Members of this genus have been detected also in association with vertebrate and invertebrate animals: daphnia, termites, and humans (Fall et al. 2007; Tóth et al. 2008; El-Shatoury et al. 2009).

As other actinomycetes, also the members of the genus *Nocardioides* are most probably involved in the turnover of the organic material in different ecosystems, as they can degrade a wide range of organic substrates. Their ability to metabolize aromatic (even polyaromatic) substances and toxic chemicals suggests (Iizuka and Komagata 1964; Behrend and Heesche-Wagner 1999; Hamamura and Arp 2000; Cho et al. 2000;

Ebert et al. 2001; Hamamura et al. 2001; Schippers et al. 2005; Inoue et al. 2007; Cui et al. 2009; Yoon et al. 2009) that they can play a significant role in natural degradation processes of these compounds.

Members of the genus *Marmoricola* occurs mainly in different environments—soil (Dastager et al. 2008b), sandy sediment (Lee 2007b), and volcanic ash (Lee et al. 2011b; Lee and Lee 2010)—and strains of this genus were isolated also from a marble statue (Urzí et al. 2000). Except of *M. korecus*, they are able to degrade several substrates; most of them are able to grow even alkaline conditions.

Most type strains of *Aeromicrobium* species were isolated both from terrestrial and aquatic habitats. Species of *A. erythreum*, *A. alkaliterrae*, *A. panaciterrae*, and *A. ginsengisoli* were cultivated from different soil samples (Miller et al. 1991; Yoon et al. 2005a; Cui et al. 2007; Kim et al. 2008b) while *A. marinum* and *A. ponti* from seawater (Bruns et al. 2003; Lee and Lee 2008). The type strain of *A. tamlense* originated from dried seaweed collected from Samyang Beach in Jeju Island, Korea (Lee and Kim 2007), while *A. halocynthiae* originate from the siphon tissue of a marine ascidian, *Halocynthia roretzi*, collected off the coast of Gangneung, Korea (Kim et al. 2010). The isolation source of strains of *A. fastidiosum* was herbage (Collins and Stackebrandt 1989). The type strain of *A. flavum* was isolated from an air sample from the campus of Wuhan University, China (Tang et al. 2008).

Most *Kribbella* species (*K. flavida, K. sandramycini, K. koreensis, K. antibiotica, K. jejuensis, K. yunnanensis, K. alba, K. karoonensis, K. swartbergensis, K. hippodromi, K. ginsengisoli*, and *K. amoyensis*) were isolated from different soils (Li et al. 2004, 2006; Song et al. 2004; Kirby et al. 2006; Cui et al. 2010) including a gold-mine cave in Korea (Lee et al. 2000), a racecourse soil in South Africa (Everest and Meyers 2008), and a rhizosphere soil of a pharmaceutical plant (*Typhonium giganteum* Engl.) located in Xiamen City, China (Xu et al. 2012). An acidic and heavy-metal-containing rock surface in a medieval alum slate mine located in Thuringia, Germany was the isolation source of the type strain of *K. aluminosa* (Carlsohn et al. 2007). The type strain of *K. solani* originated from a potato tuber with scab lesions (Song et al. 2004), while *K. lupini* from root nodules of *Lupinus angustifolius* growing near a former uranium mine in Salamanca, Spain (Trujillo et al. 2006). Type strains of two *Kribbella* species (*K. catacumbae* and *K. sancticallisti*) were isolated from whitish-grey patinas in the catacombs of St Callistus in Rome, Italy (Urzí et al. 2008).

Members of the genus *Actinopolymorpha* thrive in soil (Wang et al. 2001) and rhizosphere of plants (Cao et al. 2009; Yuan et al. 2010) or can exist as plant endophytes (Kaewkla and Franco 2011a).

The type strains of *Thermasporomyces* and *Flindersiella* genera were isolated from mature compost produced by a field-scale composter which was used for the treatment of livestock excreta (Yabe et al. 2011) and the surface-sterilized root tissue of an endemic Australian tree, *Eucalyptus microcarpa*, known as Grey Box (Kaewkla and Franco 2011b), respectively.

Pathogenicity, Clinical Relevance

Though the members of the genus *Nocardioides* have been isolated and also associated with human diseases (Harris et al. 2007), they are considered nonpathogenic to humans or other warm-blooded animals.

Application

Bioremediation

An important characteristic of many members of the genus *Nocardioides* is the ability to metabolize recalcitrant and complex compounds, including toxic environmental pollutants, alkanes of various lengths, crude oils, and derivatives (Hamamura and Arp 2000; Iizuka and Komagata 1964; Hamamura et al. 2001; Schippers et al. 2005). Degradation of N-heterocyclic aromatic compound originating from crude oil, creosote, and shale oil was also observed (Inoue et al. 2007). There are reports on the ability of members of this genus to degrade phenols and nitrophenolic compounds (Gundersen and Jensen 1956; Collins et al. 1994; Cui et al. 2009; Yoon et al. 2009). Some species are able to utilize heterocyclic compounds such as dibenzofurans and chloroaromatics, and also dibenzo-p-dioxins (Futamata et al. 2004; Inoue et al. 2007; Kubota et al. 2005; Sukda et al. 2009). Some species are able to degrade different herbicides, like 2,4,5-trichlorophenoxyacetic acid (Ebert et al. 1999, 2001) and atrazine (Mulbry et al. 2002; Vibber et al. 2007). *Nocardioides* sp. PD653 is reported to mineralize hexachlorobenzene, a recalcitrant environmental pollutant (Takagi et al. 2009). *Nocardioides* sp. JS614 is capable of aerobic growth with ethane (known as a plant hormone)and vinyl chloride (Chuang and Mattes 2007; Mattes et al. 2005, 2007; Owens et al. 2009), and Ikunaga et al. (2011) observed also the degradation capacity of a mycotoxin, deoxynivalenol, by *Nocardioides* sp. WSN05-2. Fokina et al. (2003) demonstrated the bioconversion of steroids by *N. simplex* VKM Ac-2033D.

Formation of Added-Value Products

Representatives of the genus *Nocardioides* inhabiting marine shellfish were found to show wide-spectrum antimicrobial effect and antitumor activities (El-Shatoury et al. 2009). Insecticidal activities were also observed in some *Nocardioides* strains (Dellweg et al. 1988). Macrolide antibiotics are produced by some *Nocardioides* strains (Omura et al. 1987). *N. albus* DSM 3176 and DSM 3177 synthesize leucylblasticidin S and a peptidyl nucleoside (Dellweg et al. 1988). A piericidin producer *Nocardioides* strain was detected by Kubota et al. (2003) which compound inhibited cell division of fertilized starfish (*Asterina pectinifera*) eggs. *Nocardioides aromaticivorans* IC177 was described as a carbazole degrader bacterium (Inoue et al. 2006).

Aeromicrobium erythreum (Miller et al. 1991) produces the macrolide antibiotic erythromycin A. As a biologically valuable secondary metabolite, sandramycin antibiotic is produced by *Kribbella sandramycini* (Park et al. 1999).

The type strain of *Aeromicrobium halocynthiae* (Kim et al. 2010) produces taurocholic acid, a bile acid, as a major secondary metabolite.

Enzymes

A *Nocardioides* strain (N106) was isolated by Masson et al. (1995) which was highly active in chitosan degradation. The histamine dehydrogenase (homodimeric enzyme, catalyzes oxidative deamination of histamine) was studied on the genetic level by Fujieda et al. (2004). Gesheva and Vasileva-Tonkova (2012) demonstrated that an Antarctic *Nocardioides* strain (A-1) produces a broad spectrum of hydrolytic enzymes. This strain had also strong antimicrobial effect against several Gram-positive and Gram-negative bacteria.

34 The Family *Nocardiopsaceae*

Erko Stackebrandt
Leibniz Institute DSMZ-German Collection of Microorganisms and Cell Cultures, Braunschweig, Germany

Abstract
The family *Nocardiopsaceae* has been defined on phylogenetic grounds (Rainey et al. 1996). It is one of ten families included in the order *Streptosporangiales* Goodfellow (*Bergey's Manual of Systematic Bacteriology*, vol 5 Part B, Springer, New York, 2012). Morphologically, members of the family are characterized by an extensively branched mycelium, which bear nonmotile spores of different numbers and shapes. Diaminopimelic acid is the diagnostic amino acid of peptidoglycan. Fatty acids and polar lipid patterns are complex. Menaquinones have 9–11 isoprenoid units with varying degrees of hydrogenation. Members are widely distributed in soil, especially saline and hypersaline soils. The four genera described at the time of the latest release of *Bergey's Manual of Systematic Bacteriology*, e.g., *Nocardiopsis* (Hozzein and Trujillo 2012), *Haloactinospora* (Trujillo and Goodfellow 2012), *Streptomonospora* (Cui 2012) and *Thermobifida* (Trujillo and Goodfellow 2012) cover extensively the taxonomic properties, enrichment, ecology and presence of secondary metabolites of the species. This communication will cover additional species and genera described since 2012.

Phylogeny and Taxonomy

In the past few years several additional species of the genus *Nocardiopsis* and *Streptomonospora* and four new genera have been described. The position of many of these taxa is shown in the neighbor-joining tree of *Fig. 34.1*. In contrast to its genus affiliation, Nocardiopsis arabia clusters closely with *Streptomonospora halophila*, already mentioned by Hozzein and Trujillo (2012). As a consequence of its position, this species has been reclassified as *Streptomonosopra arabia* (Zhang et al. 2013) as DNA-DNA similarities were sufficiently low to distinguish two genomospecies. The genus description of the *Streptomonospora* has been emended by Cui et al. (2001), Li et al. (2003) and by Zhang et al. (2013). Based upon genome sequences of *Streptosporangium roseum* DSM 43021^T (Nolan et al. 2010), *Thermobifida fusca* strain YX (Lykidis et al. 2007) and *Nocardiopsis dassonvillei* subsp. *dassonvillei* DSM 43111^T Sun et al. 2010) the isolated phylogenetic position of the order *Streptosporangiales* could be confirmed by molecular signatures (indels) (Gao and Gupta 2012). The genome of an additional species of *Nocardiopsis*, *N. alba*, has been sequenced by Qiao et al. (2012). Taxonomic properties of the novel species of *Nocardiopsis* and *Streptomonospora* are listed in *Tables 34.1* and *34.2*, respectively. The salient features of the novel genera affiliated to the family are shown in *Table 34.3*.

E. Rosenberg et al. (eds.), *The Prokaryotes – Actinobacteria*, DOI 10.1007/978-3-642-30138-4_340,

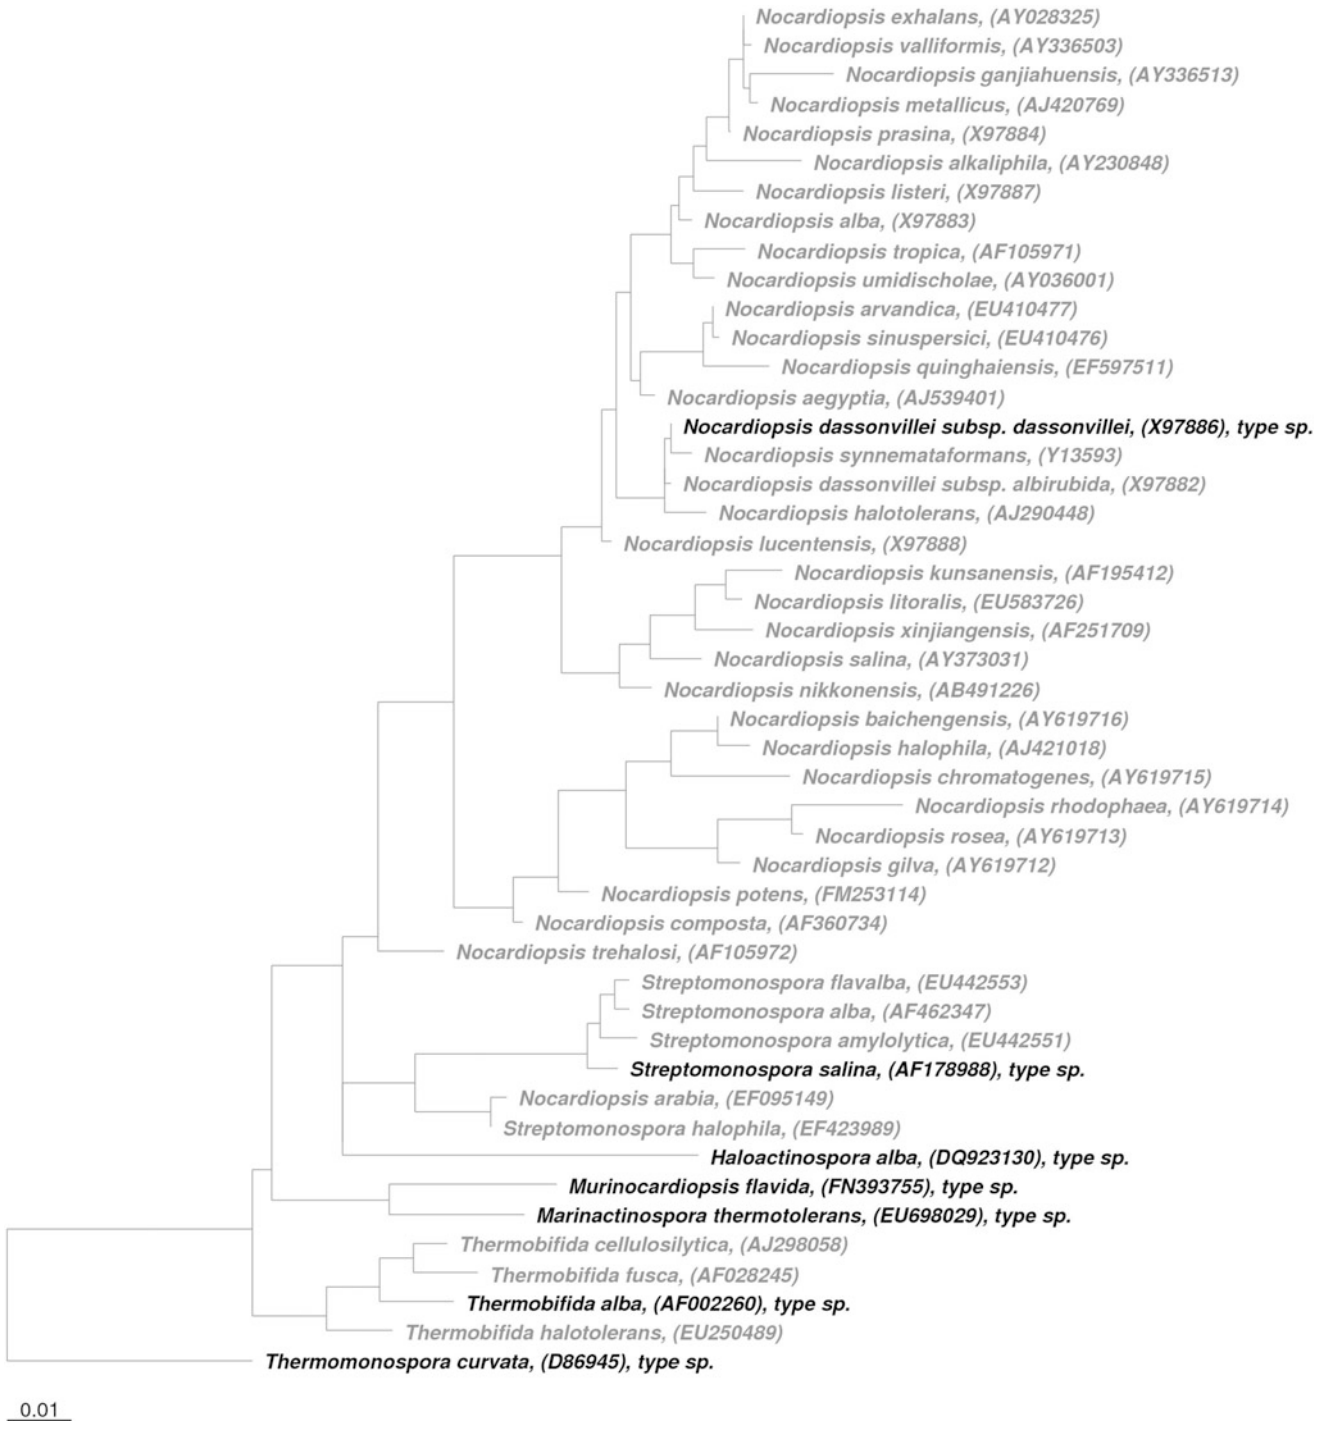

Fig. 34.1

Maximum likelihood genealogy reconstruction based on the RAxML algorithm (Stamatakis 2006) of the validly described species in the family *Nocardiopsaceae* The tree was reconstructed by using a subset of sequences representative of close relative genera to stabilize the tree topology (Yarza et al. 2010). In addition, a 40 % conservational filter for the whole bacterial domain was used to remove hypervariable positions. The bar indicates 1 % sequence divergence. Sequences of recently described taxa are not included

35 The Family *Promicromonosporaceae*

Peter Schumann · Erko Stackebrandt
Leibniz Institute DSMZ-German Collection of Microorganisms and Cell Cultures, Braunschweig, Germany

Abstract
The family *Promicromonosporaceae*, composed of 7 genera and 26 validly named species, is a family of the order *Micrococcales*. Morphologically, most members of the family form a primary mycelium; aerial hyphae are sparse and are formed only on certain media. Individual cells, often fragmentation products of vegetative mycelium, are nonmotile and short rods to coccoid in shape. Chemotaxonomically, members are defined by L-lysine at position 3 of the peptide subunit of the peptidoglycan and a dicarboxylic amino acid in its interpeptide bridge (peptidoglycan type A4α). Members are similar with respect to their polar lipids, major menaquinones, and principal fatty acids. Certain members of *Cellulosimicrobium* have been isolated in the clinical environment and should be considered as opportunistic pathogens. Several species are of industrial significance due to the presence of glucanases, cellulases, xylanases, and mannases. Culture and nonculture studies revealed their presence in diverse environmental samples but rarely in significant numbers.

Taxonomy, Historical and Current

The monogeneric family *Promicromonosporaceae* was established to accommodate *Promicromonospora* because of its distinct phylogenetic position within the suborder *Micrococcineae*, *Actinobacteria*, and the presence of a taxon-specific set of 16S rRNA signature nucleotides (Stackebrandt et al. 1997). In the following years, several new genera were added, either by reclassification of misclassified species [i.e., *Cellulosimicrobium*, by reclassifying *Cellulomonas cellulans* (Stackebrandt and Keddie 1986) as *Cellulosimicrobium cellulans* (Schumann et al. 2001); *Xylanimicrobium*, by transferring *Promicromonospora pachnodae* (Cazemier et al. 2003) as *Xylanimicrobium pachnodae* (Stackebrandt and Schumann 2004); and *Isoptericola*, by reclassifying *Cellulosimicrobium variabile* (Bakalidou et al. 2002) as *Isoptericola variabilis* (Stackebrandt et al. 2004)], or as novel taxa, such as *Myceligenerans* (Cui et al. 2004), *Xylanimonas* (Rivas et al. 2003), and *Xylanibacterium* (Rivas et al. 2004). A molecular emendation of the family was given by Zhi et al. (2009) by revising the set of 16S rRNA gene sequence signature nucleotides, consisting of nucleotides at the following positions: 120 : A; 131–231 : A-G; 196 : U; 342–347 : C-G; 444–490 : A-U; 580–761 : C-G; 602–636 : G-U; 670–736 : A-U; 822–878 : G-C; 823–877 : G-C; 826–874 : C-G; 827: U; 843 : U; 950–1231 : U-A;

E. Rosenberg et al. (eds.), *The Prokaryotes – Actinobacteria*, DOI 10.1007/978-3-642-30138-4_173,

1047–1210 : G-C; 1109 : C; 1145 : G; 1309–1328 : G-C; 1361 ; G; 1383 : C. The type genus is *Promicromonospora* Krasil'nikov, Kalakoutskii and Kirillova 1961, 107^{AL}.

With the second edition of *Bergey's Manual of Systematic Bacteriology*, the class *Actinobacteria* was emended to phylum level (Goodfellow 2012) and the suborder *Micrococcineae* was elevated to the order *Micrococcales* (Busse 2012). Within this order, *Promicromonosporaceae* (Schumann and Stackebrandt 2012a) is 1 of 15 families.

Members of the family resemble each other in most of their chemotaxonomic properties (*Table 35.1*), such as diaminoacid of the peptidoglycan (L-lysine), phospholipid composition (phosphatidylglycerol, diphosphatidylglycerol), major menaquinone (MK-9[H]$_4$), predominant fatty acids (iso- and anteiso-branched), and mol% G+C content of DNA (70–75 mol%). Differences are seen in the structure of the peptidoglycan–interpeptide bridge, where variations occur in the presence of a monocarboxylic amino acid and the nature of the dicarboxylic D-amino acid. By and large, each of the multispecies genera is rather homogeneous with respect to the peptidoglycan structure (*Table 35.1*). Morphologically, the four multispecies genera form a well-developed substrate mycelium that is lacking in the three monospecific genera. Many representatives of the family are capable of degradation of polysaccharides, such as cellulose, chitin, mannan, and xylan.

The phylogenetic structure of the family, as analyzed by the neighbor-joining algorithm, shows the species of the genera *Promicromonospora, Cellulosimicrobium, Isoptericola*, and *Myceligenerans* cluster according to their taxomomic affiliation (*Fig. 35.3b*). The three monospecific genera cluster together as a sister clade of the genus *Isoptericola*. In contrast, according to the maximum-likelihood algorithm (*Fig. 35.3a*), the genus *Myceligenerans* as well as the three monospecific genera branch from within the radiation of *Isoptericola* species. Also, *Promicromonospora flava* does not group with the other members of its genus. Nevertheless, the family appears as a phylogenetically homogeneous entity, well separated from neighboring families—which are, according to the TLP tree (http://www.arb-silva.de/fileadmin/silva_databases/living_tree/LTP_release_106/LTPs106_SSU_tree.pdf), *Rarobacteraceae*, and slightly less close, *Sanguibacteraceae*, *Cellulomonadaceae*, and some other families. This is consistent with the position according to the road map in *Bergey's Manual of Systematic Bacteriology*, second edition (Ludwig et al. 2012).

Molecular Analyses

DNA-DNA Hybridization

DNA-DNA relatedness between selected type strains of the family were mostly performed by the spectroscopic method of Huss et al. (1983) or the colorimetric microdilution plate method of Ezaki et al. (1989) and applied to confirm the species status of the isolates. Some similarity values were moderately high (~40–63 %), such as for *Promicromonospora endophytica* and *P. xylanilytica* (62.6 %, Kaewkla and Franco 2012), *Isoptericola dokdonensis* and *I. jiangsuensis* CLG^T (58.7 %, Wu et al. 2010), *Myceligenerans halotolerans* and *M. xiligouense* (56 %, Wang et al. 2011) and *Cellulosimicrobium cellulans* and *C. funkei* (47 %, Brown et al. 2006). The majority of values, however, were lower than 30 %. At the intraspecies level, data were obtained for *Cellulosimicrobium funkei* (76–79 %, Brown et al. 2006) using the hydroxyapatite method of Brenner et al. (1982).

Phages

Some actinophages that cause true lysis and/or clearing of host cells have been described. P1 (DSM 49141), P2 (DSM 49106), P3 (DSM 49107), and P4 (DSM 43108) are effective against strains of *Promicromonosporas citrea* and *P. sukumoe* (Stackebrandt and Prauser 1991), but other strains of the family have not been tested. *Cellulosimicrobium cellulans* strains are hosts of O5 (DSM 49112; host strain DSM 43881; Stackebrandt and Prauser 1991) and O13 (DSM 49139; host strain DSM 43879^T; Prauser 1986).

RiboPrinting

Both restriction enzymes *Pvu*II and *Pst*I are suited for the generation of RiboPrint patterns for strains of the family *Promicromonosporaceae*. *Pvu*II seems to provide a more complete digestion of the DNA under the conditions used by the RiboPrinter® System because the patterns display less undigested DNA (band at ca. 50 kbp) when compared to the *Pst*I patterns (*Fig. 35.1*). The *Pvu*II- and *Pst*I-generated patterns of all type strains in *Fig. 35.1*, including those of the pairs *Promicromonospora aerolata—P. vindobonensis* and *Cellulosimicrobium funkei—C. cellulans* showing the highest similarities in matrix-assisted laser desorption/ionization–time of flight (MALDI-TOF) mass spectra and 16S rRNA gene sequences (see below), can easily be differentiated by their band positions.

In many cases, RiboPrint patterns are strain-specific, as demonstrated by an example in the genus *Myceligenerans* (Groth et al. 2005). One of the three strains of *M. crystallogenes* shared the *Pvu*II RiboPrint pattern with the type strain HKI 0369^T, whereas the third isolate HKI 0371 differed from this Ribogroup by displaying an additional strain-specific band. Distinct RiboPrint patterns and the DNA-DNA similarity value of < 15 % support the differentiation of *M. crystallogenes* from its close relative *M. xiligouense* (Groth et al. 2005).

MALDI-TOF Mass Spectrometry

MALDI-TOF mass spectrometry (MS) is well suited for the differentiation of species of the family *Promicromonosporaceae*. The pairs of species *Promicromonospora vindobonensis*—*P. aerolata*, *Cellulosimicrobium funkei*—*C. cellulans*, and *Isoptericola nanjingensis*—*I. variabilis* show branching points with the lowest distance levels in the dendrogram based on mass spectra (Fig. 35.2). The species forming these pairs are highly related, as revealed by 16S rRNA gene sequence comparison (Fig. 35.3). However, the high mass spectral similarity of *Promicromonospora kroppenstedtii* and *P. sukumoe* is not supported by a notably high 16S r RNA gene sequence similarity (Fig. 35.3). The MALDI-TOF spectra of *Promicromonospora citrea and P. flava*—the two most deeply branching members of the genus in Fig. 35.3—fall outside of the cluster of the *Promicromonospora* spectra. Spectra of the *Isoptericola* species cluster together, whereas one species each of the genera *Cellulosimicrobium* and *Myceligenerans* (*C. terreum* and *M. halotolerans*) represent a separate lineage in the dendrogram (Fig. 35.2).

Genome Analysis

Full genome sequences are available for *Xylanimonas cellulosilytica* DSM 15894^T (Foster et al. 2010) and the non-type strain *Isoptericola variabilis* 225 (Lucas et al. 2011 unpublished).

The genome of strain DSM 15894^T (accession number CP001821), comprising the main circular chromosome and one 88,604-bp-long plasmid, is 3,831,380 bp with a DNA GC content of 72.5 %. Of the 3,546 genes predicted, 3,485 were protein-coding genes (2,426 with predicted functions) and 61 were RNAs. The number of rRNA operons was 3. In addition, 42 pseudogenes were identified. The majority of genes (68.4 %) were assigned with a putative function, while the remaining genes were annotated as hypothetical proteins. The distribution of 2,403 genes into Clusters of Orthologous Groups functional categories shows that 294 genes (8.4 %) were assigned to carbohydrate transport and metabolism function, whereas 414 genes (6.1 %) were assigned to amino acid transport and metabolism function.

The number of nucleotides of the strain 225 genome (direct submission, accession number NC_015588) is 3,307,740, the number of protein genes is 2,881 (approximately 2,200 are proteins with functional assignments), the number of RNA genes is 60, and the number of rRNA copies is 9.

Phenotypic Analyses

The Family *Promicromonosporaceae* Rainey, Ward-Rainey and Stackebrandt 1997, 484^{VP}, emend. Zhi, Li and Stackebrandt 2009, 598

Pro.mi.cro.mo.no.spo.ra'ce.ae. N.L. fem. n. *Promicromonospora*, type genus of the family; L. suff. *–aceae*, ending to denote a family; N.L. fem. pl. n. *Promicromonosporaceae*, the *Promicromonospora* family.

As of February 2014, the family contained 7 genera and 26 validly named species. The latest edition of *Bergey's Manual of Systematic Bacteriology* (Goodfellow 2012) covers all genera and 16 species. The phylogeneric relationships at the intrafamily and intrageneric levels are depicted in Fig. 35.3, whereas

[a]Data from type strain descriptions. References are indicated in column headings

Table 35.1 shows the properties defining the genera. The present format lists the salient phenotypic and chemotaxonomic differences of presently validly named species per genus; the original descriptions should be consulted for additional information.

Promicromonospora Krasil'nikov, Kalakoutskii and Kirillova 1961, 107[AL]

pro.mi.cro.mo.no.spo'ra. Gr. pref. *pro* before, primitive; Gr. adj. *mikros* small; Gr. adj. *monos* single, solitary; Gr. fem.n. *spora* a seed, and in microbiology a spore.; N.L.fem.n. *Promicromonospora*, the genus name, was coined to reflect the combination of traits then thought to be characteristic of the actinomycete form genera "*Proactinomyces*" (the tendency of the mycelium to fragment) and *Micromonospora* (the formation of single spores on the substrate mycelium).

Cells are Gram-stain-positive. The members produce branching septate hyphae. The substrate mycelium, which may penetrate into the agar, is well developed and fragments into nonmotile, coccoid, Y-shaped, V-shaped, or curved bacillary elements. If indicated, hyphae are 0.2–0.5 to 0.4–1.0 μm in diameter, whereas fragmented elements are 0.3–0.5 × 0.6–1.5 μm. In some species single-sessile, oval spores are observed on some media (*P. endophytica* [0.5 × 0.6 μm], *P. kroppenstedtii*). No diffusible pigments were produced. Colonies of all type strains were cream to pale yellow, or white to yellowish-white to orange except for *P. thailandica*, whose colonies were pale greenish-yellow. Several type strains degrade xylane and cellobiose.

The chemotaxonomic properties are indicated in *Table 35.1*. Detailed fatty acid patterns were provided by Martin et al. (2010b) and Qin et al. (2012). No study on phenotypic properties compares all type strains; the methods used are often not comparable and the number of tests vary greatly. Although several studies include or concentrate on acid production from carbohydrates, the same selection is not used in all studies. Similarly, the selection of carbohydrates applied in assimilation tests of recently described type strains only allows the comparison of a small dataset. To avoid a large number of undetermined entries, the table of phenotypic properties was split. *Table 35.2* displays the phenotypic reactions for those strains investigated by a large set of reactions, whereas

[a]In the original description (Bakalidou et al. 2002) the murein was described to contain the amino acids lysine, aspartic acid, glutamic acid and alanine in a molar ratio of 1.0:0.9:2.0:1.8. This molar ratio was later corrected to 1:0.9:1:2 of lysine, aspartic acid, glutamic acid, and alanine (Stackebrandt et al. 2004)

Table 35.3 lists those type strains for which a smaller set was determined, either acid production from or assimilation of carbohydrates. For additional reactions, the reader is referred to the original description (shown under the species names in the column headings).

The type species is *Promicromonospora citrea* Krasil'nikov, Kalakoutskii and Kirillova 1961, 107^{AL}. In addition to the validly named species, the literature refers to "*Promicromonospora cymbopogonis*" (Chen et al. unpublished), with a 16S rRNA gene sequence accession number of EU200679.

Isoptericola Stackebrandt, Schumann and Cui, 2002, 686^{VP}

I.sop.te.ri´co.la N.L.n. *Isoptera* order of termites, L. masc. suffix –cola inhabitant; N.L. masc. n. *Isoptericola* inhabitant of termites.

Cells are rod-shaped, V-shaped or coccoid, non-motile (0.8–1.1 × 0.8–4.4 μm), and non-spore-forming. Primary mycelium may be formed, which may fragment into short, irregular, non-motile rods and cocci in the stationary growth phase. An aerial mycelium is absent. The diameters of the colonies are 1–4 mm; they are mostly pale-yellow or orange-yellow. Cells are aerobic to facultative anaerobic, and acid is produced from some carbohydrates. Some strains are cellulolytic and/or xylanolytic. *N*-glycolylmuramic acid, mycolic acids, and hydroxy fatty acids are absent. The acyl type is acetyl. The chemotaxonomic properties are indicated in *Tables 35.1* and *35.4*, whereas the physiological properties are indicated in *Table 35.5*.

The type species is *Isoptericola variabilis* (*Cellulosimicrobium variabile* Bakalidou et al. 2002, 1189^{VP}) Stackebrandt, Schumann, and Cui 2004, 687^{VP}. Strains of the invalidly named species *Promicromonospora yunnanensis* were reclassified as strains of *Cellulosimicrobium cellulans* (Zhang and Liu 2006).

Cellulosimicrobium Schumann, Weiss and Stackebrandt, 2001, 1009^{VP}, emend. Brown, Steigerwalt, Morey, Daneshvar, Romero and McNeil, 2006; emend Yoon, Kang, Schumann, and Oh, 2007

Cel.lu.lo.si.mi.cro'bi.um. N.L. n. *cellulosa* cellulose; Gr. adj. *micros* small; Gr. masc. n. *bios* life; N.L. neut. n. *Cellulosimicrobium* cellulose microbe.

Cells are Gram-positive but very readily decolorized; they are not acid-fast. In young cultures, a primary mycelium is produced; it later fragments (at 1–4 weeks) into irregular, curved, and Y- and club-shaped rods, which may be arranged in V forms. After exhaustion of the medium, the rods are transformed into shorter rods or even spherical cells. Cells, which do not form endospores, are motile or non-motile and chemoorganotrophic. The metabolism

Table 35.5

Distinguishing physiological properties of *Isoptericola* type strains (Data from Huang et al. (2012b). Although some of the data differ from those given in the original species description, the data from Huang et al. (2012b) were used because all type strains were included in the same study, using comparable conditions)

All taxa are positive for Gram-staining; catalase; hydrolysis of aesculin and starch; utilization of glycerol, L-arabinose, D-xylose, D-galactose, D-glucose, D-fructose, D-mannose, arbutin, salicin, cellobiose, maltose, sucrose, starch, and glycogen; and the activity of esterase lipase (C8), leucine arylamidase, valine arylamidase, cystine arylamidase, naphthol-AS-BI-phosphohydrolase, β-galactosidase, α- and β-glucosidase. All taxa are negative for motility and utilization of erythritol, L-xylose, D-adonitol, L-sorbose, dulcitol, inositol, D-sorbitol, xylitol, D-tagatose, D-fucose, L-arabitol, L-fucose, potassium gluconate, and potassium 2- and 5-ketogluconate

– negative, + positive, *n.d.* not determined

is respiratory and the cells are facultatively anaerobic. Acid is produced from several carbohydrates. Cells are catalase positive and cellulolytic. Nitrate reduction is positive or negative. The major menaquinone is MK-9(H_4); other chemotaxonomic and physiological properties differentiating between type strains are indicated in Table 35.6.

C. cellulans forms acetic acid as the main acidic intermediary product of aerobic glucose dissimilation. Anaerobically, the resting cells of this species ferment glucose predominantly to CO_2, acetic acid, and L-lactic acid, whereas ethanol and formic acid are minor end products. Other species were not investigated. Additional properties are indicated in the original descriptions, summarized by Schumann and Stackebrandt (2012b).

The type species is *Cellulosimicrobium cellulans*.

The rational for the reclassification of *Nocardia cellulans*, *Oerskovia xanthineolytica*, and related species first as *Cellulomonas cartae* (Stackebrandt and Kandler 1980), then as *Cellulomonas cellulans* (Stackebrandt and Keddie 1986) and subsequently as *Cellulosimicrobium cellulans*, (Schumann et al. 2001) has been outlined by Stackebrandt et al. (2002) and Schumann and Stackebrandt (2012b).

The morphological cycle of strains of *C. cellulans* (described for *Nocardia cellulans* by Metcalfe and Brown 1957) on nutrient agar (similar on yeast-extract peptone agar) includes the following stages: After 2 days of incubation at 25 °C, the cells consist of branching aseptate filaments that are 30–40 μm in length, often with swellings at intervals. Shorter filaments are present, but few are less than 7.0 μm in length. Fragmentation commences after the fourth day, and the number of short rods (1.5–2.0 × 1.0 μm) increases rapidly. Branched filaments (up to 10 μm in length) are present until the 10th day or later. Hyaline spore-like structures are produced from the seventh day on as slight terminal swellings on the filaments. After 28 days, the colonies consist of very short rods, cocci, and spore-like cells.

In *C. funkei*, rods are short (1 μm) and thin, whereas those of *C. terreum* are 0.4–0.8 × 0.4–2.0 μm. The color of the colonies depends upon the media composition; it ranges from creamy yellow to bright yellow.

Myceligenerans Cui, Schumann, Stackebrandt, Kroppenstedt, Pukall, Xu, Rohde and Jiang 2004, 1292^{VP}, emend. Wang, Tang, Lou, Mao, Jin, Klenk, Zhang and Li 2011, 976^{VP}

My.ce.li.ge.ne.rans. N.L. neut. n. *mycelium*, filamentous cell; L. part. adj. *generans*, producing; N.L. neut. subst. *Myceligenerans*, hyphae-forming microbe.

Cells are Gram-positive. The substrate mycelium is well developed and branched in and on the media. The aerial mycelium is absent or sparse (*M. halotolerans*). The surface of the substrate mycelium bears fragmented cells and spore chains, with one or two non motile spores at the tips of the mycelium. Spores are coccoid to rod-shaped and nonmotile. (The description of *M. halotolerans* does not mention spores but indicates fragmentation of the mycelium.) Mycolic acids are absent. Cells are aerobic to microaerophilic. The peptidoglycan type is A4α, with variation L-Lys ← L-Thr ← D-Glu. If determined, the acyl type is acetyl. Other chemotaxonomic as well as physiological differentiating properties are indicated in Table 35.7.

The type species is *Myceligenerans xiligouense*.

The three monospecific genera *Xylanimicrobium*, *Xylanibacterium*, and *Xylanimonas* are compared together because of their ability to degrade xylan and a high number of common physiological reactions (see Table 35.7). They can be distinguished from each other by several chemotaxonomic properties (see Table 35.1).

Xylanimicrobium Stackebrandt and Schumann, 20041385^{VP}

Xy.la.ni.mi.cro'bi.um. N.L. neut. n. *xylanum* xylan, a polysaccharide; Gr. adj. *mikros* small; Gr. masc. n. bios life; N. L. neut. n. *Xylanimicrobium* xylan-hydrolysing microbe.

White, dry, and wrinkled colonies are formed on plates with basal medium 2 containing glucose. In addition to the properties listed in Tables 35.1 and 35.8, growth occurs

Table 35.6

All strains are positive for catalase; hydrolysis of casein, hypoxanthine, and xanthine; acid production from D-glucose and sucrose; utilization of D-glucose, cellobiose, D-mannose, D-xylose, L-arabinose, sucrose, maltose, alkaline phosphatase, esterase (C4), esterase lipase (C8), acid phosphatase, naphthol-AS-BI-phosphohydrolase and α-glucosidase. All are negative for hydrolysis of tyrosine; acid production from L-rhamnose, D-mannitol, inositol and D-sorbitol; utilization of L-malate, lipase (C14), leucine arylamidase, valine arylamidase, cystine arylamidase, trypsin, α-chymotrypsin, α-galactosidase, β-glucuronidase, α-mannosidase and α-fucosidase

For abbreviations see the footnote of *Table 35.1*

[a]Sottnek et al. (1977)

under aerobic and anaerobic conditions and is accompanied by secretion of xylanases and endoglucanases. Fermentation products on glucose and xylose are formate, lactate, ethanol, and acetate. Optimum growth is at a pH of 7.5 and a temperature of 35 °C. The type species is *Xylanimicrobium pachnodae* Cazemier et al. 2003).

Xylanibacterium Rivas, Trujillo, Schumann, Kroppenstedt, Sánchez, Mateos, Martinez-Molina, Velázquez 2004, 560^{VP}

Xy.la.ni.bac.te'ri.um. N.L. neut. n. *xylanum* xylan, a polysaccharide; N.L. neut. n. *bacterium* from Gr. neut. n. baktron small rod; N.L. neut. n. *Xylanibacterium* xylan-hydrolyzing small rod.

In addition to the properties listed in *Tables 35.1* and *35.8*, other physiological traits are indicated in the original species description of the type species *Xylanibacterium ulmi* (Rivas et al. 2004). The optimal pH for growth is 7. Colonies grown on yeast extract + dextrose (YED) medium are circular convex, white, opaque, and usually 1–3 mm in diameter within 7 days at 28 °C.

Xylanimonas Rivas, Sánchez, Trujillo, Zurdo-Piñeiro, Mateos, Martinez-Molina, Velázquez 2003, 102^{VP}

Xy.lan.i.mo.nas. N.L. n. *xylanum* xylan, a polysaccharide; Gr. n. *monas* a unit; N.L. n. *Xylanimonas* a monad from xylan.

In addition to the properties listed in *Tables 35.1* and *35.8*, other physiological traits are indicated in the original species description of the type species *Xylanimonas cellulosilytica* (Rivas et al. 2003). Optimal growth occurs at a temperature of 30 °C and a pH of 7. Colonies grown on YED medium are circular, convex, white, and opaque and usually 1–3 mm in diameter within 7 days at 28 °C.

5-Ketogluconate	–	+	+

All strains are xylanolytic and aerobic or facultatively anaerobic. All strains use the following compounds of the API 50CH substrate panel: glycerol, L-arabinose, D-xylose, L-lyxose, galactose, D-fructose, D-mannose, cellobiose, Aesculin, sucrose, trehalose, β-gentiobiose, and D-turanose. None of the strains use erythritol, D-arabinose, D-arabitol, adonitol, dulcitol, inositol, mannitol, melizitose, melibiose, methyl α-D-glucoside, methyl α-D-mannoside, methyl β-xyloside, sorbitol, D-raffinose, L-sorbose, inulin, L-arabitol, or L-xylose

Isolation, Enrichment and Maintenance Procedures

Isolation and Enrichment

A wide range of isolation techniques and isolation media were reported in the original descriptions of *Promicromonosporaceae* type strains. Rather than listing the techniques individually, the most salient isolation features are compiled in *Table 35.9*. In some cases, antibiotics were used in the isolation medium to suppress the growth of Gram-negative bacteria and eukaryotes (e.g., 20–25 mg nalidixic acid, 50 mg L^{-1} cycloheximide, and 50–100 mg L^{-1} nystatin). Variations and different combinations of the methods and media listed were also used by other authors, such as Al-Awadhi et al. (2007), who studied alkaliphilic and halophilic hydrocarbon-utilizing bacteria from the Kuwaiti coasts of the Arabian Gulf; Radwan et al. (2010), who isolated epilithic hydrocarbon-utilizing diazotrophic bacteria from the Arabian Gulf coasts; and Ten et al. (2005) who used dye-labelled substrates for simultaneous screening of polysaccharide-degrading and protein-degrading micro-organisms. Snow samples spiked with different concentrations of glucose, starch, and a combination of both carbohydrates were used in the isolation of promicromonosporas from Antarctic snow (Antony et al. 2009, 2012).

Maintenance Procedures

Most members of the family can be maintained in trypticase-soy-yeast extract (TSY) medium (per liter: trypticase soy broth 30.0 g, yeast extract 3.0 g, agar 15.0 g, pH 7.0–7.2) or in glucose-yeast extract-malt extract (GYM) Streptomyces medium (per liter: glucose 4.0 g, yeast extract 4.0 g, malt extract 10.0 g, CaCO3 2.0 g, agar 12.0 g, with pH adjusted to 7.2 before adding agar and $CaCO_3$ deleted if liquid medium is used). See the DSMZ catalogue of strains (DSMZ; http://www.dsmz.de/catalogues/catalogue-microorganisms.html) for the maintenance media of family members.

The recommended provisions for preservation are serial transfers at 4-week intervals, followed by maintenance at 4 °C and storage of cells as 20 % (w/v) glycerol suspensions at −20 °C and −80 °C. Long-term preservation methods include freeze-drying in skim milk or in liquid TSY medium supplemented with 5 % dimethyl sulfoxide and maintenance in the vapor phase of liquid nitrogen at −196 °C.

Ecology

As of July 2012, BLAST 16S rRNA gene sequence hits greater than 98 % confirmed and extended the range of habitats of

Table 35.9

Isolation source, sample treatment, isolation medium and isolation conditions described for members of *Promicromonosporaceae*

Type strain of	Origin	Sample treatment	Isolation medium	Isolation conditions
Promicromonospora				
P. xylanilytica	Leaves of *Maytenus austroyunnanensis*	Qin et al. (2008, 2009)	Xylan-arginine agar [per liter: 2.5 g xylan, 1.0 g arginine, 1.0 g $(NH_4)_2SO_4$, 2.0 g $CaCl_2$, 1.0 g K_2HPO_4, 0.2 g $MgSO_4$, $7H_2O$, 10 mg $FeSO_4 \times 7H_2O$, 15.0 g agar; pH 7.2]	28 °C, 2 weeks
P. endophytica	Root of Grey Box tree	Sterilization with 70 % ethanol and 6 % hypochlorite for 5 min each, rinsed several times with sterile water and then with 10 % $NaHCO_3$ for 10 min followed by rinsing with sterile water	VL70 medium (Schoenborn et al. 2004)	27 °C, 3 weeks
P. thailandica	Marine sediment	Thawai et al. (2005)	HV agar (Hayakawa and Nonomura 1987)	n.i.[a]
P. enterophila	Fresh excrement from *Chromatoiulus projectus* Verh. (Diplopoda)	Direct plating	Diverse, such as nutrient agar (Difco); synthetic glucose agar (Márialigeti 1979); glycerol-arginine agar (El-Nakeeb and Lechevalier 1963)	28 °C, 2 weeks
P. kroppenstedtii	Sandy soil	Direct plating	Yeast extract-malt extract agar (Shirling and Gottlieb 1966)	28 °C, 5 days
P. flava	Sediment sample Baltic Sea, Germany	Direct plating	Fucose-proline medium [per liter Baltic Sea water: 5 g fucose, 1 g proline, 1 g $(NH_4)_2SO_4$, 1 g NaCl, 2 g $CaCl_2$, 1 g K_2HPO_4, 1 g $MgSO_4 \times 7H_2O$, 20 g agar; pH 7.2]	28 °C, 3 weeks
P. umidemergens	Wall colonized with molds	1 g sample material was shaken for 15 min in 10 ml 0.9 % NaCl solution containing 0.01 % (v/v) Tween 80	M79 agar (Prauser and Falta 1968)	28 °C, 2 weeks
P. vindobonensis *P. aerolata*	Air of the 'Virgilkapelle'; Vienna, Austria	BIOTEST Hycon RCS Plus air-sampler	PYES agar (Zlamala et al. 2002)	n.i.
P. citrea	Garden soil (Krasil'nikov et al. 1961)	n.i.	n.i.	n.i.
P. sukumoe	Soil sample collected at Sukumo city (Japan) Takahashi et al. (1987)	n.i.	n.i.	n.i.
Cellulosimicrobium				
C. cellulans	Soil beneath a chalk grassland plant community, UK	Washed filter paper placed on the surface of basal medium impregnated silica gel (Metcalfe and Brown 1957) was seeded with minute soil crumbs	Alternate growth in yeast-extract peptone agar and tubes containing liquid basal medium with strips of washed filter paper	25 °C, 2–3 days for first growth, duration for obtaining pure cultures not indicated
C. funkei	Blood of an endocarditis patient	Isolation protocol for the type strain or related strains is not recorded	Isolates of related strains were inoculated onto heart infusion agar with 5 % rabbit blood (BBL Microbiology Systems)	n.i.
C. terreum	Soil sample from Dokdo, Korea	Dilution plating	10× diluted nutrient agar (Difco)	25 °C
Isoptericola				
I. variabilis	Gut contents of *Mastotermes darwiniensis* (Froggatt)	Intestinal content of 10 termites was suspended in 10 ml sterile 0.85 % (w/v) NaCl solution. Aliquots of 0.5 ml were suspended in 4.5 ml of Medium A containing 0.2 g/l yeast extract and 5 g/l xylan. After 3 days 100 µl of enrichment culture was plated on Medium A solidified by 15 g/l agar (Schäfer et al. 1996)	Medium A (Kuhnigk et al. 1994): 10.8 mM K_2HPO_4, 6.9 mM KH_2PO_4, 21.5 mM KCl, 24.1 mM NaCl, 5.3 mM $MgSO_4$, 0.53 mM $CaCl_2$, 10 ml/l vitamin and trace element solution (Balch et al. 1979)	aerobic cultivation at 28 °C

Table 35.9 (continued)

Type strain of	Origin	Sample treatment	Isolation medium	Isolation conditions
I. hypogeus	Tufa sample from the catacomb of Domitilla Rome, Italy	Dilution plating	PY-BHI agar (Yokota et al. 1993)	n.i.
I. halotolerans	Saline soil, China	Dilution plating	Modified Horikoshi medium (Horikoshi and Grant 1998).	n.i.
I. dokdonensis	Soil sample from Dokdo, Korea	Dilution plating	Nutrient agar (Difco).	25 °C
I. chiayiensis	Mangrove soil sample, Chiayi County, Taiwan	Direct plating	HV agar (Hayakawa and Nonomura 1987)	30 °C, 4 weeks
I. nanjingensis	Soil sample, Nanjing, Jiangsu Province, China	Dilution plating	Sucrose–mineral salts medium: [per liter: 10.0 g sucrose, 0.5 g yeast extract, 1 g $(NH_4)_2SO_4$, 2 g K_2HPO_4, 0.5 g $MgSO_4$, 0.1 g NaCl, 0.5 g, $CaCO_3$ and 15 g agar	n.i.
I. jiangsuensis	Beach sand, Lianyungang, Jiangsu Province, China	Direct plating	Colloidal chitin as a sole carbon source. No medium indicated	n.i.
Myceligenerans				
M. halotolerans	Soil sample Qijiaojing salt lake, Xinjiang province, China	Direct plating	Glucose-tryptone-yeast medium with 5 % (w/v) NaCl (Tang et al. 2010).	37 °C, 2 weeks
M. crystallogenes	Tufa sample from the catacomb of Domitilla Rome, Italy	Dilution plating	PY-BHI agar (Yokota et al. 1993)	28 °C, 10 days
M. xiligouense	Pasture near an alkaline salt marsh in the Qinghai province, China	Dilution plating	Marine agar, pH 7.2 (Bacto)	28 °C
Xylanibacterium ulmi	*Ulmus nigra* wood decay, Spain	1 g, suspended in sterile water, was stirred for 60 min	100 µl was spread on XED medium (0.7 % xylan, 0.3 % yeast extract, 2.5 % agar)	28 °C, 10 days
Xylanimonas cellulosilytica	*Ulmus nigra* sawdust from a decayed tree, Spain	1 g, suspended in sterile water, was stirred for 30 min	100 µl was spread on XED medium (0.7 % xylan, 0.3 % yeast extract, 2.5 % agar)	28 °C
Xylanimicrobium pachnodae	Hindgut of larvae of the rose chafer *Pachnoda marginata* (Scarabaeidae, Coleoptera)	Isolated after enrichment of bacteria by using Media I and II under aerobic and anaerobic conditions. The hindgut suspension in medium I was plated on solidified Medium II containing xylan (1 g/l) or carboxymethylcellulose (10 g/l). Colonies with cellulolytic or hemicellulolytic activity were selected for restreaking on Medium II plates with xylan or carboxymethylcellulose (Cazemier et al. 2003)	Medium I: peptone, 5 g/l; yeast extract, 2 g/l; K_2HPO_4, 1 g/l; $MgSO_4.7H_2O$, 0.2 g/l; $Na_2S.9H_2O$, 0.16 g/l; cysteine, 0.32 g/l.; Na_2CO_3, 10 g/l (sterilized separately); pH 10.3. Medium II: K_2HPO_4, 1.9 g/l; KH_2PO_4, 0.94 g/l; $NaHCO_3$, 1.68 g/l; KC1, 1.6 g/l; NaCl, 1.43 g/l; NH_4Cl, 0.15 g/l; $MgSO_4.7H_2O$, 0.037 g/l; $CaCl_2.2H_2O$, 0.017 g/l; yeast extract, 0.1 g/l; $Na_2S.9H_2O$, 0.16 g/l and cysteine, 0.32 g/l; 0.2 ml/l trace element solution (Vishniac and Santer 1957); pH 7–7.2. Resazurine (0.0001 %, w/v) was added as a redox indicator to the anaerobic media The gas phase was N_2/CO_2 (80/20, at 0.5 atm overpressure). For cultivation under aerobic conditions $Na_2S.9H_2O$, cysteine and resazurine were omitted from media I and II and $NaHCO_3$ from medium II	Cultures were incubated on a rotary shaker (100 rpm) at 30 °C

[a] *n.i.* not indicated

cultured and as as-yet uncultured strains. Many records, however, do not indicate the isolation source of organisms and DNA. *Promicromonospora* strains were recorded as endophytes of *Jatropha* spp. (Madhaiyan and Ji unpublished; JQ659853); medicinal plants in Panxi plateau, China (Zhao et al. 2011); scabby potatoes (Wanner unpublished; EU080946), tropical plants (Qin et al. 2009), and native plants of unrecorded origin (Kaewkla and Franco unpublished; GU434253);

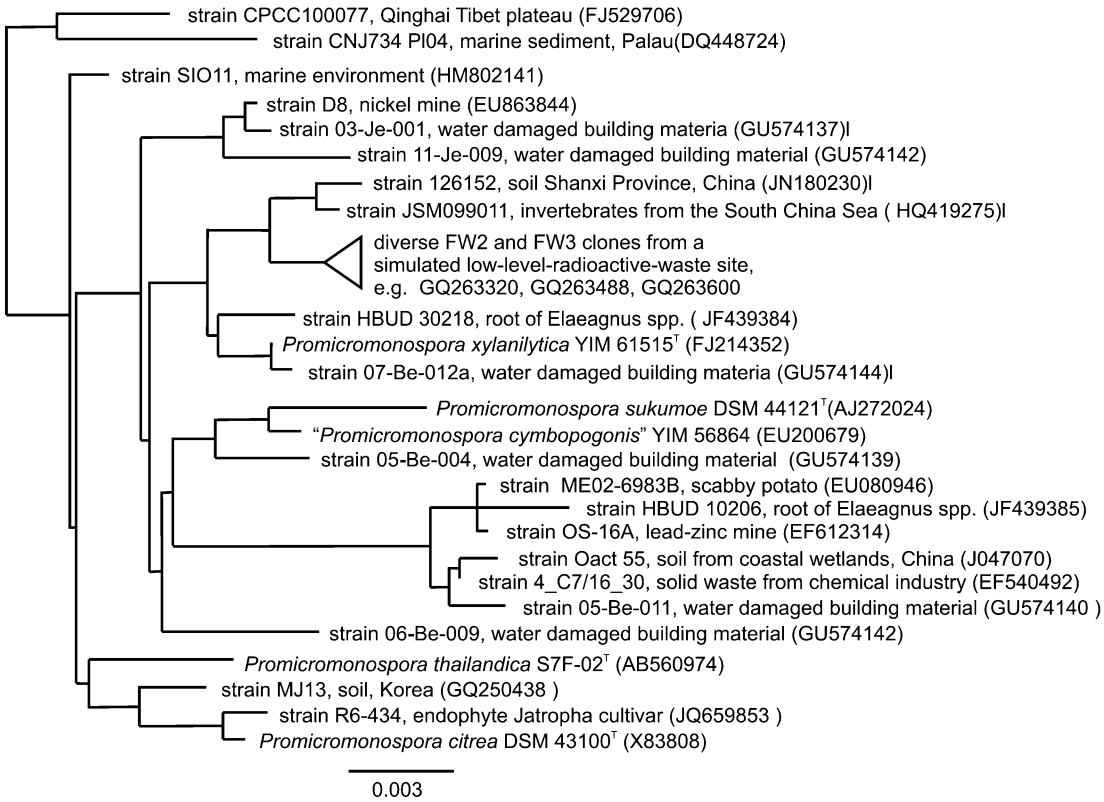

Fig. 35.4
BLAST Fast Minimum Evolution tree of 16S rRNA sequences of *Promicromonospora* clones and isolates

laboratory-scale composters (Xu et al. 2011); in root nodules of *Elaeagnus angustifolia* (Chen and Zhang unpublished; JF439384); marine invertebrates (Chen unpublished; HQ419275); soil (Lee unpublished; GQ250438; Kim unpublished; DQ906913), straw-decomposing microorganisms (Wang and Sun unpublished; JQ798496), members of communities in coal beds (Tan et al. unpublished; JF417733), nickel mines (Lan and Rahman unpublished; EU863844), and lead-zinc mines (Mendez et al. 2008); chemically contaminated waste (Vedler et al. unpublished; EF540492) and hydrocarbon-contaminated soil (Paidisetti unpublished; DQ297997); marine microbial communities (Xu et al. unpublished; HM802141; Donachie et al. unpublished; AY345426; Yu et al. unpublished; HM802141); and brackish water (Jia et al. unpublished; JQ801173). Several entries for the strain originate from mold-colonized water in damaged building materials (Schäfer et al. 2010) and for clones from a low-level radioactive waste site (Field et al. 2010) (see *Fig. 35.4*).

A similar broad range of habitats has also been reported for strains and clones from *Isoptericola* (*Fig. 35.5*), ranging from soil (Valenzuela-Encinas et al. 2009; Cao et al. unpublished, EU910875; Zhang et al. unpublished, FJ906972; Yamaguchi et al. unpublished, AB637292; Osman unpublished, JF508368; Tudahong et al. unpublished, HM448811), rhizosphere (Lee et al. unpublished, e.g., FN178383), a lake (Xia et al. unpublished, HQ738825), river delta (Jia et al. unpublished, e.g., JQ7162209), mangrove sediment (Liao et al. unpublished, FJ176393), deep-sea sediment (Xu et al. unpublished, EU181261), the gut of the moth *Helicoverpa armigera* (Rajagopal and Gayatri Priya unpublished; JF714416), compost (Narihiro et al. 2004; Hayakawa et al. unpublished, AB562485), and phenol-chemostat enrichment (Futamata et al. 2005; AB167235).

Cellulosimicrobium spp. have been found in compost (Narihiro et al. 2004; Hiraishi et al. 2003; Ohnishi et al. unpublished; AB210965), degradation of phenol (Chen and Wei unpublished; HQ619223), bagasse (Tong et al. unpublished; DQ530364), toluene (Chen et al. unpublished; GU966673), cellulose hydrolysis (Lo et al. 2009), Indian lake water (Joshi et al. 2008), deep sea sediment (Luo et al. unpublished; HM222665), hexane-degrading biofilters (Friedrich unpublished; AJ313025), poly(L-lactic acid) depolymerization (Wang et al. unpublished; GQ274926), the gut of *Holotrichia parallela* larvae (Huang et al. 2012a; JQ291586), the gut of the red turpentine beetle *Dendroctonus valens* (Morales-Jiménez et al. 2009), the intestinal tracts of earthworms *Eisenia fetida* (Hong et al. 2011), and formation of 7-prenylindole (Zhu et al. unpublished; HM623867). Strains of *C. funkei* were identified as culturable airborne bacteria from duck houses (Martin et al. 2010a), whereas Murphy et al. (2005) isolated *Cellulosimicrobium* strains from duck feces. No high scores are reported for *C. terreum*.

The presence of a strain of *Xylanimicrobium pachnodae* in the midgut and hindgut of *Pachnoda ephippiata* was reported by Egert et al. (2003). No close relatives were found for *Xylanimonas*

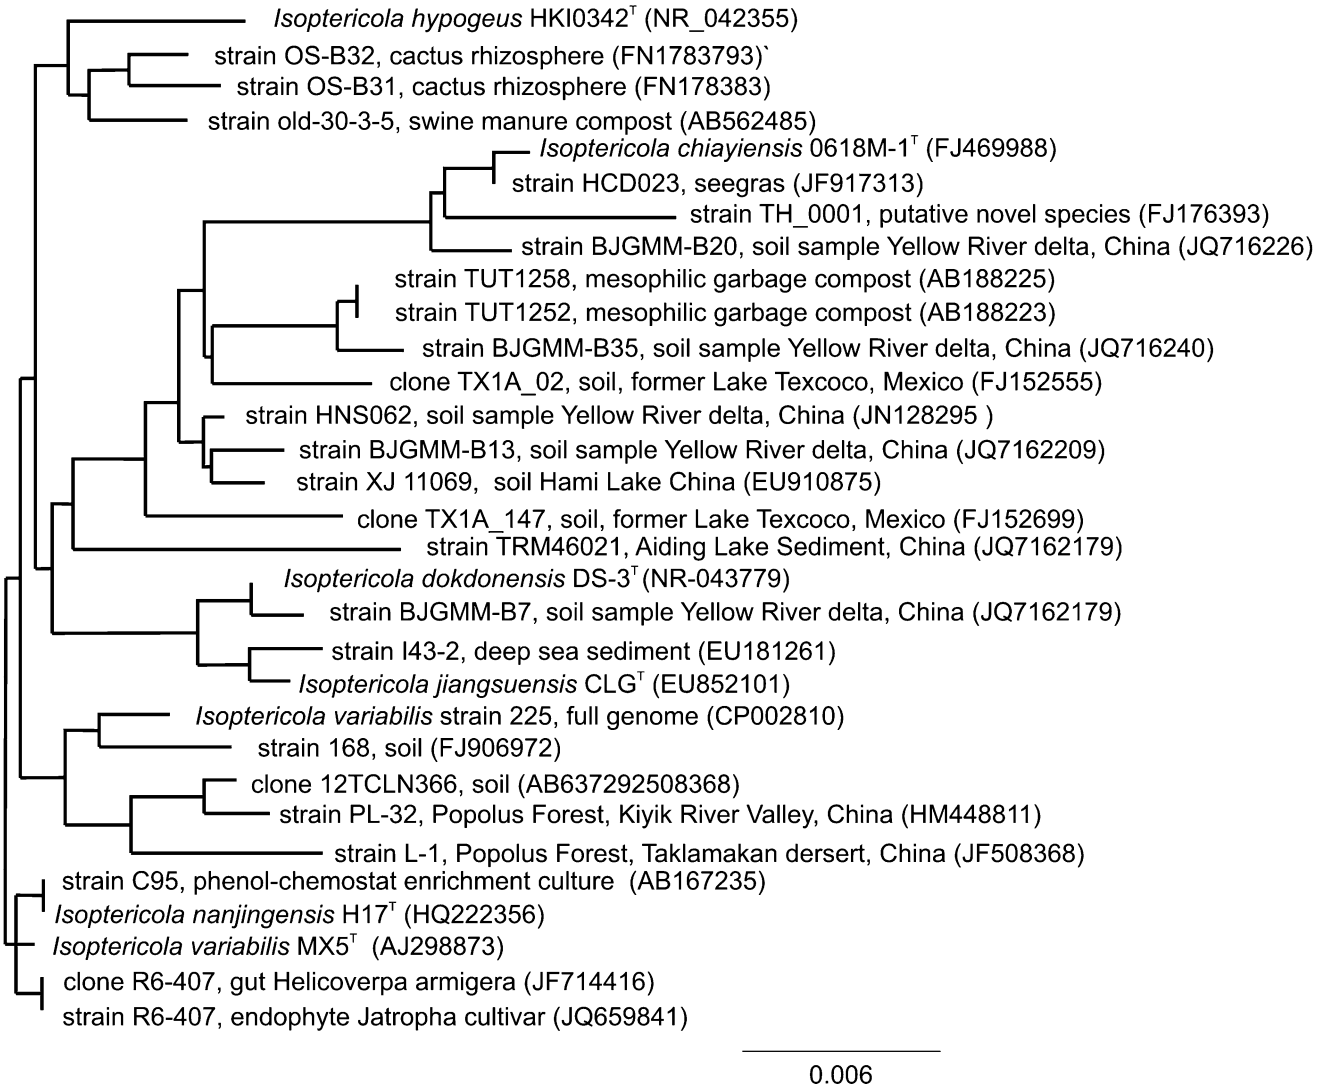

Fig. 35.5
BLAST Fast Minimum Evolution tree of 16S rRNA sequences of *Isoptericola* clones and isolates

cellulosilytica or Xylanibacterium ulmi (see Fig. 35.6). Likewise, besides entries for type strains of *Myceligenerans*, public databases only list two additional strain entries: one for an isolate from soil of Iriomote Island, Japan (Hayakawa et al. unpublished; AB546279) and the other for isolate LC 347 from a Lechuguilla cave, New Mexico (Barton et al. unpublished; JQ024522).

Pathogenicity, Clinical Relevance

Strains of *Cellulosimicrobium cellulans* were isolated from fetal tissues or placentas from cases of equine abortion, premature birth, and term pregnancies of horses, suggesting the causative role of these bacteria (Bolin et al. 2004). *Cellulosimicrobium*

C. funkei	Human: bacteremia and possibly prosthetic valve endocarditis	API coryne strip, 16S rRNA gene sequence (HQ402902), physiological tests	Vancomycin Gentamicin	Petkar et al. (2011)

cellulans was discussed as etiological agent of chronic tongue ulcerations in an immunocompromised patient (Heym et al. 2005). The strains of *Cellulosimicrobium funkei* are isolates from human sources that were received by the Special Bacteriology Section and the Actinomycete Reference Laboratory at the Center for Disease Control (Atlanta, Georgia, USA) between 1957 and 1977 and were classified earlier as strains of *Oerskovia turbata* (McNeil et al. 2004). The type strain W6122^T and strain W4083 were isolated from blood from patients from Colorado and California, respectively, and the lung isolate W2796 and strain W6123 originated from patients from New York. Although the isolation sites were suggestive of invasive infections, the clinical significance of these strains cannot be elucidated because no satisfactory case histories were available. The only strain of *Cellulosimicrobium terreum* was isolated from Korean soil (Yoon et al. 2007).

Of all the species included in the family, only two species of *Cellulosimicrobium* have been associated with human infection, although rarely (*Table 35.10*). Reports on clinical significance are available for *Cellulosimicrobium cellulans* (formerly *Oerskovia xanthineolytica*, to which the older literature refers) and *Cellulosimicrobium funkei;* these are considered to be opportunistic pathogens that mostly enter a wound by foreign bodies or cause infections due to medical devices, which have to be removed for resolution of the infection. *C. funkei* was misleadingly named *Oerskovia turbata* by Betancourt Castellanos et al. (2011) [see Chap. 9, "The Family Cellulomonadaceae" by Stackebrandt and Schumann, this volume]. Several case reports have been published describing infection due to *Oerskovia* spp. and *Cellulosimicrobium spp*., including bacteremia, endophthalmitis, endocarditis, peritonitis, meningitis, gangrenous cholecystitis, keratitis, pyonephrosis, and soft-tissue infection, as well as an association with bone marrow transplantation (compiled by Rowlinson et al. 2006; Magro-Checa et al. 2011 and Betancourt Castellanos et al. 2011); however, identification might not have been reliable in some of the early literature. Infections often occur in patients with chronic underlying illnesses such as neoplasms, chronic renal failure, Crohn disease, and acquired immunodeficiency syndrome (Lujan-Zilbermann et al. 1999; Kailath et al. 1988; Niamut et al. 2003; Tucker et al. 2008).

C. cellulans has been reported to be resistant to Amikacin (minimum inhibitory concentration [MIC] $\geq$ 64 µg/ml), ciprofloxacin (MIC $\geq$ 4 µg/ml), imipenem, erythromycin and other macrolides, lincosamides, aminoglycosides, and penicillin. It is considered to be variably susceptible to cephalosporins (but resistant to ceftazidime) and ciprofloxacin, but susceptible to vancomycin, cotrimoxazol, rifampin, moxifloxacin, and amikacin (see *Table 35.9*).

Strains of *Cellulosimicrobium funkei* are also resistant to Amikacin (MIC $\geq$ 64 µg/ml), trimethoprim-sulfamethoxazole (MIC $\geq$ 4–76 µg/ml), and CIprofloxacin (MIC $\geq$ 4 µg/ml) and sensitive to imipenem (MIC $\geq$ 16 µg/ml) (Brown et al. 2006).

All *Isoptericola* type strains are susceptible to carbenicillin (100 mg), chloramphenicol (30 mg), gentamicin (10 mg), neomycin (30 mg), novobiocin (30 mg), polymyxin B (30 mg), roxithromycin (15 mg), tetracycline (30 mg), and vancomycin (30 U). They are resistant to kanamycin (30 mg).

Table 35.11

Examples of the presence and characterization of genes of putative industrial importance

Strains of	Product	Genes and proteins, e.g.	Mode of action	References
Cellulosimicrobium cellulans (investigated as *Oerskovia xanthineolytica* LL G109), *C. cellulans* DSM 10297, and *C. cellulans* (investigated as *Arthrobacter luteus* ATCC 21606 (strain 73–14)	Wide heterogeneity of glucanases, strain dependent	β*gllIA* 28.6, kDa and β*gll* 40.8 kDa (family 16 of glycosyl hydrolases, release of biose and glucose). 54.5 kDa (family 64 of glycosyl hydrolases, release of pentoses)	Lyse viable yeast cells, spheroplasting for structural analyses of yeast and fungal cell wall, in cell wall permeabilization for the selective recombinant protein recovery from yeast cells or in biocatalysis	Review Ferrer (2006)
Cellulosimicrobium cellulans DK-1	Carbohydrate-binding module (CMB) appended recombinant endo-1,3-β-glucanase	Carbohydrate-binding module family 13	Hypothesis: insoluble carbohydrates bind to the catalytic domain and to the CBM of an endo-1,3-β-glucanase molecule; hence, the recombinant protein could accelerate hydrolysis, releasing shorter glucans as products.	Tamashiro et al. (2012)
Cellulosimicrobium cellulans DK-1	Endo-1,3-β-glucanase isolated from Tunicase, a crude enzyme preparation	Recombinants of a 41-kDa protein (glycoside hydrolase family 16); Accession no. EU589324	Hydrolysis of β-1,3- or both β-1,3- and β-1,4-glucosidic linkages; Hydrolysis of laminaripentaose and laminariheptaose	Tanabe and Oda (2011)
Cellulosimicrobium sp. strain HY-13	Endo-β-1,4-mannanases	Man H. 44.0 kDa mannanase; Accession no. JF519824	High specific activity towards ivory nut mannan and locust bean gum	Kim et al. (2011a)
Cellulosimicrobium sp. strain HY-13	Endo- β -1, 4-xylanase, lacking cellulase activity	XylK1. 58.3 kDa, unique modular xylanase; Accession no. FJ859907	Birch wood xylan, oat spelt xylane, p-nitrophenyl-β-D-cellobioside	Kim et al. (2009)
Cellulosimicrobium sp. strain HY-13	Endo- β -1,4-xylanase, displaying transglycosylation activity	XylK2. 79.6 Da, structurally analogous to XylK1t (90 %) and to *Xylanimonas cellulosilytica* DSM 15894 β-1,4-cellobiohydrolase (ACZ30181) (68 %)	Degradation of birchwood xylan, xylotriose, and xylotetraose	Kim et al. (2012)
Cellulosimicrobium sp. strain HY-13	Endo-β-1,4-mannanases	ManK. 34.93 Da	Highly specific for locust bean gum, guar gum, mannotetraose, and mannopentaose	Kim et al. (2011b)
Cellulosimicrobium sp. HY-12	Endo-β-1,4-xylanase, lacking cellulose activity	XylACspHY-12. 39.0 kDa (glycoside hydrolase family 10 endoxylanases)	Beechwood xylan Oat spelt xylan, Birchwood xylan, low p-nitrophenyl-β-D-cellobioside activity	Oh et al. (2008)
Cellulosimicrobium cellulans ST26 (from a petal of Casa Blanca Lily)	Hypothetical pathway: Glucose-glycogen-trehalose via malto-oligosyltrehalose synthase and malto-oligosyltrehalose trehalohydrolase		Trehalose (α-D-glucopyranosyl-[1,1]-α-D-glucopyranose) production	Seto et al. (2004)
Cellulosimicrobium cellulans GS6 from farmland in central Taiwan	Entrapped in modified calcium alginate capsules		Solubilizes insoluble phosphate complexes [$CaHPO_4$, $Ca_3(PO_4)_2$, $FePO_4$, and $AlPO_4$]	Liu et al. (2008)
Promicromonospora sp. RL26 from mangrove soil	Macrocyclic dilactone—JBIR-101		Cytotoxic activities against human malignant pleural mesothelioma ACC-MESO-1 cells and human cervical carcinoma HeLa cells	Izumikawa et al. (2011)
Isoptericola jiangsuensis CLG	Chitobiosidase Is-chiA endochitinase Is-chiB	Recombinant proteins Is-chiA 92 kDa and Is-chiB 60 kDa, glycosyl hydrolase family 18		Wu et al. (2011)

Application

The biological interest in *Promicromonospora* strains originates from a study by Lyons et al. (1969) who detected alpha-galactosidase activity in several members of Actinomycetales. Alpha-galactosidase activity can be exploited in several fields, such as the possible elimination of the flatus-inducing factor(s) in beans and soy, elimination of raffinose during beet-sugar processing, and the analytical determination of raffinose.

Most publications, however, are related to members of *Cellulosimicrobium* (see Table 35.11), which are rich sources of endo-1,3-β-glucanase, endo-β-1,4-mannanases, and endo-β-1,4-xylanases. The latter two enzymes were isolated from an exo-symbiotic bacterium capable of hydrolyzing xylan in the gut of the mole cricket, *Gryllotalpa orientalis*. In particular, the endo-β-1,4-xylanase lacking cellulose activity XylK1 was praised by the authors (Kim et al. 2009) for its potential role in removing hemicellulose without attacking cellulase and for its use as a biocatalyst in the bleaching process in the paper and pulp industry. Its pH activity, which is around 6.0, would make it superior to commercial fungal xylanases, which generally have an optimum pH of 5.0; when used to improve the digestion of foods by herbivorous animals, they are most active at a pH of 6.0–6.5 (Morgavi et al. 2000).

36 The Family *Propionibacteriaceae*: Genera other than *Propionibacterium*

Erko Stackebrandt
Leibniz Institute DSMZ-German Collection of Microorganisms and Cell Cultures, Braunschweig, Germany

Abstract

The family *Propionibacteriaceae* constitutes a phylogenetically coherent family. Together with the family *Nocardioidaceae*, it is a member of the order *Propionibacteriales* which, according to the Road Map of the Phylum Actinobacteria (Ludwig et al. 2012), form a large clade containing also the orders *Actinopolysporales*, *Corynebacteriales*, *Glycomycetales*, *Jiangellales*, *Micromonosporales*, and *Pseudonocardiales* (note, that the names of these orders have not yet been validated). Besides the genus *Propionibacterium*, that will be dealt with in a separate chapter, the family embraces 14 genera, most of which are monospecific. Members of the family have been isolated from a broad range of different habitats, including activated sludge, the marine environment, contaminated soil, human samples, and spiders and their webs. Chemotaxonomically the family is defined by similar menaquinone types, fatty acid composition, polar lipids, and, if investigated, polyamine pattern, but shows a wider spectrum of different peptidoglycan types and variations as well as more than 15 mol% differences in the G+C content of DNA.

Taxonomy: Historical and Current

A systematic-phylogenetic reevaluation of Gram-positive bacteria with a base composition G+C of DNA higher than 50 mol% has led to the description of the class *Actinobacteria* Stackebrandt et al. 1997 that embraces six orders. The order *Actinomycetales* Buchanan 1917, emend Stackebrandt, Rainey and Ward-Rainey 1997, has been defined to include 10 suborders, one of which was *Propionibacterineae*, containing the family *Propionibacteriaceae* Delwiche 1957, emend Rainey, Ward-Rainey and Stackebrandt 1997. Recently, the order *Actinomycetales* and the suborder *Propionibacterineae* were elevated to ranks of class and order, respectively (Ludwig et al. 2012). At that time of the description of the suborder, it contained the genera *Propionibacterium* (Orla-Jensen 1909), *Luteococcus* (Tamura et al. 1994), *Microlunatus* (Nakamura et al. 1995a), and *Propioniferax* (Yokota et al. 1994). The suborder was emended by Zhi et al. (2009) and the pattern of 16S rRNA signatures revised to consist of nucleotides at positions 127 : 234 A–U, 598 : 640 U–A, 657 : 749 G–C, 828 U, 829 : 851 A–C, 832 : 854 U–C, 833 : 853 G–U, 952 : 1229 C–G and 986 : 1219 U–A. In the same communication

E. Rosenberg et al. (eds.), *The Prokaryotes – Actinobacteria*, DOI 10.1007/978-3-642-30138-4_194,

also, the family *Propionibacteriaceae* was emended and a new set of 16S rRNA signatures provided [328 U, 407 : 435 C–G, 451 A, 453 G, 819 G, 825 : 875 A–U, 827 C, 828 U, 832 : 854 U–C, 833 : 853 G–U and 844 U] for all members that were described until 2007: In addition to those existing in 1997, these were *Aestuariimicrobium* (Jung et al. 2007), *Brooklawnia* (Bae et al. 2006a), *Friedmanniella* (Schumann et al. 1997), *Granulicoccus* (Maszenan et al. 2007), *Micropruina* (Shintani et al. 2000), *Propionicicella* (Bae et al. 2006b), *Propionicimonas* (Akasaka et al. 2003), *Propionimicrobium* (Stackebrandt et al. 2002), and *Tessaracoccus* (Maszenan et al. 1999a). Recently, the genus *Auraticoccus* (Alonso-Vega et al. 2011) and *Propioniclava* (Sugawara et al. 2011) have been added to the family (*Table 36.1*).

The phylogenetic tree (*Fig. 36.1*), based upon the RAxML algorithm of Stamatakis (2006) sees members of the family as a phylogenetically coherent group, consisting of several subgroups. One subgroup contains the genera *Friedmaniella*, *Microlunatus*, and *Auraticoccus*, while a second one embraces *Micropruina*, *Propionicimonas*, *Propionicicella*, and *Propioniciclava*. A third, small subgroup includes *Granulicoccus* and *Propioniferax*, while all other genera, including *Propionibacterium*, are members of a fourth subgroup. The membership to genera is consistent with most of the dendrograms included in the species descriptions, though the topology may differ. For example, while three species of *Tessaracoccus* and *Propionibacterium* are sister lineages in the RaxML tree, *Propionciclava* tarda branches with the genus *Propionibacterium* in the Neighbor-Joining tree (not shown). In both trees, *Tessaracoccus oleiagri* clusters more closely to *Brooklawnia cerclea* and *Propionicimicrobium lymphophilum* than with the other three species of *Tessaracoccus*. The branching pattern of genera does not correlate with the distribution of peptidoglycan types and variations.

Another member of the family has been proposed by Lee and Lee (2008b), "*Ponticoccus gilvus*." The generic name has already been used for a taxon in the alpha-proteobacterial family *Rhodobacteraceae*, the proposal to name a second genus with the same name has been denied.

As the majority of the recently described genera are monospecific, the description of metabolic properties may change with new species included. Also, the descriptions of the taxa were not always done in a comparable manner and many properties should be re-evaluated. This should not only be done for general metabolic properties but also for chemotaxonomic markers such as amino acid composition and linkage of the peptidoglycan, polar lipids, whole cell sugars, and polyamine composition. Membership to the family is based on distinct phylogenetic position and an exclusive set of some 16S rDNA signature nucleotides not found in other families. These signatures should be re-evaluated when new members are added to the family.

Members of the *Propionibacteriaceae* thrive in diverse habitats, covering human epidermal surfaces, dairy products, silage, soil, water, Antarctic sandstone, and sewage treatment plants. They are either aerobic or facultatively anaerobic, cover different morphologies, exhibit different peptidoglycan types and ariations, and the base composition of DNA ranges between 53 and 73 mol%. The peptidoglycan composition sees four variations, either the directly linked meso-A_2pm diaminopimelic acid at position 3 of the peptide subunit [variation A1γ according to Schleifer and Kandler (1972); or A31 according to Schumann (2011)], LL-A_2m at position 3 and glycine as the interpeptide bridge. This type has two variations:

Table 36.1
Validly published genera and species in the family *Propionibacteriaceae* except *Propionibacterium*. Type strains numbers relate to those species indicated in *Figure 36.1* and in *Tables 36.3–36.6*

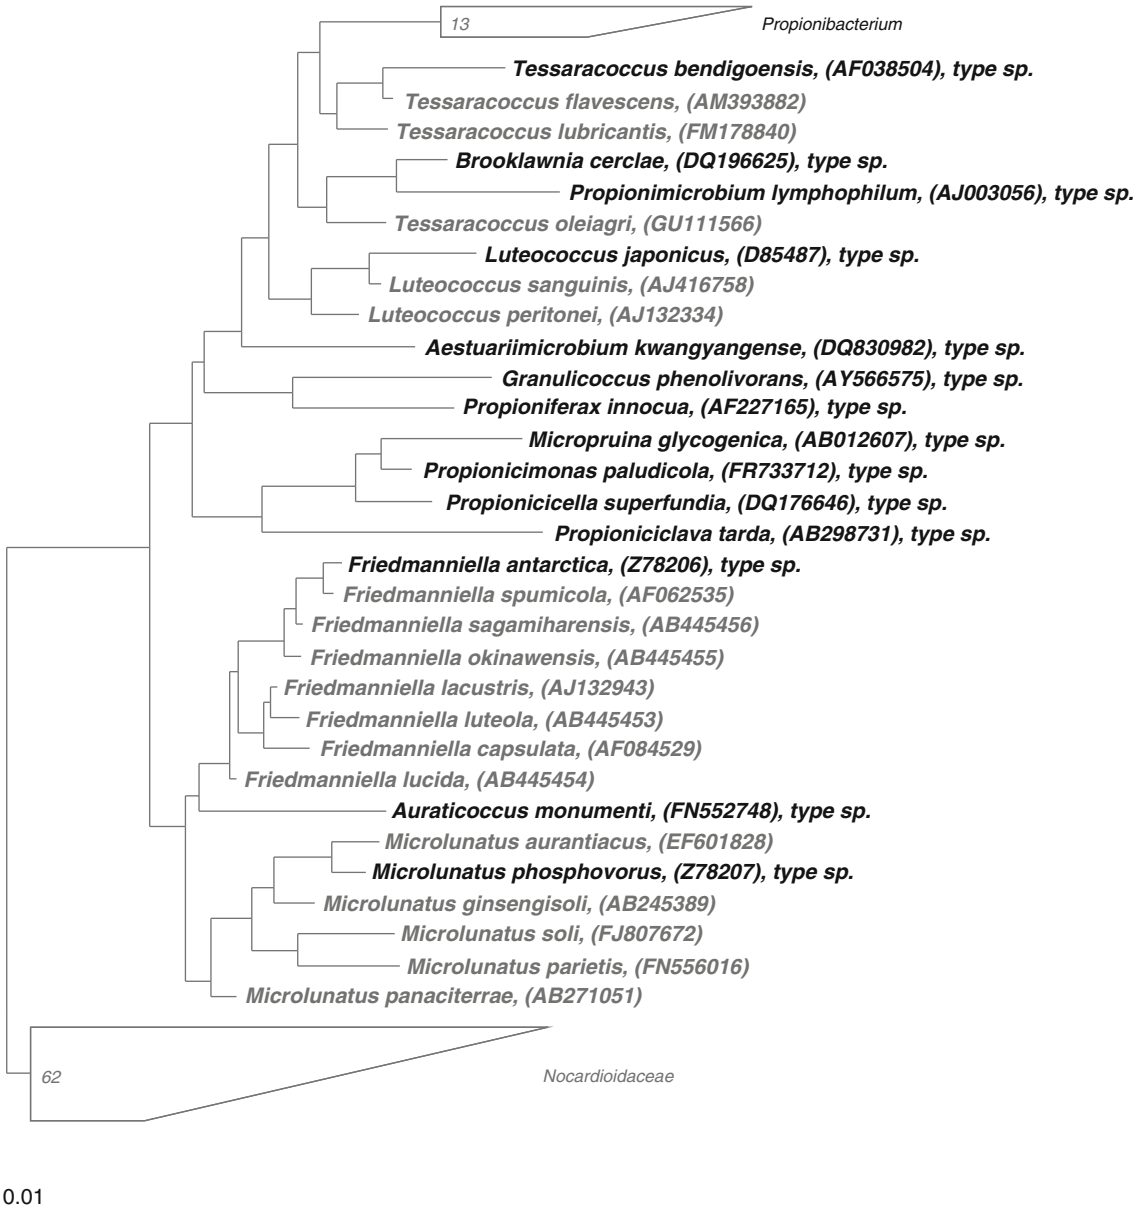

Fig. 36.1

Maximum likelihood genealogy reconstruction based on the RAxML algorithm (Stamatakis 2006) of the sequences of all members of the family *Propionibacteriaceae* present in the LTP_106 (Yarza et al. 2010). The tree was reconstructed by using a subset of sequences representative of close relative genera to stabilize the tree topology. In addition, a 60 % conservational filter for the whole bacterial domain was used to remove hypervariable positions. The bar indicates 1 % sequence divergence. Type strain numbers are included in *Table 36.1*

one with alanine at position 1 of the subunit (A3γ, A41.1), the other with glycine at position A3γ (A42.1), the fourth one with L-lysine at position 3 and D-aspartic acid as the interpeptide bridge (A4α, A11.31). The three diaminopimelic variations are also found among members of *Propionibacterium*. However, with respect to certain chemotaxonomic properties, such the combination of the few patterns of polyamines available (Busse and Schumann 1999), major menaquinones, and fatty acids, they appear rather homogeneous. Salient features differentiating members of the family are indicated in *Table 36.2*.

Molecular Analyses

DNA-DNA Similarities

DNA-DNA hybridization experiments, using different formats such as the methods of Ezaki et al. (1989), DeLey et al. (1970), and Ziemke et al. (1998), were performed to confirm the presence of genomospecies (Maszenan et al. 1999b; Collins et al. 2003; Wang et al. 2008; Kämpfer et al. 2009) and to affiliate isolates to the same species (Tamura et al. 1994; Jung et al. 2007).

Table 36.2

Properties differentiating genera of the family *Propionibacteriaceae*. The order is based on the phylogenetic position of the genera, as shown in the RaXML dendrogram *Fig. 36.1*

Genus	Cell morphology	Diagnostic amino acids in peptidoglycan	Position 1 in peptide subunit of peptidoglycan	Major menaquinone	Polar lipids	Major fatty acids	Mol% DNA G+C
Tessaracoccus	Spherical or rods	LL-A_2pm-Gly[a]	Glycine[a]	MK-9H_4, MK7H_4 or MK8 in some species	DGP, PG. PI, PE, PL, GL may occur	ai-$C_{15:0}$. i-$C_{16:0}$ may occur[b]	68.4–74
Brooklawnia	Pleomorphic rods	meso-A_2pm-direct	nd	MK-9H_4	nd	ai-$C_{15:0}$, $C_{15:0}$[c]	67.6
Propionimicrobium	Pleomorphic rods, spherical cells may occur	Lys-D-Asp	Alanine	MK-9H_4	nd	$C_{18:1}\omega9c$, ai-$C_{15:0}$, $C_{16:0}$	53–56
Luteococcus	Spherical or pleomorphic rods	LL-A_2pm-Gly[a]	Alanine[a]	MK-9H_4	DPG, PG, PI[a]	$C_{16:1}$, $C_{17:1}$, $C_{15:1}$. $C_{18:1}$ may occur	64–67
Aestuariimicrobium	Spherical to short rods	LL-A_2pm-nd	nd	MK-9H_4	nd	ai-$C_{15:0}$	69
Granulicoccus	Spherical, single, pairs	LL-A_2pm-Gly	Alanine	MK-9H_4, MK-8H_4	DPG, PG, 3GL, 3PL	i-$C_{15:0}$, i-$C_{15:0}$DMA	69
Propioniferax	Pleomorphic rods	LL-A_2pm-Gly	Alanine	MK-9H_4	PG, PE, PL, GL	nd	59–63
Micropruina	Spherical	meso-A_2pm-direct	nd	MK-9H_4	nd	i-$C_{14:0}$, ai-$C_{15:0}$	70.5
Propionicella	Rods	meso-A_2pm-direct	nd	MK-9	nd	ai-$C_{15:0}$, $C_{15:0}$, i-$C_{16:0}$	69.9
Propioniciclava	Pleomorphic rods	meso-A_2pm-direct	nd	MK-9H_4	nd	ai-$C_{15:0}$, i-$C_{15:0}$	69.5
Auraticoccus	Spherical, single, pairs, clusters	LL-A_2pm-Gly	Alanine	MK-8H_2, MK-9H_2, MK-9H_4	DPG, PG, PG2, 2PL, 4GL, 2 L	ai-$C_{15:0}$, i-$C_{15:0}$, ai-$C_{15:1}$, ai-$C_{17:0}$, i-$C_{14:0}$	73.5
Friedmanniella	Spherical, single, pairs, clusters	LL-A_2pm-Gly	Glycine[a]	MK-9H_4. MK-9H_2 and MK-7H_2 may occur	PG, PI. DPG and PC in most species. PL, GL may occur	ai-$C_{15:0}$, i-$C_{15:0}$. $C_{18:1}$ may occur	69–75
Microlunatus	Spherical	LL-A_2pm-Gly[a]	Glycine[a]	MK-9H_4. MK-8H_2 may occur	DGP, PG. PI, PE, PL, GL may occur[a]	ai-$C_{15:0}$. i-$C_{15:0}$, i-$C_{16:0}$ in most species. One species with $C_{18:1}\omega9c$	65–71
Propionicimonas	Irregular rods	meso-A_2pm-direct	nd	MK-9H_4, MK-10H_4	nd	$C_{13:0}$, $C_{15:0}$, ai-$C_{15:0}$	68.7
Propionibacterium	Spherical or pleomorphic rods,	LL-A_2pm-Gly, or meso-A_2pm-direct	Alanine (most species) or glycine	MK-9H_4[d]	nd	branched, or straight, or ω–cyclohexane	57–68

Abbreviation: *PG* phosphatidylglycerol, *DPG* diphosphatidylglycerol, *PE* phosphatidylethanolamine, *PI* phosphatidylinositol, *GL* unknown glycolipid, *PL* unknown phospholipid, *L* unknown lipid

[a]Properties only detected in a single or a few species

[b]For some species Lee et al. (2007) and Kämpfer et al. (2009) report a different composition

[c]No $C_{15:0}$ but $C_{16:0}$ has been reported by Cai et al. (2011)

[d]Kusano et al. (1997)

Within Friedmanniella, *F. antarctica* shares 98.8 % 16S rRNA gene sequence similarity and 50 % DNA-DNA reassociation DDH with *F. spumicola* (Maszenan et al. 1999b). With sequence similarity levels of >97 %, *F. luteola* and *F. lucida* are moderately related to the closely related pair *F. capsulata* and *F. lacustris* (99 %). The two spider isolates, showing 46 % DDH among themselves, showed 29 % and 43 % DDH relatedness to *F. lacustris* and *F. capsulata*, respectively (Iwai et al. 2010). No DDH values are available for the latter strain pair. With sequence similarity levels of 98 % (19 % DDH), *F. sagamiharensis* and *F. okinawensis* are most closely related to *F. antarctica* and *F. spumicola*. The DDH values obtained for these two pairs of strains were between 11 % and 30 % (Iwai et al. 2010).

Probes

The presence of *Micropruina* ssp. cells in an aerobic: anaerobic sequencing batch reactor with no phosphorus removal was verified by using the fluorescent in situ hybridization FISH in combination with microautoradiography FISH/MAR. The fluorescent 16S rRNA gene probe MIC 184 with the sequence CATTCCTCAAGTCTGCC was derived from the sequences of *Micropruina glycogenica* (Kong et al. 2001).

Another FISH probe was designed for the identification of *Microlunatus phosphoreus* in sludge of an enhanced biological phosphorous removal process. The sequence of the fluorescently labeled 16S rRNA targeting MP2 probe is GAGCAAGCTCTTCTCAACCG (Kawaharasaki et al. 1998).

Phages

Phages have been reported for *Microlunatus phosphovorus* (Lee et al. 2006). All of the 13 phages, obtained from an activated sludge reactor by the agar overlay plate technique, were double-stranded DNA phages. Based upon restriction patters, two types were recognized. The genome size was determined to be 42–48 kb for MP1 and 21–28 kb MP2. Both bacteriophages, belonging to the family *Siphoviridae*, had an icosahedral head and a long flexible tail, which appeared to be non-contractile. Host range studied showed the phages to be specific for *M. phosphovorus* JCM9379. Other members of the family, such as *Micropruina glycogenica* JCM10248, *Friedmanniella antarctica* NBRC16127, *F. capsulata* strain Ben108^T, *F. spumicola* strain Ben107^T, and *Tessaracoccus bendigoensis* NBRC16165, were not lysed. Using the fluorescently labeled phage technique, both phage types were able to tag *M. phosphoreus* added to activated sludge (Lee et al. 2006).

Genome Sequence

The genome sequence of *Microlunatus phosphovorus* NM-1^T has been deposited under the accession number AP012204 (Hosoyama et al., Unpublished).

Phenotypic Analyses

As seen in ● *Table 36.1* the family, excluding *Propionibacterium*, consists of 14 genera and 4 of these contain more than the type species only *Friedmanniella*: 8 species, *Microlunatus*: 6 species, *Tessaracoccus*: 4 species, and *Luteococcus*: 3 species. Species of each genus share the same relationship to oxygen and the same peptidoglycan type and variation, but differ in many other chemotaxonomic and metabolic properties which, together with moderate 16S rRNA gene sequence similarities below 97 %, were used for their definition. The following description of genera will point out only some of the species properties and the reader is referred to the original descriptions for a more comprehensive information which are helpful in the identification of novel isolates.

Friedmanniella Schumann, Prauser, Rainey, Stackebrandt, Hirsch 1997, 282^{VP}

Fried. man.ni.el'la. M. L. dim. ending *-ella;* M. L. fem. n. *Friedmanniella*, named after E. Imre Friedmann, an American microbiologist, in recognition of his contributions to Antarctic microbiology.

The genus *Friedmanniella* contains eight Gram-positive, nonmotile, aerobic coccoid, packets-forming species, two of which, *F. antarctica* (Schumann et al. 1997) and *F. lacustris* (Lawson et al. 2000), originate from Antarctic environment; two other species, *F. spumicola* and *F. capsulata* (Maszenan et al. 1999b), were isolated from sewage treatment plants in Australia, while the other four species were isolated from spiders or spider webs (Iwai et al. 2010). Generally, the cells occurred in packets which resulted from cell division in three perpendicular planes, no thin sections are available for the spider and spider web isolates. The packets adhered to one another, forming aggregates. Packets are often surrounded by extracellular polymer.

Most strains are catalase positive, oxidase negative, do not reduce NO_3 to NO_2 and produce extracellular polymers. Some strains accumulate polyphosphate (● *Table 36.3*) and, if investigated, polyamines are spermidine and spermine. Strains exhibit the same rare peptidoglycan type in which one glycine residue is defining the interpeptide bridge, while a second one is found at position 1 of the peptide subunit. Other properties of the genus are indicated in ● *Table 36.2*. The metabolic properties clearly differentiate between the eight species, though the intra-species diversity of strains is yet to be elucidated for more strains.

Microlunatus Nakamura, Hiraishi, Yoshimi, Kawaharasaki, Masuda, Kamagata 1995, 21^{VP}

Mi.cro.lu.na'tus. Gr. adj. *micros*, small; M. *L.* n. *lunatus*, half moon; M. L. n. *Microlunatus*, small moon-like microorganism.

[a]Negative in Wang et al. (2008)

This genus has been described to accommodate the Gram-positive, nonmotile, coccoid, and aerobic organism *Microlunatus phosphovorus* (Nakamura et al. 1995a). The description is based on the properties of two strains NM-1 and NM-2; the latter strain differing from the type strain NM-1^T JCM 9379^T only by flocculent growth. These strains, isolated from activated sludge in Japan, are chemoorganotrophic organisms which store polyphosphate under aerobic condition and take up organic substances such as glucose by utilizing polyphosphate as the energy source under anaerobic condition (Nakamura et al. 1995a, b). It also stores polyhydroxyalkanoates, mainly polyhydroxybutyrate (Akar et al. 2006).

The original description did not link *M. phosphovorus* to the genera *Luteococcus*, *Propioniferax*, and *Propionibacterium* but was closely affiliated to *Aeromicrobium* and *Nocardioides*, later included in the family *Nocardioidaceae* (Stackebrandt et al. 1997). Only with the inclusion of novel members of *Propionibacteriaceae*, the membership of *Microlunatus* to this family became obvious with which it shares the same peptidoglycan composition (*Table 36.2*). The other members of the genus match the circumscription as given above except for *M. parietis*, for which irregular rods in young cultures and short rods and spherical forms were described in older cultures >5 days of growth (Kämpfer et al. 2010b). Spermidine and spermine has been identified as polyamines in one species (Kämpfer et al. 2010a). Chemotaxonomic properties and some differentiating metabolic and cultural properties are indicated in *Tables 36.2* and *36.4*, respectively. All strains were positive

for utilization of L-arabinose, D-glucose, D-mannose, maltose, melibiose, L-rhamnose, D-ribose, and D-sorbitol. All strains were negative for the utilization of: D-gluconate, adipate, itaconate, L-alanine, 3-hydroxybenzoate, and phenylacetate.

Tessaracoccus Maszenan, Seviour, Patel, Schumann, Rees 1999, 466[VP]

Tes.sa.ra'coc.cus. Gr. adj. *tessara* four;Gr. n. *coccus* grain; L. n. *Tessaracoccus* four round cells.

The genus *Tessaracoccus* has been described for the nonmotile, coccoid, facultatively anaerobic Gram-positive strain *T. bendigoensis* Ben 106 [T], isolated from activated sludge biomass (Maszenan et al. 1999a). The sludge, originating from the Biological Nutrient Removal plant in Bendigo, Australia, had been processed in a laboratory scale sequencing batch reactor. The morphology of this strain, i.e., spherical or clusters of cocci arranged in tetrads, resembles that of the Gram-negative so-called G-bacteria (Carucci et al. 1994; Cech and Hartman 1993), commonly detected in activated sludge samples.

The G-bacteria constitute a phylogenetically diverse group of organisms belonging to the Actinobacteria and Proteobacteria (Seviour et al. 2000). The description of *Tessarococcus bendigoensis* extends the range of spherical species described to thrive in similar habitats, e.g., four Gram-negative species of *Amaricoccus* (Maszenan et al. 1997) from wastewater treatment plants in Italy, Czech Republic, Macau, and Australia, and the Gram-positive species *Microlunatus phosphovorus* (Nakamura et al. 1995a) from activated sludge, and *Microsphaera multipartita* [*Nakamurella multipartita*] (Yoshimi et al. 1996) from sugar containing synthetic wastewater, both from Japanese plants. While *Amaricoccus* is a member of the *Alphaproteobacteria*, *Microsphaera* is a member of the actinobacterial suborder *Frankineae*. The role of these organisms in this habitat is no yet settled, but they are all defined by depositing storage polymers intracellularly under aerobic conditions. *Tessarococcus bendigoensis* stores polyphosphate and may thus participate in phosphate removal (Seviour et al. 2000). The presence of storage compounds was not reported in the other species of the genus.

The type strains of two species, *T. lubricantis* and *T. flavescens*, were analyzed with respect to their polyamine pattern. Like in related genera, both strains contain spermidine and spermine and small amounts of putrescine, 1,3-diaminopropan and cadaverine were present in the latter strain (Kämpfer et al. 2009). *T. flavescens* differs from other members of the genus in the composition of menaquinones, as it has, in addition to the common MK-9H_4 type, MK-8H_0 that is present in considerable amounts (12 %) (Cai et al. 2011). The phospholipid composition of *T. flavescens* consists of diphosphoglycerol and phosphoglycerol only, while those of the other species is more complex.

All strains are Gram-positive, positive for catalase, negative for oxidase, urease, and indole production. Acid is produced from D-glucose, L-rhamnose, and maltose (Cai et al. 2011). Other properties are listed in ❯ *Tables 36.2* and *36.5* and in the original species descriptions.

The species *Tessaracoccus profundi*, described by Finster et al. (2009), has been effectively published but not yet validated. The type strain, isolated from the Chesapeake meteor impact crater drill core sample at 940-m depth, shows 95–96 % identity to other members of the genus. Morphology, oxidase and catalase reaction, relationship to oxygen, and peptidoglycan type are as reported for the other genus members. The G+C content of DNA is 68 mol%. Differences are seen in menaquinone composition and metabolic properties.

Luteococcus Tamura, Takeuchi, Yokota 1994, 355[VP]

Lu.te.o.- coc'cus. Lat. adj. *luteus* yellow; Gr. masc. n. *coccus* a grain; M.L. masc. n. *Luteococcus* yellow coccus.

This genus comprises three species, which are morphologically distinct but share chemotaxonomic and phylogenetic similarities. The type species *Luteococcus japonicus* (Tamura et al. 1994), isolated from soil and water, and *Luteococcus sanguinis* (Collins et al. 2003), isolated from human blood, are spherical. *L. peritonei* (Collins et al. 2000), isolated from human specimen exhibits, has a pleomorphic rod morphology. The most salient feature of the genus is the presence of monounsaturated long-chain fatty acids (>80 % of total), i.e., $C_{15:1}$, $C_{16:1}$, $C_{17:1}$, and $C_{18:1}$. If investigated, polyamines are spermidine and spermine. Strains are catalase positive. Acid is produced from glucose, maltose, D-mannitol, and sucrose, but not from D-xylose. The main end-product of glucose fermentation of *T. japonicus* is propionic acid. Other properties are indicated in ❯ *Tables 36.2* and *36.6* and in the original species descriptions.

Other Genera

The remaining genera of the family are monospecific, and they will be listed in alphabetical order together with some specific properties which are not already indicated in ❯ *Table 36.2*.

Aestuariimicrobium Jung, Kim, Song, Lee, Oh, Yoon 2007, 2117[VP]

Aes.tu.a.ri.i.mi.cro'bi.u.m. L. n. *aestuarium* part of the sea coast which, during the flood-tide, is overflowed, but at ebb-tide is left covered with mud or slime, a tidal flat; N.L. n. *microbium* microbe; N.L. neut. n. *Aestuariimicrobium* a microbe isolated from tidal flat.

[b] Lee et al. 2008a

The type species *A. kwangyangense* consists of aerobic, catalase positive, and oxidase negative short rods or spherical cells (0.6 – 1.0 × 1.2 – 2.0 μm). It grows between 4 °C and 40 °C, with an optimum of 30 °C and at a pH range of 7.5–8.5. Phylogenetically it is moderately related to the *Tessaracoccus/Luteococcus* cluster (Fig. 36.1).

Auraticoccus Alonso-Vega, Carro, Martínez-Molina, Trujillo 2011, 1101[VP]

Au.ra.ti.coc'cus. L. adj. *auratus* golden; N.L. masc. n. *coccus* from Gr. masc. n. kokkos a grain, seed a coccus; N.L. masc. n. *Auraticoccus* golden coccus.

The type species *A. monumenti* is an aerobic, catalase and oxidase positive coccus (0.8–1.2 μm). It grows between 15 and 30 °C, with an optimum of 28 °C and at a pH range of 6.5–9.0. It tolerates up to 5 % NaCl. Phylogenetically, it is moderately related to the *Friedmanniella/Microlunatus* cluster ❯ *Fig. 36.1* but contains alanine instead of glycine at position 1 of the peptide subunit.

Brooklawnia Rainey, da Costa and Moe 2006, 1981[VP]

Brook.law'ni.a. N.L. fem. n. *Brooklawnia* named after Brooklawn, the contaminated site from which members of the genus were first isolated.

The type species *B. cerclae* is a facultative anaerobic, catalase positive, and oxidase negative pleomorphic rod that grows between 10 and 40 °C, with an optimum of 37 °C and at a pH range of 4.5–8.0 optimum 6.5. It tolerates up to 3 % NaCl. Phylogenetically it is related to *Propionimicrobium lymphophilum* (❯ *Fig. 36.1*) but differ from this species in several chemotaxonomic properties (❯ *Table 36.2*).

Granulicoccus Maszenan, Jiang, Tay, Schumann, Kroppenstedt, Tay 2007, 733[VP]

Gra.nu.li.coc'cus. L. neut. n. *granulum* a small grain; L. masc. n. *coccus* a berry; N.L. masc. n. *Granulicoccus* a coccus from sludge granules.

The type species *G. phenolivorans* is a facultative anaerobic, catalase positive, and oxidase negative coccus (0.3–1.4 μm) that grows between 17 and 37 °C, with an optimum of 30 °C and at a pH range of 5.0–8.5 optimum 7.0. It contains intracellular polyphosphate granules and produces extracellular material. Phylogenetically it is related to *Propioniferax innocua* (❯ *Fig. 36.1*) with which it shares several common chemotaxonomic properties but differs in cell morphology and mol% G+C content of DNA (❯ *Table 36.2*).

Micropruina Shintani, Liu, Hanada, Kamagata, Miyaoka, Suzuki, Nakamura 2000, 205[VP]

Mi.cro.prui'na. Gr. adj. *micros* small, fine; M. L. fem. n. *pruina* hoarfrost; M. L. fem. n. *Micropruina* fine hoarfrost.

The type species *M. glycogenica* is an aerobic, catalase and oxidase positive coccus (0.5–2.2 μm) that grows between 20 °C and 30 °C, with an optimum of 30 °C and at a pH range of 6.0–8.0, optimum 7.0. It accumulates glycogen intracellularly. Phylogenetically it is related to *Propionicimonas paludicola* and *Propionicella superfundia* (>98 % similarity, ❯ *Fig. 36.1*) with which it shares the same meso-A_2pm peptidoglycan composition properties but differs in cell morphology and in the composition of other chemotaxonomic properties (❯ *Table 36.2*).

Propionicicella Rainey, da Costa and Moe 2006, 411, effective publication Validation List N° 111

Pro.pi.o.ni.ci.cel'la, N.L. n. *acidum propionicum*, propionic acid; L. fem. n. *cella*, a storeroom, chamber and in biology a cell; N.L. fem. n. Propionicicella, propionic acid-producing cells.

The type species *P. superfundia* is a facultative anaerobic, catalase and oxidase negative rod (0.5 × 1.7–2.5 μm) that grows between 15 °C and 37 °C, with an optimum of 30 °C and at a pH range of 4.5–8.5, optimum 6.5. It tolerates up to 4 % NaCl. Propionic acid, acetic acid, and formic acid are end-products of

glucose fermentation. Phylogenetically it is related to *Propionicimonas paludicola* and *Micropruina glycogenica* (Fig. 36.1), with which it shares the same meso-A_2pm peptidoglycan composition. The menaquinone is fully unsaturated MK-9 which is unique among members of the family.

Propionicimonas Akasaka, Ueki, Hanada, Kamagata, Ueki 2003, 1996[VP]

Pro.pi.on.i.ci.mo'nas. N.L. n. *acidum propionicum* propionic acid; Gr. fem. n. *monas* a unit, monad; N.L. fem. n. *Propionicimonas* propionic acid-producing monad.

The type species *P. paludicola* is a facultative anaerobic, catalase and oxidase negative irregular rod (0.4–0.5 × 1.8–2.0 µm) that grows between 10 °C and 40 °C, with an optimum of 35 °C and at a pH range of 4.5–7.5, optimum 6.5. It tolerates up to 2 % NaCl and has a requirement for cobalamin. Propionic acid, acetic acid, lactic acid, and minor succinic acid are end-products of glucose fermentation. Phylogenetically it is related to *Propionicicella* and *Micropruina* (Fig. 36.1), with which it shares the same meso-A_2pm peptidoglycan composition.

Propioniciclava Sugawara, Ueki, Abe, Kaku, Watanabe, Ueki 2011, 2302[VP]

Pro.pi.on.i.ci.cla'va. N.L. n. acidum propionicum propionic acid; N.L. fem. n. *clava* club; N.L. fem. *Propioniciclava* propionic acid-producing club.

The type species *P. tarda* is a facultative anaerobic, catalase positive and oxidase negative irregular rod (0.5–0.8 × 0.6–1.8 µm) that grows between 20 °C and 37 °C, with an optimum of 35 °C and at a pH range of 5.3–8.0, optimum 7.5. Growth is inhibited in the presence of NaCl, but cobalamin or a B-vitamin mixture stimulates growth. Propionic acid and acetic acid are the main end-products of carbohydrate fermentation. *P. tarda*, too, is defined by a meso-A_2pm peptidoglycan type. The 16S rRNA gene sequence similarities with other members of the family are low <92 % and its phylogenetic position is not clear-cut. Branching remotely to the *Propionicicella/Propionicimonas/Micropruina* lineage in the RaxML tree, it appears as a sister lineage to the genus *Propionibacterium* in the neighbor-joining tree of the LTP. According to the NJ tree of Sugawara et al. (2011), the *Propioniclava* lineage branches even deepest within *Propionibacteriaceae*.

Propioniferax Yokota, Tamura, Takeuchi, Weiss, Stackebrandt 1994, 581[VP]

Pro.pi.on.i.fe'rax. M.L. *n. acidum propionicum*, propionic acid; L. adj. *ferax*, fertile; M.L. n. *Propioniferax*, propionic acid-producing.

Propioniferax innocua is a facultative anaerobic, catalase and oxidase positive pleomorphic rod (0.5 × 1.2 µm) that grows between 10 °C and 40 °C, with an optimum of 37 °C and at a pH optimum of 7.0. Isolated from human epidermal surface. Originally, the species was affiliated to *Propionibacterium* because of the presence of genus-specific characteristics such as the presence of LL-diaminopimelic acid in the peptidoglycan, coryneform morphology, base composition of DNA, and the formation of propionic acid as the main end-product of glucose fermentation. 16S rRNA analysis placed *Propionibacterium innocuum* as a remotely related member of the genus *Propionibacterium*. However, outside reference organisms that would have shown the position of *P. innocuum* in relation to other coryneform and actinomycete species were not included in the phylogenetic analysis. With the description of *Luteococcus japonicus*, *P. innocuum* emerged as the nearest phylogenetic neighbor (94.5 % 16S rRNA gene sequence similarity), and both species branched as a sister clade to *Propionibacterium* species. In the light of this information, certain properties of *P. innocuum* were re-evaluated: In contrast to the descriptions of most *Propionibacterium* species (Charfreitag et al. 1988; Kusano et al. 1997), strains of *P. innocuum* show aerobic and facultatively anaerobic growth, contain arabinose in cell wall hydrolysates, and do not require blood, serum, or Tween 80 for growth. The principal carboxylic acid produced from glucose, sucrose, maltose, trehalose, fructose, mannose, and glycerol is propionic acid. Polyamines are spermidine and spermine. Phylogenetically it is remotely related to *Granulicoccus phenolivorans*, with which it shares the same peptidoglycan composition.

Propionimicrobium Stackebrandt, Schumann, Schaal, Weiss 2002, 1926[VP]

Pro.pi.on.i.mi.cro«bi.um. N.L. n. *acidum propionicum* propionic acid; Gr. adj. *micros* small; Gr. masc. n. *bios* life. N.L. neut. n. *Propionimicrobium* propionic acid-producing microbe.

Originally described as "*Bacillus lymphophilus*" Torrey 1916, "*Corynebacterium lymphophilum*" Torrey 1916 Eberson 1918 and "*Mycobacterium lymphophilum*" Torrey 1916 Krasil'nikov 1949, strain VIP 0202 has been included in a taxonomic study by Johnson and Cummins (1972) on coryneforms and propionibacteria. The type strain ATCC 27520^T was tentatively classified as *Propionibacterium lymphophilum*, because of low DNA reassociation with members of *Corynebacterium*, anaerobic growth, and the formation of propionic acid. *Propionibacterium lymphophilum* was transferred to a new genus *Propionimicrobium* as it shared less than 91.8 % sequence similarity with the other *Propionibacterium* species (Dasen et al. 1998) which themselves show higher than 93 % similarity among each other.

Main end-products of glucose fermentation are propionic acid, acetic acid, succinic acid, and iso-valeric acid. Formic acid is produced in smaller amounts. Lysine instead of A_2pm is the dicarboxylic amino acid of the peptidoglycan (Johnson and Cummins 1972; Stackebrandt et al. 2002) and aspartic acid

forms the interpeptide bridge. The DNA base composition of 56 mol% G+C is significantly lower than those described for other family members.

Isolation, Enrichment, and Maintenance Procedures

Due to their isolation from different habitats and by different research groups, the isolation procedures and the incubation time from 2 to 10 days to up to 4 weeks of members of the family are quite different. Rather than listing detailed protocols for all species, organisms will be grouped according to similar procedures and only examples will be given. Several strains were reported to be anaerobic or facultative anaerobic. The recently enriched and isolated strains were isolated in an anaerobic chamber on plate count agar 9 (Bae et al. 2006a) or sheep-blood agar (Bae et al. 2006b). Other authors used the anaerobic role tube method of Holdemann et al. (1977) using either PYAS medium and a vitamin B mixture (Sugawara et al. 2011) or a peptone-yeast medium supplemented with carbohydrates, a plant residue extract, and cobalamin (Akasaka et al. 2003).

Most of these strains can be maintained in modified PYG–medium 104 according to the DSMZ catalogue (2001); http://www.dsmz.de/catalogues/catalogue-microorganisms/culture-technology/list-of-media-for-microorganisms.html (*Table 36.7*).

A nutrient complex medium were used for the isolation/maintenance of most of the aerobic members of the family, such as standard agar medium plus 1 % horse serum (Maszenan et al. 1999b), nutrient broth Difco (Tamura et al. 1994), ISP medium (Wang et al. 2008), Luedeman agar (Luedemann 1968) (Alonso-Vega et al. 2011), nutrient agar (Kämpfer et al. 2010a), and modifications of DSMZ media 776, 65, and 92 for strains of *Micropruina*, *Friedmanniella*, and *Microlunatus*. R2A (An et al. 2008) and 1/5 strength R2A media (Cui et al. 2007) media were used in the isolation of other *Microlunatus* strains. Inorganic salt agar media, such as the one recommended by the SIM Committee on microbiological deteriorations of fuels (Bushnell and Haas 1941), were used for the isolation of *Aestuariimicrobium kwangyangense* (Jung et al. 2007) and for *Tessaracoccus oleiagri* (Cai et al. 2011). Some Friedmanniella type strains were isolated on PYGV medium (*Table 36.8*).

Friedmaniella spumicola strain Ben 107^T *Friedmaniella capsulata* strain Ben 108^T ACM 5121^T was isolated by micromanipulation (Skerman 1968).

If indicated, strains can be maintained as glycerol 20 % cultures. Long-term preservation is done by lyophilization and under a N_2 atmosphere.

Table 36.7
Composition of DSM medium 104

Trypticase peptone	5.00 g
Peptone	5.00 g
Yeast extract	10.00 g
Beef extract	5.00 g
Glucose	5.00 g
K_2HPO_4	2.00 g
Tween 80	1.00 mL
Cysteine-HCl × H_2O	0.50 g
Resazurin 1.00 mg	
Salt solution, see below	40.00 mL
Distilled water	950.00 mL
Haemin solution, see below	10.00 mL
Vitamin K1 solution, see below	0.20 mL
The vitamin K1, haemin solution, and the cysteine are added after the medium has been boiled and cooled under CO_2. Adjust pH to 7.2 using 8 N NaOH. Distribute under N_2 and autoclave	
Salt solution:	
$CaCl_2$ × $2H_2O$	0.25 g
$MgSO_4$ × $7H_2O$	0.50 g
K_2HPO_4	1.00 g
KH_2PO_4	1.00 g
$NaHCO_3$	10.00 g
NaCl	2.00 g
Distilled water	1000.00 mL
Haemin solution:	
Dissolve 50-mg haemin in 1-mL 1 N NaOH; make up to 100 mL with distilled water. Store it refrigerated	
Vitamin K1 solution:	
Dissolve 0.1-mL of vitamin K1 in 20-mL 95 % ethanol and filter-sterilize. Store it refrigerated in a brown bottle	

Ecology

As indicated above, members of *Propionibacteriaceae* genera have been isolated from a wide range of habitats. As in most cases, a single strain only was taxonomically characterized, questions about the actual ecological niche and the functional role of most of the species must remain unanswered. The presence and action of *Microlunatus phosphovorus*, *Micropruina glycogenica*, and *Tessaracoccus bendigoensis* in activated sludge has been reported (Nakamura et al. 1989, 1991, 1995a, b; Seviour et al. 2000; Mino 2000; Kong et al. 2001) but the presence of *Granulicoccus phenolivorans*, *Propioniciclava tarda*, *Friedmanniella spumicola*, and *F. capsulata*, also isolated from similar habitats, has not been reported in other studies. Several strains of different genera were isolated from the Antarctic environment (Lawson et al. 2000; Schumann et al. 1997; Peeters et al. 2011; Shiwaji et al., Unpublished [accession numberJQ396532]), others from soil, the marine environment, associated invertebrates, or freshwater sediments (Krett and Palatinszky 2009). Most additional reports about the presence of family members in different habitats than that indicated for the type strain of species come from non-culture studies.

Table 36.8
Medium PYGV Staley 1968, medium DSM 621

Mineral salt sol. "Hutner/Cohen-Bazire"	20.00 mL
Peptone Bacto	0.25 g
Yeast extract Bacto	0.25 g
Agar Bacto	15.00 g
Distilled water	965.00 mL
Sterilize 20 min/121 °C. After cooling to 60 °C add to the medium:	
Glucose sol. 2.5 %, sterile-filtered	10.00 mL
Vitamin sol. double conc.	5.00 mL
Adjust pH to 7.5, the medium is only weakly buffered; one needs approx. 10 drops/L medium of 6 N KOH	
Mineral salt solution:	
Nitrilotriacetic acid NTA	10.00 g
$MgSO_4 \times 7H_2O$	29.70 g
$CaCl_2 \times 2H_2O$	3.34 g
$Na_2MoO_4 \times 2H_2O$	12.67 mg
$FeSO_4 \times 7H_2O$	99.00 mg
Metall salt sol. "44" see medium 590	50.00 mL
Distilled water	900.00 mL
Dissolve NTA first by neutralizing with KOH, then add other salts. Adjust pH to 7.2 with KOH or H_2SO_4. Adjust volume to 1,000.0 mL with distilled water	
Vitamin solution double conc.:	
Biotin	4.00 mg
Folic acid	4.00 mg
Pyridoxine-HCl	20.00 mg
Riboflavin	10.00 mg
Thiamine-HCl $\times 2H_2O$	10.00 mg
Nicotinamide	10.00 mg
D-Ca-pantothenate	10.00 mg
Vitamin B12	0.20 mg
p-Aminobenzoic acid	10.00 mg
Distilled water	1.0 L
Store in the dark and cold at 5 °C	

Each of the type strain of the type species of *Microlunatus*, *Friedmanniella*, and *Propionimicrobium* is closely to highly related (>96 % BLAST similarity) to clone sequences obtained from DNA which was retrieved from even other sides than those reported for the type strains. The data indicate the presence of many more species to be described once the respective organisms will have been cultured. Only a few reports have been published, e.g., a single clone, originating from DNA of a *Microlunatus* strain, which could not be isolated on any of the seven media provided, was found to be associated with the marine sponge *Hymeniacidon perleve* from the South China Sea (Sun et al. 2010). *Microlunatus* spp. were also found in natural nests of the temperate fungus-growing ant *Trachymyrmex septentrionalis* by culture-independent 16S rRNA gene amplicon 454-sequencing but not in an accompanying culture-dependent study, using a chitin, minimum carbon medium. The results of the culture-independent studies showed a diverse actinobacteria populations, including most prominently *Solirubrobacter* (12.2–30.9 % of sequence reads), *Pseudonocardia* (3.5–42.0 %), but also an abundant presence of *Microlunatus* spp. (0.4–10.8 %). *Microlunatus* were associated with ant garden workers, outside workers and, between July and August, with reproductive females (Ishak et al. 2011). A single clone sequence similar to that of *Propionicimonas paludicola* was found as an ectosymbiont of the ant *Acromyrmex subterraneus brunneus* (Zucchi et al. 2011). The phylogenetic positions of some of the clone sequences have been included in the descriptions of *Auraticoccus monumenti* (Alonso-Vega et al. 2011), *Brooklawnia cerclae* (Bae et al. 2006a), and *Propionicicella superfundia* (Bae et al. 2006b).

Pathogenicity: Clinical Relevance

No clinical significance has been reported for *Luteococcus sanguinis*, *L. peritonei*, and *Propionimicrobium lymphophilum* though they were originally isolated from human material (the reisolate of *P. lymphophilum* originated from urinary tract infections and mesenteric ganglion of a monkey). Schofield and Schaal (1981) indicate a submaxillary tissue as the origin of the type strain ATCC 27529^T. There are neither additional clinical reports nor additional clone sequences related to the 16S rRNA gene sequences of the two *Luteococcus* species. *Propionimicrobium lymphophilum* has been reported in the vaginal epithelium (Hyman et al. 2005; Isaacs, Unpublished [HM021413]; Sizova et al., Unpublished [JN809767]), joint arthrodesis (Goldenberger, Unpublished [HM135521]) and several clone sequences, e.g., HM257519, from the NIH Intramural Skin Microbiome Consortium (Kong et al., Unpublished). *Propioniferax innocua* was isolated from human epidermal surface. The latter study also report several clone sequences to be closely related to *P. innocua*. Even higher related are clone sequences from samples collected from human skin and the surface of human habitations (Taubel et al. 2009).

Application

Microlunatus phosphovorus is physiologically close to other phosphate-accumulating bacteria (PAO) found in enriched sludges and it is one of the few successfully isolated PAOs so far. In a reactor containing about 9 % PAOs of the total bacteria as detected by DAPI stain for polyphosphate, about 2.7 % of the total bacteria belonged to *M. phosphoreus* (Kawaharasaki et al. 1998).

It accumulates large amounts of polyphosphate under aerobic conditions (up to than 48 % of its dry weight in glucose medium), which is then consumed along with the anaerobic uptake of carbon sources like glucose and casamino acids, accompanied by the accumulation of glycogen under anaerobic

conditions (Nakamura et al. 1995a, b). However, it lacks key metabolic characteristics of other organisms involved in enhanced biological phosphate removal as it neither takes up acetate nor accumulates PHA under anaerobic conditions (Minoa et al. 1998; Seviour et al. 2003). A conceptual model for anaerobic carbon metabolism in an EBPR process has been reviewed by Mino (2000). According to Akar et al. (2006), it does produce significant amounts of PHAs under various growth conditions and with different carbon sources. Polyhydroxybutyrate was produced at about 20–30% of the cellular dry weight.

M. phosphoreus contains an ATP-dependent polyphosphate-dependent glucokinase that produces glucose-6-P from glucose and polyphosphate (Tanaka et al. 2003). As determined by tracer studies, *M. phosphovorus* fermented glucose to acetate via an Embden-Meyerhof pathway but was unable to grow under anaerobic *conditions* (Santos et al. 1999). In the aerobic period of the process, acetate was oxidized and growth was strictly dependent on the availability of external phosphate.

The rate of glucose consumption by *M. phosphovorus* was stimulated by phosphate release and, reciprocally, the availability of glucose caused an increase in the rate of phosphate release.

Micropruina glycogenica was originally isolated from an enhanced biological phosphorus removal sequencing batch reactor (SBR) fed with acetate and peptone (Liu et al. 1997). It is one of the few so-called G-bacteria that has been isolated and formally described (another actinobacterium being *Amaricoccus* Maszenan et al. 1997). *M. glycogenica* assimilates organic substrates anaerobically and accumulates glycogen in pure culture; this process has been studied in an aerobic-anaerobic non-P removing SBR biomass fed a mixture of acetate and glucose with fluorescent in situ hybridization FISH in combination with microautoradiography FISH/MAR (Kong et al. 2001). *M. glycogenica*, seen as small aggregate cocci assimilating glucose and acetate while producing polyhydroxybutyrate, was detected by the FISH probe MIC 184 to constitute about 76 % of the high G+C bacteria (22 % of the total bacteria number) which themselves were present in 29 % of total bacteria as detected by molecular analysis.

For other species, a direct application has not been demonstrated but their ability to thrive in the presence of oil and hazardous chemical compounds provides a bioremediation potential. *Brooklawnia cerclae* (Bae et al. 2006a) and *Propionicicella superfundia* (2006b) were isolated from chlorosolvent-contaminated groundwater. Though both type strains did not utilize 1,2-dichloroethane (1,2-DCA) and 1,1,2-trichloroethane (1,1,2-TCA), both strains fermented glucose in the presence of high concentrations of these compounds (*B. cerclae* tolerated up to 9.8 mm of both compounds, while *P. superfundia* grew in the presence of 9.8 mM 1,2-DCA and 5.9 mM 1,1,2-TCA). The type strains of *Tessaracoccus oleiagri* (Cai et al. 2011) and *Aestuariimicrobium kwangyangense* (Jung et al. 2007) were isolated from crude-oil-contaminated saline soil and oil-contaminated tidal flat sediment, respectively. However, in none of the two descriptions, experiments on their oil-degrading properties have been evaluated.

A strain distantly related to *Luteococcus peritonei* was recently isolated from a highly diluted sample of activated sludge of paper mill effluent (Thorenoor et al. 2009). This strain was able to grow on anisole, phenetole, benzene, toluene, phenol, styrene, and biphenyl, producing 2-methoxyphenol and 2-ethoxyphenol from the degradation of anisole and phenetole, respectively. PCR analysis revealed that the genomic DNA encoded at least three ring-hydroxylating dioxygenase large subunits. The authors suggest that the isolate may play a major role in the degradation of lignin-like *O*-aryl alkyl ethers and various aromatic hydrocarbon pollutants in activated sludge of paper mill effluent.

E. Rosenberg et al. (eds.), *The Prokaryotes – Actinobacteria*, DOI 10.1007/978-3-642-30138-4_190,

Abstract

The order *Pseudonocardiales* is made of up a single family *Pseudonocardiaceae* as it now contains all the genera that belonged to the other family in the order, the *Actinosynemmataceae*. It also covers the suborder *Pseudonocardineae* which forms a distinct cluster between the *Frankineae* and *Streptomycineae* when members of the taxa are subjected to 16S rRNA gene phylogenetic analysis. The family has 26 genera *Pseudonocardia*, *Actinoalloteichus*, *Actinokineospora*, *Actinomycetospora*, *Actinophytocola*, *Actinosynnema*, *Alloactinosynnema*, *Allokutzneria*, *Amycolatopsis*, *Crossiella*, *Goodfellowiella*, *Haloechinothrix*, *Kibdelosporangium*, *Kutzneria*, *Labedaea*, *Lechevalieria*, *Lentzea*, *Prauserella*, *Saccharomonospora*, *Saccharopolyspora*, *Saccharothrix*, *Sciscionella*, *Streptoalloteichus*, *Thermocrispum*, *Umezawaea*, and *Yuhushiella*. These genera contain strains which are heterogenous in their morphological and chemotaxonomic features. In general, they are predominantly mycelial actinobacteria with 8 genera having sporangia, pseudosporangia and synnemata, and motile spores as a feature of at least one genus. There are no common chemotaxonomic features though the majority contain galactose in their cell walls and phophatidylethanolamine and the menaquinone MK9 (H_4), though the latter is absent in the type species of the family.

There are 8 monophyletic genera and another 8 that contain between 2 and 5 species, with three genera *Amycolatopsis* (60), *Pseudonocardia* (47), and *Saccharopolyspora* (22) containing at least half the 237 species of the family. For ease of differentiating the taxa, the majority of the morphological, chemotaxonomic, and physiological traits have been placed in comprehensive tables.

Like most actinobacteria, members of the family are predominantly soil dwelling chemoorganotrophs, but some metabolic diversity is reported with growth on carbon dioxide, hydrocarbons, and recalcitrant compounds. Some are halophiles but very few have been isolated from marine sources. Recently new species have been sourced as endophytes indicating that members of certain genera have adapted to living within plant hosts. There have been a few reports of strains isolated from human clinical samples indicating they are opportunistic pathogens. However, some *Crossiella* species have been implicated in equine placentitis. A number of genera including those with large numbers are known to produce antibiotics and other bioactive secondary metabolites, some of which have found clinical use.

Order *Pseudonocardiales* Labeda and Goodfellow 2012, 1301^{VP}

Pseu.do.no.cardi.a.les. N.L. fem. n. *Pseudonocardia* the type genus of the order; suff. -*ales* ending to denote an order; *Pseudonocardiales* the *Pseudonocardia* order.

The removal of the family *Actinosynnemmataceae* Labeda and Kroppenstenstedt 2000 by Labeda et al. (2010a) emended the family *Pseudonocardiaceae* to include genera that belonged to this extant family and consequently elevated the suborder *Pseudonocardineae* Stackebrandt, Rainey and Ward-Rainey 1997, 486^{VP} emend. Zhi, Li and Stackebrandt 2009, 599, to the order *Pseudonocardiales*. Therefore, this order contains a single family *Pseudonocardiaceae* with the type genus *Pseudonocardia* Henssen 1957, 408^{AL}.

Family 1. *Pseudonocardiaceae* Embley, Smida, and Stackebrandt 1989, 205^{VP} emend. Labeda, Goodfellow, Chun, Zhi, and Li 2010a

Pseu.do.no.cardi.a.ce'a.e. N.L. fem. n. *Pseudonocardia* the type genus of the family; suff. -*aceae* ending to denote a family; N.L. fem. pl. n *Pseudonocardiaceae* the *Pseudonocardia* family.

The 16S rRNA signatures consist of nucleotides at positions 127:234 (G–C), 564 (U), 72:734 (U–G), 831:855 (U–G), 832:854 (G–Y), 833:853 (U–G), 952:1229 (U–A), and 986 (U–A).

This family comprises actinobacteria that are aerobic, Gram-stain positive, nonacid fast, and catalase positive and grow in the mesophilic or thermophilic temperature range. The type species is *Pseudonocardia* (Henssen 1957) emend. Park et al. (2008) and 25 other genera: *Actinoalloteichus* Tamura et al. (2000), *Actinokineospora* (Hasegawa 1988) Labeda et al. (2010b), *Actinomycetospora* Jiang et al. (2008), *Actinophytocola* Indananda et al. (2010), *Actinosynnema* Hasegawa et al. (1978), *Alloactinosynnema* Yuan et al. (2010), *Allokutzneria* Labeda and Kroppenstedt (2008), *Amycolatopsis* (Lechevalier et al. 1986) Lee (2009), *Crossiella* Labeda (2001), *Goodfellowiella* Labeda et al. (2008), *Haloechinothrix* Tang et al. (2010b), *Kibdelosporangium* Shearer et al. (1986a), *Kutzneria* Stackebrandt et al. (1994), *Labedaea* Lee (2012), *Lechevalieria* Labeda et al. (2001), *Lentzea* (Yassin et al. 1995) Labeda et al. (2001), *Prauserella* (Kim and Goodfellow 1999) Li et al. (2003b), *Saccharomonospora* Nonomura and Ohara 1971, *Saccharopolyspora* (Lacey and Goodfellow 1975) Li et al. (2009a), *Saccharothrix* (Labeda et al. 1984) Labeda and Lechevalier (1989a), *Sciscionella* Tian et al. (2009), *Streptoalloteichus* (Tomita et al. 1987) Tamura et al. (2008b), *Thermocrispum* Korn-Wendisch et al. (1995), *Umezawaea* Labeda and Kroppenstedt (2007), and *Yuhushiella* Mao et al. (2011).

Figure 37.1 shows the phylogenetic tree of the genera and species of the family *Pseudonocardiaceae* in the order *Pseudonocardiales* based on 16S rRNA gene sequence data analysis.

The morphological characteristics of the members of the family vary with vegetative mycelium that branches and aerial mycelium when present fragments into chains of rod-shaped or square-shaped spores, generally with smooth surfaces. In some species aerial mycelium is not produced. Spores are found on aerial mycelia and can be single or in short chains that have rod-shaped elements with smooth surfaces for some genera or in some taxa are in sporangia, pseudosporangia, or synnemata. Other taxa may fail to produce aerial mycelia, while some genera produce motile spores. While most species of the family are chemoorganotrophs, some autotrophs are notably also present. A few species are implicated as human or animal pathogens, but the majority has been isolated predominantly from soils and other environmental sources such as manure and plant material. In recent years, many members of the family have been isolated as endophytes from a range of plant species including trees and medicinal plants.

Chemotaxonomic properties of the genera of the order are shown in *Table 37.1*. *Meso*-diaminopimelic acid is present in the cell walls of all members of the family and the majority of genera contain galactose as a whole-cell sugar except for some members of the genus *Kutzneria* and the single *Thermocrispum* species. Most genera contain tetrahydrogenated menaquinones with nine isoprene units, but three genera, including the type genus, contain eight isoprene units, and two genera have 9 isoprene units. No mycolic acids are present in any members of the family. The phospholipid composition varies between genera with phosphotidylethanolamine or its hydroxide being the most prevalent, followed by diphosphatidylglycerol, with phosphatidylinositol also present in more than half the species.

The G = C content is 64.1–79.6 (mol%)

Type genus: *Pseudonocardia* Henssen 1957, 408^{AL}, emend. Park, Park, Lee and Kim 2008, 2477^{T}

Further Taxonomic Information

The family *Pseudonocardiaceae* Embley, Smida, and Stackebrandt 1989, 205^{VP} emend. Zhi, Li, and Stackebrandt, 2009, 599 was

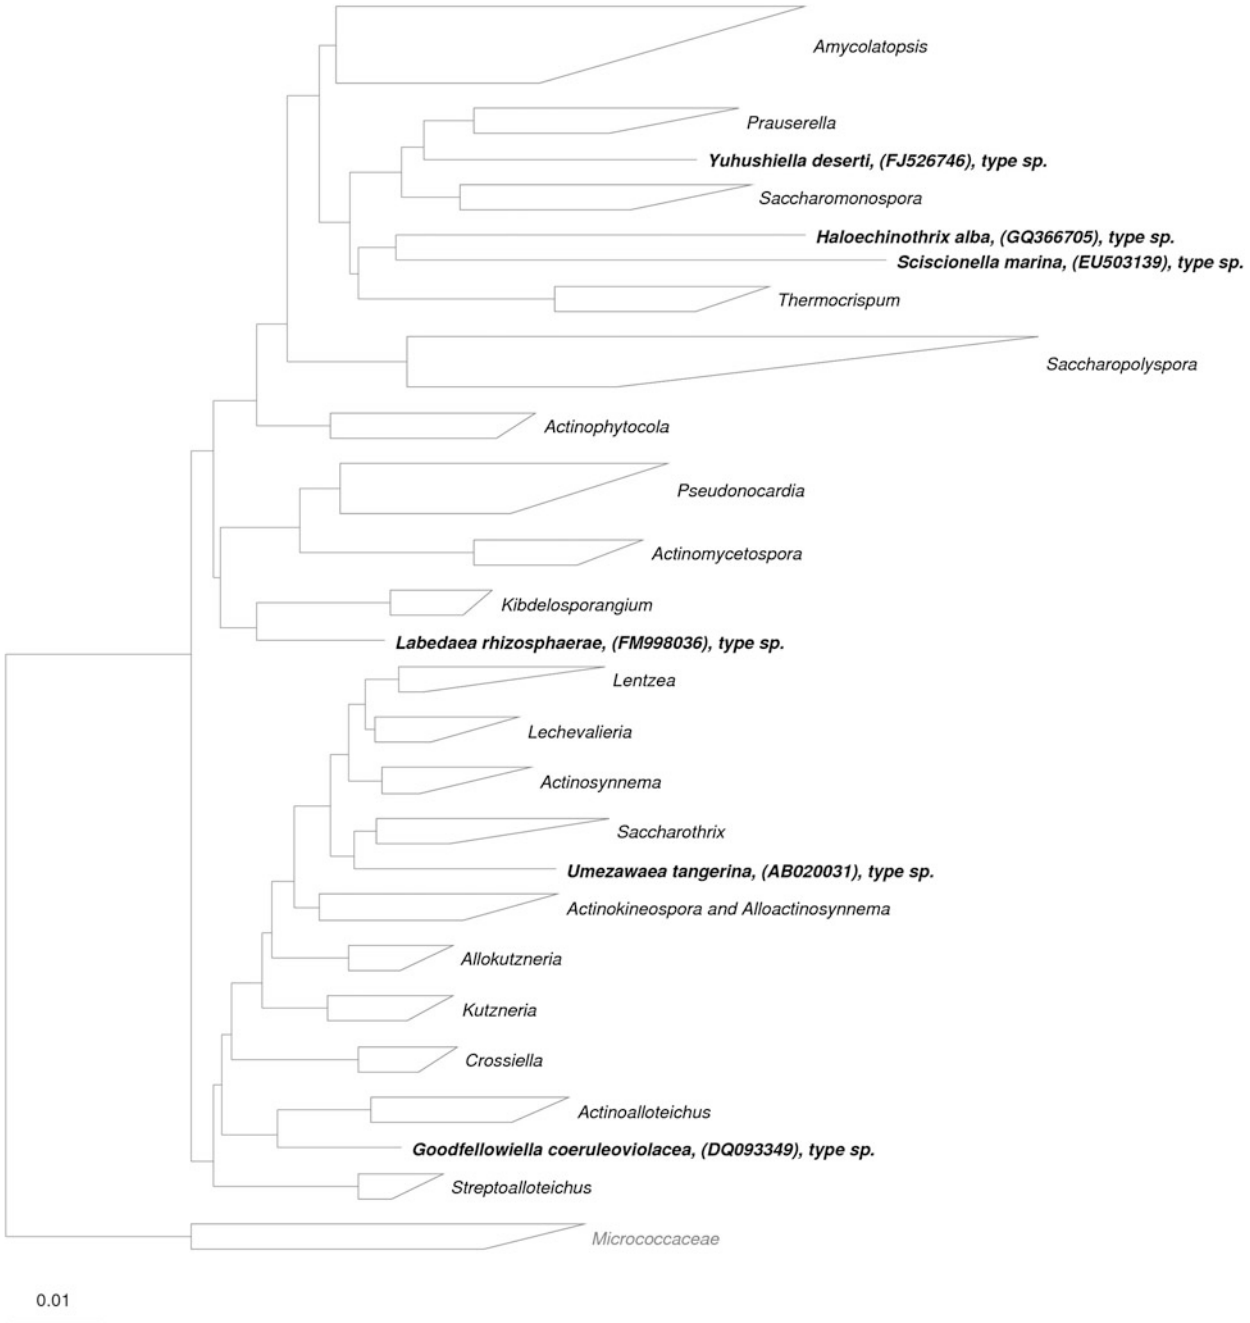

Fig. 37.1

Phylogenetic reconstruction of the family *Pseudonocardiales* based on 16S rRNA gene sequences and created using the maximum likelihood algorithm RAxML (Stamatakis 2006). These sequence datasets and alignments were used according to the All-Species Living Tree Project (LTP) database (Yarza et al. 2010; http://www.arb-silva.de/projects/living-tree). Representative sequences from closely related taxa were used as outgroups. In addition, a 40 % maximum frequency filter was applied in order to remove hypervariable positions and potentially misplaced bases from the alignment. Scale bar indicates estimated sequence divergence

first proposed by Embley et al. (1988, 1989) and later by Warwick et al. (1994) who used 16S rRNA phylogeny to include the genera *Actinokineospora* and *Saccharothrix* and combine the *Amycolata* into an emended genus *Pseudonocardia*. After the family was emended by Stackebrandt et al. (1997), Labeda and Kroppenstedt (2000) proposed the removal of the genera *Actinosynnema, Actinokineospora, Lentzea*, and *Saccharothrix* into a new family *Actinosynnemataceae* based on 16S rRNA phylogenetic analyses. Recently, Labeda et al. (2010a) studied all the 16S rRNA gene sequences available at the time for members of the families *Actinosynnemataceae* and *Pseudonocardiaceae* and reached the conclusion that the genera within the family *Actinosynnemataceae* be placed into the family *Pseudonocardiaceae* (Fig. 37.2).

Table 37.1

Comparison of selected features of genera within the order *Pseudonocardiales*

Genus	Sporangia produced	Motile spores	Whole-cell sugar pattern	Phospholipids[a]	Predominant menaquinones	DNA Mol% G+C
Pseudonocardia	None	No	Arabinose, galactose, (mannose, ribose, glucose)	PC, PE, PME, PI, PIM, OH-PE, PG	MK-8(H_4)	68.2–78.8
Actinoalloteichus	None	No	Glucose, galactose, mannose, ribose, rhamnose	PI, PG, (PE, PIM, DPG, PME, GluNu)	MK-9(H_4) MK-9(H_6)	72–76.6
Actinokineospora	None	Variable	Galactose, arabinose, (rhamnose, mannose, glucose, glucosamine)	PE	MK-9(H_4) MK-10	68.2–73.8
Actinomycetospora	None	No	Arabinose, galactose, (glucose)	PC, PC, DPG	MK-8(H_4)	69.0–74.0
Actinophytocola	None	No	Arabinose, galactose, rhamnose	PE, OH-PE,(DPG)	MK-9(H_4) MK-10(H_4)	69.7–72.5
Actinosynnema	Synnemata	Yes	Galactose, mannose	PE, OH-PE, DPG	MK-9(H_6)	71.0–73.0
Alloactinosynnema	Pseudosporangia	No	Galactose, ribose	DPG, PG, PC	MK-9(H_4)	68.2
Allokutzneria	Yes, no spores	No	Arabinose, galactose, mannose	PE, PME, OH-PE, PI, lyso-PME, DPG, PG, lyso-PE	MK-9(H_4)	71.7
Amycolatopsis	None	No	Arabinose, galactose,	PE, (DPG, PG)	MK-9(H_4) MK-8(H_4) MK-9(H_2) MK-11(H_4)	65.8–75.0
Crossiella	(Pseudosporangia)	No	Galactose, mannose, rhamnose, ribose	PE, DPG, PME, PI, PIM	MK-9(H_4)	71.4
Goodfellowiella	None	No	Galactose, ribose	PE, DPG, OH-PE, PI, PIM	MK-9(H_4), MK-10(H_4)	68.2
Haloechinothrix	None	No	Glucose, mannose, glucosamine, unknown sugar	DPG, PG, PE, PI, PIM, PL	MK-8(H_4)	68.1
Kibdelosporangium	Yes	No	Arabinose, galactose	PE, PI, PME, (PG, DPG, PIM)	MK-9(H_4)	66.0–67.2
Kutzneria	Yes	No	Rhamnose (galactose),	PE, DPG, PI, OH-PE	MK-9(H_4)	70.3
Labedaea	None	No	Glucose, rhamnose, galactose, ribose, mannose, arabinose, xylose	DPG, PME, PG, PI, PL	MK-9(H_4)	64.2
Lechevalieria	None	No	Galactose, mannose, (rhamnose)	PE, (DPG)	MK-9(H_4)	68.0–70.5
Lentzea	None	No	Galactose, mannose	PE, DPG, PI, PG	MK-9(H_4)	64.1–79.6
Prauserella	None	No	Arabinose, galactose, ribose	DPG, PG, PI	MK-9(H_4) MK-9(H_2)	65.8–70.1
Saccharomonospora	None	No	Arabinose, galactose	(PI, DPG, PG, PE-OH)	MK-9(H_4)	68.1–71.8
Saccharopolyspora	None	No	Arabinose, galactose	PC, DPG, PG	MK-9(H_4), MK-9(H_6)	66.3–76.9
Saccharothrix	None	No	Galactose, rhamnose,	PE	MK-9(H_4), MK-9(H_6), MK-9(H_8), MK-10(H_4)	67.0–74.0
Sciscionella	None	No	Arabinose, galactose, glucose	DPG, PC, PE, PI, PL, PME	MK-9(H_4)	69.0
Streptoalloteichus	Pseudosporangia	Variable	Galactose, mannose, (rhamnose, glucose)	PE	MK-9(H_6), MK-10(H_6)	71.6
Thermocrispum	Pseudosporangia	No	Arabinose, mannose, glucose,	PE, PI, OH-PE	MK-9(H_4)	69.0–73.0
Umezawaea	None	No	Galactose, mannose, ribose, rhamnose	PE, PI, OH-PE, *lyso*-PE, DPG, PIM	MK-9(H_4),	74.0
Yuhushiella	Pseudosporangia	No	Arabinose, galactose, glucose, ribose	PE, PIM, PME, DPG, PL, GluNu	MK-9(H_4)	69.9

Values in brackets are found in the majority, not all species

[a]Abbreviations: *DPG* diphosphatidylglycerol, *GluNu* phospholipids of unknown structure containing glucosamine, *OH-PE* phosphatidylethanolamine with hydroxy fatty acids, *lyso*-PE, phosphatidylethanolamine where one fatty acid chain is missing from the glycerol backbone, *lyso*-PME phosphatidylmethylethanolamine where one fatty acid chain is missing from the glycerol backbone, *PC* phosphatidylcholine, *PE* phosphatidylethanolamine, *PG* phosphatidylglycerol, *PI* phosphatidylinositol, *PIM* phosphatidylinositol mannosides, *PL* unknown phospholipids, *PME* phosphatidylmethylethanolamine

Phylogenetic tree of the genera *Pseudonocardia, Actinomycetospora, Kibdelosporangium* and *Labedaea*

Pseudonocardia Henssen 1957, 408[AL], emended Park, Park, Lee and Kim 2008, 2477[VP]

Pseu.do.no.cardi.a. Gr. adj. *pseudês* false; N.L. fem. n. *Nocardia* a bacterial genus name; N.L. fem. n. *Pseudonocardia* false *Nocardia*.

Phenotypic Analyses

Pseudonocardia species are aerobic, Gram-stain positive, nonacid fast, nonmotile, catalase positive, and mesophilic or thermophilic. Substrate and aerial mycelium can form apical or intercalary swellings and produce spores that are smooth with two species known to have spiny or "knobby" spore surfaces. Thickness of hyphae is variable and can fragment into rod-shaped elements or chains that are oval or square-shaped or chains with two or more spores. Some species are facultative autotrophs. Chemotaxonomic analysis of the cell wall shows that most *Pseudonocardia* species possess *meso*-diaminopimelic acid and whole-cell hydrolysates contain arabinose and galactose. Menaquinone MK-8 (H_4), or MK-8 (H_2) or MK-9 within a limited number of taxa, is the predominant isoprenoid quinone, and iso-branched hexadecanoic acid is the predominant fatty acid. No mycolic acids are detected and the phospholipids are type II, III or IV depending on the species, but the following are commonly found: phosphatidylcholine, phosphatidylethanolamine, phosphatidylglycerol, phosphatidyl methylethanolamine, and glucosamine-containing phospholipids.

The G+C content of the DNA of members of the genus *Pseudonocardia* ranges from 68.2 to 78.8 (mol%).

The type species in *Pseudonocardia thermophila* ATCC 19285^T (Huang and Goodfellow 2012).

Isolation Procedures

A range of isolation techniques that were utilized to obtain the type species of *Pseudonocardia* are presented in *Table 37.2*.

Taxonomy, Historical, and Current

The phylogenetic position of *Pseudonocardia*, as determined by 16S rRNA gene sequence analysis, forms a distinct clade in the order *Pseudonocardiales* (*Figs. 37.1*, *37.2*, *37.3*, *37.4*, and *37.5*: 16S rRNA gene tree of the order *Pseudonocardiales*). The closest genera are *Actinomycetospora*, which have no aerial mycelium, and *Kibdelosporangium*, which form pseudosporangia and contain MK-9 (H_4) as the predominant menaquinone, whereas most species of the genus *Pseudonocardia* contain MK-8(H_4). *Pseudonocardia* spp. have distinct common 16S rRNA gene sequence regions which correspond to nucleotide positions 179–219 and 813–833 of the *Streptomyces ambofaciens* 16S rRNA gene (Pernodet et al. 1989).

The genus *Pseudonocardia* was proposed for a thermophilic strain and two other actinomycetes which formed aerial spores in chains by exhibiting acropetal budding of substrate and aerial hyphae (Henssen 1970; Henssen and Schäfer 1971; Henssen and Schnepf 1967). These strains were *Pseudonocardia thermophila*, (Henssen 1957). *Pseudonocardia compacta* (Henssen 1957) and *Pseudonocardia spinosa* (Henssen and Schäfer 1971; Schäfer 1969). Huang et al. (2002) found that the *Actinobispora* and *Pseudonocardia* species shared key chemical markers with MK-8(H_4) as the major menaquinone and proposed that the genus *Actinobispora* (Xu et al. 1999) which contained *Actinobispora alaniniphila*, *Actinobispora aurantiaca*, *Actinobispora xinjiangensis*, and *Actinobispora yunnanensis* should become part of the genus *Pseudonocardia*. In 1994, Warwick et al. (1994) analysed the 16S rRNA gene sequences of the type strains of *Amycolata* and showed that they were more closely related to *Pseudonocardia* species. *Amycolata autotrophica* was classified to a new genus *Pseudoamycolata* (Akimov et al. 1989) as it lacked phosphatidylcholine. However, apart from this difference other characteristics were very similar to *Pseudonocardia* species and McVeigh et al. (1994) proposed its reclassification as *Pseudonocardia halophobica*.

The chemotaxonomic and physiological properties of the species of the genus *Pseudonocardia* are shown in *Tables 37.3* and *37.4*.

Ecology

Pseudonocardia species have a versatile metabolism with some species being facultative autotrophs. *Pseudonocardia autotrophica*, *Pseudonocardia petroleophila*, and *Pseudonocardia saturnae* can utilize CO_2 and oxidize hydrogen (Lechevalier et al. 1986), whereas *Pseudonocardia carboxydivorans* can utilize CO_2 as sole carbon source (Park et al. 2008) and *Pseudonocardia ammonioxydans* can grow both autotrophically on nitrifying medium as well as heterotrophically on a complex nitrogen source (Liu et al. 2006). *Pseudonocardia hydrocarboxydans* and *Pseudonocardia petroleophila* can utilize simple hydrocarbons as well as hexanes (Hirsch and Engel 1956; Nolof and Hirsch 1962); *Pseudonocardia ascaccharolytica* and *Pseudonocardia sulfidoxydans*, *Pseudonocardia benzenivorans*, *Pseudonocardia chloroethenivorans*, *Pseudonocardia dioxanivorans*, and *Pseudonocardia dinitrificans* can utilize DMSO, chlorobenzenes, chloroethane, dioxane, and urethane, respectively (Schatz et al. 1954; Reichert et al. 1998; Kämpfer and Kroppenstedt 2004; Lee et al. 2004; Mahendra and Alvarez-Cohen 2005).

The nutritional requirements, degradation, and enzyme activity of selected members of this genus are described in *Table 37.5*.

More than half of the 45 species of the genus *Pseudonocardia* have been reported over the last 10 years with a high proportion of these new species isolated from plant or plant-associated samples (Gu et al. 2006; Chen et al. 2009; Duangmal et al. 2009; Kaewkla and Franco 2010, 2011; Li et al. 2012; Qin et al. 2010b, 2011; Reichert et al. 1998; Zhao et al. 2011a, b, c, d, 2012a, b).

Table 37.2
Origin of isolate and method of isolation for *Pseudonocardia* species

Species	Source	Province/country	Method of isolation	References
Pseudonocardia thermophila	Fresh and rotten manure	nr	nr	Huang and Goodfellow (2012)
Pseudonocardia acaciae	Roots of *Acacia auriculiformis* A. Cunn. ex Benth. (earpod wattle)	Bangkok, Thailand	Surface-sterilized roots using starch–casein agar (Küster and Williams 1964) supplemented with antibacterial and antifungal agents (nalidixic acid and ketokonazole at 25 and 50 μg ml^{-1}, respectively); incubated at 28 °C for 21 days	Duangmal et al. (2009)
Pseudonocardia adelaidensis	Stem of a gray box tree (*Eucalyptus microcarpa*)	Adelaide, South Australia	Internal tissue of a surface-sterilized stem sample was inoculated onto 10 isolation media supplemented with nalidixic acid (20 μg ml^{-1}) and nystatin (100 units ml^{-1}); incubated at 27 °C for 8 weeks	Kaewkla and Franco (2010)
Pseudonocardia ailaonensis	Soil sample	Ailao Mountain, Yunnan Province, China	Isolated from Yunnan soil sample on modified starch casein agar [0.3 g mannose, 2 g KNO_3, 0.3 g casein, 0.05 g $MgSO_4 \cdot 7H_2O$, 2 g NaCl, 2 g K_2HPO_4, 0.02 g $CaCO_3$, 10 mg $FeSO_4 \cdot 7H_2O$, and 15 g agar in 1,000 ml tap water (pH 7.2–7.4)]; incubated at 28 °C for 2 weeks	Qin et al. (2008b)
Pseudonocardia alaniniphila	Soil sample	Xichou, Yunnan Province, China	Strains were isolated using AV agar (Ochi 1995; Nonomura and Ohara 1971) and HV agar (Hayakawa 1990) from soil samples. Plates were incubated at 28 °C for 21–28 days	Xu et al. (1999), Huang et al. (2002)
Pseudonocardia alni	Root nodules and rhizospheres of alders *Alnus glutionosa* (L.) Gaerth. and *Alnus incana* (L.) Moench. and from marine sediments	Pushchino, USSR	nr	Evtushenko et al. (1989), Warwick et al. (1994)
Pseudonocardia ammonioxydans	Coastal sediment	Jiao-Dong peninsula, near Qingdao, Shandong Province, China	Isolated from coastal sediment using modified nitrifying medium; incubated at 30 °C for 1 month	Liu et al. (2006)
Pseudonocardia antarctica	Rock and soil samples	McMurdo Dry Valley, Antarctica	Isolated from moraine sample using YPD agar; incubated at 25 °C for 4 days	Prabahar et al. (2004)
Pseudonocardia antitumoralis	Deep -sea sediment	Northern South China	Strain was isolated through a serial dilution plate method followed by incubation at 28 °C for 3 weeks on Gause No. 1 medium prepared with seawater	Tian et al. (2013)
Pseudonocardia artemisiae	Roots of *Artemisia annua* L	Yunnan Province, China	Isolated from surface-sterilized tissue of *Artemisia annua* L. on TWYE agar plates; incubated at 28 °C until the outgrowth of endophytic actinomycetes were discerned	Zhao et al. (2011b)
Pseudonocardia asaccharolytica	Tree-bark compost biofilters from an animal-rendering plant	nr	Isolated using tree-bark compost enrichment using biofilters supplied with methyl sulfide containing off-gas from an animal-rendering plant; Tubes (50 ml) sealed with Teflon lined screw caps and were filled with mineral salts medium and incubated at 25 °C for several weeks	Reichert et al. (1998)

Table 37.2 (continued)

Species	Source	Province/country	Method of isolation	References
Pseudonocardia aurantiaca	Soil sample	Jianchuan, Yunnan Province, China	Strains were isolated using AV agar (Ochi 1995; Nonomura and Ohara 1971) and HV agar (Hayakawa 1990) from soil samples. Plates were incubated at 28 °C for 21–28 days	Xu et al. (1999), Huang et al. (2002)
Pseudonocardia autotrophica	Phosphate buffer solution, aluminum hydroxide gel, vegetable matter, soil, and clinical specimens	nr	nr	Huang and Goodfellow (2012), Warwick et al. (1994)
Pseudonocardia babensis	Plant litter	Ba Be National Park, Vietnam	Isolated from plant litter samples using yeast extract soluble starch medium; incubated at 28 °C for 10–14 days	Sakiyama et al. (2010)
Pseudonocardia bannensis	Roots of *Artemisia annua* L	Yunnan Province, China	Surface sterilized from the roots of *Artemisia annua* L. on HV agar plates; incubated at 28 °C for 4–6 weeks	Zhao et al. (2011c)
Pseudonocardia benzenivorans	Soil sample	Bitterfeld, Germany	Isolated from contaminated soil using selective medium containing 1,2,3,5-tetrachlorobenzene as the sole carbon source; incubated at 25 °C	Kämpfer and Kroppenstedt (2004)
Pseudonocardia carboxydivorans	Soil sample	Seoul, Korea	Isolated from soil using enrichment medium [400 p.p.m. CO in air, 0.005 % (w/v) yeast extract] and solid mineral medium; incubated at 30 °C for 2–6 weeks	Park et al. (2008)
Pseudonocardia chloroethenivorans	Aerobic laboratory enrichment	Department of Civil and Environmental Engineering, University of Washington, Seattle, USA	Isolated from laboratory enrichment using mineral-medium agar plates; incubated at 25 °C for 5 days	Lee et al. (2004)
Pseudonocardia compacta	Garden soil	Wohra, near Marburg, Germany	nr	Henssen et al. (1983)
Pseudonocardia dioxanivorans	1,4-dioxane-contaminated sludge sample	Darlington, South Carolina, USA	Isolated from enriched 1,4-dioxane contaminated industrial sludge, grown aerobically in ammonium mineral salts (AMS) liquid medium (Parales et al. 1994) at 30 °C with 5 mM 1,4-dioxane	Mahendra and Alvarez-Cohen (2005)
Pseudonocardia endophytica	Tissue sample of plant *Lobelia clavata*	Xishuangbanna, Yunnan Province, China	Surface sterilized tissue of *L. Clavata* plated onto TWYE containing nalidixic acid (10 mg ml^{-1}), nystatin and cycloheximide (each at 50 mg ml^{-1}); incubated at 28 °C for 4 weeks	Chen et al. (2009)
Pseudonocardia eucalypti	Roots of a native Australian eucalyptus tree (*Eucalyptus microcarpa*)	Adelaide, South Australia	Surface sterilized root tissue were plated onto Humic acid–vitamin B (HV) medium (Hayakawa and Nonomura 1987) but solidified with 0.8 % of gellan gum instead of agar; plates incubated at 27 °C for up to 12 weeks	Kaewkla and Franco (2011)
Pseudonocardia halophobica	Soil sample	nr	nr	Huang and Goodfellow (2012), McVeigh et al. (1994)

Table 37.2 (continued)

Species	Source	Province/country	Method of isolation	References
Pseudonocardia hispanensis	Sample from oil refinery wastewater treatment plant	Palos de la Frontera, Huelva, Spain	Isolated by using a modified Czapek agar (sucrose, 2 %, w/v; yeast extract, 0.2 %, w/v, $FeSO_4$, 0.001 %; KCl, 0.001 %; K_2HPO_4, 0.1 %; $MgSO_4$. $7H_2O$, 0.05 %; $NaNO_3$, 0.2 %; agar 1.5 %, w/v; distilled water, 1 l) plate supplemented with nalidixic acid (20 mg l^{-1}); incubated for 14 days at 28 °C	Cuesta et al. (2013)
Pseudonocardia hydrocarbonoxydans	Air contaminant	nr	Isolated from a silica gel plate	Huang and Goodfellow (2012), Warwick et al. (1994)
Pseudonocardia khuvsgulensis	Soil sample from Khuvsgul Lake	Khuvsgul province, Mongolia	Dried soil samples inoculated using the rehydration–centrifugation method (Hayakawa et al. 2000) on humic acid–vitamin agar (Hayakawa and Nonomura 1987) containing trimethoprim (20 mg l^{-1}) and nalidixic acid (10 mg l^{-1}), incubated at 28 °C for 3–4 weeks	Ara et al. (2011b)
Pseudonocardia kongjuensis	Gold mine cave	Kongju, Republic of Korea	Isolated from soil by dilution plating method on tap water agar (Lee 1996). Cells were obtained after the organisms were grown on trypticase soy broth (BBL) with shaking at 30 °C for 3 days	Lee et al. (2001)
Pseudonocardia kunmingensis	Surface-sterilized roots of *Artemisia annua* L	Yunnan Province, China	Isolated from surface-sterilized roots followed by plating on HV agar plates (Hayakawa and Nonomura 1987); incubated at 28 °C until the outgrowth of endophytic actinomycetes were discerned	Zhao et al. (2011a)
Pseudonocardia mongoliensis	Soil sample	Khuvsgul province, Mongolia	Dried soil samples inoculated using the rehydration–centrifugation method (Hayakawa et al. 2000) on humic acid–vitamin agar (Hayakawa and Nonomura 1987) containing trimethoprim (20 mg l^{-1}) and nalidixic acid (10 mg l^{-1}), incubated at 28 °C for 3–4 weeks	Ara et al. (2011b)
Pseudonocardia nitrificans	Soil sample	nr	Isolated on distilled water basal medium supplemented with 0.2 % urethane and 0.02 % trace metals. All the samples were incubated aerobically at 28 °C to 30 °C in the dark	Warwick et al. (1994)
Pseudonocardia oroxyli	Root of *Oroxylum indicum*	Yunnan Province, China	Surface-sterilized root elongation zone of *Oroxylum indicum*, plated onto BL-2 agar plates supplemented with penicillin (100 μg ml^{-1}); incubated at 27 °C for 2–4 weeks	Gu et al. (2006)
Pseudonocardia parietis	Wall of an indoor environment colonized with moulds	Stuttgart, Germany	Isolated from a wall colonized with moulds. After extraction of 1 g material sample for 15 min in 10 ml 0.9 % NaCl solution containing 0.01 % (v/v) Tween 80 and dilution on M79 agar (containing 10 g glucose, 10 g Bacto peptone, 2 g casein hydrolysate, 2 g yeast extract, 6 g NaCl, 15 g agar) for 2 weeks at 28 °C	Schäfer et al. (2009)

Table 37.2 (continued)

Species	Source	Province/country	Method of isolation	References
Pseudonocardia petroleophila	Soil sample	Germany	nr	Warwick et al. (1994)
Pseudonocardia rhizophila	Rhizosphere soil of *Tripterygium wilfordii Hook* F	Yunnan Province, China	Isolated from the rhizosphere soil of *Tripterygium wilfordii* Hook. f., by the standard serial dilution technique using raffinose–histidine agar (Vickers et al. 1984) and the plates were incubated at 28 °C for 2–3 weeks	Li et al. (2010)
Pseudonocardia saturnea	Air and compost	Germany	nr	Huang and Goodfellow (2012), Warwick et al. (1994)
Pseudonocardia seranimata	Leaves of *Artemisia annua* L	Yunnan Province, China	Isolated from surface-sterilized leaves followed by plating on sodium propionate asparagine–plant extract agar plates (Li et al. 2010) containing nalidixic acid (25 mg l^{-1}), nystatin (50 mg l^{-1}) and cycloheximide (50 mg l^{-1}); incubated at 28 °C for 4–8 weeks	Zhao et al. (2011d)
Pseudonocardia sichuanensis	Root of *Jatropha curcas* L	Sichuan Province, China	Isolated from surface sterilized root and plated onto tap water–yeast extract agar (TWYE) (Crawford et al. 1993); incubated at 28 °C for 2–8 weeks	Qin et al. (2011)
Pseudonocardia spinosa	Soil sample	Turkey	nr	Huang and Goodfellow, (2012)
Pseudonocardia spinosispora	Soil from a gold mine	Kongju City, Korea	Isolated by dilution plating of soil sample on tap-water agar (Lee 1996)	Lee et al. (2002)
Pseudonocardia sulfidoxydans	Tree-bark compost biofilters from an animal-rendering plant	nr	Isolated using tree-bark compost enrichment using biofilters supplied with methyl sulfide containing off-gas from an animal-rendering plant; tubes (50 ml) sealed with Teflon lined screw caps and were filled with mineral salts medium and incubated at 25 °C for several weeks	Reichert et al. (1998)
Pseudonocardia tetrahydrofuranoxydans	Sludge of a wastewater treatment plant	Göttingen, Germany	Enriched and recovered on a selective medium containing tetrahydrofuran (THF) as the single carbon source from sludge from a wastewater plant	Kämpfer et al. (2006)
Pseudonocardia tropica	Stem of *Maytenus austroyunnanensis*	Yunnan Province, China	Isolated from surface-sterilized stems and were spread onto sodium propionate agar (Qin et al. 2009), incubated at 28 °C for 3 weeks	Qin et al. (2010b)
Pseudonocardia xinjiangensis	Soil sample	Xinjiang Province, China	Strains were isolated using AV agar (Nonomura and Ohara 1971) and HV agar (Hayakawa 1990) from soil samples. Plates were incubated at 28 °C for 21–28 days	Huang et al. (2002), Xu et al. (1999)
Pseudonocardia xishanensis	Roots of *Artemisia annua* L	Yunnan Province, China	Isolated by surface-sterilizing root samples described by Li et al. (2008), incubated on humic acid–vitamin agar (Hayakawa and Nonomura 1987) supplemented with 25 mg l^{-1} nalidixic acid and 50 mg l^{-1} nystatin at 28 °C for 35 days	Zhao et al. (2012b)

Table 37.2 (continued)

Species	Source	Province/country	Method of isolation	References
Pseudonocardia yuanmonensis	Soil sample	Yunnan Province, China	Soil sample was air dried at room temperature followed by serial dilution and was incubated on ISP 5 medium agar plate, supplemented with nalidixic acid (25 mg l^{-1}) and nystatin (50 mg l^{-1}). The plate was incubated at 28 °C for 1 week	Nie et al. (2012b)
Pseudonocardia yunnanensis	Soil sample	Yunnan Province, China	The strain was isolated by plating the soil sample on glycerine–asparagine agar and incubated for 2 weeks at 28 °C	Jiang et al. (1991), Huang et al. (2002)
Pseudonocardia zijingensis	Soil sample	Yunnan Province, China	Isolated on a yeast extract/starch agar (Emerson, 1958) plate, which had been seeded with a soil suspension and incubated at 28 °C for 3 weeks	Huang et al. (2002)

Symbols: *nr* not reported

Another well-established relationship, in which Pseudonocardiae plays a major role, is the mutualistic association in Attine leaf-cutting ants. The role of the actinobacterial partner is believed to be in inhibiting the growth of the *Escovopsis* parasites that would attack the fungal gardens (Cafaro and Currie 2005; Currie et al. 1999a, b, 2003; Kost et al. 2007), which are a nutrient source for the ants (Chapela et al. 1994; Martin 1970; Weber 1966, 1972).

Application

Pseudonocardia are well known as a source of biologically active natural products, such as vancomycin, erythromycin, and rifamycin (Platas et al. 1998; Bredholdt et al. 2007). *Pseudonocardia* strains produce antimicrobial compounds such as the novel glycopeptides, helvecardins A and B (Takeuchi et al. 1991), and phenazostatin D (Maskey et al. 2003) and eight new quinolone compounds with selective and potent anti-*Helicobacter pylori* activity (Dekker et al. 1998). *Pseudonocardia autotrophica* produces a broad spectrum antifungal compound (Kim et al. 2009). *Pseudonocardia* strain No. G495-11 (ATCC 53205) produces Boxazomycin A and B which inhibited growth of aerobic Gram-positive bacteria and anaerobes (Kusumi et al. 1988).

Pseudonocardia autotrophica has been reported recently to be able to bioconvert vitamin D_3 to its physiologically active forms, namely, 25-hydroxyvitamin D_3 and 1α,25-dihydroxyvitamin D_3 clinically used for chronic renal failure, hypoparathyroidism, osteoporosis, and psoriasis (Takeda et al. 2006; Fujii et al. 2009). Vitamin D_3 exerts its physiological activity by being converted to 25-hydroxyvitamin D_3 in the mammalian liver and subsequently to 1α,25-dihydroxyvitamin D_3 in the kidney via approximately 20 steps, but the yield is very low (approximately 1 %). The microbial reaction has an advantage to reduce the number of steps of synthesis.

Genetics and Molecular Analyses

There have been a number of genetic studies on *Pseudonocardia* strains because of their metabolic versatility and their ability to utilize simple and recalcitrant carbon sources as well as their ability to produce antibiotics (Huang and Goodfellow 2012).

Pseudonocardia dioxanivorans CB1190 was selected as the first member of the genus to have its annotated genome sequence published as it was the first actinobacterium capable of growing on 1,4-dioxane (Sales et al. 2011). The genome consists of four replicons, namely, the 7.1 Mb chromosome, two circular plasmids (137 with gaps, and 192 kb), and a 15 kb linear plasmid. Eight putative gene clusters encoding bacterial multicomponent monooxygenases were found, that could be involved in the aerobic degradation of 1,4 dioxane, as well as degradation of tetrahydrofuran, similar to that found in *Pseudonocardia tetrahydrofuranoxydans* strain K1 (Vainberg et al. 2006).

Pathogenicity

Pseudonocardia strains are not known or their pathogenicity though some *Pseudonocardia autotrophica* have been isolated from clinical specimens (Mishra et al. 1980; Schaal and Beaman 1984) indicating their presence in immunocompromised patients (*Fig. 37.3*).

Actinoalloteichus Tamura, Zhiheng, Yamei, and Hatano 2000, 1439^{VP}

Ac.ti.no.al.lo.tei.chus. Gr. n. *aktis*, *aktinos* ray -used to refer to actinomycetes; Gr. adj. *allos* another, the other; Gr. masc. n. *teichos* wall; N.L. masc. n. *Actinoalloteichus* actinomycete with a different wall.

Table 37.5

Nutritional requirements, degradation, and enzyme activity of *Pseudonocardia* species

Species	Nutrition and growth media	Degradation and enzyme activity	References
P. thermophila	nr	Possesses an inducible exo- and intracellular carboxymethylcelluase and β-D-glucosidase activity; calcium alginate-immobilized cells of this strain have been used to produce optically active a-hydroxy-esters; produces cobalt-containing nitrile hydratases; Constitutively expressed thermostable amidase; exhibits cellulase and xylanase activity	Malfait et al. (1984), Ishihara et al. (1997), Miyanaga et al. (2001), Peplowski et al. (2007), Egorova et al. (2004), Li et al. (1984), Zimmermann et al. (1988)
P. ammonioxydans	Oxidizes ammonia to nitrate as an energy source; grows autotrophically on modified nitrifying medium and heterotrophically on Luria-Bertani medium	nr	Liu et al. (2006)
P. asaccharolytica	Uses dimethyl disulfide as an energy source	nr	Reichert et al. (1998)
P. autotrophica	Autotroph; growth in the presence of CO_2, H_2, and O_2	Converts vitamin D3 into hydroxylated active forms, such as 1a and 2a, 25-dihydroxyvitamin D3; metabolizes 4-ethylpyridine and 4-methylpyridine and polyethylene glycol; degrades lignin, vanillinic acids, and its derivatives	Hirsch and Engel (1956), Kim et al. (2002b), Takeda et al. (2006), Lee et al. (2006), Yamashita et al. (2004), Malarczyk et al. (1987)
P. benzenivorans	Uses 1, 2, 3, 5-tetrachlorobenzene as a sole carbon source; grows on 4-aminobutyrate, 4-hydroxybutyrate, serine, and succinate	Degrades tetrahydrofuran (THF)	Kämpfer and Kroppenstedt (2004), Kämpfer et al. (2006)
P. carboxydivorans	Uses CO as a sole carbon source	nr	Park et al. (2008)
P. chloroethenivorans	Degrades chloroethene, *cis*-1,2-dichloroethene, and trichloroethene, and metabolizes phenol as a source of carbon and energy	nr	Lee et al. (2004)
P. dioxanivorans	Autotroph; degrades 1,4-dioxane	Degrades tetrahydrofuran (THF)	Mahendra and Alvarez-Cohen (2005), Kämpfer et al. (2006)
P. hydrocarbonoxydans	Good growth in the presence of simple hydrocarbons; oxidizes hydrocarbons	Degrades tetrahydrofuran (THF)	Hirsch and Engel (1956), Kämpfer et al. (2006), Lechevalier et al. (1986)
P. hydrocarbonoxydans	Able to partially oxidize sebacic and succinic acid	nr	Lacey (1988), Nolof (1962), Nolof and Hirsch (1962)
P. nitrificans	Converts ethyl-, ethyl-*N*-ethyl, *n*-butyl-, and *n*-propyl-carbamates to nitrite and uses these compounds as sole carbon, energy, and nitrogen sources; oxidizes urethane to nitrite as a sole source of carbon, nitrogen, and energy	nr	Isenberg et al. (1954), Schatz et al. (1954)

Table 37.5 (continued)

Species	Nutrition and growth media	Degradation and enzyme activity	References
P. petroleophila	Poor growth on most media; autotroph; grow in the presence of CO_2, H_2, and O_2	nr	Hirsch and Engel (1956), Lechevalier et al. (1986)
P. petroleophila	Good growth in the presence of simple hydrocarbons; oxidizes the cyclohexane ring of methylcyclohexane	nr	Nolof and Hirsch (1962), Tonge and Higgins (1974)
P. saturnea	Autotroph; grows in the presence of CO_2, H_2, and O_2	nr	Takamiya and Tubaki (1956)
P. sulfidoxydans	Uses dimethyl disulfide as an energy source; grows on 4-aminobutyrate, 4-hydroxybutyrate, serine, and succinate	Degrades tetrahydrofuran (THF)	Reichert et al. (1998), Kämpfer et al. (2006)
P. tetrahydrofuranoxydans	nr	Degrades tetrahydrofuran (THF)	Kämpfer et al. (2006)
P sp. *strain TY-7*	Oxidizes propane to 1-propanol and 2-propanol	Degrades 1.4-dioxane and other ether pollutants; used for in situ and ex situ systems to treat recalcitrant pollutants	Kotani et al. (2006), Vainberg et al. (2006)

Symbols: *nr* not reported

Phenotypic Analyses

Actinoalloteichus species are aerobic, Gram-stain-positive, nonacid-fast, nonmotile actinobacteria. Substrate mycelia are fine, branched, and non-fragmenting. Aerial mycelia are formed and fragment, with straight spore chains forming from the aerial mycelium. Good growth occurs at 20–37 °C. As found in all genera of this order, the cell wall contains *meso*-diaminopimelic acid, and whole-cell hydrolysates contain glucose, galactose, mannose, and ribose. Present in all species are the cellular fatty acids *iso*-$C_{16:0}$, *anteiso*-$C_{15:0}$, anteiso-, $C_{17:0}$ anteiso-, and $C_{15:0}$ anteiso- are the major cellular fatty acids present in all species. The major menaquinone is MK-9(H_4); small amounts of MK-9(H_6) are also present. Phosphatidylglycerol and phosphatidylinositol are present as the major diagnostic phospholipids. Mycolic acids are not detected. The acyl type of the cell wall is acetyl.

The G+C content of the DNA of members of this genus ranges between 72 and 76.6 (mol%).

The type species is *Actinoalloteichus cyanogriseus* NBRC 14455^T (Tamura et al. 2000).

Isolation Procedures

Isolation procedures for species of this genus are described in *Table 37.6*.

Taxonomy, Historical, and Current

The genus *Actinoalloteichus* forms a distinct clade and all four species have less than 95 % sequence similarity with the nearest genera *Goodfellowiella* (Labeda and Kroppenstedt 2006), *Streptoalloteichus* (Tomita et al. 1987), and *Crossiella* (Labeda 2001). The genus *Goodfellowiella* has $C_{17:0}$10-methyl and anteiso-branched 2-hydroxy fatty acids. *Streptoalloteichus* develops motile spores in sporangia, and *Crossiella* has substrate mycelia that fragment into rods and can develop sclerotia-like pseudosporangia. Species of the genus *Actinoalloteichus* do not develop sporangia or pseudo-sporangia and do not have motile spores (Tamura et al. 2008a).

Liu et al. (1984) described *Actinoalloteichus cyanogriseus* as a new taxon with blue and gray aerial mycelium with straight spore chains and bluish-violet soluble pigment. Itoh et al. (1987) found it contained glutamic acid, alanine and *meso*-diaminopimelic acid, and menaquinone 9(H_4). The phylogenetic position of *Actinoalloteichus cyanogriseus* was placed in the order *Pseudonocardiales* based on its 16S rRNA gene sequence (Stackebrandt et al. 1997; Tamura and Hatano 1998). Later, based on significant taxonomic differences as described above, it was proposed as a new genus with *A. cyanogriseus* gen. nov., sp. nov. as the type species of the new genus (Tamura et al. 2000).

Streptomyces caeruleus was reclassified as *Actinoalloteichus cyanogriseus* on the basis of 16S rRNA gene sequence analysis and DNA–DNA hybridization (Tamura et al. 2008a).

Table 37.6

Physiological characteristics and isolation procedures of *Actinoalloteichus* species[a]

Symbols: + positive, *w* weakly positive, – negative, *nr* not reported

Characteristics that differentiate the four *Actinoalloteichus* species are shown in Tables 37.6 and 37.7.

The four different species of the genus *Actinoalloteichus* are *Actinoalloteichus cyanogriseus* CIP 106755^T = DSM 43889^T = NBRC 14455^T = JCM 6095^T = NRRL B-16252^T (Tamura et al. 2000); *Actinoalloteichus hymeniacidonis* CGMCC 4.2500^T = JCM 13436^T (Zhang et al. 2006); *Actinoalloteichus nanshanensis* CGMCC 4.5714^T = NBRC 106685^T. (Xiang et al. 2011); and *Actinoalloteichus spitiensis* DSM 44848^T = JCM 12472^T = MTCC 6194^T = NBRC 102582^T (Singla et al. 2005).

Actinokineospora Hasegawa 1988, 449^{VP}

Ac.ti.no'ki.ne.o.spo.ra actis, *actinos* Gr. n., ray; *kinesis* Gr. n., motion; *spora* L. n., spore; *Actinokineospora*, actinomycete bearing zoospores.

Phenotypic Analyses

Actinokineospora strains form hyphae (approximately 0.5 µm in diameter) which differentiate into a vegetative mycelium that penetrates the agar medium forming colonies on the surface from which aerial mycelium grow. The aerial hyphae form chains of conidia capable of producing flagella in a suitable aqueous environment in all but two species, *Actinokineospora fastidiosa* and *Actinokineospora soli*. Cells are Gram-stain positive, catalase positive, and aerobic. The cell wall contains *meso*-diaminopimelic acid as the diamino acid along with glycine, D-glutamic acid, and L-alanine, properties characteristic of a type A1γ peptidoglycan. All species contain the cellular fatty acid iso-$C_{16:0}$, with iso-$C_{15:0}$ present in 9 of the 13 species. The major menaquinone is MK-9(H_4), except for 1 member which contains MK-10 as the sole menaquinone. Phosphatidylethanolamine is present as the major diagnostic phospholipid. Mycolic acids are not detected. Chemotaxonomic properties of the genus are shown in Table 37.8.

The G+C content of the DNA of members of this genus ranges between 68.2 and 73.8 (mol%).

The type species is *Actinokineospora riparia* ATCC 49499^T = DSM 44259^T = NBRC 14541 = JCM 7471^T = NRRL B-16432^T = VKM Ac-1980^T(Hasegawa 1988).

Isolation Procedures

Isolation procedures for species of this genus are described in Table 37.8.

Taxonomy, Historical, and Current

Differentiation of *Actinokineospora* species has generally relied on both 16S rRNA gene sequence phylogeny and physiological characterization utilizing variations on the methods of Shirling and Gottlieb (1966), Tamura et al. (1995), and Otoguro et al. (2001) although the characterization of the nonmotile species *Actinokineospora fastidiosa* and *Actinokineospora soli* utilized methods more typically applied to strains of *Amycolatopsis*. The comparison of the morphological and physiological characteristics of the species within *Actinokineospora* can be seen in Table 37.9. The two species that have not been observed to produce motile spores appear to be phylogenetically separated from the species of *Actinokineospora* sensu *strictu* and could represent a separate genus (Fig. 37.3). The sole *Alloactinosynnema* sp. fall within this 16S rRNA gene cluster but can be differentiated on the basis of its ability to produce pseudosporangia and because it has ribose, phosphatidylcholine, and phospatidylglycerol in its cell wall.

The twelve species of the genus *Actinokineospora* are *Actinokineospora riparia* ATCC 49499^T = DSM 44259 = NBRC 14541 = JCM 7471^T = NRRL B-16432^T = VKM Ac-1980^T (Hasegawa 1988); *Actinokineospora auranticolor* YU 961-1^T = DSM 44650^T = NRBC 16518^T = JCM 11646^T (Otoguro et al. 2001); *Actinokineospora baliensis* ID03-0561^T = BTCC B-554^T = NBRC 104211^T; *Actinokineospora cianjurensis* ID03-0810^T = BTCC B-558^T = NBRC 105526^T; *Actinokineospora cibodasensis* ID03-0748^T = BTCC B-555^T = NBRC 104212^T (Lisdiyanti et al. 2010); *Actinokineospora diospyrosa* YU8-1^T = DSM 44255^T = NRBC 15665^T = JCM 9921^T = NRRL B-24047^T = VKM Ac-1984^T (Tamura et al. 1995); *Actinokineospora enzanensis* YU 924-101^T = DSM 44649^T = NRBC 16517^T = JCM 11647^T (Otoguro et al. 2001); *Actinokineospora fastidiosa* ATCC 31181^T = DSM 43855^T = JCM 3276^T = NBRC 14105^T = NRRL B-16697^T = VKM Ac-1419^T (Labeda et al. 2010b); *Actinokineospora globicatena* YU6-1^T = DSM 44256^T = NRBC 15664^T = JCM 9922^T = NRRL B-24048^T = VKM Ac-1981^T; *Actinokineospora inagensis* YU4-1^T = DSM 44258^T = NRBC 15663^T = JCM 9923^T = NRRL B-24050^T = VKM Ac-1982^T (Tamura et al. 1995); *Actinokineospora soli* YIM 75948^T = DSM 45613^T = JCM 17695^T (Tang et al. 2012); and *Actinokineospora terrae* YU6-3^T = DSM 44260^T = NRBC 15668^T = JCM 9924^T = NRRL B-24049^T = VKM Ac-1983^T (Tamura et al. 1995).

Actinomycetospora Jiang, Wiese, Tang, Xu, Imhoff, and Jiang 2008, 408^{VP}, emended Tamura, Ishida, Hamada, Otoguro, Yamamura, Hayakawa, and Suzuki 2011, 1275

Ac.ti′no.my.ce.to.spo′ra. N. Gr. n.*actinomyces -etos* an actinomycete; Gr. fem. n. *spora* a seed and, in bacteriology, a spore; N.L. fem. n. *Actinomycetospora* referring to an actinomycete with spore chains.

Phenotypic Analyses

Actinomycetospora species are aerobic, Gram-stain-positive, nonacid-fast, nonmotile actinomycetes. Substrate mycelium

Symbols:+ positive, – negative, *v* variable reaction, *w* weak positive reaction, *nr* not reported

fragments into rod-shaped elements and is yellow, greenish yellow, or orange. No aerial mycelium is produced. Bud-like short spore chains are formed directly from substrate mycelium. Spores are white short rods or have a slight oval shape with smooth surfaces ranging from approximately 0.4–0.8 × 0.7–2.0 μm. The cell wall contains *meso*-diaminopimelic acid; whole-cell hydrolysates contain arabinose and galactose. Phosphatidylcholine and phosphatidylethanolamine are the diagnostic phospholipids. The predominant menaquinone is MK-8 (H_4). The major cellular fatty acid is iso-$C_{16:0}$, with $C_{16:1}$*cis-9*, $C_{17:1}$*cis-9*, iso-$C_{16:0}$2-OH, and $C_{17:0}$10-methyl also present.

The G+C content of the DNA of members of the genus ranges between 69 and 74.2 (mol%).

The type species is *Actinomycetospora chiangmaiensis* CCTCC AA 205017^T (=DSM 45062^T). The strain was isolated from soil collected from a tropical rainforest in Thailand (Jiang et al. 2008).

Isolation Procedures

Isolation procedures for the species of this genus are described in *Table 37.10*.

Taxonomy, Historical, and Current

The phylogenetically nearest neighboring genus within the order *Pseudonocardiales* is *Pseudonocardia* (*Figs. 37.6* and *37.7*), but the ten *Actinomycetospora* species form a distinct clade and showed less than 95.1 % sequence similarity to *Pseudonocardia* strains. In addition, the *Actinomycetospora* species are distinct as they do not produce aerial mycelia and bud-like spore chains are formed on the substrate mycelia (*Actinomycetospora* *Figs. 37.8*, *37.9*, and *37.10*).

The type species *Actinomycetospora chiangmaiensis* was originally described by Jiang et al. (2008) as containing MK-9(H_4) as the major menaquinone and phosphatidylcholine, phosphatidylglycerol, and phosphatidylinositol. This was emended by Tamura et al. (2011) who found that the type species contained MK-8(H_4) as the major menaquinone with no MK-9(H_4) and that the major phospholipids included phosphatidylethanolamine and phosphatidylcholine, as was found in all seven of the new *Actinomycetospora* species proposed.

The ten species of the genus *Actinomycetospora* can be readily differentiated by physiological characteristics and chemotaxonomic properties as can be seen in *Tables 37.10* and *37.11*, respectively.

These species are *Actinomycetospora chiangmaiensis* NBRC 104400^T (Jiang et al. 2008); *Actinomycetospora chibensis* NBRC103694^T = KACC 14256^T; *Actinomycetospora chlora* NBRC105900^T = KACC 14252^T; *Actinomycetospora cinnamomea* NBRC105527^T = KACC 14250^T; *Actinomycetospora corticicola* NBRC103689^T = KACC 14253^T (Tamura et al. 2011); *Actinomycetospora irimotoensis* NBRC106365^T = KCTC 19783^T (Yamamura et al. 2011a); *Actinomycetospora lutea* NBRC103690^T = KACC 14254^T (Tamura et al. 2011); *Actinomycetospora rishiriensis* NBRC106356^T = KACC19782^T (Yamamura et al. 2011b); *Actinomycetospora straminea* NBRC105528^T = KACC 14251^T; and *Actinomycetospora succinea* NBRC103691^T = KACC 14255^T (Tamura et al. 2011) (*Fig. 37.4*).

Actinophytocola Indananda, Matsumoto, Inahashi, Takahashi, Duangmal, and Thamchaipenet, 1141^{VP}

Ac.ti.no.phy.toco.la. Gr. n. *aktis, aktinos* ray; Gr. n. phyton, a plant; L. masc. suff. -cola (from L. n. incola) a dweller, inhabitant; N.L. masc. n. *Actinophytocola* actinobacterial dweller inside a plant.

Phenotypic Analyses

Actinophytocola species are aerobic, Gram-stain positive, nonacid fast, and nonmotile. Vegetative hyphae are non-fragmenting and aerial mycelium, which are produced on some media, fragments into cylindrical spores (0.5 × 2 μm) with smooth surfaces but no sporangium-like structures (*Actinophytocola* *Figs. 37.11* and *37.12*). Good growth occurs at 18–28 °C on oatmeal agar and oatmeal nitrate agar. The cell wall contains *meso*-diaminopimelic acid, alanine, glutamic acid, and acetylated muramic acid. Mycolic acids are absent. Whole-cell sugars are arabinose, galactose, and rhamnose. Mycolic acids are absent. The major fatty acid is iso-$C_{16:0}$, and the major menaquinone is MK-9(H_4) with MK-10(H_4) as the sole menaquinone in one species. The polar phospholipids are phosphatidylethanolamine in all species, with diphosphatidylglycerol and ninhydrin-positive phosphoglycolipids in 4 of 5 species. Chemotaxonomic and physiological properties distinguishing the *Actinophytocola* species are detailed in *Tables 37.12* and *37.13*, respectively.

The G+C content of the DNA of members of this genus ranges between 69.7 and 72.5 (mol%).

The type species is *Actinophytocola oryzae* NBRC 105245^T (Indananda et al. 2010).

Taxonomy, Historical, and Current

The genera most closely related to *Actinophytocola* include *Kibdelosporangium*, *Amycolatopsis*, *Pseudonocardia*, *Saccharopolyspora*, and *Thermocrispum* (Korn-Wendisch et al. 1995)

Table 37.10

with 94–95 % nucleotide similarity. Rhamnose as a whole-cell sugar is found only in *Actinophytocola* and not in the other related genera. It can be differentiated from *Kibdelosporangium* and *Thermocrispum* which have sporangium-like structures and a fragmentation of substrate mycelium, while *Actinoalloteichus* species do not have these structures. The phospholipid profile of *Actinophytocola* is clearly distinct from members of closely related genera as all strains contain phosphatidylethanolamine and (except for the type species) diphosphatidylglycerol but lack phosphatidylcholine, phosphatidylglycerol, and phosphatidylinositol.

Isolation Procedures

Methods for the isolation of species of the genus *Actinophytocola* are shown in *Table 37.12*.

The five species of the genus *Actinophytocola* are *Actinophytocola oryzae* BCC 31372^T = JCM 17236^T = NBRC 105245^T (Indananda et al. 2010); *Actinophytocola burenkhanensis* NBRC 105883^T = VTCC D9-23^T (Ara et al. 2011a); *Actinophytocola coralline* BTCC B-674^T = NBRC 105525^T; *Actinophytocola timorensis* BTCC B-673^T = NBRC 105524^T (Otoguro et al. 2011); and *Actinophytocola xinjiangensis* CGMCC 4.4663^T = NBRC 106673^T (Guo et al. 2011).

Actinosynnema Hasegawa, Lechevalier, and Lechevalier 1978, 305^{AL}

Ac.ti.no.syn'ne.ma Gr. n. *aktis*, *aktinos* ray; Gr. adv. *syn* together; Gr. n.*nema*, *nematos* thread; *Actinosynnema* indicates a synnema-forming actinomycete.

Phenotypic Analyses

Actinosynnema species are mesophilic, aerobic, Gram-stain-positive, nonacid-fast, and catalase-positive filamentous actinomycetes, typically isolated directly from plant tissue. The fine mycelia (approximately 0.5 μm in diameter) differentiate into long-branching substrate mycelia that penetrate the growth medium and also form dome-like bodies, also called synnemata or flat colonies on the agar surface. Aerial hyphae (0.5–1.0 μm in diameter) arise from synnemata or flat colonies and bear chains of spores that can become motile in a suitable aqueous environment. The cell walls contain *meso*-diaminopimelic acid. The whole-cell sugar pattern consists of galactose and mannose. Principal phospholipids include phosphatidylethanolamine, phosphatidylethanolamine containing 2-hydroxy fatty acids, and diphosphatidylglycerol. Menaquinones are predominantly MK-9(H_6).

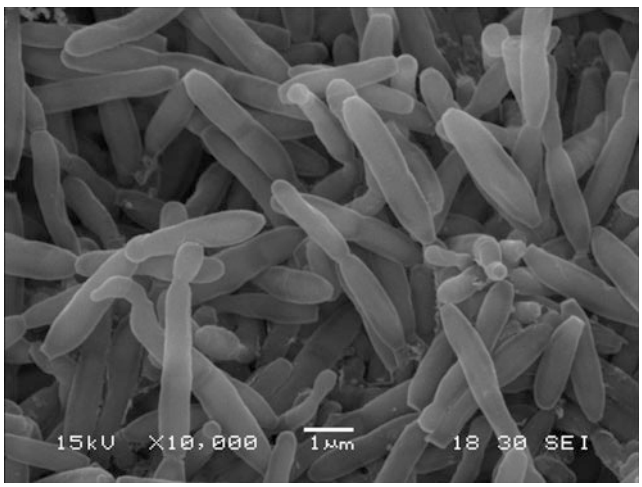

Fig. 37.9
Scanning electron micrograph of *Actinomycetospora corticicola* 014–5 showing bud-like spores (Micrograph courtesy of H. Yamamura)

The G+C of the DNA of members of this genus ranges from 71 to 73 (mol%).

The type species is *Actinosynnema mirum* ATCC 29888^T = DSM 43287^T = NBRC 14064^T = IMRU 3971^T = JCM 3225^T = NRRL B-12336^T = VKM Ac-843^T (Hasegawa et al. 1978).

Taxonomy, Historical, and Current

Phylogenetic analyses based on the sequence of the 16S rRNA gene demonstrates that the genus *Actinosynnema* is related to the genera *Lechevalieria*, *Lentzea*, and *Saccharothrix*, being intermediate between the first two genera and *Saccharothrix* and was the type genus for the family *Actinosynnemataceae* (Labeda and Kroppenstedt 2000).

The genus *Actinosynnema* was described by Hasegawa et al. (1978) to contain actinomycetes that produce unique morphological structures called synnemata (*Actinosynnema* *Fig. 37.13*) or dome-like bodies on most media. Aerial mycelia are produced on these synnemata or dome-like bodies and are initially whitish in color and become yellow to yellowish orange in color. Regular septation occurs in mature aerial hyphae making it look bamboo-like when observed microscopically and then the hyphae become chains of spores. Suspension of the aerial mycelia in liquid media under a coverslip permits the observation of peritrichously motile zoospores (*Actinosynnema* *Fig. 37.14*) within 30 min to 1 h.

Strains of *Actinosynnema* can be easily differentiated from other actinomycetes by observation of the characteristic synnemata produced on most growth media. Numerous other actinobacterial genera produce motile zoospores, notably *Actinokineospora*, *Actinoplanes*, *Planobispora*, *Planomonospora*, *Spirillospora*, and several others, but none produce synnemata. The chemotaxonomic profile of *Actinosynnema* species (*Table 37.14*) is different from the other genera in the order, except *Lentzea*, particularly the whole-cell sugar pattern consisting of only galactose and mannose as the diagnostic sugars. The phospholipid pattern of *Actinosynnema* strains is quite similar to that of *Saccharothrix* species, but the lack of rhamnose in the whole-cell sugar pattern and the presence of MK-9(H_6) and lack of MK-10(H_4) menaquinones differentiate them from this genus.

The physiological characteristics of *Actinosynnema* species are summarized in *Tables 37.15* and *37.16* can be used to differentiate between species.

Isolation, Enrichment, and Maintenance Procedures

The isolation procedures of *Actinosynnema* species from blades of grass are outlined in *Table 37.14*. Working cultures of *Actinosynnema* can be maintained as plate or agar slant cultures on an appropriate medium such as NZ-amine agar (DSMZ medium 554) with biweekly subculturing. Survival of the cultures is often better at room temperature than at 4 °C. Longer-term preservation of strains is best accomplished as frozen stocks in 40 % (v/v) aqueous glycerol at −80 °C (mechanical freezer) to −172 °C (liquid nitrogen vapour phase) or by using traditional lyophilization techniques.

Alloactinosynnema Yuan, Zhang, Yu, Liu, Guan, Lee, Kim, and Zhang 2010, 21[VP]

Al.lo.ac.ti.no.syn'ne.ma.Gr. adj *allos* other; N. L. neut. N. *Actinosynnema* a bacterial genus name; N.L. neut . n. *Alloactinosynnema*, the other *Actinosynnema*, referring to the fact that it is morphologically similar to *Actinosynnema*, but chemotaxonomically and phylogenetically distinct.

Phenotypic Analyses

The sole *Alloactinosynnema* species is an aerobic, Gram-stain-positive, lysozyme-resistant actinomycete that forms extensively branched, white- or buff- to pink-colored substrate mycelium that may fragment into rod-shaped elements. White-colored aerial hyphae are produced and these differentiate into long chains of smooth-surfaced spores which may aggregate with the aerial mycelia into clusters. Sporangium-like structures are also produced on some media. Cell walls contain the *meso*-isomer of diaminopimelic acid, and whole-cell hydrolysates contain galactose and ribose. Phosphatidylcholine is the predominant phospholipid, along with phosphatidylglycerol and diphosphatidylglycerol. The principal menaquinone is MK-9(H_4).

The G+C content of the DNA of the type species is 68.2 (mol%).

The type species is *Alloactinosynnema album* DSM 45114^T = JCM 17965^T = KCTC 19294^T (Yuan et al. 2010), the only species in the genus.

Taxonomy, Historical, and Current

The genus *Alloactinosynnema* is phylogenetically most near the genus *Actinokineospora*, as can be seen in the *Pseudonocardiales* phylogenetic tree (*Fig. 37.3*). The polar lipid content of *Alloactinosynnema* is distinct from phylogenetically near genera in that it contains ribose in its cell wall, and phosphatidylcholine as the predominant phospholipid, along with phosphatidylglycerol and diphosphatidylglycerol. It also forms pseudosporangia which are not formed by members of the genus *Actinokineosporia*.

The 16S rRNA gene contains a genus-specific pattern of diagnostic nucleotide signatures, namely, 603:635 (C–G), 617:623 (U–C), and 619 (U).

The chemotaxonomic, morphological, and physiological characteristics of the type species *Alloactinosynnema album* are shown in *Tables 37.8* and *37.9*.

Allokutzneria Labeda and Kroppenstedt 2008, 1474[VP]

Phenotypic Analyses

Allokutzneria species are aerobic, Gram-staining-positive, nonacid-fast, nonmotile actinomycetes that produce sporangium-like bodies containing hyphae but no spores (*Allokutzneria* ◉ *Fig. 37.15*). Chains of aerial spores are also produced and the vegetative mycelium also fragments to varying degrees. Cell walls contain *meso*-diaminopimelic acid as the diamino acid, the muramic acid in the peptidoglycan is acetylated and the whole-cell sugar pattern consists of arabinose, galactose, and mannose. The principal phospholipids include phosphatidylethanolamine, phosphatidylmethylethanolamine, hydroxyphosphatidylethanolamine, phosphatidylinositol, *lyso*-phosphatidylmethylethanolamine, diphosphatidylglycerol, phosphatidylglycerol, and *lyso*-phosphatidylethanolamine. The menaquinones present are predominantly MK-9(H_4) with traces of MK-9(H_2), MK-9(H_6), and MK-10(H_4). Mycolic acids are not present and the major fatty acid components are iso- and anteiso-fatty acids.

The G+C content of the DNA of the type species is 71.7 (mol%).

The type species is *Allokutzneria albata* DSM 44149^T (ATCC 55061^T = JCM 9917^T = NBRC 101910^T = NRRL B-24461^T) (Tomita et al. 1993; Labeda and Kroppenstedt, 2008).

Isolation Procedures

A soil sample collected in Mindanao Island, Philippines, was dried, ground, and transferred with a nylon sponge to agar medium containing 5 g of soluble starch, 5 g of glucose, 1 g of yeast extract, 1 g of NZ-case, 1 g of $CaCO_3$, 20 ml of V-8 juice (Campbell Japan Corp.), and 16 g agar made up to 1 L with distilled water, pH 7.2. This was supplemented with 4 μg/ml ampicillin, 10 μg/ml nalidixic acid, and 80 μg/ml nystatin. The plates were incubated at 43 °C (Tomita et al. 1993).

Taxonomy, Historical, and Current

Kibdelosporangium albatum was described by Tomita et al. (1993) for the actinomycete strain producing the antiviral antibiotics, the cycloviracins, based on morphological and chemotaxonomic characteristics. A phylogenetic analysis using 16S rRNA gene sequences for species within the order *Pseudonocardiales* by Labeda and Kroppenstedt (2000) demonstrated that this species clearly did not belong to the genus *Kibdelosporangium* (◉ *Fig. 37.18*) and chemotaxonomic analyses, specifically the presence of arabinose in the whole-cell sugar pattern and the presence of *lyso*-phospholipids in the polar lipid profile,

Amycolatopsis Lechevalier, Prauser, Labeda and Ruan 1986, 34^{VP}emend. Lee 2009, 1403

A.my.co.la.top'sis.N.L. fem. n. *Amycolata* genus belonging to the order *Actinomycetales*; Gr. fem. n. *opsis* aspect, appearance; N.L. fem. n. *Amycolatopsis* that which appears similar to *Amycolata*.

Phenotypic Analyses

Amycolatopsis are Gram-stain-positive, aerobic to facultatively anaerobic, nonacid-fast, nonmotile, catalase-positive actinobacteria that grow in the mesophilic to thermophilic temperature range. The substrate hyphae branches and fragments into squarish and rod-shaped elements. Aerial hyphae may not bear spores or can differentiate into chains of spore-like structures similar in shape to the hyphal fragments.

Symbols: *nr* not reported

[a]*Gal* galactose, *Man* mannose

[b]*PE* phosphatidylethanolamine, *OH-PE* phosphatidylethanolamine containing 2-hydroxy fatty acids, *DPG* diphosphatidyl glycerol

Chemotaxonomic analysis of the cell wall shows that most *Pseudonocardia* species possess *meso*-diaminopimelic acid and the muramic acid is *N*-acetylated, and whole-cell hydrolysates contain arabinose and galactose. Menaquinone MK-9(H_4) is the predominant isoprenoid quinone, with two taxa possessing MK-8(H_4) and one taxon each containing only MK-9(H_2), MK-11(H_4), or MK-12(H_4). The diagnostic phospholipid is phosphatidylethanolamine, with a majority of species also containing diphosphatidylglycerol and phosphatidylglycerol. No mycolic acids were detected.

The physiological characteristics and chemotaxonomic traits reported for the type species of the genus *Amycolatopsis* are described in *Tables 37.19* and *37.20*, respectively.

G+C content of the DNA of the members of the genus ranges from 65.8 to 75 (mol%).

The type species is *Amycolatopsis orientalis* (Pittenger and Brigham 1956).

Isolation Procedures

Members of this genus are nutritionally versatile and include facultative autotrophs and can be isolated from soil and other environmental samples using a range of media. Isolation procedures of all the species are shown in *Table 37.21*.

Taxonomy, Historical, and Current

The genus *Amycolatopsis* was proposed for actinobacteria that possessed substrate hyphae that fragmented into square elements and aerial mycelia which were either sterile or also fragmented into square to oval spore-like structures. Initially the members of this genus when first isolated were described as either *Actinomyces* or *Nocardia* or *Proactinomyces* or *Streptomyces*. The type species *Amycolatopsis orientalis* (Krasil'nikov 1981) was classified according to these genera in the same order (Pridham 1970; Rautenstein et al. 1975; Pittenger and Brigham 1956). In a similar fashion *Amycolatopsis mediterranei* was initially termed *Nocardia mediterranei* (Thiemann et al. 1969) and then "*Streptomyces mediterranei*" (Margalith and Beretta 1960). When *Amycolatopsis orientalis* subsp. *lurida* (Grundy et al. 1957; Lechevalier et al. 1986) was accepted as a valid type species of the new genus, it became *Amycolatopsis orientalis* subsp. *orientalis* (Pittenger and Brigham 1956) which reverted to its earlier name *Amycolatopsis orientalis* (Pittenger and Brigham 1956; Lechevalier et al. 1986). *Amycolatopsis orientalis* subsp. *lurida* was later afforded its own species name to become *Amycolatopsis lurida* (Stackebrandt et al. 2004).

Amycolatopsis species can be differentiated from other members of the family *Pseudonocardiaceae* using 16S rRNA and *gyrB* gene sequencing (Everest and Meyer 2009) as well as MALDI-TOF MS profiles (Groth et al. 2007) and ribotyping patterns (Wink et al. 2003, 2004).

Application

The importance of this genus is due to their ability to produce bioactive secondary metabolites belonging to a number of chemical structural classes, as described in *Table 37.22*. Of these classes the two that are effective in human antibacterial therapy are the ansamycins, e.g., rifamycin, and glycopeptides, e.g., vancomycin and balhimycin.

Pathogenicity

Some evidence of human and equine pathogenicity has been published which implicates *Amycolatopsis benzoatilytica* as an agent of submandibular mycetoma (Majumdar et al. 2006; Scharfen 1971) in humans. Members of the genus have also been found in clinical samples such as *Amycolatopsis orientalis* in cerebrospinal fluid and *Amycolatopsis palatopharyngis* from the palatopharygeal mucosa of a 70-year-old male (Huang et al. 2004), *Amycolatopsis kentuckyensis*, *Amycolatopsis lexingtonensis*, and *Amycolatopsis pretoriensis*, as the causal agent of placentitis and abortion in horses (Donahue and Williams 2000; Giles et al. 1993; Hong et al. 1993; Labeda et al. 2003).

Ecology and Metabolism

Apart from the strains isolated from clinical specimens, the majority of taxa have been isolated from soils of different types, including rhizosphere soils, dusts from catacombs, and ocean sediments. To date only one species has been recovered as an endophyte. Some of the facultative autotrophs can degrade a range of organic substrates and use different carbon sources as their sole source of energy and growth (Chun et al. 1999; De Boer et al. 1990; Groth et al. 2007). *Amycolatopsis benzoatilytica* is the only member of this genus which can grow on *m*-hydroxybenzoate.

Molecular Analyses

The genetic analyses of some members of the genus *Amycolatopsis* is based on species which produce economically important antibiotics (as described in detail by Tan and Goodfellow 2012).

To date three genome sequences of *Amycolatopsis* species have been fully annotated.

Amycolatopsis mediterranei U3, an industrial strain producing the antimycobacterial antibiotic rifamycin, has a circular chromosome containing 10,236,715 base pairs (bp) with a G+C content of 71.3 (mol%) and a predicted 9,228 protein-coding genes (Zhao et al. 2010). It has a core region which carries the rifamycin biosynthesis gene cluster with the majority of *rif* genes encoded on the leading strand of replication and a novel "quasi-core" region which has 21 out of the total 26 gene clusters for secondary metabolite production – 4 polyketides (PK), 11 non-ribosomal peptides (NRP), PK-NRP hybrids, and 4 terpenoids, with the rest being other chemical structures. There are 55 genes encoding cytochrome P450 enzymes (notably including the enzyme involved in the conversion of rifamycin SV to B) and 86 antibiotic-resistant genes, which are evenly distributed along the chromosome.

The genome sequence of another more thoroughly investigated rifamycin producer, *Amycolatopsis mediterranei* S699 (GenBank accession number CP002896), was reported a year later (Verma et al. 2011). Strain S699 has a gene order and

Umezawaea tangerinus	JCM 10302^T	Formamicin	Kinoshita et al. (1999)

nucleotide identity very similar to that of *Amycolatopsis mediterranei* U32. However, it is reported to contain a 10,236,779 bp circular chromosome and 9,575 coding sequences, and in addition to the well-known 90-kb rifamycin gene cluster, five other PK, twelve NRPS, and three PK-NRPS hybrid clusters were observed.

Vongsangnak et al. (2012) not only performed genome sequencing and analysis of *Amycolatopsis balhimycina* but also used the information to construct a genome-scale metabolic model. The purpose of the model was to facilitate the application of rational engineering strategies to increase the production of balhimycin. The *Amycolatopsis balhimycina* genome sequence is reported to have 10,562,587 base pairs with a G+C content of 69 (mol%), which includes 8,585 open reading frames (ORFs).

Amycolatopsis sp. strain ATCC 39116 was selected for genome sequencing as it can depolymerize lignin (Antai and Crawford 1981) and catabolize the resulting aromatic components (Sutherland 1986). It has a genome size of 8,442,518 bp (AFWY00000000) with a G+C content of 71.9 (mol%) and predicted 8,264 candidate protein-encoding genes (Davis et al. 2012).

Crossiella Labeda 2001, 1578^{VP}

Cross.i.el'la.M.L. dim. ending *-ella*; M.L, fem. n. *Crossiella* named for Thomas Cross, a microbiologist at the University of Bradford who made many contributions to actinomycete biology and systematics.

Phenotypic Analyses

Crossiella species are aerobic, Gram-stain-positive, nonacid-fast, catalase-positive, nonmotile actinomycetes. Generally, branched substrate mycelium (approximately 0.5 µm diameter) is produced on all growth-supported media, and aerial mycelia may also be produced on some media. The vegetative mycelium may fragment into rod-shaped elements with age and sclerotia-like pseudosporangia may also be produced on the substrate mycelium (*Crossiella* ❯ *Fig. 37.16a*). Swelling of the aerial hyphae may be observed, particularly at or near the apical tip (see *Crossiella* ❯ *Fig. 37.16b*). The peptidoglycan is acylated, containing the *meso*-isomer of diaminopimelic acid as the diamino acid and whole-cell hydrolysates contain galactose, mannose, rhamnose, and ribose as the diagnostic sugars. Phosphatidylethanolamine, phosphatidylmethylethanolamine, phosphatidylinositol, diphosphatidylglycerol, and phosphatidylinositol mannosides are observed as the characteristic phospholipids. The predominant menaquinone present is MK-9(H_4) and mycolic acids are not observed. Both species have a fatty-acid profile rich in branched chain and saturated components.

The G+C content of the DNA of both *Crossiella* species is 71.4 (mol%).

Type species is *Crossiella cryophila* NRRL B-16238^T = ATCC 51143^T = DSM 44230^T = IFO 14475^T = NBRC 14475^T(Labeda 2001).

Isolation Procedures

Isolation procedures of all the species are shown in ❯ *Table 37.23*.

Taxonomy, Historical, and Current

The phylogenetically nearest neighboring genera within the order *Pseudonocardiales* are *Streptoalloteichus, Goodfellowiella*, and *Actinoalloteichus* (❯ *Fig. 37.3*), but both *Crossiella* species

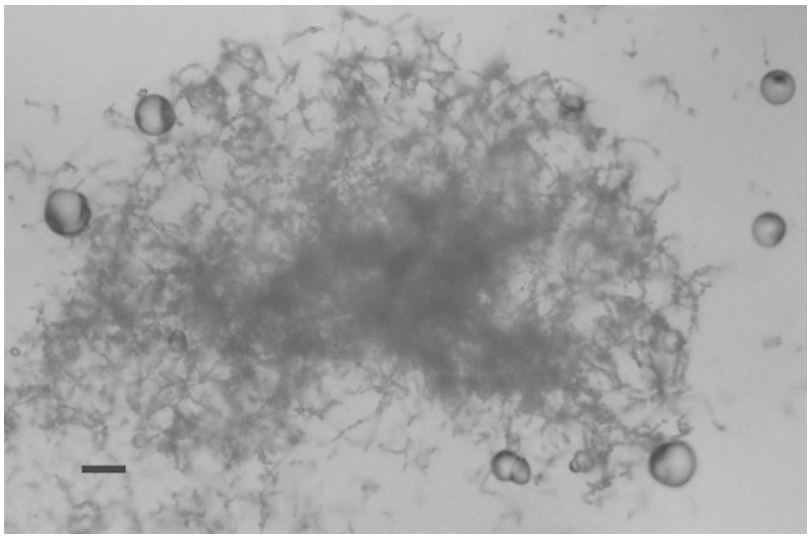

Fig. 37.15

are quite distinct from them based on chemotaxonomy and morphology, since neither produces sporangia.

The type species, a novel soil isolate that produced the antibiotic dopsisamine, was originally described by Takahashi et al. (1986) as *Nocardiopsis mutabilis* subspecies *cryophilis*. On the basis of more complete chemotaxonomic investigations, the transfer of *Nocardiopsis mutabilis* and its subspecies to the genus *Saccharothrix* was proposed by two independent studies (Grund and Kroppenstedt 1989; Labeda and Lechevalier 1989). The DNA relatedness of *Nocardiopsis mutabilis* subspecies *cryophilus* to the other valid species of the genus *Saccharothrix* was very low (2–11 %) and a new species named *Saccharothrix cryophila* was proposed. Subsequent phylogenetic analysis of the species of the genera within the suborder *Pseudonocardineae* based on 16S rRNA gene sequences (Labeda and Kroppenstedt 2000) demonstrated that a number of *Saccharothrix* species were misclassified and consideration of the morphological, chemotaxonomic, and phenotypic properties of the type strain of *Saccharothrix cryophilus* resulted in the proposal for the new genus *Crossiella* to accommodate it (Labeda 2001).

The species of the genus *Crossiella* can be readily differentiated by chemotaxonomic and physiological characteristics, as can be seen in *Tables 37.23* and *37.24*, respectively. An interesting observation during the assessment of numerous strains of *Crossiella equi* was that during testing for acid production from carbohydrates, all strains absorbed the pH indicator dye bromothymol blue from the growth medium.

Pathogenicity and Clinical Relevance

Nocardioform placentitis is an emergent disease causing placentitis and abortions in thoroughbred mares, first recognized in Kentucky in 1986 (Donahue and Williams 2000; Giles et al. 1993; Hong et al. 1993). The infection is typically diagnosed because of lesions in the chorionic surface of the placenta and the isolation of Gram-stain-positive branching microorganisms. *Crossiella* biomass may infiltrate up to 30 % of the surface area of a placenta but does not invade the fetus and likely contributes to death or weakening of the unborn foal by competing for nutrients. The placental infection may result in spontaneous abortions, stillbirth, and full-term deliveries of weakened foals, or there may be no apparent effect with the birth of healthy foals. Strains isolated from placental tissues are phylogenetically very near to *Crossiella cryophila*, having 16S rRNA gene sequences that are 98.1 % similar, exhibiting morphological and chemotaxonomic characteristics that are typical for this genus, and therefore the species *Crossiella equi* was proposed for these isolates (Donahue et al. 2002). The manner in which *Crossiella equi* strains infect equine placentas is still unknown and studies have been hampered by the fact that the incidence of *Crossiella equi* equine placentitis is quite variable and numbers of infected placentas observed is relatively low in most years.

Goodfellowiella Labeda, Kroppenstedt, Euzeby, and Tindall 2008, 1048^{VP}

Good.fel.low'i.el.la M.L., fem. n. *Goodfellowiella* named for Michael Goodfellow, a microbiologist at University of Newcastle, in recognition of his contributions to microbial systematics.

Phenotypic Analyses

Goodfellowiella species are aerobic, Gram-stain-positive, nonacid-fast, nonmotile actinomycetes that produce branching

substrate mycelium (approximately 0.5 μm in diameter). Aerial mycelia are also produced on some growth media and the substrate mycelia fragment into coccoid conidia. Typical of all genera within the *Pseudonocardiales*, the cell wall contains *meso*-diaminopimelic acid as the diamino acid, and whole-cell hydrolysates contain galactose and ribose. As can be seen in *Pseudonocardiales* Chemotaxonomy Table (*Table 37.1*), the polar lipid content includes diphosphatidylglycerol, phosphatidylethanolamine, hydroxyphosphatidylethanolamine, and traces of phosphatidylinositol and phosphatidylinositol mannosides. The predominant menaquinones are MK-9(H_4) and MK-10(H_4). The fatty-acid profile of *Goodfellowiella* is rich in branched chain and saturated components including 10-methyl branched heptadecanoic acid and anteiso-branched 2-hydroxy fatty acids. This single species genus is to be phylogenetically nearest to the genus *Actinoalloteichus* as can be seen in *Figs. 37.1*, *37.2*, *37.3*, *37.4*, and *37.5*.

The G+C content of the DNA of the type species is 68.2 (mol%).

The genus only contains a single species, *Goodfellowiella coeruleoviolacea* NRRL B-24058^T = DSM 43935^T = INA 3564^T = JCM9110^T = NBRC14988^T = VKM Ac-1083^T (Preobrazhenskaya and Terekhova 1987; Labeda and Kroppenstedt 2006; Labeda et al. 2008), whose characteristics are shown in *Tables 37.23* and *37.24*.

Taxonomy, Historical, and Current

Preobrazhenskaya and Terekhova (1987) and Preobrazhenskaya et al. (1976) first described *Goodfellowiella coeruleoviolacea* as *Actinomadura coeruleoviolacea* that was subsequently transferred by Kroppenstedt et al. (1990, 1991)into the genus *Saccharothrix* as *Saccharothrix coeruleoviolacea*. During a phylogenetic evaluation of the species within the genus *Saccharothrix* based on almost complete 16S rRNA sequences (Labeda and Kroppenstedt 2000), it was noted that the type strain of *Saccharothrix coeruleoviolacea* was not near to the other species of *Saccharothrix* and likely represented a new genus within the suborder *Pseudonocardineae*. The strain was subsequently shown to be chemotaxonomically distinct from *Saccharothrix* as well as other genera within the suborder, and the new genus *Goodfellowia* was proposed by Labeda and Kroppenstedt (2006). This genus name was afterward discovered to be taxonomically illegitimate because it had been used previously in 1903 as the name of an avian genus. This situation was corrected by the publication of a proposal to emend the genus name to *Goodfellowiella* (Preobrazhenskaya and Terekhova 1987; Labeda et al. 2008).

Goodfellowiella coeruleoviolacea is most closely related to the genus *Actinoalloteichus* (*Fig. 37.3*) but can be distinguished from this genus based on chemotaxonomic properties (*Table 37.1*). The chemotaxonomic properties of

Goodfellowiella distinguish it from *Actinoalloteichus* by the lack of mannose in whole-cell hydrolysate sugar pattern as well as the lack of inositol-containing phospholipids and the presence of hydroxylated phosphatidylethanolamine in its polar lipid profiles. Substantial quantities of menaquinone MK-10(H_4) are present and this is distinct from other taxa within the suborder. Scanning electron microscopic observations of colony growth on several different media have not revealed the presence of sporangia, and the substrate mycelium appears to fragment into coccoidal rod elements (*Goodfellowia* ❯ *Fig. 37.17*). Spore chains typical of those observed in *Actinoalloteichus* species were not found.

Haloechinothrix Tang, Wang, Zhang, Lee, Lou, Kim, and Li 2254^{VP}

Ha.lo.e.chi.no'thrix. Gr. n. hals, halos salt; Gr. n. echinos hedgehog; Gr. fem. n. thrix hair; N.L. fem. n. Haloechinothrix halophilic, hedgehog-like filament, referring to halophilic filamentous actinobacterium with spiny aerial mycelium.

Phenotypic Analyses

Haloechinothrix species are strictly aerobic, Gram-stain-positive, nonacid-fast, moderately halophilic, filamentous actinobacteria. The substrate mycelium is well developed and fragments into rodlike elements, while the aerial mycelium is "hedgehog-like" or spiny and does not form spores at maturity. As shown in ❯ *Table 37.25*, the aerial mycelium is white and the substrate mycelium yellow–white. The cell wall contains *meso*-diaminopimelic acid as the diamino acid and whole-cell sugars consist of glucose, glucosamine, mannose, and an unknown sugar. The phospholipids are diphosphatidylglycerol, phosphatidylglycerol, phosphatidylethanolamine, phosphatidylinositol, phosphatidylinositol mannosides, and an unknown phospholipid. The predominant menaquinone is MK-8(H_4) and the major fatty acid is iso-$C_{16:0}$ (❯ *Table 37.26*).

The mol% G+C content of the DNA of the sole species is 68.1 (mol%).

The type species is *Haloechinothrix alba* YIM 93221^T = DSM 45207^T; CCTCC AB 208140^T (Tang et al. 2010b).

Isolation Procedures

As shown in ❯ *Table 37.26*, the strain was isolated from a soil sample collected from Qijiaojing Lake, a salt lake in Xinjiang Province, China, after 3 weeks of incubation at 37 °C on cellulose–casein multi-salts medium (Tang et al. 2010b).

Taxonomy, Historical, and Current

Phylogenetic analysis based on 16S rRNA gene sequences indicated that *Haloechinothrix alba* YIM 93221^T formed a distinct lineage within the order *Pseudonocardiales* and has the highest sequence similarity to a *Saccharopolyspora* species. The neighbor-joining algorithm however places the genera *Haloechinothrix* and *Sciscionella* in a distinct clade supported by a high bootstrap value (66 %).

The type strain is a halophilic actinobacterium that cannot grow without NaCl, whereas members of the genera *Sciscionella, Thermocrispum*, and *Saccharopolyspora* (except for *Saccharopolyspora halophila* and *Saccharopolyspora qijiaojingensis*) are

Symbols: *nr* not reported

PL unknown phospholipids, *PME* phosphatidylmethylethanolamine, *OH- PE* hydroxyl phosphatidylethanolamine, *PIM* phosphatidylinositol mannosides

PL unknown phospholipids, *GluNu* phospholipids containing glucosamine, *AL* unknown aminolipid

[a]PC phosphatidylcholine, *PE* phosphatidylethanolamine, *PS* phosphatidylserine, *DPG* diphosphatidylglycerol, *PG* phosphatidylglycerol, *PI* phosphatidylinositol

[b]*Gal* galactose, *Ara* arabinose, *Glc* glucose, *Rib* ribose, *Man* mannose

not halophilic. *Haloechinothrix* has MK-8(H_4) as the predominant menaquinone and phospholipids containing phosphatidylglycerol (no phosphatidylcholine), whereas the genera *Sciscionella*, *Thermocrispum*, *Yuhushiella*, and *Saccharopolyspora* have arabinose and/or galactose as the diagnostic sugars, MK-9(H_4) as the predominant menaquinone and phospholipids containing phosphatidylcholine (no phosphatidylglycerol).

Table 37.21
Method of isolation for the species of the genus *Amycolatopsis*

Species	Source	Province/country	Method of isolation	References
Amycolatopsis orientalis	Soil, vegetable matter, and clinical specimens	nr	nr	Krasil'nikov (1981)
Amycolatopsis alba	Soil	nr	Isolated from soil by using the dilution plating technique. Cells were grown on a rotary shaker (250 rpm) for 72 h at 30 °C in a medium containing 30 g of trypticase soy broth (BBL, Becton Dickinson, Cockeysville, Md.), 3 g of yeast extract, 2 g of $MgSO_4 \cdot 7H_2O$, 5 g of glucose, and 4 g of maltose in 1 L of deionized water	Mertz and Yao (1993)
Amycolatopsis albidoflavus	Soil	nr	nr	Lee and Hah (2001)
Amycolatopsis australiensis	Arid soil	Western Australia	Isolated on SM2 agar plates that had been inoculated with suspensions of a composite arid Australian soil sample and incubated at 28 °C for 3 weeks, as described by Tan et al. (2006)	Tan et al. (2006)
Amycolatopsis azurea	Soil	Japan	nr	Henssen et al. (1987)
Amycolatopsis balhimycina	Soil	India	nr	Wink et al. (2003)
Amycolatopsis bartoniae	Dry sandy soil	Kings Canyon, Australia	Isolated on SM2 agar plates that had been inoculated with suspensions of arid sandy soil sample and incubated at 28 °C for 3 weeks, as described by Tan et al. (2006)	Zucchi et al. (2012a)
Amycolatopsis benzoatilytica	Submandibular mycetoma tissue	Czechoslovakia	nr	Majumdar et al. (2006), Yuan et al. (2012)
Amycolatopsis bullii	Dry sandy soil	Kings Canyon, Australia	Isolated on SM2 agar plates that had been inoculated with suspensions of arid sandy soil sample and incubated at 28 °C for 3 weeks, as described by Tan et al. (2006)	Zucchi et al. (2012a)
Amycolatopsis cihanbeyliensis	Soil	Cihanbeyli Salt Mine; Central Anatolia region of Turkey	Soil suspension was inoculated on modified Bennett's agar supplemented with 5 % NaCl (w/v); incubated at 28 °C for 3 weeks	(Tatar et al. 2013)
Amycolatopsis circi	Soil sample	Kenilworth Racecourse, Cape Town, South Africa	Soil sample was ground with a sterile pestle and mortar before being heated at 60 °C for 1 h. 0.1 g of soil was then added to 1 ml of sterile distilled water and agitated by vortexing for 1 min. The sample was serially diluted in sterile distilled water and spread plated on SM1 agar, SM3 agar (Tan et al. 2006) and soil extract agar (Hamaki et al. 2005) adjusted to pH8, all containing cycloheximide (50 μg ml^{-1}) and nalidixic acid (μg ml^{-1}). Strain was then isolated from SM1 agar after incubation for 21 days at 30 °C	Everest and Meyers (2011)
Amycolatopsis coloradensis	Soil	Colorado, USA	nr	Labeda (1995)
Amycolatopsis decaplanina	Soil	India	nr	Wink et al. (2004)
Amycolatopsis dongchuanensis	Soil sample from dry and hot river valley	Yunnan Province, China	2 g of air-dried soil sample was shaken in a flask with 18 ml of sterile water and several glass beads at 200 rpm for 1 h at 30 °C. The resultant suspension	Nie et al. (2012a)

Table 37.21 (continued)

Species	Source	Province/country	Method of isolation	References
			was serially diluted (1000-fold) with sterile water and spread onto modified ISP (International Streptomyces Project; Shirling and Gottlieb 1966) 5 medium supplemented with nalidixic acid (25 mg l^{-1}) and nystatin (50 mg l^{-1}) and incubated at 28 °C for one week	
Amycolatopsis echigonensis	Filtration material made from volcanic soil	Niigata, Japan	Isolated using a filtration substrate as the substrate on NY medium (1.6 g nutrient broth, 0.5 g yeast extract, 1 L deionized water and 1.5 % agar, pH 7.0), with cycloheximide (0.05 l^{-1}) and kabicidin (0.1 g l^{-1}); maintained on NY medium or oatmeal agar at 27 °C	Ding et al. (2007)
Amycolatopsis endophytica	Seeds of *Jatropha curcas* L	Sichuan Province, China	Seeds were surface-sterilized according to the five-step sterilization procedure (Qin et al. 2008). Surface sterilized seeds were aseptically crumbled into smaller fragments using a commercial Joyoung blender, spread onto sodium propionate agar (Qin et al. 2009), and incubated at 28 °C for 2–6 weeks	Miao et al. (2011)
Amycolatopsis equina	Soil sample	Kenilworth Racecourse, Cape Town, South Africa	Soil sample was ground with a sterile pestle and mortar before being heated at 60 °C for 1 h. 0.1 g of soil was then added to 1 ml of sterile distilled water and agitated by vortexing for 1 min. The sample was serially diluted in sterile distilled water and spread plated on SM1 agar, SM3 agar (Tan et al. 2006) and soil extract agar (Hamaki et al. 2005) adjusted to pH 8, all containing cycloheximide (50 μg ml^{-1}) and nalidixic acid (10 μg ml^{-1}). Strain was then isolated from soil extract agar after incubation for 10 days at 30 °C	Everest and Meyers (2011)
Amycolatopsis eurytherma	Scrubland soil	India and Turkey	Isolated on starch casein agar (Küster and Williams 1964) that had been supplemented with cycloheximide (50 μg ml^{-1}) and rifampicin (0.5 μg ml^{-1}) and incubated at 55 °C for 7 days	Kim et al. (2002a)
Amycolatopsis granulosa	Arid soil sample	Marla, Australia	Isolated from SM2 agar plates (Tan et al. 2006)	Zucchi et al. (2012b)
Amycolatopsis halophila	Soil sample	Xinjiang, China	Isolated on cellulose–casein multi-salt medium (Tang et al. 2008), incubated at 37 °C for 3 weeks	Tang et al. (2010a)
Amycolatopsis halotolerans	Soil	Natural cave on Jeju Island, Republic of Korea	Serial dilution of sample suspensions were transferred onto starch casein agar; incubated at 30 °C for 14 days	Lee (2006)
Amycolatopsis helveola	Soil	Amami Oshima Island, Japan	Isolated using the yeast extract–SDS method (Hayakawa and Nonomura 1989) with humic acid–vitamin (HV) agar (Hayakawa and Nonomura 1987)	Tamura et al. (2010)
Amycolatopsis hippodromi	Soil sample	Kenilworth Racecourse, Cape Town, South Africa	Soil sample was ground with a sterile pestle and mortar before being heated at 60 °C for 1 h. 0.1 g of soil was then added to 1 ml of sterile distilled water and agitated by vortexing for 1 min. The sample was serially diluted in sterile distilled water and spread plated on SM1 agar, SM3 agar (Tan et al. 2006), and soil extract agar (Hamaki et al. 2005) adjusted to pH8, all containing cycloheximide (50 μg ml^{-1}) and nalidixic acid (10 μg ml^{-1}). Strain was then isolated from soil extract agar after incubation for 10 days at 30 °C	Everest and Meyers (2011)
Amycolatopsis japonica	Soil	Japan	nr	Goodfellow et al. (1997)

Table 37.21 (continued)

Species	Source	Province/country	Method of isolation	References
Amycolatopsis jejuensis	Dried bat dung	Jeju Island, Republic of Korea	Serial dilution of sample suspensions were transferred onto starch casein agar and incubated at 30 °C for 14 days	Lee (2006)
Amycolatopsis kentuckyensis	Equine placentas	Kentucky, USA	nr	Labeda et al. (2003)
Amycolatopsis keratiniphila	Marsh soil	Kuwait	Isolated using animal wool as bait	Al-Musallam et al. (2003)
Amycolatopsis keratiniphila subsp. *keratiniphila*	Marsh soil	Kuwait	Isolated using animal wool as bait	Wink et al. (2003)
Amycolatopsis keratiniphila subsp. Nogabecina	Soil	India	nr	Wink et al. (2003)
Amycolatopsis lexingtonensis	Equine placentas	Kentucky, USA	nr	Labeda et al. (2003)
Amycolatopsis lurida	Soil	na	nr	Stackebrandt et al. (2004)
Amycolatopsis magusensis	Arid soil	Magusa, northern Cyprus	Isolated on Stevenson's medium No. 2 (Tan et al. 2006) supplemented with cycloheximide (50 μg ml^{-1}), nystatin (50 μg ml^{-1}), neomycin sulfate (4 μg ml^{-1}) and melezitose (1 %, w/v); incubated at 28 °C for 21 days	(Camas et al. 2013a)
Amycolatopsis marina	Ocean sediment	South China Sea	Serial dilutions of sample suspensions were transferred onto the selective isolation medium (SM1; Tan et al. 2006) for the genus *Amycolatopsis* and incubated at 28 °C for 4 weeks	Bian et al. (2009)
Amycolatopsis mediterranei	Soil sample collected in a Pinus arboretum	St. Raphael, France	nr	Lechevalier et al. (1986)
Amycolatopsis methanolica	Soil	New Guinea	nr	De Boer et al. (1990)
Amycolatopsis minnesotensis	Prairie soil	Minnesota, USA	Isolated from a prairie soil by using the dilution plating method with oatmeal agar and were maintained as 20 % (v/v) glycerol suspensions at −70 and −20 °C	Lee et al. (2006b)
Amycolatopsis nigrescens	Wall of St. Callistus hypogean Roman catacomb	St. Callistus	Isolated from the wall of the last arcosolium near the exit of the Roman catacomb of St. Callistus by touching the stone with a sterile cotton swab and suspending the adherent bacteria in 1:10-diluted organic medium 79 (Prauser and Falta 1968). Aliquots of this suspension were spread over nutrient agar (Difco) plates, which were incubated at 28 °C for 14 days	Groth et al. (2007)
Amycolatopsis niigatensis	Filtration material made from volcanic soil	Niigata, Japan	Isolated using a filtration substrate as the substrate on NY medium (1.6 g nutrient broth, 0.5 g yeast extract, 1 L deionized water and 1.5 % agar, pH 7.0), with cycloheximide (0.05 g L^{-1}) and kabicidin (0.1 g L^{-1}); maintained on NY medium or oatmeal agar at 27 °C	Ding et al. (2007)
Amycolatopsis orientalis subsp. *orientalis*	Soil, vegetable matter, and clinical specimens	nr	nr	Yuan et al. (2012)

Table 37.21 (continued)

Species	Source	Province/country	Method of isolation	References
Amycolatopsis palatopharyngis	Infected palatopharyngeal mucosa of a 70-year-old male patient	nr	Isolated on a brain–heart infusion agar plate that had been seeded using swabs and incubated at 37 °C for 5 days under microaerophilic conditions	Huang et al. (2004)
Amycolatopsis pigmentata	Soil sample from pineapple field	Iriomote Island, Japan	Isolated using the yeast extract–SDS method (Hayakawa and Nonomura 1989) with humic acid–vitamin (HV) agar (Hayakawa and Nonomura 1987)	Tamura et al. (2010)
Amycolatopsis plumensis	Brown hypermagnesian ultramafic soil	New Caledonia	Isolated from a suspension of a brown hypermagnesian ultramafic soil, which was used to inoculate a yeast extract/malt extract agar plate (ISP 2 medium; Shirling and Gottlieb 1966) supplemented with 10 μg ml^{-1} streptomycin sulfate and 100 μg ml^{-1} cycloheximide (Vobis 1992) and incubated at 30 °C for 2 weeks	Saintpierre-Bonaccio et al. (2005)
Amycolatopsis pretoriensis	Equine placentas	Pretoria, South Africa	nr	Labeda et al. (2003)
Amycolatopsis regifaucium	Arid soil	Australia	Strains were isolated on SM2 agar plates that had been inoculated with tenfold dilutions of a composite Australian soil sample and incubated at 28 °C for 21 days, as described by Tan et al. (2006b)	Tan et al. (2007)
Amycolatopsis rifamycinica	Arid soil	Alice Springs, Australia	nr	Bala et al. (2004)
Amycolatopsis ruanii	Arid soil sample	nr	Isolated from starch–casein agar plate (Küster and Williams 1964) which had been inoculated with soil suspension, incubated at 28 °C for 21 days	Zucchi et al. (2012b)
Amycolatopsis rubida	Soil sample from conifer forest	Guangxi Province, China	Isolated on a glucose–asparagine agar (GAA); glucose, 10 g; L-asparagine, 0.5 g; K_2HPO_4, 0.5 g; distilled water, 1 L; (pH 7.2) plate, which had been seeded with a soil suspension and incubated at 28 °C for 14 days	Huang et al. (2001)
Amycolatopsis saalfeldensis	Surfaces of acidic and heavy-metal-containing rocks; medieval alum slate mine	Thuringia, Germany	Isolated from rock in the central grotto (second level of the mine) by touching it with a sterile cotton swab and dispersing adhering bacteria in 1 ml sterile distilled water. Aliquots of the resultant suspension were spread over casein mineral agar plates (Altenburger et al. 1996), supplemented with cycloheximide (50 μg ml^{-1}), and incubated at 28 °C for 4 weeks	Carlsohn et al. (2007)
Amycolatopsis sacchari	Floor dust	Lucknow, India	Isolated using a wind-tunnel technique (Lacey 1971; Lacey and Dutkiewicz 1976); the Andersen sampler was loaded with petri dishes containing half-strength nutrient agar supplemented with 50 μg ml^{-1} actidione (Gregory and Lacey 1963)	Goodfellow et al. (2001)
Amycolatopsis salitolerans	Hypersaline habitat	Xinjiang Province, China	Isolated under aerobic conditions on GTY agar (5 g glucose, 0.5 g tryptone, 2 g yeast extract, 1 g $CaCO_3$, 0.5 K_2PO_4, 16.0 g agar, 1 L distilled water; pH 7.0–7.5) supplemented with 10 % (w/v) NaCl	Guan et al. (2012)

Table 37.21 (continued)

Species	Source	Province/country	Method of isolation	References
Amycolatopsis samaneae	Roots of *Samanea saman* (Jacq.) Merr	Bangkok, Thailand	Isolated from a leguminous plant using starch casein agar (Küster and Williams 1964) supplemented with ketokonazole (100 μg ml^{-1}) and nalidixic acid (25 μg ml^{-1}). Plates that had been inoculated with surface-sterilized crushed root suspensions of *Samanea saman* were incubated at 28 °C for 14 days	Duangmal et al. (2011)
Amycolatopsis sulphurea	Soil	nr	nr	Lechevalier et al. (1986)
Amycolatopsis taiwanensis	Soil sample	Yilan County, Taiwan	Isolated using HV agar (Hayakawa and Nonomura 1987), and incubated at 28 °C for 4 weeks	Tseng et al. (2006)
Amycolatopsis thailandensis	Soil sample	Northern Thailand	1 g soil sample was suspended in 10 ml basal medium [containing 0.4 % $(NH4)_2SO_4$, 0.2 % K_2HPO_4, 0.05 % $MgSO_4 \cdot 7H_2O$, and 0.1 % yeast extract] with a 25 mg sample of 0.1 % (w/v) PLA film, as described by Tomita et al. (1999) incubated at 30 °C with rotary shaking at 150 r.p.m for 14 days. The enriched culture broth was spread onto 0.1 % (w/v) emulsified PLA agar and incubated at 30 °C for 14 days	Chomchoei et al. (2011)
Amycolatopsis thermalba	Arid soil sample	Marla, Australia	Isolated from SM3 agar plates (Tan et al. 2006b)	Zucchi et al. (2012b)
Amycolatopsis thermoflava	Heat treated soil sample	Hainan Island, China	nr	Chun et al. (1999)
Amycolatopsis thermophila	Composite arid soil sample	Australia	Isolated from SM1 agar plates (Tan et al. 2006b), inoculated with suspension of composite soil sample, incubated at 28 ° C for 21 days	Zucchi et al. (2012c)
Amycolatopsis tolypomycina	Soil	Tokyo, Japan	nr	Wink et al. (2003)
Amycolatopsis tucumanensis	Groundwater sediments polluted with copper	Tucuman, Argentina	Isolated from groundwater sediments polluted with copper (Albarracín et al. 2005). It was stored at 4 °C on starch–casein agar slants, containing (L^{-1}): 10.0 g starch, 1.0 g casein, 0.5 g K_2HPO_4, 15 g agar; pH 7.0	Albarracín et al. (2010)
Amycolatopsis ultiminotia	Rhizosphere soil of *Peucedanum japonicum* Thunb plant	Mara Island, Jeju, Republic of Korea	Serially diluted rhizosphere soil samples (10-fold dilutions) were inoculated on starch–casein agar and incubated at 30 °C for 14 days, as described by Lee (2006)	Lee (2009)
Amycolatopsis umgeniensis	Soil	KwaZulu Natal province, South Africa	Soil samples were air dried and 0.1 g of soil was added to 1 ml of sterile distilled water and vortexed for 1 min. Serially diluted (in sterile distilled water) samples were spread onto Czapek Solution Agar (Atlas, 2004) and incubated for 14 days at 30 °C	Everest et al. (2013)
Amycolatopsis vancoresmycina	Soil	India	nr	Wink et al. (2003)
Amycolatopsis viridis	Composite arid soil sample	Australia	Isolated from SM2 agar plates (Tan et al. 2006), inoculated with suspension of composite soil sample, incubated at 28 °C for 21 days	Zucchi et al. (2012c)
Amycolatopsis xylanica	Soil sample	Qinghai Province, China	Selective isolation on medium MY10S, which contained xylan as the only carbon and energy source, after incubation at 28 °C for 2 weeks	Chen et al. (2010)

nr not reported

Table 37.22

Diversity of antibiotic compounds discovered as products of *Amycolatopsis* species

Species	Antibiotic	Class of compound	References
Amycolatopsis alba	Compound VIcd	1-(10 aminodecyl) pyridinium	Dasari et al. (2012)
Amycolatopsis azurea	Octacosamicin A and B	Guanidines	Dobashi et al. (1988)
	Azureomycins A and B	Glycopeptide	Omura et al. (1979)
Amycolatopsis balhimycina	Balhimycin	Glycopeptide	Nadkarni et al. (1994)
Amycolatopsis coloradensis	Avoparcin	Glycopeptide	Kunstmann et al. (1968)
Amycolatopsis decaplanina	Decaplanin	Glycopeptide	Wink et al. (2004)
Amycolatopsis keratiniphila subsp. *nogabecina*	Nogabecin	Glycopeptide	Shorin et al. (1957)
Amycolatopsis lurida	Benzathrins	Quinones	Philip et al. (1957), Theriault et al. (1986), Rasmussen et al. (1986)
	Ristocetin	Glycopeptide	Grundy et al. (1957)
Amycolatopsis mediterranei	Rifamycin W, 34a-deoxy Proansamycin B	Polyketide	Stratmann et al. (2002)
	31-Homorifamycin W	Quinones	Wang et al. (1994)
	Dethymicin	Unknown	Ueno et al. (1992)
	3-Hydroxyrifamycin S	Ansamycin	Traxler et al. (1981)
	Protorifamycins	Ansamycin	Ghisalba et al. (1978), Ghisalba et al. (1979), Ghisalba et al. (1980)
	Kanglemycin A	Ansamycin	Wang et al. (1988)
	Rifamycin SV	Ansamycin	Krishna et al. (1999)
Amycolatopsis orientalis	Orienticin A, chloro Orienticin B, chloro Orienticin C, chloro Orienticin D, chloro, Orienticin E	Glycopeptide	Tsuji et al. (1988)
	UK-69,753	Pyrans	Pacey et al. (1989)
	MM 47761 and MM 49721	Glycopeptide	Box et al. (1990)
	MM 55266 and MM 55268	Glycopeptide	Box et al. (1991)
	Quartromicin (A1, A2, and A3) and (D1, D2, and D3)	Lactones	Tsunakawa et al. (1992b)
	Vancomycin	Glycopeptide	Pittenger and Brigham (1956)
	Muraceins	Muramyl peptide	Bush et al. (1984)
	N-Demethylvancomycin	Vancomycin analog	Boeck et al. (1984)
Amycolatopsis regifaucium	Kigamicin A, B, C, D, and E	Oxazoles	Kunimoto et al. (2003)
Amycolatopsis sulphurea	Azicemicin A(1) and B(2)	Benz (a) Anthracenes	Tsuchida et al. (1995)
Amycolatopsis sp.	Amythiamicin A, B, C, and D	Thiazoles	Shimanaka et al. (1994)
Amycolatopsis sp.	Ochracenomicins A, B and C	Benz[a]anthraquinone	Igarashi et al. (1995)
Amycolatopsis sp.	XR651	Naphthacenes	Bahl et al. (1997)
Amycolatopsis sp.	Epoxyquinomicin A, B, C and D	Quinones	Matsumoto et al. (1997)
Amycolatopsis sp.	Tigloside	Tigloylated tetrasaccharide	Breinholt et al. (1998)
Amycolatopsis sp.	Actinotetraose hexatiglate	Hexa-ester	Rickards et al. (1998)

Kibdelosporangium Shearer, Colman, Ferrin, Nisbet, and Nash 1986, 48^{VP}

Kib.del′o.spo.ran.gi.um.Gr. adj *kibdelos* false, ambiguous; Gr. n. *spora* seed; Gr. n. *angeion* a vessel; M. L. neut. n. *Kibdelosporangium* false or ambiguous sporangium.

Phenotypic Analyses

Kibdelosporangium species are aerobic, catalase-positive, Gram-stain-positive, non acid-fast, filamentous actinobacteria that forms both substrate mycelium that penetrates the agar and forms a compact layer on top of the agar, as well as aerial mycelium that develops from the substrate mycelium. Fragmentation of the substrate mycelium varies and generally features specialized structures which appear to be dichotomously branched, with septate hyphae radiating from a common stalk. Long chains of nonmotile spores and sporangium-like structures may also be observed on the aerial mycelium. These sporangium-like elements are surrounded by well-defined walls which do not contain spores but produce one or more germ tubes when placed on solid growth media. As can be seen in ❯ *Table 37.27*, the cell walls contain *meso*-diaminopimelic acid as the diamino acid and whole-cell sugars consist of arabinose and galactose. The major phospholipids are phosphatidylethanolamine, phosphatidylinositol, and phosphatidylmethylethanolamine. Mycolic acids are not present.

The species within this genus produce sporangium-like structures of the substrate mycelium, whereas the spore chains are on the aerial mycelium and consist of rod-shaped spores (*Kibelosporangium* ❯ *Fig. 37.18*).

The sporangium-like structures originate as small round swellings at the tips of the hyphae that enlarge to 9–35 μm in diameter when mature (*Kibdelosporangium* Fig. ❯ *37.19*). The sporangia are surrounded by a well-defined wall and contain septate, branched hyphae in an amorphous matrix (*Kibdelosporangium* ❯ *Fig. 37.20*), and will germinate within 24–48 h when placed on a suitable medium, producing one or more germ tubes.

The G+C content of the DNA of members of this genus range from 66 to 67.2 (mol%).

The type species is *Kibdelosporangium aridum* ATCC 39323^T = DSM 43828^T = NBRC 14493^T = JCM 7912^T = NRRL B-16436^T = VKM Ac-1316^T.

Isolation and Maintenance Procedures

The isolation methods used to obtain some of the species is shown in ❯ *Table 37.27*.

Serial transfer of strains is not an acceptable method of maintenance for *Kibdelosporangium* species as they cannot be subcultured by serial plating because the sporangium-like structures are often lost on transfer. Therefore frozen stocks in glycerol (10–20 %, v/v) are maintained at −80 °C for medium-term storage or lyophilized in skim milk for long-term storage.

Taxonomy, Historical, and Current

The genus *Kibdelosporangium* is phylogenetically within the order *Pseudonocardiales* based on 16S rRNA gene sequences as can be seen in *Pseudonocardiales* phylogenetic tree (❯ *Figs. 37.1*, ❯ *37.2*, ❯ *37.3*, ❯ *37.4*, and ❯ *37.5*) and also shares similar chemotaxonomic characteristics with many of the genera within the order as can be seen in ❯ *Table 37.1*.

The morphological and physiological characteristics of the species of *Kibdelosporangium* can be seen in *Kibdelosporangium* ❯ *Table 37.28*. Gross morphology and 16S rRNA gene sequences

Kutzneria Stackebrandt, Kroppenstedt, Jahnke, Kemmerling, and Gürtler 1994, 267^{VP}

Kutz.ne´ri.a. M. L. fem. n. *Kutzneria*, named for Hans-Jürgen Kutzner, a German microbiologist.

Phenotypic Analyses

Kutzneria species are aerobic, Gram-stain-positive, mesophilic actinomycetes that form branched, cottony aerial mycelium and large (10–48 μm in diameter) globose sporangia with thick and strong sporangial walls. The sporangiophores within the sporangia may be more than 50 μm long and are the coiled, unbranched hyphae septate into spherical, rod-shaped, or ovoid nonmotile conidia. Some species are thermotolerant and all are chemoorganotrophic. As can be seen in *Table 37.17*, the cell walls of *Kutzneria* strains contain *N*-acetylated muramic acid and *meso*-diaminopimelic acid, and usually galactose is the characteristic sugar although rhamnose may also be present in some species. The predominant menaquinones are MK-9(H_4) and the predominant phospholipids present include diphosphatidylglycerol, hydroxyphosphatidylethanolamine, phosphatidylethanolamine, and phosphatidylinositol. The fatty-acid profile of *Kutzneria* species contains iso-$C_{16:0}$, 2-OH-iso-$C_{16:0}$, 10-methyl-$C_{16:0}$, anteiso-$C_{17:0}$, and 2-OH-anteiso-$C_{17:0}$ as the major components, while $C_{10:0}$, iso-$C_{14:0}$, and $C_{14:0}$ fatty acids are absent.

The G+C content of the DNA of all 3 members of this genus is 70.3 (mol%).

The type species is *Kutzneria viridogrisea* DSM43850^T (Stackebrandt et al. 1994).

Taxonomy, Historical, and Current

The species currently classified within the genus *Kutzneria* were originally described as *Streptosporangium* species, based on their production of sporangia (*Kutzneria* *Fig. 37.21*). The sporangia are produced on long sporophores (*Kutzneria* *Fig. 37.22*) containing chains of nonmotile spores. The new genus *Kutzneria* was proposed for these species by Stackebrandt et al. (1994) because phylogenetic analysis based on 16S rRNA genes (Kemmerling et al. 1993), as well as earlier studies based on 5S rRNA genes (Kudo et al. 1993) and electrophoretic mobility of ribosomal protein AT-L30 (Ochi and Miyadoh 1992), clearly demonstrated that they were phylogenetically distinct from species of the genus *Streptosporangium*. The chemotaxonomic characteristics of the species transferred to *Kutzneria* were also observed to be distinct from those of *Streptosporangium* sensu *strictu*, as can be seen in *Pseudonocardiaceae* *Table 37.1*, particularly with regard to the lack of madurose in the whole-cell sugar pattern, the lack of ninhydrin-positive and sugar-containing phospholipids in their polar lipid patterns (Labeda 2012).

The physiological and morphological characteristics of the three species in the genus *Kutzneria*: *Kutzneria albida* DSM 43870^T = ATCC 25243^T = NBRC 13901^T = JCM 3240^T = NRRL B-24060^T; *Kutzneria kofuensis* DSM 43851^T = ATCC 27102^T = NBRC 13989^T = JCM 3157^T = NRRL B-24061^T; and *Kutzneria viridogrisea* DSM43850^T = ATCC 25242^T = NBRC 15561^T = JCM 3282^T = NRRL B-24059^T = VKM Ac-1297^T (Stackebrandt et al. 1994) are shown in *Table 37.18*.

Labedaea Lee 2012, 1775^{VP}

La.be.da'e.a. N. L. fem. N. *Labedaea* named after David P. Labeda, a microbiologist who has contributed significantly to the systematics of actinomycetes.

Phenotypic Analyses

Labedaea species are mesophilic, aerobic, Gram-stain-positive, nonacid-fast, nonmotile filamentous actinomycetes. Branched aerial hyphae are produced and fragment into rod-shaped elements. Hyphal swelling occurs at the tips of some of the branched aerial mycelia, and single spherical spores (1 μm) can be observed arising from the substrate mycelium on minimal media such as soil extract agar. The substrate mycelium is not observed to fragment and sporangium-like structures are also not observed. The chemotaxonomic profile is quite similar to the other genera in the *Pseudonocardiales* (Table 37.1), having *meso*-diaminopimelic acid as the diamino acid in the cell wall, glucose, rhamnose, galactose, ribose, mannose, arabinose, and xylose in whole-cell hydrolysates and MK-9(H_4) as the predominant menaquinone. The polar lipid profile is unique compared to other genera in the *Pseudonocardiales*, containing phosphatidyl dimethylethanolamine along with phosphatidylglycerol, diphosphatidylglycerol, phosphatidylinositol, and an unknown phospholipid, as shown in Table 37.29.

The G+C content of the DNA of the type species is 64.2. (mol%).

The type species is *Labedaea rhizosphaerae* DSM 45361^T = KCTC 19662^T (Lee 2012).

Isolation Procedures

The isolation protocol for the type species is shown in *Table 37.29*.

Taxonomy, Historical, and Current

The genus *Labedaea* is composed of a single species, *Labedaea rhizosphaerae*, represented by a single strain RS-49^T (=KCTC 19662^T = DSM 45361^T) isolated from soil from the rhizosphere of *Peucedanum japonicum* Thunb. (Japanese common name botan-bofu) on Mara Island, Jeju, Republic of Korea. The strain exhibits fairly unique morphological characteristics of swollen mycelia tips (*Labedaea* *Fig. 37.23*) similar to that observed in *Crossiella* species. Single spores seen arising from the substrate mycelium of this strain (*Labedaea* *Fig. 37.24*) are also similar to that observed in *Actinophytocola* and *Kibdelosporangium* species. *Labedaea rhizosphaerae* is phylogenetically closer to the genus *Actinomycetospora* but is chemotaxonomically distinct from these three genera on the basis of a unique phospholipid profile.

The morphological and physiological characteristics of the type strain are summarized in *Table 37.30*.

Lechevalieria Labeda, Hatano, Kroppenstedt, and Tamura 2001, 1049^{VP}

Le. che. val. i. er´ i. a. M. L. fem. n. *Lechevalieria*, named for Hubert and Mary Lechevalier, American microbiologists who contributed substantially to the field of actinomycete biology during their careers at the Waksman Institute of Microbiology.

Phenotypic Analyses

Lechevalieria strains produce branching substrate mycelium (approximately 0.5 μm in diameter) and scant to extensive aerial mycelium depending upon the species and growth medium. The substrate mycelium fragments into coccoid to coccoidal-rod-shaped elements and sporangia, coremia, or motile spores are not produced. Species are Gram-stain positive, aerobic, catalase positive, and resistant to lysozyme. As can be seen in *Table 37.31*, the whole-cell hydrolysates *Lechevalieria* species contain galactose, mannose, and traces of rhamnose. The phospholipid present in all species is phosphatidylethanolamine with diphosphatidlglycerol also fund for the majority of species. The major menaquinone is MK-9(H_4), which is typical of most genera within the order. The morphological and physiological characteristics of *Lechevalieria* species are

[c]*Ara* Arabinose, *Gal* galactose

nr not reported

summarized in *Table 37.32* and permits differentiation between species. Although gross morphology can be useful for distinguishing between the species, many of them appear quite similar when growing on agar media.

The G+C content of the DNA of members of this genus ranges from 68 to 70.5 (mol%).

The type species is *Lechevalieria aerocolonigenes* ATCC 23870^T = BCRC 13661^T = CIP 107109^T = DSM 40034^T = NBRC 13195^T = ISP 5034^T = JCM 4150^T = JCM 4614^T = NRRL B-3298^T = NRRL ISP-5034^T (Labeda et al. 2001).

Isolation Procedures

The isolation protocols for the species of this genus are shown in *Table 37.31*.

Taxonomy, Historical, and Current

The phylogenetic position of the genus, based on 16S rRNA gene sequences, has become uncertain with the addition of several

recent species which results in polyphyletic distribution of the taxa (◉ *Fig. 37.3*) but the original species comprising *Lechevalieria* sensu *strictu*, including *Lechevalieria aerocolonigenes* and *Lechevalieria flava* as well as the later species *Lechevalieria xinjingensis*, appear to be closely related to the genera *Allokutzneria* and *Kutzneria*. The more recently described species, including *Lechevalieria atacamensis*, *Lechevalieria deserti*, *Lechevalieria roselyniae*, and *Lechevalieria fradiae*, appear to be more closely related to species of the genus *Lentzea*, with the later species being observed within the radiation of *Lentzea* species (◉ *Fig. 37.3*). The taxonomic status of these 4 species is uncertain, but it is interesting to note that the 16S rRNA gene sequences of all of the *Lechevalieria* species contain the genus-specific diagnostic nucleotide signature pattern of CCG (618–620) along with TT (844–845) as can be seen in Figure *Actinosynnema*, *Lechevalieria*, *Lentzea*, *Saccharothrix*, and *Umezawaea* nucleotide signatures.

The genus *Lechevalieria* was described by Labeda et al. (2001) to contain two species observed to be incorrectly classified as members of the genus *Saccharothrix* on the basis of phylogenetic analysis of 16S rRNA gene sequences. These species, *Lechevalieria aerocolonigenes* and *Lechevalieria flava*, had been previously reclassified from the genera *Streptomyces* and *Nocardiopsis*, respectively, on the basis of chemotaxonomic properties (Labeda 1986; Grund and Kroppenstedt 1989). The phylogeny of *Saccharothrix* species and related taxa based on 16S rRNA sequences elucidated the significance of previously unrecognized chemotaxonomic markers which are essential for distinguishing *Lechevalieria* species from neighboring taxa as can be seen in ◉ *Table 37.1*.

Species of the genus *Lechevalieria* can be distinguished from the genera *Actinosynnema*, *Allokutzneria*, and *Saccharothrix* by their lack of hydroxy-substituted fatty acids in the phosphatidylethanolamine component of the diagnostic phospholipids,

similar to the species of the genera *Kutzneria* and *Lentzea*. *Lechevalieria*, *Saccharothrix*, and *Umezawaea* strains tend to contain varying amounts of rhamnose in whole-cell hydrolysates, while *Lentzea* strains are observed to totally lack or contain only trace amounts of rhamnose and may also contain ribose. *Actinosynnema* species have only galactose and mannose as their diagnostic whole-cell sugar pattern while *Allokutzneria* contains arabinose, galactose, and mannose.

The seven species of the genus *Lechevalieria* are *Lechevalieria aerocolonigenes* ATCC 23870^T = BCRC (formerly CCRC) 13661^T = CIP 107109^T = DSM 40034^T = NRBC 13195^T = ISP 5034^T = JCM 4150^T = JCM 4614^T = NRRL B-3298^T = NRRL ISP-5034^T (Labeda et al. 2001); *Lechevalieria atacamensis* CGMCC 4.5536^T = JCM 17492^T = NRRL B-24706^T; *Lechevalieria deserti* CGMCC 4.5535^T = JCM 17493^T = NRRL B-24707^T (Okoro et al. 2010); *Lechevalieria flava* ATCC 29533^T = BCRC (formerly CCRC) 13328^T = CIP 107110^T = DSM 43885^T = NRBC 14521^T = INA 2171^T = JCM 3296^T = NRRL B-16131^T (Labeda et al. 2001); *Lechevalieria fradiae* CGMCC 4.3506^T = JCM 14205^T (Zhang et al. 2007); *Lechevalieria roselyniae* CGMCC 4.5537^T = JCM 17494^T = NRRL B-24708^T (Okoro et al. 2010); and *Lechevalieria xinjiangensis* CGMCC 4.3525^T = DSM 45081^T = JCM 15473^T (Wang et al. 2007).

Lentzea Yassin, Rainey, Brzezinka, Jahnke, Weissbrodt, Budzikiewicz, Stackebrandt, and Schaal 1995, 362^{VP} emended Labeda, Hatano, Kroppenstedt, and Tamura 2001, 1049

Lent´ ze.a. M. L.fem. n. *Lentzea*, named after Friedrich A. Lentze, a German microbiologist who devoted a considerable part of his life to studying pathogenic actinomycetes.

Phenotypic Analyses

Lentzea strains produce branching vegetative mycelia (approximately 0.5–0.7 µmin diameter) as well as aerial mycelium that fragments into rod-shaped elements. Members of the genus are aerobic, Gram-stain positive, catalase positive, and resistant to lysozyme. Typical of all genera within the *Pseudonocardiales* as can be seen in ❯ *Table 37.33*, the whole-cell hydrolysates contain galactose, but mannose is also present in the majority of species. The diagnostic phospholipids present are significant amounts of phosphatidylethanolamine along with diphosphatidylglycerol, phosphatidylglycerol, and phosphatidylinositol, and MK-9(H_4) is the principal menaquinone.

Phylogenetically, the genus *Lentzea* represents a line of descent adjacent to the genus *Actinosynnema* and close to the genera *Lechevalieria*, *Saccharothrix*, and *Umezawaea*. Sequence of the 16S rRNA gene contains genus-specific diagnostic nucleotide signature patterns of TCAA (617–620) and GCC (843–845) as can be seen in Figure *Actinosynnema*, *Lechevalieria*, *Lentzea*, *Saccharothrix*, and *Umezawaea*.

The G+C content of the DNA of the members of this genus ranges from 64.1 to 79.6 (mol%).

The type species is *Lentzea albidocapillata* ATCC 51859 = CCUG 48294^T = CIP 104842^T = DSM 44073^T = NBRC 15855^T = IMMIB D-958^T = IMSNU 21253^T = JCM 9732^T = NBRC 100372^T = NRRL B-24057^T (Yassin et al. 1995).

Isolation Procedures

The isolation protocol for some species is shown in *Table 37.33*.

Taxonomy, Historical, and Current

The genus *Lentzea* was originally proposed by Yassin et al. (1995) based on a single isolate from a tissue sample taken from an abdominal mass of a patient with peritoneal carcinomatosis. The proposal was based on the phylogenetic position of the strain based on its 16S rRNA gene sequence as well as chemotaxonomic properties that distinguished it from the most closely related genus *Saccharothrix*. A later proposal to consider *Lentzea* as a member of the genus *Saccharothrix* was made by Lee et al. (2000) based on their chemotaxonomic and phylogenetic studies. A subsequent study by Labeda et al. (2001) demonstrated that the genus *Lentzea* was valid and could be differentiated from *Saccharothrix* and *Lechevalieria* on the basis of phylogenetic position (*Fig. 37.3*), diagnostic signature nucleotides TCAA (617–620) and GCC (843–845) in 16S rRNA gene sequences

(Figure *Actinosynnema*, *Lechevalieria*, *Lentzea*, *Saccharothrix*, and *Umezawaea* nucleotide signatures), and distinct chemotaxonomic characteristics. *Lentzea kentuckyensis* and *Lentzea jangxiensis* are not observed to have the characteristic nucleotide signatures and cluster closely with a strain identified as *Lechevalieria fradiae* in the phylogenetic tree, raising some questions regarding the correct generic assignment of these three species. *Lentzea* species lack phosphatidylethanolamine containing 2-hydroxy-fatty acids among their polar lipids, thus differentiating them from species of the genus *Saccharothrix*, and their whole-cell sugar pattern, consisting of galactose, mannose, and small quantities of ribose, is distinct from *Lechevalieria* and *Saccharothrix* species. *Lentzea* species are morphologically quite similar to those in the genera *Lechevalieria* and *Saccharothrix* and produce aerial mycelium which may exhibit a "zig-zag" morphology (*Lentzea* ◉ *Fig. 37.25a*) and fragments into coccoidal-rod-shaped elements (*Lentzea* ◉ *Fig. 37.25b*), thus making it difficult to differentiate members of these genera on the basis of gross morphology alone.

The eight species of the genus *Lentzea* are *Lentzea albidocapillata* ATCC 51859^T = CCUG 48294^T = CIP 104842^T = DSM 44073^T = NRBC 15855^T = IMMIB D-958^T = IMSNU 21253^T = JCM 9732^T = NBRC 100372^T = NRRL B-24057^T (Yassin et al. 1995); *Lentzea albida* DSM 44437^T = NRBC 16102^T = JCM 10670^T = NRRL B-24073^T; *Lentzea californiensis* DSM 43393^T = IMRU 550^T = JCM

The physiological characteristics of *Lentzea* species are summarized in ❯ *Table 37.34* and can be used to differentiate between species, although a common set of physiological tests has not been used in the description of all species. Gross colonial morphology provides some additional information of the species based on the color of the substrate mycelium, production and color of aerial mycelium, and production and color of soluble pigments when growing on agar media. The distinct fatty-acid profiles of each *Lentzea* species, as shown in ❯ *Table 37.33*, can also be used to differentiate between species.

Prauserella Kim and Goodfellow 1999, 510^{VP} emended Li, Xu, Tang, Xu, Kroppenstedt, Stackebrandt, and Jiang 2003C, 1547

Prau.se.rel'la.N.L. fem. dim. n. *Prauserella* named after Helmut Prauser, a German microbiologist who made many contributions to actinomycete systematics.

Phenotypic Analyses

Prauserella cultures consist of extensively branched substrate mycelium of approximately 0.6–0.8 μm in diameter. Fragmentation into irregular rod-shaped elements occurs within 24–48 h on rich media. Some strains form aerial hyphae that may be branched short or long chains that are straight or flexuous. Growth is limited to temperatures of 10–45 °C. The optimal temperature for growth is between 28 °C and 34 °C with an optimal pH range of 6.8–7.2. Optimal growth occurs in the presence of 8–15 % NaCl (w/v). Most strains are halophilic or halotolerant. *Prauserella* species are aerobic, Gram-stain positive, nonacid or alcohol fast, nonmotile, with motile spores. As shown in ❯ *Table 37.35* the cell wall contains *meso*-diaminopimelic acid and whole-cell hydrolysates contain arabinose, galactose, and ribose (Lechevalier et al. 1986; Li et al. 2009; Mertz and Yao 1993). The predominant menaquinone is MK-9(H_4), however, *Prauserella rugosa* also contains MK-9(H_2). Diagnostic phospholipids include diphosphatidylglycerol, phosphatidylglycerol, and phosphatidylinositol. Mycolic acids are not present. Branched chain and saturated fatty acids present include iso-$C_{16:0}$ in all species (Li et al. 2009; Schäfer et al. 2010; Wang et al. 2010).

The G+C content of the DNA for members of the genus *Prauserella* ranges between 65.8 and 70.1 (mol%).

The type species is *Prauserella rugosa* is DSM 43194^T = ATCC 43014^T = NCIMB 89263^T (Kim and Goodfellow 1999).

Isolation and Maintenance Procedures

Details of the source samples and methods of isolation of the 9 species of *Prauserella* are shown in *Table 37.36*.

Prauserella can be maintained on agar media commonly used for actinobacteria supplemented with 10 % (w/v) NaCl for halophilic and halotolerant strains.

Taxonomy, Historical, and Current

Sequencing of 16S rRNA places the genus *Prauserella* in the order *Pseudonocardiales*. Within the order, *Prauserella* is most closely related to the genus *Saccharomonospora* (Labeda et al. 2010a). *Prauserella halophila* and *Prauserella muralis* share 95.8 % 16S rRNA sequence similarity. *Prauserella flava* and *Prauserella salsuginis* share 100 % 16S rRNA sequence similarity and 56.9 % DNA–DNA relatedness (Li et al. 2009). *Prauserella* can be distinguished from other members of the order *Pseudonocardiales* by chemotaxonomic and morphological features and by comparative 16S rRNA gene sequence analyses (Cook and Meyers 2003; Kim and Goodfellow 1999; Labeda 2010a).

The genus *Prauserella* was proposed by Kim and Goodfellow (1999). The type species *Prauserella rugosa* was isolated from the rumen of a cow and originally designated "*Nocardia rugosa*" (di Marco and Spalla 1957). The type species was later moved to the genus *Amycolatopsis* as *Amycolatopsis rugosa* (Lechevalier et al. 1986), then removed due to differences in fatty acid composition (Henssen et al. 1987; Mertz and Yao 1993), DNA–DNA relatedness (Labeda 1995) and phenotype (De Boer et al. 1990). There are currently 9 species in the genus *Prauserella*. The genus description was emended by (Li et al. 2003b). Members of the genus can be differentiated by the chemotaxonomic features, as well as DNA–DNA relatedness (Li et al. 2003b; Li et al. 2009) and fatty-acid profiles (Li et al. 2009; Schäfer et al. 2010; Wang et al. 2010).

The nine different species of the genus *Prauserella* are *Prauserella rugosa* ATCC 43014^T = CIP 106520^T = DSM 43194^T = NRBC 14506^T = IMRU 3760^T = JCM 9736^T = NCIMB 8926^T = NRRL B-2295^T = VKM Ac-1243^T (Kim and Goodfellow 1999); *Prauserella aidingensis* YIM 90636^T = CCTCC AA 208053^T = DSM 45266^T (Li et al. 2009); *Prauserella alba* YIM 90005^T = CCTCC AA 001016^T = DSM 44590^T = JCM 13022^T (Li et al. 2003b); *Prauserella flava* YIM 90630^T = CCTCC AA 208052^T = DSM 45265^T (Li et al. 2009); *Prauserella halophila* YIM 90001^T = CCTCC AA 001015^T = DSM 44617^T = JCM 13023^T (Li et al. 2003b); *Prauserella marina* MS498^T = CCTCC AA 208056^T = DSM 45268^T (Wang et al. 2010); *Prauserella muralis* CCM 7635^T = CCUG 57426^T = DSM 45305^T = JCM

Saccharomonospora Nonomura and Ohara 1971, 899[AL]

Sac.cha.ro.mon.o.spo'ra. Gr. n. *sakchâr* sugar; Gr. adj. *monos* single, solitary; Gr. fem. n. *spora* seed; N.L. fem. n. *spora* a spore; N.L. fem. n. *Saccharomonospora* the sugar (−containing) single-spored (organism).

Phenotypic Analyses

Saccharomonospora cultures consist of rarely fragmented substrate mycelia with various pigmentation as shown in Table 37.38. Aerial mycelium is white, yellow white, green and dark to light blue. Both substrate and aerial mycelia are irregularly branched. Spores are single or paired and occasionally in short chains and are ovoid, ellipsoidal, or round (0.7–1.1 × 1.0–1.8 μm) in shape. Spore surfaces are smooth, warty, or wrinkled. *Saccharomonospora* species are Gram-stain positive, aerobic, chemoorganotrophic, and thermotolerant or mesophilic. As can be seen in Table 37.39, the cell wall contains *meso*-diaminopimelic acid, arabinose, and galactose. The diagnostic phospholipid is phosphatidylinositol, but some species may also contain diphosphatidylglycerol. The predominant menaquinone is MK-9(H_4), while MK-8(H_4), MK-9(H_2), and MK-7(H_4) are variably present. Mycolic acids are not present. The temperature range for growth is 24–60 °C and sodium chloride is required for growth of some species (Table 37.39).

The G+C content of the DNA of members of this genus is 68.1–71.8 (mol%).

The type species is *Saccharomonospora viridis* ATCC 15386^T = CCUG 5913^T = DSM 43017^T = IFO NBRC 12207^T = JCM 3036^T = NRRL B-3044^T = VKM Ac-681^T (Schuurmans et al. 1956; Nonomura and Ohara 1971).

Isolation and Maintenance Procedures

Details of the source samples and methods of isolation of species of this genus are shown in Table 37.38.

Taxonomy, Historical, and Current

Saccharomonospora viridis was published as "*Thermoactinomyces viridis*" (Schuurmans et al. 1956) and later reclassified as "*Thermomonospora viridis*" (Küster and Locci 1963). Nonomura and Ohara (1971) proposed the genus *Saccharomonospora* based on morphological and chemotaxonomic criteria, later supported by phenetic data (Goodfellow and Pirouz 1982; McCarthy and Cross 1984).

The genus *Saccharomonospora* currently contains nine species. Recently, the sequenced genome (4.8 Mb) of *Saccharomonospora azurea* type strain (NA-128^T) was published and predicted to contain 4,472 protein coding and 58 RNA genes (Klenk et al. 2012).

The nine different species of the genus *Saccharomonospora* are *Saccharomonospora viridis* ATCC 15386^T = CCUG 5913^T = DSM 43017^T = NRBC 12207^T = JCM 3036^T = NRRL B-3044^T = VKM Ac-681^T (Schuurmans et al. 1956; Nonomura and Ohara 1971); *Saccharomonospora azurea* NA-128^T = SIIA 86128^T = ATCC 43670^T = DSM 44631^T = NRBC 14651^T = JCM 7551^T (Runmao 1987); *Saccharomonospora cyanea* NA-134^T = SIIA 86134^T = ATCC 43724^T = DSM 44106^T = NRBC 14841^T = JCM 7552^T (Runmao et al. 1988); *Saccharomonospora glauca* K62^T = DSM 43769^T = NRBC 14831^T = JCM 7444^T (Greiner-Mai et al. 1988); *Saccharomonospora halophila* DSM 44411^T = JCM 11761^T = NRRL B-24125^T (Al-Zarban et al. 2002); *Saccharomonospora marina* CCTCC AA 209048^T = KCTC 19701^T (Liu et al. 2010); *Saccharomonospora paurometabolica* BCRC 16315^T = CCTCC AA 00101^T = DSM 44619^T = JCM 13241^T = YIM 90007^T (Li et al. 2003a); *Saccharomonospora saliphila* YIM 90502^T = DSM 45087^T = JCM 15627^T = KCTC 19234^T (Syed et al. 2008); and *Saccharomonospora xinjiangensis* CCTCC AA 97021^T = DSM 44391^T = JCM 11270^T (Jin et al. 1998).

The genera most closely related to *Saccharomonospora* are *Prauserella* and *Thermocrispum* (Kim and Goodfellow 1999). The type strains share 95.2–98.5 % 16S rRNA gene sequence similarity. The DNA–DNA relatedness of *Saccharomonospora saliphila* to *Saccharomonospora azurea*, *Saccharomonospora halophila*, and *Saccharomonospora paurometabolica* is 46.0 %, 41.0 %, and 42.5 %, respectively (Syed et al. 2008). The DNA–DNA relatedness of *Saccharomonospora paurometabolica* and *Saccharomonospora halophila* is 53.8 % (Li et al. 2003a).

The production of single spores at the end of aerial hyphae allows *Saccharomonospora* to be distinguished from other members of the family *Pseudonocardiaceae*. The absence of fragmented substrate hyphae differentiates the genus from *Prauserella*, *Saccharopolyspora*, and *Thermoscrispum*. The absence of sporangia-like structures differentiates the genus from *Crossiella*, *Kibdelosporangium*, *Kutzneria*, *Streptoalloteichus*, and *Thermocrispum*. Phospholipid patterns type PII and type PIV distinguish *Saccharomonospora* from *Saccharopolyspora* (type PIII).

Saccharomonospora isolates can be detected by a PCR-based method (Salazar et al. 2000) and by fluorescence in situ hybridization (FISH) (Neef et al. 2003).

Isolation, Enrichment and Maintenance Procedures

Saccharomonosporae have been isolated from a wide range of habitats as shown in Table 37.39. *Saccharomonospora* have been isolated on modified glycerol–asparagine agar, half-strength tryptone–soy agar, HV agar (Hayakawa 1990) and R8 agar (Amner et al. 1989). Cycloheximide (50 μg/ml) can prevent bacterial growth. *Saccharomonospora* can be maintained on yeast extract and malt extract (ISP 2) agar, inorganic salts–starch (ISP 4) agar, CzapekDox yeast extract–Casamino acids (CYC)

Table 37.38

Cultural characteristics and methods of isolation of *Saccharomonospora*[a, b] species

Species	Characteristics					Origin of isolation sample	Method of isolation
	Aerial mycelium colour	Substrate mycelium colour	Colour of diffusible pigment	Spores in pairs	Spore ornamentation		
S. viridis	Green	Green	Green	–	Warty	Manure, compost, overheated fodder, soil, lake sediments, peat	nr
S. amisosensis	White	Yellowish to pale orange	Moderate reddish orange	+	nr	Sediment sample; Southern back sea coast, Turkey	Isolated from the sediment sample by using SM3 medium (Tan et al. 2006), supplemented with filter sterilized cycloheximide (50 μg ml^{-1}), nalidixic acid (10 μg ml^{-1}), novobiocin (10 μg ml^{-1}) and nystatin (50 μg ml^{-1}); incubated at 28 °C for 30 days.
S. azurea	Azure	nr	Absent	–	Smooth	Soil, Sichuan, China	Oatmeal agar (ISP 3); incubated at 28 °C for 2–4 weeks
S. cyanea	Light to dark blue	nr	Absent	–	Warty	Soil, Sichuan, China	Procedure of Shirling and Gottlieb (1966) with a basal mineral salts agar (CM medium).
S. glauca	Light blue to greenish	Dark green	Dark green	–	Warty	Mouldy hay, soil, compost, and manure	nr
S. halophila	Light blue to greenish	nr	Absent	+	Warty	Marsh soil, Kuwait	nr
S. marina	White, gray to orange-white	nr	nr	+	Smooth/ wrinkled	Ocean sediment, East China sea	PLA emulsified agar (Pranamuda and Tokiwa 1999) at 28 °C for 4 weeks
S. paurometabolica	White	Orange to yellow, light yellow brown, light yellow orange, white	Absent	–	Smooth/ wrinkled	Soil sample, Xinjiang Province, China	Modified glycerol/asparagine agar (Shirling and Gottlieb 1966) [ISP5 medium containing 20 % (w/v) NaCl] and incubated at 28 °C for about 4 weeks
S. saliphila	Gray red	Grayish red, dark red, blackish red	Absent	+	Smooth/ wrinkled	Muddy soil, Karnataka, India	Modified glycerol/asparagine agar (Shirling and Gottlieb 1966) [ISP5 medium containing 20 % (w/v) NaCl] and incubated at 28 °C for about 4 weeks
S. xinjiangensis	Yellow-white, light green gray	Light yellow	Light yellow-brown	+	Smooth	Soil, Xingiang Province, China	Glycerol–asparagine agar and HV agar

agar (Cross and Attwell 1974), starch–nitrate agar with 10 % (w/v) NaCl (Al-Zarban et al. 2002), and tryptic soy agar (TSA).

Pathogenicity and Clinical Relevance

Saccharomonospora viridis may be one of the causative agents of hypersensitivity pneumonitis including farmer's lung disease (Greene et al. 1981; Harvey et al. 2001; Roberts et al. 1976; Treuhaft et al. 1980; Wenzel et al. 1974).

Application

Several strains produce antibiotics effective against Gram-positive bacteria, including *Saccharomonospora viridis*, *Saccharomonospora glauca*, "*Saccharomonospora caesia*," and "*Saccharomonospora internatus*" (Greiner-Mai et al. 1988). *Saccharomonospora viridis* produces thermoviridin (Schuurmans et al. 1956).

Several *Saccharomonospora* produce enzymes that degrade proteins, starch, mushroom compost, rice straw, synthetic food waste compost, and polyester (Abdulla and El-Shatoury 2007; Collins et al. 1992; Dolashka et al. 1998; Song et al. 2001; Tseng et al. 2007).

Saccharopolyspora Lacey and Goodfellow 1975, 76^{AL} emended Korn-Wendisch, Kempf, Grund, Kroppenstedt and Kutzner 1989, 438

Sac.cha.ro.po.ly.spo'ra.N.L. n. *Saccharum* generic name of sugar cane; Gr. adj. *polus* many; Gr. n. *spora* a seed, and in biology a spore; N.L. fem. n. *Saccharopolyspora* the many spored (organism) from sugar cane.

Phenotypic Analyses

Cultures of *Saccharopolyspora* consist of branched substrate mycelium that may remain intact or fragment into rod-shaped and/or coccoid structures. Fragmentation occurs in older parts of cultures. Colonies have a wrinkled surface and are thin, raised, or convex. Substrate hyphae are 0.4–0.6 μm in diameter, buff, brownish red, orange, or yellow and mucoid or gelatinous. Aerial hyphae segment into bead-like chains of spores inside a smooth sheath. Aerial hyphae are 0.5–0.7 μm in diameter, white to gray or pinkish white. Spore chains are straight, hooked, loops, or loose spirals. Spore shape is round to oval, 0.7–1.3 × 0.5–0.7 μm in size, with a hairy, smooth, spiny, rough, or warty surface. The cultural characteristics distinguishing each *Saccharopolyspora* species is shown in ➤ *Table 37.40*.

As shown in ➤ *Table 37.41*, the cell wall contains *meso*-diaminopimelic acid and whole-cell hydrolysates contain arabinose and galactose. Diagnostic phospholipids are diphosphatidylglycerol, phosphatidylglycerol, and phosphatidylcholine. The predominant menaquinone is MK-9(H_4), but *S. thermophila* contains MK-9(H_6). Predominant fatty acids are iso-$C_{16:0}$ and anteiso-$C_{17:0}$. No mycolic acids are present.

The G+C content of the DNA of species of *Saccharopolyspora* ranges from 66.3 to 76.9 (mol%).

The utilization of sole carbon sources is shown in ➤ *Table 37.41*.

The type species is *Saccharopolyspora hirsuta* (Lacey and Goodfellow 1975) ATCC 27875^T = DSM 43463^T = NBRC 13919^T = JCM 3170^T = NRRL B-5792^T = NRRL B-16205^T = VKM Ac-666^T.

Isolation Procedures

Details of the source samples and methods of isolation of species of this genus are shown in ➤ *Table 37.40*.

Taxonomy, Historical, and Current

The genus *Saccharopolyspora* was originally proposed in 1975 and can be distinguished by the production of aerial mycelia with bead-like chains of spores in a hairy sheath (Lacey and Goodfellow 1975). Sequence analysis of 16S rRNA genes places *Saccharopolyspora* in the family *Pseudonocardiaceae* (Labeda et al. 2010a; Lu et al. 2001). The genus currently has 21 species, ten of which were identified only in the last 10 years. The most closely related *Saccharopolyspora* species are *Saccharopolyspora hirsuta* subsp. *kobensis* and *Saccharopolyspora jiangxiensis* with 16S rRNA gene sequence similarity of 99 %. The most distantly related are *Saccharopolyspora erythraea* and *Saccharopolyspora thermoflava* with a sequence similarity of 92 %.

Saccharopolyspora and *Streptomyces* strains (Embley et al. 1988) are phylogenetically distant, evident in the poor expression of erythromycin biosynthesis genes in *Streptomyceslividans* (Stanzak et al. 1986; Thompson et al. 1982). Similarly, *Streptomyces* phages may be unstable in *Saccharopolyspora* strains (Gayer-Herkert et al. 1989; Yamamoto et al. 1986). Both *Saccharopolyspora erythraea* and *Saccharopolyspora rectivirgula* have been successfully transformed (Gayer-Herkert et al. 1989; Yamamoto et al. 1986).

Isolation, Enrichment, and Maintenance Procedures

Saccharopolyspora have been isolated from a variety of sources (see ➤ *Table 37.40*) on various media, including half-strength nutrient agar (Lacey 1971, 1974), starch–casein–arginine agar (Iwasaki et al. 1979), R8 agar (Amner et al. 1989), half-strength tryptone–soy agar supplemented with casein hydrolysates (Lacey 1989), yeast extract and malt extract agar (Yuan et al. 2008), oatmealagar (Lu et al. 2001), cellulose–casein multi-salts agar (Tang et al. 2009a), and starch–casein agar supplemented with ketoconazole and nalidixic acid (Duangmal et al. 2010). To inhibit fungal growth, medium can be supplemented with

Table 37.40

Cultural characteristics and methods of isolation of the type strains of species belonging to the genus *Saccharopolyspora*

Species	Characteristics					Origin of isolation sample	Method of isolation	References
	Spore chains	Spore surfaces	Aerial mycelium colour	Substrate mycelium colour	Diffusible pigment colour			
Saccharopolyspora hirsuta	Straight to loose spirals	Hairy	White	Colourless to buff	Yellow	Soil	nr	Korn-Wendisch et al. (1989)
Saccharopolyspora hirsute subsp. *kobensis*	nr	nr	White	Yellow to pink	Yellow to red	Soil	nr	Kim and Goodfellow (2012)
Saccharopolyspora antimicrobica	Straight	Rough	White	White to buff to pink	Buff, pink to brown	Soil, Beijing and Sichuan, China	Yeast extract and malt extract agar medium (ISP 2; Shirling and Gottlieb 1966), incubated at 28 °C for 21 days	Yuan et al. (2008)
Saccharopolyspora cebuensis	Straight	Smooth	White	White	Brown	Marine sponge (*Haliclona* sp.); Cebu, Philippines	Isolated on M1 agar	Pimentel-Elardo et al. (2008)
Saccharopolyspora erythraea	Open spirals	Smooth	Pink to Brownish gray to white	Orangish yellow to reddish brown	Faint yellow to pinkish orangish brown	Soil	nr	Korn-Wendisch et al. (1989)
Saccharopolyspora flava	Straight	Smooth	White	Yellow	–	Garden soil; Xishan, China	Oatmeal agar plate (Shirling and Gottlieb 1966) seeded with a soil suspension; incubated at 28 °C for 5 days	Lu et al. (2001)
Saccharopolyspora gloriosae	Hooks/ curved	Smooth	White	Pale orange - yellow	–	Stem of *Gloriosa superba* L; Yunnan, China	Tap water–yeast extract agar (Crawford et al. 1993), incubated at 28 °C for 4 weeks	Qin et al. (2010a)
Saccharopolyspora gregorii	Hooks/ flexuous	Smooth	White to yellow	Colourless to buff	Pale yellowish to buff	Grass, hay, straw, barley grain, and soil	Half-strength nutrient agar supplemented with cycloheximide and a wind tunnel/ Andersen sampler method (Gregory and Lacey 1963; Lacey 1971)	Goodfellow et al. (1989)
Saccharopolyspora halophila	Straight	Smooth	White to yellow	Yellow to orangish yellow	–	Saline lake; Xinjiang, Northwest China	Cellulose-casein multi-salt (CCMS) medium; incubated at 37 °C for 3 weeks	Tang et al. (2009a)
Saccharopolyspora hordei	Hooks/ spirals	Smooth	White to yellow	Colourless to buff	Colourless to light buff	Barley and oat grains, grass hay, straw, and sugar cane bagasse	Half-strength nutrient agar supplemented with cycloheximide and a wind tunnel/ Andersen sampler method (Gregory and Lacey 1963; Lacey 1971)	Goodfellow et al. (1989)
Saccharopolyspora jiangxiensis	Straight to flexuous	Smooth or irregularly rough	White-buff	Colourless to buff	–	Grass field soil; Jiangxi, China	Glucose–yeast extract and malt extract medium (GYM), incubated at 28 °C for 14 days	Zhang et al. (2009)

Saccharopolyspora lacisalsi	Bead-like chains	Smooth	White, yellowish gray	Yellow, yellowish bluff	–	Sediment of Lop Nur salt lake; Xinjiang, North-west China	Isolated on YC medium containing (g l^{-1}): yeast extract, 3.0 g; casein hydrolysate acid, 0.5 g; KNO_3, 0.5 g; $CaCO_3$, 0.1 g; NaCl, 200 g; KCl, 20 g; $MgCl_2$, 2 g; 1.2 ml trace element solution (Slobodkin et al. 1997); agar, 20.0 g; pH 7.5	Guan et al. (2011)
Saccharopolyspora phatthalungensis	Hooks/ open loops	Spiny	White	Yellowish to yellowish brown	Brownish black	Rhizosphere soil of rubber trees(*Hevea brasiliensis*); Phatthalung, Thailand	Starch casein agar plates (Küster and Williams 1964) supplemented with ketoconazole and nalidixic acid as antifungal and antibacterial agents; incubated at 28 °C for 14 days	Duangmal et al. (2010), Kim and Goodfellow (2012)
Saccharopolyspora qijiaojingensis	Straight	Smooth	White to yellow	White to yellow	–	Salt lake; Xinjiang, China	Cellulose-casein-multisalts (CCMS) medium, described by Tang et al. (2008), incubated at 28 °C	Tang et al. (2009b)
Saccharopolyspora rectivirgula	Straight	Smooth or irregularly rough	White to light pink	Yellow to orange	–	Mouldy hay, soil, compost, and manure	nr	Korn-Wendisch et al. (1989)
Saccharopolyspora rosea	Straight	Smooth	Yellowish to white	Yellowish to brownish yellow	Pink	Bronchial lavage sample	Löwenstein–Jensen medium and Columbia agar supplemented with 5 % sheep blood agar and brain–heart infusion agar	Yassin (2009)
Saccharopolyspora shandongensis	Spiral	Spiny	White	Colourless to buff	Brown	Wheat-field soil; Shandong Province, China	Glucose–yeast extract and malt extract (GYM), incubated at 28 °C for 2 weeks	Zhang et al. (2008)
Saccharopolyspora spinosa	Hooks/ open loops	Spiny	White to pink	Gray to orangish yellow to brown	Brown	soil collected in a sugar mill rum still; Virgin Islands	Medium containing 30 g of tryptic soy broth, 3 g of yeast extract, 2 g of $MgS0_4 \cdot 7H_2O$, 5 g of glucose, and 4 g of maltose in 1 L of deionized water with novobiocin as inhibitor, incubated at 30 °C for 72 h	Mertz and Yao (1990)
Saccharopolyspora spinosporotrichia	Spiral	Warty	White-grey	Brown to red	Brown	Soil; China	nr	Zhou et al. (1998)
Saccharopolyspora taberi	–	–	–	Colourless - yellow	–	Soil	nr	Korn-Wendisch et al. (1989)
Saccharopolyspora thermophila	Hooks/ flexuous	Smooth	White	Colourless to buff	–	Garden soil; Xishan, China	Oatmeal agar plate (Shirling and Gottlieb 1966), 28 °C for 5 days	Lu et al. (2001)
Saccharopolyspora tripterygii	Straight	Smooth	White	Orange to yellow	–	Stem sample of *Tripterygium hypoglaucum*; Yunnan, China	Isolation procedures were performed as described by Li et al. (2009)	Li et al. (2009)

Symbols: – negative/absent, *nr* not reported

50 µg/ml cycloheximide (Cross et al. 1968). The ideal pH range for most strains is 5.0–9.0 (Qin et al. 2008a; Tang et al. 2009b; Zhang et al. 2009) with growth occurring at temperatures from 28 °C to 40 °C.

Application

Saccharopolyspora erythraea produces erythromycin A, erythronolide B (Martin and Rosenbrook 1967), a trypsin-like protease (Yoshida et al. 1971), a rennin-like enzyme (Sternberg 1976), and an *N*-acetylmuramidase (Morita et al. 1978). *Saccharopolyspora spinosa* produces the glycosylated polyketide-derived macrolide insecticides, spinosyn A and D (Hong et al. 2006, 2008; Huang et al. 2009).

Saccharopolyspora aurantica produces pesticidal compounds designated CL307-24 (Etienne et al. 1993). *Saccharopolyspora hirsuta* produces a cyclic polyketide, nodusmicin (Whaley et al. 1980); the macrolide, nargenicin A (Ikeda et al. 1985); and the aminoglycoside complex, apramycin (Kamiya et al. 1983; O'Connor et al. 1976).

Saccharopolyspora hirsuta subsp. *kobensis* produces sporaricin and related compounds (Deushi et al. 1979; Umezawa et al. 1987). *Saccharopolyspora* sp. strain AC 3440 synthesizes 4-deamino-4-hydroxyapromycin (Awata et al. 1983).

Bacteriophages

Saccharopolyspora phages have an icosahedron capsid enclosing a double-stranded genome with *cos* termini and variable tail length (Grund and Hutchinson 1987; Katz et al. 1988; Kurup and Heinzen 1978; Schneider et al. 1987; Schneider and Kutzner 1989). The use of *Saccharopolyspora* phages as cloning vectors (Katz et al. 1988; Schneider and Kutzner 1989) has mostly focused on those isolated from *Saccharopolyspora erythraea* and *Saccharopolyspora rectivirgula* (Donadio et al. 1986; Grund and Hutchinson 1987; Katz et al. 1988; Kempf et al. 1987; Schneider et al. 1987). Methods were adapted from *Streptomyces* species (Hopwood et al. 1985; Lanning and Williams 1982), with modifications to baiting and indicator strains (Greiner-Mai et al. 1987; Grund and Hutchinson 1987; Kurup and Heinzen 1978).

Saccharopolyspora erythraea and *Saccharopolyspora rectivirgula* phages are able to infect either host (Korn-Wendisch et al. 1989; Smorawinska et al. 1988), and some *Saccharopolyspora erythraea* phages are also able to infect *Saccharopolyspora hirsuta* and *Saccharopolyspora taberi* (Grund and Hutchinson 1987; Korn-Wendisch et al. 1989).

Molecular Analyses

The erythromycin biosynthesis and resistance genes from *Saccharopolyspora erythraea* have been mapped and cloned and found to be located together on the same chromosome (Baltz et al. 1986; Stanzak et al. 1986; Tuan et al. 1986; Vanden Boom 2000; Weber et al. 1985). The *Saccharopolyspora spinosa* biosynthetic gene cluster is 74 kb in size and contains genes that may be involved in synthesising the tetracyclic polyketide aglycone nucleus of spinosyns (Hong et al. 2008; Matsushima and Baltz 1994; Waldron et al. 2001). The cluster contains five large open reading frames which encode a type 1 polyketide synthase (Waldron et al. 2001). Recently, genes involved in the spinosyn biosynthesis pathway were characterized, specifically those involved in the synthesis of D-forosamine [(4-dimethylamino)-2,3,4,6-tetrade-oxy-b-D-threo-hexopyranose] (Hong et al. 2008).

Mobile genetic elements can encode proteins with important functions. The integrated and conjugative element (AICE), PSE102, identified in *Saccharopolyspora erythraea* encodes a putative aminoglycoside phosphotransferase which may confer antibiotic resistance (Brown et al. 1988, 1994; te Poele et al. 2008).

Both *Saccharopolyspora erythraea*, *Amycolatopsis mediterranei*, and *Amycolatopsis methanolica* contain AICEs with a highly conserved structure of four functional modules enabling conjugative transfer, excision/integration, regulation, and replication.

The sequenced genome (8.2 kb) of *Saccharopolyspora erythraea* NRRL 2338 has been published (Oliynyk et al. 2007) and shows considerable divergence from the *Streptomyces* species, being circular, rather than linear. A core region covering half of the chromosome contains genes for erythromycin biosynthesis, primary metabolism, cell division, information transfer, and sporulation (Katz and Khosla 2007). The remainder of the chromosome contains genes involved in secondary metabolism, polyketide, ribosomal peptide, and terpenoid biosynthesis. Recent transcriptional profiling using a DNA microarray identified genes involved in distinct growth phases, as well as gene clusters for secondary metabolism (Peano et al. 2007). Recently, the sequenced genome (8.6 kb) of *Saccharopolyspora spinosa* NRRL 18395 was published (Pan et al. 2011). It has a G+C content of 67.94 % and is predicted to contain 8,302 coding sequences (CDSs), including a gene cluster involved in the synthesis of spinosyns.

Pathogenicity, Clinical Relevance

Saccharopolyspora rectivirgula is a known cause of extrinsic allergic alveolitis condition known as farmer's lung (Campbell 1932; Pepys et al. 1963). The condition is caused by the inhalation of large numbers of spores released from the disturbance of mouldy vegetative material (Lacey 1981). The disease is chronic (Lacey 1988), affecting up to up to 8.6 % of farm workers in western Scotland and the Orkneys (Grant et al. 1972) and 8.4 % of Wisconsin dairy farmers (Roberts et al. 1976). Infection is detected using an enzyme-linked immunosorbent assay (Ramasamy et al. 1987), to identify antibodies in the sera of patients (Brummund et al. 1988; Mäntyjärvi and Kurup 1988). Up to 75 individual antigenic components have been identified in *Saccharopolyspora* (Lacey 1989).

Sac´char.o.thrix. Gr. neut. n. *sakchâr*, sugar: Gr. fem. n. *thrix* hair; *Saccharothrix*, sugar-containing hair.

Phenotypic Analyses

Saccharothrix species are aerobic actinomycetes that produce branching vegetative mycelia (approximately 0.5–0.7 µm in diameter) as well as aerial mycelia on many growth media. Both the vegetative and aerial hyphae fragment into coccoid to coccoid-rod, nonmotile elements, and a "zig-zag" morphology of the aerial hyphae is typically observed during sporulation of most species. Cells are Gram-stain positive, resistant to lysozyme, and catalase positive. The cell walls of *Saccharothrix* strains contain *meso*-diaminopimelic acid, galactose, rhamnose, and a trace of mannose, as can be seen in the *Table 37.42*. The presence of phosphatidylethanolamine is diagnostic for this genus. The principal menaquinone is MK-9(H_4); and in addition some species also contain MK-9(H_6), MK-9(H_8) and MK-10(H_4). The typical fatty-acid profile for *Saccharothrix* species consists predominantly of iso-$C_{15:0}$, iso-$C_{16:0}$, and anteiso-$C_{17:0}$.

The G+C content of the DNA of members of this genus ranges from 67 to 74 (mol%).

The type species is *Saccharothrix australiensis* NRRL 11239^T = ATCC 31497^T = DSM 43800^T = NRBC 14444^T = JCM 3370^T = VKM Ac-894^T (Labeda et al. 1984).

Isolation Procedures

Details of the source samples and methods of isolation of some species of this genus are shown in *Table 37.42*.

Taxonomy, Historical, and Current

Phylogenetically, the genus *Saccharothrix* represents a line of descent closest to the genera *Actinosynnema*, *Lentzea*, and *Lechevalieria* as can be seen in the *Fig. 37.3*. The 16S rRNA gene sequences for all described species contains the genus-specific diagnostic nucleotide signature pattern of CAC (607–609) and GTG (617–619) as can be seen in Figure *Actinosynnema*, *Lechevalieria*, *Lentzea*, *Saccharothrix*, and *Umezawaea* nucleotide signatures.

Following the description of the genus *Saccharothrix* by Labeda et al. (1984), predominantly based on chemotaxonomic and morphological properties, a number of species were subsequently transferred into this genus from other actinomycete genera, including *Actinomadura* and *Nocardiopsis*. Evaluation of the phylogenetic relationships among the species of the genus based on 16S rRNA gene sequences and reassessment of chemotaxonomic properties resulted in transfer of many of the species into other genera, including *Crossiella cryophila*, *Goodfellowiella coeruleoviolacea*, *Lechevalieria aerocolonigenes*, *Lechevalieria flava*, *Lentzea waywayandensis*, and *Umezawaea tangerina* that were all validly described as species within the genus *Saccharothrix* (Labeda 2001; Labeda et al. 2001; Labeda and Kroppenstedt 2006, 2007).

The aligned sequences of the 16S rRNA gene for *Saccharothrix*, *Actinosynnema*, *Lechevalieria*, *Lentzea*, and *Umezawaea* species illustrate that *Saccharothrix* strains can easily be distinguished from the other genera on the basis of the diagnostic nucleotide signatures CAC (607–609) and GTG (617–619). Salazar et al. (2002) also reported a set of specific PCR primers for the genus *Saccharothrix*, Stx2 (5′-AAGGCCCTTCGGGGTACACGAG-3′) and Stx1 (5′-TCGACCGCAGGCTCCACG-3′), that with a PCR annealing temperature of 66 °C permitted the rapid detection of all species except *Saccharothrix texasensis*.

The phylogenetically near genera *Lechevalieria* and *Lentzea* can be chemotaxonomically differentiated from *Saccharothrix* because they lack phosphatidylethanolamine containing 2-hydroxy fatty acids in their phospholipid profiles (Labeda et al. 2001). Although the species of the genus *Actinosynnema* contain this phospholipid, they can be easily be differentiated because of their unique colonial morphology. *Umezawaea* also contains 2-hydroxy fatty acid containing phospholipids but uniquely also contains *lyso*-phosphatidylethanolamine.

The species of the genus are *Saccharothrix australiensis* NRRL 11239^T = ATCC 31497^T = DSM 43800^T = NRBC 14444^T = JCM 3370^T = VKM Ac-894^T (Labeda et al. 1984); *Saccharothrix algeriensis* NRRL B-24137^{T}DSM 44581^T = JCM 13242^T = NBRC 101915^T (Zitouni et al. 2004); *Saccharothrix coeruleofusus* DSM 43679^T = ATCC 35108^T = NBRC 14520^T = INA 1335^T = JCM 3313^T = NRRL B-16115^T = VKM Ac-855^T (Grund and Kroppenstedt 1989); *Saccharothrix espanaensis* NRRL 15764^T = ATCC 51144^T = DSM 44229^T = JCM 9112^T = VKMAc-1969^T (Labeda and Lechevalier 1989); *Saccharothrix longispora* ATCC 35109^T = DSM 43749^T = NRBC 14522^T = INA 10222^T = JCM 3314^T = NRRL B-16116^T = VKM Ac-907^T; *Saccharothrix mutabilis* subsp. *capreolus* ATCC 23892^T = DSM 40225^T = NRBC 12847^T = JCM 4248^T = JCM 4630^T = NRRL 2773^T = VKM Ac-1848^T; *Saccharothrix mutabilis* subsp. *mutabilis* NRRL B-16077^T = ATCC 31520^T = DSM 43853^T = NBRC 14310^T = JCM 3380^T = VKM Ac-2023; *Saccharothrix syringae* DSM 43886^T = ATCC 51364^T = NBRC 14523^T = INA 2240^T = JCM 6844^T = NRRL B-16468^T = VKM Ac-1858^T (Grund and Kroppenstedt 1989); *Saccharothrix texasensis* NRRL B-16134^T = ATCC 51593^T = DSM 44231^T = NBRC 14971^T = JCM 9113^T = VKM Ac-1968^T (Labeda and Lyons 1989b); *Saccharothrix variisporea* NRRL B-16296^T = ATCC 31203^T = DSM 43911^T = JCM 3273^T = NBRC 14104^T (Kim et al. 2011); *Saccharothrix violaceirubra* NBRC 102064^T = JCM 16955^T = KCTC 19326^T (Otoguro et al. 2009); and *Saccharothrix xinjiangensis* JCM 12329^T = NBRC 101911^T (Hu et al. 2004).

The species of the genus *Saccharothrix* can be readily differentiated from each other on the basis of their morphological and physiological characteristics, which are summarized in ❯ *Table 37.43*.

Sciscionella Tian, Zhi, Qiu, Yun-Qi, Zhang, Tang, Xu, Zhang, and Li 2009, 222[VP]

Sci.sci.o.nel'la.N.L. fem. dim. n. Sciscionella arbitrary name formed from the acronym of the South China Sea Institute of Oceanology, SCISCIO, which isolated and characterized this taxon.

Phenotypic Analyses

Sciscionella species are aerobic, Gram-stain-positive, nonacid-fast, nonmotile actinobacteria which form yellow colonies. Substrate mycelium fragments into rod-shaped elements, 2.5–3.5 mm long. Sparse aerial mycelium forms on some media containing natural seawater.

The type IV cell wall contains *meso*-diaminopimelic acid and the whole-cell sugars present are galactose, arabinose, and glucose. Phospholipids are type III, including diphosphatidylglycerol, phosphatidylmethylethanolamine, phosphatidylethanolamine, phosphatidylcholine, phosphatidylinositol, and unknown phosphoglycolipids. The predominant menaquinone is MK-9(H_4). The major cellular fatty acids are iso-$C_{16:0}$ and iso-$C_{16:0}$ 2-OH.

The G+C content of the DNA of the single type species is 69 (mol%).

The type strain of this genus is *Sciscionella marina* SCSIO 00231^T =5KCTC 19433^T = 5CCTCC AA208009^T, which was isolated from a sediment sample collected from the northern South China Sea (Tian et al. 2009).

Isolation Procedures

Strain SCSIO 00231 T was isolated on Gauze No. 1 medium prepared with seawater instead of distilled water, and incubated at 28 °C for 3 weeks. Enrichment and isolation procedures are described in ❯ *Table 37.26*.

Taxonomy, Historical, and Current

Phylogenetic analysis showed that *Sciscionella* belongs to the order *Pseudonocardiales*, in which it forms a distinct lineage and is associated with the genus *Thermocrispum*, which showed a 93 % sequence (16S rRNA gene) similarity. The other closest phylogenetic genera are *Saccharopolyspora* and *Amycolatopsis* with 92.6 % and 93.1 % sequence similarities, respectively.

Physiological and chemotaxonomic characteristics of *Sciscionella marina* SCSIO 00231^T and its closest phylogenetic neighbors are compared in ❯ *Tables 37.25* and ❯ *37.26*, respectively.

Streptoalloteichus Tomita, Nakakita, Hoshino, Numata, and Kawaguchi 1987, 211[VP] emended Tamura, Ishida, Otoguro, Hatano, and Suzuki 2008, 689

Strep.to.al.lo.tei'chus. Gr. adj. *streptos* bent; Gr. adj. *allos* different; Gr. n. *teichos* wall; N.L. masc. n. *Streptoalloteichus* intended to mean streptomycete with different wall.

Phenotypic Analyses

Streptoalloteichus cells are aerobic, Gram-stain positive, and nonacid fast. Cultures form vegetative hyphae (0.5 µm diameter), which are well branched and non-fragmenting. Vegetative and aerial mycelium color varies (❯ *Table 37.44*), with chains of five to 50 spores (0.5–1.2 µm diameter) occurring at the tips of aerial hyphae. *Streptoalloteichus* species form sporangia-like structures and produce motile or nonmotile spores that have a smooth surface. The cell wall contains *meso*-diaminopimelic acid and the diagnostic phospholipid is phosphatidylethanolamine (pattern type PII). Menaquinones MK-9(H_6) and MK-10(H_6) are found in both species, but *S. tenebrarius* also contains MK-9(H_4) and MK-10(H_4). Predominant whole-cell hydrolysates are galactose and mannose but may also contain L-rhamnose and D-glucose. Predominant fatty acids are iso-$C_{15:0}$, and anteiso-$C_{17:0}$ (❯ *Table 37.45*).

The G+C content of the DNA of the type species was not reported; for *Streptoalloteichus tenebrarius* it is 71.6 (mol. %).

The type strains of the genus are *Streptoalloteichus hindustanus* ATCC 31217^T = IFO 15115^T (Tomita et al. 1987) and *Streptoalloteichus tenebrarius* NBRC 16177^T = ATCC 17920^T = DSM 40477^T = JCM 4838^T = NRRL B-12390^T = ISP 5477^T (Tamura et al. 2008b).

Taxonomy, Historical, and Current

The genus *Streptoalloteichus* was originally proposed in Tomita et al. (1978), and the type and species *Streptoalloteichus hindustanus* was first published in Tomita et al. (1987). *Streptoalloteichus tenebrarius* was originally published as *Streptomyces tenebrarius* (Higgins and Kastner 1967).

The two type strains share 99.5 % 16S rRNA gene sequence similarity, but only 24.3–37.9 % DNA–DNA relatedness (Tamura et al. 2008b), (Lechevalier et al. 1977), (Ohkuma et al. 1988).

Thermocrispum Korn-Wendisch, Rainey, Kroppenstedt, Kempf, Majazza, Kutzner, and Stackebrandt 1995, 73[VP]

Ther.mo.crispum. Gr. adj. *thermos* warm, hot; L. neut. adj. *crispum* tightly curled; N.L. neut. n. *Thermocrispum* a heat-loving, tightly curled organism.

Phenotypic Analyses

Cultures of *Thermocrispum* consist of yellow to light brown branched substrate mycelium (Table 37.46). Aerial mycelium is white and straight to flexuous and aggregates into pseudosporangia that contain septate hyphae and fragment into rodlike structures. No soluble pigments are produced. Cells are aerobic, Gram-stain positive, catalase positive, nonacid fast, lysozyme sensitive, and thermophilic.

As shown in Table 37.47, *Thermocrispum* cell walls contain *meso*-diaminopimelic acid. Whole-cell hydrolysates contain arabinose, mannose, and glucose. The sugar pattern is type C. The phospholipids are phosphatidylethanolamine, phosphatidylinositol, and hydroxyphosphatidylethanolamine. No mycolic acids are present. The predominant menaquinone is MK-9(H_4). Fatty-acid profiles consist mainly of iso-$C_{16:0}$ and $C_{17:1}$.

Thermocrispum has a DNA G+C content 69–73 (mol%).

The type species is *Thermocrispum municipale* ATCC 51796^T = DSM 44069^T = NRBC 15806^T = JCM 9704^T (Korn-Wendisch et al. 1995).

Isolation Procedures

The source material and isolation protocol is shown in Table 37.47.

Thermocrispum can be maintained on CYC agar, GYM agar, Hickey Tresner agar (Hickey and Tresner 1952), oatmeal agar, potato–carrot agar, PM agar, R2A agar, R8 agar (Amner et al. 1989), and TSA.

Taxonomy, Historical, and Current

Sequence analysis of the 16S rRNA gene places the genus *Thermocrispum* in the family *Pseudonocardiaceae* (Figs. 37.1, 37.2, 37.3, 37.4, and 37.5). Chemotaxonomic profiles can be used to distinguish *Thermocrispum* from other genera in the family *Pseudonocardiaceae*. *Thermocrispum* has a type III cell-wall chemotype, whereas *Actinopolyspora*, *Amycolatopsis*, *Kibdelosporangium*, *Pseudonocardia*, *Saccharomonospora*, and *Saccharopolyspora* have a type IV chemotype. *Thermocrispum* has a type PII phospholipid pattern, which is different from that of *Actinopolyspora*, *Pseudonocardia*, and *Saccharopolyspora*. *Thermocrispum* contains themenaquinone MK-9(H_4), but not MK-8(H_4) found in *Pseudonocardia* and *Saccharomonospora*. Sequence similarity of the 16S rRNA gene shows neighboring genera as *Amycolatopsis*, *Kibdelosporangium*, *Prauserella*, *Saccharomonospora*, and *Saccharopolyspora*. Restriction fragment patterns of the 16S rRNA gene can be used to distinguish between related genera (Cook and Meyers 2003).

The two species are *Thermocrispum agreste* and *Thermocrispum municipale*, with a 98.2 % 16S rRNA gene sequence similarity between these strains (Korn-Wendisch et al. 1995). Possible heterogeneity exists within strains of *Thermocrispum municipale*, evident in differences in phage sensitivity and fatty-acid profile (Korn-Wendisch et al. 1995).

Thermocrispum is resistant to phages that infect the genera *Amycolatopsis*, *Pseudonocardia*, *Saccharomonospora*, *Saccharopolyspora*, and *Saccharothrix* and is sensitive to genus-specific phages. The two species of *Thermocrispum* can be distinguished by band patterns of esterases (Korn-Wendisch et al. 1995) and phage sensitivity.

Thermocrispum agreste CHB77T can be lyzed by its corresponding phage, f77, but is sensitive to only two of the five phages isolated for *Thermocrispum municipale* strains MKD8, MKD10, MKD19, MKD35T, and MKD38, even if high phage titres are used. In contrast, only four of the nine *Thermocrispum municipale* strains can be lyzed by a high titre of f77. The strains of *Thermocrispum municipale* form three subgroups: group 1, strains MKD8, TMK2, and TMD78, can be lyzed by all five phages isolated for strains MKD8, MKD10, MKD19, MKD35T, and MKD38; group 2, strains TMS14 and MKD38, are not lyzed by f10 even if high phage titres are used, and strain MKD35T can be lyzed by this phage only if a high phage titre is used; group 3, strains MKD10, MKD19, and MKD57, are sensitive to phages f35 and f38 only if high phage titres are used.

Activity

Thermocrispum agreste shows slight activity against *Micrococcus luteus* and *Rhodococcus rhodochrous* and also inhibits *Azotobacter chroococcum*, *Candida albicans*, *Geotrichum candidum*, and *Saccharomyces cerevisiae*, but not against *Escherichia coli*, *Corynebacterium glutamicum*, *Bacillus subtilis*, or *Staphylococcus aureus*. *Thermocrispum municipale* does not display any antimicrobial activity.

Umezawaea Labeda and Kroppenstedt 2007, 2761[VP]

Um.e.za'wa.e.a N.L, fem. n. *Umezawaea* named for the late Hamao Umezawa, of the Institute of Microbial Chemistry, Tokyo, in recognition of his leadership and contributions to the study of the biology and natural products of actinomycetes.

[c]*Ara* arabinose, *Man* mannose, *Glc* glucose

Phenotypic Analysis

Umezawaea are aerobic, Gram-stain-positive, nonacid-fast, and nonmotile actinomycetes that produce branched substrate mycelium (approximately 0.3–0.5 μm in diameter) and, on some media, aerial mycelia. The substrate mycelium fragments into ovoid or cylindrical conidia (0.3–0.5 μm by 1.1–1.9 μm) and pseudosporangia are produced on some media. The chemotaxonomic profile of *Umezawaea* is quite similar to that of *Saccharothrix* species (See *Table 37.42*), but *lyso*-phosphatidylethanolamine is uniquely found in the phospholipid pattern. The phylogenetically nearest neighboring genus is *Saccharothrix* (*Fig. 37.3*) but the nucleotide signatures for *Umezawaea tangerina* are distinctly different, as can be seen in Figure nucleotide signatures.

The G+C content of the DNA of the type species is 74 (mol%).

The type species is *Umezawaea tangerine* NRRL B-24463^T = DSM 44720^T = FERM P-16053^T = JCM 10302^T = NBRC 16184^T (Labeda and Kroppenstedt 2007).

Taxonomy, Historical, and Current

Originally described as a species *of Saccharothrix* (Kinoshita et al. 1999), *Umezawaea tangerina* had been observed to produce pseudosporangia on the aerial mycelium in the initial description. Phylogenetic analyses of all of the species of the genus *Saccharothrix* showed that this strain was consistently phylogenetically distant from *Saccharothrix* sensu *strictu.* Reevaluation of the chemotaxonomic characteristics of this strain determined that it was significantly different from *Saccharothrix* and other genera in the family *Pseudonocardineae*, primarily in the presence of significant quantities of *lyso*-phosphatidylethanolamine

in the phospholipid profile which supported the creation of the new genus (Labeda and Kroppenstedt 2007). Morphological and physiological characteristics of the type species *Umezawaea tangerina* in comparison to those of the species from the genus *Saccharothrix* are seen in Table 37.43.

Yuhushiella Mao, Wang Dai, Zhang, Tang, Ren, Yang, Goodfellow, Zhang, and Liu 2011, 621[VP]

Yu.hu.shi.el'la.N.L. dim.ending -ella; N.L. fem. n. Yuhushiella named after Professor Yuhu Shi, a Chinese microbiologist.

Phenotypic Analyses

Yuhushiella species are aerobic, Gram-stain-positive, nonacid-fast, nonmotile, thermotolerant actinobacteria. Substrate mycelium is straight to flexuous, smooth, and branched (Table 37.25). Swelling and aggregation of the hyphae occur but fragmentation is seldom observed. The cell wall (type IV) contains *meso*-diaminopimelic acid (Table 37.26). Whole-cell hydrolysates contain ribose, arabinose, glucose, and galactose. The diagnostic phospholipids are diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylmethylethanolamine, phosphatidylinositol mannosides, phospholipids of unknown structure, and glucosamine-containing phospholipids of unknown structure. Mycolic acids are absent and *N*-acetylated-type muramic acid is present. The predominant menaquinone is MK-9(H_4) with minor amounts of MK-9, MK-9(H_2), MK-10(H_2), MK-8(H_2), and MK-8. The predominant fatty acid is iso-$C_{16:0}$.

The G+C content of the genomic DNA of the type strain is 69.9 (mol%).

The type species is *Yuhushiella deserti* RA45^T = CGMCC 4.5579^T = JCM 16584^T, which was isolated from a desert region in Xinjiang Uighur Autonomous Region, China (Mao et al. 2011).

Isolation Procedures

The isolation protocol is shown in Table 37.26.

Taxonomy, Historical, and Current

Comparative analysis of the 16S rRNA gene sequence and phenotypic characterization revealed that strain RA45^T belonged to the order *Pseudonocardiales* with more than 5 % 16S rRNA gene sequence divergence from recognized species of the genera in the order, forming a distinct lineage within the evolutionary radiation occupied by the genera *Amycolatopsis*, *Prauserella*, *Thermocrispum*, *Saccharomonospora*, *Saccharopolyspora*, and *Sciscionella*, but distinct from each of them. The affiliation to the family was supported by the presence of suborder- and family-specific 16S rRNA signature nucleotides. *Yuhushiella* differed from known genera of the family in its polar lipid composition (phospholipid type IV). The study observed no aerial mycelium under any of the culture conditions tested.

38 The Family *Rubrobacteraceae*

Luciana Albuquerque[1] · *Milton S. da Costa*[2]
[1]Center for Neuroscience and Cell Biology, University of Coimbra, Coimbra, Portugal
[2]Department of Life Sciences, University of Coimbra, Coimbra, Portugal

Abstract
Rubrobacteraceae, a family of the order *Rubrobacterales*, class *Actinobacteria*, embraces the genus *Rubrobacter* with three species: *Rubrobacter xylanophilus*, *R. taiwanensis*, and *R. radiotolerans* (Carreto et al. Int J Syst Bacteriol 46: 460–465, 1996; Chen et al. Int J Syst Evol Microbiol 54: 1849–1855, 2004; Suzuki et al. FEMS Microbiol Lett 52: 33–40, 1988). These three species tolerate extremely high levels of ionizing radiation and possess unique straight-chain internally branched fatty acids. Moreover, the species are moderately thermophilic or thermophilic. These organisms have been primarily isolated from hot springs and deteriorated ancient walls or wall paintings. The species "*R. bracarensis*" has been effectively published, but the name has not yet been validated.

Taxonomy, Historical and Current

Short Description of the Family

The subclass *Rubrobacteridae*, the order *Rubrobacterales*, and the family *Rubrobacteraceae* were proposed by Stackebrandt et al. (1997), to comprise only the species of the genus *Rubrobacter*. After this publication, several deep lineages of the class *Actinobacteria* underwent a number of taxonomic assignments. Later, the families *Thermoleophilaceae*, *Conexibacteraceae*, and *Solirubrobacteraceae* were proposed to encompass the species of the genera *Thermoleophilum*, *Conexibacter*, and *Solirubrobacter*, respectively (Stackebrandt 2004, 2005a, b). The next year the family *Patulibacteraceae* was proposed for species of the genus *Patulibacter* (Takahashi et al. 2006). Therefore, the order *Rubrobacterales* comprised five families of deep lineages of the class *Actinobacteria*, namely, the families *Thermoleophilaceae*, *Conexibacteraceae*, *Solirubrobacteraceae*, *Patulibacteraceae*, and *Rubrobacteraceae*. However, more recently, the family *Thermoleophilaceae* was elevated in taxonomic rank to constitute the order *Thermoleophilales*, and the families *Conexibacteraceae*, *Patulibacteraceae*, and *Solirubrobacteraceae* were assigned to the order *Solirubrobacterales* (Reddy and Garcia-Pichel 2009) based on phenotypic and chemotaxonomic properties and 16S rRNA gene sequence signature nucleotides leaving the family *Rubrobacteraceae* as the sole family of the *Rubrobacterales*. This taxonomic reshuffle led the same authors to emend the description of the order *Rubrobacterales*. Later in the same volume of the International Journal of Systematic and Evolutionary Microbiology, Zhi et al. (2009) emended the subclass *Rubrobacteridae*, the order *Rubrobacterales*, and the family *Rubrobacteraceae* but maintained the families *Conexibacteraceae*, *Patulibacteraceae*, *Solirubrobacteraceae*, and *Thermoleophilaceae* within the order *Rubrobacteriales*. These taxa were also emended on the basis of 16S rRNA gene sequence signature nucleotides. In this chapter the classification of Reddy and Garcia-Pichel (2009) will be considered since, as shown later, it better reflects the characteristics of these taxa.

Recently, a new organism named *Gaiella occulta* was described and included in a separate family and order of the subclass *Rubrobacteridae*, namely, the family *Gaiellaceae* of the order *Gaiellales* because of unique phenotypic characteristics and phylogenetic analysis (Albuquerque et al. 2011). The proposal of the order *Gaiellales* also conforms to the classification of Reddy and Garcia-Pichel (2009) for the subclass *Rubrobacteridae*.

Rubrobacteraceae Rainey et al. 1997; emend. Stackebrandt 2004; emend. Zhi et al. 2009

Rubrobacteraceae (Ru.bro.bac.te.ra' ce.ae. N.L. masc. n. *Rubrobacter*, type genus of the family; suff. *-aceae*, ending to denote a family; N.L. fem. pl. n. *Rubrobacteraceae*, the *Rubrobacter* family).

The members of the family *Rubrobacteraceae* of the order *Rubrobacterales* stain Gram-positive. The organisms form irregular cells but do not form endospores. Strictly aerobic and chemoorganotrophic. Members contain L-Lys as the diamino acid at position 3 of the peptidoglycan and menaquinone 8 (MK-8) as the predominant respiratory lipoquinone. Straight-chain internally branched fatty acids are major

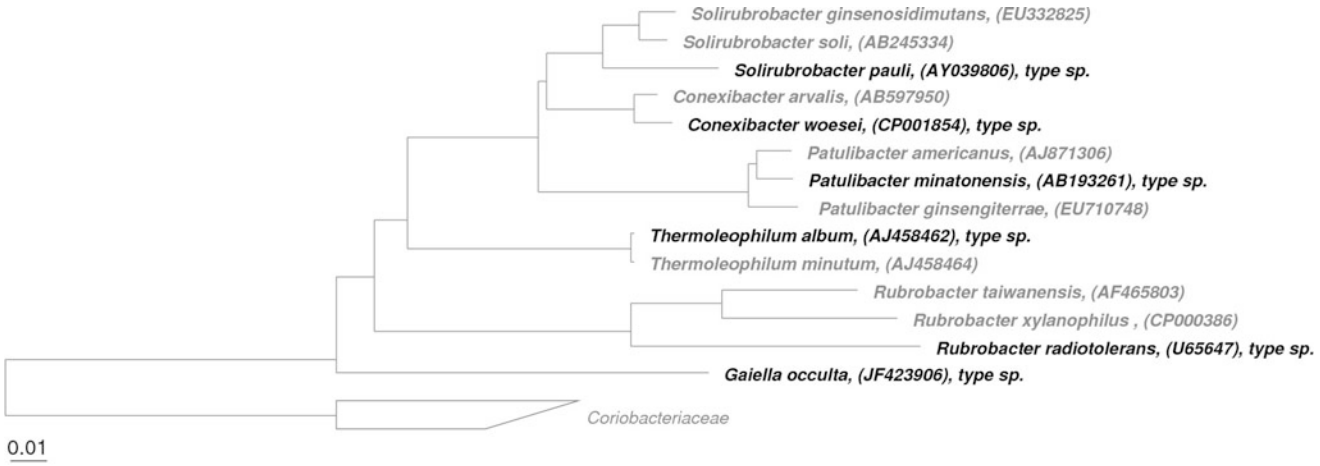

Fig. 38.1

Phylogenetic reconstruction of the family *Rubrobacteraceae* based on 16S rRNA and created using the neighbor-joining algorithm with the Jukes-Cantor correction. The sequence dataset and alignment were used according to the All-Species Living Tree Project (LTP) database (Yarza et al. 2010; http://www.arb-silva.de/projects/living-tree). The tree topology was stabilized with the use of a representative set of nearly 750 high-quality type strain sequences proportionally distributed among the different bacterial and archaeal phyla. In addition, a 40 % maximum-frequency filter was applied in order to remove hypervariable positions and potentially misplaced bases from the alignment. Scale bar indicates estimated sequence divergence

constituents. The pattern of 16S rRNA signatures consists of nucleotides at positions: 52: 359 (G-C), 63: 104 (C-G), 70: 98 (A-U), 127: 234 (G-C), 139: 224 (U-A), 144: 178 (G-C), 145:177 (G-C), 291:309 (U-A), 293: 304 (G-U), 370: 391 (C-G), 377: 386 (G-C), 408: 434 (G-C), 409:433 (G-C), 580: 776 (U-A), 590: 649 (C-G), 600: 638 (U-G), 657: 749 (G-C), 670: 736 (A-U), 681: 709 (C-G), 722: 733 (G-C), 823: 877 (G-C), 906 (A), 941: 1342 (A-U), 953: 1228 (U-A), 954: 1226 (C-G), 955: 1225 (U-A), 999:1041 (U-A), 1051: 1207 (C-G), 1115: 1185 (C-G), 1311: 1326 (A-U), 1313: 1324 (U-A), and 1410: 1490 (U-A) (Reddy and Garcia-Pichel 2009; Zhi et al. 2009). The family comprises the type and only genus *Rubrobacter*.

Phylogenetic Structure of the Family and Its Genus

The family *Rubrobacteraceae* (order *Rubrobacterales*) comprises the genus *Rubrobacter* with three validly named species. The type species of the family is *Rubrobacter radiotolerans* (Suzuki et al. 1988); the two additional species being *R. xylanophilus* and *R. taiwanensis* (Carreto et al. 1996; Chen et al. 2004). This family represents one deep-branching lineage of the phylum Actinobacteria, which is most closely related to the species of the families *Thermoleophilaceae*, *Conexibacteraceae*, *Solirubrobacteraceae*, and *Patulibacteraceae*. The 16S rRNA sequence analysis of the type species of the family *Rubrobacteraceae* (*R. radiotolerans* DSM 46359^T, X87134) with the type strains of the families *Solirubrobacteraceae* (*S. pauli* B33D1^T, AY039806), *Patulibacteraceae* (*P. minatonensis* KV-614^T, AB193261), *Conexibacteraceae* (*C. woesei* DSM 14684^T, CP001854), *Thermoleophilaceae* (*T. minutum* ATCC 35268^T, AJ458464), and *Gaiellaceae* (*G. occulta* F2-233^T, JF423906) shows very low similarities of between about 83 % to 84 % (*Fig. 38.1*).

Phenotypic Analyses

The main features of *Rubrobacter radiotolerans, Rubrobacter xylanophilus, and Rubrobacter taiwanensis* are listed in *Table 38.1*.

Rubrobacter Susuki et al. 1989

Rubrobacter (Ru. bro. bac'ter. L. adj *ruber -bra -brum*, red; N.L. masc. n. *bacter*, rod; N.L. masc. n. *Rubrobacter*, red rod).

Rubrobacter forms non-motile pleomorphic cells (rods or coccoid) that stain Gram-positive. Moderately thermophilic or thermophilic. Catalase and oxidase positive. Nitrate is reduced to nitrite. The principal amino acid of the cell wall peptidoglycan is L-lysine. The peptidoglycan type is A3α′. The peptidoglycan of strain PRD-1^T and strain P-1^T contained lysine, glutamic acid, and alanine at a molar ratio of 1:1:3. The major respiratory lipoquinone is MK-8. Mycolic acids are absent. Polar lipids consist of diphosphatidylglycerol, phosphatidylglycerol, one unidentified phosphoglycolipid, one unidentified glycolipid, and unidentified phospholipids. Major fatty acids are internally branched straight-chain saturated fatty acids, such as $C_{16:0}$ 12-methyl and $C_{18:0}$ 14-methyl. The G + C content of the DNA is in the range 64.9–68.5 mol%. The type species is *Rubrobacter radiotolerans*. The type strain P-1^T (=IAM 12072^T = JCM 2153^T)

was isolated from a radioactive hot spring at Misasa, Japan (Suzuki et al. 1988; Yoshinaka et al. 1973). The type strain of *Rubrobacter xylanophilus* PRD-1^T (=DSM 9941^T) was isolated from a thermally polluted runoff from a carpet factory in Wilton, Wiltshire, United Kingdom (Carreto et al. 1996). A third species is *Rubrobacter taiwanensis*: the type strain is LS-293^T (=ATCC BAA-406^T = BCRC 17173^T) isolated from Lu-shan hot springs in Taiwan. Strain LS-286 (=ATCC BAA-452 = BCRC 17198), isolated from the same source, is a reference strain (Chen et al. 2004).

The species of the genus *Rubrobacter*, namely, *R. radiotolerans*, *R. xylanophilus*, and *R. taiwanensis*, are some of the most extremely radiation-resistant organisms known; the dose required to reduce the number of viable units to 37 % (the mean dose required to reduce a single colony-forming unit of the irradiated population) is in the range of 7.6–9.0 kGy (kGray) for the type strain of *R. radiotolerans* and the closely related isolate RSPS-4 and 4.6–5.2 kGy for the type strain of *R. xylanophilus* and closely related RSPS-21 (Ferreira et al. 1999). Comparable results were obtained by Chen et al. (2004) for the type strain of *R. taiwanensis* with a reduction to 37 % similar to that of the type strain of *R. radiotolerans*. The ionizing-radiation resistance of these three organisms is comparable and in some cases appears to be slightly higher than those of the most radiation resistant species of the genus *Deinococcus*. *R. xylanophilus* and *R. taiwanensis* have much higher growth temperature than *Deinococcus* spp. (Carreto et al. 1996; Chen et al. 2004; Ferreira et al. 1997, 1999).

A species assigned to the genus *Rubrobacter*, and named "*R. bracarensis*," was isolated from a green discolored interior wall of a church (Jurado et al. 2012). This organism has a lower growth temperature range (10–45 °C) and a higher salinity range (0–30 % NaCl) than any of the three other known *Rubrobacter* spp. However, resistance to ultraviolet light or ionizing radiation was not examined. Moreover, the new organism does not possess the archetypal internally branched chain fatty acids present in large levels in the three validly named species (Carreto et al. 1996; Chen et al. 2004; Ferreira et al. 1999; Suzuki et al. 1988). Rather, this organism possesses large amounts of anteiso-$C_{17:1}$ ω9*c* (about 90 %). The incongruent fatty acid results cannot be explained at this time, but it should be noted that Suzuki et al. (1988) and Carreto et al. (1996) used mass spectrometry to

identify the internally branched fatty acids of *Rubrobacter* spp., while Jurado et al. (2012) did not. It should also be stated that iso- and anteiso-branched fatty acids have not been detected, or are detected in trace amounts, in the other species of the genus *Rubrobacter*.

Isolation, Enrichment, and Maintenance Procedures

Rubrobacter radiotolerans was isolated from a radioactive hot spring at Misasa, Japan (Yoshinaka et al. 1973). Water containing mud, fur, and moss was collected from the hot spring at Misasa, which is reported to have a very high radon content. Samples were poured into sterilized test tubes with cotton plugs and irradiated with cesium-137 γ-rays at a dose rate of 1.7×10^5 rad/h for 5 h at 25 °C in the controlled environment radiation facility. Immediately after irradiation, 0.1 ml of the sample was placed on the surface of solid B-agar (10 g beef extract, 10 g bacto-peptone, 5 g yeast extract, 2 g glucose, 1 L deionized water, pH 7.2) plate with the aid of a glass spreader. The plates were incubated at 37 °C for 3 weeks. After a week of incubation, one pink colony was selected, purified, and maintained on the same medium. *Rubrobacter radiotolerans* is routinely grown in *Thermus* medium (Williams and da Costa 1992).

Rubrobacter xylanophilus was isolated from thermally polluted runoff (temperature, 50 °C) from a carpet factory in Wilton, Wiltshire, United Kingdom (Carreto et al. 1996). This strain was isolated by spreading a biofilm sample with a glass rod on tryptone soya agar. After incubation at 50 °C for 5 days, one pink-pigmented colony appeared on a culture plate and was purified on the same medium. *Rubrobacter xylanophilus* is routinely grown in *Thermus* medium.

Rubrobacter taiwanensis was isolated from samples of water, thermally heated soil, and mud from natural hot springs in the Lu-shan area, Nantou, Taiwan (Chen et al. 2004). Aliquots (100 ml) of untreated water samples were spread directly onto *Thermus* agar plates (Williams and da Costa 1992), which were subsequently sealed in plastic bags and incubated at 50 °C for 7 days. Pink-pigmented colonies were picked from the plates and subcultured for purification. *Rubrobacter taiwanensis* is routinely grown in *Thermus* medium.

Members of this family do not require special procedures for maintenance and long-term storage. Generally strains are maintained on *Thermus* medium at 4 °C for a few days and can be stored frozen at −70 °C in *Thermus* medium containing 15 % glycerol without loss of viability. Long-term preservation is by lyophilization.

Ecology

Habitat

The type strains of *R. radiotolerans*, *R. xylanophilus*, and *R. taiwanensis* were isolated from hot springs or a thermally polluted stream. Other strains with very high 16S rRNA sequence similarity with the type strains of *R. radiotolerans* and *R. xylanophilus* have been isolated, after gamma-irradiation of the samples, from hot spring water at the S. Pedro do Sul and Alcafache hot springs in Central Portugal (Ferreira et al. 1999). Other unclassified 16S rRNA clone sequences have been detected, and strains of the genus *Rubrobacter* have also been isolated from discolored and deteriorated ancient walls and wall paintings (Imperi et al. 2007; Laiz et al. 2009; Schabereiter-Gurtner et al. 2001), as well as arid soils (Holmes et al. 2000). The type strains of the species of *R. radiotolerans*, *R. taiwanensis*, and *R. xylanophilus* are among the most ionizing radiation-resistant organisms known (Chen et al. 2004; Ferreira et al. 1997, 1999; Suzuki et al. 1988). These organisms are also halotolerant which may give them selective advantage in colonizing dry environments and saline environments. To achieve colonizing saline environments, *R. xylanophilus* and *R. radiotolerans* accumulate the compatible solutes trehalose and mannosylglycerate. However, it should be noted that the high levels of trehalose and mannosylglycerate accumulate constitutively, changing very little when the concentrations of salt are added to the growth medium, with the growth temperature and upon the addition of oxidative stress agents to the medium (Empadinhas et al. 2007).

Many 16S rRNA clone sequences have been retrieved from a variety of habitats. Some derive from desert soils (JF706680, HQ910287), coastal (saline) soils (HQ397509, JX240777), and dry, discolored, and sun-exposed walls (AM746686, JN020173), indicating that these organisms are desiccation resistant, are able to grow in environments with moderate salinities, and are probably radiation resistant, as well.

39 The Families *Sanguibacteraceae* and *Rarobacteraceae*

Peter Schumann · Erko Stackebrandt
Leibniz Institute DSMZ-German Collection of Microorganisms and Cell Cultures, Braunschweig, Germany

Abstract
The monogeneric family *Sanguibacteraceae*, defined on the basis of 16S rRNA gene sequence comparison and signature nucleotides, is a member of the order *Micrococcales*. Its precise 16S rRNA gene sequence-based phylogenetic position among the other 14 families of the order has not yet been determined with confidence as this lineage branches with varying neighbors depending upon algorithms and selection of sequences used in the analyses. The monogeneric family *Rarobacteraceae* was included in this chapter as it branches adjacent to *Sanguibacteraceae* in several ML and NJ trees. The six species of *Sanguibacter* possess a DNA mol% G+C between 69 and 73 mol%, an A4α peptidoglycan type, the predominant menaquinone MK-9(H_4), straight-chain saturated, as well as iso- and anteiso-methyl-branched fatty acids and resemble certain members of *Cellulomonadaceae* and *Promicromonosporaceae*. Some type strains were isolated from blood of apparently healthy cows while others were found in soil, sand, and sediment. An extended range of habitats was revealed by non-culture studies and encompasses terrestrial and aquatic ecosystems. Strains are medically nonrelevant and have limited application potential. The genus *Rarobacter* embraces two species with yeast-lysing abilities. The ornithine-containing peptidoglycan type is A4β, and menaquinones are fully unsaturated and of the MK-9 type. Members of the genus must be considered rare actinobacteria as the literature mentions almost no additional cultures or 16S rRNA gene clones.

Taxonomy: Historical and Current

The history of the family began with a polyphasic study on six strains isolated from venous blood of apparently healthy dairy cows in Western Spain (Fernández-Garayzábal et al. 1995). The motile, facultatively anaerobic, catalase positive and oxidase negative strains formed two physiologically separate groups, each being highly related by 16S rRNA gene sequence among, and closely related between each other (98.6 % similarity). The nearest neighbors of the organisms were members of the *Cellulomonas/Oerskovia* clade (93–96 % similarity) and *Terrabacter tumescens* (95.7 %). An unrooted dendrogram showed the milk isolates and *T. tumescens* form one lineage, adjacent to cellulomonads and oerskoviae. Based upon chemotaxonomic evidence, the authors expressed their surprise about the phylogenetic clustering as peptidoglycan structure as well as fatty acid compositions differed markedly among the organisms of this group: While the cow blood isolates possessed, like oerskoviae, a type A4α peptidoglycan (L-Lys–L-Ser–D-Glu vs. L-Lys–L-Thr–D-Glu, respectively), it differed from those of cellulomonads (A4β) and *Terrabacter* (A3γ). Also with respect to fatty acid composition, a higher similarity was detected between the blood isolates and cellulomonads/oerskoviae (mainly straight-chain and anteiso-methyl-branched, and lower amounts of iso-branched types), whereas those of *T. tumescens* were mainly unsaturated, iso-branched, and unsaturated methyl-branched acids. An artificially close genealogical relationship was given as an explanation for the position of the two groups of blood isolates within the *Cellulomonas/Oerskovia/Terrabacter* cluster which were described as members of a new genus *Sanguibacter*, containing the type species *S. keddieii* and *S. suarezii* (Fernández-Garayzábal et al. 1995).

The second half of the 1990s saw an enormous increase of 16S rRNA gene sequences, rapidly changing the closely branching lineages among spore-forming actinomycetes and their non-spore-forming relatives. The branching pattern available in 1997 was used by Stackebrandt and collaborators to outline a hierarchic system of the *Actinobacteria* in which

E. Rosenberg et al. (eds.), *The Prokaryotes – Actinobacteria*, DOI 10.1007/978-3-642-30138-4_174,

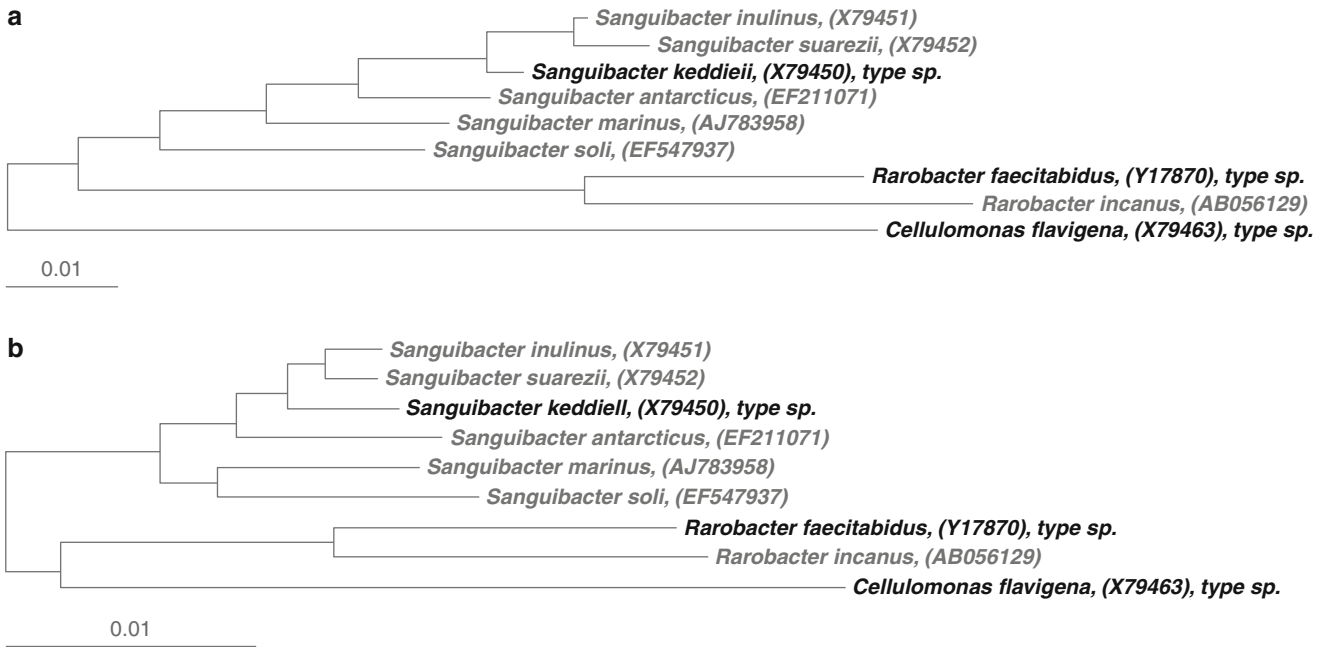

Fig. 39.1

Maximum likelihood based on the RAxML algorithm (Stamatakis 2006) (a) and Neighbor-Joining (b) genealogy reconstruction of the sequences of all members of the family *Sanguibacteraceae* present in the LTP_106 (Yarza et al. 2010). The trees were reconstructed by using a subset of sequences representative of close relative genera to stabilize the tree topology. In addition, a 60 % conservational filter for the whole bacterial domain was used to remove hypervariable positions. The bar indicates 1 % sequence divergence. Type strain numbers referring to the accession numbers are those indicated in Table 39.1

Sanguibacter, together with *Terrabacter* and *Intrasporangium*, defined the family *Intrasporangiaceae* within the suborder *Micrococcineae*, order *Actinomycetales* (Stackebrandt et al. 1997). The family *Intrasporangiaceae* was more closely related to *Dermabacteraceae*, *Jonesiaceae*, and *Brevibacteraceae* than to *Micrococcaceae* or *Cellulomonadaceae*. This sequence- and topology-based scheme did not take into account any physiological or chemotaxonomic data, and it did not take long that the membership of *Sanguibacter* within *Intrasporangiaceae* was questioned, e.g., on the basis of polyamine composition (Busse and Schumann 1999).

A few years later, the phylogenetic position supported the view that *Sanguibacter* species group with the genus *Rarobacter* but separate from both *Intrasporangiaceae* and *Cellulomonadaceae*. Based upon genealogy and supported by chemotaxonomic evidence, the family *Sanguibacteraceae*, among others, was created on the basis of a set of 16S rRNA signature nucleotides (Stackebrandt and Schumann 2000). In an update of the hierarchic classification system (Zhi et al. 2009), this set was revised and the family description emended accordingly (see below).

The phylogenetic dendrogram of *Actinobacteria* has not yet stabilized, and in the latest edition of *Bergey's Manual*, volume 5 (Actinobacteria), the family *Sanguibacteraceae* appears as a specific relative of *Oerskovia* (Ludwig et al. 2012). The same situation is seen in the maximum-likelihood dendrogram of Ivanova et al. (2009). The most recent RaXML version (http://www.arb-silva.de/fileadmin/silva_databases/living_tree/LTP_release_106/LTPs106_SSU_tree.pdf) clusters *Sanguibacteraceae* with *Rarobacteraceae* as a sister clade of both *Cellulomonadaceae* and *Promicromonosporaceae* (see Fig. 39.1).

Another six isolates, also recovered from blood of apparently healthy cows in Spain, constituted the species *Sanguibacter inulinus* (Pascual Ramos et al. 1996). It was phylogenetically close to *S. keddieii* and *S. suarezii* (99.2–99.4 % 16S rRNA gene sequence similarities) but could be distinguished from each other phenotypically and by DNA-DNA hybridization.

The genus *Rarobacter* with the type species *Rarobacter faecitabidus* was described by Yamamoto et al. (1988) for facultative anaerobic isolates capable of lysing yeast cells. Its physiological and chemotaxonomic properties differed from other actinobacterial genera with an L-ornithine-based peptidoglycan described in 1988, e.g., *Cellulomonas*, *Curtobacterium*, and *Aureobacterium*. The second species, *R. incanus*, was described by Goto-Yamamoto et al. (1993) for a different group of yeast-cell-lysing strains from Japan and Brazil which was separated from *R. faecitabidus* by low DNA hybridization values and, as determined for the type strain YLM-32^T, the lack of serine in the peptidoglycan.

Molecular Analyses

The DNA-DNA hybridization (DDH) method was used to relate strains at the intraspecies level (*S. inulinus* and *S. suarezii*)

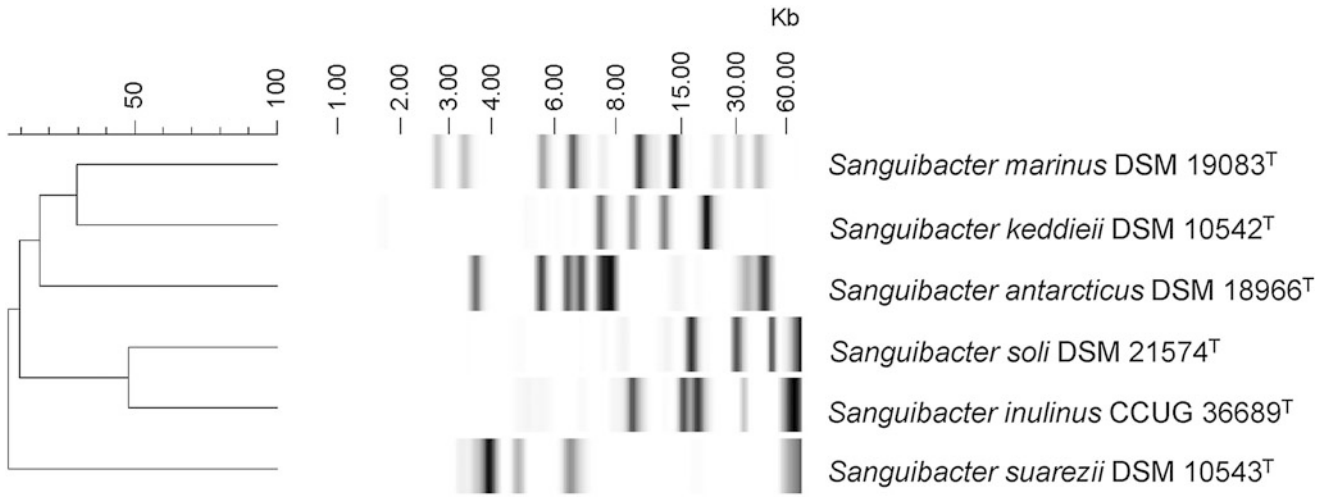

Fig. 39.2

Riboprint patterns of the type strains of the family *Sanguibacteraceae* generated by using the restriction enzyme *Pvu*II. The dendrogram has been calculated with the BioNumerics software (Applied Math, Kortrijk, Belgium)

as well as to confirm their species status and that of *S. keddieii* (Pascual Ramos et al. 1996). The molecular intraspecies similarities were also determined by comparative analysis of the 16S rRNA gene sequence 5′ terminus (Fernández-Garayzábal et al. 1995; Pascual Ramos et al. 1996). The other three species were defined by only the type strain which showed less than 98 % 16S rRNA gene sequence similarities among other type strains of the genus which made it unnecessary to perform DDH (Stackebrandt and Ebers 2006).

Extensive DDH was performed for *Rarobacter* strains of different origin, and five clusters with intracluster similarities >50 % were identified (Goto-Yamamoto et al. 1993). Two of these clusters corresponded to *R. faecitabidus* and *R. incanus*, while the other clusters were not formally described as new species.

Riboprinting

Multiband Riboprint patterns obtained by digestions of the DNA with *Pvu*II, the preferred restriction enzyme for the majority of members of the order *Micrococcales*, differentiate all six *Sanguibacter* type strains. Residual amounts of undigested DNA (band >60 kbp) remained for *S. soli*, *S. inulius* and *S. suarezii* (*Fig. 39.2*).

Mass Spectral Analyses (MALDI-TOF Mass Spectrometry)

S. inulinus ST 50^T shows a 16S rRNA gene sequence similarity as high as 98.92 % to both *S. suarezii* ST 26^T and *S. keddieii* DSM 10542^T (calculated by the EzTaxon-e server; Kim et al. 2012). While *S. inulinus* CCUG 36689^T and *S. suarezii* DSM 10543^T can easily be differentiated by their MALDI-TOF mass spectra, the spectra of *S. inulinus* CCUG 36689^T and *S. keddieii* DSM 10542^T are highly similar. Except for *S. keddieii* and *S. inulinus*, the species of the genus *Sanguibacter* can be identified on the basis of their dissimilar whole cell MALDI-TOF mass spectra.

The MALDI-TOF mass spectra of *Rarobacter faecitabidus* DSM 4813^T and *Rarobacter incanus* DSM 10596^T form a cluster distant from those of the type strains of the genus *Sanguibacter* and differ significantly from one another (*Fig. 39.3*).

Genome Sequence

The full genome of *Sanguibacter keddieii* DSM 10542^T has been sequenced (Ivanova et al. 2009) within the frame of the Tree of Life project (http://genome.jgi.doe.gov/programs/bacteria-archaea/index.jsf). The genome with a mol% G+C content of 71.9 % (original description 70.0 %) is 4.253 Mbp long. 3.805 genes were predicted, 3.735 of which were genes coding for proteins while 70 genes coded for RNAs. Most of the genes (74.4 %) could be annotated and assigned a putative function (71.1 %) to clusters of orthologous genes (COGs), while the remaining ones were annotated as hypothetical proteins. The majority of genes with COG functions were linked to carbohydrate and metabolism (354, 12 % of total), as well as transcription (317, 10 % of total), 237 genes (8 % of total) were associated with the functional category amino acid transport and metabolism, and 199 genes (7 % of total) were involved in inorganic iron transport and metabolism. The metabolic network statistics lists 205 metabolic pathways, 714 enzymes and 935 metabolic reactions. The comparative values for one of the nearest neighbors of *Sanguibacter keddieii* with a complete sequenced genome of a similar size, *Cellulomonas flavigena* DSM 20109^T, are generally a few percent lower.

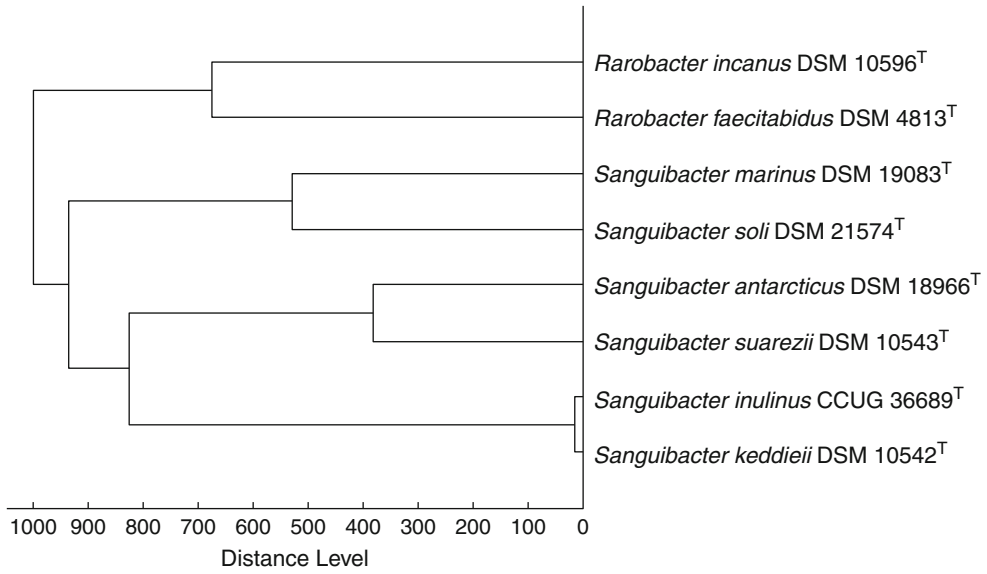

Fig. 39.3

Phenotypic Analyses

Sanguibacteraceae Stackebrandt and Schumann 2000, 1284^{VP}; emend Zhi et al. 2009, 599

San.gui.bac.te.ra'ce.a.e. M.L. masc. n. *Sanguibacter* type genus of the family; -*aceae* ending to denote a family; M.L. fem. pl. n. *Sanguibacteraceae* the *Sanguibacter* family.

The family *Sanguibacteraceae* is monogeneric and contains six species. The original set of signatures given for the family by Stackebrandt and Schumann (2000) was revised by Zhi et al. (2009) on the basis of three species. It contains (position : composition) 120 : A; 131–231 : C-G; 196 : U; 342–347 : C-G; 444–490 : A-U; 580–761 : C-G; 602–636 : G-U; 670–736 : A-U; 822–878 : G-C; 823–877 : G-C; 826–874 : C-G; 827: U; 843 : C; 950–1231 : U-A; 1047–1210 : G-C; 1109 : C; 1145 : G; 1309–1328 : G-C; 1361 : G; 1383 : C. Note that the set of signatures given by Pascual Ramos and Fernández-Garayzábal (2012) is not the revised set of Zhi et al. (2009).

Phenotypically, the description of the family is as given for the genus. The description differs from that given by Fernandez-Garáyzabál et al. (1995) by the inclusion of properties of four additional species (see *Table 39.1*): Cells are Gram-positive and motile rods or irregular rods. Catalase positive, most strains are oxidase negative. Mesophilic and organotrophic. Facultative anaerobic (not determined for one type strain). Acid produced from a wide range of carbohydrates. Mycolic acids are not produced. The long-chain cellular fatty acids are primarily of the straight-chain saturated and anteiso(ai)-methyl-branched chain types; Iso(i)-methyl branched chain acids are present in small amounts. MK-9(H_4) is the major menaquinone. The cell wall murein is L-Lys–L-Ser–D-Glu (type A4α, according to Schleifer and Kandler 1972; A11.48 according to the revised scheme of Schumann (2011) and www.peptidoglycan-types.info). The few species investigated contain minor amounts of the polyamines putrescine and spermidine (Busse and Schumann 1999). Data on polar lipids and, except for *Sanguibacter suarezii* ATCC 51766 (galactose, mannose, ribose) (Brown et al. 2005), whole cell sugars were not reported. The DNA mol% G+C ranges between 69.0 and 73.5. The family contains the type genus *Sanguibacter* Fernández-Garayzábal et al. (1995).

The availability of the type strain of *Sanguibacter inulinus* from public resource centers appears to be a moot-point after a comparative study by Riboprinting, MALDI-TOF MS, and 16S rRNA gene sequencing on strains NCIMB 703024^T, DSM 17437^T (obtained as CIP 106681^T), and CCUG 36689^T. MALDI-TOF and Riboprinting dendrograms indicate the same pattern for strains NCIMB 703024^T and DSM 17437^T which are identical with those of *Sanguibacter suarezii* DSM 10543^T. This finding is in agreement with 99 % similarity of the partial 16S rRNA gene sequences of strains DSM 17437^T and DSM 10543^T, detected already in 2005 and the reason why strain DSM 17437^T has never been included in the DSMZ Catalogue of Strains. Considering the history documented in www.StrainInfo.net and a personal communication from Takuji Kudo (Japan Collection of Microorganisms), the type strain JCM 11442^T is also identical with the type strain of *S. suarezii*. As a consequence, CIP and JCM have removed the type strain of *S. inulinus* from their strain catalogs.

Table 39.1

Phenotypic differences between the type strains of *Sanguibacter* (*S.*) and *Rarobacter* (*R.*) species (Data compiled from Hong et al. (2008) and Kim et al. (2008), supplemented with data from the original species descriptions (*S. keddieii* and *S. suarezii*, Fernández-Garayzábal et al. 1995; *S. inulinus*, Pascual Ramos et al. 1996; *S. soli*, Kim et al. 2008; *S. marinus*, Huang et al. 2005; *S. antarcticus*, Hong et al. 2008). Data for *Rarobacter* type strains were from Yamamoto et al. (1988) and Goto-Yamamoto et al. (1993))

The original deposition of the type strain *Sanguibacter inulinus* ST-50^T (Pascual Ramos et al. 1996) was with the National Collection of Food Bacteria, Reading, UK (incorporated into NCIMB), as NCFB 3024^T and according to www.StrainInfo.net, the CCUG (Culture Collection, University of Göteborg) obtained the type strain directly from there, assigning to it the number CCUG 36689^T. Riboprint and MALDI-TOF data show that the type strains *S. inulinus* CCUG 36689^T and *S. suarezii* DSM 10543^T are indeed different. The sequence of the 5′ terminal 460 nucleotides of the 16S rRNA sequence of strain CCUG 36689^T displays 100 % identity with the sequence X79451 originally deposited for *Sanguibacter inulinus* ST-50^T (attention, the species designations are sometime in error in the description fields of the 16S rRNA gene sequences of both type strains ST-26^T and ST-50^T deposited in public sequence databases). Our study revealed that CCUG 36689^T is the authentic type strain of *Sanguibacter inulinus*, while the authenticity of *Sanguibacter inulinus* strains deposited in other collections needs to be re-examined.

Rarobacteraceae Stackebrandt and Schumann 2000, 1284^{VP}, emend Zhi et al. 2009, 598

Ra.ro.bac.te.ra.ce'a.e. N. L. masc. n. *Rarobacter* type genus of the family; L. suff. *–aceae* ending to denote a family; N.L.fem.pl.n *Rarobacteraceae* the *Rarobacter* family.

The set of 16S rRNA signature oligonucleotides are (position : composition) 120 : A; 131–231 : C-G; 196 : A; 342–347 : C-G; 444–490 : A-U; 580–761 : C-G; 602–636 : G-U; 670–736 : A-U; 822–878 : G-C; 823–877 : G-C; 826–874 : C-G; 827: U; 843 : U; 950–1231 : U-A; 1047–1210 : G-C; 1109 : C; 1145 : G; 1309–1328 : G-C; 1361 : G; 1383 : C.

Except for two single base exchanges (pos. 196, 843), this set is similar to the one defining *Sanguibacteraceae*. Members of the family contain an A4β peptidoglycan type, the fully unsaturated menaquinone MK-9, anteiso-branched (major), iso-branched, and straight-chain fatty acids. Endospores are not formed, and cells are not acid-fast. Facultative anaerobic, both type strains require catalase, heme or hemoproteins as well as biotin and thiamine (*R. faecitabidus* only). Carbon dioxide is required for anaerobic growth. Major end product of aerobic glucose utilization is acetic acid, while formic acid, ethanol, and acetic acid are formed under anaerobic conditions. Phenotypically, the description of the family is as given for the genus (Yamamoto et al. 1988). Cells of both species are irregular rods, motile by multitricous flagella. The two species differ in the composition of the amino acid composition of peptidoglycan and in the percentage of fatty acid composition determined under aerobic and anaerobic conditions. Major fatty acids are of the ai-$C_{15:0}$ type (18–54 %), while i-$C_{16:0}$ (7–22 %) and $C_{16:0}$ (7–14 %) occur in lower amounts. Both strains are similar with respect to their ability to form acid from carbohydrates (Table 39.1). While *R. faecitabidus* forms acid from cellobiose, *R. incanus* does not. Other properties are indicated in the original species descriptions.

All type strains of *Sanguibacter* form acid from glucose, L-arabinose, fructose, maltose, sucrose, cellobiose, and D-xylose but not from melizitose, adonitol, and D-arabinose. Phenotypic properties, including minor fatty acid components (<10 %) not listed in Table 39.1, should be looked at in the original species description.

The two type strains of *Rarobacter* form acid from glucose, dextrin, D-fructose, and maltose but not from L-arabinose, trehalose, erythritol, adonitol, or dulcitol.

Isolation, Enrichment and Maintenance Procedures

As strains of *Sanguibacter keddieii*, *S. suarezii*, and *S. inulinus* were originally recovered from blood as presumptive members of the genus *Listeria*, a selective *Listeria* agar (Dominguez Rodriguez et al. 1984) was used for their isolation. The medium contained per liter: peptone 3 g, neopeptone 5 g, proteose peptone 3 g, esculin 1 g, NaCl 5 g, disodium phosphate 2-hydrate 12 g, ammonia-ferric citrate 40 mg, Acriflavin HCl 6 mg, defibrinated sheep blood 50 mL, and agar 15 g. Subcultures grew on tryptose soy agar (TSA, Difco).

S. marinus was isolated on Difco marine agar and maintained on nutrient agar or TSA agar. *S. soli* was isolated from serially diluted soil, spread onto 1/10-strength R2A agar (Difco), while *S. antarcticus* was isolated on ZoBell agar (Zobell 1946) supplemented with 0.4 % colloidal chitin.

DSMZ-kept strains are maintained in trypticase soy yeast extract medium No 92 (http://www.dsmz.de/?id=441, containing the following components per liter: trypticase soy broth 30.0 g, Yeast extract 3.0 g, and agar 15.0 g; pH 7.0—7.2), between 28 °C and 30 °C. The medium for *S. antarcticus* contains in addition *N*-acetyl glucosamine 1 g L^{-1}.

The type strain of *Rarobacter faecitabidus* YLM-1^T was isolated from activated sludge of the waste water treatment system of an alcoholic beverage factory. Bacto agar (Difco), supplemented with activated sludge extract, was cooled to 45 °C after sterilization at 120 °C for 10 min. Before pouring to a plate, 18 mL of the agar were mixed with 2 mL of a suspension of living yeast cells (*Hansenula anomala* J 45–1, 2×10^9 cells per mL) and 0.1 mL of the sample suspension. The yeast-lysing bacteria were isolated from plaques formed after incubation at 30 °C for 3–5 days. The procedure was repeated until no other bacteria could be detected. Strain YLM-1^T was separated from yeast cells in liquid media by centrifugation at 3,000 rpm for 10 min followed by filtration of the supernatant through membrane filters with pore sizes of 0.8 or 1.2 µm (Hasuo et al. 1984). Strain YLM-1^T was maintained on YM-catalase agar, which contained (per liter) 5 g of yeast extract (Oxoid Ltd., London, United Kingdom), 5 g of malt extract (Difco Laboratories, Detroit, Mich.), 5.74 g of K_2HPO_4, 205 mg of $MgSO_4 \cdot 7H_2O$, 1.15 g of $NH_4H_2PO_4$, 60 mg of catalase (C-10; Sigma Chemical Co., St. Louis, Mo.), and 15 g of agar. Catalase and $MgSO_4 \cdot 7H_2O$ were separately sterilized by filtration (Yamamoto et al. 1988).

Rarobacter incanus YLM-32^T was isolated from activated sludge mixed in soft agar-yeast plates containing 5.74 g of K_2HPO_4, 1.15 g of $NH_4H_2PO_4$, 0.205 g of $MgSO_4 \cdot 7H_2O$, 10^{10} viable cells of *Saccharomyces cerevisiae* K-701 and 7 g of agar per liter. The plates were incubated at 30 °C for 3–10 days, and plaque-forming colonies were isolated (Goto-Yamamoto et al. 1993).

Strain YLM-32^T was maintained on TYMC agar containing 5.0 g of trypticase peptone (BBL), 3.0 g of yeast extract (Difco), 3.0 g of malt extract (Difco), 5.8 g of K_2HPO_4, 1.15 g of $MgSO_4.7H_2O$, 0.12 g of catalase C-10 (Sigma) per liter (Goto-Yamamoto et al. 1993).

While DSMZ cultivates *R. faecitabidus* DSM 4813^T aerobically on YM-catalase agar as described by Yamamoto et al. (1988), anaerobic cultivation is preferred for *R. incanus* DSM 10596^T on medium No 104 (http://www.dsmz.de/?id=441) at 30 °C.

Strains of both families are maintained in glycerol (10 % v/v) at −80 °C on medium-term and preserved in liquid nitrogen or as freeze-dried cultures on long-term.

Habitat

The type strains and additional isolates of *S. keddieii*, *S. suarezii*, and *S. inulinus* originate from bovine blood of Western Spain, and single isolates came from samples of a coastal sediment of the Eastern China Sea (*S. marinus*), a ginseng field in South Korea (*S. soli*), and sea sand on King George Island, Antarctica (*S. antarctica*). The literature on additional *Sanguibacter* isolates is sparse. *S. keddieii* was found as a major taxon among airborne organisms recovered from bioaerosols of plant processing industries in Poland (herb and grain processing, flax threshing, grain storing, baking, and cereals production) (Góra et al. 2009). Two isolates with identical 16S rRNA gene sequence with that of *S. suarezii* were found as folate producers in Skandinavian cereal samples (Herranen et al. 2010), and one isolate of this species has been found in natural maple sap from Canada (Lagacé et al. 2004).

The range of isolation places appears to be even broader when entries of 16S rRNA gene sequences referring to named *Sanguibacter* species or *Sanguibacter* spp. are considered. Rarely clone sequences but a few additional cultures have been recovered from the cold environments such Arctic (Vardhan Reddy et al. 2009; Shiwaji et al. unpublished, JQ396627) and Antarctic environments (e.g., AF479343; Christner 2002), Mt. Everest glacial meltwater (e.g., EU584528; Liu, unpublished), but also temperate freshwater (FJ006928; Baiket al. unpublished), subsurface oil reservoir (AB126692; Nunoura et al. unpublished), Caribbean marine sponges (Tabares et al. 2011), and even in the gastrointestinal intestine of pigs (Leser et al. 2002). *Figure 39.4* shows a BLAST tree view for the present phylogenetic relatedness among cultures and uncultured *Sanguibacter* strains (May 2012).

The Japanese strains of *Rarobacter faecitabidus* were isolated from activated sludge of a wastewater treatment system or from discharge water, both of an alcohol beverage factory. Strains of *R. incanus* were isolated from various Japanese and Brazilian samples (e.g., soil, flowers, fermented foods). BLAST analysis using the 16S rRNA gene sequence of *R. faecitabidus* YLM-1 (accession number NR_026484) as source revealed, besides three isolates deposited in culture collections, only a single entry with 99 % identity which belong to a clone (nbw93e11c1, GQ065838.1) obtained from the occiput skin of a human (Grice et al. unpublished; NISC Comparative Sequencing Program).

Pathogenicity: Clinical Relevance

A comment that some of the isolates recovered from bovine blood and from milk in Western Spain have the ability to establish a low-grade bacteremia in cattle originates from the publication of Fernández-Garayzábal et al. (1995). However, as the isolates comprised members of *Oerskovia xanthineolytica* and *Sanguibacter* and no strain numbers were indicated, it is not obvious which taxa caused bacteremia. Funke et al. (1997) list *Sanguibacter* among other coryneforms as "medically nonrelevant."

Another study reports the pathogenicity of strain C4 (named CHPR4 for the deposited 16S rRNA sequence AY289118; see *Fig. 39.2*) for locusts. This nonmotile irregular rod produces chitinase and causes histopathologic changes in the midgut of the grassland locusts *Myrmeleotettix palpalis* (Zub). Its phylogenetic position, determined by

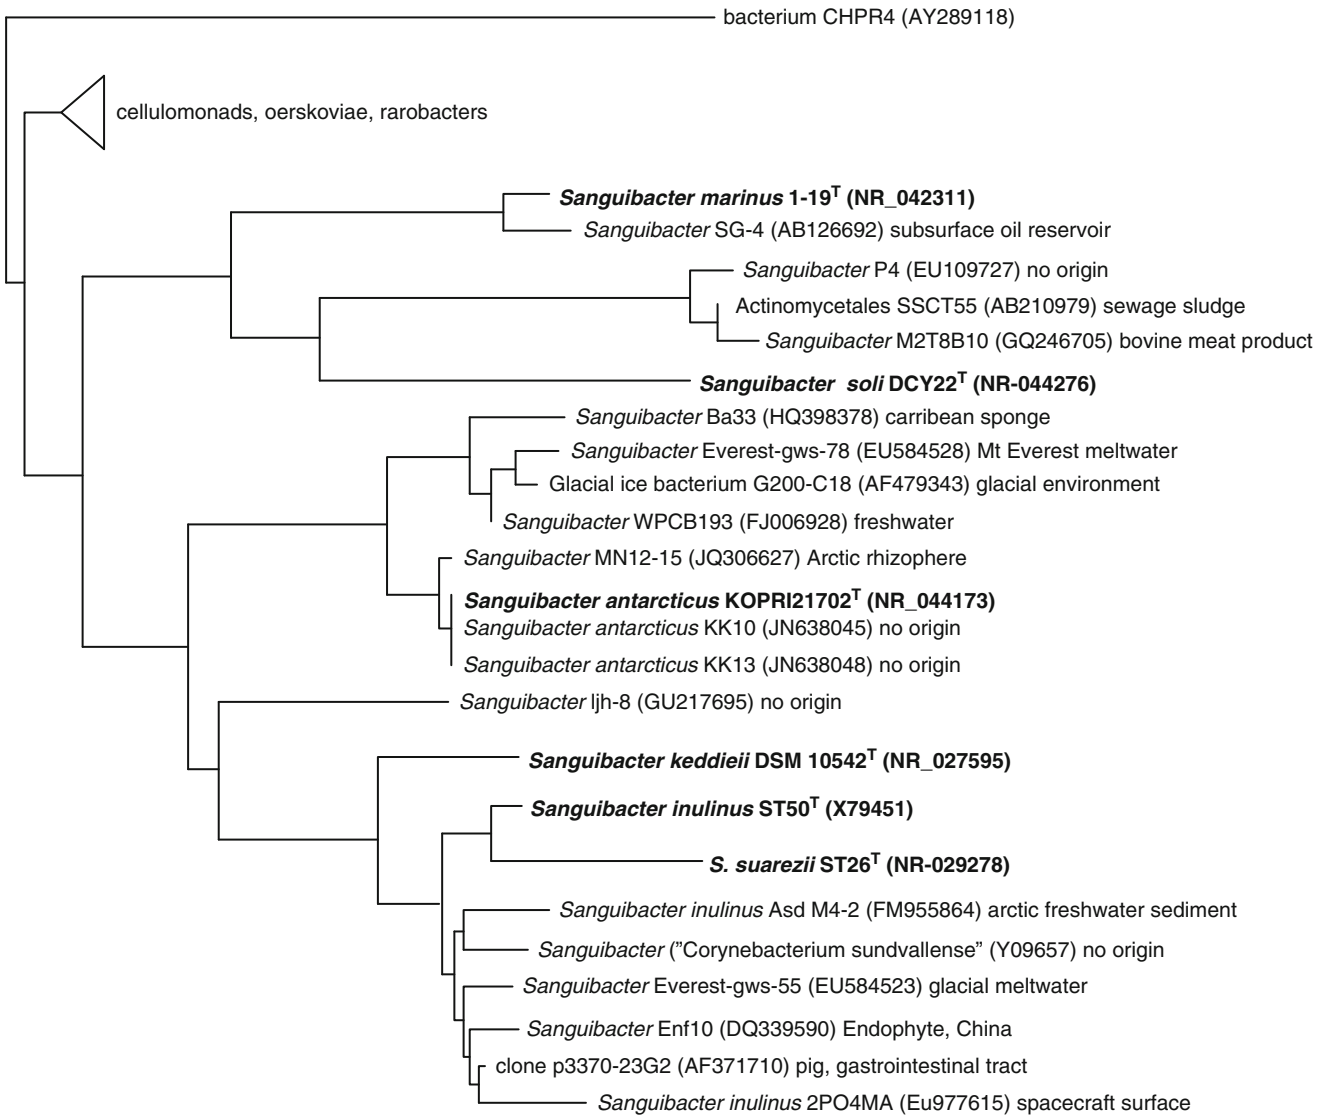

Fig. 39.4

Fast Minimum Evolutionary tree showing the relatedness of *Sanguibacter* type strains (in *bold*) and relatives reported to occur in various environments. Numbers in brackets are accession numbers (Source: NCIB, BLAST; http://blast.ncbi.nlm.nih.gov/)

BLAST similarity analysis, between *Sanguibacter*aceae, *Cellulomonadaceae*, and *Micrococcaceae* questions a specific phylogenetic closeness of strain C4 and members of *Sanguibacter* (Yong et al. 2005).

Application

As mentioned in the previous subchapter, strain C4 (CHPR4) is probably not an authentic member of *Sanguibacter*, but it appears under this genus designation in the literature (see *Fig. 39.2*, top entry). For characterization of its chitinase gene, see Tao et al. (2006). Due to its potential role in pest control, the open reading frame of the chitinase gene was cloned and expressed (Yong et al. 2005). The *Chi58* ORF was a modular enzyme composed of a signal peptide sequence, a polycystic kidney disease I domain, and a glycosyl hydrolase family 18 domain, showing a high level of amino acid similarity to the chitinase A of *Serratia marcescens* (95.5–99.6 %), *Burkholderia cepacia* (99.5 %), *Serratia plymuthica* (93.1 %), and *Enterobacter* (99.3 %), but a low sequence homology with chitinase A from *Bacillus* spp. (28.3–29.8 %).

Optimization parameters for the expression of a cold-active endochitinase of *Sanguibacter antarcticus* KOPRI 21702^T were determined (Han et al. 2011), resulting in 7.5-fold increase in Chi21702 production over unoptimized conditions. In order to express this enzyme in a methylotrophic *Pichia pastoris* strain, 25 amino acids of the putative signal peptide of the *S. antarcticus* gene were eliminated and the coding region of the mature chitinase gene optimized according to the nuclear

codon usage of *Pichia* (Lee et al. 2010). Optimal activity for the chitinase was observed at 37 °C, and a pH of 7.6. 63 % of the optimal activity was retained at 10 °C and 44 % activity at 0 °C.

The search for yeast-lysing (*Saccharomyces*, *Hansenula*, *Candida*) bacteria led to the isolation of 50 strains belonging to named and as-yet not named *Rarobacter* species. Subsequently, a serine protease with mannose-binding activity was characterized in *R. faecitabidus* (Shimoi and Tadenuma 1991) and its molecular structure determined (Shimoi et al. 1992). Its action on SDS-extracted cell wall of *Saccharomyces cerevisiae* resulted in the solubilization of a glycoprotein with a molecular weight of 40,000, named gp40 (Shimoi et al. 1995).

Acknowledgments

This chapter has been prepared under the EMbaRC project (EU Seventh Framework Programme Research Infrastructures INFRA-2008-1.1.2.9: Biological Resources Centres (BRCs) for microorganisms (Grant agreement number: FP7-228310)) to support science in BRCs. We wish to thank Rüdiger Pukall, Cathrin Spröer, Ulrike Steiner, Nicole Mrotzek and Anika Wasner (all DSMZ) for molecular analysis on *S. inulinus* and Peter Green (NCIMB), Ed Moore (CCUG), and Takuji Kudo (JCM) for their input in solving the authenticity problem of its type strain. We are deeply grateful to Rie Homma (Sapporo, Japan) for the translation of the Hasuo et al. (1984) article, originally printed in Japanese.

40 The Family *Segniliparaceae*

Johannes Sikorski
Leibniz Institute DSMZ – German Collection of Microorganisms and Cell Cultures, Braunschweig, Germany

Abstract
Segniliparaceae, a family within the order *Actinomycetales* and suborder *Corynebacterineae*, comprises the sole genus *Segniliparus* with two species. The two type strains have been isolated from human sputum and are described to be opportunistic pathogens. They are aerobic, mesophilic, and chemoorganotroph. The most distinctive characteristic is the presence of ultralong C60–C100 mycolic acids. These are non-oxygenated α-mycolates with high levels of *cis* unsaturation, a feature solely present on *Segniliparus* species Hong (PLoS One 7: e39017, 2012). The type strain of *Segniliparus rotundus* is CDC 1076^T (=ATCC BAA-972^T = CIP 108378^T = DSM 44985^T) and of *Segniliparus rugosus* CDC 945^T (=ATCC BAA-974^T = CIP 108380^T = DSM 45245^T). Of each species, further strains have been isolated, mainly from the human habitat.

Taxonomy, Historical and Current

Short Description of the Family

Segniliparaceae Butler et al. 2005

Segniliparaceae (Seg'ni.li.par.a'ce.ae. N.L. masc. n. *Segniliparus* type genus of the family; -aceae ending to denote a family; N.L. fem. pl. n. *Segniliparaceae*, the *Segniliparus* family).

Members of the family are non-spore forming and nonmotile. The genus *Segniliparus* is the only genus in the family with the two species *Segniliparus rotundus* and *S. rugosus* (Butler et al. 2005). The family belongs to the suborder *Corynebacterineae*, order *Actinomycetales*, subclass *Actinobacteridae*, class *Actinobacteria*, and phylum Actinobacteria (Garrity and Holt 2001; Ludwig et al. 2012; Stackebrandt et al. 1997; Zhi et al. 2009). The cells are rod-shaped without any branching. They are aerobic, strongly acid-fast, and produce multiple chemical functional groups of high-molecular-mass, nonpolar, mycolic acids.

Molecular Analyses

The DNA–DNA association value between the type strains of *Segniliparus rotundus* and *S. rugosus* was <28 % using the hydroxyapatite method with an optimum reassociation temperature of 70 °C (Butler et al. 2005). A complete genome sequence has been obtained for *Segniliparus rotundus* (Sikorski et al. 2010) and a high-quality draft genome sequence for *S. rugosus* has been published by Earl et al (2011), revealing genome sizes of 3.16 and 3.64 megabases and a DNA coding region of 92.3 % and 86.4 %, respectively. The number of genes associated with the general COG functional categories is similar in both strains; however, there is a larger proportion of genes not in COGs in *S. rugosus* (46.1 %) compared to *S. rotundus* (41.3 %) (Earl et al. 2011; Sikorski et al. 2010).

Phylogenetic Structure of the Family and its Genus

The 16S rRNA gene sequences of the two type strains of the genus *Segniliparus* differ by only 1.1 % (Sikorski et al. 2010) (*Fig. 40.1*). The next closest relatives of the genus *Segniliparus*, as based on 16S rRNA gene sequences, are the members of the genus *Rhodococcus*, family of *Nocardiaceae*, which share 93.3–94.8 % 16S rRNA genes sequence similarity with strain *Segniliparus rotundus* CDC 1076^T (Ludwig et al. 2012; Sikorski et al. 2010). A BLAST survey against the nucleotide database identified only very few entries at a similarity above 93 %, e.g., as obtained from wastewater (Del Casale et al. 2011), suggesting a rather limited ecological distribution of the genus *Segniliparus*.

Phenotypic Analyses

Segniliparus Butler et al. 2005

Segniliparus (Seg.ni.li.pa'rus. L. adj. segnis slow; Gr. adj. liparos fat/fatty; N.L. masc. n. *Segniliparus* the slow fatty one, the one

E. Rosenberg et al. (eds.), *The Prokaryotes – Actinobacteria*, DOI 10.1007/978-3-642-30138-4_279,

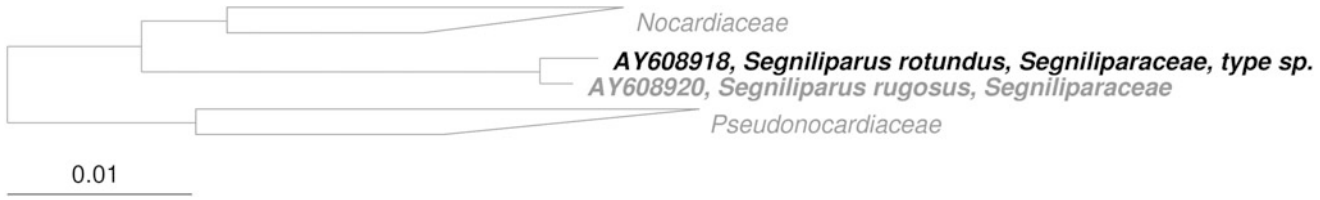

Fig. 40.1

Phylogenetic reconstruction of the family *Segniliparaceae* based on 16S rRNA and created using the neighbor-joining algorithm with the Jukes-Cantor correction. The sequence datasets and alignments were used according to the All-Species Living Tree Project (LTP) database (Yarza et al. 2010; http://www.arb-silva.de/projects/living-tree). The tree topology was stabilized with the use of a representative set of nearly 750 high-quality type strain sequences proportionally distributed among the different bacterial and archaeal phyla. In addition, a 40 % maximum frequency filter was applied in order to remove hypervariable positions and potentially misplaced bases from the alignment. Scale bar indicates estimated sequence divergence

Table 40.1

Phenotypic and chemotaxonomic characteristics of the type strains of *Segniliparus rotundus* and *S. rugosus*. Both strains are nonmotile. The range and optimum of NaCl and pH for growth, the presence of oxidase and polar lipids, the assimilation of aliphatic hydrocarbons, the resistance to radiation, and the peptidoglycan type were not determined

Properties	*Segniliparus rotundus* CDC 1076^{T} [a, b]	*Segniliparus rugosus* CDC 945^{T} [a, c]
Morphology	Similar-sized short rods	Irregular-sized rods

with slow fats, to indicate the possession of slowly reacting fatty acids, i.e., late-eluting mycolic acids detected with HPLC). The genus comprises two species, *Segniliparus rotundus* and *S. rugosus*.

The main features of the sole genus in the family *Segniliparaceae* are listed in *Table 40.1*. *Segniliparus* species form nonmotile rod-shaped cells with 0.4–0.9 μm width and 1.0–4.5 μm length. The cells are aerobic and acid–alcohol fast. Spores or aerial mycelium have not been observed, though the cells are occasionally V-shaped but not with true branching (Butler et al. 2005). The cells grow in 3–4 days on days on Löwenstein–Jensen (LJ), Middlebrook 7H10, and Middlebrook 7H11 agar at an optimal temperature of 33 °C and yield nonpigmented, non-photochromogenic colonies that do not produce a diagnostic odor. The growth on heart infusion (HI) agar is poor. The cells show arylsulfatase activity but are negative for niacin production. A semiquantitative catalase test produces bubbles of >45 mm (Butler et al. 2005). A definite range of salinity tolerance is not known, but growth tolerance with

sodium chloride on LJ and American Trudeau Society (ATS) media in 14 days is described to be positive (Butler et al. 2005). Urea is hydrolyzed but acetamide, adenine, casein, citrate, esculin, hypoxanthine, tyrosine, and xanthine are not. D-glucose, maltose, and trehalose are used as carbon sources and produce acid, whereas adonitol, L-arabinose, cellobiose, dulcitol, i-erythritol, galactose, i-myoinositol, lactose, mannose, melibiose, raffinose, L-rhamnose, salicin, and sodium citrate are not (Butler et al. 2005). Utilization of D-fructose, glycerol, D-mannitol, D-sorbitol, and sucrose is variable. The API CORYNE test kit numerical profile is 2040000 and revealed that the two species are positive for β-glucosidase and pyrazinamidase activities but negative for alkaline phosphatase, β-galactosidase, β-glucuronidase, α-glucosidase, *N*-acetyl-β-glucosaminidase, and pyrrolidonyl arylamidase activity at 33 °C. The antimicrobial susceptibility patterns have been determined from several strains of both species using serial twofold broth microdilution assays and are listed in detail in *Table 40.2*. The species have the same fatty acid composition, with prominent fatty acids of $C_{10:0}$, $C_{14:0}$, $C_{16:0}$, and tuberculostearic acid (Butler et al. 2005). The quinones are mainly MK-8(H_4) and MK-8(H_2) with some MK-8(H_6) and traces of MK9(H_2) (Sikorski et al. 2010). The species do not produce a *Rhodococcus equi*-specific ChoE virulence factor (Butler et al. 2005). The gas–liquid chromatography thermal cleavage product of the mycolic acids is a $C_{24:0}$ acid–methyl ester. The high-performance liquid chromatography mycolic acid pattern consists of three late-emerging groups of peaks with the final peak co-eluting with the high-molecular-mass internal standard. Thin-layer chromatography demonstrates three nonpolar α^+ (C_{84}-C_{100}) -, α (C_{73}-C_{83}) -, and α' (C_{60}-C_{66}) – mycolic acid chemical functional groups. These ultralong non-oxygenated α-mycolates with high levels of *cis* unsaturation are a special and sole phenotypic characteristic of *Segniliparus* species. Overall 65 homologous mycolic acids have been observed in *Segniliparus*. The overall length of the mycolic acids, which is among the longest lipids known in cell biology, is distinctly atypical of rapid growing mycolata (Hong et al. 2012; Lanéelle et al. 2013).

Isolation, Enrichment, and Maintenance Procedures

The type strain of *S. rotundus* was isolated from human sputum in a public health laboratory in Tennessee, USA, in 2005 or before (Butler et al. 2005). The type strain of *S. rugosus* was isolated from human sputum in a public health laboratory in Alabama, USA, in 1998 (Earl et al. 2011). Information of case histories on the type strains is not available. Several other strains have been isolated from humans, for some of them also case histories have been published (Butler et al. 2007; Hansen et al. 2009; Koh et al. 2011).

Strains of the genus *Segniliparus* do not require special procedures for maintenance and long-term storage. Can be stored frozen at –24 °C in appropriate medium or water containing 43 % glycerol and in liquid nitrogen in appropriate medium or water containing 5 % dimethylsulfoxide without loss of viability. Long-term preservation is by lyophilization with 20 % skin milk.

Ecology

Habitat

The type strains of the genus *Segniliparus* have been isolated from human sputum in 2005 or before (Butler et al. 2005; Earl et al. 2011). Further strains have been isolated from patients with cystic fibrosis (*S. rugosus*, most probably USA, but also in Australia) and bronchiectasis (*S. rotundus*, South Korea), from sputum, bronchus, or nasal samples (Butler et al. 2007; Hansen et al. 2009; Koh et al. 2011). The presence of *S. rugosus* in *Ixodes ricinus* ticks was identified by denaturating gradient gel electrophoresis (DGGE) of 16S rRNA gene amplicons and subsequent sequencing of the DGGE band. The ticks were collected in Sunnmøre, Norway, in May/June/September 2010 both as host-seeking ticks and feeding ticks picked from cats and dogs (Tveten and Sjåstad 2011). This suggests that transmission of *S. rugosus* between mammalian hosts can take place via ticks (Tveten and Sjåstad 2011). Further isolates of *S. rugosus* have been obtained from a subadult female California sea lion (*Zalophus californianus*) stranded on the beach of San Onofre, California, USA, in April 2010 (Evans 2011). Though in environmental databases hardly any 16S sequences related to *Segniliparus* are present, this finding addresses the question of whether *S. rugosus* could be free-living in the oceans or part of the flora of any number of ocean-dwelling vertebrates or invertebrates (Evans 2011; Sikorski et al. 2010).

Pathogenicity, Clinical Relevance

Although both *S. rugosus* and *S. rotundus* are officially classified to belong to risk group 1 (TRBA 2010), occasionally members of the species are suspected to behave as opportunistic pathogens in immunocompromised humans. This appears to be specifically true for humans suffering from cystic fibrosis (CF) (Butler et al. 2007; Hansen et al. 2009) and lung diseases such as tuberculosis and bronchiectasis (Koh et al. 2011). Hence, it is supposed that *Segniliparus* species can cause pneumonia in patients with bronchiectasis (Koh et al. 2011). Clinically, the CF cases exhibited a marked and rapid decline in lung function and radiologic studies over a short period of time which was not characteristic of CF or infections usually associated with this disease (Butler et al. 2007). However, the public health significance of *Segniliparus* species is still unclear. Also other mammalians such as sea lions may be affected by *Segniliparus* species (Evans 2011). Potentially, members of *Segniliparus* may be transmitted via ticks (Tveten and Sjåstad 2011), but may also originate from an environmental source (Butler et al. 2007).

41 The Family *Sporichthyaceae*

Tomohiko Tamura
Biological Resource Center (NBRC), National Institute of Technology and Evaluation (NITE), Kisarazu-shi, Chiba, Japan

Abstract
Sporichthyaceae, a family within the order "*Frankiales*," includes the genus *Sporichthya*. Members of this family are facultative anaerobes and have a cell wall containing a large amount of LL-diaminopimelic acid. *Sporichthya* aerial hyphae grow upright on the surface of the medium through holdfasts, which are outgrowths of the basal cell wall. No substrate mycelium forms.

Taxonomy: Historical and Current

Short Description of the Families

The family descriptions are based mainly on phylogenetic positions and patterns of 16S rRNA gene sequence signatures. However, the family *Sporichthyaceae* exhibits some diagnostic phenotypic characteristics differing from each other and from four neighboring families of the order "*Frankiales*" (◉ *Table 41.1*).

Sporichthyaceae Rainey, Ward-Rainey and Stackebrandt 1997, 487[VP] Emend. Zhi, Li and Stackebrandt 2009, 596[VP]

Spo.rich.thy.a'ce.ae. N.L. fem. n. *Sporichthya*, type genus of the family; L. suff. *-aceae*, ending to denote a family; N.L. fem. pl. n. *Sporichthyaceae*, the *Sporichthya* family (Stackebrandt et al. 1997).

Phylogenetically, a member of the order *Frankiales* (Ludwig et al. 2012) in the phylum Actinobacteria.

The family currently only contains the genus *Sporichthya* (Lechevalier et al. 1968). Species *Sporichthya polymorpha* and *Sporichthya brevicatena* have been proposed to be members of the genus *Sporichthya*. This family was proposed by Stackebrandt et al. (1997), and emended by Zhi et al. (2009).

Short aerial hyphae made up of rod-shaped spores are present. No substrate mycelium. Motile. Cross-linkage of the peptidoglycan is by the A type; diagnostic diamino acids include LL-diaminopimelic acid. Methyl 14-methylpentadecanoate (iso-$C_{16:0}$), hexadecanoic acid ($C_{16:0}$), heptadecanoic acid ($C_{17:1}$), and/or 10-methylated octadecanoic acid may also be present as prominent fatty acids. Menaquinones MK-9(H_6) and MK-9(H_8) are the predominant isoprenoid quinones. The pattern of 16S rRNA signatures consists of nucleotides at positions 184:193 (A–G), 195 (C), 196 (A), 416:427 (G–C), 600:638 (U–G), 601:637 (G–U), 602:636 (C–G), 612:628 (U–A), 841 (U), 952:1229 (U–A), 986:1219 (A–U), 1042 (A), and 1059:1198 (U–A). Predominant polar lipids include phosphatidylethanolamine, phosphatidylglycerol, phosphatidylserine, phosphatidylinositol, and several phospholipids and glycolipids may also be present. Mycolic acids and teichoic acids are absent. Galactose and mannose as whole cell sugars are detected. DNA G+C values are approximately 71 mol%. Members of the genus *Sporichthya* have been isolated from soil.

Phylogenetic Structure of the Family and Its Genus

At the present time, the family *Sporichthyaceae* includes only two validly described species of the genus *Sporichthya*. The phylogenetic tree indicates that these two species form a coherent clade (◉ *Fig. 41.1*). The family *Sporichthyaceae* was identified by Stackebrandt et al. (1997) based on phylogenetic position and the presence of a unique set of 16S rRNA gene

E. Rosenberg et al. (eds.), *The Prokaryotes – Actinobacteria*, DOI 10.1007/978-3-642-30138-4_182,

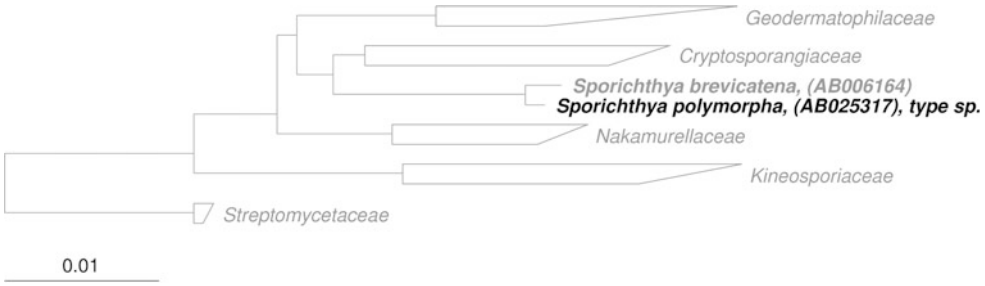

Fig. 41.1

Phylogenetic reconstruction of the family *Sporichthyaceae* based on 16S rRNA gene sequences and created using the neighbor-joining algorithm. The sequence dataset and alignment were used according to the All-Species Living Tree Project (LTP) database (Yarza et al. 2010; http://www.arb-silva.de/projects/living-tree). Representative sequences from closely related taxa were used as outgroups. In addition, a 40 % maximum frequency filter was applied in order to remove hypervariable positions and potentially misplaced bases from the alignment. Scale bar indicates estimated sequence divergence

sequence signature nucleotides. On the basis of modifications in this set and due to newly described actinobacterial species and the availability of their 16S rRNA gene sequences, the description of the family *Sporichthyaceae* was amended (Zhi et al. 2009). Since only one genus and two validly described species have been reported for this family, the pattern of the 16S rRNA signatures is based solely on the 16S rRNA gene sequences of the two strains. The pattern may change when additional information regarding members of the family *Sporichthyaceae* is obtained.

Molecular Analyses

DNA-DNA Hybridization Studies

DNA-DNA hybridization (DDH) values between *Sporichthya polymorpha* and *Sporichthya brevicatena* range from 20 % to 28 % (Tamura et al. 1999).

Genome Analyses

The incomplete genome sequence of the type strain of *Sporichthya polymorpha* DSM 43042^T (GOLD ID Gi02549) has been released. The genome of the type strain of *S. polymorpha* is 5,500,153 bp, contains 5,279 orfs, and a mol% G+C content of 71 %.

Phages

A *Sporichthya* phage, which is assigned as Sp1 (= DSM 49146 = IMET7840), has been identified. This phage causes true lysis of *Sporichthya polymorpha* DSM 46113 and increases plaque size (3.0-mm diameter), as well as producing clear plaques with distinct margins. This phage is used for classification and identification (Prauser 1984).

Phenotypic Analyses

Sporichthya Lechevalier Lechevalier and Holbert 1968, AL

Gr. n. *spora*, a seed and, in biology, a spore; Gr. n. *ikhthus*, fish; N.L. fem. n. *Sporichthya*, an organism with fish-like spores.

Sporichthya strains form short chains of aerial mycelium, but not substrate mycelium. Aerial hyphae are maintained upright on the basal cell on the surface of the medium by holdfasts. Most spore chains are short, but some are long (15–20 μm). Ordinary cells are rod-shaped or oval (approximate 0.5–1.5 μm). Primary mycelium is not formed. The sparingly branched aerial mycelium contains rod-shaped to coccoid spores, which may become polarly flagellated and motile in the presence of water (Williams et al., 1989). Many spores showed motility after incubation at 28 °C for 30 min in distilled water. *Sporichthya* strains grow under strictly aerobic or facultatively anaerobic conditions. The physiological characteristics and cellular fatty acids compositions of the members of the genus *Sporichthya* are shown in *Tables 41.2* and *41.3*. The phylogenetic relationship and chemotaxonomical characteristics shown in the family description were reported by Rainey et al. (1993).

The mol% G+C content is 71 %.

The type species is *Sporichthya polymorpha* (Lechevalier et al. 1968). The type strain is ATCC 23823 = BCRC 13424 = DSM 43042 = IFM 1245 = IMSNU 21310 = JCM 3089 = KACC 20041 = KCTC 9797 = NBRC 12702 = NRRL B-3709 = VKM Ac-1863.

Isolation, Enrichment, and Maintenance Procedures

Sporichthya polymorpha was isolated from greenhouse soil collected in New Brunswick, NJ, USA (Lechevalier et al. 1968). Only five *Sporichthya* strains have been isolated in the laboratory of Lechevalier et al. over the past 20 years.

Sporichthya brevicatena (Tamura et al. 1999) was isolated from soil samples collected in Yamanashi Prefecture, Japan, on

Table 41.2

*Data from Rainey et al. (1993) and Tamura et al. (1999).

HV agar (Hayakawa and Nonomura 1987) using the capillary method (Hayakawa et al. 1991), which was improved to include vanillin as a chemoattractant. Agar plates were incubated at 28 °C for approximately 3 weeks. Subcultivation of the isolate was conducted using ISP 2 medium and yeast extract-starch agar.

Because *Sporichthya* also has motile zoospores, isolation of *Sporichthya* was reported using the RC method (Takeuchi et al. 1996; Hayakawa et al. 2000). This technique involves immersing the air-dried source material in 10 mM phosphate buffer containing 10 % soil extract, incubating the preparation at 30 °C for 90 min, followed by centrifugation of the fluid at 1,500 × g for 20 min. Portions of the supernatant containing actinomycete zoospores were plated on humic acid-vitamin agar supplemented with nalidixic acid and trimethoprim. The *Sporichthya* strain was isolated from a soil sample collected from a corn field. Suzuki et al. (1999) developed a selective isolation method for *Sporichthya* strains. This method involves the RC method using a flooding solution containing 0.1 % skim milk in 10 mM MOPS (morpholinepropanesulfonic acid) (pH 8.0), and then incubating the preparation at 27 °C for 60 min to obtain high yields of motile spores followed by centrifugation at 1,000 × g for 10 min, the use of gellan gum plus 2 mM $CaCl_2$ as selective medium for stimulated growth, and dry heat treatment of soil samples at 80 °C for 60 min to increase the ratio of *Sporichthya*. They isolated a number of *Sporichthya* strains from 21 soil samples, which were collected in Belgium, France, India, Japan, Papua New Guinea, Spain, Taiwan, the United Kingdom, and the United States.

Members of the family *Sporichthyaceae* grow in complex liquid or on solidified media, such as ISP-2 medium, Bennett's agar containing 1 g/L yeast extract, 1 g/L beef extract, 2 g/L NZ amine, 10 g/L glucose, and 20 g/L agar (pH 7.3), YS agar and yeast extract-glucose broth containing 10 g/L yeast extract, and 10 g/L glucose. Members of these families do not require special procedures for maintenance or preservation. Cultures can be

maintained by serial transfers onto the appropriate solid media. Growth on agar slants can be maintained at 4 °C for over 1 month. Medium-term preservation is in 12–15 % (v/v) glycerol suspensions at −80 °C. Long-term preservation of liquid cultures supplemented with 12–15 % (v/v) glycerol or 7 % (v/v) dimethylsulfoxide is recommended in the vapor phase of liquid nitrogen (−150 °C). Freeze-drying and L-drying methods can be also applied for long-term storage.

Ecology

The main habitat of *Sporichthyaceae* strains appears to be soil. *Sporichthya* strains are widely distributed throughout the world (Suzuki et al. 1999). *Sporichthya* sp. I10A-02001 (GenBank accession number JX273674) which has 93.3–93.8 % of 16S rRNA gene sequence similarities to previous known species, *Sporichthya* sp. KAR54 (EF451684) which has 93.3–92.6 %, and *Sporichthya* sp. 1252 (AB054908) which has 925–91.9 % were isolated from surface-sterilized root of a medicinal plant, *Perilla frutescens*, at suburb of Beijing, China, permafrost (Hansen et al. 2007), mudflow deposit of the Mt. Pinatubo, respectively. In addition, uncultured bacterium clone FFCH14579 (EU132514) which has 97.0–97.3 % similarities, uncultured bacterium clone 0502TCLN027 (AB695759) which has 95.6–96.3 % similarities, and uncultured *Sporichthya* sp. clone CH1-4 (JX079395) which has 96.0–95.5 % similarities were collected from soil of an undisturbed mixed grass prairie preserve at Kessler farm, Oklahoma, USA (Elshahed et al. 2008), soil at Tottori, Japan, and contaminated soil at India, respectively.

Pathogenicity and Clinical Relevance

Pathogenicity has not been reported for any member of the family *Sporichthyaceae*.

No information regarding antibiotic sensitivity and resistance is available for members of the genus *Sporichthya*.

Application

There have been several reports regarding the special use of members of the family *Sporichthyaceae*.

Abstract
The family *Streptomycetaceae* comprises the genera *Streptomyces*, *Kitasatospora*, and *Streptacidiphilus* that are very difficult to differentiate both with genotypic and phenotypic characteristics. A separate generic status for *Kitasatospora* and *Streptacidiphilus* is questionable. Members of the family can be characterized as non-acid-alcohol-fast actinomycetes that generate most often an extensively branched substrate mycelium

E. Rosenberg et al. (eds.), *The Prokaryotes – Actinobacteria*, DOI 10.1007/978-3-642-30138-4_184,

that rarely fragments. At maturity, the aerial mycelium forms chains of few to many spores. A large variety of pigments is produced, responsible for the color of the substrate and aerial mycelium. The organisms are chemoorganotrophic with an oxidative type of metabolism and grow within different pH ranges. *Streptomyces* are notable for their complex developmental cycle and production of bioactive secondary metabolites, producing more than a third of commercially available antibiotics. Antibacterial, antifungal, antiparasitic, and immunosuppressant compounds have been identified as products of *Streptomyces* secondary metabolism. *Streptomyces* can be distinguished from other filamentous actinomycetes on the basis of morphological characteristics, in particular by vegetative mycelium, aerial mycelium, and arthrospores. The genus comprises at the time of writing more than 600 species with validated names. 16S rRNA gene sequence-based analysis for species delineation within the *Streptomycetaceae* is of limited value. The variations within the 16S rRNA genes—even in the variable regions—are too small to resolve problems of species differentiation and to establish a taxonomic structure within the genus. Comprehensive comparative studies including protein-coding gene sequences with higher phylogenetic resolution and genome-based studies are needed to clarify the species delineation within the *Streptomycetaceae*.

Taxonomy, Historical and Current

Short Description of the Family

Family *Streptomycetaceae* Waksman and Henrici 1943, 339^{AL} emend. Stackebrandt, Rainey, and Ward-Rainey, 1997, 486, emend. Kim, Lonsdale, Seong and Goodfellow, 2003, 113

Strep.to.my.ce.ta'ce.ae. N.L. masc. n. *Streptomyces*, type genus of the family; L. suff. *-aceae*, ending to denote a family; N.L. fem. pl. n. *Streptomycetaceae*, the *Streptomyces* family

The family *Streptomycetaceae* belongs to the *Actinomycetales* suborder *Streptomycinae* Rainey, Ward-Rainey, and Stackebrandt 1997 of the class *Actinobacteria* Stackebrandt, Rainey, and Ward-Rainey 1997. Type genus is *Streptomyces* Waksman and Henrici 1943, 107^{AL}. Organisms are Gram-positive, aerobic, non-acid-alcohol-fast actinomycetes that generate an extensively branched substrate mycelium that rarely fragments. At maturity, the aerial mycelium forms chains of three to many spores. Members of a few species produce short spore chains on the substrate mycelium. A large variety of pigments is produced, responsible for the color of the substrate and aerial mycelium. The organisms are chemoorganotrophic with an oxidative type of metabolism and grow within different pH ranges. Cell walls of the substrate mycelium contain either LL- or *meso*-diaminopimelic acid as the predominant diamino acid; aerial or submerged spores contain LL-diaminopimelic acid (peptidoglycan type A3γ). Whole-organism lipid profiles usually comprise complex mixtures of saturated *iso*- and *anteiso*-fatty acids and as major polar lipids hexa- and octa-hydrogenated menaquinones with nine isoprene units as the predominant isoprenologues, diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylinositol, and phosphatidylinositol mannosides. Mycolic acids are not present. Sugar profiles may contain major quantities of either galactose or galactose and rhamnose. The mol% G+C of the DNA ranges between 66 % and 74 %. The 16S rRNA gene sequence signature pattern consists of nucleotides at positions: 71 (G), 80–89 (G-C), 81–88 (C-G), 82–87 (U-G), 127–234 (G-C), 209 (C), 210 (C), 211 (G), 610 (G), 671–735 (U-A), 819 (G), 837–849 (C-G), 950–1231 (U-G), 955–1225 (C-G), 965 (C), 1254–1283 (A-U), and 1409–1491 (GG).

Phylogenetic Structure of the Family and Its Genera

The family *Streptomycetaceae* was established by Waksman and Henrici in 1943 to accommodate actinomycetes with branched slender mycelia and spores on aerial hyphae that show rarely or no presence of a septate and no fragmentation into oidia (Waksman and Henrici 1943). At that time, the description was primarily based on morphological characteristics. In the 8th edition of *Bergey's Manual of Determinative Bacteriology*, Pridham and Tresner (1974a) listed the genera *Streptomyces*, *Streptoverticillium*, *Sporichthya*, and *Microellobospora* as members of the family. Other genera, such as *Actinopycnidium*, *Actinosporangium*, *Chainia*, *Elytrosporangium*, *Kitasatoa*, and *Microellobospora* have been differentiated from *Streptomyces* by morphological criteria; however, they harbor many common phenotypic and genotypic features with *Streptomyces* and have therefore been proposed as synonyms of this genus (Goodfellow et al. 1986a, b, c, d, e). The genus *Sporichthya* is now classified within the family *Sporichthyaceae* of the suborder *Frankineae* (Stackebrandt et al. 1997).

The genus *Streptoverticillium* was also found to share many characteristics with streptomycetes but is distinguishable from *Streptomyces* by its verticillate sporophores. The proposal that the genus became a synonym of streptomycetes (Witt and Stackebrandt 1990) was further supported by numerical phenetic (Williams et al. 1983a; Kämpfer et al. 1991) and rRNA/DNA similarities (Gladek et al. 1985; Witt and Stackebrandt 1990). The unification of *Kitasatospora* with *Streptomyces* was proposed by Wellington et al. (1992) on the basis of morphological, biochemical, and 16S rRNA gene sequence similarities. Nevertheless, the genus was revived by Zhang et al. (1997) mainly on the basis of the ratio of *meso*-A_2pm to LL-DAP in whole-cell hydrolysates. The *meso*-A_2pm content in *Kitasatospora* strains is 49–89 % and 1–16 % in *Streptomyces* strains. In addition, galactose is only contained in whole-cell hydrolysates of *Kitasatospora* strains but not in hydrolysates of *Streptomyces* strains. The genus *Streptacidiphilus* was proposed by Kim et al. (2003) as an additional member of the family. These acidophilic actinomycetes grow over a pH range of 3.5–6.5 with an optimum of 4.5–5.5 and have been isolated from acidic soils and litter.

Table 42.1

Morphological, physiological, and chemotaxonomic characteristics of *Streptomyces*, *Kitasatospora*, *and Streptacidiphilus* strains[a] (According to Kim et al. 2003)

	Streptomyces	*Kitasatospora*	*Streptacidiphilus*
Long chains of spores formed on aerial hyphae	+	+	+
pH range for growth	5.0–11.5	5.5–9.0	3.5–6.0
Optimal pH range	6.5–8.0[b]	Not determined	4.5–5.5
Diagnostic sugars in whole-organism hydrolysates	None	Galactose[c]	Galactose, rhamnose
Isomer(s) of diaminopimelic acids in whole-organism hydrolysates	LL-A_{2pm}	LL-/*meso*[d] A_{2pm}	LL-A_{2pm}
Fatty acid pattern[e]	2c	2c	2c
Predominant phospholipids[f]	DPG,PE,PI,PIMs	DPG,PE,PI,PIMs	DPG,PE,PI,PIMs
Major menaquinones[g]	MK-9($H_{6'}$ H_8)	MK-9($H_{6'}$ H_8)	MK-9($H_{6'}$ H_8)
G + C content of DNA (mol%)	66–73	70–74	70–72

[a]Data obtained from Kim et al. (2003) and previous studies (Shirling and Gottlieb 1977; Ōmura et al. 1989; Lonsdale 1985; Williams et al. 1989; Nakagaito et al. 1992; Antony-Babu and Goodfellow 2008); [b]Alkalophilic strains, which grow between pH 5.0 and 11.0, have an optimum at pH 9 to 9.5 (Mikami et al. 1982; Antony-Babu and Goodfellow 2008); [c]Rhamnose was detected in whole-organism hydolysates of *Kitasatospora mediocidica* (Labeda 1988); [d]Aerial and submerged spores contain LL-A_{2pm} and vegetative mycelia *meso*-A_{2pm}; [e]Fatty acid group sensu Kroppenstedt (1985); [f]DPG, diphospatidylglycerol; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PIMs, phosphatidylinositol mannosides; [g]MK-9($H_{6'}$ H_8), hexa- and octa-hydrogenated menaquinones with nine isoprene units

The genera *Streptomyces*, *Kitasatospora*, and *Streptacidiphilus* are very difficult to differentiate on the basis of phenotypic characteristics (including the few distinguishing chemotaxonomic markers indicated above). The few distinctive features of the three genera are presented in *Table 42.1*. Even though 16S rRNA gene sequence analyses have offered a framework for prokaryotic classification, the current classification based on this molecule has not resolved the taxonomic problems within the family *Streptomycetaceae* (Kämpfer 2006). In phylogenetic analyses based on nearly full-length 16S rRNA gene sequences, *Kitasatospora* and *Streptacidiphilus* form stable, separate subbranches within the family *Streptomycetaceae*; however, they are grouped within the large *Streptomyces* tree (*Fig. 42.1*) and the 16S rRNA gene sequences similarities are equally high to many *Streptomyces* species groups. Multilocus sequence analysis (MLSA) based on concatenated partial sequences of five housekeeping genes showed the formation of distinct separate clusters with high bootstrap support for species of the genera *Kitasatospora* and *Streptacidiphilus*. However, only a selection of species was investigated and the distinct separation was not supported by all single gene-based phylogenies (Han et al. 2012). A very high agreement with the genome sequence data for *Streptomyces* and *Kitasatospora* was also found on the basis of DNA-DNA microarray hybridizations, when the genome content of *Streptomyces avermitilis*, *Streptomyces cattleya*, *Streptomyces maritimus*, and *Kitasatospora aureofaciens* was compared with that of *Streptomyces coelicolor* A3(2) (Hsiao and Kirby 2008).

Due to all these reasons, it remains uncertain, whether a separate generic status for *Kitasatospora* and *Streptacidiphilus* is justified. In the 2nd edition of *Bergey's Manual*, these genera are cited as genera incertae sedis (Kämpfer 2012).

Molecular Analyses

The genetics of streptomycetes is a rapidly developing area, and plenty of information has been published within the last years (for reviews and more information, see, e.g., Chen et al. 2002; Donadio et al. 2002; Paradkar et al. 2003; Schrempf 2006; Ventura et al. 2007; Hopwood 2003 2007; Hsiao and Kirby 2008; Dyson 2010, and references therein). Information on the complex structure of *Streptomyces* genomes is increasing, mainly because streptomycetes are very abundant and important as soil inhabitants, where they are regarded as major components in the cycling of organic carbon compounds. They are also capable of forming many and diverse hydrolytic exoenzymes, like cellulases and chitinases.

Streptomyces are notable for their complex developmental cycle and production of bioactive secondary metabolites, producing more than a third of commercially available antibiotics. Antibacterial, antifungal, antiparasitic, and immunosuppressant compounds have all been identified as products of *Streptomyces* secondary metabolism (Omura et al. 1992; Hopwood 2007). The agar liquefying strain designated *Streptomyces coelicolor* A3(2) (reviewed by Hopwood 1999) is widely considered the model organism. This strain exhibits the main features of its genus with several distinctive characteristics, most notably production of the red mycelial bound pigment undecylprodigiosin and the diffusible blue pigment actinorhodin.

The whole-genome sequences of several *Streptomyces* strains have been examined and are published or available online: e.g., *S. coelicolor* A3(2) (representing the model streptomycete; Bentley et al. 2002); *Streptomyces ambofaciens* strains ATCC 15154, DSM 40697, ETH 9247, and ETH 11317 (*S. ambofaciens* is known for its remarkable genetic instability); *S. avermitilis* MA-4680 (the producer of avermectin; Ikeda et al. 2003); *S. griseus* subsp. *griseus* NBRC 13350 (producer of bioactive

(a–f) Phylogenetic reconstruction of the family *Streptomycetaceae* based on 16S rRNA and created using the maximum likelihood algorithm RAxML (Stamatakis 2006). The sequence datasets and alignments were used according to the All-Species Living Tree Project (LTP) database (Yarza et al. 2010; http://www.arb-silva.de/projects/living-tree). Representative sequences from closely related taxa were used as outgroups. Scale bar indicates estimated sequence divergence

secondary metabolites, including streptomycin; Ohnishi et al. 2008); *S. scabies* 87.22 (causing potato scab); *S. bingchenggensis* BCW-1, producer of the anthelmintic macrolide milbemycins (Wang et al. 2010); the chloramphenicol producer *S. venezuelae* ATCC 10712 (EMBL accession number FR845719); and *S. cattleya* NRRL 8057, a rare synthesizer of fluorinated antibiotics (Barbe et al. 2011).

All *Streptomyces* strains studied so far contain a large genome, typically of linear topology. The chromosomes of sequenced *Streptomyces* range in size from 6,283,062 bp for *S. cattleya*, if the 1,809,491 bp linear plasmid comprising its second replicon is excluded from the comparison, to 11,936,683 bp predicted to code for 10,023 genes in *S. bingchenggensis*; the latter is thought to be the largest bacterial genome sequenced to date. The *S. coelicolor* A3(2) genome was originally considered to be circular, by analogy with other well-studied bacteria such as *Escherichia coli*. However, on the basis of analysis of cosmid libraries in combination with comparisons of physical maps from the wild-type and mutant strains of *S. coelicolor* A3(2) and *S. lividans*, it was established that the chromosome is present in a linear form in wild-type strains (Lin et al. 1993; Redenbach et al. 1996). The presence of a linear chromosome in other streptomycetes, including *S. ambofaciens* (Leblond et al. 1996), *S. antibioticus*, *S. lipmanii*, *S. moderatus*, *S. parvulus*, *S. rochei* (Lin et al. 1993), *S. griseus* (Lezhava et al. 1995), and *S. hygroscopicus* (Pang et al. 2002a, b) has been revealed by pulse-field gel electrophoresis (PFGE) studies. In addition, a linear arrangement of the chromosome has also been shown for a *Streptoverticillium* sp. (Redenbach et al. 1998).

The *S. coelicolor* A3(2) chromosome contains about 8,667 mega base pairs (Mbp) which correspond to 7,825 genes. Twenty-six gene clusters encode known or predicted secondary metabolites (Bentley et al. 2002). It is interesting to note that the *S. coelicolor* chromosome was shown to carry more genes (i.e., 7,825) than the eukaryote *Saccharomyces cerevisiae* (containing 6,203 genes). The genome size of *S. avermitilis* MA-4680 comprises about 9,025 Mbp (average G+C content 70.7 mol%), which corresponds to 7,574 potential open reading frames, 35 % of which constitute 721 paralogous families (Omura et al. 2001; Ventura et al. 2007). In total, 30 gene clusters encode for secondary metabolites. It has been determined that one large region of 6,500 Mbp is highly conserved in the *S. coelicolor* A3(2) and *S. avermitilis* MA-4680 genomes with respect to gene order and thus may contain essential genes. The terminal regions are not conserved and contain "nonessential genes" (Ikeda et al. 2003). Moreover, it is worth mentioning that an ancient synteny (conservation of gene order) has been uncovered between the central core of the *S. coelicolor* A3(2) chromosome and the whole chromosomes of *Corynebacterium diphtheriae* and *Mycobacterium tuberculosis* (Bentley et al. 2002).

Whole-genome synteny plots have revealed that common genes present in the genomes of *S. coelicolor* A3(2) and *S. avermitilis* MA-4680 display a high conservation in their overall position and orientation (Ventura et al. 2007). Ikeda et al. (2003) estimated by reciprocal BLAST analysis that about two-thirds (5,283) of the corresponding genes represent conserved orthologs. Similarly, it has been found that 4,837 genes are orthologues between these two strains (Ventura et al. 2007). When *S. scabies* ATCC 49173 is added to this comparison, the number of conserved genes among the three strains decreases to 4,190, and, as pointed out by Ventura et al. (2007), a four-way analysis, including the hitherto unpublished sequence of *S. venezuelae*, ATCC 10595 reduces the number to 3,566 genes. Presumably, that number will decrease further as more

Streptomyces genomes are available. In addition, Ventura et al. (2007) showed that only about 17 % of the 3,566 genes common to the four *Streptomyces* genomes are present in *E. coli* K-12 and *Bacillus subtilis* 168.

Hsiao and Kirby (2008) used DNA-DNA microarray hybridization to compare the genome content of *S. avermitilis* ATCC 31267, *S. cattleya* ATCC 35852, *S. maritimus* Yang-Ming, and *Kitasatospora aureofaciens* ATCC 10762 with that of *S. coelicolor* A3(2). Using this approach an accordance of about 93 % with the genome sequence data available for *S. avermitilis* ATCC 31267 was detected and a number of trends in the genome structure for *Streptomyces* and closely related *Kitasatospora* species could be shown. The central core region was found to be well conserved, and also a low degree of gene conservation within the terminal regions of the linear chromosome across all four strains was determined. Between these regions, two areas of intermediate gene conservation were identified by microarray analysis. Nevertheless some conserved genes were also detected in the terminal regions.

The replication process of the *Streptomyces* chromosome has been summarized by Schrempf (2006) and Ventura et al. (2007). The replication of linear *Streptomyces* chromosomes and plasmids proceeds bidirectionally towards the telomeres and is initiated from a fairly centrally located replication origin rich in DnaA box sequences. The chromosomal replication origin (*oriC*) region shows high conservation among *S. coelicolor* A3(2) (Calcutt and Schmidt 1992), *S. lividans* 66 (Zakrzewska-Czerwinska and Schrempf 1992), *S. lividans* TK21, *S. antibioticus* ETH 7451, and *S. chrysomallus* ATCC 11523 (Jakimowicz et al. 1998). Interestingly, it has been revealed that in contrast to the high overall G+C content (69–73 mol%) of *Streptomyces* DNA, the region of the origin (*oriC*) is rich in A + T (64 mol%). The chromosomes of *Streptomyces* species typically contain terminal inverted repeats (TIRs) at their ends, which are covalently bound to terminal proteins. TIR lengths among available sequenced *Streptomyces* chromosomes vary considerably with 174 bp for *S. avermitilis*, 18,488 bp for *S. scabies*, 21,653 bp for *S. coelicolor* M145, and approximately 198 kb for *S. ambofaciens* (Ventura et al. 2007). The chromosomal telomeres are replicated by a special mechanism, which is initiated by priming from the terminal protein covalently bound to the 5′-ends. These ends are made up of approximately 250–320 characteristic nucleotides and possess a complex secondary structure (Ventura et al. 2007).

The origin of the linearity of the *Streptomyces* chromosome is believed to have occurred by single-crossover recombination between an initially circular chromosome and a linear plasmid. Quite a few examples of exchange of ends between chromosomes and linear plasmids, resulting in hybrid molecules with different right and left ends, have been reported. Streptomycete genome architecture is extensively reviewed by Kirby and Chen (2011).

Several examples of apparent redundancy of metabolic genes have been determined in the genomes of streptomycetes, which are considered to be due to the complex morphological and physiological differentiation of streptomycetes. The metabolic genes include those that function in carbon storage transactions, genes coding for enzymes of the pentose phosphate pathway, genes specific for different hyphal cell types, and several *fabH*-like genes, which are essential for the first step in fatty acid biosynthesis (some of these are linked with secondary metabolism gene sets) (Ventura et al. 2007). It is worth mentioning that a number of genes are not present in streptomycetes genomes. For instance, two of the three subunits of exonuclease V (the *recB* and *recC* genes) are not found in streptomycetes; nevertheless they are present in other actinobacteria such as mycobacteria. The XerCD pathway, which is responsible for the resolution of circular chromosomes after replication, is absent from streptomycetes, consistent with the linearity of *Streptomyces* chromosomes. The conserved *ftsA* gene, which is involved in the complex cell division process and widely distributed in the domain Bacteria, is commonly not found in *Actinobacteria*. Moreover, the *minC* and *minE* genes, which are involved in the choice of division site in many unicellular bacteria, are not present in *Streptomyces* strains (Ventura et al. 2007).

Streptomyces colonies frequently display a high spontaneous variability in pigmentation, sporulation, and antibiotic biosynthesis. The various antibiotic resistances, A-factor formation, and synthesis of tyrosinase or arginosuccinate are encoded by unstable genes. This genetic instability can be stimulated by mutagens, such as ethidium bromide, mitomycin, and ultraviolet light, and by gyrase (topoisomerase II)-inhibiting antibiotics. Often, these variations are a result of large chromosomal deletions, preferentially taking place at the telomeric and subtelomeric regions and including up to 2 Mbp of DNA (Hütter and Eckhardt 1988; Schrempf et al. 1989; Leblond and Decaris 1994; Chen 1995). More information about these processes is published (Schrempf 2006). The variability of the chromosomal DNA is additionally enhanced by its interaction with linear and circular plasmids, phages, transposons, and insertion elements. Since streptomycetes inhabit rapidly changing environments, the high plasticity of the genome likely represents an effective prerequisite for quick adaptation.

Streptomyces Extrachromosomal Elements

Streptomyces can contain small, covalently closed circular (ccc) high copy-number plasmids, larger ccc low copy-number plasmids, ccc plasmids that arise by reversible site-specific recombination from the chromosome, and linear plasmids that share features of the chromosome: a centrally located origin of replication and terminal inverted repeats with bound terminal proteins to prime end patching (reviewed by Vogelmann et al. 2011). A property common to maybe all is their self-transmissibility and ability to mobilize chromosomal DNA, making them supremely important in promoting genetic exchange and streptomycete evolution. The frequency of plasmid transfer between strains can approach 100 % and is apparent in laboratory conditions by the formation of "pocks" on a lawn of recipient bacteria. These pocks are zones of (so far unexplained) retarded development surrounding the primary site of plasmid transfer: the retarded development is

a consequence of intrahyphal spread of copies of the newly transferred plasmid. The conjugation mechanism (reviewed by Vogelmann et al. 2011) is quite unlike that of enteric bacteria such as *E. coli*. For the latter, conjugation depends on the function of more than 30 genes (e.g., the transfer region of the F-plasmid). In contrast, a single *tra* gene is responsible for the transfer of circular streptomycete plasmids (e.g., pIJ101, pSN22, pSG5, SCP2, and pSAM2). In addition, "spread" genes (*spd*) promote subsequent intrahyphal spread, leading to the appearance of pocks. The F-plasmid *E. coli* paradigm involves transfer of a single DNA strand from donor to recipient after the two strains have been temporarily united via the sex pilus, processes specified by more than 30 F-plasmid *tra* genes. In *Streptomyces*, plasmid transfer is likely to be initiated by the fusion of donor and recipient hyphae growing together, perhaps promoted by plasmid functions: certain plasmids, such as the linear SLP2 of *S. lividans*, encode a muramidase-like function that could remodel the peptidoglycan of the fusing hyphae. For other plasmids, this may be unnecessary: the Tra protein of pSG5 localizes to growing hyphal tips, where peptidoglycan is constantly being remodeled as part of the growth process of hyphal extension. The streptomycete plasmid Tra proteins belong to the same family as FtsK, first characterized in *E. coli* as being involved in chromosomal DNA segregation at cell division. FtsK is assembled as a hexameric ring with a hole as an integral part of the septum formed during cytokinesis. Two DNA double helices are accommodated in the hole as FtsK pumps a looped circular double-stranded chromosomal DNA molecule between compartments in an ATP-dependent manner. The emerging evidence is that *Streptomyces* plasmid Tra proteins also hydrolyze ATP as they transfer double-stranded DNA between hyphae. Similar to FtsK, the Tra proteins also have a membrane-spanning domain that could promote the fusion of membranes necessary for interhyphal DNA transfer. The purified Tra protein of pSVH1 binds noncovalently, as a hexameric assembly, to a specific plasmid sequence, *clt*: this binding presumably permits specific transfer of the plasmid, but there is no DNA processing (e.g., nicking) during conjugal transfer as is necessary for single-stranded F-plasmid transfer between *E. coli* strains.

The mobilization of chromosomal DNA during the transfer of circular plasmids is believed to be a consequence of transient recombination between a plasmid and the chromosome, leading to transfer of the resulting cointegration as a loop through a Tra protein ring. It is unclear whether this normally leads to complete or partial transfer of the donor chromosome. A model for chromosome transfer by linear plasmids invokes mobilization due to interactions between the terminal proteins of both replicons, giving rise to "end-first" transfer of the chromosome. If the two ends of the plasmid are bound to the two ends of the chromosome, transfer of the entire quasi-circular loop is possible.

Plasmid-encoded functions include antibiotic production (Kinashi et al. 1991; Gravius et al. 1994) and mercury resistance (Ravel et al. 1998). The replication mechanism is best understood for pSLA2. It is initiated bidirectionally near the center of the plasmid and proceeds towards its telomeric ends, generating 3′ leading-strand overhangs. It should be mentioned that various other members of the order *Actinomycetales* contain genes on linear plasmids, among them those required for biphenyl degradation (*Rhodococcus erythropolis* and *Rhodococcus globerulus*; Kosono et al. 1997), hydrogen autotrophy (*Rhodococcus opacus*, formerly *Nocardia opaca*; Kalkus et al. 1993), isopropylbenzene and trichlorethylene catabolism (*Rhodococcus erythropolis*; Kebeler et al. 1996), and fasciation in plants (*Rhodococcus fascians*; Crespi et al. 1992). Linear plasmids have also been identified in *Mycobacteria* (*M. arium*, *M. branderi*, *M. celaturum*, and *M. xenopi*). Their termini correspond to those of linear plasmids from *Streptomyces* and *Rhodococcus* species (Picardeau and Vincent 1998); it remains an open question whether circular and linear plasmids are exchanged during conjugation among these other actinomycetes. There is only limited information about *Streptomyces* transposons; a summary of this topic is provided by Schrempf (2006). Phages with broad or narrow host ranges can be recovered from soil and several of them have been applied for classifying strains (for review, see Kutzner 1981). Nevertheless, in present taxonomic studies, phage host range studies are not carried out.

The use of *Streptomyces* plasmids for gene cloning is discussed in chapter 11 of the book by Kieser et al. (2000).

DNA Regions in Mycelial Actinobacterial Genomes Acquired by HGT

Regardless of the large synteny between the central regions of *Streptomyces* genomes, hundreds of insertion-deletion (indel) differences exist between *S. coelicolor* A3(2) and *S. avermitilis* MA-4680, most of them involving one or a few genes. This circumstance frequently complicates the recognition of synteny at the level of small groups of genes. Streptomycetes also contain several larger islands of species-specific DNA (Ventura et al. 2007). Prior to the publication of other *Streptomyces* genome sequences, 14 islands of likely laterally acquired DNA were identified by Bentley et al. (2002) in the *S. coelicolor* A3(2) genome on the basis of gene content, atypical GC content, and location next to a tRNA determinant. Approximately 50 % of these islands were shared with *S. ambofaciens*. This clearly illustrates that in pairwise synteny plots the genes in the "subtelomeric arms" of *Streptomyces* chromosomes display much less conservation between species than those in the central regions, or "cores," and that the cores contain most of the genes conserved with other actinobacteria (Bentley et al. 2002; Ikeda et al. 2003; Choulet et al. 2006).

DNA-DNA Hybridization

The percent DNA-DNA hybridization and the decrease in thermal stability of hybrids are currently used as the "gold standards" for species delineation in taxonomy (Wayne et al. 1987).

DNA-DNA hybridizations of total chromosomal DNA have been widely used in the classification of *Streptomyces* species. Strains of the *Streptomyces albidoflavus* cluster 1, which were earlier defined by Williams et al. (1983a) using numerical phenetic methods, were the subject of an initial DNA-DNA hybridization study performed by reassociation of labeled DNA on nitrocellulose filters (Mordarski et al. 1986). Good correlation was found between the results of the two approaches, and the homogeneity of the *Streptomyces albidoflavus* subcluster *albidoflavus* was confirmed. Nevertheless, two other subclusters obtained by DNA-DNA hybridization were not matching with the *S. anulatus* or *S. halstedii* subclusters established by Williams et al. (1983a), although some correlation was found with the groupings of Kämpfer et al. (1991). DNA-DNA hybridization data further supported the assignment of *Streptoverticillium* strains to the genus *Streptomyces* (reassociation of labeled DNA on filters; Witt and Stackebrandt 1990), which was later confirmed in the numerical phenetic study of Kämpfer et al. (1991).

The most extensive DNA-DNA hybridization studies on strains assigned to some of the major phenetic groups of Williams et al. (1983a) were performed by Labeda et al. (Labeda 1993, 1996, 1998 and Labeda and Lyons 1991a, b). Here only little correlation between the DNA-DNA pairing and numerical phenetic data was found with respect to the *S. cyaneus* (Labeda and Lyons 1991a), *Streptomyces violaceusniger* (Labeda and Lyons 1991b), *S. lavendulae* (Labeda 1993), the verticil-forming streptomycetes (formerly *Streptoverticillium* species; Labeda 1996; Hatano et al. 2003), and *S. fulvissimus* and *S. griseoviridis* phenotypic clusters (Labeda 1998); nevertheless, some concordance was found with phenotypic groups delimited by Kämpfer et al. (1991; ❯ *Table 42.2*). The fact that certain regions within the *Streptomyces* chromosome display substantial genetic instability supports the continued use of DNA-DNA hybridization (Redenbach et al. 1993). Yet, data obtained by DNA-DNA pairing can be influenced by the presence of large plasmids in *Streptomyces* strains.

Fingerprinting Techniques

In randomly amplified polymorphic DNA polymerase chain reaction (RAPD-PCR), single primers with arbitrary nucleotide sequences are used to amplify DNA at low annealing temperatures in order to detect polymorphisms. The method is used as a rapid screening method to identify similarities among streptomycetes. To obtain validated results, the reaction parameters of this technique have to be stringently standardized including annealing temperature, primer sequence, PCR-reagents, and concentration and quality of template DNA. RAPD-PCR produces a distinctive fingerprint of PCR products and allows the detection of chromosomal dissimilarities between individual isolates without having any prior information of chromosomal sequences.

Mehling et al. (1995) applied this method to identify different actinomycete species; however, they were only capable of detecting characteristic banding patterns for closely related species when a highly specific actinomycete primer was used. Similar results were obtained when the method was used to determine interspecific relationships among members of the *Streptomyces albidoflavus* cluster of Williams et al. (1983a), even so the resulting fingerprints contained only four bands (Huddleston et al. 1995). Anzai et al. (1994) studied 11 primers with different fragment patterns from zero to 20 bands and found that variations in fingerprint patterns can be achieved by substitution of a single base on the arbitrary primer, whereas alteration of the primer sequence at the 3′ end resulted in the most significant differences. Anzai and colleagues used an optimized procedure to investigate the relationship of *Streptomyces lavendulae* and *Streptomyces virginiae* strains; members of these taxa were assigned to the same numerically defined groups by Williams et al. (1983a) and Kämpfer et al. (1991). RAPD-PCR data showed good correlation with other methods such as low-frequency restriction fragment analysis (LFRFA), DNA-DNA hybridization, and cultural and physiological tests; nevertheless interspecific relationships of *S. lavendulae* and *S. virginiae* strains could not be clarified.

Restriction Digests of Total Chromosomal DNA

Low-frequency restriction fragment analysis (LFRFA) is based on the digestion of the entire bacterial chromosomal DNA with restriction endonucleases that cut infrequently and produce a distinctive band pattern after separation by pulsed-field gel electrophoresis (PFGE). Because of their high DNA G+C content, rare adenine-thymine cutting enzymes are used for streptomycetes. In the first study, Beyazova and Lechevalier (1993) studied 59 strains from eight species groups and discovered that the method was valuable since related strains were clustered together. Nevertheless, some discrepancies were found, such as for the strains grouped into the *Streptomyces cyaneus* cluster of Williams et al. (1983a). Like RAPD-PCR, the method seems to be useful for the identification of very closely related strains, but cannot be used to determine interspecific relationships. In addition, one has to be careful with the interpretation of fingerprints, as misinterpretation of banding patterns can result from large chromosomal amplifications or deletions (Rauland et al. 1995).

Nucleic Acid Sequence Comparisons of 16S rRNA and Other Genes

In an early review about the application of 16S rRNA gene sequence analysis for classifying streptomycetes, the importance of the gene region selected for comparison was highlighted (Stackebrandt et al. 1992). It was discovered that relationships between strains were influenced by the variable region (*a*, *b*, or *c*) used for comparison. By sequencing the c region, Kataoka et al. (1997) were able to determine inter- and intraspecies relationships between 89 streptomycete type strains, representing several clusters of Williams et al. (1983a). In total, 42 of the strains were

VIII: D-Mannitol

IX: i-Inositol

X: Salicin

XI: Sucrose

found to possess unique sequences, while the remaining strains were assigned to 15 groups. In a more extensive study, the c region sequences of 485 *Streptomyces* strains were deposited in GenBank, which was the first large set of streptomycete 16S rDNA sequence data that was publicly available (Kataoka et al. 1997). Anderson and Wellington (2001) published a phylogenetic tree based on the comparison of the *c* regions of representatives of the major cluster groups defined by Williams et al. (1983a). In this study the taxonomic status of the phenotypic groups was confirmed, apart from the *S. olivaceoviridis* and *S. griseoruber* strains which displayed identical c regions; these strains were present in clusters 20 and 21 of Williams et al. (1983a), respectively, and however formed cluster 9 by Kämpfer et al. (1991). The sequence data also displayed that the 60 strains, earlier assigned to three species groups in the *Streptomyces albidoflavus* group (Williams et al. 1983a), could be sorted into six groups (Kataoka et al. 1997); the three phenotypic subgroups of Williams et al. (1983a) were maintained, but did not cluster together.

Hain et al. (1997) designed 16S rRNA oligonucleotide probes to identify intraspecific relationships within the *Streptomyces albidoflavus* group and discovered that the resulting sequences were helpful for species differentiation but not for delineating strains. The intergenic 16S-23S rRNA spacer regions were found to be more suitable for the delineation of intraspecific relationships within that cluster. In addition, genus-specific probes have also been developed based on the 5S rRNA gene (Park et al. 1991) and the 23S rRNA gene (Mehling et al. 1995) sequences. By using 5S rRNA sequence data, it was possible to confirm the reclassification of the genera *Chainia*, *Elytrosporangium*, *Kitasatoa*, *Microellobosporia*, and *Streptoverticillium* into the genus *Streptomyces* (Park et al. 1991).

By now, for nearly all *Streptomyces* type strains complete 16S rRNA gene sequences are available from public databases. In Kämpfer (2012) a phylogenetic tree based on nearly full-length 16S rRNA gene sequences was calculated including type strains of all species of the genera *Streptomyces*, *Kitasatospora*, and *Streptacidiphilus*. Grouping in that tree was the basic for species arrangement given in ❯ *Table 42.2*. A phylogenetic 16S rRNA gene sequence-based tree containing all current *Streptomyces* species is shown in ❯ *Fig. 42.1* showing a similar clustering to the previously published tree (Kämpfer 2012). A comprehensive study based on nearly full-length 16S rRNA gene sequences was currently also performed by Labeda et al. (2012). Within this study 130 clades were defined based on clustering of species in a phylogenetic trees calculated with the neighbor-joining method. Clades defined by Labeda et al. are also listed in ❯ *Table 42.2*. Each clade represented a cluster of species, which was supported by high bootstrap value (>60 %). A comparison with phylogenetic trees calculated with different treeing methods showed that 106 of the clades were confirmed in phylogenetic trees generated with the maximum-parsimony and maximum-likelihood treeing methods but the relationship among the defined clades changed dependent on the treeing methods used. This illustrated the limited resolution of the 16S rRNA gene sequence-based analysis for species delineation within the *Streptomycetaceae*. The variations within the 16S rRNA genes—even in the variable regions—are too small to

resolve problems of species differentiation and to establish taxonomic structure within the genus (Witt and Stackebrandt 1990; Stackebrandt et al. 1991, 1992; Andersen and Wellington 2001). The fact that *Streptomyces* species may harbor different 16S rRNA gene sets causes further difficulties. For example, *S. coelicolor* A3(2), *S. lividans*, and several other *Streptomyces* species contain six ribosomal rRNA gene sets, whereby each set of rRNA genes includes one gene copy for 5S, 16S, and 23S rRNA (van Wezel et al. 1991) and lacks tRNA genes. So far, phylogenetic analysis based on 16S rRNA genes and resulting clustering may be the basis for further studies of highly similar species to reexamine or evaluate species delineation within the *Streptomycetaceae*. Comprehensive comparative studies of closely related species including DNA-DNA hybridization studies, investigation of protein-coding gene sequences with higher phylogenetic resolution, or even comparison based on core genomes are needed to clarify the species delineation within the *Streptomycetaceae*.

Next to rRNA genes, single protein-coding genes with a higher phylogenetic resolution were used to establish inter- and intraspecies level relationships within the genus. Hatano et al. (2003) studied the partial sequences of the *gyrB* gene of 64 whorl-forming streptomycetes. The *gyrB* gene encodes the B-subunit of DNA gyrase. Most members of the 46 species, eight subspecies, and 13 invalidly published species (including 10 strains studied by the International *Streptomyces* Project [ISP]) examined were assigned to two major groups. The larger group, which contained typical whorl-forming species (59 strains), was further subdivided into six major clusters of three or more species, seven minor clusters of two species, and five single-member clusters at the 97 % *gyrB* sequence similarity level. The major clusters included *S. abikoensis*, *S. cinnamoneus*, *S. distallicus*, *S. griseocarneus*, *S. hiroshimensis*, and *S. netropsis* strains, results that were consistent with previous data from phenotypic analyses. Members within each major and minor cluster proved to be very similar, with the exception of the *S. netropsis* cluster (which was phenotypically divided into the *S. netropsis* and *S. eurocidicus* subclusters) and the *S. distallicus* cluster (which was divided into the *S. distallicus* and *S. stramineus* subclusters). In addition to the cluster assignment, Hatano et al. classified these 59 strains of typical whorl-forming *Streptomyces* species into the following 18 species (including subjective synonym(s)): *S. abikoensis*, *S. ardus*, *S. blastmyceticus*, *S. cinnamoneus*, *S. eurocidicus*, *S. griseocarneus*, *S. hiroshimensis*, *Streptomyces lilacinus*, *S. luteoreticuli*, *S. luteosporeus*, *S. mashuensis*, *S. mobaraensis*, *S. morookaense*, *S. netropsis*, *S. orinoci*, *S. stramineus*, *S. thioluteus*, and *S. viridiflavus* (Table 42.2). All of the strains, which displayed 98.5–100 % *gyrB* sequence similarities, had also high DNA-DNA similarities (70–100 %), suggesting that *gyrB* sequences give a better resolution than corresponding 16S rRNA gene sequences.

By sequencing the RNA polymerase ß-subunit genes (*rpoB*) and 16S rRNA genes of 57 *Streptomyces* strains, five *Kitasatospora* strains, and a single *Micromonospora* strain, Kim et al. (2004) found that the resulting phylogenetic trees had similar topologies. Moreover, they found good concordance between the *rpoB* sequence and corresponding numerical phenetic data of Williams et al. (1983a). In the *rpoB* gene tree, the five *Kitasatospora* strains were clearly separated from the *Streptomyces* strains. These results illustrate that sequence analysis of additional genes (i.e., other housekeeping genes) will help to give a better insight into the intraspecific structure of the genus *Streptomyces* (Stackebrandt et al. 2002).

Beside 16S rRNA gene or single protein-coding gene phylogenies, multilocus sequence analysis (MLSA) was introduced in prokaryotic taxonomy because multilocus protein-coding gene sequence studies enable a higher phylogenetic resolution among species within genera or among closely related genera (Stackebrandt et al. 2002; Tindall et al. 2010). In MLSA studies approximately six to ten partial sequences of protein-coding genes, mainly conserved housekeeping genes, are used for phylogenetic studies. Single gene tree phylogenies and mainly concatenated sequence phylogenies are analyzed and, compared to the 16S rRNA gene-based phylogeny, reveal most often a higher and more stable phylogenetic resolution within a genus or closely related genera. MLSA schemes can be applied for the differentiation of prokaryotic species but have to be validated by DNA-DNA hybridization experiments (Tindall et al. 2010). Guo et al. (2008) established an MLSA scheme for the genus *Streptomyces* including partial sequences of the 16S rRNA gene and five housekeeping genes, the ATP-synthase F1 b-subunit (*atpD*), the DNA gyraseB subunit (*gyrB*), the recombinase A (*recA*), the RNA polymerase b-subunit (*rpoB*), and the tryptophan synthase b-subunit (*trpB*). With exception of the primers for *gyrB* (Hatano et al. 2003), all primers for amplification and sequencing of partial gene sequences were designed by Guo et al. based on full-length gene sequences of genome sequenced *Streptomyces* strains. The MLSA scheme was first supplied to study 45 valid species and subspecies of the *Streptomyces griseus* 16S rRNA gene clade. Guo et al. showed that all protein-coding gene sequences had a higher number of variable sides among the investigated strains (up to 48 % for the partial *gyrB* sequence) compared to the nearly full-length 16S rRNA gene (15.5 %). Several of the investigated species were assigned to four clusters, which included type strains with identical 16S rRNA gene sequences. Some of the strains with identical 16S rRNA gene sequences were assigned to different clusters, when phylogenetic trees were constructed based on the housekeeping gene sequences (clusters shown in Table 42.2). The trees based on individual gene sequences gave a slightly different resolution between strains compared to the tree based on concatenated sequences. It was concluded by the authors that phylogenetic trees generated on more than one gene sequence are more reliable and have a higher resolution power and topological stability. The study of the *S. griseus* 16S rRNA gene clade was enlarged by the inclusion of 18 more species in a subsequent study performed by Rong and Huang (2010). Again type strains that shared identical 16S rRNA gene sequences were grouped together, and single and concatenated protein-coding gene sequence phylogenies showed a higher resolution with differences in cluster formation (see Table 42.2). Including DNA-DNA hybridization values and phenotypic data, Rong and Huang (2010)

proposed the combination of 29 species and three subspecies of the *S. griseus* 16S rRNA gene clade as 11 genomic species; *S. griseinus* and *S. mediolani* were reclassified as later heterotypic synonyms of *S. albovinaceus*; *S. praecox* as a later heterotypic synonym of *S. anulatus*; *S. olivoviridis* as a later synonym of *S. atroolivaceus*; *S. griseobrunneus* as a later heterotypic synonym *of S. bacillaris*; *S.cavourensis* subsp. *washingtonensis* as a later heterotypic synonym of *S. cyaneofuscatus*; *S.acrimycini*, *S. baarnensis*, *S. caviscabies*, and *S. flavofuscus* as later heterotypic synonyms of *S. fimicarius*; *S. flavogriseus* as a later heterotypic synonym of *S. flavovirens*; *S. erumpens*, *S. ornatus*, and *S. setonii* as later heterotypic synonyms of *S. griseus*; *S. graminofaciens* as a heterotypic synonym of *S. halstedii*; *S. alboviridis*, *S. griseus* subsp. *alpha*, *S. griseus* subsp. *cretosus*, and *S. luridiscabiei* as later heterotypic synonyms of *S. microflavus*; and *S. californicus* and *S. floridae* as later heterotypic synonyms of *S. puniceus*.

Similar to the studies of Rong and Huang (2010), the MLSA scheme of Guo et al. was used in combination with DNA-DNA hybridization studies to reclassify the *Streptomyces albidoflavus* 16S rRNA gene clade (Rong et al. 2009). Within that study ten species and subspecies were reclassified as heterotypic synonyms of *S. albidoflavus* including *S. canescens*, *S. champavatii*, *S. coelicolor*, *S. felleus*, *S. globisporus* subsp. *caucasicus*, *S. griseus* subsp. *solvifaciens*, *S. limosus*, *S. odorifer*, and *S. sampsonii*.

Rong and Huang (2012) used the MLSA scheme to investigate the *S. hygroscopicus* 16S rRNA gene clade including *S. violaceusniger* and related species as well as five valid subspecies of the species *S. hydroscopicus*. In all, 58 species and subspecies were included in the study. Based on 16S rRNA gene sequence phylogenetic analysis, the authors grouped the investigated species into 13 clusters (I–XIII; see *Table 42.2*), which were supported by high bootstrap values. Similar to the previous studies, the 16S rRNA gene clusters were compared to clusters obtained by phylogenetic analysis based on concatenated protein-coding gene analysis. Again MLSA showed differences in clustering with higher phylogenetic resolution compared to that obtained by 16S rRNA gene-based analysis. Based on MLSA, DDH, and phenotypic data, 18 species and two subspecies were proposed to be heterotypic synonyms of eight genomic species; *S. luteoverticillatus* was reclassified as later heterotypic synonym of *S. ehimensis*; *S. demainii*, *S. endus*, and *S. sporocinereus* as heterotypic synonyms of *S. hygroscopicus* subsp. *hygroscopicus*; *S. yogyakartensis* as later heterotypic synonym of *S. javensis*; *S. libani* subsp. *libani* as later heterotypic synonym of *S. nigrescens*; *S. olivaceiscleroticus* as later heterotypic synonym of *S. niger*; *S. aureoversilis* as later heterotypic synonym of *S. rectiverticillatus*; *S. asiaticus*, *S. cangkringensis*, and *S. indonesiensis* as later heterotypic synonyms of *S. rhizosphaericus*; and *S. antimycoticus* and *S. sporoclivatus* as later heterotypic synonyms of *S. castelarensis*. In addition the two *S. hydroscopicus* subspecies *S. hydroscopicus* subsp. *globosus* and *S. hydroscopicus* subsp. *oassamyceticus* were reclassified to two separate species, *S. globosus* and *S. oassamyceticus*. Both clustered in different clusters determined by the MLSA phylogenetic analysis.

Based on the correlation of MLSA and DNA-DNA hybridization studies including data for the *S. griseus* (Rong and Huang 2010), the *S. albidoflavus* (Rong et al. 2009), and the *S. hydroscopicus* 16S rRNA gene clade (Rong and Huang 2012), Rong and Huang (2012) proposed an MLSA-based species cut-off value for the species *Streptomyces*. A five gene MLSA evolutionary distance of 0.007 showed a good correlation with the 70 % DDH values as species threshold. The authors illustrated that in contrast to the concatenated data, none of the single gene-based evolutionary distances showed a good correlation to the DDH values indicating the single gene tree phylogenies may not be sufficiently reliable to resolve *Streptomyces* species and do not have the power for species delineation.

The five-gene-based MLSA scheme of Guo et al. (2008) was furthermore applied by Labeda (2011) for the investigation of 10 phytopathogenic *Streptomyces* species including *S. scabiei*, *S. acidiscabies*, *S. europaeiscabiei*, *S. luridiscabiei*, *S. niveiscabiei*, *S. puniciscabiei*, *S. reticuliscabiei*, *S. stelliscabiei*, *S. turgidiscabies*, and *S. ipomoeae*, and an additional 52 species of which 19 species were closely related to the phytopathogenic species based on 16S rRNA gene analysis. The application of the MLSA scheme enabled a better and more reliable phylogenetic resolution of the investigated species. Reclassifications were not performed within that study.

Labeda et al. (2012) gave some examples illustrating the application of the MLSA scheme developed by Guo et al. 2008 where the uncertain affiliation of *Streptomyces* species obtained by 16S rRNA gene sequence-based analysis was resolved more clearly. For example, the stable 16S rRNA clade 112 contained species, which were proposed as heterotypic synonyms of *Streptomyces albidoflavus* by Rong et al. (2009), including *S. canescens*, *S. champavatii*, *S. coelicolor*, *Streptomyces felleus*, *S. globisporus* subsp. *caucasicus*, *S. griseus* subsp. *solvifaciens*, *S. limosus*, *Streptomyces odorifer*, and *S. sampsonii*. Here, the MLSA studies confirmed the high phylogenetic similarity obtained by 16S rRNA gene sequence analysis and supported the reclassification of species as heterotypic synonyms. In contrast, MLSA data confirmed the clustering of *S. reticuliscabiei* and *S. turbiscabiei* (Labeda clade 22), but based on single housekeeping gene sequence-based analysis (*atpD* and *trpB*), the species could clearly be distinguished as it was proposed earlier (Bouchek-Mechiche et al. 2006). With those and further examples, Labeda et al. clearly demonstrated that MLSA data could help to resolve the phylogenetic resolution within the genus *Streptomyces*.

Furthermore the study of Han et al. (2012) also showed that the application of the MLSA scheme of Guo et al. (2008) helped to distinguish species of the genera *Streptomyces*, *Kitasatospora*, and *Streptacidiphilus*. The phylogenetic tree based on concatenated protein-coding gene sequences revealed the formation of two distinct separate clusters including *Kitasatospora* and *Streptacidiphilus* species, respectively. However, single-gene-based phylogenies did not fully support the separation of the three genera. In all, 33 *Streptomyces*, 10 *Kitasatospora*, and 9 *Streptacidiphilus* type strains were investigated in that study. One result obtained was that *S. xanthocidcus* clustered within the *Kitasatospora* cluster, which was also confirmed by the

phylogenetic analysis performed in parallel based on concatenated sequence of ribosomal genes including the 5S, 16S, and 23S rRNA gene. Based on those data Han et al. proposed the transfer of this *Streptomyces* species to the genus *Kitasatospora*.

All current data indicated that the application of the MLSA scheme of Guo et al. (2008) enables a better phylogenetic resolution within the *Streptomycetaceae* compared to the 16S rRNA gene sequence phylogeny and is promising to replace DDH studies. However, MLSA studies should be treated with care because the resolution of the concatenated sequence base tree is strongly affected by single genes included in the analysis. MLSA studies are performed based on nucleotide sequences, and differences among closely related *Streptomyces* species are often based on synonymous substitutions of the third codon position, which may lead to an overestimation of the phylogenetic resolution. Therefore it is recommended to include a comparison of respective protein sequences because the amino acid sequences are considered to be a more reliable and stable indicator of phylogenetic relationships, since the function of proteins is closely tied to their primary sequences, and the pressure of selection only works at the protein level (Kämpfer and Glaeser 2012). Furthermore interpretations of MLSA studies based on different single gene-based affiliations within the *Streptomycetaceae* need to acknowledge that *Streptomyces* species are strongly affected by homologous recombination events and horizontal gene transfer, which may negatively impact on MLSA results (Doroghazi and Buckley 2010). In the current era of high throughput sequencing, the comparison of (partial) genome sequence data, e.g., by calculating and comparing average nucleotide identity (ANI) values, will be more promising to resolve the phylogenetic relationships of closely related *Streptomyces* species in future studies.

Rapid Methods for Gene Analysis in *Streptomycete* Taxonomy

Various alternative methods for gene analysis have been described which do not require sequencing. These methods involve either restriction analysis (Clarke et al. 1993; Fulton et al. 1995) or specialized gel electrophoresis techniques, which are used to examine the mobility of products (Hain et al. 1997; Heuer et al. 1997). Clarke et al. (1993) used a combination of several restriction enzymes, including *Bgl*I, *Eco*RI, *Pst*I, and *Pvu*II, to obtain restriction fragment length polymorphism (RFLP) patterns of purified rRNA extracted from members of the *Streptomyces albidoflavus* cluster (subgroups 1A and 1B of Williams et al. (1983a)). By using this approach they were able to differentiate between phenotypically similar strains, even though profiles differed considerably between *S. albidoflavus* species groups. Fulton et al. (1995) used *Mse*I fingerprints of rRNA operons (RiDiTS) for ribosomal restriction analysis of 98 named streptomycete strains, including members of cluster groups A (comprising clusters 1–41) and F (comprising clusters 55–67) of Williams et al. (1983a) as well as some other strains, which resulted in 11 pattern types with varying degrees of similarity to the Williams subclusters. Cluster groups A and F were discriminated although at a low resolution (70 % similarity), but individual clusters could not be.

Other techniques used to evaluate genotypic variation between streptomycetes include denaturing gradient gel electrophoresis (DGGE; Muyzer et al. 1993) with or without DNA-binding agents (Hain et al. 1997). Anderson and Wellington (2001) recommended DGGE in combination with other techniques. By using variable 16S rRNA regions, this method enables the differentiation of genus and species groups. Isolates ASB33, ASB37, and ASSF22 were assigned to *S. albidoflavus*, *S. griseoruber*, and *S. albidoflavus*, respectively, by using a combination of methods, including sequence comparisons, PFGE, and numerical taxonomy (Huddleston et al. 1995, 1997).

Phage Typing

Phage typing can be used for host identification at the genus and the species levels (Welsch et al. 1957; Kutzner 1961a, b; Korn et al. 1978; Wellington and Williams 1981a). For streptomycetes, two different groups of phages exist, in particular polyvalent phages (e.g., ϕC31; Chater et al. 1986) and species-specific phages (Andersen and Wellington 2001; ❯ *Table 42.3*). Several actinophages, mainly virulent, have been used for phage typing and are specific at the genus level (e.g., Wellington and Williams 1981a; Korn-Wendisch 1982; Prauser 1984). Actinophage host range studies helped to substantiate the transfer of the genera *Actinopycnidium*, *Actinosporangium*, *Chainia*, *Elytrosporangium*, *Microellobosporia*, *Kitasatoa*, and *Streptoverticillium* to the genus *Streptomyces* (Goodfellow et al. 1986a, b, c, d; Witt and Stackebrandt 1990). Likewise, other studies supported the transfer of *Actinoplanes armeniacus* to the genus *Streptomyces* (Kroppenstedt et al. 1981; Wellington and Williams 1981b) and *Streptomyces erythraeus* to the genus *Saccharopolyspora* (Labeda 1987). Phage typing has been shown to be less useful for species or group identification of *Streptomyces*; nevertheless, there are a few exceptions (❯ *Table 42.3*).

Phages are widely used in genetic studies (see Chater 1986) and in industrial microbiology (Carvajal 1953; Ogata 1980), as illustrated in chapter 12 of Kieser et al. (2000). The temperate phage, ϕC31, has a broad host range within the genus *Streptomyces* and is one of the best-investigated temperate actinophages (Lomovskaya et al. 1980). This phage has been employed for various purposes (e.g., transfection, transduction, detection of transposon-like elements of host DNA, and cloning); details can be found in chapter 12 of Kieser et al. (2000).

Protein Profiling

Total protein extracts can be analyzed by polyacrylamide gel electrophoresis (PAGE), resulting in more or less complex banding patterns. These patterns have been used to elucidate relationships between species and subspecies level of various bacterial genera. By using one-dimensional (1-D) and

[b]Clusters according to Kämpfer et al. (1991)

two-dimensional (2-D) protein electrophoresis, it is possible to determine such protein patterns. Manchester et al. (1990) used one-dimensional protein electrophoresis to analyze 37 *Streptomyces* strains, including 5 streptoverticillia, and observed some taxonomic correlations between the resulting profiles, groups established on phenotypes (Williams et al. 1983a; Kämpfer et al. 1991), and DNA hybridization data (*Table 42.2*). Nevertheless, only few of these correlations were confirmed by Lanoot et al. (2002).

A combination of PAGE and DNA-DNA hybridization was used to clarify the taxonomy of *Streptomyces* isolates that caused common potato scab (Paradis et al. 1994). By sodium dodecylsulfate (SDS)-PAGE analysis, the isolates could be assigned to two groups with a correlation coefficient of 0.75. The same groups were recovered by DNA-DNA hybridization, but not in the corresponding fatty acid analysis. This lack of correlation is due to the influence of growth conditions on fatty acid profiles (Saddler et al. 1986, 1987). Protein profiling does not allow the discrimination of pathogenic and nonpathogenic *Streptomyces* strains. Lanoot et al. (2002) used SDS-PAGE of whole-cell proteins in a study of 93 *Streptomyces* reference strains. Twenty-four clusters were established by subsequent computer-assisted numerical analysis and included strains with very similar protein profiles. Several type strains were assigned to five clusters, which had visually identical patterns. DNA-DNA hybridizations of these type strains displayed similarities higher than 70 %. Based on these results, *Streptomyces albosporeus* subsp. *albosporeus* LMG 19403^T was considered to be a subjective synonym of *Streptomyces aurantiacus* LMG 19358^T, *Streptomyces aminophilus* LMG 19319^T a subjective synonym of *Streptomyces cacaoi* subsp. *cacaoi* LMG 19320^T, *Streptomyces niveus* LMG 19395^T and *Streptomyces spheroides* LMG 19392^T subjective synonyms of *Streptomyces caeruleus* LMG 19399^T, and *Streptomyces violatus* LMG 19397^T a subjective synonym of *Streptomyces violaceus* LMG 19360^T (*Table 42.2*).

Two-dimensional PAGE of the total cellular proteins provides greater resolution than one-dimensional analysis. Very complex patterns can be obtained with 2-D PAGE, yet this method seems to be too sensitive to discriminate between proteins with high rates of evolution (Hori and Osawa 1987). 2-D PAGE studies designed to differentiate between ribosomal proteins of streptomycetes were first described by Mikulik et al. (1982) and later Ochi (1989). Hence, ribosomal AT-L30 proteins were found to give genus-specific profiles (Ochi 1992), whereas analyses of the N-terminal sequences of the AT-L30 protein allowed the assignment of streptomycete strains to different taxonomic groups (Ochi 1995). These groups were classified to phylogenetic groupings which suggested that the genus *Streptomyces* was well described. However, no correlation was found between Ochi's groupings and earlier established numerical phenetic groups (Williams et al. 1983a; Kämpfer et al. 1991). Details of these groupings are presented in *Table 42.2*.

Multilocus enzyme electrophoresis (MLEE) is based on the relative mobilities of cellular enzymes in a gel matrix. MLEE produces more specific patterns when compared to protein profiling. For instance, inter- and intraspecific characterization of 24 *Streptomyces* strains was achieved in a small study, when the appropriate enzymes were used (Oh et al. 1996).

The isolation and sequencing of specific proteins resulted in more detailed taxonomic studies of some *Streptomyces*. For example, the *Streptomyces* subtilisin inhibitor protein (SSI),

which plays a role in development (reviewed by Chater et al. (2010)), was used by Taguchi et al. (1996) to clarify the taxonomic status of *S. lividans* 66, *S. coelicolor* Müller ISP 5233^T, and *S. coelicolor* A3(2). Alignments of the SSI sequences supported the results of ribosomal sequence comparisons indicating that *S. coelicolor* A3(2) is more closely related to *S. lividans* 66 (cluster 21 of Williams et al. (1983a)) than to the type strain, *S. coelicolor* Müller ISP 5233^T (cluster 1).

Phenotypic Analyses

Genus *Streptomyces* Waksman and Henrici 1943, 339^{AL} emend. Witt and Stackebrandt 1990, 370 emend. Wellington, Stackebrandt, Sanders, Wolstrup and Jorgensen, 1992, 159

Strep.to.my'ces. Gr. adj. *streptos*, pliant, bent; Gr. n. *myces*, fungus; M.L. masc. n. fungus. *Streptomyces*, pliant or bent fungus[1].

The type species is *Streptomyces albus* (Rossi-Doria 1891) Waksman and Henrici 1943, 339. *Streptomyces* are Gram-positive, aerobic, non-acid-fast bacteria, which form extensively branched substrate and aerial mycelia. They are chemoorganotrophic with an oxidative type of metabolism. The vegetative hyphae, with a diameter of 0.5–2.0 μm, rarely fragment. At maturity the aerial mycelium generates chains of three to many spores. Some species form short chains of spores on the substrate mycelium and others have pycnidial-, sclerotia-, sporangia-, and synnemata-like structures. The spores are nonmotile. Frequently, colonies initially have a smooth surface but later develop a weft of aerial mycelium that may appear floccose, granular, powdery, or velvety. Colonies are discrete and lichenoid, leathery, or butyrous. *Streptomyces* produce a wide range of pigments responsible for the color of the vegetative and aerial mycelia. Additionally, colored diffusible pigments may be generated. Many strains are able to produce one or more antibiotic substances.

The optimal growth temperature for most species lies in the range of 25–35 °C. However, some species can grow at temperatures within the psychrophilic and thermophilic range. The optimum pH range for growth is between 6.5 and 8.0. They are widely distributed and abundant in soil, including composts. A few species are phytopathogens; a few others are pathogenic for humans and animals. *Streptomyces* are catalase positive. They usually degrade polymeric substrates such as casein, gelatin, hypoxanthine, and starch in addition to adenine and L-tyrosine and reduce nitrates to nitrites. Most species utilize a variety of organic compounds as sole carbon sources for energy and growth. The cell wall peptidoglycan contains major quantities of LL-diaminopimelic acid (L-A_2pm). Sometimes, low amounts of *meso*-diaminopimelic acid (*meso*-A_2pm) are present. The lipid profile contains major amounts of saturated, *iso*- and *anteiso*-fatty acids but lacks mycolic acids. In addition, they typically possess either hexa- or octa-hydrogenated menaquinones with nine isoprene units as the predominant isoprenolog, but menaquinones with eight and ten isoprene units are also found. A complex polar lipid pattern normally contains diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylinositol, and phosphatidylinositol mannosides. The mol% G+C content of the DNA lies between 69 and 78 (T_m).

[1] AL denotes the inclusion of this name on the Approved Lists of Bacterial Names (1980).

Differentiation of the Genus *Streptomyces* from Other Genera

Unknown actinomycetes are generally assigned to genera based on 16S rRNA gene sequence analyses. However, it may turn out to be problematic, especially in the case of *streptomyces*, to distinguish between species by using this approach (e.g., Stackebrandt et al. 1991, 1992; Kumar & Goodfellow 2002).

Members of the genus *Streptomyces* can usually be differentiated from other filamentous actinomycetes by their colony morphology (*Tables 42.4* and *42.5*), notably by substrate mycelium, aerial spore mass, and soluble pigment colors. Traditional methods highly recommended for this purpose are described by Korn-Wendisch and Kutzner (1992). A computer-assisted numerical analysis on the basis of the color-grouping method of Williams et al. (1969) was used by Antony-Babu et al. (2010) to group 321 alkaliphilic streptomycetes grown on

Table 42.5

	S. galbus (40089); *S. tendae* (40101)

[a]DSM no. 40XXX = ISP no. 5 XXX

oatmeal agar (ISP 3) and peptone-yeast extract-iron agar (ISP medium 6). Using this approach, large numbers of streptomycetes can be assigned without using polyphasic taxonomic approaches.

Furthermore, *streptomyces* can often be distinguished from other filamentous actinomycetes on the basis of morphological characteristics, in particular by vegetative mycelium, aerial mycelium, and arthrospores (◗ *Figs. 42.2*–◗ *42.6*). Detailed information on the procedure used to determine such properties can be found in Korn-Wendisch and Kutzner (1992) and chapter 3 of Kieser et al. (2000). Members of the genus *Streptomyces* can also be differentiated from related taxa using chemotaxonomic methods (Lechevalier and Lechevalier 1970b). Streptomycetes typically produce major quantities of *iso*- and *anteiso*-methyl-branched fatty acids (Kroppenstedt 1985); they lack mycolic acids and contain LL-A_2pm in cell wall or whole-cell hydrolysates (Lechevalier and Lechevalier 1970b, c) (◗ *Table 42.1*). Major menaquinones are hexa- and octa-hydrogenated menaquinones with nine isoprene units (Kim et al. 2003). A major chemotaxonomic feature for the differentiation of *Streptomyces* from *Kitasatospora* is the presence of *meso*-A_2pm in whole-cell hydrolysates (◗ *Table 42.1*). In *Streptomyces* strains, the *meso*-A_2pm content is 1–16 %, while in *Kitasatospora* strains it is 49–89 % (Zhang et al. 1997). The predominant diamino acid of strains belonging to the genus *Streptacidophilus* is (like in *Streptomyces*) LL-diaminopimelic acid (Kim et al. 2003).

Genus *Kitasatospora* Ōmura Takahashi, Iwai, and Tanaka 1983, 672[VP]: Genera Incertae Sedis

(Ki.ta.sa.to.spo'ra. Jpn. n. Kitasato, a Japanese bacteriologist (1852–1931); M. L. fem. n. *spora* spore; M. L. fem. n. *Kitasatospora*, Kitasato spore).

The type species of the genus is *Kitasatospora setae* Ōmura, Takahashi, Iwai, and Tanaka 1982. They are Gram-positive, aerobic, non-acid-alcohol-fast actinomycetes which form an intensively branched, non-fragmenting mycelium. They form a stable substrate mycelium similar to that of *Streptomyces*, and the aerial mycelium generates long spore chains of more than 20 spores. They do not form sporangia. Organisms are chemoorganotrophic and grow from 15 °C to 42 °C and within the pH range of 5.5 to 9.0. Depending on the type of cells analyzed, the major constituents of the cell wall are galactose, glycine, and *meso*-A_2pm or LL-A_2pm. When cells are grown in liquid media, submerged spores which contain LL-A_2pm are formed, while the filamentous mycelia contain *meso*-A_2pm. When cells are grown on agar media, the substrate mycelium contains *meso*-A_2pm, whereas aerial spores contain LL-A_2pm. Whole-cell hydrolysates contain galactose but lack arabinose, madurose, and xylose. Cells generate large amounts of saturated, *iso*- and *anteiso*-fatty acids and have complex polar lipid patterns, which contain diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylinositol, and phosphatidylinositol mannosides. The predominant isoprenologues are hexa- and octa-hydrogenated menaquinones with nine isoprene units are. The glycolate test is negative. The mol% G+C content is between 66 and 73 (T_m).

Differentiation of the Genus *Kitasatosporia* from Other Genera

Despite some differences, members of the family *Streptomycetaceae* are morphologically and chemically homogeneous (◗ *Table 42.1*). Identification of most species is problematic, because in many cases only one (the type) or a few strains have been examined. *Kitasatospora* species may be differentiated from other genera in the family by slight differences in cell wall sugars and the presence of *meso*-A_2pm in the peptidoglycan (◗ *Table 42.1*). ◗ *Table 42.6* lists some phenotypic features, which can be used to distinguish between *Kitasatospora* species.

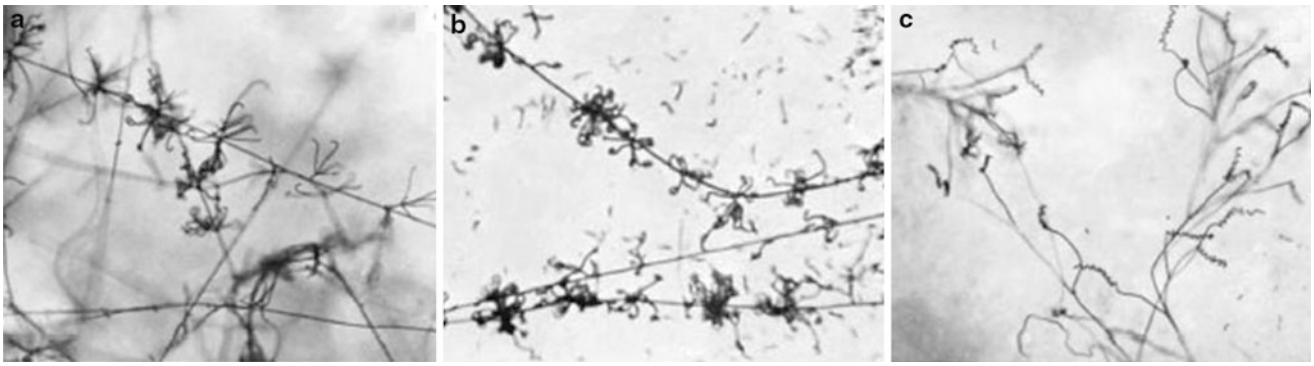

Fig. 42.2
Morphology of the aerial mycelium of three streptomycetes. (a) A *Streptoverticillium* species: spore chains arranged in typical verticils along straight, long aerial hyphae; the end of the spore chain is sometimes hook-like or forms one to two turns. (b) "*Streptomyces pallidus*": despite the verticil-like arrangement of spore chains, this organism was described as *Streptomyces* by Shirling and Gottlieb (1972). (c) A *Streptomyces* species: sympodially branched aerial hyphae; spore chains form spirals with up to 10 turns. All photos: ×250

Genus *Streptacidiphilus* Kim, Lonsdale, Seong, Goodfellow 2003, 1219^{VP}: Genera Incertae Sedis

Streptacidiphilus (strept.a.ci.di'phi.lus. Gr. adj. *streptos* pliant, twisted; L. neut. n. *acidum* acid; Gr. adj. *philos* loving; N.L. masc. n. *Streptacidiphilus* twisted, acid-loving).

The type strain of the genus is *Streptacidiphilus albus* (Kim et al. 2003). They are Gram-positive, aerobic, non-acid-alcohol-fast actinomycetes that form an intensively branched, non-fragmenting mycelium. At maturity the aerial mycelium bears long spore chains. Discrete leathery or lichenoid colonies are formed. A range of pigments is produced that are responsible for the color of the substrate and aerial mycelium. Colored diffusible pigments may be formed. Organisms are chemoorganotrophic with an oxidative type of metabolism. They utilize a wide range of carbon compounds as sole carbon sources for energy and growth. Most strains grow at temperatures between 15 °C and 30 °C and between pH 3.5 and 6.0 with an optimum around pH 5. They are widely distributed in acidic soil and litter. The major diamino acid in the peptidoglycan layer is LL-diaminopimelic acid. Whole-cell hydrolysates contain major amounts of galactose and rhamnose. Hexa- and octahydrogenated menaquinones with nine isoprene units are the predominant isoprenologues. Cells are rich in saturated, *iso*- and *anteiso*-fatty acids and produce complex polar lipid patterns that contain diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylinositol, and phosphatidylinositol mannosides. The mol% G+C of the DNA is 70–72. Phenotypic characteristics that differentiated *Streptacidiphilus* species among each other are listed in ❯ *Table 42.7*.

Differentiation of the Genus *Streptacidiphilus* from Other Genera

Members of the family *Streptomycetaceae* are morphologically and chemically homogeneous (❯ *Table 42.1*). In addition, identification of most species is difficult because in many instances only one (the type) or a few strains have been studied. *Streptacidiphilus* may be distinguished from the other genera in the family *Streptomycetacae* by slight differences in cell wall peptidoglycan composition and by growth at low pH values, as well as by 16S rRNA gene sequencing and MLSA analysis (❯ *Table 42.1*).

Further Descriptive Information on Streptomycetes

Morphology, Fine Structure, and Life Cycle

Early analyses of streptomycetes were ruled by a strong emphasis on morphology. The complex life cycle of streptomycetes (see below) presents three phenotypic traits for detailed microscopic characterization: (a) vegetative (substrate) mycelium (on solid and in liquid medium), (b) aerial mycelium bearing chains of arthrospores (sometimes called "sporophores") and (c) the arthrospores themselves (Kutzner 1981). Most diagnostic information for taxonomists has been provided by the last two characteristics.

It was pointed out by some early studies that streptomycetes formed spore chains on the vegetative mycelium in both solid and liquid culture (e.g., Carvajal 1947; Glauert and Hopwood 1960; Tresner et al. 1967). At least for one species, *S. venezuelae*, the spores produced in submerged culture have similar characteristics as aerial spores (Glazebrook et al. 1990).

The fine structure and development of the aerial arthrospores have been studied extensively (Locci and Sharples 1984, add recent refs). Aerial arthrospores are formed within a thin fibrous sheath by septation and disarticulation of preexisting hyphal elements. The spore wall is generated, at least in part, from wall layers of the parent hypha. This process is termed *holothallic development* (Locci and Sharples 1984) and was found to be characteristic for many other sporoactinomycetes

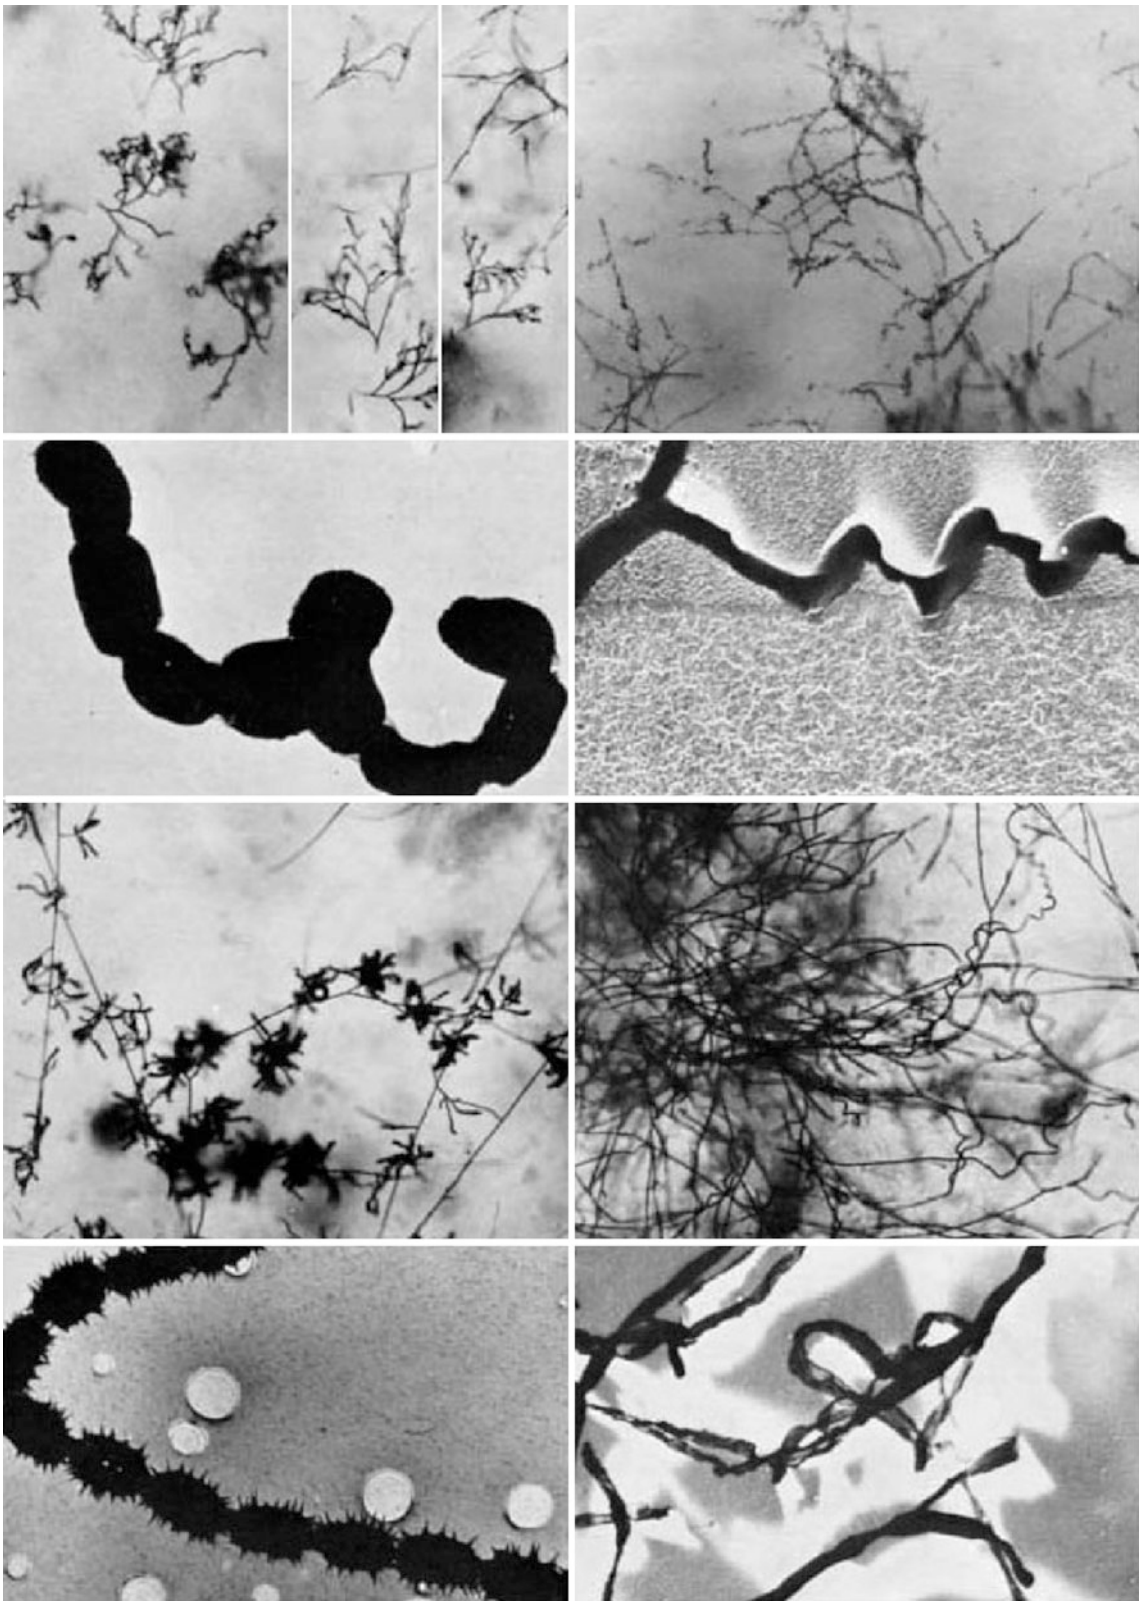

Fig. 42.3
Aerial mycelium of the fertile (*left*) and the sterile (*right*) strain of two streptomycetes. *First and third lines*, light microscopy (@ 250); *second and fourth lines*, electron microscopy (×15,000). (From Kutzner [1956], with permission.)

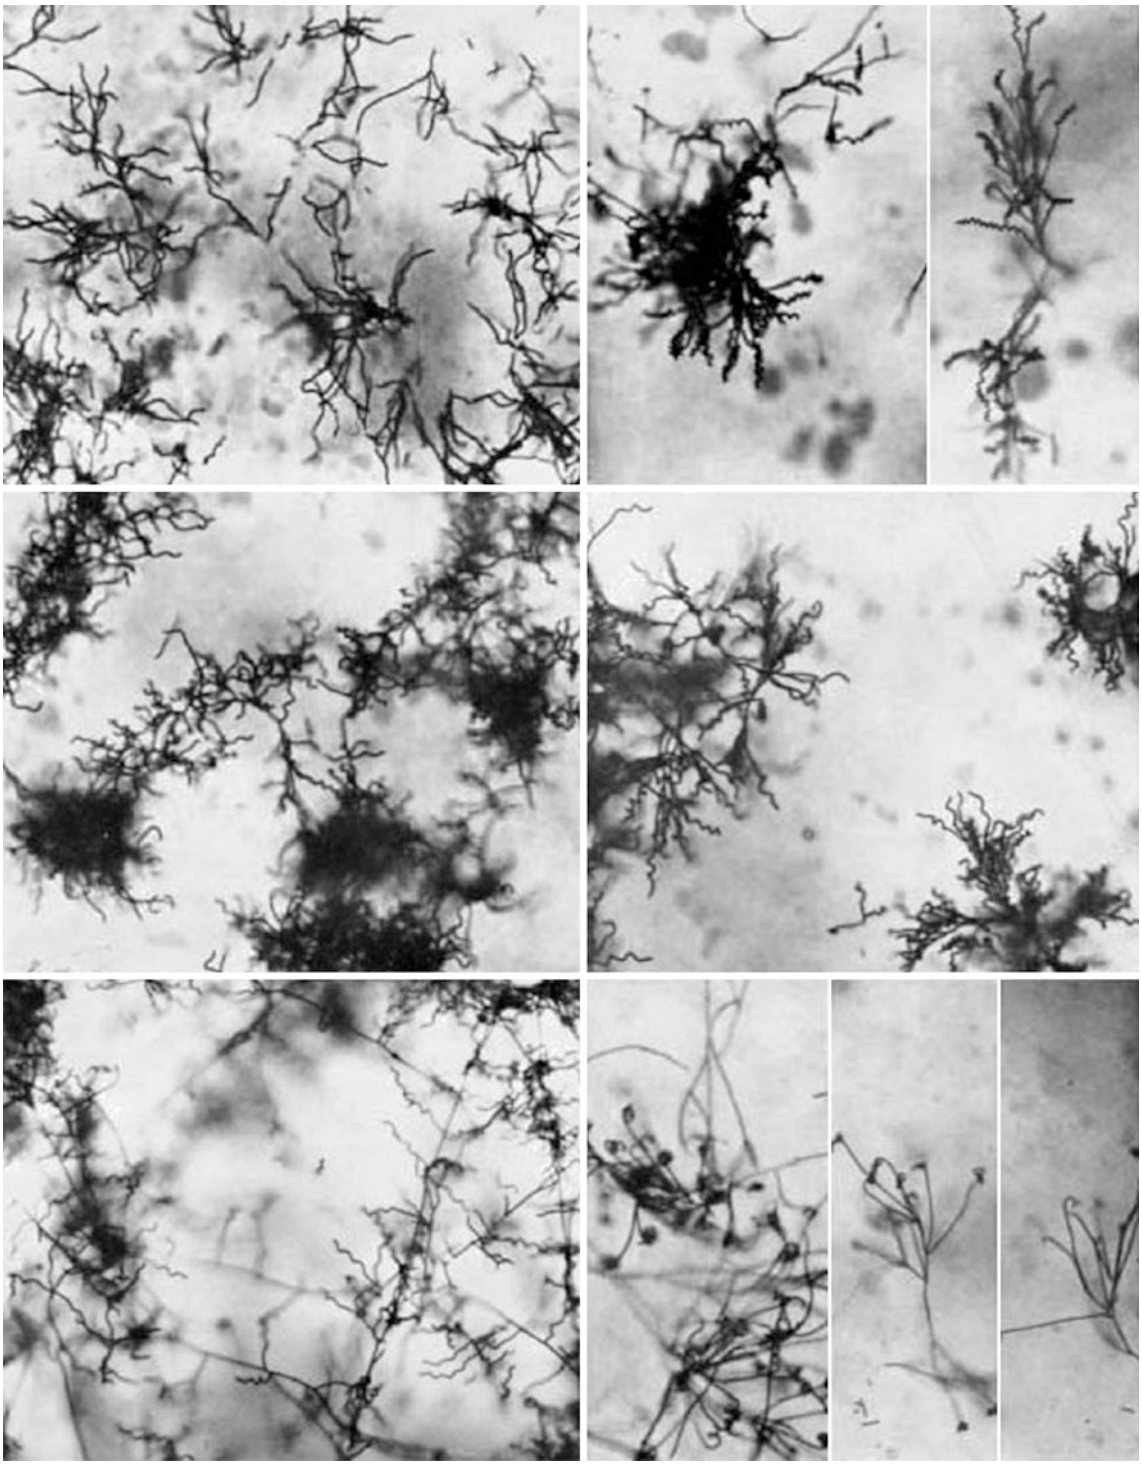

Fig. 42.4
Morphology of the aerial mycelium of some strains of *Streptomyces* (×250). (From Flaig and Kutzner [1960b], with permission.)

(Williams et al. 1973). The organization of the spore chains (or sporophores) has played a very important role in species descriptions for many years. Frequently, the chains are long and include more than 50 arthrospores. The variety of spore chain morphologies is enormous, and many categories have been established by some scientist: for instance, Ettlinger et al. (1958a) classified strains into 15 morphological types. A simpler and more practical scheme was proposed by Pridham et al. (1958) and adopted for the International *Streptomyces* Project (ISP; Shirling and Gottlieb 1966). There were three categories recognized:

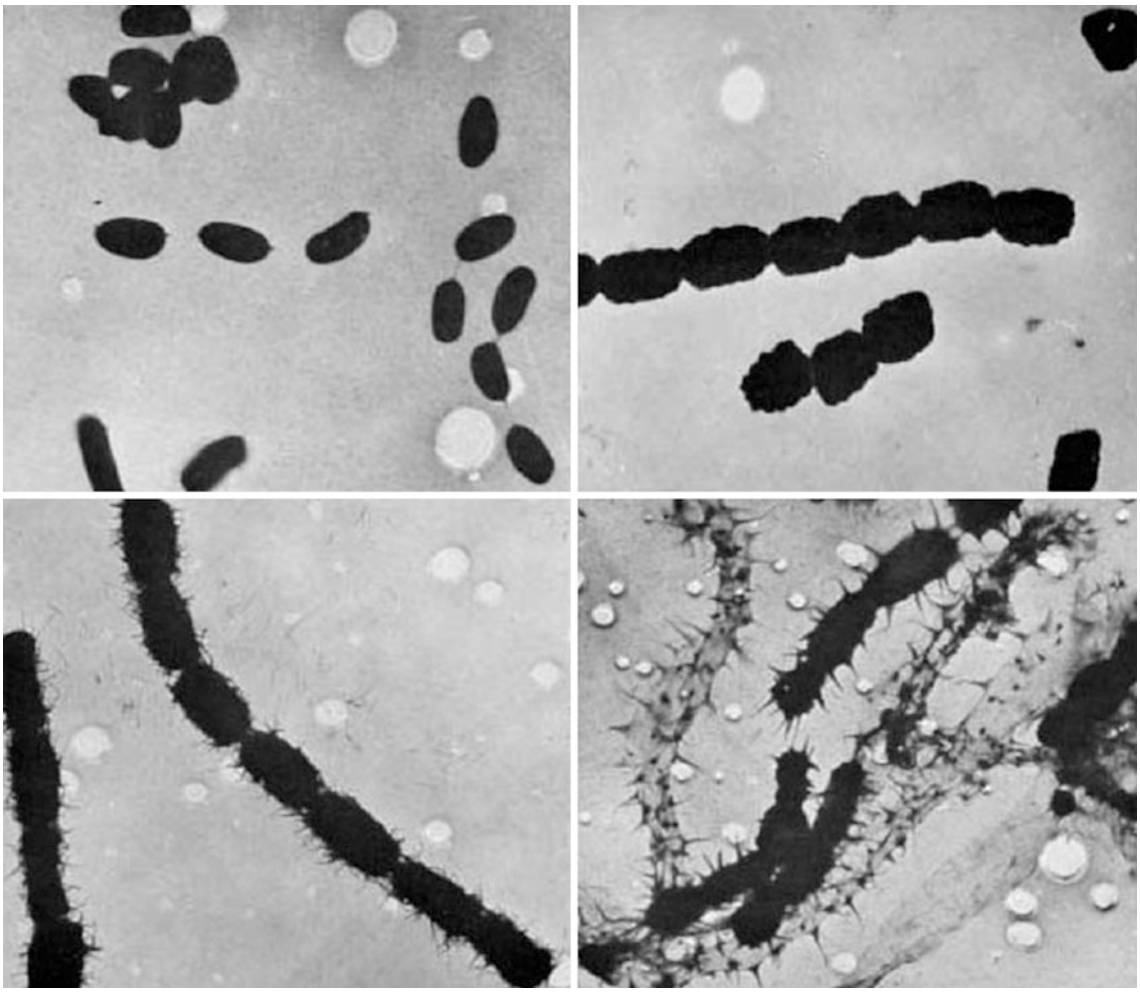

Fig. 42.5
Electron micrographs of four types of arthrospores of streptomycetes: smooth, warty, hairy and spiny. The spores are about 1 m long. (From Kutzner (1956), with permission.)

(a) straight to flexuous (*Rectiflexibiles*); (b) hooks, loops, or spirals with one to two turns (*Retinaculiaperti*) (Fig. 42.2a, b); and (c) spirals (*Spirales*) (Fig. 42.2c). However, it should be considered that even this simple system might cause problems, because it is not unusual that more than one category can be observed in the same culture, and the distinction between *Retinaculiaperti* and *Spirales* is not always clear (Shirling and Gottlieb 1977; Williams and Wellington 1980). Aerial filaments can also differentiate into verticils (Fig. 42.7), which is common for most of the species formerly grouped into the genus *Streptoverticillium* (Locci and Schofield 1989). An overview of different morphological forms of the aerial mycelium of *Streptomyces* and *Streptoverticillium* spp. is depicted in Figs. 42.2–42.4 and Fig. 42.7.

In addition, spore surface ornamentation has also been adopted as a characteristic for taxonomic description. The ornaments, which are in fact borne on the spore sheath, can be clustered into the categories hairy, smooth, warty, hairy, and spiny. A further type, rugose, was proposed by Dietz and Mathews (1971) (Figs. 42.5 and 42.6). Spore surface ornamentation is a stable character, but the differences between smooth, warty, and rugose types can be difficult to distinguish. Nevertheless, these problems can be resolved by using scanning electron microscopy.

Morphological Development

Unusually for a bacterium, *Streptomyces* exhibit a complex multicellular cycle of development and reproduction. Differentiation of the organism into distinct tissues from vegetative mycelium to aerial hyphae bearing spores progresses is depicted in Fig. 42.8 for the model organism *S. coelicolor* A3(2). Induction of germination may be induced by many factors including water, carbon dioxide, amino acids, and vitamins. Under favorable conditions germination begins with swelling of the spore. Spore polarity is established followed by emergence of one or more germ tubes. These grow by tip extension (Gray et al. 1990)

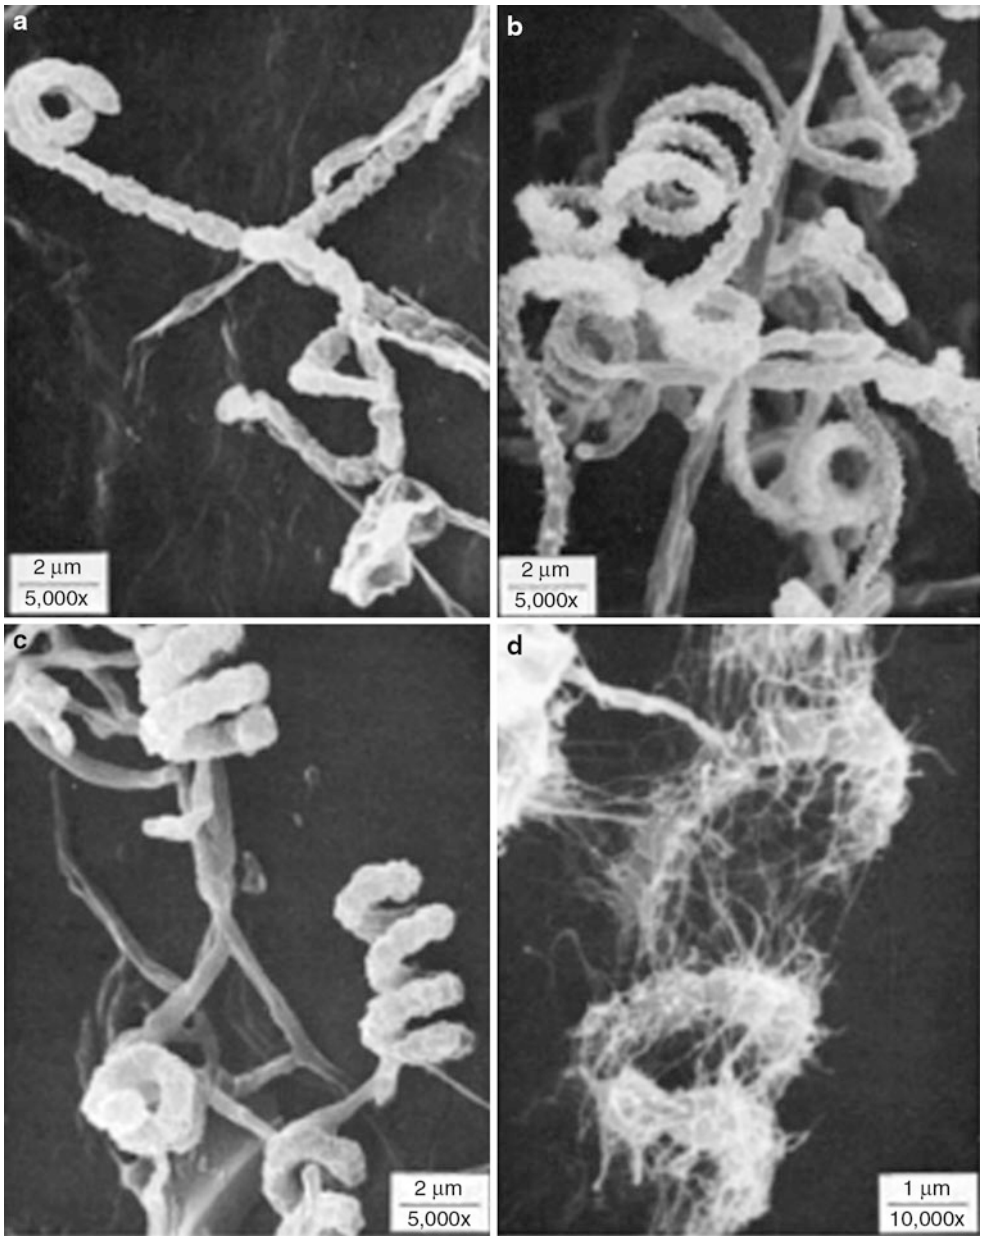

Fig. 42.6
Scanning electron microscopy of arthrospore chains. (a) *Streptomyces torulosus* (knobby); (b) *S. bluensis* (spiny); (c) *S. antimycoticus* (rugose); and (d) "*S. karnatakensis*" (hairy). (Courtesy of A. Dietz.)

and branching, forming branched hyphal filaments comprising a multi-nucleoid, irregularly septated substrate mycelium. Tip extension and the initiation of new branches are directed by a polarisome-like complex involving the essential polarity protein DivIVA (reviewed by Flardh et al. 2012). Phosphorylation of DivIVA by the serine/threonine kinase AfsK (that also regulates antibiotic production; see below) regulates the function of the polarisome and, hence, apical growth and branching (Hempel et al. 2012). Differentiation of the mycelia is initiated by a complex regulatory cascade in response to physiological stress, primarily nutrient depletion, resulting in formation of aerial hyphae coupled with production of extracellular proteins (Chater et al. 2010) and production of secondary metabolites to protect the nutrient source (*Fig. 42.8*). Formation of the aerial hyphae is controlled by the *bld* genes, so called because the inability of mutants defective in these genes to produce aerial hyphae gives them a "bald" appearance on certain media. Lysis is initiated in the compartments of much of the substrate mycelium in an ordered manner regarded as programmed cell death. As a result valuable nutrients may be channeled to fuel the extending aerial hyphae (Manteca et al. 2010). Sporulation begins with condensation and multiple replication of the chromosome in the apical compartments of the extended aerial hyphae, which begin to form multiple septa. Glycogen

Taxa: 1, *K. arboriphila* sp. nov. HKI 0189^T; 2, *K. azatica* DSM 41650^T; 3, *K. cystarginea* DSM 41680^T; 4, *K. gansuensis* sp. nov. HKI 0314^T; 5, *K. kifunensis* DSM 41654^T; 6, *K. kifunensis* HKI 0316; 7, *K. mediocidica* DSM 43929^T; 8, *K. nipponensis* sp. nov. HKI 0315^T; 9, *K. paranensis* sp. nov. HKI 0190^T; 10, *K. phosalacinea* DSM 43860^T; 11, *K. putterlickiae* DSM 44665^T; 12, *K. terrestris* sp. nov. HKI 0186^T

For the following properties, tests for which strain DSM 41680^{T}was not tested are indicated by "*a*." Spores of all of the tested strains are cylindrical with smooth surface. All strains were positive for the production of H_2S^a and growth on (+)-D-glucose and produced acid phosphatise, alkaline phosphatise, esterase (C4), esterase lipase (C8), and leucine arylamidase (API ZYM tests). They did not utilize cellulose^a as a sole carbon source; did not produce α-chymotrypsin, cystine arylamidase, α-galactosidase, β-glucuronidase, α-fucosidase, lipase (C14), trypsin, or valine arylamidase (API ZYM tests); and did not grow in the presence of NaCl (4 %, w/v) or at 42 °C and ph 4.0 or pH 10. Good growth occurred at temperatures of 15–32 °C and pH 5.0–7.0. All strains were sensitive to chloramphenicol (30 μg)^a, ciprofloxacin (5 μg)^a, imipenem (10 μg)^a, kanamycin sulfate (30 μg)^a, nalidixic acid (50 μg mL^{-1} agar)^a, oxytetracycline (30 μg)^a, rifampicin (30 μg)^a, streptomycin sulfate (10 μg)^a, and vancomycin (30 μg)^a

reserves accumulated in the substrate mycelium are degraded or converted to trehalose which may play in role in protecting aerial hyphae and spores from desiccation (Braña et al. 1986). Synchronous cell division occurs as septation proceeds resulting in prespore compartments containing a single copy of the chromosome. Maturation of spores is regulated by the *whi* genes. Compartment walls thicken, change shape, and acquire their characteristic gray-brown pigment specified by the *whiE* cluster (Davis and Chater 1990; Shen et al. 1999). The cycle producing millions of spores, which will remain in a quiescent state until they encounter a suitable environment for germination, from a small biomass of substrate is therefore complete.

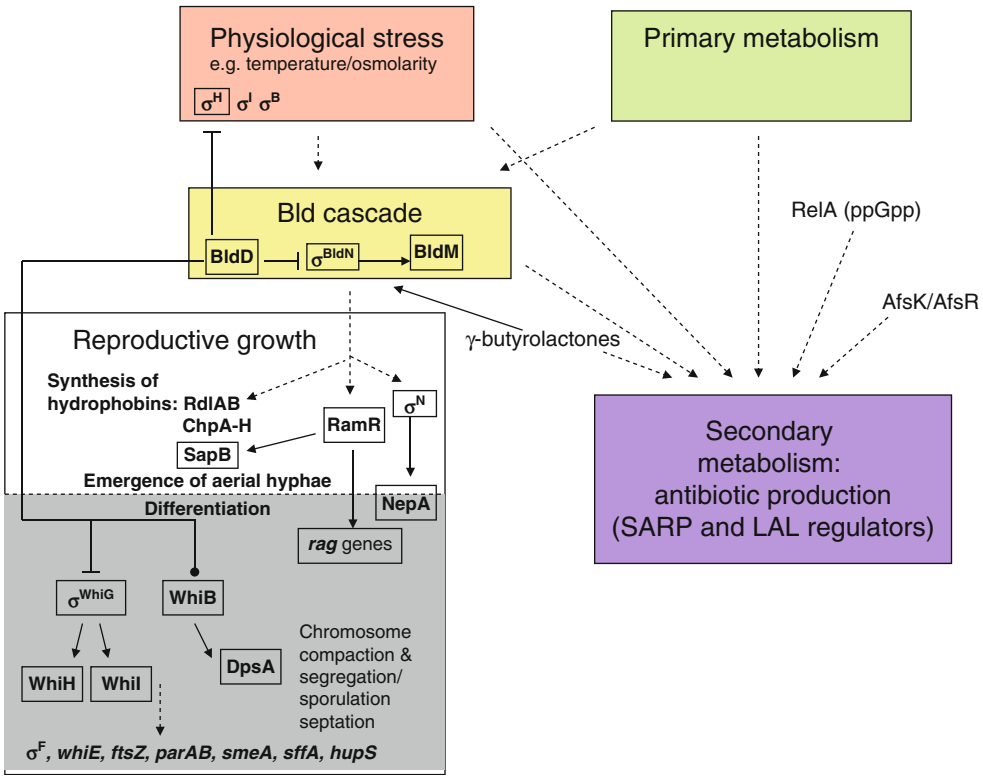

Fig. 42.8

Overview of regulation of morphological development and antibiotic production. Large boxes represent different processes of growth and metabolism, connected by arrows representing influences and dependencies of one process on another. A few of the key individual genes or proteins implicated in each process referred to in the text are indicated. *Dashed arrows* indicate that the precise mechanism of the interaction or dependency is unknown. *Solid arrows* joining boxed genes/proteins indicate a positive effect of one protein on expression of the dependent gene/protein. Perpendicular lines represent a negative or repressing effect. A line ending in a bullet indicates that the effect on gene expression is unclear

Mechanism and Regulation of Morphological Differentiation in the Model Organism *S. coelicolor*

The *bld* Genes

The formation of aerial hyphae and therefore spores is the result of extensive cell-cell signaling directed by the *bld* genes (Willey et al. 1993). Only a handful of genes involved in this process are thought to have been identified. With the exception of *bldB*, which is unconditionally blocked in aerial hyphae and antibiotic production, mutants disrupted in these genes have a carbon-source-dependent phenotype (Pope et al. 1996).

The *bldA* gene was identified by genetic complementation restoring aerial growth and actinorhodin production in *bldA* mutants (Piret and Chater 1985). Mutants defective in this gene are unable to form aerial hyphae and the diffusible blue pigment in a carbon-source-dependent manner. *bldA* encodes a tRNA that adds leucine to growing polypeptides in response to the UUA codon in mRNA (Lawlor et al. 1987), one of six different leucyl tRNA codons. Due to the high GC ratio content in Streptomycetes, UUA codons, corresponding to TTA in DNA, are very rare with only 145 of the predicted genes in *S. coelicolor* containing this codon (Chater 2006). This, coupled with the unusual nature of the UUA codon in that it cannot be translated efficiently by any other tRNA, mediates *bldA*'s translational regulatory effect. This effect has been demonstrated in regulation of undecylprodigiosin production by the *bldA*-dependent translation of the *redZ* TTA codon-containing mRNA. The target of the RedZ transcription factor is *redD*, encoding a pathway-specific regulator of antibiotic production (White and Bibb 1997).

bldB encodes a small peptide with DNA-binding activity. *bldB* mutants are unable to sporulate or produce antibiotics regardless of the carbon source indicating BldB, which forms oligomers and likely operates by interaction with another protein, may be a global regulator of morphogenesis, catabolite control, and antibiotic production (Pope et al. 1998; Eccleston et al. 2002).

BldC is required for normal and sustained transcription of the actinorhodin pathway-specific regulator gene *actII-4* and may be involved indirectly in *redD* transcription (Hunt et al. 2005). *bldC* encodes a DNA-binding protein; mutants present a carbon-source-dependent bald phenotype and are unable to produce actinorhodin (Merrick 1976; Hunt et al. 2005).

BldD belongs to a family of XRE transcription factors. It possesses a helix-turn-helix binding motif for DNA (Elliot and Leskiw 1999; Kim et al. 2006). *bldD* mutants are phenotypically

similar to *bldA* and *bldH* in that they and are blocked in morphological and physiological development on rich media, but development is at least partially restored on minimal media containing mannitol (Merrick 1976; Champness 1988). A BldD recognition sequence was identified in the promoter region of several known developmental regulatory genes and the transcription factor was found to repress expression of a number of these including *sigH* (Kelemen et al. 2001), *bldN*, *bldM*, and *whiG* (Elliot et al. 2001), discussed later in this chapter (Fig. 42.8). Subsequent transcriptomic analysis comparing a *bldD* mutant and the wild type demonstrated a large regulon controlled by BldD with at least 167 putative targets, including *bldC*, *bldB*, *ftsZ*, *sti1*, *ssgA*, and *ssgB*, around 80 % of which contain a readily recognized 15 bp palindromic binding motif (den Hengst et al. 2010). Transcription of many BldD target promoters is increased in *bldD* mutants (Elliot et al. 1998, 2001; Elliot and Leskiw 1999). BldD is capable of specifically recognizing its own promoter (Elliot and Leskiw 1999), but apart from this autoregulatory effect, the mechanism of transcriptional control of *bldD* is not yet understood (Elliot and Leskiw 1999; Kelemen et al. 2001).

bldG mutants are deficient in aerial hyphae formation and unable to produce pigmented antibiotics (Champness 1988). The *bldG* gene was predicted to encode an anti-anti-sigma factor involved in morphological and physiological differentiation (Bignell et al. 2000). Its antagonist was initially identified as the product of the cotranscribed *apgA* (antagonist partner of BldG) gene with interaction of the two proteins indicating their involvement in a partner-switching mechanism (Parashar et al. 2009). The regulatory target of the BldG-ApgA complex has not yet been identified but BldG has been shown to physically interact with this protein and the anti-sigma factor UshX (also known as PrsH), the antagonist of SigH, an alternative sigma factor involved in morphological development (Sevcikova et al. 2010).

bldH encodes the *S. coelicolor* ortholog of *S. griseus* AdpA which is autoregulated (Wolanski et al. 2011), dependent on *bldA* for translation of a TTA codon, and directly controlled by BldD (Nguyen et al. 2003; Takano et al. 2003). *bldH* mutants are phenotypically similar to *bldA* and *bldG* mutants (Champness 1988). σ^{AdsA}, part of the AdpA regulon in *S. griseus*, is orthologous with σ^{BldN} in *S. coelicolor* (Yamazaki et al. 2000). *bldN* encodes an extracytoplasmic function (ECF) family sigma factor which is unconditionally required for formation of aerial mycelium, and expression from the *bldN* promoter in *S. coelicolor* requires *bldH* (Bibb et al. 2000). Transcriptomic comparison between *bldN* mutants and the wild type showed all eight of the chaplin genes failed to be upregulated in the mutant strain, although it is unclear how this effect is mediated (Elliot et al. 2003). The only confirmed target of σ^{BldN} is *bldM* (Bibb, Molle and Buttner 2000). The product of *bldM*, an atypical response regulator BldM, may not require phosphorylation for its biological function (Molle and Buttner 2000), and its targets are as yet unknown.

BldJ is an oligopeptide proposed to be one of the first signals in the *bld* cascade and response to this factor is dependent on the presence of the oligopeptide import system encoded by the *bldK* gene cluster (Nodwell and Losick 1998). This cluster encodes the five subunits of an ABC membrane-spanning transporter which may be responsible for the import of an extracellular signal required for initiation of morphological differentiation (Nodwell et al. 1996). The *bldK* locus is well conserved among Streptomycetes; recent characterization of an orthologous cluster in *S. griseus* found mutation of *bldKB* in this cluster leads to impaired sporulation and secondary metabolite production reflective of *bldKB* and *bldKC* mutation in *S. coelicolor* (Akanuma et al. 2011).

The characterized *bld* mutants are all defective in production of SapB, a small morphogenic surfactant lantibiotic-like peptide implicated in aerial hyphae production, and wild-type phenotypes can be restored by exogenous supply of the modified peptide (Willey et al. 1991). It is the product of the *ramS* gene, itself part of the *ram* gene cluster whose expression is controlled by the response regulator RamR. SapB and morphological differentiation can be restored by growth of different *bld* mutants in close proximity by a process known as "cross-feeding" or extracellular complementation (Willey et al. 1993). Complementation is unidirectional and hierarchical; mutants can restore the phenotypes of all those mutants to the left but not to the right; bldJ → bldK/L → bldA/H → bldG → bldC → bldD/M, culminating in restoration of SapB production and aerial hyphae formation (Kelemen and Buttner 1998; Nodwell et al. 1999; Bibb et al. 2000; Willey et al. 2006; Chater 2006). The "donor" produces a signal the "recipient" is not competent to produce but is able to respond to, thus demonstrating the putative and, to date, incomplete signaling cascade mediated by these genes. This simple linear hierarchy is complicated by the fact that several *bld* mutants, including *bldB*, *bldI*, and *bldN*, do not fit into the cascade model (Nodwell et al. 1999), but many putative additional signals which may help unravel some of this complexity are yet to be identified. The *bld* gene cascade activates expression of *ramR* that is needed, in turn, for expression of *ramS* (Fig. 42.8). The SapB lantibiotic-like peptide is derived from proteolytic cleavage and posttranslational processing of the C-terminal half of the *ramS* gene product (Kodani et al. 2004). Unusually for this class of proteins, SapB does not have antibiotic activity but rather provides a structural role on the colony surface, tightly associated with the spore surface and in the medium around the colony. The putative operon within which RamS is encoded comprises four genes; *ramA*, *ramB*, *ramC*, and *ramS*. RamC is thought to be responsible for some of the posttranslational modification of SapB, and RamAB are considered components of an ABC transporter required for its export (Willey et al. 2006). The RamR response regulator also activates expression of the *rag* operon whose products are important in subsequent development of the aerial hyphae (San Paolo et al. 2006).

The Hydrophobic Coating of Aerial Hyphae and Mature Spores

Streptomyces forms a hydrophobic sheath that coats its aerial (but not vegetative) mycelium and mature spores (Hopwood

et al. 1970). The sheath, comprising of two classes of proteins, lowers the surface tension of the aqueous substrate enabling extension of the hyphae up from the colony surface and into the air. One class of secreted proteins involved in formation of the hydrophobic sheath is the chaplins (chap is the abbreviated form of *Coelicolor Hydrophobic Aerial Protein*) (Claessen et al. 2003; Elliot et al. 2003). Unlike SapB, which is required for aerial hyphae formation only on rich media (Willey et al. 1991), the chaplins (Chp) are synthesized under all the tested growth conditions and are required for SapB-independent formation of aerial mycelium on soy flour mannitol or minimal media (Capstick et al. 2007), so providing alternative mechanisms for aerial hyphae to emerge from an aqueous environment based on nutritional availability in the soil environment. There are eight known chaplins which have been divided into two groups; ChpA–C, the long chaplins, and ChpD–H, the short chaplins. The long chaplins are around 225 amino acids in length and contain two copies of the hydrophobic chaplin domain that defines this class. ChpA–C have a C-terminal sortase signal indicative of cell wall attachment where, along with the rodlins, anchored fibrils organize the short chaplins which are polymerized into a paired rodlet ultrastructure (Elliot et al. 2003). Short chaplins have only one chaplin domain and are approximately 55 amino acids long. ChpC, E, and H are the minimal requirements for normal aerial hyphal formation (Di Berardo et al. 2008). The mechanism of polymerization into amyloid fibers is not known, but recently two amyloid domains were identified in the model chaplin, ChpH, and in vitro studies indicated these contribute to their assembly (Capstick et al. 2011).

The second class of proteins implicated so far in formation of the hydrophobic hyphal and spore coating is the rodlin proteins, encoded by *rodA* and *rodB*, which influence the organization of the chaplins but are not required for formation of hydrophobic aerial hyphae (Claessen et al. 2002). RodA and RodB are present at the surface of aerial structures but mutation in their genes does not affect aerial hyphae formation, though the rodlet layer is absent in these mutants (Claessen et al. 2002, 2004).

NepA, a small secreted protein, may be involved in this process. *nepA* is the only known target for the alternative sigma factor σ^N, apart from its autoregulation (Fig. 42.8). *sigN* null mutants are delayed in development in a carbon-source-dependent manner and transcription of the gene is absent in *bld* but not *whi* mutants, indicating a role in aerial hyphae formation (Dalton et al. 2007). Interestingly, transcription of *nepA* is absent in mutants where all eight chaplins have been deleted (de Jong et al. 2009) indicating its expression is coupled to aerial hyphae formation. Its role is as yet undefined due to conflicting reports on its localization within *S. coelicolor*. Confinement of expression of NepA in the "subapical stem," a compartment just below the apical sporogenic cell, was observed by Dalton et al. (2007). However, by transcriptomic and localization analysis of EGFP-tagged, NepA, expression was also detected in mature spore chains where it is proposed that NepA, minus its export signal peptide, is incorporated as a highly insoluble spore wall protein with a role in maintaining spore dormancy until conditions become favorable for germination (de Jong et al. 2009).

The *whi* Genes and Sporulation

While emergence of hyphae from the colony surface of the aerial mycelium is controlled by the *bld* genes, the subsequent development of the apical hyphal compartment and multiple synchronous cell division into unigenomic spores is controlled, in part, by the *whi* genes. Mutants defective in *whi* gene products have a characteristic white appearance on the colony surface due to their inability to form mature spores and their gray-brown polyketide coating. The "early" *whi* genes are *whiA*, *whiB*, *whiG*, *whiH*, *whiI*, and *whiJ*, and these are strictly and non-conditionally required for the early stages of conversion from aerial hyphae to spores (reviewed by McCormick and Flärdh 2012).

whiG encodes σ^{WhiG}, an RNA polymerase sigma factor highly similar to the motility sigma factor in *Bacillus subtilis* which is required at the earliest known stage of differentiation from hyphae to spores (Chater et al. 1989) and directly controls *whiH* and *whiI* (Fig. 42.8). *whiI* encodes an atypical orphan response regulator lacking conserved residues in the conventional phosphorylation pocket. Transcription from its promoter requires σ^{WhiG}, and it is implicated in autoregulation and regulation of expression of *whiH* (Aínsa et al. 1999). The product of *whiH* shares most similarity with a large family of bacterial repressor proteins involved in carbon metabolism and is believed to negatively control its own expression (Ryding et al. 1998).

A role for WhiA and WhiB has been predicted in cessation of aerial hyphae formation as microscopically *whiA* and *whiB* mutants have been observed to have very long, tightly coiled, poorly septated hyphae (Chater 1972; Aínsa et al. 2000). Since transcription of these genes does not require σ^{WhiG}, proposed models assume that WhiA and WhiB act via a parallel pathway that converges with the σ^{WhiG} -mediated pathway involving WhiH and WhiI (Aínsa et al. 2000). A link between the two pathways governing aerial hyphae and sporulation, *bld* and *whi*, exists in BldD. A binding site for BldD has been identified in the *whiB* promoter sequence (den Hengst et al. 2010) and since WhiB is capable of upregulation of *whiA* transcription (Jakimowicz et al. 2006), BldD may play a role, albeit indirect in the case of *whiA*, in regulating the expression of these two genes. BldD also directly represses the first *whi* gene in the cascade, *whiG*, preventing σ^{WhiG} -mediated transcription of *whiH* and *whiI* (Elliot et al. 2001), thus regulating both arms of the putative signaling cascade. As yet, the only confirmed target of the transcription factor WhiB is the *dpsA* gene whose product is one of several nucleoid-associated proteins involved in chromosome compaction during sporulation (Facey et al. 2011).

whiJ encodes a transcription factor belonging to the same family as BldD. *whiJ* is unusual among the characterized *whi* genes in that it is not required for sporulation—a complete deletion of the gene has no phenotypic effect. The morphological deficiencies resulting in the white phenotype were the result of mutant alleles allowing synthesis of a truncated protein with an intact N-terminal DNA-binding domain (Aìnsa et al. 2010). Aìnsa et al. (2010) proposed a model for WhiJ as a repressor of developmental genes which is released from the operator sequences by binding to the product of its adjacent gene,

SCO4542, since deletion of the latter gene results in a medium-dependent white colony phenotype which can be completely suppressed by deletion of *whiJ* in the mutants.

The eight genes comprising the *whiE* cluster are predicted to encode components of type II polyketide synthase and are responsible for production of the spore wall-associated gray polyketide pigment that coats mature spores (Davis and Chater 1990). Two promoters have been identified for *whiE* transcription with transcription of both *whiEP1* and *whiEP2* dependent on *whiA*, *whiB*, *whiG*, *whiH*, *whiI*, and *whiJ* and mutation of *sigF* blocked transcription from *whiEP2* (Kelemen et al. 1998).

There are several homologues of *whiB* in *S. coelicolor* and these form part of a family known as the *whiB*-like (*wbl*) genes. Orthologs of these genes have been found in many actinomycetes, include some of those with a simpler lifecycle, but not in any other organisms (Soliveri et al. 2000). Two *wbl* genes are required for normal sporulation in *S. coelicolor*; *whiD* and *wblA*. Transcriptional analysis indicates that *whiD* is required at the time of sporulation septa formation (Molle et al. 2000). Disruption of *wblA* has a wide-ranging effect on gene regulation, affecting primary and secondary metabolism in addition to morphological differentiation. Mutants exhibit aerial hyphae that are almost entirely deficient in spore chains and appear red due to ectopic production of the pigmented antibiotics (Fowler-Goldsworthy et al. 2011).

whiA, *whiB*, *whiG*, and *whiI* have been implicated in transcriptional regulation of the sporulation-specific sigma factor, σ^F, which is required for wild-type spore formation (Kelemen et al. 1996). This sigma factor is expressed in developing and mature spore chains (Sun et al. 1999). Mutation of the gene leads to irregular, thin-walled, poorly pigmented spores with reduced chromosomal DNA condensation (Kelemen et al. 1996).

SsgA and the SsgA-like proteins (SALPs) are small proteins found as multiple paralogues only in sporulating or mycelial actinobacteria. In addition to SsgA, *S. coelicolor* possesses six SALPs including SsgB (Noens et al. 2005). Each of the SALPs is thought to act at different stages of spore formation performing a function related to septa and spore wall peptidoglycan buildup and degradation, with SsgA and SsgB carrying out an essential function in sporulation-specific cell division (Noens et al. 2005). Deletion of *ssgA* or *ssgB* critically affects aerial hyphal septation and therefore spore formation (van Wezel et al. 2000; Sevcikova and Kormanec 2003). Transcription of *ssgA* is linked to the adjacent upstream gene *ssgR* with the transcription of *ssgA* absent in *ssgR* mutants (Traag et al. 2004; Wolanski et al. 2011). *ssgR*-independent overexpression of SsgA induces irregular, unusually thick, septation of hyphae which are wider than in the wild type (van Wezel et al. 2000). Transcription of *ssgA* and *ssgR* is independent of the *whi* genes, despite the white colony phenotype of mutants, but both genes are targets for BldD (den Hengst et al. 2010). *ssgB* is also regulated by the stress response sigma factor, σ^H, which is repressed by BldD (Kelemen et al. 2001; Sevcikova and Kormanec 2003). Thus, BldD provides another link between aerial hyphae formation and sporulation.

Formation of spores requires tightly regulated cell division to ensure only one copy of the genome is inherited by each of the progeny. A number of proteins have been implicated in this process in *S. coelicolor* including FtsZ, CrgA, ParA, ParB, and SmeA and the spore nucleoid-associated proteins DpsA, DpsB, DpsC, and HupS. FtsZ has been demonstrated to be necessary for the formation of both crosswalls in vegetative mycelium and sporulation septa (McCormick et al. 1994). Division is directed by FtsZ which forms polymeric spiral structures in the synctial hyphae which are subsequently modified to form regularly spaced Z-rings along the sporogenic cell (Grantcharova et al. 2005). These tubulin-like proteins form a cytoskeleton which provides the force for constriction of the cell at sporulation septa and provide a base for sequestered proteins involved in cell division (Erickson et al. 2010). A BldD binding site has been identified in the *ftsZ* promoter region; however, the promoter to which it is proposed to bind is presumed to be constitutively rather than developmentally expressed (den Hengst et al. 2010). To date the developmental control of Z-ring assembly is not well understood with few proteins involved in FtsZ polymerization and cellular organization identified. CrgA, a small transmembrane protein, may have a role in cell division. Mutants disrupted in this gene erect aerial hyphae and produce antibiotics precociously and overexpression leads to aerial hyphae lacking sporulation septa (Del Sol et al. 2003). Overexpression of CrgA prevents FtsZ localization, and therefore it may have a role in Z-ring formation (Del Sol et al. 2006).

The *parAB* operon is developmentally controlled and involved in partitioning of DNA during multiple septation of the apical compartment; mutation of *parB* leads to incorrect allocation of DNA to around a tenth of the resultant spores (Kim et al. 2000). The small membrane protein SmeA is expressed specifically in sporogenic cells and influences septal placement and chromosomal segregation and condensation (Ausmees et al. 2007). The three *dps* genes of *S. coelicolor* influence sporulation, septal positioning, and spore nucleoids with developmental control of *dpsA* involving binding of WhiB to the *dpsA* promoter region (Facey et al. 2009, 2011). HupS is nucleoid associated in spores, developmentally upregulated in the apical compartment of aerial hyphae and dependent on WhiA, WhiG, and WhiI for transcription (Salerno et al. 2009).

γ-Butyrolactones and *bldH*

It has long been known that bacteria communicate within their environment. Quorum sensing involves secretion of signaling molecules that act as inducers and affect gene expression of the recipients after binding to their receptors. In some bacteria the signaling molecules are *N*-acyl-L-homoserine lactones (Swift et al. 1996). By this mechanism colonies can coordinate gene expression and therefore development. The first signaling molecules in *Streptomyces*, the γ-butyrolactones, were identified in the 1960s and have been extensively studied since. These hormone-like regulators are important for antibiotic production and morphological differentiation though their role and the current understanding of regulation varies within the genus. The well-characterized A-factor

(2-isocapryloyl-3R-hydroxymethyl- γ-butyrolactone) of *S. griseus* is involved in induction of antibiotic biosynthesis and onset of morphological differentiation (Ohnishi et al. 1999). The A-factor dependent protein AdpA mediates the response to this signaling molecule. A-factor binds to ArpA, the *adpA* repressor, and releases the ArpA dimer from the *adpA* promoter region thus allowing transcription of *adpA*. AdpA then transcriptionally activates a large regulon including the pathway-specific regulator of streptomycin biosynthesis, the *S. griseus* SapB homolog, and *ssgA* and is therefore a positive regulator of streptomycin biosynthesis and aerial mycelium formation in this organism (Ohnishi et al. 1999).

A-factor homologues have been found in many Streptomycetes. The role of γ-butyrolactones in *S. coelicolor* is less well defined than in *S. griseus*. Three have so far been identified in *S. coelicolor* and are known as the *S. coelicolor* butanolides (SCBs). SCB1, the most abundant of these, stimulates actinorhodin and undecylprodigiosin production (Takano 2006). The AdpA ortholog in *S. coelicolor* is BldH which also has a key role in development but the mechanism is not yet well understood (Nguyen et al. 2003; Takano et al. 2003). Transcription of several sporulation genes including the *ramR* cluster, *bldN*, *bldM*, and *whiI*, is dramatically decreased in *bldH* mutants (Xu et al. 2010). The presence of a TTA codon in the coding sequence of this gene may explain many of the affects of *bldA* mutation on morphogenesis as this codon cannot be translated by the *bldA* tRNA in this mutant (Nguyen et al. 2003; Takano et al. 2003).

Although many of the genes involved in aerial hyphae formation and sporulation have been identified along with some of their regulators, the pathways through which the signals are mediated still require a great deal of elucidation.

A link exists between alternative sigma factors, stress, and morphological development in *S. coelicolor* (Fig. 42.8). The *S. coelicolor* genome encodes around 66 sigma factors, at least nine of which are *B. subtilis* σ^B paralogues (Bentley et al. 2002). The stress response in *B. subtilis* is mediated by σ^B, the first alternative sigma factor identified in bacteria, isolated from the RNA polymerase holoenzyme following physiological stress (Haldenwang and Losick 1979). In descending order of homology to *B. subtilis* σ^B, *S. coelicolor* σ^B (formerly σ^J), σ^L, σ^I, σ^N, σ^F, σ^H, σ^K, σ^M, and σ^G are involved in stress responses and development. In addition to these "SigB-like" sigma factors numerous anti- and anti-anti-sigma factors similar to the antagonists RsbW and RsbV (regulators of SigB) are found within the genome. Following global analysis of gene expression following salt, heat, and ethanol stress, it was demonstrated that different sets of proteins are simulated in response to different types of stress coordinated with morphological development in this organism (Vohradsky et al. 2000).

sigF encodes a sigma factor important for spore maturation (Kelemen et al. 2001). This developmental role does not appear to be linked to a stress response. Mutants disrupted in *sigF* exhibit an unconditional *whi* phenotype, with smaller thin-walled spores (Potúcková et al. 1995). A lack of σ^F expression has been identified in a number of spore compartments of *ftsK* mutants (Wang et al. 2007). Autonomous expression of σ^F in spore compartments may play a role as a checkpoint ensuring that FtsK-coupled chromosome segregation and cell division occurs properly (Wang et al. 2007). *sigF* is adjacent to *sigN*, but the genes are expressed independently (Dalton et al. 2007). σ^N is thought to play a role in the formation of aerial hyphae, controlling expression of *nepA*. Mutants have a conditionally *bld* phenotype in a carbon-source-dependent manner (Dalton et al. 2007). The role of σ^G, which shows the most homology with σ^F, is as yet unknown. Disruption of this gene does not result in an obvious phenotype, with no observable difference in growth, morphology, differentiation, or pigmented antibiotic production (Kormanec et al. 1999). σ^K has a role in the correct timing of aerial hyphae formation. Deletion of σ^K leads to increased expression of the key chaplins, ChpE and ChpH, with an earlier switch from vegetative to aerial growth and increased production of actinorhodin and undecylprodigiosin (Mao et al. 2009).

σ^B, σ^H, σ^I, σ^L, and σ^M have all been implicated in the osmotic stress response, underlining the complexity of the stress response in *S. coelicolor* which may involve multiple sigma factors regulating single types of stress. A potential hierarchy exists between σ^B, σ^L, and σ^M. Transcription of these three sigma factors is induced by osmotic stress. *sigL* mutants are unable to sporulate or produce actinorhodin following salt stress, and *sigM* mutants sporulate poorly (Lee et al. 2005). *sigL* transcription is absent in *sigB* mutants and *sigM* transcription is absent in *sigB* or *sigL* mutants, indicating a hierarchical relationship where σ^B controls σ^L and σ^M expression and σ^L controls σ^M expression (Lee et al. 2005).

σ^B, σ^H, and σ^I are specifically induced by osmotic stress (Cho et al. 2001; Kelemen et al. 2001) each with their own induction profile (Viollier et al. 2003). Transcription of *sigI* has been observed following osmotic stress only, and it is not present under normal growth conditions nor induced by heat or ethanol stress (Viollier et al. 2003). This indicates that σ^I is not required for differentiation of *S. coelicolor* with further evidence provided by lack of a distinguishable phenotype in mutants disrupted in this gene (Lee et al. 2005; Homerova et al. 2012). σ^I is regulated by a partner-switching mechanism reminiscent of the RsbW/RsbU system in *B. subtilis*. Transcription of *sigI* is directed from a single promoter induced by osmotic stress and the activity of σ^I is regulated posttranslationally by its antagonist PrsI and the anti-sigma factor antagonist ArsI (Homerova et al. 2012).

sigH is involved in morphological development and the response to osmotic stress (Kelemen et al. 2001). Along with its putative anti-sigma factor PrsH (putative regulator of *sigH* also known as UshX), σ^H is cotranscribed from two developmentally regulated promoters, *sigHp1* and *sigHp2*, as part of a two-gene operon (Kelemen et al. 2001). Contradictory phenotypes have been reported in *sigH* mutants; no significant phenotypic difference could be observed between the wild type and mutants by Viollier et al. (2003), contrasting with the previously reported osmosensitivity of *sigH* mutants which were poorly septated and rarely possessed spore chains when grown in conditions of high external osmolarity (Sevciková et al. 2001). PrsH regulates σ^H by direct interaction of the two proteins. The anti-anti-sigma factor BldG is the antagonist of PrsH and the two

proteins have also been shown to interact directly (Sevcikova et al. 2010). Under normal growth conditions σ^H forms the σ^H:PrsH complex with its antagonist and σ^H-mediated transcription is prevented. In response to unknown signals including conditions of high external osmolarity, BldG is activated, likely by dephosphorylation if this system draws parallels the Rsb system in *B. subtilis*, and is able to interact with PrsH. Formation of this BldG:PrsH complex releases σ^H which is now free to associate with RNA polymerase and direct σ^H-dependent transcription of genes containing the recognition sequence for this form of the holoenzyme. In addition, *sigH* is transcriptionally regulated by the *bldD* gene product. The transcription factor BldD has been found to bind the σ^H promoter *sigHp2*, developmentally expressed exclusively in sporulating aerial hyphae, negatively regulating its transcription (Kelemen et al. 2001). Interestingly, simultaneous deletion of *sigH* and *prsH* also results in a developmental block indicating the latter may also have an antagonist role for additional sigma factors (Viollier et al. 2003), which had previously been observed with the σ^U antagonist, RsuA (Gehring et al. 2001). Among targets of σ^H are the sporulation-specific *ssgB* (Keijser et al. 2003; Sevcikova and Kormanec 2003) and *sigJ*, encoding an ECF sigma factor, the expression of which is induced during sporulation but mutation results in no observable morphological defect (Mazurakova et al. 2006).

σ^B is a key regulator of sporulation and the osmotic stress response (Cho et al. 2001; Kelemen et al. 2001; Viollier et al. 2003; Lee et al. 2005). Mutants precociously produce pigmented antibiotics and are unable to produce aerial hyphae when high concentrations of osmolyte are present in the growth media. *sigB* forms part of an operon which includes the upstream genes, *rsbB* and *rsbA*, under the control of the constitutive *sigBp2* promoter (Cho et al. 2001). A second inducible promoter, *sigBp1*, is locating directly upstream of the coding region of *sigB* which is induced during differentiation and following osmotic stress in a σ^B-dependent manner (Cho et al. 2001). σ^B has been proposed as a master regulator of morphogenesis in addition to osmotic and oxidative stress. More than 280 genes were found to be expressed in a σ^B-dependent manner in response to osmotic stress, including *sigB* itself, and its antagonist *rsbV* (Lee et al. 2005).

The genes immediately preceding *sigB*, *rsbA* and *rsbB*, encode an anti- and anti-anti-sigma factor, respectively. The C-terminal domain of RsbA shows a high level of homology with RsbW, the *B. subtilis* σ^B anti-sigma factor. RsbA coelutes from *S. coelicolor* total protein with σ^B and prevents σ^B-mediated transcription in vitro indicating it is indeed the antagonist for this sigma factor (Lee et al. 2004). Despite the homology of *rsbB* with *rsbV* of *B. subtilis*, the σ^B anti-anti-sigma factor, the former lacks a highly conserved serine residue, which is phosphorylated in the latter to prevent its association with RsbW. This coupled with the lack of observable phenotype in these mutants makes it unlikely that RsbB is the RsbA antagonist. A putative six-gene operon lies separately on the chromosome from *sigB*, *rsbA*, and *rsbB*. σ^B-mediated transcription of *rsbV*, *rsbR*, *rsbS*, *rsbT*, *rsbU1*, and *rsbU* is induced following osmotic stress and RsbV is able to phosphorylate and inhibit the activity of RsbA in vitro providing evidence of a role for RsbA as the σ^B anti-anti-sigma factor (Lee et al. 2004). It is proposed that these antagonists along with RsbU, and other as yet uncharacterized members of the cascade, regulate σ^B activity in a partner-switching mechanism similar to that observed in *B. subtilis*. Following osmotic induction of *sigB* and its regulon, permitting physiological adaptation, SigB activity is subsequently antagonized by an anti-sigma factor domain of the product of the osmoadaptation gene *osaC* (Fernandez-Martinez et al. 2009).

Cell division in *Streptomyces* is initiated, as in other bacteria, by the polymerization of the FtsZ protein on the inner surface of the cytoplasmic membrane to form the Z-ring structure at the future division site (Lutkenhaus 1997; Margolin 2003). Transcription studies of *S. griseus* genes suggest that *ftsZ* is expressed during both sporulation and vegetative growth (Dharmatilake and Kendrick 1994). For *S. coelicolor* A3(2), FtsZ is necessary for septation within the vegetative substrate mycelium as well as for the synchronous formation of septae within the developing aerial hyphae prior to detectable separation of nucleoids (Grantcharova et al. 2003). However, in other ways these two types of cell division are different both in terms of their outcome and underlying mechanisms. The highly regular formation of multiple sporulation septa is dependent on components of the typical bacterial "divisome" such as FtsW, FtsQ, and FtsI and leads to unigenomic spores that separate from each other. In contrast, irregular and infrequent cross-wall formation in the vegetative hyphae occurs independent of the majority of divisome components, with the exception of FtsZ, and the hyphal compartments remain joined after this type of cell division (Mistry et al. 2008). The cycle of differentiation is typically observed on solid media; however, for some strains (i.e., *S. griseus*; McCue et al. 1996; *S. venezuelae*, Glazebrook et al. 1990) sporulation in liquid culture has also been reported. *S. coelicolor* A2(3) also sporulates at the air interface of standing liquid cultures (van Keulen et al. 2003). The basis for hyphal buoyancy in standing liquid cultures is not clearly understood: although *S. coelicolor* A2(3) has two *gvp* gene clusters encoding proteins that resemble gas vesicle proteins of cyanobacteria and their homologues within halophilic archaea, the hyphae of *gvp* mutants exhibit similar buoyancy to the wild type (van Keulen et al. 2005). Interestingly, all sequenced *Streptomyces* genomes, and many other actinomycetes, have *gvp* gene clusters. The structure and role of "gas vesicles" in actinomycetes remains enigmatic. For various *Streptomyces* strains, a transient slow down during growth in liquid culture is reported before entering the stationary phase. In this transition phase, a decrease in GTP and a *relA*-dependent increase in ppGpp (guanosine 3′, 5′-bispyrophosphate) as well as the activation of genes essential for secondary metabolism is detected (Chakraburrty et al. 1997). The synthesis of two ribosomal proteins is drastically reduced when the culture approaches the stationary phase (Blanco et al. 1994).

Peptidoglycans

The chemical composition and ultrastructure of the cell walls of streptomycetes is characteristic for Gram-positive bacteria

(Schleifer and Kandler 1972). Under the electron microscope, cell walls which are composed of multilayered peptidoglycan strands appear as homogeneous electron dense layers with a diameter of about 16–35 nm. The heteropolymer peptidoglycan is made of heteropolysaccharide chains (the so-called sugar backbone), which are connected by peptide cross-links. The sugar backbone is composed of alternating β-1,4-linked units of the sugar derivatives *N*-acetylglucosamine and *N*-acetylmuramic acid. The carboxyl group of the muramic acid is further substituted by an oligopeptide of alternating D- and L-amino acids (Schleifer and Kandler 1972). In *Streptomyces*, the substitution is a tetrapeptide L-Ala–D-Glu–LL-A_2pm–D-Ala being crosslinked by a pentaglycine bridge extending from the C-terminal D-alanine of the peptide unit to the amino group located on the D carbon of LL-A_2pm. The resulting macromolecular structure forms the cell envelope. This LL-A_2pm-Gly_5 is also termed A3γ peptidoglycan type (Schleifer and Kandler 1972) and is typical for streptomycetes as well as some other combined-wall chemotype I actinomycetes (Lechevalier and Lechevalier 1970a, b, c).

In a study by Lechevalier et al. specific amino acids in purified cell walls were used to group aerobic actinomycetes into four so-called wall chemotypes. Cell walls with *meso*-A_2pm and LL-A_2pm were the first to be detected. Cell wall composition may vary with the developmental stage of streptomycetes. Takahashi and coworkers (1984) reported that submerged mycelium of strains having a cell wall with *meso*-A_2pm and LL-A_2pm consists of LL-DAP and glycine (wall chemotype I), while in the spores only *meso*-A_2pm could be detected (wall chemotype III according to Lechevalier and Lechevalier (1970a, b, c)). The quantitative distribution of cell wall amino acids and cell wall sugars differed in the cell wall composition of aerial, substrate, and submerged mycelium of 11 streptomycetes. *N*-acetylmuramic acid is present as the glycolyl type in the cell walls of *Streptomyces*, as in all other actinomycetes (Uchida and Aida 1977).

Muramic acid phosphate residues are necessary as attachment points to teichoic acids, which are polymeric substances containing repeating phosphodiester groups. They are composed of *N*-acetylamino sugars or polyols (i.e., the sugar alcohols glycerol and ribitol) or both and are helpful for the identification of Gram-positive bacteria. The structure of teichoic acids does not differ between streptomycetes and other Gram-positive bacteria. The polymers are made of either ribitol phosphate or glycerol phosphate. Important for the teichoic acids of actinomycetes is the absence of ester-bound D-alanine; instead, ester-linked acetic acid and sometimes succinic acid residues are present (Naumova et al. 1980).

The synthesis of either ribitol phosphate (e.g., *S. streptomycinii* and *S. violaceus*) or glycerol phosphate polymers (e.g., *S. antibioticus*, *S. levoris*, *S. rimosus*, and *S. thermovulgaris*) in streptomycetes has been reported (Naumova et al. 1980). In ribitol teichoic acids, positions 1 and 5 of ribitol are connected to the phosphates but in glycerol teichoic acids, position 1 is commonly connected to 3, and in other types, links to 2 (as in *S. antibioticus*) are uncommon. Polyol phosphates can be substituted with diverse combinations of sugars or amino sugars or even both. The sugars or amino sugars are linked to ribitol or glycerol via glycosidic bonds. The role of teichoic acid in the taxonomy of *Streptomyces* is unclear, since only a few strains have been analyzed in detail (Naumova et al. 1980).

Cell Wall Polysaccharides

Cell wall polysaccharides seem to have no diagnostic value (Lechevalier et al. 1971) for strains, which contain LL-DAP in their cell wall. Occasionally, diagnostic sugars present in actinomycetes (i.e., arabinose, galactose, and xylose) have been reported in streptomycetes. The presence of diagnostic sugars in streptomycetes was extensively examined by Kroppenstedt (1977) who analyzed hundreds of strains. Glucose, mannose, and ribose are usually detected in small amounts.

Phospholipids and Glycolipids

The lipids of streptomycetes consist mainly of diphosphatidylglycerol (DPG), phosphatidylethanolamine (PE), phosphatidylinositol (PI), and phosphatidylinositol mannosides (PIMs). A summary of the lipid composition of actinomycetes can be found in Lechevalier et al. (1977). Glycolipids are not useful for the identification of streptomycetes, because they do not occur consistently. In addition, culture conditions largely determine their qualitative and quantitative lipid composition. For example, the glycolipid content increases significantly under phosphate limiting conditions.

Polar lipids have an important taxonomic value in actinomycetes, as demonstrated by Lechevalier et al. (1977). The phospholipids of 97 actinomycete strains, representing 20 genera, were analyzed and assigned to five phospholipid types by Lechevalier et al. (1977). These phospholipid groups are characterized by the presence or absence of certain nitrogenous phospholipids. Members of the family *Streptomycetaceae* have a phospholipid type II. The marker lipids of this type are phosphatidylethanolamine (PE), hydroxy-PE, lyso-PE, and methyl-PE. However, differentiation can be achieved by using additional lipids (e.g., phosphomonoester [PME] and hydroxyphosphatidylethanolamine [OH-PE]) and the presence or absence of PG and PI (*Fig. 42.9*). In *S. coelicolor*, the anionic phospholipid cardiolipin is enriched at hyphal tips, branch points, and anucleate regions; overexpression of cardiolipin synthase results in weakened hyphal tips, misshaped aerial hyphae, and anucleate spores and demonstrates that synthesis of this phospholipid is a requirement for morphogenesis in *Streptomyces* (Jyothikumar et al. 2012).

Menaquinones

Streptomycetes contain only menaquinones (Collins and Jones 1981). The synthesized quinones include a partly saturated

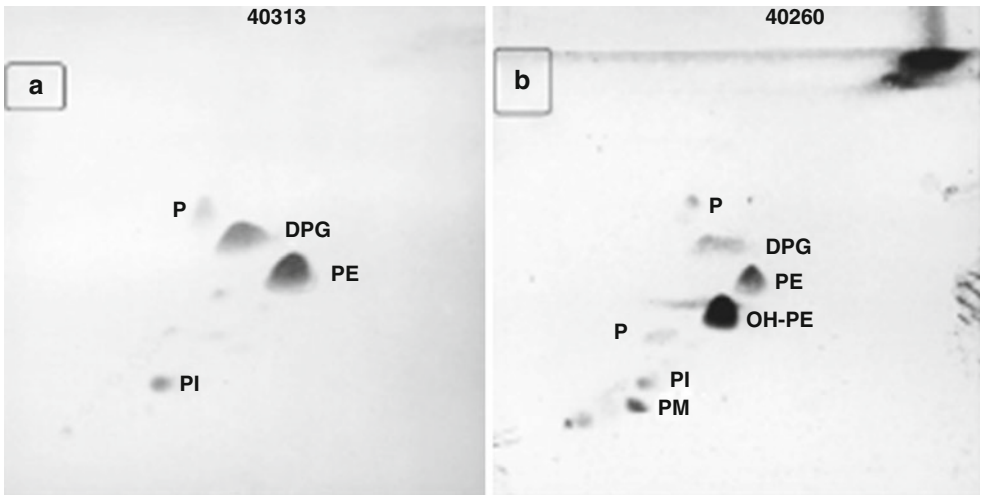

Fig. 42.9

Two-dimensional thin layer chromatograms of polar lipids of (a) *Streptomyces albus* (DSM 40313) and (b) *Streptomyces rimosus* (DSM 40260). Abbreviations: DPG, diphosphatidyglycerol; PI, phosphatidylinositol; PIM, phosphatidylinositol mannosides; PE, phosphatidylethanolamine; OH-PE, hydroxy-phosphatidylethanolamine; and P, phospholipids of unknown structure. (Courtesy of R. M. Kroppenstedt.)

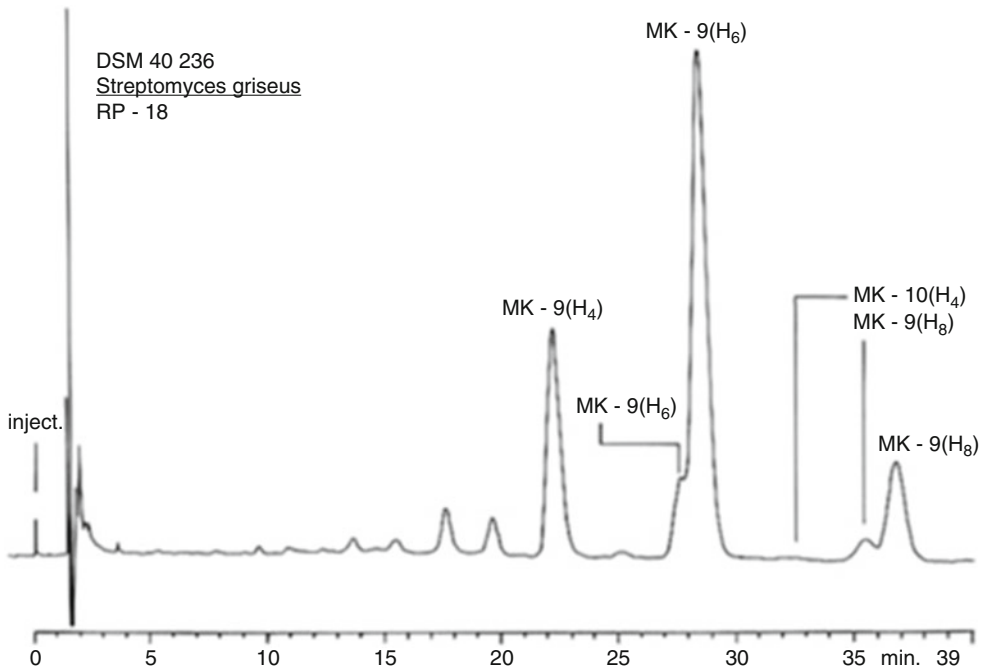

Fig. 42.10

Menaquinone profile of *Streptomyces griseus* (DSM 40236). The extent of hydrogenation of the isoprene units is shown by the subscript of the abbreviation. For instance, MK-9 (H_8) is a menaquinone with four hydrogenated isoprene units. (Courtesy of R. M. Kroppenstedt.)

isoprenoid side chain at position 3 of the naphthoquinone ring. In this, streptomycetes resemble the majority of actinomycetes. The composition of menaquinones provides a great taxonomic value for the identification of actinomycetes. The following three variations are useful for identification and classification: (1) the different numbers of isoprene units, (2) the different degrees of hydrogenation, and (3) the position of hydrogenated isoprene units (*Fig. 42.10*). The menaquinones of streptomycetes have three to four (rarely five) saturated isoprene units with a highly hydrogenated isoprenoid chain. The actinomycetes, which belong to this type, can be differentiated by a different degree of saturation.

Fatty Acid Analysis

Hofheinz and Grisebach (1965) studied selected *Saccharopolyspora erythraeus* (formerly *Streptomyces erythraeus*) and *Streptomyces halstedii* strains to clarify the biosynthetic pathway of branched chain fatty acid synthesis. It was found that *Streptomyces* species synthesize terminally branched fatty acids. From 2-methylbutyrate, as starting compound, *anteiso*-branched fatty acids with an odd number of carbon atoms are formed. In contrast, isobutyrate and isovalerate as starting compounds lead to the formation of *iso*-branched fatty acids with odd and even numbers of C-atoms, respectively. Therefore *iso*- and *anteiso*-branched fatty acids appear in pairs with odd numbers of C-atoms only.

Hofheinz and Grisebach also identified individual *iso*- and *anteiso*-branched fatty acids with chain lengths of 15 and 17 carbon atoms in both *Saccharopolyspora erythraeus* and *S. halstedii*. In addition, high amounts of 14-methyl pentadecanoic acid (*iso*-C16:0) were detected, while small amounts of unbranched fatty acids, tuberculostearic acid, and their homologues were only detected in the *Saccharopolyspora erythraea* strains, but not in *S. halstedii*.

A few streptomycetes produce minor quantities of hydroxy fatty acids in the presence of optimal amounts of oxygen. These fatty acids are easily destroyed in a non-deactivated injection port of capillary gas chromatography systems and are therefore not always detected. Nevertheless, some streptomycetes synthesize hydroxy fatty acids which are of high diagnostic value, when strains are grown under reproducible culture conditions. Hydroxy fatty acids have been found in all strains of *S. coelicolor* (30), in 20 of 27 *S. hygroscopicus* strains, in *S. rimosus* (14), and *S. violaceusniger* (18), but not in *S. albus* (33), *S. fradiae* (25), *S. glaucescens* (8), *S. griseus* (22), *S. lavendulae* (18), *S. violaceoruber* (16), and *S. viridochromogenes* (25; Kroppenstedt 1992; R. M. Kroppenstedt, unpublished observations).

Saddler and coworkers (1986) studied the fatty acid profiles of *Streptomyces cyaneus* strains and associated soil isolates, which formed a blue aerial spore mass; 13 of 19 blue-spored strains belonged to the *S. cyaneus* cluster (Hütter 1962; Pridham and Tresner 1974; Korn et al. 1978). It was shown that 8 of 10 blue-spored isolates were grouped together based on their fatty acid profile, while 17 of 34 *S. cyaneus* strains were assigned to a separate cluster. Saddler and his colleagues were able to demonstrate that the *Streptomyces cyaneus* taxon as defined by Williams et al. (1983a) was heterogeneous. They also concluded that conventional characteristics, such as color, ornamentation, and chain morphology of spores, were not reliable for the classification of streptomycetes but would be helpful for presumptive identification, a point also made by Williams et al. (1983a).

Generally, fatty acid patterns cannot be used to classify *Streptomyces* species (Phillips 1992; R. M. Kroppenstedt, unpublished observation); however, when used under standardized conditions, they are still helpful for the rapid characterization (independent of the taxonomic status) of large quantities of wild-type streptomycetes isolated from the environment (Saddler et al. 1987).

Curie-Point Pyrolysis Mass Spectrometry

A different method that has been used for the identification and classification of actinomycetes is pyrolysis mass spectrometry (PyMS; Sanglier et al. 1992; Ferguson et al. 1997). The exposure of whole cells to high temperatures causes their degradation in a nonoxidative environment leading to the generation of pyrolysate which can be analyzed by mass spectrometry. This method results in the generation of a fingerprint for each organism; however, it needs to be rigorously standardized.

Sanglier et al. (1992) applied this method to strains belonging to *Streptomyces albidoflavus* species group defined by Williams et al. (1983a) and was able to recover members of the *S. albidoflavus* and *S. anulatus* strains in distinct groups. The six *S. halstedii* strains (the third subgroup) were divided to three groups. *Streptomyces albidoflavus* strains and *S. anulatus* strains were also reassigned in different groups by Kämpfer et al. (1991). They also determined that *S. anulatus* ISP 5361^T, the strain used to name the *Streptomyces anulatus* cluster, formed a single-membered cluster (Kämpfer et al. 1991).

Serology

Serological methods have infrequently been used in *Streptomyces* taxonomy. Ridell et al. (1986) used antisera against the mycelia of streptomycetes, streptoverticillia and *Nocardiopsis* species to verify the high similarity between *S. lavendulae* and streptoverticillia (Witt and Stackebrandt 1990; Kämpfer et al. 1991). The antisera used by Kirby and Rybick (1986) proved to be genus specific and to a certain degree also group specific when tested against *S. cattleya* (cluster 47 of Williams et al. 1983a) and *S. griseus* (*S. anulatus*, cluster 1B of Williams et al. (1983a)). Wipat et al. (1994) generated a monoclonal antibody to *Streptomyces lividans* 1326, which was specific for *Streptomyces lividans* strain 1326 and for strains assigned to cluster 21 by Williams et al. (1983a).

Colonial Characteristics

Streptomycetes possess various colonial features, such as substrate mycelium, pigmentation of spores, and diffusible exopigments, together with the morphology of colonies and the texture of the aerial mycelium (❯ *Figs. 42.11* and ❯ *42.12*). The formation of different pigments has been widely used for identification and classification; however, it is important to mention that colony morphology is too variable for use as a taxonomic character.

One feature, generally used in streptomycete taxonomy, is spore mass color. Strains showing different spore colors have been assigned to "sections," "series," and "species groups" (Burkholder et al. 1954; Flaig and Kutzner 1954, 1960a; Hesseltine et al. 1954; Gauze et al. 1957; Ettlinger et al. 1958; Pridham et al. 1958; Krasil'nikov 1960). In the 8th edition of *Bergey's Manual* (Pridham and Tresner 1974b), *Streptomyces*

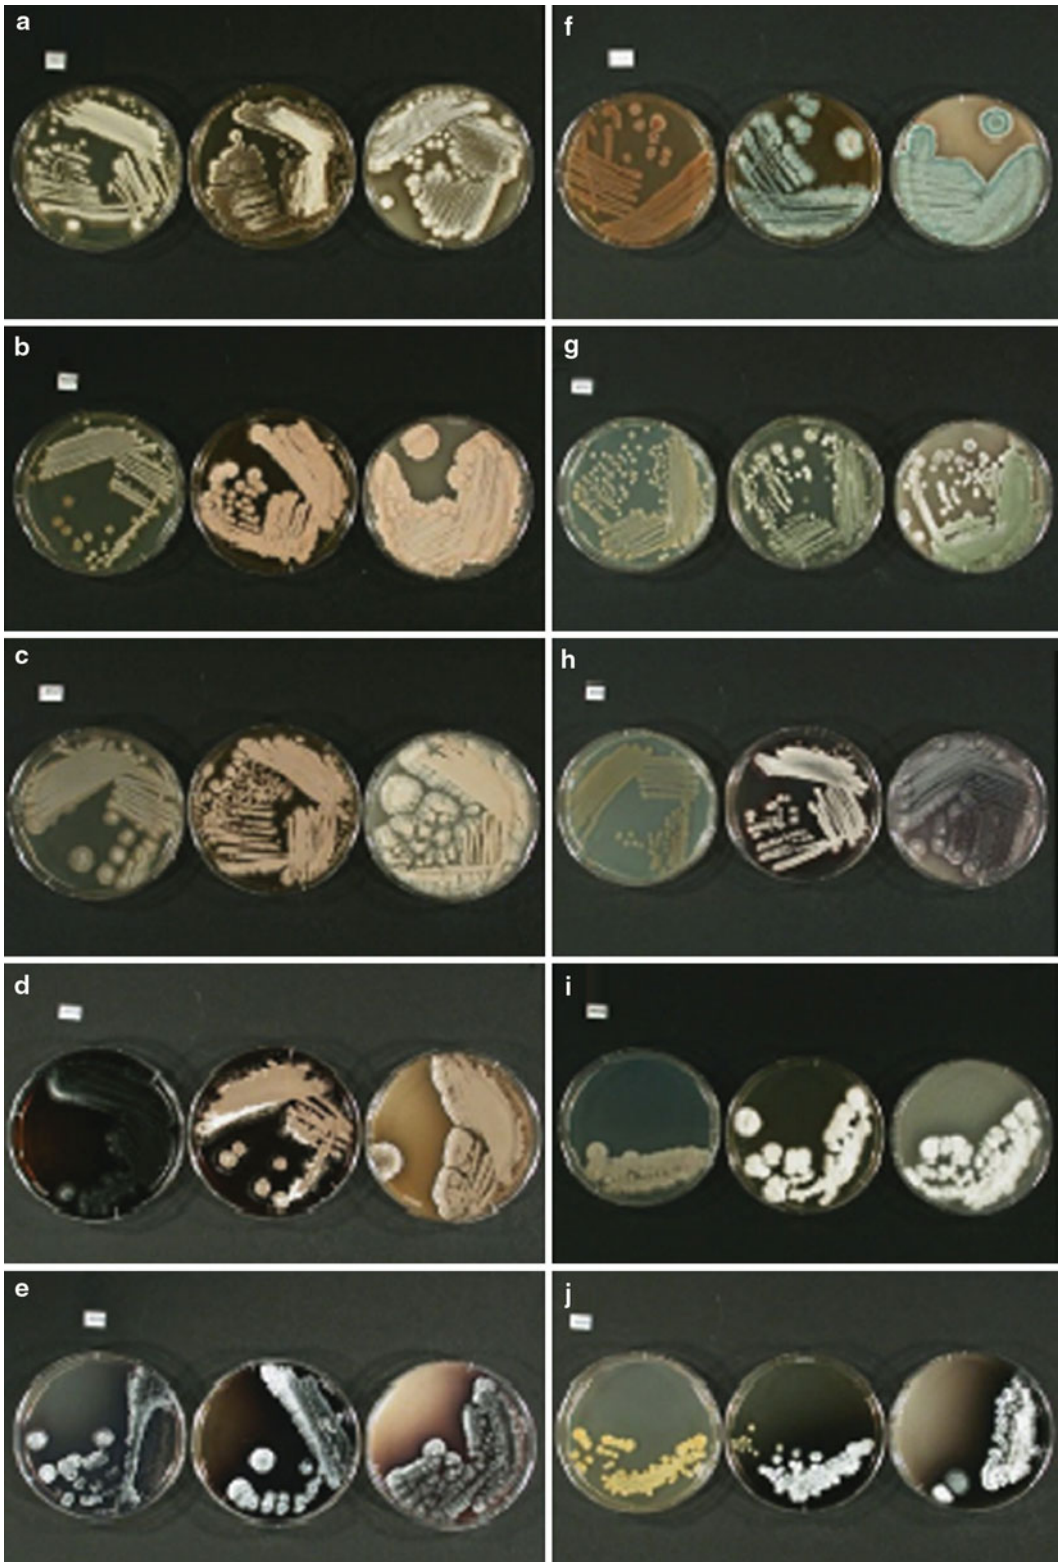

Fig. 42.11
a–j: Color of the aerial mycelium of *Streptomyces* strains grown on different agar media after 3 weeks of incubation at 28 °C. *Left*: starch-casein-nitrate agar; *middle*: GYM agar; *right*: oatmeal agar (for compositions, see *Table 42.8* and *42.9*). Species names and strain numbers are given in *Table 42.4*

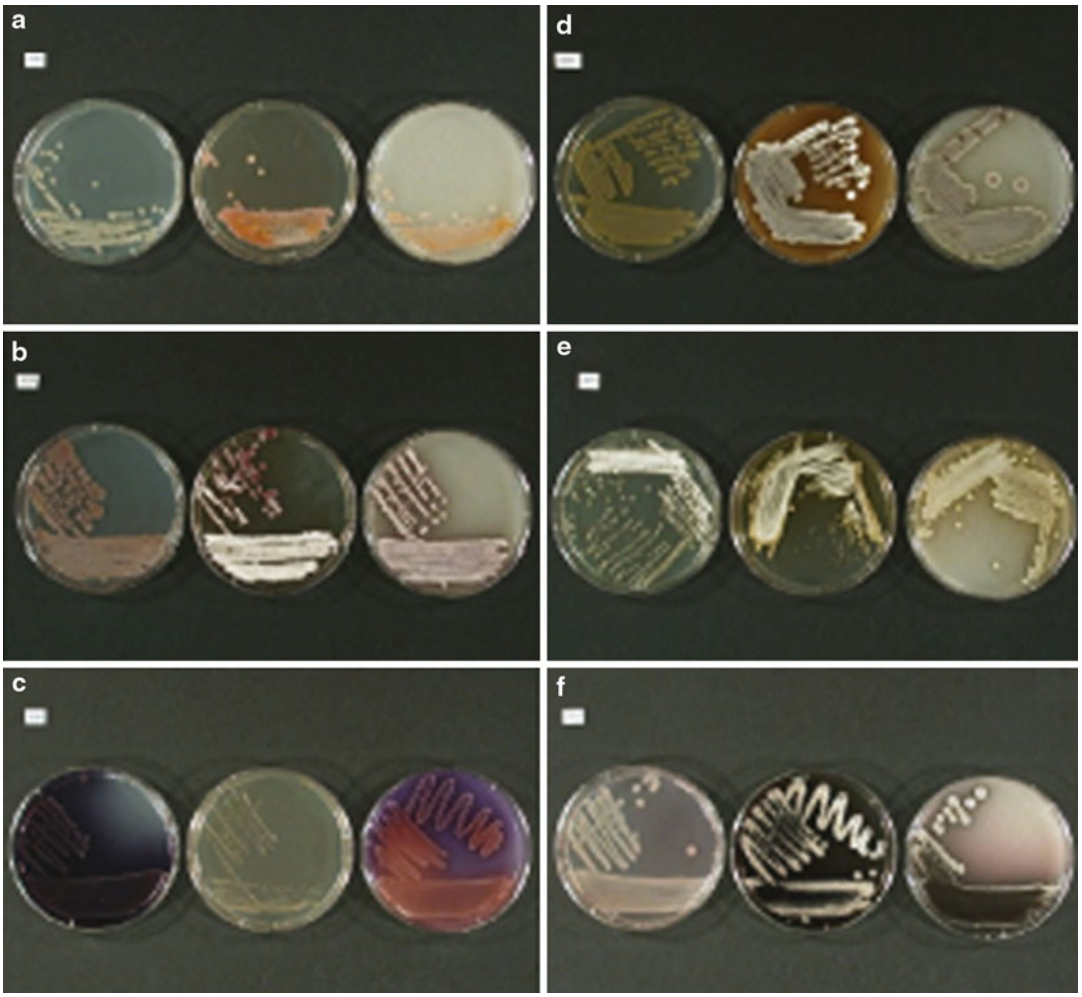

Fig. 42.12
a–f: Color of the substrate mycelium and soluble pigments of *Streptomyces* strains grown on different agar media after 7 days of incubation at 28 °C. *Left*: starch-caseinnitrate agar; *middle*: GYM agar; *right*: oatmeal agar (for compositions, see *Table 42.8* and *42.9*). Species names and strain numbers are given in *Table 42.5*

species were assigned to seven color series: blue, gray, green, red, violet, white, and yellow. In a later study, the series were extended to accommodate additional colors (Kutzner 1981). The color of the spore mass is still a useful criteria, but its determination may be difficult, since the color can be influenced by different factors such as the growth conditions, the medium, and age of the culture. Sometimes the color cannot clearly be attributed to any established category.

The color of the soluble pigment and the substrate mycelium are of high taxonomic value when they are evident, e.g., blue, dark green, red, and violet (*Fig. 42.12*). The color of the substrate mycelium has also been used in a preliminary approach to group streptomycetes (Baldacci et al. 1954; Baldacci 1958; Krasil'nikov et al. 1961b). Nevertheless, the expression of the various pigments is again often influenced by the medium composition, pH, temperature, and age of the culture (Kutzner 1981). In addition, diffusible pigments and their pH sensitivity have been used as taxonomic characters (Waksman and Curtis 1916; Jensen 1930; Shirling and Gottlieb 1970), and chemically different pigments can exhibit the same color (Krasil'nikov 1970; Kutzner 1981). Some *Streptomyces* strains produce anthracycline glycoside, diazaindophenol, naphthoquinone, phenoxazinone, and prodigiosin pigments (Kutzner 1981).

Production of Extracellular Enzymes

Streptomycetes are widely distributed in soil and play an important role in the recycling of organic matter. Consequently, *Streptomyces* genomes encode high numbers of predicted secreted proteins. *S. coelicolor* A3(2) expresses ca. 800 predicted secreted proteins including 60 proteases, 13 chitinases/chitosanases, eight cellulases/endoglucanases, three amylases, and two pectate lyases (Bentley et al. 2002; Ventura et al. 2007; Chater et al. 2010). Most of the *Streptomyces* strains studied so far can utilize chitin not only as a carbon but also as a nitrogen source (Blaak and Schrempf 1995), and, often, several chitinases are produced

(Robbins et al. 1988; Miyashita et al. 1991). For more information, see Schrempf (2006) and Chater et al. (2010). Amylases and their inhibitors are also commonly present in streptomycetes. An α-amylase gene (*aml*) of *S. limosus* ATCC 19778 has been cloned by Virolle and Bibb (1988). From sequence information it can be concluded that the genome of *S. coelicolor* A3(2) contains many genes which code for glucosyltransferases. Furthermore, xylanases and their genes have been identified from several streptomycetes, i.e., *S. lividans* 10–164 (Pagé et al. 1996), *S. halstedii* JM8 (Ruiz-Arribas et al. 1998), and the thermophilic *S. thermoviolaceus* OPC-520 (Tsujibo et al. 1997). Laccases, including those produced by *S. cyameus* CECT 3335, can be efficiently applied for biobleaching of kraft pulps (Arias et al. 2003).

Extracellular proteases are widely distributed among streptomycetes, and several corresponding genes have been characterized (Kim and Lee 1995). Streptomycetes also possess many genes encoding for protease inhibitors (Taguchi et al. 1996), including leupeptin and subtilisin (Hiraga et al. 2000). Chater et al. (2010) proposed a general model for an extracellular protease cascade that contributes to *Streptomyces* development. Moreover, keratinases are frequently detected (for review, see Kutzner 1981). A small number of extracellular lipases and their genes have also been examined from different *Streptomyces* strains (Servín-González et al. 1997; Sommer et al. 1997), among them lipolytic enzymes expressed by *S. rimosus* R6-554 W (Vujaklija et al. 2002).

Streptomyces encode at least three different protein secretion systems: the general secretory (Sec) pathway, the twin arginine translocation (Tat) pathway, and the ESX-1/type VII secretion pathway (reviewed by Palmer and Hutchings 2011). In addition, they encode numerous ABC transporters, often linked to the export of lantibiotics (modified bioactive peptides). The most remarkable aspect of protein secretion concerns the large number of non-cofactor-containing proteins exported by the Tat machinery in *Streptomyces*; in other bacteria this is generally not the case.

Primary Metabolism

In contrast to secondary metabolism of streptomycetes, relatively few studies have been published on the primary metabolism. Some genes have been identified; among them those encoding key pathway enzymes like glucose kinase, phosphofructokinase, and glucose-6-phosphate dehydrogenases (reviewed in Van Keulen et al. 2011). Butler et al. (2002) identified one gene (*devB*) encoding a 6-phosphogluconolactonase and two *zwf* genes determining isozymes of glucose-6-phosphate dehydrogenases, the first enzyme in the oxidative pentose phosphate pathway [PPP]) in *S. lividans* 66. The pentose phosphate pathway and the tricarboxylic cycle relative to glucose uptake have been examined in *S. noursei* ATCC 11455 (Jonsbu et al. 2001). *S. tenebrarrius* was shown to distribute carbon almost evenly over glycolysis and the Entner-Doudoroff pathway during exponential growth on glucose (Borodina et al. 2005).

Analogous to enteric bacteria, glutamine synthetase I (GSI) in *S. coelicolor* A3(2) is posttranslationally controlled by adenylyltransferase (Hesketh et al. 2002b). In *S. clavuligerus* NRRL-3585 *a* novel class of glutamate dehydrogenases (GDH) has been found (Minambres et al. 2000). Furthermore, *S. coelicolor* A3(2) is capable of using fatty acids (C4–C18) as sole carbon sources (Banchio and Gramajo 1997), and the glyoxylate cycle also seems to be present, at least in *S. clavuligerus* NRRL-3585 (Soh et al. 2001). The genes *matB* and *matC* were used to generate strain variants of *Streptomyces* for the production of antibiotics (Kim and Goodfellow 2002).

In order to improve knowledge on metabolic fluxes (Obanye et al. 1996) as well as the biotechnological production of pharmacologically active compounds, the genes and pathways required for the biosynthesis of primary compounds, including their regulation pattern (Rodríguez-García et al. 1997), should be studied in more detail. Detailed analyses of proteins involved in primary and secondary metabolism are available (Hesketh et al. 2002a; Huang et al. 2001). Proteomic and metabolomic data are currently being studied (e.g., Novotna et al. 2003). Borodina et al. (2008) used an integrated approach of genome-scale modeling of the metabolic network of *S. coelicolor* A3(2) with metabolic flux analyses coupled with genome-wide transcriptomic analyses of wild type and a phosphofructokinase (*pfkA2*) mutant strain to demonstrate extensive remodeling of metabolism at the glucose-6-phosphate node at the transition stage from primary to secondary metabolism. This study showed a successful rational approach for metabolic engineering of central carbon metabolic pathways to improve secondary metabolite production.

Secondary Metabolism

Streptomycetes have been the most important source of antibiotics since the discovery of actinomycin D, streptomycin, and streptothricin in the 1940s by Waksman and coworkers (for a review, see Hopwood 2007). Streptomycetes produce an enormous range of chemically diverse substances, many of them acting as antibiotics, cytostatics, fungicides, or as modulators of immune responses (see, e.g., Horinouchi 2002; Bérdy 2005; Challis and Hopwood 2003; Van Wezel and Vijgenboom 2004, and Hopwood 2007, for more detailed information). Subsequently, the study of *Streptomyces* genomes has been of great interest and has led to the discovery of 30 gene sets that code for these compounds in the *S. avermitilis* MA-4,680 genome and 26 in that of *S. coelicolor* A3(2) (Ventura et al. 2007). Interestingly, many of these gene sets are present in one genome but not in others. Also the same position in different chromosomes can be occupied by different secondary metabolism clusters, for instance, the *pks1* cluster of *S. avermitilis* MA-4680 is substituted in *S. ambofaciens* ATCC 23877 by a different secondary metabolism cluster of 28 genes, and in *S. coelicolor* A3(2) by a 31-gene insertion (Choulet et al. 2006).

Gene clusters for secondary metabolism, especially those that are species specific, are often located in the subtelomeric

chromosome arms. The more abundant genes for secondary metabolism, like the ones responsible for the production of the odor compound geosmin, different siderophores, and pentalenolactone, are typically harbored in syntenous locations within the central core region (Bentley et al. 2002; Ikeda et al. 2003). Furthermore, certain linear plasmids may also carry such gene clusters, thereby explaining the impact of lateral gene transfer between chromosomes present in different streptomycetes (Ventura et al. 2007).

Various important pharmacologically active compounds are encoded by genes, which are located within DNA stretches of 20 kb to more than 100 kb. Successful cloning has been achieved by screening total genomic DNA or gene libraries with homologous or heterologous gene probes generated by cloning, by complementing mutants, or with the help of polymerase chain reactions (PCR), as well as by transposon mutagenesis (Schrempf 2006). It is interesting that the genes responsible for antibiotic biosynthesis are often located near one or more genes mediating resistance to the corresponding antibiotic. The following listing has been adapted from Schrempf (2006): By complementation of mutants, the gene cluster for the biosynthesis of the polyketide actinorhodin was achieved (Malpartida and Hopwood 1984). Additional gene clusters for polyketides were cloned using a gene probe for the predicted key step for polyketide synthesis. These polyketides include daunorubicin (Stutzman-Engwall and Hutchinson 1989), frenolicin (Bibb et al. 1994), granaticin (Sherman et al. 1989), griseusin B (Yu et al. 1994), jadomycin B (Han et al. 1994), mithramycin (Lombo et al. 1996), tetracyclines (Binnie et al. 1989), tetracenomycin C (Motamedi and Hutchinson 1987), tetrangomycin (Hong et al. 1997), and urdamycin A (Decker and Haag 1995).

Several gene clusters encoding for macrolides have been identified, including the genes for carbomycin (Epp et al. 1987), oleandomycin (Swan et al. 1994), rapamycin (Schwecke et al. 1995), and tylosin (Fishman et al. 1987). Genes for peptide antibiotics, such as actinomycin (Stindl and Keller 1994; Hsieh and Jones 1995) and bialaphos (Murakami et al. 1986), and cyclopentenoid antibiotics (such as methylenomycin; Chater and Bruton 1985) have also been detected. Additionally, genes have been found for the production of aminoglycosides such as puromycin (Lacalle et al. 1992), ansamycins such as rubradirin (Sohng et al. 1997), carbapenems (Nakata et al. 1989), cephamycin (Aharonowitz and Cohen 1992; Paradkar et al. 1996) and cyclophilins (Pahl et al. 1997), nikkomycin (a nucleoside peptide; Bormann et al. 1996) and nosiheptide (a thiopeptide; Dosch et al. 1988), rifamycin (August et al. 1998), streptomycin (Ohnuki et al. 1985; Distler et al. 1987), and undecylprodigiosin (a pyrrole; Feitelson and Hopwood 1983; Malpartida et al. 1990).

Many secondary metabolite biosynthetic gene clusters contain at least one pathway-specific regulatory gene, encoding a *Streptomyces* antibiotic regulatory protein (SARP) or a transcriptional regulator of the LAL family (large ATP-binding regulators of the LuxR family). The former are transcriptional activators containing a winged helix-turn-helix motif towards their N-termini that is also found in the OmpR family of proteins. The SARP family of proteins has been found only in actinomycetes, and mostly within the streptomycetes. A very complex set of regulatory cascades link physiological, environmental, and developmental signals to the expression of pleiotropic regulatory genes and ultimately these pathway-specific regulators, thereby controlling secondary metabolism after the main growth phase of the bacterium (◉ *Fig. 42.8*; reviewed by van Wezel and McDowall 2011). Examples of the pleiotropic regulators are the products of the *bld* genes that also regulate the growth of aerial hyphae. The gamma-butyrolactone signaling molecules also impact on antibiotic production (reviewed by Gottelt et al. 2011). They are effective in nanomolar concentrations, and the best characterized is A-factor produced by *S. griseus*. Unusually, A-factor is required for both secondary metabolism (streptomycin and grixazone biosynthesis) and morphological development. A-factor, specified by the *afsA* gene, binds to its cytoplasmic receptor protein ArpA, thereby preventing the latter from binding and repressing the *adpA* promoter. AdpA is required for activation of transcription of both *strR*, the pathway-specific regulatory gene for streptomycin production, and other members of the *adpA* regulon, some of which are required for morphological differentiation. Gamma-butyrolactones produced by other species specifically regulate secondary metabolism. Examples are the virginiae butanolides controlling virginiamycin biosynthesis in *Streptomyces virginiae* and SCB1 that regulates production (possibly indirectly) of the pigmented antibiotics of *S. coelicolor*. A pleiotropic regulator of antibiotic production in *S. coelicolor*, AfsR, shares in its N-terminal region significant amino acid homology with the SARP family of proteins while containing ATP-binding sequences in its central region. AfsR plays a role in a signal transduction phosphorelay that regulates synthesis of the pigmented antibiotics Act and Red and also the CDA specified by the *cda* cluster (Horinouchi 2003). A membrane-associated serine/threonine protein kinase, AfsK, when activated by an as yet unknown environmental cue, autophosphorylates and in turn phosphorylates cytoplasmic AfsR. AfsR-P then activates transcription of *afsS*, encoding a 63-amino acid protein that functions in an unknown way to enhance the production of Act, Red, and CDA. Interestingly, AfsK serves to link growth and antibiotic production as another of its targets is DivIVA, a component of the polarisome that directs apical growth and branching of hyphae (Hempel et al. 2012).

The analysis of complete genome sequences has revealed an impressive number of cryptic gene clusters potentially encoding as yet unidentified secondary metabolites. As these are a potential source of new antibiotics, it is of interest that at least for a few examples their activation has been accompanied by synthesis of new metabolites. This is exemplified in *S. ambofaciens*, where genetic manipulation leading to ectopic expression of a pathway-specific regulatory gene triggered expression of previously silent genes and led to isolation of a new macrolide antibiotic, stambomycin (Laureti et al. 2011).

More detailed information on the secondary metabolism of streptomycetes, including the generation of new compounds by

combinatorial biosynthesis, is covered in text books and/or reviews (e.g., Bérdy 2005; Challis and Hopwood 2003; Van Wezel and Vijgenboom 2004; Hopwood 2007; Dyson 2010; Olano et al. 2011; van Wezel and McDowall 2011).

Isolation, Enrichment, and Maintenance Procedures

The procedures used to isolate streptomycetes are extensively summarized by Korn-Wendisch and Kutzner (1992). These procedures are briefly described here. Further information about isolation for special purposes, growth, and preservation of streptomycetes can be found in the excellent textbook *Practical Streptomyces Genetics* (Kieser et al. 2000).

In general, isolation procedures for microorganisms are dependent on the number of individuals relative to the number of other microbes within the habitat as well as on the nature of the microorganism to be isolated (Stolp and Starr 1981). Direct plating of a serial dilution on a nutrient agar medium can readily lead to a pure culture, if the chosen organism is best adapted to the selected isolation conditions. Nevertheless, this procedure does not work well for isolation of streptomycetes. Instead enrichment cultures or selective media and/or specific isolation conditions are typically used.

The following selective criteria can be applied to isolate members of the family *Streptomycetaceae* (Korn-Wendisch and Kutzner 1992; Williams and Wellington 1982a, b; Williams et al. 1984a): (1) choice of sample material containing the microorganisms of interest; (2) pretreatment of the sample and, in some cases, enrichment of the chosen microbial groups; (3) use of selective media or selective incubation conditions or both; and (4) colony selection on the basis of colony morphology.

Streptomycetes exist in and can be isolated from a wide range of habitats. In most cases, the organisms are extracted from soil or other environmental samples, followed by dilution of cells (cell aggregates) to allow cultivation on solid media.

Isolation from Soil

Vegetative mycelia and spore chains of streptomycetes are often closely associated with soil mineral and organic particles. For isolation, vigorous shaking of the sample with the diluent is often necessary to suspend the spores or mycelial fragments. In addition, it can be helpful to use glass beads and agitate the sample on a shaker. Other isolation methods are described in the literature, including the use of mechanical devices such as the Turmix blender, Ultra-Turrax homogenizer, Ultrasonics sonicator-disrupter, Waring blender, or a mortar and pestle. Nevertheless, the efficiency of these pretreatments has not been compared in detail. Additional procedures described comprise the use of chemical disruption methods to separate mycelia from spores. For instance, Herron and Wellington (1990) gently agitated soil samples with an ion-exchange resin Chelex-100 (Biorad) followed by differential centrifugation and filtration. The dispersion and differential centrifugation (DDC) technique, which is a multistep procedure that combines several physicochemical treatments, was introduced by Hopkins et al. (1991). It can also be used to increase the yield and diversity of actinobacteria from natural habitats (Goodfellow and Fiedler 2010).

Subsequent handling of samples (i.e., preparing dilutions and plating) differs little from standard microbiological practice. Before dilutions are prepared, coarse particles of the soil suspensions should be allowed to settle. Another option is to utilize the soil particles for the incubation of "soil plates" (Warcup 1950); this method is also used to isolate fungi. For streptomycetes, the addition of lime to soil can be a helpful enrichment factor (see chapter 2 of Kieser et al. (2000) and references therein). Distribution of diluted samples on isolation plates may be carried out with a sterile glass rod (or Drigalski spatula).

To avoid the spread of motile bacteria via water films, plates can be dried at 45 °C before incubation (Vickers and Williams 1987). A 100-fold increase of streptomycete colonies on isolation plates can be accomplished by the addition of $CaCO_3$ to air-dried soil samples (10:1 w/w) and subsequent incubation at 26 °C for 7–9 days in a water-saturated atmosphere (Tsao et al. 1960; El-Nakeeb and Lechevalier 1963). Another highly recommended procedure is to mix the soil suspension with the molten agar (Korn-Wendisch and Kutzner 1992).

Jensen (1930) enriched streptomycetes by supplementing soil with keratin; it has also been described that adding chitin to soil increases the growth of streptomycetes (Williams and Mayfield 1971). In addition, enrichment of acidophilic and neutrophilic streptomycetes in acidic soil and litter can be achieved adding fungal chitin (Williams and Robinson 1981). Chitin in the form of insect wings has also been used as an isolation strategy (Jagnow 1957; Okafor 1966; Veldkamp 1955). Other selective isolation methods studied by Porter and Wilhelm (1961) include the use of various other organic materials, such as cottonseed meal, dried blood flour (15 mg/g of soil), peanut meal, and salmon viscera meal. Additionally, the number of streptomycetes were enhanced up to 1000fold, when the enrichment cultures were incubated under moist conditions (Porter and Wilhelm 1961).

Arginine glycerol agar is frequently used for the selective isolation of streptomycetes (El-Nakeeb and Lechevalier 1963), as well as colloidal chitin agar (Hsu and Lockwood 1975), HV agar (Hayakawa and Nonomura 1987a, b), and reduced arginine starch salts agar.

To reduce or inhibit other microbes, several biological, chemical, and physical methods have been examined (see reviews by Goodfellow and Williams 1986, and Goodfellow 2010). The centrifugation of soil suspensions for 20 min at 1600 × g has been described to separate streptomycetes spores (in the supernatant) from other bacteria and fungal spores (in the sediment) (Nüesch 1965). However, this method has not been very successful. El-Nakeeb and Lechevalier (1963) applied a similar approach, but obtained a significantly lower number of streptomycete colonies as compared to the control. A simple sedimentation method was reported by Voelskow (1988/1989),

who suspended 1 g of soil in 15 mL of salt solution and mixed the preparation by vigorously shaking followed by ultrasonic treatment. Samples were taken from different levels of this solution after 1, 2, and 4 h of sedimentation, further diluted, and plated onto agar surfaces.

Arthrospores display relatively high resistance to low moisture tension; therefore initial heating and drying procedures can be applied to environmental samples to reduce the number of unwanted bacteria. A relative increase in streptomycete concentrations can be achieved by drying samples or by prolonged storage at room temperature for mesophiles and at 50–60 °C for thermophiles. The vegetative bacterial proportion in a soil sample can be reduced without affecting the colony counts of streptomycetes by heat treatment (40–50 °C, 2–16 h), as reported by Williams et al. (1972b).

Membrane filtration has been used for the enrichment of streptomycetes from water (Burman et al. 1969) and from seawater and mud (Okami and Okazaki 1972) samples. This method was also applied as a first step in the isolation of streptomycetes from soil. Trolldenier (1966) filtered 1 mL aliquots of a tenfold dilution series through membranes (0.3-µm pore size) and subsequently placed them upside down on a suitable agar medium supplemented with 10 % compost soil. This procedure allowed streptomycetes to grow through the pores and develop colonies between the agar surface and the membrane filter, whereas other bacteria and fungi were unable to grow through the pores. In total a 3–5-fold increase in the number of streptomycete colonies was noted when compared with poured plates without supplemented soil.

The use of cellulose ester membrane filters (pore size 0.01–3.0 µm) was introduced by Hirsch and Christensen (1983). The membrane filters were placed onto nutrient agar containing antifungal antibiotics (cycloheximide and candicidin) and samples of soil, water, and vegetable material were used as inoculum. The hyphae of actinomycetes were capable of penetrating the pores of the membrane filters and grow on the underlying agar medium after 4 days, whereas the growth of the other bacteria was restricted to the surface of the filters. Afterwards, the membrane filters were removed and the plates reincubated to allow further development of actinomycete colonies. Filters (0.22–0.45 µm) can also be used for the exclusive recovery of actinomycetes, as described by Polsinelli and Mazza (1984) and Hanka et al. (1985).

To improve the isolation efficiency of streptomycetes, the addition of chemicals to environmental samples has also been described by several authors. One recommended method to reduce unwanted bacteria and fungi involves phenol treatment of a dense soil suspension (1.4 % for 10 min). However El-Nakeeb and Lechevalier (1963) obtained less favorable results with this method. Burman et al. (1969) found that streptomycetes and other actinomycetes were somewhat more resistant to ammonia, chloramine, and sodium hypochlorite than other bacteria. Thus they used these agents for the treatment of water samples.

Isolation from Aquatic Habitats

The media listed in *Table 42.8* can be used to isolate streptomycetes from aquatic habitats. Hsu and Lockwood (1975) found that chitin agar was more effective for the incubation of actinomycetes from aquatic habitats than egg albumin, glycerol-arginine, starch-casein, and *Actinomyces* isolation agars (see also *Table 42.8*).

Following dilution, it is possible to streak water samples directly onto solid medium. If low quantities of actinomycetes are expected, they can be concentrated by membrane filtration of the sample [for details, see Burman et al. (1969)].

The selective isolation of streptomycetes from marine habitats can be increased, when media are supplemented with seawater or an equivalent. Media containing 25 or 75 % seawater (Weyland 1981a, b), artificial seawater (Goodfellow and Haynes 1984), and deionized water supplemented with 3.0 % NaCl (Okami and Okazaki 1978) have all proved to be effective. See Weyland (1981a) and Goodfellow and Haynes (1984) for further details.

Isolation of Airborne Spores

Streptomyces spores from self-heating material such as hay or compost can be agitated in a sedimentation chamber (see below; Lacey and Dutkiewicz 1976b) or a wind tunnel (Lacey and Dutkiewicz 1976a). The resulting aerosol can be further used in an Andersen sampler to inoculate agar plates (Goodfellow and Williams 1986). This method is widely employed for the isolation of thermophilic actinomycetes; however, it can also be used for the isolation of mesophilic streptomycetes from soil. Other devices such as filtration samplers (e.g., Sartorius MD 8) can also be applied for the sampling of airborne streptomycetes.

Isolation of Thermophilic Streptomycetes

Most thermophilic actinomycetes derive from samples taken from high temperature environments (e.g., compost materials, fodders, and manure heaps). Therefore, it is recommended to use high temperatures (45–60 °C) for the selective isolation of such organisms (Festenstein et al. 1965).

It is also important to culture thermophilic streptomycetes in a humid atmosphere (Greiner-Mai et al. 1987) by incubating plates in large jars with water at the bottom; another effective method is to seal Petri dishes with masking tape.

Interestingly, the media recommended for the isolation of thermophilic actinomycetes, including streptomycetes, contain higher nutrient concentrations than those used for mesophilic strains. Sometimes, such media are also supplemented with antibacterial and antifungal agents (Lacey and Dutkiewicz 1976a; Goodfellow et al. 1987). Special procedures recommended for the isolation of thermophilic actinomycetes are available (Uridil and Tetrault 1959; Fergus 1964; Gregory and Lacey 1963; Cross 1968; Kim et al. 1996, 1998, 2000).

Isolation of Antibiotic-Producing Actinomycetes

Antibiotic-producing streptomycetes can be isolated following the same procedures as stated above. The antibiotic-producing activity of streptomycetes is normally tested after the isolation of pure cultures; nevertheless, procedures are available to detect them directly on isolation plates. Antibiotic-producing strains can, for instance, be detected on initial dilution plates by flooding or spraying them with appropriate indicator organisms; the plates are then incubated until zones of inhibition are detected (Lindner and Wallhäusser 1955; Wilde 1964). Alternatively, antibiotic activity of the colonies against selected sensitive organisms can be examined by using a simple replication procedure (Lechevalier and Corke 1953). Additional information about protocols which can be applied for the selective isolation and screening of antibiotic-producing actinomycetes can be found in Nolan and Cross (1988). Procedures for the selective isolation of streptomycetes with the generation of spore suspensions and for more sophisticated experimental techniques are described by Kieser et al. (2000).

Table 42.9

Nutrients and selective agents recommended for isolation of streptomycetes from soil (According to Korn-Wendisch and Kutzner 1992)

Nutrients and selective agents in the medium			
Antibiotic	Preferred C and N source	Others	Reference[a]
Rifampicin	Starch, casein, KNO_3		1
Cycloheximide, nystatin, penicillin, polymyxin	Starch, casein, KNO_3		2
Cycloheximide	Starch, casein, KNO_3	Rose Bengal	3
Cycloheximide, pimaricin, nystatin	Glycerol, arginine		4
Cycloheximide	Dextrose, asparagine		5
	Asparagine	Propionate	6
	Chitin		7
	Starch, KNO_3		8
	Starch, casein, KNO_3		9
	Glycerol, casein, KNO_3		9
	Glycerol, arginine		10
	Raffinose, histidine		1

Isolation from Diseased Plants

Three general steps have been recommended for the isolation of streptomycetes from diseased plant material such as scabby potatoes or beet surface layers (see also Korn-Wendisch and Kutzner 1992): (1) sterilization of the surfaces of tubers, beets, or roots; (2) maceration of plant tissues; and (3) use of appropriate isolation media. Several authors have described detailed methods for the isolation of *Streptomyces scabies* from potatoes (Taylor 1936; KenKnight and Munzie 1939; Menzies and Dade 1959; Adams and Lapwood 1978; or Archuleta and Easton 1981).

Optimal Growth Conditions and Use of Selective Media for Enrichment

For the isolation of streptomycetes, various media have been empirically formulated. In *Table 42.9*, selected carbon and nitrogen compounds are listed, which are especially suitable for the isolation of these organisms. The most frequently used media with their formulas are listed in *Tables 42.8* and *42.10*. Nevertheless, streptomycetes can also be grown on very poor media such as water agar.

Early on, it was recognized that streptomycetes are capable of breaking down chitin (Veldkamp 1955; Jagnow 1957). Based on this observation, Lingappa and Lockwood (1962) described a chitin medium for selective isolation. However, this chitin medium proved to be only slightly better than water agar, which was recognized by the authors and later also by El-Nakeeb and Lechevalier (1963). Hsu and Lockwood (1975) developed a useful medium for the isolation of actinomycetes (*Streptomyces*, *Nocardia*, and *Micromonospora*) from water samples by adding mineral salts to the chitin medium (*Table 42.8*). However, the medium was only poorly effective for isolation of actinomycetes from soil. It has to be considered that chitinolytic activity is not a genus-specific feature for *Streptomyces*. From over 300 strains tested, only 25 % were strongly chitinolytic (Williams et al. 1983a). As a result, this commonly used medium selects only for chitinolytic streptomycete strains which might not be the most abundant in soil. The vast majority of streptomycetes degrade starch, and therefore it represents a suitable selective carbon source for enrichment of streptomycetes. The combination of starch and nitrate is utilized by numerous streptomycetes in contrast to other bacteria (Flaig and Kutzner 1960b). Küster and Williams (1964 a, b), who improved this medium, stated: "The three best media, allowing good development of streptomycetes while suppressing bacterial growth, were those containing starch or glycerol as the carbon source with casein, arginine or nitrate as the nitrogen source." Additionally, streptomycete isolation is favored by a combination of glycerol and arginine (Benedict et al. 1955). Further studies by El-Nakeeb and Lechevalier (1963) revealed that this medium (*Tables 42.8* and *42.10*) was superior to nine other media, resulting in higher numbers and proportions of streptomycete colonies.

Moreover, other compounds have been successfully used for the selective isolation of streptomycetes such as cholesterol (Brown and Peterson 1966), elemental sulfur (Wieringa 1966), pectin (Wieringa 1955), poly-ß-hydroxybutyrate (Delafield et al. 1965), rubber (Nette et al. 1959), and natural and artificial humic acids (Hayakawa and Nonomura 1987a, b). The selective mechanisms of most of these compounds are based on the production of visible clearing zones or other changes in the medium.

To suppress fungal growth, agents with antifungal activity (antibiotics), such as cycloheximide (actidione, 50–100 µg/mL), are commonly used to supplement isolation media (*Table 42.9*),

Table 42.10

Composition of some media suitable for the cultivation of streptomycetes[a] (According to Korn-Wendisch and Kutzner 1992)

	Ingredients		Comments
1.	**Inorganic salts-starch agar**		
	Starch (soluble)	10.0 g	Make a paste of the starch with a small amount of cold distilled water and bring to a volume of 1 L; then add the other ingredients. The pH should be between 7.0 and 7.4. Do not adjust it if it is within this range
	$CaCO_3$	2.0 g	
	K_2HPO_4 (anhydrous basis)	1.0 g	
	NaCl	1.0 g	
	$(NH_4)_2SO_4$	2.0 g	
	$MgSO_4 \cdot 7H_2O$	1.0 g	
	Trace salts solution (see no. 5)	1.0 mL	
	Agar	12.0 g	
	Distilled water	1 L	
2.	**Glucose-yeast extract-malt extract (GYM) agar**		
	Glucose	4.0 g	Addition of $CaCO_3$ (2.0 g/L) is advantageous for many streptomycetes. Adjust medium to pH 7.2
	Malt extract	10.0 g	
	Yeast extract	4.0 g	
	Agar	12.0 g	
	Distilled water	1 L	
3.	**Glycerol-asparagine agar**		
	Glycerol	10.0 g	The pH should be between 7.0 and 7.4. Do not adjust if it is within this range
	L-Asparagine (anhydrous basis)	1.0 g	
	K_2HPO_4	1.0 g	
	Trace salts solution (see no. 5)	1.0 mL	
	Agar	12.0 g	
	Distilled water	1 L	
4.	**Oatmeal agar**		
	Oatmeal	20.0 g	Cook 20.0 g oatmeal in 1 L distilled water for 20 min. Filter through cheesecloth. Add distilled water to restore volume of filtrate to 1 L, and then add trace salts solution and agar. Adjust to pH 7.2
	Trace salts solution (see no. 5)	1.0 mL	
	Agar	12.0 g	
	Distilled water	1 L	
5.	**Trace salts solution**		
	$FeSO_4 \, 7H_2O$	0.1 g	
	$MnCl_2 \, 4H_2O$	0.1 g	
	$ZnSO_4 \, 7H_2O$	0.1 g	
	Distilled water	100.0 mL	
6.	**Trace elements solution SPV-4**		
	$CaCl_2 \, 2H_2O$	4.0 g	SPV-4 is used as an alternative to (5). Add 5 mL of this stock solution to 1 L of medium
	$CoCl_2$	0.022 g	
	$CuSO_4 \, 5H_2O$	0.04 g	
	Fe (III) citrate	1.0 g	
	$MnSO_4$	0.2 g	
	$Na_2B_4O_7 \, 10H_2O$	0.1 g	
	$Na_2MoO_4 \, 2H_2O$	0.025 g	
	$ZnCl_2$	0.1 g	
	Distilled water	1 L	

[a]Recipes 1–5 from Shirling and Gottlieb (1966) and recipe 6 from Voelskow (1988/1989)

as described by Williams and Davies (1965). In addition, these authors found that nystatin and pimaricin (each 10–50 μg/mL) were even more effective.

Compounds with antibacterial activity need to be used with caution as some actinomycetes may also be sensitive to them. For example, penicillin (1 μg/mL) and polymyxin (5 μg/mL) inhibit the growth of many unwanted bacteria but also suppress some streptomycetes (Williams and Davies 1965). Actinobacterial genera, most notably streptomycetes, vary significantly in their sensitivity to antibacterial agents (Preobrazhenskaya et al. 1978). Hence, it may be recommended to use antibacterial compounds for the isolation of other actinobacterial genera (Cross 1982).

Nevertheless, the selective isolation of certain species or groups of *Streptomyces* can be facilitated by media containing antibiotics, as displayed by the use of starch-casein agar supplemented with rifampicin (50 μg/mL) for the selective isolation of members of the *Streptomyces diastaticus* cluster by Williams et al. (1983a) and Vickers et al. (1984). Wellington et al. (1987) described a similar effect, by using several media containing different C and N sources, as well as media supplemented with inhibitory compounds.

The isolation of streptoverticil-producing *Streptomyces* species was favored by a selective isolation medium supplemented with cycloheximide and nystatin (each 50 μg/mL) to suppress fungal growth and oxytetracycline (25 μg/mL) to inhibit growth of other actinomycete genera, including *Streptomyces* groups (Hanka et al. (1985)). The selectivity of this medium was further enhanced by the addition of lysozyme (1,000 μg/mL) (Hanka and Schaadt 1988). Starch-casein-nitrate agar (Ottow 1972) containing Rose Bengal (35 mg/L) inhibits the growth of most bacteria and controls spreading of fungi across isolation plates. Fungi can also be suppressed by the addition of sodium propionate (Crook et al. 1950; ❯ *Table 42.9*).

Soil stimulates growth, sporulation and pigmentation of actinomycetes/streptomycetes (Trolldenier 1966) and is therefore often supplemented to isolation media to increase the number of colonies. The addition of montmorillonite or Ca-humate to liquid media promotes the growth and metabolic activity of some actinomycetes (Martin et al. 1976). A similar effect has been observed for clay in dialysis tubes after a short lag period, an observation which may be explained by the adsorption of one or more inhibitory substances produced during growth. Adsorbing materials have a positive effect on the genetic stability of other bacteria and on fungi (Martin et al. 1976).

The environmental requirements and tolerances of streptomycetes have been described in detail by Kutzner (1981). Streptomycetes are usually regarded as obligate aerobes with a limited capacity for growth under microaerophilic conditions (Kutzner 1981, Van Keulen et al. 2003, 2007), and dissimilatory reduction of nitrate is common (Van Keulen et al. 2007; Fischer et al. 2010). Despite poor growth under anaerobic or microaerophilic conditions, many *Streptomycetes* are able to withstand long periods of anaerobic stress (Van Keulen et al. 2007). Whether streptomycetes grow aerobically or microaerophilically is mainly dependent on the nutritional composition of the medium. In a nutrient rich medium, streptomycetes grow aerobically at the surface of the semisolid agar column, but in poor media or in a medium with a nonutilizable carbon source, they grow microaerophilically in semisolid agar. In stationary liquid culture, streptomycetes grow as pellicles at the air-liquid and liquid–solid surface interfaces, whereas the medium itself stays completely clear (Van Keulen et al. 2003).

Most streptomycetes are neutrophilic organisms, which means they grow optimally between pH 5.0 and 9.0 with an optimum close to pH 7.0. Thus, most isolation media have pH values of 7.0–7.5. Only a few of the type strains studied by Williams et al. (1983a) were capable to grow at pH 4.3, although large populations of acidophilic and acidoduric strains have been isolated from acidic soils (Williams et al. 1971; Khan and Williams 1975; Hagedorn 1976). Acidophilic streptomycetes grow in a pH ranging from 3.5 to 6.5, and optimally between pH 4.5 and 5.5. However, a wide range of pH requirements are present among streptomycetes from acidic environments (Flowers and Williams 1977b). Acidophilic strains are capable to produce diastases (Williams and Flowers 1978) and chitinases which have pH optima below that of the corresponding enzymes from neutrophilic strains. Populations of alkaliphilic streptomycetes, with a growth optimum at pH 9.0–9.5, have been isolated from soils in Japan. Also six of the type strains tested were able to grow at pH 11.5 (Mikami et al. 1982). Moreover, large populations of alkaliphilic streptomycetes have been isolated from a beach and dune sand system at Ross Links in Northumberland, UK (Antony-Babu and Goodfellow 2008).

The majority of streptomycetes isolated from soils are mesophilic; hence, their optimal growth temperature lies between 22 °C and 37 °C (in most cases at 28 °C). In contrast, several thermotolerant and thermophilic strains grow well at higher temperatures (40, 45, 50, or 55 °C), while psychrophilic strains (e.g., from marine environments) grow best at 15–20 °C. A series of type strains studied by Williams et al. (1983a) grew at 10, 37, and 45 °C, although a few grew slowly at 4 °C (Williams et al. 1983a). Nevertheless, in many cases, the optimal temperature for maximal yield or rapid growth may not be the best option for studying the production of secondary metabolites (e.g., antibiotics and pigments). This means that culture conditions are dependent on the aims of the study. Mesophilic actinomycetes usually produce visible colonies within 7–14 days of incubation, whereas thermophilic strains tend to form colonies faster within 2–5 days. Marine and other psychrophilic actinomycetes grow much slower and may need several weeks (up to 10) for visible colonies to appear on isolation media.

In general, colonies of *Streptomyces* can be easily identified by their macroscopic and microscopic appearance. Purification is usually facilitated by transferring colonies from isolation plates into nonselective medium. Williams and Wellington (1982a) stated that purification is "undoubtedly the most time-consuming and often the most frustrating stage of the isolation procedure." Acidophilic streptomycetes can be readily isolated on acidified starch-casein agar supplemented with cycloheximide and nystatin (Kim et al. 2003).

Cultivation and Preparation of Inoculum

Most streptomycetes are nonfastidious organisms with a chemoorganotrophic metabolism. For optimal growth streptomycetes require an organic carbon source, such as starch, glucose, glycerol, and lactate, and usually the provision of a suitable inorganic nitrogen source, like ammonium or nitrate (Kutzner 1981). Nevertheless, different isolates can vary significantly in their carbon and nitrogen source utilization patterns, which are frequently used as taxonomic characteristics (e.g., Shirling and Gottlieb 1966; Pridham and Tresner 1974b; Williams et al. 1983a; Kämpfer et al. 1991). Commonly used carbon sources comprise cellobiose, glucose, glycerol, d-mannose, and trehalose; valuable nitrogen sources are ammonium, L-arginine, L-asparagine, and nitrate. The majority of strains can degrade casein, esculin, gelatin, and hypoxanthine, but only a small number utilize organic acids, inulin, l-methionine, nitrite, or xylitol. Streptomycetes grow well on many different media, but spore formation is usually most prolific on those with a high carbon-nitrogen ratio (Kutzner 1981). In general streptomycetes require a good supply of free water for growth but are unable to develop at high osmotic or matric potentials. Survival of streptomycetes in dry conditions is supported by the resistance of arthrospores to desiccation, as opposed to vegetative mycelia (Williams et al. 1972).

The need to supplement culture media with specific trace elements has not been examined in detail. Spicher (1955) described the positive effect of trace elements in soil on the growth of streptomycetes. Nevertheless, many of the early used media (even the "synthetic" media) were not supplemented with trace elements. In fact, recipes of many authors (*Tables 42.8* and *42.10*) included only a selected number of metal ions. A rather complete mixture (SPV-4; *Table 42.10*) has been found to be optimal for the growth of actinomycetes and other bacteria (Voelskow 1988/1989).

"Synthetic media" can be used for the cultivation of streptomycetes. However, the need for specific nutritional requirements with respect to vitamins and organic growth factors has not been addressed. Growth rates and biomass production can be improved by using complex organic substrates such as malt extract, oatmeal, or yeast extract. In addition, a combination of a complex organic carbon source with a single amino acid as nitrogen source (e.g., glutamic acid, arginine, or asparagine) is also suitable.

"General media" have been recommended for the cultivation of streptomycetes, as they allow the completion of the *Streptomyces*' life cycle, including germination of spores, growth of substrate and aerial mycelium, and visible formation of spores (visible, because of the typical color of the spores). Some of these media were used in the International *Streptomyces* Project (ISP), among them glucose-yeast extract-malt extract, glycerol-asparagine, inorganic salts-starch, and oatmeal agars (Shirling and Gottlieb 1966). Numerous general media have been proposed for the growth of streptomycetes, four of which are of considerable practical value (*Table 42.10*). For additional media formulations, see Waksman (1961) and Williams and Cross (1971).

$CaCO_3$ is added to some media, as Ca^{2+} supports growth and neutralizes acids produced by many streptomycetes; such media also allow good sporulation. Cultures should be examined microscopically to detect the extent of macroscopically heavy aerial mycelia as they may contain very few spores, whereas aerial mycelia which are hardly detectable by the naked eye may be a good source of spores.

A list of specialized media, especially for the study of streptomycetes genetics, is provided by Kieser et al. (2000).

Solid media in dishes or slants are recommended for the growth of streptomycetes for subcultivation and maintenance as well as for most diagnostic tests. Numerous strains produce aerial mycelia and spores on solid media when the entire surface is covered by confluent growth. In contrast to many molds, *Streptomyces* colonies only spread over a limited area; thus, a point inoculation will usually not result in confluent growth. However, if streaked onto an agar plate, some strains require empty spaces between the streaks (cross-hatch inoculation) to induce sporulation. Dry conditions are usually more suitable for sporulation. A horizontal incubation of slants for the first 2 days allows liquid to soak into the agar surface (Hopwood et al. 1985). A suspension of inoculum in liquid should be used as starting material for sporulation (Kieser et al. 2000).

For the generation of cultures, single colonies should be selected and streaked onto fresh media. When streptomycetes are cultivated on solid media, morphological heterogeneity is frequently observed. More details can be found in Kieser et al. (2000). Successive rounds of mass culture should be avoided, especially in genetic studies because this technique reduces the accumulation of revertants or increases the gradual loss of selected plasmids or both (Kieser et al. 2000).

For some diagnostic tests, precultivation of grown colonies in liquid media is necessary to obtain a homogeneous suspension (Kämpfer et al. 1991). Streptomycetes should be cultivated in liquid medium without agitation. This precultivation step is required for the provision of cell material for biochemical analysis, for certain physiological studies (e.g., degradation tests), and for the production of secondary metabolites (e.g., antibiotics) or enzymes. For many detailed studies, e.g., for preparation of protoplasts for fusion, transfection, or transformation, liquid cultures should also be started from an inoculum of spores.

The multicellular lifestyle of streptomycetes causes some problems in the study of metabolic properties, as not all cells of the initial suspension are in the same physiological state. Commonly, streptomycetes grow by mycelial elongation and branching. Nevertheless, physiological homogeneity cannot be maintained when nutrients become limited to central parts of the colony. Hence, spore germlings are used in physiological studies, although large quantities of spores are needed. To circumvent this problem, liquid cultures can be supplemented, e.g., with dispersants like agar, carboxymethylcellulose, Junlon®, polyethylene glycol, starch, and sucrose. A summary of the advantages and disadvantages of these methods can be found in chapter 2 of Kieser et al. (2000). Due to the highly aerobic nature of streptomycetes, it is necessary to shake cultures during

incubation. Recommended procedures include Erlenmeyer flasks with the use of indentations or stainless steel springs, but tubes in a slanted position on a shaker or roller also facilitate an excellent supply of oxygen for small quantities of broth, with 3–5 mL being sufficient for some physiological tests. However, it should be taken into account that a few secondary metabolites (e.g., antibiotics and pigments, which are formed on solid media) may not be produced under these culture conditions.

Two media recommended by Korn-Wendisch and Kutzner (1992) have been widely used for submerged cultivation of streptomycetes (g/L): (1) GPYB broth (glucose, 10.0; peptone from casein, 5.0; yeast extract, 5.0; beef extract, 5.0; $CaCl_2 \cdot 2H_2O$, 0.74; pH 7.2) and (2) soybean meal-mannitol nutrient medium (soybean meal, 20.0; mannitol, 20.0; pH 7.2). For subculturing streptomycetes, arthrospores and vegetative mycelium can be used as inoculation material; vegetative mycelium occasionally includes "submerged spores" (Wilkin and Rhodes 1955). Similar procedures are recommended by Kieser et al. (2000).

Spore suspensions stored at 4 °C can be used for several weeks. As spores tend to settle and clump, a few glass beads should be added to the screw-cap tubes, which help to resuspend spores before use. The preparation of mycelia for detailed DNA or RNA studies is described in chapters 8 and 9 of Kieser et al. (2000).

Maintenance Procedures

Several different procedures have been used (Kirsop and Snell 1984) for the short- and long-term preservation of microorganisms. Korn-Wendisch and Kutzner (1992) described three short-term preservation methods: (1) agar slope cultures may be stored at 4 °C for few months, (2) spore suspensions can be mixed with soft water agar and kept at 4 °C (Kutzner 1972), and (3) glycerol can be added to spore suspensions (final concentration, 10 %, v/v) and stored at −20 °C (Wellington and Williams 1978). After thawing, these cultures can serve as inocula for most diagnostic tests, except carbon utilization (Williams et al. 1983a).

For long-term preservation, Kieser et al. (2000) proposed the preparation of spore suspensions in 20 % glycerol which can be stored at −20 °C. In another method, strains are cultured in complex media (like trypticase soy broth [TSB] agar), then 20 % glycerol plus 10 % lactose are added, and the samples are stored in the vapor phase of liquid nitrogen. A third method employs drying on unglazed porcelain beads (Lange and Boyd 1968), followed by soil culture (Pridham et al. 1973), and lyophilization (Hopwood and Ferguson 1969).

Spore suspensions or homogenized mycelia are mixed with glycerol to give a final concentration of 25 %; this mixture can be kept at −25 °C for long-term preservation (Wellington and Williams 1978). Alternatively, spores and mycelia suspended in 10 % skim milk can be lyophilized. Liquid nitrogen cryopreservation is a very simple, reliable, and time-saving method. In this method, living cells are stored in small polyvinyl chloride (PVC) tubes ("straws") at −196 °C; this procedure has been tested for several actinomycetes. First, bacteria are harvested from well-sporulated cultures grown on suitable agar media in Petri dishes by a 2 × 25-mm piece of sterile PVC tubing that is pressed into the mycelial mat and agar, and then carefully raised to excise the agar plug. This procedure is repeated until the tube is filled with agar, latter is then placed in a sterile cryovial (the screw cap marked with the strain accession number). In total up to 13 tubes can be placed into a 1.8-mL vial. Two vials prepared for each strain are then fixed to a metal clamp for freezing in the gas phase of a liquid nitrogen container. After 10–15 min, when temperature falls below −130 °C, the clamp can be immersed in the liquid phase at −196 °C. A container with a capacity of 250 L will hold at least 8,000 vials or 4,000 strains. For viability testing, one tube is removed from the vial within the nitrogen gas atmosphere of the container and thawed directly on a suitable agar medium. The mycelium will be visible after a few days of incubation. Plugs may be pushed out of the tubes with a sterile needle when strains do not produce abundant mycelium.

Isolation, Enrichment, and Maintenance Procedures for the Genus *Kitasatospora*

Enrichment, isolation, and maintenance procedures are as described for *Streptomyces* species.

Isolation, Enrichment, and Maintenance Procedures for the Genus *Streptacidiphilus*

Kim et al. (2003) described the isolation of eighteen strains of streptoacidiphili on acidified starch agar plates supplemented with cycloheximide and nystatin (each 50 μg mL^{-1}) using the isolation procedure reported by Goodfellow and Dawson (1978). *S. jiangxiensis* was isolated by plating acidic rhizosphere soil suspensions, prepared using a differential centrifugation procedure (Wang et al. 2003), onto an acidified selective isolation medium containing aspartate, sucrose, and L-glutamate as carbon sources. Acidified starch-casein-nitrate agar (Küster and Williams 1964b) can also be applied (Wang et al. 2006) in combination with differential centrifugation, as described by Sembiring et al. (2000). Another method for the isolation of acidophilic actinobacteria from soil is described by Cho et al. (2006).

Kim et al. (2003) reported that short-term storage would be achieved by growing strains on acidified modified Bennett's agar (Jones 1949). Acidified oatmeal (ISP medium 3, Shirling and Gottlieb 1966) and acidified inorganic salts-starch (ISP medium 4, Shirling and Gottlieb 1966) agar can also be used for this purpose. For long-term preservation lyophilization, freezing in glycerol and storage in liquid nitrogen can be used. Glycerol suspensions are prepared by scraping aerial growth or substrate mycelium or both from heavily inoculated plates and making heavy suspensions in 3 mL of aqueous glycerol in small (e.g., bijoux) bottles, which are stored at −20 °C.

Ecology

Streptomycetes are highly abundant in soil, which is their major natural habitat. As stated above, most streptomycetes are able to degrade complex and fractious animal and plant materials, which are usually polymeric residues such as proteins (e.g., elastin and keratin), polysaccharides (e.g., cellulose, chitin, pectin, and starch), lignocellulose, and aromatic compounds. The biodegradative activities and complex extracellular biology of actinomycetes have been discussed in various reviews (Lechevalier 1988; Crawford 1988; Peczynska-Czoch and Mordarski 1988; Chater et al. 2010).

Streptomycetes are capable of breaking down lignin, which naturally occurs in a lignocellulose complex together with cellulose and xylan (hemicellulose). Using ^{14}C-labeled lignin, it has been shown that streptomycetes (Crawford 1978; Antai and Crawford 1981) as well as other genera of actinomycetes are involved in the process of lignin degradation (McCarthy and Broda 1984; McCarthy et al. 1984, 1986), although fungi play a more important role in this process (Crawford 1981, 1988; Janshekar and Fiechter 1983; Kirk and Farell 1987).

Ligniolytic streptomycetes can also decompose the cellulose of the lignocellulose complex. For detailed information, see Ramachandra et al. (1988), Wang et al. (1990), Crawford et al. (1993), Chamberlain and Crawford (2000), Kormanec et al. (2001), Gottschalk et al. (2003), and Kaneko et al. (2003). Additionally, mesophilic and thermophilic streptomycetes have been reported to possess multicomponent cellulases, which consist of several endo- and exoglucanases (Enger and Sleeper 1965; Crawford and McCoy 1972; MacKenzie et al. 1984; Harchand and Singh 1997; Marri et al. 1997; Ulrich and Wirth 1999; Wirth and Ulrich 2002). Chater et al. (2010) have reviewed the nonenzymatic proteins that *Streptomycetes* employ to target and bind to cellulose and its degradative processes which include a combined oxidative and cellulolytic attack using catalase/peroxidase enzymes and Avicelases.

Xylanases, which are involved in the degradation of the lignocellulose complex, seem to be common among thermophilic actinomycetes; however, they have also been detected in mesophilic streptomycetes (Kluepfel and Ishaque 1982; McCarthy et al. 1985; Kluepfel et al. 1986; Deobald and Crawford 1987; Godden et al. 1989; Schäfer et al. 1996; Morosoli et al. 1999).

Other polymer degrading enzymes found in streptomycetes include pectinolytic complexes (Sato and Kaji 1975, 1977, 1980a, b) and chitinolytic complexes, which consist of chitinase and chitobiase. These have been isolated from *S. griseus* (Berger and Reynolds 1958), *S. antibioticus* (Jeuniaux 1966), and other streptomycetes (Beyer and Diekmann 1985). Specialized chitin-binding (CHB) proteins and CHB domains in chitinases allow *Streptomycetes* to interact strongly with various types of α-chitin and β-chitin (reviewed in Chater et al. 2010). Genes for family 18 and 19 chitinases, which use different reaction mechanisms to hydrolyze the glycolytic bonds between saccharides in chitin and chitosan, have both been identified in various *Streptomyces* genome sequences. For example, the genome sequence of *S. coelicolor* A3(2) contains 11 deduced family 18 chitinases and two family 19 chitinases, with various modular arrangements comprising catalytic, substrate-binding, and linker domains (Chater et al. 2010). This potentially enables them to hydrolyze the natural diversity of chitin types.

Starch, which is primarily used as material in the food, paper, and textile industry, can be degraded by numerous fungi and bacteria. The enzymes involved are amylases, some of which have been found in several streptomycetes (Mordarski et al. 1970; Suganuma et al. 1980; Fairbairn et al. 1986; McKillop et al. 1986).

Actinomycetes are also capable of using keratin as the sole source of C, N, S, and energy (reviewed by Kornillowicz-Kowalska and Bohacz 2011). Native keratin in feathers, nails, horns, and hair are subjected to intensive degradation by keratinolytic actinomycetes, mostly *Streptomycetes*, e.g., *S. fradiae*, *S. pactum*, *S. thermoviolaceus*, or other genera, e.g., *Thermoactinomyces*.

In addition to degrading polymeric compounds, streptomycetes have the ability to degrade other organic materials, such as wool (Noval and Nickerson 1959), cotton and plant fibers (Khan et al. 1978; Lacey and Lacey 1987), plastics (Pommer and Lorenz 1986), and hydrocarbons in emulsions and jet fuel (Genner and Hill 1981). Lacey (1988) and Behal (2000) give a detailed review about the biodegradation of natural and synthetic substances. An important waste material accumulating worldwide is rubber due to difficulties with reusing natural and synthetic rubber materials. Actinomycetes of the CNM (Corynebacterium, Nocardia, Mycobacterium) group are the most potent rubber-degrading bacteria isolated so far, which require direct contact with the rubber substrates. Another group of rubber-degrading bacteria generally also belong to the actinomycetes (e.g., *Actinoplanes*, *Streptomyces*, and *Micromonospora*) (recently reviewed by Yikmis and Steinbüchel 2012). *Streptomyces* sp. K30 excretes via the Tat pathway a so-called Latex-clearing protein (Lcp) and heteromultimeric aldehyde dehydrogenases, which enable degradation of poly(*cis*-1,4-isoprene) to isoprenoid acids, which can be further metabolized via β-oxidation (reviewed by Yikmis and Steinbüchel 2012).

As well as efficient degraders of (recalcitrant) organic matter, *Streptomyces* spp. have also been isolated from polluted environments, e.g., natural heavy metal containing and polluted sites in Germany, Italy, and China (Amoroso et al. 2000; Schmidt et al. 2007; Lin et al. 2011a). One of the German isolates, *S. acidiscabies E13* could grow on media containing as high as 10 mM nickel chloride, whereas it was also tolerant for copper, cadmium, chromium, and iron (Schmidt et al. 2007). Furthermore, two *S. mirabilis* strains, isolated from an uranium mine, were able to grow on media containing as high as 100 mM nickel chloride, whereas they could also tolerate up to 100 mM zinc (Schmidt et al. 2009). The draft genome sequence of *S. zinciresistens* K42 (CCNWNQ 0016 T), isolated from a Chinese copper-zinc mine tailing with a maximum level of resistance to Zn^{2+} of 35 mM (Lin et al. 2011a), showed a large number of genes encoding proteins predicted to be involved in conferring metal resistance (Lin et al. 2011b). Many of these genes appear to have been acquired through horizontal gene transfer.

In soil, streptomycetes can show distinct mycelial growth. In this habitat, they are adapted to multiple and often rapidly changing physical conditions (e.g., frost, drought, shifts in aeration, hydrostatic pressure, moisture tension, pH, and anaerobic conditions) by the formation of spores, which are semidormant stages in the life cycle and allow the survival in soil for long periods (Mayfield et al. 1972; Ensign 1978). Viable cultures of cells have been reported by Morita (1985) from 70-year-old soil samples. Streptomycetes are mainly present in soil as inactive spores. One disadvantage of persisting as a spore is the very low germination efficiency, which may be caused by competition with other microorganisms. Spores, which pre-germinate, can grow for a short time and then re-sporulate (Lloyd 1969). A number of factors may cause the germination of spores. In addition to special signaling factors, the presence of exogenous nutrients, water, and Ca^{+2} seems to be necessary components (Ensign 1978). Beside germination, nutrients also influence the degree of hyphal growth and the time of differentiation into aerial hyphae. Fodder and other organic material, freshwater, and marine habitats as well as potable water systems can come into contact with soil (Korn-Wendisch and Kutzner 1992), e.g., by human and other activities. Natural materials (e.g., fodder, hay, grain, and wood) and synthetic products (e.g., cotton textiles, fabric, paper, rubber, plastics, and plasticizers), which can be found in or transported to soil, can be degraded with the help of mesophilic and especially thermophilic streptomycetes.

The Terrestrial Habitat

The soil pore network is contained within the soil matrix. Bacterial communities (in the form of single cells or microcolonies) are often found within the soil pores in close association with soil surfaces. Bacterial communities are often limited in movement to under a micrometer (Trevors et al. 1990) through the soil column without the aid of a transporting agent, such as water flow, growing roots, or burrowing organisms. The fate and activity of these organisms is therefore largely dependent on their site of origin. The soil matrix acts as a migratory barrier to non-hyphal bacteria. However hyphal bacteria may overcome this constraint by crossing air-filled spaces by hyphal/mycelial growth (Schäfer et al. 1998). Filamentous organisms also benefit from their ability to transfer carbonaceous compounds over the whole distance of the organism providing resources across the whole hyphal matrix, thus allowing them to cross nutrient-poor sites (Nazir et al. 2010). A tentative model has been proposed for *S. coelicolor* A3(2) incorporating the two previous observations (Yeo and Chater 2005). It is hypothesized that in tiny enclosed spaces in soil, nonreproductive "exploratory" aerial hyphae grow through the gas phase until they encounter a new, potentially colonizable surface with nutrients and/or water (Yeo and Chater 2005). It is proposed that the accumulation of signaling molecules in the vapor phase of the enclosed space might determine the choice of this nonreproductive developmental pathway, which is possibly linked to inhibition of sigma factor WhiG. Importantly, the exploratory aerial hyphae are thought to deposit and use "phase I" glycogen, which is normally found in the region of vegetative mycelium near aerial hypha branches. This is in contrast to deposition and use of "phase II" glycogen in apical compartments of reproductive aerial hyphae as they are undergoing sporulating septation (Yeo and Chater 2005).

Soil is one of the most diverse habitats known for microorganisms (Dance 2008), with a significantly higher diversity of prokaryotes compared to any other natural environment (Gans et al. 2005). The main factor driving the biodiversity of soil is its heterogeneity, providing a range of microhabitats which differentially select prokaryotic or fungal types (Standing and Killham 2007). The growth and metabolism of microorganisms in soil can lead to changes in pH, redox potential, and the ionic strength of soil (Haferburg and Kothe 2007). Soil microorganisms also have a major influence on particle aggregation as well as soil texture and the availability of nutrients for plants (Barto et al. 2010).

The dynamics of the composition of a microbial community in soil is therefore dependent on abiotic and biotic factors, especially vegetation, soil type, content and type of organic matter, pH, temperature, season and climate, and circulation of water and air. Actinobacteria have been identified as one of the predominant phylotypes in several metagenomic studies of soils (e.g., Buckley and Schmidt 2003; Smith et al. 2006) and phylogenetic analysis has revealed that actinobacterial populations may be cosmopolitan, with several dominant phylotypes being identified at different geographical locations. Culture-independent molecular ecological studies on soils usually group actinobacteria and often do not specify the (changes in) distribution of *Streptomyces* species (e.g., Sheik et al. 2011; Sagova-Mareckova et al. 2011). Nonetheless, many *Streptomyces* species are found distributed over a diverse range of soil habitats.

A culture-independent study on microbial community dynamics in petroleum hydrocarbon-contaminated wetlands microcosms showed that enhanced degradation after addition of inorganic nutrients was linked to an increase in the amount of *Streptomyces* (Bachoon et al. 2001), suggesting that *Streptomyces* could be used for bioremediation of oil pollution.

Jenkins et al. (2009) showed that soil pH is a major driver of change in actinobacterial communities in long-term managed grasslands. The relative abundance of *Streptomyces* spp. increased after additions of farm yard manure to relatively acidic plots (pH 5.6–5.8). A higher relative abundance of *Streptomycetes* was also correlated to soil water content (Jenkins et al. 2009). *Streptomyces* abundance was also higher in grassland soils compared to forest soils (Nacke et al. 2011). This study also confirmed that soil pH is a major determinant for bacterial community structure. *Streptomyces* was also in the top 20 of most abundant bacterial genera in soils of a grass monoculture pasture and a mixture of grasses at a conservation site in the Texas High Plains region (USA), but they were much less abundant in two managed agricultural soils (Acosta-Martinez et al. 2008).

Among the 48 genera of nonphototrophs detected in the bacterial communities in biological soil crusts from the

Colorado Plateau, actinobacteria (particularly *Streptomyces* spp.) were very common and diverse, with 18 genera and an average contribution to the total 16S rDNA amplificate of 11.8 % (Gundlapally et al. 2006). Many of the actinobacterial and *Streptomyces* isolates are mycelial and it is suggested that these abundant nonphototrophic crust bacteria may play a significant role in the physical process of crust formation and maintenance—a role typically assigned to filamentous cyanobacteria.

A comparison of the actinobacterial community composition in three alkaline and saline soils of the former lake Texcoco (Mexico) following flooding showed an inverse relationship between the abundance of actinobacteria and the salinity and alkalinity of the soil. *Streptomyces* 16S DNA sequences could be identified in the intermediate saline and alkaline soil, which had an electrolytic conductivity of 56 dS m^{-1} and a pH of 10.1 (Valenzuela-Encinas et al. 2009).

Laskaris et al. (2012) showed that neither streptomycin producers nor *S. griseus* was prevalent in the several fresh or chitin- and starch-amended soils examined (less than 0.1 % of soil actinobacteria) as determined by amplicon sequencing of *atpD*, a housekeeping gene coding for the ATP-synthase beta chain, and *S. griseus*-specific and "generic" *strA*, a streptomycin resistance gene coding for streptomycin and related phosphotransferases. This finding was unexpected as previous research from the same group showed that *S. griseus* was the prevailing species in a population of streptomycin-resistant isolates from all of the tested soils (Tolba et al. 2002). The latter study also showed that *str* gene distribution was prevalent in the streptomycin-treated soil. Other work by the same group showed that the relative abundance of the *Streptomyces* population and the number of *Streptomyces*-like chitinase gene sequences increased following chitin baiting of a sewage-sludge-amended upland grassland pasture (Metcalfe et al. 2002).

Antarctic Dry Valley desert soil harbors highly diverse actinobacterial communities (Babalola et al. 2009). Phylogenetic analysis of clones generated with actinobacterium and streptomycete-specific PCR primers revealed that the majority of the phylotypes were most closely related to uncultured *Pseudonocardia* and *Nocardioides* species. In contrast, the majority of the cultured isolates (>80 %) were *Streptomyces* species even though phylotypes affiliated to the genus *Streptomyces* were detected at a low frequency in the metagenomic study (Babalola et al. 2009).

It is not unusual for *Streptomyces* to represent the dominant actinobacterial or even microbial population in culture-dependent studies. In most cases they make up about 1–20 % of the total viable count, which is 10^4 to 10^7 colony-forming units (CFU) per g soil (Korn-Wendisch and Kutzner 1992; Watson and Williams 1974; Saadoun et al. 1998). Early culture-dependent studies by Williams et al. (1969) assigned soil streptomycetes to color groups, based on diffusible pigment colors produced on oatmeal agar and on their ability to form melanin pigments on peptone-yeast extract-iron agar. Subsequently, this classification into color groups was used as a tool by other researchers as well to study the diversity of streptomycetes in natural habitats (e.g., Goodfellow and Haynes 1984; Atalan et al. 2000; Sembiring et al. 2000). Nevertheless, this color grouping is based on subjective interpretation and comparison of data between different studies is difficult. A potential improvement of this method was recently presented by a computer-assisted numerical analysis of 321 alkaliphilic streptomycetes that were assigned to color groups (Antony-Babu et al. 2010). The authors argue that, with this method, distances between individual colors could be calculated more objectively and that the data can be compared with computer-assisted numerically defined color groups in future studies on streptomycete taxonomy in natural habitats.

While the use of colors for *Streptomyces* taxonomy is functional, most culture-dependent studies rely on molecular and metabolic methods to detect the presence, abundance, and activity of *Streptomyces*. D'Costa et al. (2006) isolated a collection of spore-forming bacteria resembling actinomycetes both morphologically and microscopically from soil samples originating from diverse locations (urban, agricultural, and forest). Amplification and sequencing of 16S ribosomal DNA from a subset of strains indicated that they belonged to the actinomycete genus *Streptomyces*. Without exception, every strain in the library was found to be multidrug resistant to seven or eight antibiotics on average, with two strains being resistant to 15 of 21 drugs. Several antibiotics, including the synthetic dihydrofolate reductase (DHFR) inhibitor trimethoprim and the new lipopeptide daptomycin, were almost universally ineffective against the library. This result was surprising as the authors had not expected to find such extensive daptomycin resistance (D'Costa et al. 2006). These findings suggest *Streptomyces* are an environmental reservoir of resistance determinants, which could possibly be mobilized into the microbial community. Surprisingly, the occurrence of the oxytetracycline resistance genes *otrA* and *otrB* genes was limited in tetracycline-resistant *Streptomyces* isolates from a range of European habitats, including bulk and rhizosphere soil and manure and seawater (Nikolakopoulou et al. 2005). This finding could imply that some of the isolates may carry tetracycline-resistance genes that were not screened for.

Phylogenetic analysis of actinomycete isolates of freshly excavated Miocene lacustrine sediment (17–19 Myr old, lacking recent organic carbon, but may contain some fossil carbon) and four sites of primary succession (initial, early, middle, and late stages; aged 1–44 years) on the same sediment after years of mining activity revealed four distinct actinomycete clusters corresponding to the stages of succession (Chronakova et al. 2010). The relative proportion of actinomycetes, specifically *Streptomyces*, among total bacterial and genetic diversity increased significantly with the age of the sampling site. Moreover, pioneer species, such as operational taxonomic units (OTU) related to *S. microflavus*, *S. flavofuscus*, *S. anulatus*, *S. atratus*, *S. exfoliatus*, and *S. avidinii*, were replaced by late succession species, such as OTUs related to *S. aureus*, *S. tauricus*, *S. prunicolor*, *S. phaeochromogenes*, and *S. griseochromogenes*, during successive colonization of early, mid, and late colliery heaps (Chronakova et al. 2010). A few isolates of *Kitasatospora* were also identified among strains from the middle and late stages. The observed shift in community structure is associated

with plant root development, increasing availability of organic matter, and possibly earthworm feeding activity. The fresh Miocene lacustrine cluster isolates showed close relationships with *S. gougerotii*, *S. champavatii*, and *Streptomyces* sp. 445. Interestingly, these "ancient" *Streptomyces* strains were present only in this soil horizon and were not retrieved from soils of the primary succession gradient, suggesting an important role during early colonization of *terra nova*. Astonishingly, >50 % of these "ancient" strains were able to produce antibiotics acting against Gram-positive and Gram-negative bacteria and yeast as shown by the agar plug method, with up to 100 % and 71 % of examined strains encoding for, respectively, non-ribosomal peptide synthases and polyketide synthases. Up to 37 % of these "ancient" strains were resistant to antibiotics such as amoxicillin. These findings suggest that antibiosis and antibiotic resistance are ancient microbial traits. Additional evidence for the coexistence and coevolution of antibiotic resistance and biosynthesis genes in soil bacteria was provided recently (Laskaris et al. 2010).

Moreover, a more recent study, combining experimental and theoretical observations, suggests that diverse *Streptomyces* communities do not represent a stable ecological state but form an intrinsically dynamic eco-evolutionary phenomenon (Vetsigian et al. 2011). All pairwise interactions were recorded among 64 *Streptomyces* strains isolated from several individual grains of soil. A rich set of "sender-receiver" interactions was observed, including inhibition and promotion of growth and aerial mycelium formation. The probability that two random isolates interact was balanced; it was neither close to zero nor one. The interactions were also not random: the distribution of the number of interactions per sender was bimodal and there was enrichment for reciprocity—if strain A inhibits or promotes B, it is likely that B also inhibits or promotes A. Such reciprocity was further enriched in strains derived from the same soil grain, suggesting that it may be a property of coexisting communities. Interactions appeared to evolve rapidly: isolates with identical 16S rRNA sequences could have very different interaction patterns. A simple eco-evolutionary model of bacteria interacting through antibiotic production showed how fast evolution of production and resistance could lead to the observed statistical properties of the network. In the model, communities were evolutionarily unstable—they were constantly being invaded by strains with new sets of interactions (Vetsigian et al. 2011).

Katsifas et al. (1999) showed that the rhizosphere was the dominant factor in determining the population structure of different Greek terrestrial ecosystems, including heavily disturbed agricultural soils, rhizospheres of rare indigenous plants, and secluded preserved areas. Cluster groups appearing in only one or two habitats were *S. griseoflavus*, *S. rimosus*, *Streptoverticillium blastmyceticum*, *Nocardia mediterranea*, and *S. fulvissimus*. The most common cluster groups were *S. cyaneus*, *S. albidoflavus*, *S. diastaticus*, and *S. exfoliatus*, which were isolated from at least six different habitats.

Unburned prairie soils amended with low- and high-complex carbon (and nitrogen) at different concentrations also affected the (relative) abundance of *Streptomyces* species and their antibiosis and substrate utilization profiles (Schlatter et al. 2009). Cellulose and lignin amendments resulted in mesocosms with the highest *Streptomyces* densities. Also, *Streptomyces* communities receiving high concentration amendments were more inhibiting, whereas those receiving low-concentration amendments used substrates more efficiently (Schlatter et al. 2009). Substrate use and inhibitory activity were positively correlated among isolates in some treatments, such as low-concentration lignin, but were negatively correlated in soils with amendments such as low glucose concentrations, whereas no significant correlation was found in high-concentration lignin or glucose communities (Schlatter et al. 2009). Williams et al. (1972b) have shown that streptomycetes resist desiccation because of their ability to form arthrospores. Besides, the water tension then needed for growth can be much lower than for other bacteria, but on the other hand, they may be very sensitive to water-logged conditions.

Most attention has been directed to neutrophilic streptomycetes which are commonly present in neutral to alkaline soils (e.g., Flaig and Kutzner 1960b). Acidotolerant and acidophilic streptomycetes are abundant in acidic soils. Since acidophilic streptomycetes produce specific and stable amylases (Williams and Flowers 1978; Williams and Robinson 1981), they can be isolated using starch-casein agar adjusted to pH 5.0 and supplemented with antifungal agents (Khan and Williams 1975; Hagedorn 1976). In contrast, alkalitolerant and alkaliphilic streptomycetes are mainly found in alkaline soils (Babu and Goddfellow 2008; Mikami et al. 1982, 1985; Taber 1959, 1960).

Streptomycetes, as well as other soil actinobacteria, have been isolated from the surface, internal organs, and the intestinal tract of terrestrial insects and arthropods, such as attine and *Allomerus* ants, beewolf wasps, bark and ambrosia beetles, stinkbugs, firebugs, and sweet potato whitefly biotype Q (Szabó et al. 1967; Bignell et al. 1980, 1981; Bignell 1984; Haeder et al. ; Barke et al. 2010; Kaltenpoth 2006; Scott et al. 2008; Grubbs et al. 2011; Zucchi et al. 2012; Sudakaran et al. 2012; Indiragandhi et al. 2010), the gut of earthworms and potworms and their surrounding soil (Brüsewitz 1959; Parle 1963a, b; Kristufek et al. 1993, 1995), and pellets formed by woodlice and millipedes (Márialigeti et al. 1984). While these *Streptomyces* species are able to grow independently, it is thought that these animal-bacterial associations are mostly mutualistic or symbiotic. The animal host provides easy access to nutrients for *Streptomyces*, who then supplies its host with beneficial and growth promoting compounds enabling protection against infection for themselves, for their offspring, or their food (reviewed recently by Seipke et al. 2012; Kaltenpoth 2009). These interactions between microbes and their symbiotic hosts based on antibiotics production are environmentally successful and have existed for a long time. This suggests that medical use of antibiotics could possibly be long-term successful as well.

Streptomycetes are also found in the rhizosphere and as plant endophytes (Goodfellow and Williams 1983; Sembiring et al. 2000; Schrey and Tarkka 2008), where they are thought to play an important role. *Streptomyces* can provide small

metabolites (i) as plant growth promoting factors, e.g., auxin (reviewed by Strap and Crawford 2006); (ii) for the promotion of hyphal elongation and growth of fungi and other mycorrhiza (Schrey et al. 2012; Schrey and Tarkka 2008); (iii) to biologically control plant diseases, e.g., faerifungin (reviewed by Seipke et al. 2012; Kinkel et al. 2012; Schrey and Tarkka 2008); and (iv) to modulate plant defense mechanisms (reviewed by Schrey and Tarkka 2008). It has been proposed ever since the discovery of antibiotics from *streptomyces* that antibiotic-producing organisms have a competitive advantage over nonproducing organisms. However, there is no clear proof for the in situ production of antibiotics in unsterilized soil (Williams 1982) except for phenazine production by pseudomonads, which can be recovered from wheat roots at concentrations of 27–43 ng/g of root within the adhering soil (Thomashow et al. 1990). Antibiotics are difficult to detect in soil as they are likely produced in low concentrations and may be instable (Brian 1957; Williams 1982). Moreover, they may be adsorbed onto soil colloids (Williams 1982) and may also be produced only at certain stages of the growth cycle (Williams and Khan 1974; Williams 1982). Further, almost all of the evidence for the involvement of antibiotics in biocontrol is indirect or circumstantial. Indirect antibiotic production in soil was reported by Rothrock and Gottlieb (1984) by co-inoculating *Streptomyces* species in soil with root rot fungi of pea and soybean. However, they could not establish a clear relationship between antibiotics activity or antagonism on agar media and reduction in disease activity. Later studies also showed that *Streptomyces* were indeed efficient biocontrol agents of root plant diseases (see above). Recently, Kinkel et al. (2012) showed that *Streptomyces* from naturally occurring disease suppressive soils displayed a significantly higher intensity of inhibition of plant-pathogenic *S. scabies* than *Streptomyces* from disease-conducive soils. The diversity of inhibitory interactions across pathogen isolates was also significantly higher among the former, antagonistic *Streptomyces* than those from disease-conducive communities. Other and recent studies have identified endophytic *Streptomyces* species as attractive biocontrol agents (reviewed in Seipke et al. 2012; Schrey and Tarkka 2008).

Antibiotic production (oxytetracycline) by *S. rimosus* in sterile soil microcosms was indirectly and qualitatively shown through co-inoculation of a genetically engineered GFP-containing tetracycline-sensitive biosensor (Hansen et al. 2001). Streptothricin biosynthesis by *S. rochei* F20 in sterile soil microcosms was shown by using reverse transcription-PCR (RT-PCR) of one of the streptothricin-biosynthetic genes *sttA*, but *sttA* expression could not be not detected in sterile and nonsterile rhizosphere or rhizoplane soil cosms with spring wheat seedlings (Anukool et al. 2004).

The Aquatic Habitat

Actinomycetes can easily be isolated from aquatic ecosystems and especially from sediments of rivers and lakes. In particular, rivers carry large amounts of various actinomycetes, including streptomycetes. In addition, actinomycetes are capable to survive as dormant spores in aquatic habitats for a long period (Al-Diwany and Cross 1978). "Soil" streptomycetes are often present in water bodies such as creeks, ponds, and rivers, especially after waterflow over land after heavy rainfalls, though they can also be redistributed through air in aerosols generated by wind flowing over dry soils. Streptomycetes also find their way into the sediments of the lakes, rivers, and, after transfer to the sea, into marine sediments. Burman (1973) found 59–200 streptomycetes and 10–20 micromonosporae per mL river water sampled from the river Thames. The streptomycetes grew on decaying vegetation on riverbanks and mud flats at low water or on floating mats of decaying algae or other vegetation.

Odorous substances formed by streptomycetes are washed into or produced in the water giving rise to "earthy tastes" in drinking water supplies and bottom-feeding freshwater fish. Geosmin and methyl-isoborneol are the two most frequently detected odorous, "off flavor-tasting" compounds in water (Gerber 1979a, b; Zaitlin and Watson 2006). Wood et al. (1983) noted that preventing the contamination of drinking water with these compounds, and thus the earthy tastes in water reservoirs and supply systems, depends on locating the production sites and identifying the distribution patterns of these substances (Silvey and Roach 1975; Lechevalier et al. 1980). Burman (1973) found that filtration processes help to reduce the quantity of streptomycetes in drinking water. He also identified a new, aquatic strain of *Streptomyces* in the distribution system (for details, see Burman 1973). It is these compounds that give moist soil its characteristic smell. A biodiversity study on the bottom sediments and water of Lake Baikal showed that 66 % of the water isolates belong to the genus *Streptomyces*, whereas 51 % of the sediment isolates belong to the genus *Micromonospora* (Terkina et al. 2002). Jiang and Xu (1996) found a similar prevalence for *Streptomyces* and *Micromonospora* species in 12 Yunnan Middle Plateau lakes in China. *Streptomyces* was also shown to be the most abundant species (17 %) of actinomycetes in water samples of different sites in Rankala Lake of Kolhapur City, India (Nakade 2012). Aquatic vegetation from three stream sites located within Savannah River Site, South Carolina (USA), was also sampled to determine the presence, distribution, and diversity of actinomycetes on submersed macrophytes. 34 % of the distinctly actinomycete isolates were *Streptomyces*, thereby forming the dominant species (Wohl and McArthur 1998).

It has been considered by several authors that *streptomyces* also occur in marine habitats, including sediments (Cross 1981a; Goodfellow and Haynes 1984; Okazaki and Okami 1976; Weyland 1981a, b;, Weyland and Helmke 1988). Streptomycetes have been found in the littoral and inshore zone and in deep-sea sediments. Even though they can be isolated from both sites, they are not necessarily part of the autochthonous microflora, but can possibly have a terrestrial origin. Streptomycetes isolated from sediments (Roach and Silvey 1959) and from decaying seaweed (Siebert and Schwartz 1956) in littoral zones were capable of growing on polymeric substances characteristic of these habitats, such as agar and chitin (Humm and Shepard 1946), alginate and laminarin (Chesters et al. 1956), and cellulose (Chandramohan et al. 1972).

In sediments, the ratio of different actinomycete taxa depends on the location and the depth of the sampling sites (Weyland 1981a; Weyland and Helmke 1988). In the open sea, only low numbers of actinomycetes are generally detected (viable counts about 100 CFU per mL of wet sediment). It is believed that the distribution of streptomycetes is correlated with the barotolerance (Helmke 1981), halotolerance, and psychrophilism (Weyland 1981b) (horizontal as well as vertical) of *Streptomyces*, *Micromonosporae*, and *Rhodococci*. In contrast, Goodfellow and Haynes (1984) did not find any correlation between depth, pH or salinity, and the number of actinomycetes recovered from marine sediments. In their study, 732 isolates were examined, of which 250 belonged to *Streptomyces*, 250 to *Micromonospora*, 140 to *Rhodococcus*, and 92 were assigned to the genus *Thermoactinomyces*. The isolated streptomycetes were subsequently identified using a computer-assisted approach (Williams et al. 1983b) and about half of them were assigned to a cluster equated with *Streptomyces albidoflavus* (Williams et al. 1983a).

Streptomycetes were primarily detected in sediments of shallow seas (70–520 m deep) with 300–1,270 colonies per cm^3, whereas *Micromonospora* prevailed in samples 700–1,600 m deep (Okami and Okazaki 1978). However, these authors did not detect actinomycetes from depths of 2,800 and 5,000 m in the Pacific Ocean. Yet, Pathomaree and coworkers (2006) were able to isolate actinomycetes, including streptomycetes, from a depth of 10,898 m in the Mariana Trench in the Pacific. Marine streptomycetes generally tolerate higher salt concentrations than their terrestrial counterparts, though salt tolerance among streptomycetes is widespread (Tresner et al. 1968). Some of the isolated marine streptomycetes were found to be obligate halophiles (Okazaki and Okami 1976).

Culture-dependent and culture-independent studies have shown that many indigenous marine actinomycetes exist in the oceans and are widely distributed in different marine ecosystems (reviewed by Lam 2006; Zotchev 2012). Interestingly, considerable new marine diversity is also being discovered within the genus *Streptomyces*, a taxonomically complex group of actinomycetes that commonly occur in soils and account for the vast majority of antibiotics discovered so far (reviewed in Ward and Bora 2006; Fenical and Jensen 2006). *Streptomyces* spp. are readily cultured from marine samples, especially when collected near shore, and many if not most of these strains are closely related or identical to strains previously reported from land. However, distinct marine phylotypes are beginning to be recognized, in addition to strains that occur both on land and in the sea. These marine actinomycetes include alkaliphilic *Streptomyces* spp. 38, the marine clade MAR4, and what seems to be a new genus within the family *Streptomycetaceae* for which the name "*Marinispora*" has been proposed, but not yet confirmed formally (Kwon et al. 2006; Fenical and Jensen 2006; Ward and Bora 2006). Several new species of "*Marinispora*" have been shown to produce marinisporolides, novel polyene-polyol macrolide compounds (Kwon et al. 2006, 2009). Numerous antibiotic-producing streptomycetes have been isolated from marine habitats (Goodfellow and Fiedler 2010; Hotta et al. 1980; Okami and Okazaki 1972; Okami et al. 1976) including seaweed (Nissen 1963). Recently, Goodfellow and Fielder (2010) provided a review on a bioprospecting strategy based upon the premise that new secondary metabolites can be found by screening relatively small numbers of dereplicated, novel actinomycetes isolated from marine sediments.

Furthermore, interactions between *Streptomyces* species and aquatic invertebrates have also been shown recently (recently reviewed in Seipke et al. 2012; Taylor et al. 2007), with similar relationships as discussed for terrestrial invertebrates. Stable *Streptomyces* associations and symbioses have been shown for marine sponges and cone snails. Antibiotic-producing bacteria associated with marine sponges offer protection against disease and biofouling. Interestingly, *Streptomyces* species isolated from cone snails have shown neurological bioactivity (Peraud et al. 2009). Results from the dorsal root ganglion (DRG) assay suggest that the compounds act directly on channels or receptors. The data support either a decrease in K^+ channel activation or an increase in Na^+ channel activation. More recently, Lin et al. (2010) showed that one cone snail associate, *Streptomyces* sp. CP32, produces a series of natural products that enhance or diminish whole-cell Ca^{2+} flux in DRG assays. These compounds include known thiazoline compounds and a series of new derivatives, pulicatins A–E.

Thermophilic Streptomycetes

The genus *Streptomyces* consists mainly of mesophilic species; however, a few streptomycetes are thermotolerant (growing up to 45 °C) and some are thermophilic. So far, all described thermophilic streptomycetes grow at temperatures between 28 °C and 55 °C and several grow at even higher temperatures. Kim et al. (1999) studied the taxonomy of thermophilic streptomycetes in detail. Additional thermophilic species (*S. thermocoprophilus* and *S. thermospinisporus*) were described by Kim et al. (2000) and Kim and Goodfellow (2002). Thermophilic actinomycetes are commonly widespread and can be isolated from diverse sources like soils (Tendler and Burkholder 1961; Craveri and Pagani 1962), pig feces (Ohta and Ikeda 1978), sewage-sludge compost (Millner 1982), freshwater habitats (Cross 1981a, b), hay (Roussel et al. 2005), and volcanic and desert steppe zone soils (Kurapova et al. 2012; Zenova et al. 2009).

As a part of their life cycle, thermophilic streptomycetes grow actively at sites of high temperatures, such as compost, manure, and self-heating hay or grain. After completion of the vegetative phase, the formation of large quantities of spores begins. The spores are returned with the compost or manure to the fields and pastures and can subsequently colonize plant material and hay directly or via soil dust (Korn-Wendisch and Kutzner 1992). Thus, the genus *Streptomyces* accounts for the majority of actinomycetes isolated from bioaerosols in the surroundings of composting facilities or in mushroom farming units that utilize compost (Kämpfer et al. unpublished observation, Lacey 1974).

Pathogenicity and Clinical Relevance

Streptomycetes as Plant Pathogens

Some of the many saprophytic *Streptomyces* species are plant pathogens and may be involved in the development of economically important diseases, including potato scab. *Streptomyces scabies* can still be considered as the dominant plant pathogen worldwide but is only one of many streptomycetes which cause very similar disease symptoms on plants. In addition, *S. scabiei* (Lambert and Loria 1989a), *S. acidiscabies* (Lambert and Loria 1989b), *S. turgidiscabies* (Miyajima et al. 1998), *S. europaeiscabiei*, *S. stelliscabiei* (Bouchek-Mechiche et al. 2000), *S. luridiscabiei*, *S. puniciscabiei*, and *S. niveiscabiei* (Park et al. 2003) have been shown to act as plant pathogens causing either common scab or netted scab, mostly in potatoes.

Streptomyces scabies (synonym *S. scabiei*) being the most important and oldest characterized potato scab pathogen has been isolated from various sources such as beets, carrot, peanut, and radish, among other crops (Loria et al. 2006). Strains of *S. scabies* are phenotypically similar to *S. bottropensis*, *S. diastatochromogenes*, or *S. neyagawaensis*, which is further underlined by 16S rRNA gene sequence analyses. *Streptomyces europaeiscabiei*, the most closely related species to *S. scabies*, has been isolated from various locations in Europe. *Streptomyces turgidiscabies* has been isolated from cases of potato scab in Finland, but also from Japan and Korea (Loria et al. 2006). Three species, *Streptomyces luridiscabiei*, *Streptomyces niveiscabiei*, and *Streptomyces puniciscabiei*, are the causal agents of potato scab in Korea. *Streptomyces acidiscabies* has been isolated from low pH soils in the northeastern United States, among other locations.

As revealed by DNA-DNA hybridization studies and 16S rRNA gene sequence analyses, the documented pathogenic strains fall outside of the described species, listed above (Loria et al. 2006). This is due to the existence of a transmissible pathogenicity island which seems to confer the pathogenic phenotype on some otherwise nonpathogenic species and to the polyphyletic nature of scab-causing species itself, as reviewed by Loria et al. (2006). The pathogenic mechanisms used by these species to manipulate their hosts have been extensively studied and summarized by Loria et al. (2006, 2008). For example, the nitrated dipeptide phytotoxin, thaxtomin, plays an important role in blocking cellulose biosynthesis of expanding plant tissues, inducing $Ca2^{+}$ spiking, and causing cell death. In addition, a secreted necrogenic protein, Nec1, contributes to virulence on different plant species. A detailed genetic analysis revealed that the genes coding for thaxtomin and *nec1* lie on a large mobilizable plasmid PAI, besides other putative virulence genes, including a cytokinin biosynthetic pathway and a saponinase homolog. During conjugation this PAI is mobilized and inserts itself site-specifically into the linear chromosome of recipient species, thereby accounting for the emergence of new pathogens in agricultural systems.

Streptomycetes as Human Pathogens

Only very few streptomycetes have been isolated from human pathological specimens so far. Some organisms cause actinomycetoma, which is a localized chronic, destructive, and progressive infection of skin, subcutaneous tissue, and eventually bone (McNeil and Brown 1994; Develoux et al. 1999). In certain tropical and subtropical regions, this disease is endemic and has a devastating effect on patients, as it frequently leads to deformities, disabilities, and eventually amputation of the affected organs. *Streptomyces somaliensis* is often implicated to cause the disease, particularly in parts of the Sudan. Nevertheless some of the main causal agents belong to other genera and species, i.e., *Actinomadura madurae*, *Actinomadura pelletieri*, *Nocardia brasiliensis*, *Nocardia otitidiscaviarum*, and *Nocardia transvalensis* (Trujillo and Goodfellow 2003). However, the identification of a second species, *Streptomyces sudanensis*, by Quintana et al. (2008) suggests that some strains identified as *S. somaliensis* (Gumaa and Mahgoub 1975; Taha 1983; Gumaa 1994; Fahal 2006) may have been misclassified. Indeed, there is evidence that streptomycetes associated with cases of actinomycetoma in the Sudan (Mahgoub 1985; Fahal and Hasan 1992; Fahal 2004, 2006) may be underspeciated (Trujillo and Goodfellow 2003; Quintana et al. 2008).

Acknowledgement

The basis of the chapters on ecophysiology, isolation, and habitats has been the excellent and comprehensive treatise of H.J. Kutzner and F. Korn-Wendisch from the 2nd edition of *The Prokaryotes*, which is still recommended for a more deep study on classical approaches in *Streptomyces* biology.

43 The Family *Streptosporangiaceae*

Misa Otoguro[1] · *Hideki Yamamura*[1] · *Erika T. Quintana*[2]
[1]Faculty of Life and Environmental Sciences, University of Yamanashi, Kofu, Japan
[2]Departmento de Microbiología, Escuela Nacional de Ciencias Biológicas, Instituto Politécnico Nacional, Mexico City, Mexico

Abstract
The family *Streptosporangiaceae* encompasses the genera *Streptosporangium* as type genus, *Nonomuraea*, *Planomonospora*, *Planobispora*, *Microbispora*, *Planotetraspora*, *Herbidospora*, *Acrocarpospora*, *Thermopolyspora*. On the basis of phylogenetic analysis, the genus *Sinosporangium* branches deeply and membership of the family is not clear. Members of this family comprehend aerobic, Gram-positive, non-acid-alcohol-fast, chemoorganotrophic actinomycetes that form a branched, nonfragmenting substrate mycelium. Members are chemically homogeneous but morphologically diverse. However, strains that bear spore vesicles (*Acrocarpospora*, *Planobispora*, *Planomonospora*, *Planotetraspora* and *Streptosporangium*) are closely related to organisms that have two or more spores in spore chains (*Herbidospora*, *Microbispora*, *Microtetraspora* and *Nonomuraea*). Molecular analyses including DNA-DNA hybridization were performed on members of several genera, and the genome sequence of *Streptosporangium roseum* NI 9100[T] has been published. Several isolation strategies were developed using baiting, chemical, physical,and physicochemical techniques for the genera *Streptosporangium, Planobispora*, *Planomonospora, Herbidospora*, *Microbispora*, *Microtetraspora*, and *Nonomuraea*. Members of the family are mainly found in soil and a few species were isolated from seashore including sand or sediments, and plant materials including roots and leafs.

Taxonomy: Historical and Current

Short Description of the Family and Their Genera

▶ *Strep.to.spo.ran.gi.a.ce'a.e.* N.L. neut. n. *Streptosporangium* type genus of the family, *-aceae* ending to denote a family; N.L. fem. pl. n. *Streptosporangiaceae* the *Streptosporangium* family (Modified from *Bergey's Manual*).

Phylogenetically a member of the order *Streptosporangiales* (Goodfellow 2012), phylum Actinobacteria. The family contains the type genus *Streptosporangium* (Chouch 1955a; emended by Stackbrandt et al. 1994), *Microbispora* (Nonomura and Ohara 1957; emended by Zhang et al. 1998), *Planomonospora* (Thiemann et al. 1967), *Microtetraspora* (Thiemann et al. 1968), *Planobispora* (Thiemann and Beretta 1968), *Planotetraspora* (Runmao et al. 1993; emended by Tamura and Sakane 2004), *Herbidospora* (Kudo et al. 1993), *Nonomuraea* (Zhang et al. 1998), *Acrocarpospora* (Tamura et al. 2000), *Thermopolyspora* (Goodfellow et al. 2005), *Sphaerisporangium* (Ara and Kudo 2007; emended by Cao et al. 2009). *Sinosporangium* (Zhang et al. 2011) is included in the order *Streptosporangiales*, but its membership to the family is not clear. Aerobic, Gram-positive, non-acid-alcohol-fast,

E. Rosenberg et al. (eds.), *The Prokaryotes – Actinobacteria*, DOI 10.1007/978-3-642-30138-4_341,

chemoorganotrophic actinomycetes that form a branched, stable non-fragmenting substrate mycelium which bears aerial hyphae that differentiate either into short chains of arthrospores or into spore vesicles containing one to many motile or nonmotile spores. Members of the family contain *meso*-A_2pm (A1γ type peptidoglycan according to Schleifer and Kandler (1972)) as diagnostic amino acid of peptidoglycan, muramic acid is in the *N*-acetylated form (Uchida et al. 1999), the cell wall contains madurose as the diagnostic sugar (wall chemotype III *sensu* Lechevalier and Lechevalier 1970a), contain major amounts of glucosamine-containing polar lipids (phospholipid type IV *sensu* Lechevalier et al. 1977), and partially tetrahydrogenated menaquinones with nine isoprene units as the predominant isoprenologue (Kroppenstedt et al. 1990). The guanine-plus-cytosine content of the DNA lies within the range of 66–74 % mol. The type genus of the family is *Streptosporangium* (Couch 1955a).[AL]

Couch (1955a) classified the genus *Streptosporangium* in the family "*Actinosporangiaceae*" together with sporangiate actinomycetes belonging to the genus *Actinoplanes*. The family was subsequently renamed *Actinoplanaceae* by Couch (1955b). In addition to the type genus *Actinoplanes* and *Streptosporangium*, this taxon encompassed the genera *Amorphosporangium*, *Ampullariella*, *Dactylosporangium*, *Kitasatoa*, *Pilimelia*, *Planobispora*, *Planomonospora*, and *Spirillospora* (Couch and Bland 1974). Members of all of these genera were considered to form spore vesicles (sporangia).

It was shown subsequently that members of the genera *Planobispora*, *Planomonospora*, *Spirillospora*, and *Streptosporangium* formed a DNA homology group that was separated from a second aggregate DNA homology group which encompassed the genera *Actinoplanes*, *Ampullariella*, and *Dactylosporangium* (Farina and Bradley 1970). Organisms of the first group contained the sugar madurose and had a wall chemotype III, whereas those in the second taxon had a wall chemotype II, i.e., they contained *meso*- and/or hydroxy-A_2pm and glycine (Lechevalier et al. 1970a). The genera *Actinoplanes*, *Dactylosporangium*, *Micromonospora*, and *Pilimelia* are now known to have many properties in common and are classified in the family *Micromonosporaceae* (Krassilnikov 1938), emended by Goodfellow et al. (1990). The genus *Kitasatoa* has become a subjective synonym of the genus *Streptomyces* (Goodfellow et al. 1986), and the genera *Amorphosporangium* and *Ampullariella* have been reduced to subjective synonyms of the genus *Actinoplanes* (Stackebrandt and Kroppenstedt 1987).

Goodfellow and Cross (1984) assigned the oligosporic genera *Actinomadura* (Lechevalier and Lechevalier 1970a), *Microbispora* and *Microtetraspora* and the sporangiate genera *Planobispora*, *Planomonospora*, *Spirillospora* Couch (1963) and *Streptosporangium* to an aggregate group, the maduromycetes. Apart from representatives of the genus *Spirillospora*, these taxa formed a recognizable suprageneric group based on 16S rRNA gene cataloging and sequencing data (Stackebrandt 1986). The genus *Spirillospora* is currently classified in the family *Thermomonosporaceae*.

Phylogenetic Structure of the Family and Its Genera

The taxonomic status of genera assigned to the maduromycetes was formalized by the proposal that *Streptosporangium* be recognized as the type genus of a new suprageneric taxon, the family *Streptosporangiaceae*. This family was also seen as a taxonomic niche for the genera *Microbispora*, *Microtetraspora* (including the *Actinomadura pusilla* group *sensu* Kroppenstedt et al. (1990)), *Planobispora*, *Planomonospora*, and tentatively for the genus *Spirillospora*. Additional genera have been added to the family, namely, *Herbidospora*, *Planotetraspora*, *Nonomuraea*, *Acrocarpospora*, *Sphaerisporangium*, *Thermopolyspora*, and *Sinosporangium*. Representatives of the ten genera classified in the family *Streptosporangiaceae* form distinct, but related taxa based on 16S rRNA gene sequence data (*Fig. 43.1*). Because the genus *Sinosporangium* is branching slightly deeper in the suborder *Streptosporangineae*, the genus *Sinosporangium* could not be placed into the family *Streptosporangiaceae*. However, signature nucleotide analysis of 16S rRNA gene clearly characterized that the genus *Sinosprangium* contained the signature nucleotide pattern defined for the suborder *Streptosporangineae* (Zhang et al. 2011).

Based on the Neighbor-joining tree, all the genera including the family formed three clades. *Thermopolyspora flexuosa* and *Sinosporangium album* branched more deeply within this suborder.

Differentiation from Closely Related Taxa

Streptosporangiaceae strains can be distinguished from all other actinomycetes using a combination of chemotaxonomic and morphological features. Members of the family show a range of morphological properties but are relatively homogeneous from a chemotaxonomic perspective (*Table 43.1*). Simplified procedures are available for detecting chemical markers, notably, cell wall constituents (Staneck and Roberts 1974; Uchida and Aida 1977, Uchida et al. 1999; Hancock 1994), fatty acids (Suzuki and Komagata 1983; Kroppenstedt et al. 1990), menaquinones (Collins et al. 1977; Kroppenstedt 1982; Minnikin et al. 1984; Suzuki et al. 1993), and polar lipids (Minnikin et al. 1984; Suzuki et al. 1993). Procedures such as these are being progressively complemented or replaced by molecular systematic methods, including the use of oligonucleotide primers (Monciardini et al. 2002) and 16S rRNA gene sequences (Stackebrandt et al. 1997; Tamura et al. 2000; Stach et al. 2003).

Primary diagnostic chemotaxonomic data can be gained by examination of whole-organism hydrolysates (Lechevalier and Lechevalier 1980). One-dimensional thin layer chromatography will determine whether an organism contains diaminopimelic acid and whether the latter is in the *LL*- or *meso*- form. Sporoactinomycetes rich in *LL*-A_2pm can be provisionally assigned to the genus *Streptomyces*. The detection of meso-A_2pm

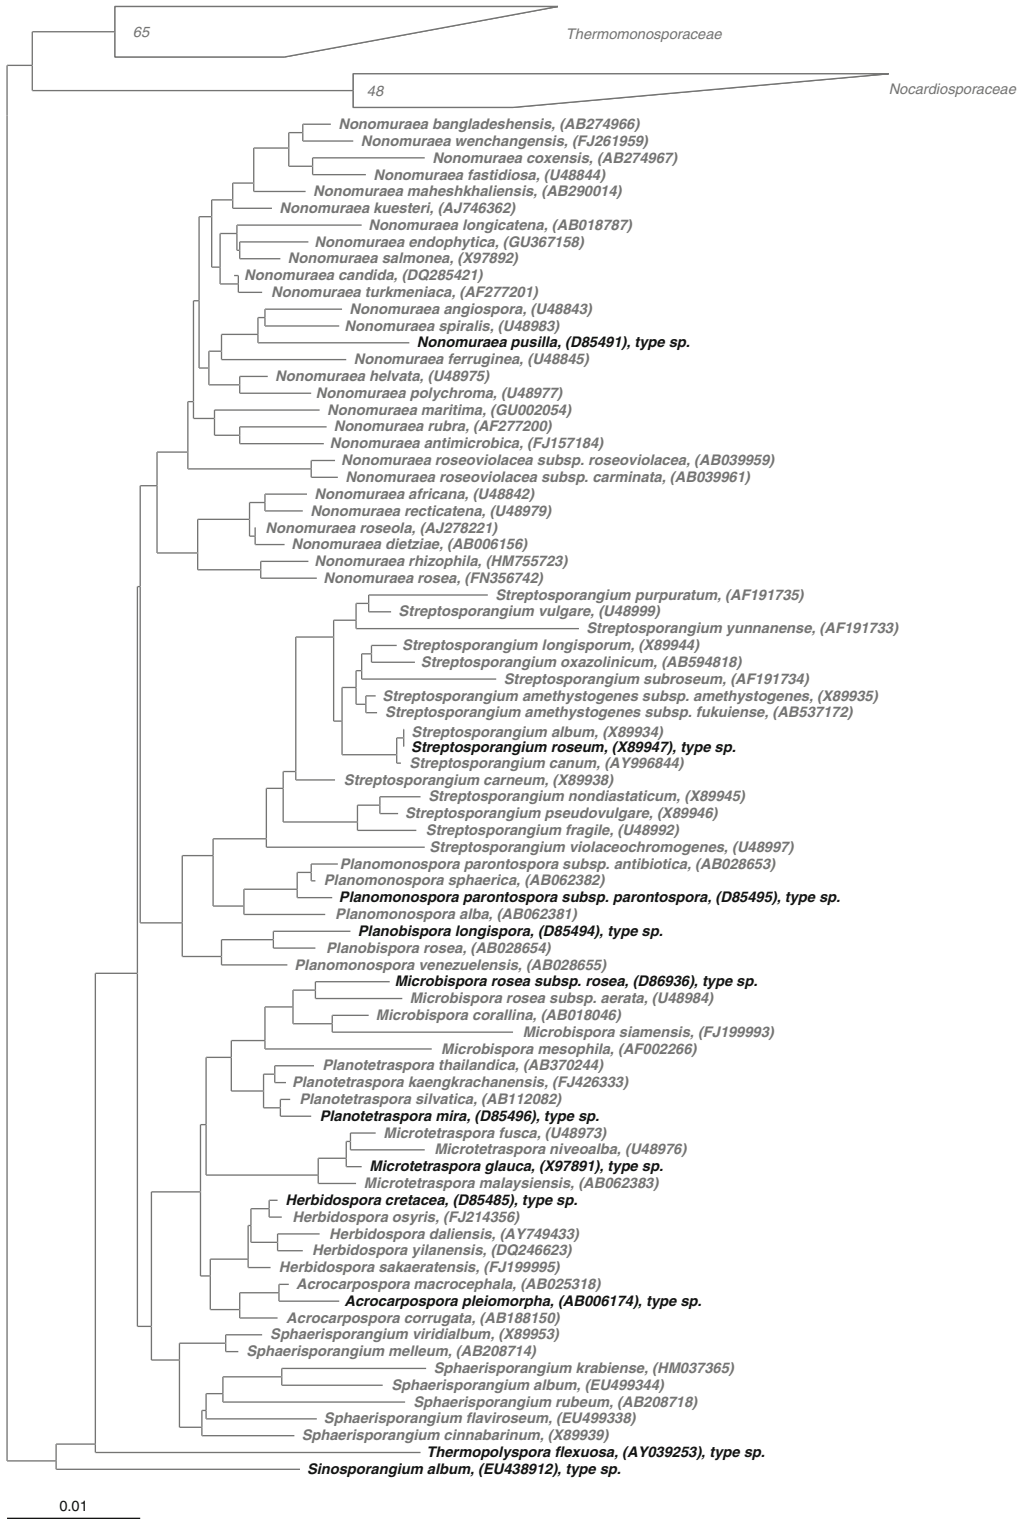

Fig. 43.1

Phylogenetic reconstruction of the family *Streptosporangiaceae* based on 16S rRNA and created using the neighbor-joining algorithm with the Jukes-Cantor correction. The sequence datasets and alignments were used according to the All-Species Living Tree Project (*LTP*) database (Yarza et al. 2010; http://www.arb-silva.de/projects/living-tree). The tree topology was stabilized with the use of a representative set of nearly 750 high quality type strain sequences proportionally distributed among the different bacterial and archaeal phyla. In addition, a 40 % maximum frequency filter was applied in order to remove hypervariable positions and potentially misplaced bases from the alignment. *Scale bar* indicates estimated sequence divergence

[a]Data taken from Goodfellow (1989a, b, 1990, 2005); Kroppenstedt et al. (1990); Kudo et al. (1993); Tamura et al. (2000); Ara and Kudo (2007); and Zhang et al. (2011))

[b]Major constituents: alanine, glutamic acid, glucosamine, and *meso*-A_2pm (Lechevalier and Lechevalier 1970b); [c]A, cross-linkage between positions 3 and 4 of adjacent peptide subunits; 1, peptide bridge absent; γ, *meso*-A_2pm at position 3 of the tetrapeptide subunits (Schleifer and Kandler 1972); [d]saturated fatty acids, unsaturated fatty acids, *iso*-fatty acids (variable) and methyl-branched fatty acids (Kroppenstedt 1985); [e]*Herbidospora* strains contain tetrahydrogenated menaquinones with ten isoprene units (Kudo et al. 1993), organisms in the remaining taxa contain tetra-hydrogenated menaquinones with nine isoprene units (Kroppenstedt 1982); [f]phospholipid patterns: PI, phosphatidylglycerol (variable); PII, only phosphatidylethanolamine; PIV, phospholipids containing glucosamine (with phosphatidylmethylethanolamine variable) (Lechevalier et al. 1977)

The family *Streptosporangiaceae* E.T. Quintana and M Goodfellow

and madurose with the absence of characteristic sugars serves to separate strains of *Streptosporangiaceae* from those of *Actinoplanes* and related genera, *Nocardia* and related genera, *Pseudonocardia* and related genera, *Nocardiopsis* and related genera, and *Thermomonospora* and related genera, but not from the genera *Dermatophilus* and *Frankia*. The latter can be distinguished readily from *Streptosporangium* and allied taxa on morphological grounds. To date, the presence of madurose is associated with wall chemotype III actinomycetes, although there is an unconfirmed report of this sugar from a wall chemotype I actinomycete with streptomycete morphology (Weyland et al. 1982). The discovery of 3-*O*-methylgalactosyl (madurosyl) units in the structure of teichoic acids of a *Nonomuraea roseoviolaceae* subsp. *carminata* strain (previously *Actinomadura carminata*; Naumova et al. 1986) is also noteworthy, as madurose is not perceived to be a cell wall constituent according to Lechevalier and Lechevalier (1981a).

Wall chemotype III actinomycetes which form spore vesicles can be identified to the genus level using morphological features (*Table 43.1*), though care must be taken to distinguish between *Spirillospora* and *Streptosporangium* strains even though only the former produces motile spores (Vobis and Kothe 1989c). Note also that the sporogenic hyphae in the spore vesicles of spirillosporae are branched, whereas those in streptosporangiae are unbranched. Chemical analyses are required if the genera *Microbispora*, *Microtetraspora*, and *Nonomuraea* are to be reliably separated from the genus *Actinomadura* (Kroppenstedt et al. 1990). Actinomadurae contain mostly hexahydrogenated menaquinones with nine isoprene units (MK-9 [H_6]) and diphosphatidylglycerol and phosphatidylinositol as predominant polar lipids (phospholipid type I *sensu* Lechevalier et al. 1977) whereas *Microbispora*, *Microtetraspora*, and *Nonomuraea* strains have major amounts of MK-9 [H_4] saturated at positions III and IV, with major amounts of diphosphatidylglycerol, hydroxylated phosphatidylethanolamine, uncharacterized glycolipids, and a glucosamine-containing phospholipid (type IV phospholipid pattern *sensu* Lechevalier et al. 1977).

The separation of the genera *Microbispora*, *Microtetraspora*, and *Nonomuraea* solely on morphological criteria is questionable. *Microbispora* is distinguished from related genera (*Table 43.2*) primarily by the formation of paired spores on aerial hyphae. These are either sessile or borne on short sporophores. In *M. rosea*, the latter were found to be attached to the base of the spore by a ball and socket arrangement (Williams 1970). *Microbispora* species are currently separated by using a range of phenotypic properties (*Table 43.2*). Cultures of *M. aerata*, *M. amethystogenes*, and *M. parva* deposit crystals with a metallic sheen in the medium, particularly when grown on Pablum extract agar (Lechevalier and Lechevalier 1957) for about 10 days (Gerber and Lechevalier 1964). These crystals are composed of iodinin (1,6-phenazinediol-5,10-dioxide), a red, water-soluble pigment. In addition, *M. aerata* produces two brown-yellow pigments (2-aminophenoaxazine-3-one and 1,6-phenazinediol), a yellow pigment (2-acetamidophenoxazine-3-one; Gerber and Lechevalier 1964), and an orange pigment (1,6-phenazinediol-5-oxide; Gerber and Lechevalier 1965). Microtetrasporae can be recognized by their ability to produce short spore chains which typically contain four spores. The identification of species within the genus is still based on phenotypic properties, notably on the color of the aerial and substrate mycelium (*Table 43.3*).

Nonomuraea strains are distinguished from members of related genera by their ability to form chains of spores or pseudovesicles on aerial hyphae. The constituent species may be distinguished by means of spore chain morphology, spore wall ornamentation, color of mature sporulated aerial mycelium, and substrate mycelium pigmentation (*Table 43.4*). Nevertheless, identification of many of these species is difficult, because in most instances, only one (the type) strain or a few strains have been examined. Even when several strains have been studied, the results of biochemical and physiological tests have proved to be variable or inconsistent when data from the literature are compared. However, numerical taxonomic evidence indicates that most of the validly described taxa merit species status (Goodfellow et al. 1979; Goodfellow and Pirouz 1982).

Streptosporangium species can be distinguished from one another using a combination of phenotypic properties, notably morphological features (see "Genus *Streptosporangium*" *Fig. 43.1*; *Table 43.5*). They can be separated by spore vesicle size, sporangiophore length, spore shape, aerial spore mass color, and substrate mycelium pigmentation and subdivided according to the nature of the vesicular wall. At one extreme, the spore vesicular membrane of *S. fragile* is so thin that it cannot be detected by light microscopy (Shearer et al. 1983). This feature may lead to difficulty in differentiating *Streptosporangium* from *Nonomuraea* strains, as members of some species of the latter produce pseudovesicles covered by a slimy substance (Nonomura and Ohara 1971c). The remaining species of *Streptosporangium* form thin vesicular membranes that are readily disrupted in water. *Streptosporangium amethystogenes* produces violet crystals of iodine after a month's incubation at 30 °C on oatmeal-yeast extract agar.

Improved phenotypic tests are needed for the identification of unknown streptosporangiae. Clearly such tests should be based on a representative set of strains. Whitham (1988) generated a probability matrix on the basis of 26 diagnostic properties for the identification of unknown streptosporangiae to established and novel *Streptosporangium* species. In a continuation of these studies, Kim (1999) assigned 65 out of 70 marker *Streptosporangium* strains and 12 out of 131 putative streptosporangiae isolated from soil to known species of *Streptosporangium*. A further 19 of the soil isolates were identified to known species when less stringent cut-off points were adopted for a positive identification.

The genera *Planobispora*, *Planomonospora*, and *Planotetraspora* may be distinguished by the shape of their spore vesicles and by the number of encased spores. *Planobispora* and *Planomonospora* species can be separated using a judicious selection of phenotypic properties (*Table 43.6*). *Planobispora longispora* and *Planobispora rosea* have many properties in common (Goodfellow and Pirouz 1982) but can be separated by

using cultural characteristics (Thiemann 1974a). *Planobispora longispora* produces a hyaline- to creamish-colored substrate mycelium and a white aerial mycelium, whereas *P. rosea* has a rose-colored substrate mycelium and an aerial mycelium with a light rose tinge. The type strain of *P. mira*, unlike that of *P. silvatica*, produces acid from lactose, mannitol, mannose, and rhamnose and uses glucose, mannitol, and xylose as sole carbon sources. Conversely, the *P. silviatica* strain degrades xanthine and uses melibiose and raffinose as sole carbon sources. The two strains can also be distinguished using colonial characteristics.

Planomonospora parontospora and *P. venezuelensis* strains can be distinguished by the morphological arrangement of their spore vesicles, different menaquinone profiles (Collins et al. 1984), and the characteristic color of the mycelium (Thiemann 1974b). *Planomonospora sphaerica* can be distinguished from the other members of the genus by its ability to form large spherical bodies when grown on inorganic salts starch agar (Mertz 1994).

Members of the genera *Acrocarpospora* and *Herbidospora* can also be recognized on morphological grounds (*Table 43.1*). The identification of species of *Acrocarpospora* is based on the discontinuous distribution of a few phenotypic properties (*Table 43.7*).

Molecular Analyses

DNA-DNA hybridization (DDH) studies have been performed on *Acrocarpospora*, *Herbidospora*, *Microbispora*, *Microtetraspora*, *Nonomuraea*, *Planotetraspora*, *Sinosporangium*, *Sphaerisporangium*, and *Streptosporangium*. However, the results of DDH were not available on *Planobispora*, *Planomonospora*, and *Thermopolyspora*.

The description of *Acrocarpospora* species includes the results of DDH studies, and moderate DDH relatedness of 45–49 % between *A. pleiomorpha* and *A. macrocephala*. *A. corrugata* and other species were more distantly related (24–12 %). The relatedness between *Acrocarpospora* species and other genera was quite low (<9 %) (Tamura et al. 2000).

In an early DDH study of *Herbidospora*, *H. cretacea* strains fell into three groups with intergroup relatedness of 44–68 % (Kudo et al. 1993). The intragroup relatedness of the of *H. cretacea* isolates was higher than 70 % (Kudo et al. 1993). The type strains of *H. cretacea* and *H. osyris* were closely related (62.9 %) (Li et al. 2009a), and subsequently, *H. osyris* was classified as asynonyms of *H. cretacea* (Ara et al. 2012). Other DDH studies found *Hebidospora* species to be moderately related (>35 % similarity) (Tsenget al. 2010; Boondaeng et al. 2011; Ara et al. 2012). With more than 73 % DDH similarity, *Streptosporangium claviforme* and *H. osyris* strains were determined to be synonymous to *H. cretacea* (Boondaeng et al. 2011; Ara et al. 2012).

Air-dried soil heated at 110 °C for 1 h, 10^{-1} soil suspension treated with 0.05 % (w/v) benzethonium chloride	Soil	LSV-SE agar	Kanamycin, nalidixic acid, norfloxacin	*Microtetraspora*	Hayakawa et al. (1996)

The genus *Microbispora* was proposed by Nonomura and Ohara (1957) and currently encompasses four species. All species descriptions include DDH studies which found them to be distantly related (12–46 %), e.g., *M. siamensis* and other members of the genus *Microbispora* (19–46 %, Boondaeng et al. 2009), and between *M. hainanensis* and *M. corallina* (12.4–13.6 %, Xu et al. 2012). According to the results of DDH studies, ten species of the genus *Microbispora* were suggested to be combined into the type species *M. rosea* with two subspecies, *M. rosea* subsp. *rosea* and *M. rosea* subsp. *aerate* (Miyadoh et al. 1990).

Microtetraspora species encompasses four species, and their descriptions were also based upon results of DDH studies. The type strains of *M. fusca* and *M. malaysiensis* were closely related

(45–58 %), while other species were distantly related (21–38 %, Nakajima et al. 2003). The intraspecies DDH relatedness of *M. malaysiensis* ranged between 72 % and 98 % similarity (Nakajima et al. 2003).

About half of the descriptions of *Nonomuraea* species contain DDH data. *N. wenchangensis* and *N. coxensis* (56.5 %, Wang et al. 2011) as well as *N. coxensis* and *N. bangladeshensis* were 57.7–58.2 % (Ara et al. 2007a) forming two closely related species pairs, while *N. endophytica* and *N. candida* (41.4 %, Li et al. 2011), *N. kuesteri* and *N. turkmeniaca* (40.5 %, Kämpfer et al. 2005), as well as *N. maheshkhaliensis* and *N. kuesteri* (39.9–45.7 %, Ara et al. 2007b) were less closely related. Other

species were even more distantly related (<40 %), e.g., *N. rhizophila* and *N. rosea* (38.5 %, Zhao et al. 2011), and *N. jiangxiensis* and other species (16.0–22.4 %, Li et al. 2012). Previously, it has been shown that some *Nonomuraea* species share high 16S rRNA gene sequence similarities (within the range 97.6–99.4 %), but low DDH values (Fischer et al. 1983; Poscher et al. 1985; Tamura et al. 2000; Kämpfer et al. 2005) and 45–48 % DDH values were reported (Stackebrandt et al. 2001) between the type strains of *N. africana*, *N. dietziae*, and *N. recticatena*, although these strains shared 98.9–99.8 % 16S rRNA gene sequence similarity. As other species of the genus shared low 16S rRNA gene sequence similarity, DDH values were not determined

The genus *Planotetraspora* was proposed by Runmao et al. (1993) and encompasses five species. Almost all of descriptions include the DDH results with moderate DDH relatedness (22.7–42 %, Tamura and Sakane 2004; Suriyachadkun et al. 2009, 2010) between the type strains.

Almost all of species of the genus *Sphaerisporangium* are closely related (40–66.6 %, Cao et al. 2009; Suriyachadkun et al. 2011). Some are more distantly related, i.e., *S. viridialbum* and *S. rubeum* (37.8 %, Suriyachadkun et al. 2011), and *S. siamense* and *S. album* (32–39 %, Duangmal et al. 2011).

The genus *Streptosporangium* was originally described by Couch (1955a), but some species were transferred to other genera (Kudo and Seino 1987; Stackebrandt et al. 1994; Tamura et al. 2000; Ara and Kudo 2007; Boondaeng et al. 2011; Ara et al. 2012). Recently described species of the genus *Streptosporangium* included DDH results with *S. canum* and *S. roseum* (64.26 %, Zhang et al. 2009) being most closely related. Other species are closely related (59.2–53.1 %), i.e., *S. canum* and *S. amethystogenes* subsp. *amethystogenes* (59.23 %, Zhang et al. 2009), *S. canum* and *S. album* (53.69 %, Zhang et al. 2009), *S.yunnanense* and *S. nondiastaticum* (56.8 %, Zhang et al. 2005), *S. yunnanense* and *S. pseudovulgare* (53.1 %, Zhang et al. 2005), *S. purpuratum* and *S. longisporum* (53.3 %, Zhang et al. 2005), and *S. anatoliense* and *S.pseudovulgare* (58.3 %, Sazak et al. 2012). *S. purpuratum* is more distantly related to other species (43.3–45.2 %, Zhang et al. 2005), as are *S. anatoliense* and *S. nondiastaticum* (43.2 %, Sazak et al. 2012) and *S. subroseum* and related species, showing 3–27 % (Zhang et al. 2002).

Data of the 16S–23S rRNA gene spacer sequences (Zhang et al. 1997, 2001) and electrophoretic mobility of ribosomal protein AT-L30 (Ochi and Miyadoh 1992; Ochi et al. 1991, 1993) are available for a few species of the genus *Streptosporangium*. 23S rRNA and 5S rRNA gene sequences were analyzed for four genera of *Streptosporangiaceae* (Wang and Zhang 2000) and *Herbidospora cretacea* K-319^T (Kudo et al. 1993), respectively. A study of the distribution of genes encoding halogenases and chitinases in the actinobacteria included some species of *Streptosporangiaceae* (Gao and Huang 2009; Kawase et al. 2004).

Genetics

Members of the family *Streptosporangiaceae* have the potential for exploitation, notably in the discovery of novel bioactive compounds, and several researchers studied genetic manipulation systems. Vectors capable of stably maintaining large segments of actinomycete DNA in *Escherichia coli* and of integrating site specifically in the *Streptomyces* genome have been developed to facilitate the manipulation of uncommon actinomycete strains, including streptosporangiae and related taxa (Donadio et al. 2002). These vectors, designated "ESAC," an abbreviation for "*E. coli-Streptomyces* artificial chromosome," are suitable for the reconstruction of gene clusters from small segments of the cloned DNA, the preparation of large insert libraries from unusual actinomycete strains, and the construction of environmental libraries. Other examples of heterologous expression of entire gene clusters in model actinomycetes have been reported (Piel et al. 2000; Tang et al. 2000; Kwon et al. 2001).

A potent antitumor antibiotic, sibiromycin, was produced by "*Streptosporangium sibiricum*" (Hurley et al. 1979), and the

Table 43.8

Specific primers developed for the identification of members of the family *Streptosporangiaceae*

Target taxa	Primer	Sequence 5′-3′	Position[a]	Reference
Streptosporangiaceae	21F	GACGAARNTGACGTGTA	407-424	Monciardini et al. (2002)
	959R	CGTTGCGTCTAATTAAGCAA	971-952	

[a]*E. coli* numbering position (Brosius et al. 1978)

biosynthesis of sibiromycin was determined based on gene cluster analysis and gene replacement techniques (Li et al. 2009b). The gene cluster coding for the biosynthesis of glycopeptide antibiotic A40926 in *Nonomuraea* strain ATCC 39727 has been isolated and characterized by Sosio et al. (2003). This glycopeptide, a member of the teichoplanin family of glycopeptides, is the precursor of dalbavancin, a second generation glycopeptide. Sosio and her colleagues also isolated the novel compound, dechloromannosyl-A40926 aglycone, following the construction of a *Nonomuraea* mutation by deleting dbr open reading frames 8–10. Recently, Marcone et al. (2010) developed the gene transfer systems of *Nonomuraea* sp. ATCC 39727 based on protoplast transformation and intergeneric conjugation from *E. coli*. Prauser (1984) reported that attempts to isolate phage from *Streptosporangiaceae* strains had been unsuccessful.

Amplification of the polyketide synthase (PKS) and non-ribosomal peptide synthetase (NRPS) genes from isolates are useful strategies to evaluate the secondary metabolite production. Janso and Carter (2010) amplified the PKS-1, -2, 3 and NPRS genes from the isolates and concluded that members of *Microbispora*, *Planotetraspora*, and *Sphaerisporangium* contain PKS-1, -2, -3 and NPRS genes. Similar research reported by González et al. (2005) showed that actinomycetes, including *Planobispora* and *Streptosporangium* isolated from lichen sample, contain genes coding for PKS-1, -2 and NPRS.

Specific Primer for *Streptosporangiaceae*

Monciardini and his colleagues (2002) designed a set of specific primers to recognize members of the family *Streptosporangiaceae*. They retrieved 423 16S rRNA gene sequences of different groups of the class *Actinomycetales* from the RDP-II Data base Release 8.0 and aligned the sequences within each genus. Aligned sequences were then visually compared for the identification of regions showing a high degree of conservation, for example, in members of the family *Streptosporangiaceae*, but having at their 3′-end one or more mismatches with other groups. The primers designed in this way were evaluated by probing their sequences against the whole RDP-II database using PROBE MATCH software (http://rdp.cme.msu.edu/html/index.html) to ensure that at least 90 % of the sequences belonging to members of the family *Streptosporangiaceae* were recognized with the primer. Non-target groups of sequences that could potentially yield a non-specific extension product with one primer were taken into account when choosing the second primers. The T_m of each primer was evaluated through Oligo Calculator version 3.01 (http://www.basic.nwu.edu/biotools.oligocalc.html) and primer lengths adjusted in order to mimic T_m differences within each primer set (*Table 43.8*).

Genome Analyses

The complete genome sequence of *Streptosporangium roseum* NI 9100^T has been published (Nolan et al. 2010) and analyzed for the Genomic Encyclopedia of Bacteria and Archaea project. The genome consists of a 10,341,314 bp long chromosome (INSDC ID CP001814) and a small 28,204 bp plasmid (INSDC ID CP001815) with a 70.9 % GC content. This value is only slightly higher than those determined by nuclease method (HPLC) performed on purified DNA (70 mol%). Besides 446 pseudogenes, 9,421 genes have been predicted, of which 9,501 were protein coding genes, and 80 were RNA genes. The majority of the genes (62.47 %) were assigned a putative function, 65.47 % of the genes were assigned to clusters of orthologous groups (COGs), while the remaining ones are annotated as hypothetical proteins. The distribution of genes into COGs functional categories indicates that the highest number of genes are involved in general function prediction only (974: 10.3 %) and transcription (966; 10.3 %), followed by genes coding for carbohydrate transport and metabolism (639; 6.8 %), and amino acid transport and metabolism (600; 6.4 %). Three hundred and fifteen genes (3.3 %) were found to code for secondary metabolites' biosynthesis, transport, and catabolism. A detailed listing of COG categories is given by Nolan et al. (2010). The sequence of the six 16S rRNA gene copies in the genome does not differ from each other, and their sequences are identical to the previously published sequence from DSM 43021 (X89947). However, the sequence of the JCM 3005^T version of strain NI 9100^T (U48996) differs by 24 nucleotides (1.7 %). Another genome project *Nonomuraea coxensis* DSM 45129^T (GOLD ID Gi11713) has been finished, but not published so far. The genome of *Microbispora mesophila* NBRC 14179^T has been projected (GOLD ID Gi21070).

Phenotypic Analyses

The description of the family *Streptosporangiaceae* (Goodfellow et al. 1990) emended by Ward-Rainey et al. (1997) is as given in the Abstract. The type genus is *Streptosporangium* Couch 1955a[AL].

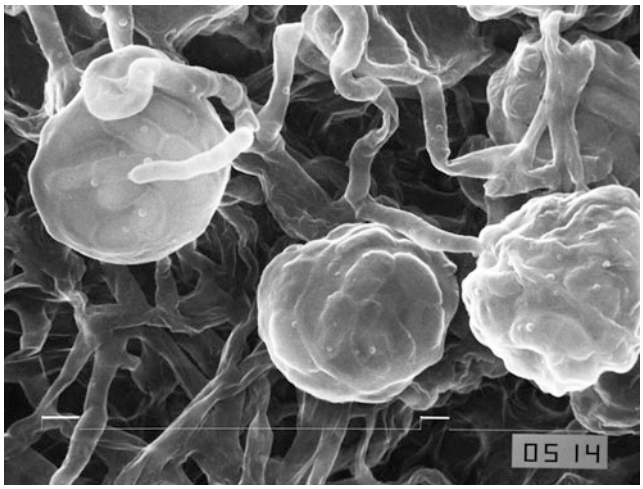
Members of the family *Streptosporangiaceae* are chemically homogeneous but morphologically diverse (◐ *Table 43.1*). However, strains that bear spore vesicles (*Acrocarpospora*, *Planobispora*, *Planomonospora*, *Planotetraspora*, and *Streptosporangium*) are closely related to organisms that have two or more spores in spore chains (*Herbidospora*, *Microbispora*, *Microtetraspora*, and *Nonomuraea*). Spore vesicles contain coiled chains of arthrospores formed by septation of an unbranched, spiral hypha within each expanded sporangiophore sheath (Vobis and Kothe 1985). Spore formation is not endogenous; hence, the term "spore vesicle" has greater precision than the original term "sporangium" (Cross 1970; Sharples et al. 1974). Studies on spore maturation have shown that spores in both spore vesicles and spore chains are formed in essentially the same way. In each case, spores are differentiated by fragmentation of a hypha within a sheath; the latter either expands to form the envelope of the spore vesicle or remains around the spore chain (Lechevalier et al. 1966; Sharples et al. 1974; Vobis and Kothe 1985).

Streptosporangium Couch 1955a, 148[AL] emend. Stackebrandt, Kroppenstedt, Jahnke, Kemmering, and Gürtler 1994, 268

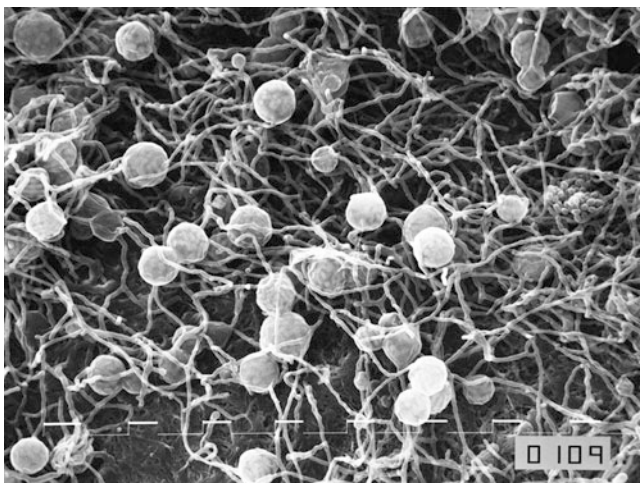
Strep.to.spo.ran'gi.um. Gr. adj. *streptos*, twisted; N.L. neut. n. *sporangium* [from Gr. n. *spora*, a seed (and in biology a spore), and Gr. n. *angeion* (Latin transliteration *angium*), vessel], sporangium; N.L. neut. n. *Streptosporangium*, spores coiled within a sporangium.

This taxon was proposed for sporangiate actinomycetes that formed nonmotile sporangiospores on abundant aerial hyphae. The genus was shown to be heterogeneous on the basis of spore and spore and spore vesicular morphology (Nonomura 1989b), electrophoretic mobility of ribosomal protein AT-L30 (Ochi and Miyadoh 1992), 16S rRNA (Kemmerling et al. 1993) and 5S rRNA (Kudo et al. 1993) gene sequences, and discontinuous distribution of chemical markers (Stackebrandt et al. 1994).

Stackebrandt and colleagues found that streptosporangiae had many chemical properties in common but could be assigned to two groups on the basis of chemical differences. Members of most species, including *S. roseum*, had a phospholipid pattern type IV and predominant proportions of MK-9 (H_2, H_4, H_6), whereas strains in the second group, which contained *S. albidum* and *S. viridogriseum*, had a MK-9 [H_4] as the predominant isoprenologue and a phospholipid pattern type II; these results were in excellent agreement with corresponding 16S rRNA gene sequence data (Kemmerling et al. 1993). Stackebrandt and colleagues proposed that *Streptosporangium albidum* Fumurai et al. (1968), *Streptosporangium viridogriseum* subsp. *kofuense* (Nonomura and Ohara 1969b), and *Streptosporangium viridogriseum* subsp. *viridogriseum* (Okuda et al. 1966) be assigned to a new taxon, the genus Kutzneria as *Kutzneria albida* comb, nov., *Kutzneria viridogrisea* comb, nov., and *Kutzneria kofuensis* comb. nov., respectively.



◘ **Fig. 43.2**
***Streptosporangium album* S16. Walls (membranes) of spore vesicles are thin (Reproduced with permission from Hayakawa; from Nonomura 1989b)**



◘ **Fig. 43.3**
***Streptosporangium vulgare* on oatmeal agar containing yeast extract. Sporangiophores are short (Reproduced with permission from Hayakawa; from Nonomura 1989b)**

Streptosporangiae characteristically form an aerial hyphae that carry, on either short or long sporophores, single or clustered spore vesicles that may be up to 40 µm in diameter (◐ *Figs. 43.2* and *43.3*). They have a wall chemotype **III** (Lechevalier and Lechevalier 1970b), that is *meso-A_2pm* (Aly type according to Schleifer and Kandler,1972) as diagnostic amino acid of peptidoglycan and a wall that lacks characteristic

sugars other than madurose (3-*O*-methyl-D- galactose; Lechevalier and Gerber 1970) Members of the taxon are rich in *iso*-, *anteiso*-, saturated, unsaturated, and methyl-branched fatty acids (pattern 3c; Kroppenstedt 1985; Kudo et al. 1993; Whitham et al. 1993; Stackebrandt et al. 1994), contain di- and tetrahydrogenated menaquinones with nine isoprene units as predominant isoprenologues (Kroppenstedt 1985; Kudo et al. 1993; Whitham et al. 1993; Stackebrandt et al. 1994), and have phospholipid patterns characterized by glucosamine-containing lipids with phosphatidylethanolamine, diphosphatidylglycerol, and phosphatidylinositol (Lechevalier el al., 1977; Lechevalier et al. 1981b; Kudo et al. 1993; Whitham et al. 1993; Stackebrandt et al. 1994). The G+C content of the DNA is 69-71 moI% (Tsyganov et al. 1966; Yamaguichi 1967; Farina and Bradley 1970; Stackebrandt et al. 1994). Type species: *Streptosporangium roseum* (Couch 1955a), 151^{AL}. Type strain: ATCC 12428^T = DSM 43021^T.

Acrocarpospora Tamura et al. 2000, 1170^{AL}

A.cro.car.po.spo'ra. Gr. adj. *akros*, uppermost, topmost, highest, at the top, end; Gr. n. *karpos*, fruit; Gr. fem. n. *spora*, a seed, and in biology a spore; N.L. fem. n. *Acrocarpospora*, an organism forming spores like fruits on the terminal mycelium.

This aerobic, Gram-positive, non-acid-alcohol-fast, nonmotile actinomycete forms a stable, branched substrate mycelium. Spherical and club-shaped structures, which contain coiled chains of smooth-surfaced, oval or rod-like spores (0.6–0.8 × 0.7–1.0 μm in diameter), are carried on the tips of aerial hyphae (*Fig. 43.4*). The organism grows well on oatmeal agar and at 20–30 °C. White aerial hyphae and pale yellow substrate mycelium, but no diffusible pigments, are formed on most standard growth media. Cell walls contain alanine, glutamic acid, and *meso*-A_2pm and *N*-acetylated muramic acid. The peptidoglycan is of the Alγ type. Strains contain di- and tetrahydrogenated menaquinones with nine isoprene units as predominant isoprenologues, glucose and madurose as major sugars, phosphatidylethanolamine as the diagnostic phospholipid, and *iso*- $C_{16:0j}$ 10-methyl $C_{17:0}$, $C_{17:0}$ and C_{17} as major fatty acids, but lack mycolic acids. The G+C content of the DNA is 68–69 mol%. Type species: *Acrocarpospora pleiomorpha* (Tamura et al. 2000), 1170^{AL}. Type strain: DSM 44706^T = NBRC 16267[7].

In addition to the type species, there are two additional species, *A. corrugata* and *A. macrocephala*. The former was originally classified as *Streptosporangium corrugatum* (Williams and Sharpies 1976). From the 16S rRNA *Streptosporangiaceae* gene tree (*Fig. 43.1*), the representatives of the *Acrocarpospora* species are apparently closely related to one another and to the type strains of *Herbidospora cretacea, Planotetraspora mira*, and *Planotetraspora silvatica.* However, the *Acrocarpospora* strains can be distinguished from *Herbidospora cretacea* using morphological and menaquinone data and from the genus *Planotetraspora* using morphological properties and whole-organism sugar composition.

Herbidospora Kudo et al. 1993, 319^{AL}

Her.bi.do.spo'ra. L. adj. *herbidus*, full of grass, grassy; Gr. n. *spora*, a seed and in biology a spore; N.L. fem. n. *Herbidospora*, organism forming spores like grass.

This aerobic mesophilic actinomycete forms a stable, branched substrate mycelium, but does not produce true aerial hyphae. Straight chains of nonmotile, smooth-surfaced spores (10–30 per chain) are borne at tips of sporophores branching in clusters from the vegetative mycelia. The substrate mycelia are yellow to brown on most media; distinctive exopigments are not formed. When sporulation occurs, the surface of the colony is white or brownish yellow. Thiamine is required for growth. The organism is susceptible to lysozyme. Cell walls contain *meso*-A_2pm and acetylated muramic acid but lack significant amounts of glycine. Whole-organism hydrolysates contain glucose, mannose, ribose, and a trace of madurose. Strains contain major amounts of iso-hexadecanoic, n-hexadecanoic, n-heptadecanoic, 10-methylheptadecanoic, and 2-hydroxy acids, phosphatidylethanolamine and glucosamine-containing phospholipids as diagnostic polar lipids, and major proportions of tetrahydrogenated menaquinones with ten isoprene units with hydrogenation at units III and IX (MK-10 [III, IX-H_4]), but lack mycolic acids. The G+C content of the DNA is 69–71 mol%. Type species: *Herbidospora cretacea* (Kudo et al. 1993). Type strain: DSM 44071^T = JCM 8553^T.

According to (Tamura et al. 2000) and to (Boondaeng et al. 2011), *Streptosporangium claviforme* (Petrolini et al. 1992) is a later heterotypic synonym of *Herbidospora cretacea* (Kudo et al. 1993).

Microbispora Nnomura and Ohara 1957, 307[AL]

Mi.cro.bi.spo'ra. Gr. adj. *mikros*, small; L. adv. num. *bis*, twice; Gr. n. *spora*, a seed and in biology a spore; N.L. fem. n. *Microbispora*, the small two-spored (organism).

This taxon was proposed for actinomycetes that form conspicuous aerial hyphae bearing longitudinal pairs of spores. It currently contains ten validly described species, excluding *Microbispora echinospora* (Nonomura and Ohara 1971b) and *Microbispora viridis* (Miyadoh et al. 1985), which have been reclassified as *Actinomadura rugatobispora* (Miyadoh et al. 1985, 1990) and *Actinomadura viridis* (Miyadoh et al. 1985, 1990), respectively. *Microbispora bispora* (Lechevalier 1965), which was originally described as *Thermopoly spor a bispora* (Henssen 1957), has been transferred to a new genus, *Thermobispora*, as *Thermobispora bispora* (Henssen 1957; Wang et al. 1996a). *Thermomonospora mesophilica* (Nonomura and Ohara 1971b), which forms single spores, has been reclassified as *Microbispora mesophila* (Nonomura and Ohara 1971b; Zhang et al. 1998).

Miyadoh et al. (1990) undertook a radical revision of the genus *Microbispora* in which they proposed *M. amethystogenes, M. chromogenes, M, diastatica, M. indica, M. kamatakensis*, and *M. rosea* to be assigned to a single taxon as *M. rosea* subsp. *rosea* and that *M. aerata, M. thermodiastatica*, and M. *thermorosea* be combined and recognized as *M. rosea* subsp. *aerata*. These proposals were based on DNA-DNA relatedness data, though it was acknowledged that most of the cut-off points used in the circumscription of the two taxa were below the 70 % guideline recommended for the delineation of genomic species (Wayne et al. 1987). However, *M. indica* ATCC 35926^T shared 83 % DNA relatedness with *M. rosea* JCM 3006^T; the corresponding number between the type strains of *M. diastatica* and *M. kamatakensis* was 91 %. In addition, Boondaneng et al. (2009) showed that *M. amethystogenes* was a separate genomic species from *M. rosea* subsp. *rosea based on* DNA-DNA relatedness values in reciprocal hybridization experiments. A combination of genotypic and phenotypic data supported the classification of *M. amethystogenes* as a separate species.

Microbispora species form a relatively distinct monophyletic group in the 16S rRNA gene tree, with most of the type strains forming distinct phyletic lines (*Fig. 43.1*). From the 16S rRNA gene tree, the taxon is apparently closely related to the genus *Microtetraspora* and *Planotetraspora*.

Microbisporae are aerobic, Gram-positive, nonmotile actinomycetes which typically form a conspicuous aerial mycelium bearing longitudinal pairs of spores (*Fig. 43.5*) that may be closely arranged along the aerial hyphae, giving the appearance of catkins; spores are not usually formed on the substrate mycelium. In some cases, the spores are borne at longer intervals (*Fig. 43.6*). They first appear as club-shaped initials that later become transformed into the paired spores visible under the light microscope. Spores are either sessile or on short sporophores, spherical to oval (usually 1.2–1.6 µm in diameter) with smooth surfaces. Mature spores are easily detached from the sporophores and each other when placed in water. B vitamins, particularly thiamine, are essential for growth on synthetic media.

Mesophilic and thermophilic species have been described. Mesophilic strains generally produce a pale yellow to distinct pink aerial spore mass, and the reverse side of the colonies is yellowish-brown to orange. Thermophilic strains form a white or pale yellowish-brown to pale pinkish-brown aerial spore mass; the reverse side of colonies is either pale yellowish-brown or yellow brown. Cell walls contain *N*-acetylated muramic acid and major amounts of meso-A_2pm but no characteristic sugars. Madurose is present in whole-organism hydrolysates. The organism contains tetrahydrogenated menaquinone with nine isoprene units as the predominant isoprenologue, phosphatidylcholine, and unknown glucosamine-containing components (such as diagnostic polar lipids, tuberculostearic acid, and its analogues), but not mycolic acids. The G+C content of the DNA is 71–73 mol%. Type species: *Microbispora rosea* (Nonomura and Ohara 1957), 307[AL]. Type strain: DSM 43839^T = JCM 3006T.

Microtetraspora Thiemann et al. 1986b, 296[AL]

Mi.cro.te.tra.spo'ra. Gr. adj. *mikros*, small; Gr. adj. *tetra*, four; Gr. n. *spora*, a seed and in biology a spore; N.L. fem. n. *Microtetraspora*, the small four-spored (organism).

This genus was proposed for actinomycetes that form short, sparsely branched aerial hyphae bearing chains of four spores (*Fig. 43.7*). This morphological trait was considered typical of the genus though chains of two or three spores, and more rarely five spores, have been reported. Initially, four species were recognized, the type species *Microtetraspora glauca*, *M. fusca*, *M. niveoalba*, and *M. viridis*; the latter has been reclassified as *Actinomadura viridis* (Nonomura and Ohara 1971a; Miyadoh et al. 1989). The taxon provided a temporary refuge for the *Actinomadura pusilla* group (Fischer et al. 1983; Poschner et al. 1985; Goodfellow et al. 1988; Kroppenstedt et al. 1990) until it became clear that members of this taxon and the three bona fide *Microtetraspora* species mentioned above can be distinguished using numerical taxonomic (Athalye et al. 1985), electrophoretic mobility of ribosomal AT-L30 protein (Ochi et al. 1991, 1993), and 16S rRNA gene sequence (Wang et al. 1996b) data. The *A. pusilla* group was subsequently classified in a new taxon, the genus *Nonomuraea* (Zhang et al. 1998). "*Microtetraspora tyrrkensis*" was proposed by Tomita et al. (1991) for an organism that formed hooked or spiral spore chains and other properties consistent with its assignment to the *A, pusilla* group. This organism probably belongs to the genus *Nonomuraea*, though the type strain is no longer available to test this proposition. An additional species, *M. malaysiensis*, has been described for strains isolated from a primary dipterocarp forest soil (Nakajima et al. 2003).

Microtetrasporae are aerobic, Gram-positive, non-acid-alcohol-fast, mesophilic, nonmotile actinomycetes which form stable, highly branched substrate and aerial mycelia. Spore chains, typically containing four spores, are borne exclusively

on short aerial hyphae. Spores are spherical (1.2–1.5 µm in diameter) or oval to short cylindrical (1.0–1.4 to 1.2–1.7 µm in diameter) and have smooth surfaces. Some species require B vitamins for growth. The organism is chemoorganotrophic, having an oxidative type of metabolism. It grows well at 20–37 °C. Cell walls contain *N*-acetylated muramic acid and major amounts of meso-A_2pm but no characteristic sugars. Madurose is present in whole-organism hydrolysates. The organism contains major proportions of menaquinone with nine isoprene units with hydrogenation at units III and IV (MK-9 [III, IV-[H_4]), phosphatidylcholine and unknown glucosamine-containing lipids are the major polar lipids. The G+C content of the DNA is 69–71 mol%. Type species: *M. glauca* Thiemann et al. 1968b, 296^{AL}. Type strain: ATCC 23057^T = DSM 43311^T.

Nonomuraea Zhang et al. 1998, 419^{AL}

No.no.mu.ra.e'a. N.L. fem. n. *Nonomuraea*, named after Hideo Nonomura, a Japanese taxonomist of actinomycetes.

This taxon was introduced to accommodate the species assigned to the *M. pusilla* group (Fischer et al. 1983; Poschner et al. 1985; Goodfellow et al. 1988; Kroppenstedt et al. 1990). The genus encompasses aerobic, Gram-positive, non-acid-alcohol-fast strains that form extensively branched substrate and aerial hyphae. The latter bear chains of spores that may be hooked, spiral, straight, or enmeshed in pseudovesicles (Figs. 43.8 and 43.9). Spore surfaces may be folded, irregular, smooth, or warty. The growth temperature range is 20–45 °C, and some strains grow up to 55 °C. Cell walls contain *meso*-A_2pm, and madurose is present in whole-organism hydrolysates (cell wall type III/B *sensu* Lechevalier and Lechevalier 1970b). The predominant menaquinones are MK-9 [H_0, H_2, H_4], the phospholipid pattern is characterized by glucosamine-containing lipids with phosphatidylethanolamine variable, phosphatidylmethylethanolamine, diphosphatidylglycerol, and phosphatidylinositol (phospholipid type IV *sensu* Lechevalier et al. 1977), and the predominant fatty acids are 10- methyl-17-, and iso-16-branched components (pattern 3c; Kroppenstedt 1985). The G+C content of the DNA is 64–69 mol%. Type species: *Nonomuraea pusilla* (Zhang et al. 1998), 419^{AL}, Type strain: ATCC 27296^T-DSM 43357^T.

The genus *Nonomuraea* contains 27 validly described species and two subspecies, namely, *N. africana* (Preobrazhenskaya and Sveshnikova 1974; Zhang et al. 1998), *N. angiospora* (Zhukova et al. 1968; Zhang et al. 1998), *N. antimicrobica* (Qin et al. 2009), *N. bangladeshensis* Ara et al. 2007a, *N. candida* le Roes and Meyers 2008, *N. coxensis* Ara et al. 2007a, *N. dietziae* (Stackebrandt et al. 2001), *N. endophytica* (Li et al. 2011), *N. fastidiosa* (Soina et al. 1975; Zhang et al. 1998), *N. ferruginea* (Meyer 1981; Zhang et al. 1998), *N. helvata* (Nonomura and Ohara 1971c; Zhang et al. 1998), *N. kuesteri* (Kämpfer et al. 2005), *N. longicatena* (Chiba et al. 1999; Zhang et al. 1998), *N. maheshkhaliensis* Ara et al. 2007b, *N. maritima* (Xi et al. 2011), *N. polychroma* (Galatenko et al. 1981; Zhang et al. 1998), *N. pusilla* (Nonomura and Ohara 1971c; Zhang et al. 1998), *N. recticatena* (Gauze et al. 1984; Zhang et al. 1998), *N. rhizophila* (Zhao et al. 2011), *N. rosea* (Kämpfer et al. 2010), *N. roseola* (Lavrova and Preobrazhenskaya 1975; Zhang et al. 1998), *N. roseoviolacea* subsp. *carminata* (Gauze et al. 1973; Gyobu and Miyadoh 2001), *N. roseoviolacea* subsp. *roseoviolacea* (Nonomura and Ohara 1971c; Zhang et al. 1998), *N. rubra* (Sveshnikova et al. 1969; Zhang et al. 1998), *N. salmonea* (Preobrazhenskaya et al. 1975; Zhang et al. 1998), *N. spiralis* (Meyer 1981; Zhang et al. 1998)., *N. turkmeniaca* (Terekhova et al. 1982; Zhang et al. 1998), and *N. wanchangensis* (Wang et al. 2011).

Planobispora Thiemann and Beretta 1968a, 157[AL]

Pla.no.bi.spo'ra. Gr. n. *planos*, wanderer; L. adv. num. *bis*, twice (double); Gr. fem. n. *spora*, a seed, and in biology a spore; N.L. fem. n. *Planobispora*, a motile, double-spored organism.

This taxon encompasses aerobic, Gram-positive, non-acid-alcohol-fast, chemoorganotrophic actinomycetes that form irregular branched, occasionally septate, substrate hyphae (0.5–1.0 μm in diameter) and sparsely branched, rarely septate aerial hyphae (1 μm in diameter) (*Table 43.9*). Cylindrical to clavate spore vesicles (1.0–1.2 μm wide, 6.0–8.0 μm long), each containing a longitudinal pair of spores, are formed singly or in bundles on short ramifications of the aerial hyphae. Spores are straight or slightly curved with rounded ends (1.0–1.2 μm in length) and are motile by means of peritrichous flagella. The spores are pushed out of opposite ends of the spore vesicle, which is easily detached from the supporting hyphae; only a small percentage of spores show motility. They are only motile after being dispersed for some time and usually germinate with one or two polar germ tubes.

It is still unclear whether spores are formed endogenously (Williams and Wellington 1980) or by simple transformation of sporangeous hyphae (Bland and Couch 1981). A transverse septum or diaphragm connected to the vesicular envelope divides the two spores (Thiemann 1970; Vobis and Kothe 1985; *Fig. 43.10*). The vesicular envelope is smooth and contains fibrillar elements (Vobis and Kothe 1985) that resemble those present in *Planomonospora* (Sharpies et al. 1974). The type strains of *P. longispora* and *P. rosea* have many phenotypic properties in common; some of these distinguish them from other sporoactinomycetes with a wall chemotype III (Goodfellow and Pirouz 1982).

The substrate mycelium of planobisporae is either without distinctive color or rose-colored. The aerial mycelium, which develops only on certain agar media, is white or has a light rose tinge. Good growth occurs at pH 6.0–9.0 and temperature 28–40 °C but not 20 °C or 45 °C. Cell walls contain meso-A_2pm and madurose is the characteristic whole-organism sugar. Planobisporae contain diphosphatidylglycerol, phosphatidylethanolamine, and unknown glucosamine-containing phospholipids as diagnostic polar lipids, major amounts of straight chain, unsaturated, *iso*- and 10-methyl branched fatty acids, and tetrahydrogenated menaquinone with nine isoprene units (MK-9 [III, IV-H_4) as the predominant isoprenologue). The G+C content of the DNA is 70–71 mol%. Type species: *Planobispora longispora* (Thiemann and Beretta 1968a), 157[AL]. Type strain: DSM 43041^T = JCM 3092^T

The genus contains an additional species, namely, *Planobispora rosea* (Thiemann 1970).

Planomonospora Thiemann et al. 1967, 29[AL]

Pla.no.mo.no.spo'ra. Gr. n. *planos*, wanderer, vagabond; Gr. adj. *monos*, solitary, single; Gr. fem. n. *spora*, a seed, and in biology a spore; N.L. fem. n. *Planomonospora*, a motile, single spored organism.

This taxon was proposed for actinomycetes that form cylindrical or clavate spore vesicles, each containing a single spore, on aerial hyphae. In the type species *Planomonospora parontospora*, the spore vesicles are sessile and occur in double parallel rows on curved sporangiophores (*Fig. 43.11*) (*Table 43.9*). A single sporangiophore can bear up to 60 spore vesicles. In the other founder member of the taxon, *P. venezuelensis*, the spore vesicles are developed singly or in groups on short lateral branches forming a characteristic palm leaf pattern (Thiemann 1970). The spores may be formed endogenously (Sharpies et al. 1974), but in the *P. parontospora* spore vesicle, development begins with the growth of a sporangeous hypha inside a thin expanding sheath (Vobis 1985; Vobis and Kothe 1985). Through thickening, the sheath becomes a massive vesicular envelope. The spores, which are released through apical pores, become motile by peritrichous flagella about 30 min after being expelled. They remain motile for up to a day during which time spore germination may begin (Thiemann 1970). The type strains of *P. parontospora* and *P. venezuelensis* were assigned to a distinct duster in an extensive numerical taxonomic analysis of sporoactinomycetes with a wall chemotype III (Goodfellow and Pirouz 1982).

The genus *Planomonospora* contains five validly described taxa, namely, *Planomonospora alba* (Mertz 1994), *Planomonospora parontospora* subsp. *antibiotica* (Thiemann et al. 1967), *Planomonospora parontospora* subsp. *parontospora* (Thiemann 1967), *Planomonospora sphaerica* (Mertz 1994), and *Planomonospora venezuelensis* (Thiemann 1970). The type strains of *P. alba* and *P. sphaerica* form spore vesicles in long parallel rows, which resemble rows of bananas (Mertz 1994). *Planomonospora sphaerica* strains form large spherical bodies when grown on inorganic salt starch agar (ISP medium 4; Shirling and Gottlieb 1966).

Planomonosporae are aerobic, Gram-positive, non-acid-alcohol-fast, chemoorganotrophic actinomycetes that form branched, occasionally septate, nonfragmenting substrate hyphae (0.6–1.0 μm in diameter) and sparsely branched rarely septate aerial hyphae (0.5–1.0 μm in diameter). Cylindrical to clavate spore vesicles (1.0–1.5 μm wide, 3.5–5.5 μm long), each containing a single spore, are formed on the aerial mycelium. Spores are fusiform or cylindrical to clavate and motile by peritrichous flagella; they are 1.0–1.6 μm in diameter and 3.5–5.4 μm in length. Colonies are flat or elevated with smooth surfaces, occasionally wrinkled or slightly crustose. Substrate mycelia show a range of colors, including light orange, brown violet to light brown, and grayish yellow. Aerial mycelia are white with a rose tinge, grayish white or pink. Growth occurs at 20–50 °C.

Cell walls contain *meso*-A_2pm. Variation is found in menaquinone, sugar, and polar lipid composition. *Planomonospora alba* and *P. sphaerica* strains contain diphosphatidylglycerol, phosphatidylglycerol, phosphatidylinositol, phosphatidylethanolamine, hydroxyphosphatidylethanolamine, and glucosamine-containing phospholipids and galactose, madurose, and xylose as whole-organism sugars (Mertz 1994), In contrast,

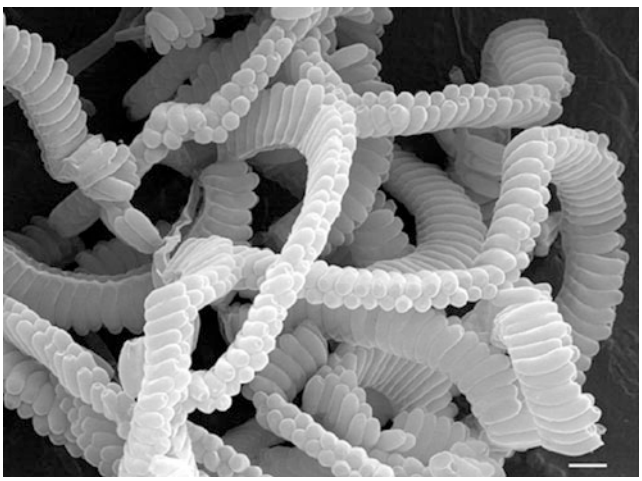

Fig. 43.11
***Planomonospora* sp. Numerous monosporous spore vesicles in double parallel rows (Reproduced with permission from Suzuki; from Suzuki et al. 2001a)**

Planomonospora parontospora and *P. venezuelensis* have madurose as the characteristic sugar (Kroppenstedt and Kutzner 1978); the diagnostic phospholipids of *P. parontospora* consist of diphosphatidylglycerol, lysophosphatidylglycerol, phosphatidylethanolamine, phosphatidylinositol, and unknown glucosamine-containing phospholipids (Hasegawa et al. 1979). Di- and tetrahydrogenated menaquinones with nine isoprene units are the major component in *P. parontospora*, whereas tetrahydrogenated menaquinones with eight isoprene units predominate in P. venezuelensis (Collins et al. 1984); the major component of *P. alba* and *P. sphaerica* is dehydrogenated menaquinone with nine isoprene units (Mertz 1994). Planomonosporae have complex mixtures of straight chains, unsaturated and branched fatty acids but lack mycolic acids. The G+C content of the DNA is 72 mol%. Type species: *Planomonospora parontospora* Tliiemann et al. 1967. Type strain: ATCC 23863^T = DSM 43177^T.

Planotetraspora Runmao et al. 1993, 468^{AL}

Pla.no.te.tra.spo'ra. Gr. n. *planos*, a wanderer; Gr. adj. *tetra*, four; Gr. fem. n. *spora*, a seed and in biology a spore; N.L. fem. n. *Planotetraspora*, a mobile, four-spored organism.

The genus *Planotetraspora* was proposed for an isolate that formed long cylindrical spore vesicles that contained four spores in a single row at the ends of short sporangiophores on aerial hyphae. The organism, *Planotetraspora mira*, was reported to contain *meso*-A_2pm in peptidoglycan and arabinose, galactose, mannose, ribose, and xylose in whole-organism hydrolysates. However, Kudo (2001) found that the strain contained madurose and rhamnose, but not arabinose or xylose in whole-organism hydrolysates. They also noted that it contained tetrahydrogenated menaquinone with nine isoprene units as the predominant isoprenologue and had a type IV phospholipids pattern. Stackebrandt et al. (1997) classified the genus in the family *Streptosporangiaceae*. A second species, *P. silvatica*, has been described for a strain isolated from a soil sample collected on Amami Island, Japan (Tamura and Sakane 2004).

Planotetrasporae are aerobic, Gram-positive, non-acid-fast actinomycetes which form moderate, irregularly branching, stable substrate hyphae (03–6.0 µm width) and sparsely branched, rarely septate aerial hyphae (0.2–0.4 µm in diameter). Long cylindrical spore vesicles are formed at the ends of short sporophores on aerial hyphae, with each spore vesicle (size about 2.1–2.7 µm, 0.6–0.9 µm) containing four spores in a single row. Spores are short, cylindrical, short rod-like or oval elements (0.4–1.4 µm, 0.8–1.5 µm) and may exhibit motility. They are released and become motile by means of single polar flagella when spore vesicles are immersed in water; active movement of the spores begins 30 min after they are released. In general, the vegetative mycelia are pale yellow to white. Good growth occurs at 25–30 °C. Cell walls contain alanine, glutamic acid, and *meso*-A_2pm and *N*-acetylmuramic acid. Galactose, glucose, madurose, 3-0-methylmannose, and rhamnose are found in whole-organism hydrolysates. The predominant isoprenologue is tetrahydrogenated menaquinone with nine isoprene units, phosphatidylethanolamine is the diagnostic phospholipid, and 10-methylated $C_{18:0}$ is the major cellular fatty acid. The G+C content of the DNA is 71 moI%.

Type species: *Planotetraspora mira* (Runmao et al. 1993), 468^{AL}. Type strain: DSM 44359^T = JCM 9131^T.

Sphaerisporangium Ara and Kudo 2007, 2449^{VP}

S.pha.eri.spo.ran.gium. L. n. *sphaera*, sphere; N.L. neut. n. *sporangium*, sporangia; N.L. neut. n. *Sphaerisporangium*, an organism with spherical sporangia.

The genus *Spaherisporangium* was proposed for developing spherical spore vesicle on aerial mycelium containing non-motile spores. The type strain of *Sphaerisporangium melleum* was isolated from a sandy soil collected in a forest side waterfall in Chokoria, Cox's Bazar, Bangladesh (Ara and Kudo 2007).

This taxon contains five validly described species, namely, *S. album* (Cao et al. 2009), *S. cinnabarinum* (Ara and Kudo 2007), *S. flaviroseum* (Cao et al. 2009), *S. krabiense* (Suriyachadkun et al. 2011), *S. rubeum* (Ara and Kudo 2007), and *S. viridialbum* (Ara and Kudo 2007).

Cells are Gram-positive, non-acid-fast, 0.4–0.9 μm wide, and 0.6–1.2 μm long with a smooth, wrinkled, and prominently ridged surface. The substrate hyphae are pale to brown yellow in color, and aerial hyphae are white. A non-fragmenting substrate mycelium was formed. The organisms grow well at 20–37 °C and pH 5–9. No growth occurs at 3 % NaCl. Cell walls contained *meso*- A_2pm and glucose, madurose, and mannose as the major whole-cell sugars. Tetrahydrogenated menaquinone with nine isoprene units is contained as the predominant isoprenologue. Shaerisporangiae contain phosphatidylethanolamine, ninhydrin-positive phospholipids and phosphatidylinositol mannosides as diagnostic polar lipids; major amounts of straight chain, unsaturated, *iso*- and 10-methyl branched fatty acids with small amount of saturated fatty acid, unsaturated fatty acid, anteiso- and 10 methyl fatty acids. The G+C content of the DNA is 67–72 mol%.

Type species: *Sphaerisporangium melleum* (Ara and Kudo 2007). Type strain: JCM 13064^T = DSM 44954^T.

Thermopolyspora Goodfellow et al. 2005, 1980^{VP}

Ther.mo.poly.spo.ra. Gr. n. thermos heat; Gr. adj. poly many; Gr. n. spora a seed; N.L. fem. n. *Thermopolyspora* the heat (-loving) many-spored organism.

The type strain of *Thermopolyspora flexuosa* DSM 41386^T was isolated from soil of the Pamir mountains and expressed the following properties (Goodfellow et al. 2005). Cells are aerobic, Gram-positive, non-acid-alcohol-fast, hooked, or irregular spiral chains of 4–10 warty to spiny spores (Fig. 43.12). The organisms produced 1.2–1.5-μm diameter spores and are arranged in clusters on long, moderately branched aerial hyphae on potato carrot agar. Color of aerial hyphae is light blue and produces a brown soluble pigment on the medium. Growth occurs at 40–60 °C (good growth 45–55 °C) and pH6.0–9.0. Cell wall contains meso-A2pm and *N*-acetylated muramic acid. Strains contain MK9, MK9[H_2], and MK9[H_4] as predominant isoprenologues and minor amounts of MK-9[H_6]; glucose and ribose in whole-organism hydrolysates; as diagnostic phospholipid; and saturated, unsaturated and branched chain components as major fatty acids, but lacks mycolic acids. The G+C content of the DNA is 77 mol%.

Type species: *Thermopolyspora flexuosa* (Goodfellow et al. 2005). Type strain: DSM 41386^T = NRRL B-24348^T.

Thermopolyspora flexuosa was proposed by Krassilnikov and Agre (1964) for a group of thermophilic actinomycetes that formed short chains of spores on short sporophores. The species was subsequently associated with a number of other genera including *Nocardia* (Becker et al. 1965; Lechevalier et al. 1966) *Actinomadura* (Cross and Goodfellow 1973; Lacey et al. 1978), *Micropolyspora* (Krassilnikov et al. 1968), *Microtetraspora* (Kroppenstedt et al. 1990), and latterly *Nonomuraea* (Zhang et al. 1998). Goodfellow et al. (2005) revived the genus Thermopolyspora according to the PCR product characteristic of this taxon using a set of the family-specific oligonucleotide primers (Monciardini et al. 2002).

***Thermopolyspora flexuosa* NBRC 14349^T on oatmeal agar. The spore surfaces are warty (Courtesy of M. Hayakawa)**

Sinosporangium Zhang et al. 2011, 596^{AL}

Si.no.spo.ran′gi.um. M.L. n. *sina* China; N.L. n. *sporangium* from Gr. n. *spora* a seed and, in biology, a spore and Gr. n. *angeion* (Latin transliteration *angium*) vessel, sporangium; N.L. neut. n. *Sinosporangium* an organism isolated in China, bearing sporangia.

This taxon proposed for producing globose sporangia originated from borne on aerial mycelia. The sporangia contained coiled spore chains.

The type strain of *Sinosporangium album* was isolated from a soil sample collected from Qinghai province, northwest China. Cells are Gram-positive, aerobic, nonmotile, and form elementary branching hyphae and abundant aerial mycelia with globose sporangia on ISP 4 and R2A media. The sporangia were a mean size of 2.8–3.0 μm × 3.4–4.2 μm and contained coiled spore chains. Spore surface is smooth. A cylindrical spore size is about 0.5–0.6-μm width × 0.6–1.2-μm long. Growth occur at pH 6.5–8.0 and 10–37 °C (optimum growth is 28–32 °C). Whole-cell hydrolysates contained ribose, galactose, and arabinose. Cell wall contains meso-A2pm. Phosphatidylmethylethanolamine, hydroxyl-phosphatidylethanolamine,

N-acetylglucosamine-containing phospholipids, two unknown phospholipids, and an unknown glycolipid are comprised as diagnostic phospholipids.

Strain contains saturated, *iso*- and 10-methyl branched fatty acids, and di and tetrahydrogenated menaquinone, with nine isoprene units (MK-9 [H_2, H_4]) as the predominant isoprenologue. The G+C content of the DNA is 69.4 mol%.

Genus-specific diagnostic nucleotide signature pattern of 16S rRNA is 600:638 (U-G), 658:748 (C-G), 990:1215 (U-G), 1012:1017 (G-U), and 1263: 1272 (G-C).

Type species: *Sinosporangium album* (Zhang et al. 2011), 596^{AL}.Type strain: DSM 45181^T = KCTC 19655^T

Because the phylogenetic position of the genus *Sinosporangium* has yet not been settled, this genus is included for convenience in the family *Streptosporangiaceae* (*Fig. 43.1*).

Isolation, Enrichment, and Maintenance Procedures

Isolation and Enrichment

Several strategies have been developed to facilitate the isolation, enumeration, and identification of "rare" and uncommon actinomycetes (Goodfellow and Williams 1986; Labeda and Shearer 1990; Kurtböke 1990; Hayakawa 2008). The design and application of new selective isolation procedures showed that some actinomycetes previously thought to be rare are common and widely distributed in natural habitats, as shown by procedures found to be effective for the isolation of actinomadurae (Athalye et al. 1981; Trujillo and Goodfellow 2003), actinoplanetes (Takizawa et al. 1993; Hayakawa et al. 2000), nocardiae (Yamamura et al. 2003), planomonosporae (Suzuki et al. 2001a), and planobisporae (Suzuki et al. 2001b). The isolation of "rare" and uncommon actinomycetes can be promoted by using baiting procedures and by pretreatment or enrichment of environmental samples prior to plating onto selective isolation media (Williams et al. 1984; Goodfellow and O'Donnell 1989). Baiting procedures have been successfully used to isolate planobisporae, planomonosporae, and streptosporangiae from environmental samples (*Table 43.5*). It can also be seen from this Table that a variety of pretreatment and selective media have been recommended for the isolation of members of the family *Streptosporangiaceae.* Hayakawa and Nonomura (1987a) found that media containing humic acid were more effective for the isolation of members of the family *Streptosporangiaceae* than those containing carbon and nitrogen sources such as asparagine, casein, chitin, glycerol, and starch.

The incorporation of antibiotics into isolation media is one of the most important approaches used to isolate members of the family *Streptosporangiaceae* from environmental samples (*Table 43.5*). The antifungal antibiotics cycloheximide and nystatin are routinely used to supplement media designed to be selective for actinomycetes in order to eliminate or control the growth of fungi on isolation plates (Williams and Davies 1965; Labeda and Shearer 1990; Sembiring et al. 2000). Media supplemented with antibacterial antibiotics have been used to good effect for the isolation of members of the family *Streptosporangiaceae* though it is well known that actinomycete counts, as well as those of unwanted bacteria, may be reduced (Williams and Davies 1965; Hayakawa et al. 1996).

The selectivity of isolation media is influenced not only by nutrient composition and selective inhibitors but also by the pH of media and by incubation conditions, notably temperature regimes (Williams et al. 1984; Nonomura and Hayakawa 1988; Hayakawa et al. 1996). The isolation of actinomycetes can also be influenced by the gelling agent used to prepare the isolation media. Suzuki et al. (1998, 1999, 2001a, b) showed that the incorporation of gellan gum, a polysaccharide produced by "*Pseudomonas elodea*," into selective media improves the isolation of "rare" and uncommon actinomycetes, such as members of the genera *Actinobispora*, *Planobispora*, *Planomonospora*, and *Sporichthya.* Suzuki et al. (2001a, b) isolated *Planomonospora parontospora* strains from 131 out of 1,200 soil samples (10.9 %) and *Planomonospora venezuelensis* strains from 13 of these soil samples (1.1 %). It is clear from this study that planomonosporae are widely distributed in soil albeit in relatively low numbers. In the present study, a procedure slightly modified from that of Suzuki et al. (2001a, b) was used to try and isolate members of the genera *Nonomuraea* and *Streptosporangium* from environmental samples.

Information was not provided on the selective isolation procedures used for *Acrocarpospora*, *Planotetraspora*, *Sinosporangium*, *Sphaerisporangium*, and *Thermopolyspora* (Tamura et al. 2000; Runmao et al. 1993; Zhang et al. 2011; Goodfellow et al. 2005). The type strain of *A. corrugata* (previously *Streptosporangium corrugatum*) was isolated on starch casein agar supplemented with antifungal antibiotics following inoculation with a suspension of beach sand (Williams and Sharples 1976). Similarly, *Herbidospora cretacea* strains have been isolated by plating soil suspensions onto yeast extract-starch agar (Kudo et al. 1993) and humic acid-vitamin agar (Hayakawa and Nonomura 1987b). Members of this species have been isolated on yeast extract agar supplemented with antifungal antibiotics, and plant material which had been desiccated at 28 °C for at least a week prior to being ground with a blender following the addition of sterile water; the resultant plates were incubated at 28 °C for 2 weeks (Kudo et al. 1993). The type strain of *Planotetrasopra silvatica* (Tamura and Sakane 2004) was isolated from a sample of forest soil on humic acid-vitamin agar (Hayakawa and Nonomura 1987b) using the yeast extract-sodium dodecylsulfate (SDS) method (Hayakawa and Nonomura 1989). *Acrocarpospora*, *Herbidospora*, and *Planotetraspora* strains grow well on oatmeal agar (Shirling and Gottlieb 1966). Similarly, acrocarposporae and herbidosporae show good growth on inorganic salts starch (Shirling and Gottlieb 1966) and yeast extract-starch agars (Kudo et al. 1993), respectively. The type strain of *Planotetraspora mira* grows well and sporulates on calcium malate (Runmao et al. 1993) and humic acid-vitamin agars (Hayakawa and Nonomura 1987b). The type strain of *P. silvatica* grows well on

glycerol-asparagine, tyrosine, and yeast extract-malt extract agars (Tamura and Sakane 2004). The type strain of *Sinosporangium album* grows well on R2A, ISP 4, ISP 5, Czapek solution agar, nutrient agar, and potato agar (Zhang et al. 2011). Species of the genus *Sphaerisporangium* were isolated on humic acid-vitamin agar (Hayakawa and Nonomura 1987b) or starch casein agar (Duangmal et al. 2011), modified glycerol-aspargine agar (Cao et al. 2009) supplemented with antifungal antibiotics. Janso and Carter (2010) reported the culturable diversity of endophytic actinomycetes associated with tropical, native plants. They isolated quite prevalent strains of endophytic *Sphaerisporangium* and *Planotetraspora* by using arginine vitamin agar (Nonomura and Ohara 1969a) supplemented with 3 % soil extract (Hayakawa et al. 2000) and 100-μg ml^{-1} cycloheximide and 50-μg ml^{-1} nystatin.

Dry heat treatment of air-dried soil samples and dilution plate culture with selective synthetic media are used for the preferential isolation and enumeration of some members of the family *Streptosporangiaceae*. The procedures outlined below have been developed for the selective isolation of the genera *Microbispora* and *Streptosporangium* (Nonomura and Ohara 1969a, b) and with modifications for the isolation of other actinomycete genera, notably *Microtetraspora* and *Nonomuraea* (Nonomura and Ohara 1971b, c). There is evidence (Nonomura and Hayakawa 1988) that pretreatment of soil suspensions with yeast extract (6 %, w/v) and sodium dodecyl sulfate (0.05 %, w/v) at 40 °C for 20 min, followed by dilution with water, activates actinomycete spores but kills vegetative cells of other soil bacteria in the suspensions.

This practice leads to an increase in the counts of actinomycetes on isolation plates. After soil samples are dried slowly at room temperature, passed through a 2-mm sieve, ground slightly in a mortar, spread on filter paper, and heated in a hot air oven at 120 °C for 1 h, the number of bacteria and streptomycetes is dramatically reduced, and the isolation frequency of *Microbispora*, *Microtetraspora*, and *Streptosporangium* strains is enhanced. Heated soil is incorporated directly onto isolation media, or a suspension is used to make dilution plates. Initially, arginine-vitamin (AV) and mineral glucose-asparagine plus soil extract (MGA-SE) agars were recommended for the selective isolation of microbisporae and streptosporangiae, but two additional formulations, chitin-V and humic vitamin (HV) agars (Hayakawa and Nonomura 1987a, b; Nonomura 1989b), have been developed. These media are supplemented with antifungal antibiotic(s); sometimes penicillin and polymyxin B are also used. Inoculated plates are incubated for 4–6 weeks at 30 °C (or 2–3 weeks at 50 °C) and examined using a light microscope with a long-working-distance objective. The highest counts and cleanest plates are usually obtained with HV agar.

Hayakawa et al. (1991) introduced an improved procedure for the selective isolation of streptosporangiae from soil. The method is based on the ability of streptosporangial spores to withstand dry heat and treatment with benzethonium chloride (BC) and the capacity of streptosporangiae to grow in the presence of leucomycin and nalidixic acid. Initially an air-dried soil sample is ground in a mortar and heated in a hot-air oven for an hour. Half a ml of a 10^{-1} dilution in water of the heated sample is transferred to 4.5 ml of sterile 5-mM phosphate buffer (pH 7.0) containing BC at a final concentration of 0.1 % (w/v). The resultant preparation is maintained at 30 °C for 30 min with occasional stirring, and a portion (1 ml) is then diluted with sterile tap water (1:10 or 1:15). Inocula of 0.1 ml or 0.2 ml of the dilution are then spread over the surface of plates of HV agar supplemented with leucomycin in ethanol (1 mg per liter) and nalidixic acid (20 mg per liter) and the plates are incubated at 30 °C for 3–4 weeks. Actinomycetes which appear on the plates are examined by light microscopy (600X) and assigned to genera on the basis of characteristic morphological properties. New species of the genus *Streptosporangium* and *Acrocarpospora* were isolated from soil with two criteria consisting of the growth on soil extract agar and showing small colonies (Hamaki et al. 2005).

Microbispora strains can be preferentially isolated by treating suspensions of dry heat pretreated soil samples with 1.5 % phenol at 30 °C for 30 min, diluting in water, and plating onto HV agar supplemented with nalidixic acid (20 mg per liter). *Microbispora karnatakensis* (Rao et al. 1987) was isolated by plating a suspension of soil onto inorganic salts-starch agar (Küster 1959).

Microtetraspora fusca, *M. glauca*, and *M. malaysiensis* were isolated from soil samples using methods that have not been disclosed (Thiemann et al. 1968b; Nakajima et al. 2003). However, the pretreatment procedure described above has been used to isolate several *Nonomuraea* species, including *N.* helvata, *N. pusilla*, *N. roseoviolacea*, and *N. spadix* (Nonomura and Ohara 1971c). *Nonomuraea* spores appear to be particularly resistant to dry heat at 100–120 °C, thereby allowing the slow-growing nonomuraea to develop into recognizable colonies on dilution plates. Soil dilutions are plated onto various media, including AV and MGA-SE agars, and incubated for several weeks at 28–30 °C (Nonomura and Ohara 1971b). *Microtetraspora niveoalba* was isolated from dry-heated soil on MGASE agar incubated at 40 °C for 1 month. Similarly, *M. glauca* strains have been isolated on plates of this medium incubated at 30 °C. Other *Nonomuraea* (previously *Microtetraspora*) species, such as *N. roseola* and *N. salmonea*, have been isolated from soil by Soviet investigators who supplemented media with antibiotics to improve their selectivity. Lavrova et al. (1972) added rubomycin (5, 10 or 20 μg ml^{-1}) to medium no. 2 of Gauze et al. (1957), Preobrazhenskaya et al. (1975) added bruneomycin (0.5, 1 or 2 μg ml^{-1}) or streptomycin (0.5, 1, or 2 μg ml^{-1}). The use of these antibiotics led to the growth of more nonomuraea colonies on isolation plates while reducing the number of streptomycetes. In contrast, *N. ferruginea* and *N. spiralis* were isolated by plating soil suspensions onto oatmeal agar or Gauze's no. 1 medium without addition of selective antibiotics (Meyer 1979).

Microbisporae, microtetrasporae, nonomuraea, and streptosporangiae grow well on rich media, including Bennett's (Jones 1949), glucose-yeast extract (Waksman 1950), oatmeal (ISP medium 3; Difco 0771), and yeast extract malt extract agars (ISP medium 2 [Difco 0770]; Shirling and Gottlieb 1966). Oatmeal-yeast

extract agar is recommended for the growth of mesophilic microbisporae and glycerol agar for the corresponding thermophilic strains (Nonomura 1989a). Streptosporangiae grow well and produce an abundant aerial spore mass on oatmeal-yeast extract agar (Nonomura and Ohara 1960). Good growth of vegetative and sporing aerial mycelia was obtained for *M. fusca* and *M. glauca* on Hickey and Tresner (1952) agar. *M. malaysiensis* strains grow well on yeast-malt extract agar (Nakajima et al. 2003). *Microtetraspora niveoalba* requires B vitamins for growth on synthetic media (Nonomura and Ohara 1971b).

The procedures used to isolate *Planobispora* and *Planomonospora* strains from soil were not revealed by Thiemann and his colleagues (Thiemann et al. 1967; Thiemann and Beretta 1968a). However, members of these taxa have been isolated from soil by baiting with natural substrates (Couch 1954; Bland and Couch 1981) as follows: a small amount of soil, approximately one level teaspoonful, is placed in a sterile Petri dish and flooded with sterile water (distilled water or filtered soil or charcoal water extracts may be used). Pollen and hair float are added at the water surface; various types of pollen have been employed including that from members of the genera Liquidamber, Pinus, and Sparganium (Schäfer 1973). After 1–4 weeks, examination of the water surface with a dissecting microscope (100X) and strong horizontal lighting should reveal white glistening spore vesicles formed in the air at the surface of the water by spore vesicle–forming members of the families *Micromonosporaceae* and *Streptosporangiaceae*.

The characteristic two-spored vesicles of *Planobispora* develop on long aerial hyphae growing between the baits. Similarly, sporulating aerial hyphae of *Planomonospora* strains grow on pollen grains. Single spore vesicles or bundles can be picked up with a thin needle and placed on the surface of agar media in small Petri dishes. After 2–4 weeks, the young colonies can be transferred to slant cultures. Similarly, *Planomonospora alba* strain A82600^T and *Planomonospora sphaerica* strain A15460^T were isolated by immersing a soil sample in water enriched for growth of microorganisms with motile spores, with sterile grass floating on the water surface as bait (Mertz 1994).

A multistage procedure was developed by Suzuki et al. (2001a) for the selective isolation of planobisporae from soil. Air-dried soil samples (500 mg) are heated at 90 °C for 60 min in a hot-air oven and then cooled to room temperature. Each heat treated sample is added to 2 ml of flooding solution (0.1 % skim milk [neutralized], 0.01 % Tween, 100-μg · ml^{-1} nalidixic acid in 5 mM-*N*-cyclohexyl-2-aminoethanesulfonic acid [CHES]; pH 9.0) and incubated at 35 °C for 60 min with occasional stirring to stimulate zoospore motility. After centrifugation (1,000 g) for 10 min at room temperature, 800 μl of supernatant is gently transferred to a sterile tube; 100-μl aliquots of this preparation are spread over humic acid-trace salts gellan gum medium (HSG) supplemented with cycloheximide (50 μg ml^{-1}), enoxacin (20 μg ml^{-1}), nalidixic acid (50 μg ml^{-1}), nystatin (50 μg ml^{-1}), sodium ampicillin (2 μg ml^{-1}), streptomycin sulfate (1 μg ml^{-1}), and trimethoprim (50 μg ml^{-1}). Following incubation at 32 °C for 14–21 days, planobisporae colonies growing on the HSG plates are recognized by their characteristic morphological features, as seen using a 40X long working district objective lens. Pure cultures are isolated by streaking onto HSG medium and tested for zoospore production using flooding solution containing 0.1 % skim milk in 5-mM CHES (pH 9.0).

A similar multistage procedure is available for the selective isolation of planomonosporae from soil (Suzuki et al. 2001b). Air-dried soil samples (500 mg) are heated at 100 °C for 60 min in a hot-air oven and cooled to room temperature. Each heat treated sample is added to 2 ml of sterile flooding solution (0.1 % skim milk in 5-mM *N*-cyclohexyl-2-amino-ethanesulfonic acid [CHES]; pH 9.0) and incubated at 32 °C for 90 min with occasional stirring to stimulate motility. The soil suspension is centrifuged (1,000 g) for 10 min at room temperature, incubated at 32 °C for 60 min, and 500 μl of supernatant is gently transferred to a sterile tube and 100-μl aliquots spread over HSG medium supplemented with cycloheximide (50 μg ml^{-1}), enoxacin (20 μg ml^{-1}), nalidixic acid (20 μg ml^{-1}), nystatin (50 μg ml^{-1}), sodium ampicillin (2 μg ml^{-1}), and trimethoprim (20 μg ml^{-1}). Inoculated plates are incubated at 35 °C for 14–21 days. Colonies of actinomycetes are observed directly under a phase-contrast microscope using a 40X long distance working objective lens.

Planomonosporae colonies, identified using morphological features (clavate spore vesicles containing single spores), are purified by single colony isolation on HSG plates and incubated at 35 °C for 14 days. Isolates are tested for motility with flooding solution containing 0.1 % skim milk in 5 mM CHES (pH 9.0). Isolates with motile spores can be assigned to two groups on the basis of morphological features: the *P. parontospora* group (spore vesicles arranged in double parallel rows resembling bananas) and the *P. venezuelensis* group (spore vesicles arranged in palm leaf patterns).

Planobisporae and planomonosporae grow on standard media used for cultivating streptomycetes (Waksman 1961), the first signs of visible growth appear after 3–4 days at 28–30 °C. *Planobispora longispora* produces aerial hyphae and abundant spore vesicles on calcium malate, soil extract, and yeast extract-malt extract agars (Shirling and Gottlieb 1966). Vesicular development in *P. rosea* is promoted by all media on which aerial mycelium is formed, notably soil extract and Hickey-Tresner agars. Spore vesicle development in *Planomonospora* strains is especially abundant on Bennett's, Hickey-Tresner, oatmeal, and soil extract agars (Thiemann et al. 1967; Vobis 1989b).

Maintenance

The most convenient method for short-term storage is by serial transfer from agar slants of appropriate media (see above) every 2 months (Meyer 1989). The tubes should be tightly closed with cotton plugs dipped in melted paraffin wax. Sporulated spore cultures can be stored at 5 °C and at room temperature. Lyophilization, storage in liquid nitrogen, and freezing in glycerol can be used for long-term preservation (Wellington and Williams 1978; Meyer 1989).

For lyophilization, the spore suspension or vegetative mycelium is suspended in a suitable fluid, such as serum plus

7.5 % (w/v) glucose or skimmed milk plus 7.5 % (w/v) glucose. For storage in liquid nitrogen, the microorganisms are inoculated into small test tubes containing the appropriate medium and incubated until satisfactory growth is visible. The tubes are then closed with cotton plugs dipped in melted paraffin wax and placed in a liquid nitrogen container.

Glycerol suspensions are prepared by scraping aerial growth or substrate mycelium or both from heavily inoculated plates and making heavy suspensions in 3 ml of aqueous glycerol in small (e.g., bijoux) bottles, which are stored at −20 °C or −80 °C. The frozen glycerol suspensions serve both as a practical means of long-term preservation and as convenient source of inoculum. Working inocula are obtained by thawing suspensions at room temperature prior to treating as for broth cultures. After use, glycerol suspensions are promptly frozen and stored again at −20 °C or −80 °C.

Ecology

Members of the family *Streptosporangiaceae* are usually associated with soil, but little is known about their role within this milieu. However, improvements in selective isolation procedures are beginning to cast light on the occurrence, distribution, numbers, and activity of actinomycete taxa in natural habitats (Suzuki et al. 2001a, b). Members of the family *Streptosporangiaceae* are probably involved in the primary decomposition of plant material in soils. In the course of screening for industrially important actinomycetes, several genera belonging to the family *Streptosporangiaceae* were isolated from tropical rainforests of Singapore and Vietnum (Wang et al. 1999; Muramatsu et al. 2003; Hop et al. 2011).

Streptosporangiae were associated with leaf litter (Van Brummelen and Went 1957; Potekhina 1965), as well as soil and dung (Nonomura and Ohara 1969a) until the introduction of a selective isolation procedure (Nonomura and Ohara 1969a) showed that these organisms were an integral part of the actinomycete community in soils. The number of streptosporangiae in various soils in Japan has been estimated at 104–106 colony forming units (cfu) per gram dry weight of soil (Nonomura and Ohara 1969a; Nonomura 1984). Slightly acid, humus-rich garden soils are a favorite habitat. They have also been isolated from lake sediments (Willoughby 1969a; Johnstone and Cross 1976), beach sand (Williams and Sharples 1976), and pasture and woodland soils (Whitham et al. 1993), but organisms labeled *Streptosporangium* type I from stream water (Willoughby 1969b), given their morphological properties and capacity to form motile spores, probably belong to the genus *Actinoplanes*. "*Streptosporangium bovinum*" was isolated from infected bovine hooves (Batista et al. 1963). Decades of environmental clones related to the genus *Streptosporangium* spp. were found in soil (GU556444, GU556247), gypsum-treated oil sands tailings pond (HQ092437), lake water (GQ411539-GQ411542, GQ468607,), and soil and water (GQ468603-GQ468605). On the based on BLAST search, undescribed member "*Streptosporangium koreanum*" (X89943) was related to *Streptosporangium roseum* with 99.9 % 16S rRNA gene sequence similarity. Other related strains were isolated from soil (EU119244-EU119248, FR692099, FJ261957), sediment (GU002049, KF007269, HQ157193), and surface-sterilized root of a medicinal plant (JX273661).

Few *Acrocarpospora* and *Herbidospora* strains have been isolated; hence, little is known about their distribution in natural habitats. The single representatives of *A. corrugata*, *A. macrocephala*, and *A. pleiomorpha* were isolated from beach sand (pH 7.8) at Freshfield, Lancashire, United Kingdom (Williams and Sharples 1976) and from soil samples collected from Saitama Prefecture, Japan (Tamura et al. 2000), and in Louisiana, United States (Tamura et al. 2000), respectively. Similarly, *Herbidospora cretacea* strains have been isolated from soil and plant material collected from several locations in Japan (Kudo et al. 1993). As the BLAST analysis, some strains related to *A. pleiomorpha* isolated from soil (AB193572, AB546293, AB649124) in Japan and Thailand.

Microbispora strains are common in soils. Using selective isolation procedures, counts of between 10^4 and 10^6 cfu per gram dry weight of soil have been reported from various Japanese soils (Nonomura and Ohara 1971b). Larger populations have been found in slightly acidic (pH 5–6), humus-rich garden soils (Nonomura and Ohara 1969a; Nonomura and Hayakawa 1988). Microbisporae have also been isolated from marine sediments (Weyland 1969). *Microbispora corallina* strains were isolated from soil samples collected in a deciduous dipterocarp forest in Thailand (Nakajima et al. 1999). For discovering of biocontrol agents, *Microbispora rosea* subsp. *rosea* were isolated from surface sterilized roots of Chinese cabbage, and the isolates exhibited the antagonistic activities to *Plasmodiophora brassicae* (Lee et al. 2008).

One species, *Microbispora rosea*, has been implicated in a case of pericarditis and pleuritis in a human (Louria and Gordon 1960). Most of the species previously assigned to the *Actinomadura pusilla* group, and now part of the genus *Nonomuraea*, originated from soil (Nonomura and Ohara 1971c; Meyer 1979; Galatenko et al. 1981). Microtetrasporae are common in soil, notably forest soils (Thiemann et al. 1968b; Nonomura and Ohara 1971b; Hayakawa et al. 1988; Nakajima et al. 2003). Using humic acid agar, Nonomura and Hayakawa (1988) recorded average counts of 3.6 10^4 cfu per gram dry weight soil for a number of forest soil samples collected in Japan. *Microtetraspora niveoalba* strains are particularly widely distributed albeit with counts of less than 10^3 cfu per gram dry weight of soil (Nonomura and Ohara 1971b). In contrast, *M. malaysiensis* strains have only been isolated from two locations, namely, from soil collected from below the leaf litter of mainly *Shorea* spp. in a primary lowland dipterocarp forest at Pasok, Negere Sembilan, and from a steep hill dipterocarp forest at the Virgin Jungle Reserve, Gombak, Selangor in Peninsular Malaysia (Nakajima et al. 2003). *Microtetraspora fusca* and *M. glauca* have been isolated from soil samples collected in Brazil, Italy, and Thailand. Some of the uncultured clones belonging to the genus *Microbispora* were deposited in DNA databank and their isolation sources from plant and

terrestrial environments including compost (GU188866; Xiao et al. 2011). Based on BLAST search, several *Microbispora* strains were found and their major isolated sample was soil.

Planomonospora strains have a worldwide distribution in soils of arid, temperate, and tropical regions. Thiemann (1970) isolated 37 strains of *P. parontospora* from 7 out of 454 soil samples (1.5 %) collected from Argentina, Chile, India, Peru, and Venezuela. He also isolated 7 strains of *P. venezuelensis* from 3 out of 454 soil samples (0.7 %) originating from Venezuela. Similarly, Suzuki et al. (2001b) isolated 246 *Planomonospora* strains from 137 out of 1,200 soil samples; 94 % of these isolates were from neutral to slightly alkaline soils (pH 7.0–9.0). Strains assigned to the *P. parontospora* group were recovered from 131 of these soil samples, notably from ones collected in Ecuador, Greece, and India. Strains classified in the *P. venezuelensis* group were isolated from 13 soil samples (1.1 %) collected in Bolivia, Cyprus, Egypt, Greece, India, Japan, New Caledonia, and Turkey. The single strains of *P. alba* and *P. sphaerica* were isolated from soil samples collected from The Sudan and India, respectively (Mertz 1994). *Planomonospora* strains have also been isolated from soil samples collected in Africa, Europe, and Central and North America (Vobis 1989b) and from the arid northeastern region of the Republic of South Africa (Kizuka et al. 1997). Until recently, planobisporae had rarely been isolated from soil. Several strains, including the type strains of *P. longispora* and *P. rosea*, were isolated from soil samples taken from a riverbank in Venezuela (Thiemann 1970). A few additional strains were recovered from soil samples collected from near Windhoek, Namibia (Vobis 1989a), and from arid regions of South Africa (Kizuka et al. 1997). Suzuki et al. (2001a) have shown that planobisporae are distributed over a much wider geographical area, as they isolated 119 strains from 51 soil samples (3.5 % of the samples tested) collected in Ecuador, Egypt, French Guiana, India, and Madagascar. Nearly 90 % of these strains were isolated from soil samples with pH values ranging from 7.0 to 7.9, results which suggest that *Planobispora* strains prefer neutral to alkaline environments. Suzuki and his colleagues were unable to isolate planobisporae from temperate regions in Europe, North America, and Oceania. Planotetrasporae, in contrast to planobisporae and planomonosporae, have only been isolated from two sources. The type strain of *Planotetraspora mira* was isolated from a soil sample collected in the village of Wolung, Sichuan, People's Republic of China (Runmao et al. 1993), and *P. silvatica* from a sample of forest soil originating from Amami Island, Kagoshima Prefecture, Japan (Tamura and Sakane 2004).

Sphaerisporangium and *Planotetraspora* isolates were discovered as endophytic actinomycetes from tropical plants roots collected from Papua New Guinea. Janso and Carter (2010) isolated 123 strains of endophytic actinomycetes and were derepricaqted by ribotying and 16S rRNA gene sequencing. Subsequently, 17 different genera and prevalent genera such as *Sphaerisporangium* and *Planotetraspora* were represented.

Several novel species of the genus *Nonomuraea* had been isolated from worldwide and habituated in several ecosystems such as soil, sea sediments, and plant rhizosphere (Kämpfer et al. 2010; Xi et al. 2011; Zhao et al. 2011). On the basis of BLAST search, undescribed members "*Nonomuraea rubescens*" (AY039255), "*Nonomuraea latina*" (AF277197), and "*Nonomuraea aurea*" (AY039254) were related to *Nonomuraea pusilla*, with 96.2 %, 96.2 %, and 95.2 %, respectively. Another related strains were isolated from mangrove soil (FJ261962), beach sand (EU741228), solar saltern (JN859005, Jose and Jebakumar 2012).

The studies of molecular based actinobacterial diversity by means of DGGE/clone library analysis in several environments had reported, however, only published paper described the presence of *Microbispora* in compost (Xiao et al. 2011). The survey of NCBI taxonomy browser lists culture-independent 16S rRNA gene sequences deposited for the genus *Acrocarpospora*, *Microbispora*, *Nonomuraea*, *Planomonospora*, *Planotetraspora*, *Sphaerosporangium*, and *Streptosporangium*. The entry of unnamed strains belonging to some of genera such as *Microbispora*, *Nonomuraea*, *Planotetraspora*, *Sphaerosporangium*, and *Streptosporangium* are abundant, but few entries for other genera. In near future, advances in DNA sequencing technology will provide more large information about culture-independent actinobacterial diversity in diverse ecosystems. Furthermore, diversity of culturable actinomycetes including the family *Streptosporangiaceae* is also important for understanding the several features in ecosystems. For example, Hop et al. (2011) suggested that the ratio of *Streptosporangium* to *Nonomuraea* isolates was different in latitude sites collected from Southeast Asia to Japan.

Pathogenicity: Clinical Relevance

Although "*Streptosporangium bovinum*" was reported to isolate from infected bovine hooves, there are no objective data for *Streptosporangiaceae* which has a role as clinical pathogens.

Applications

Members of the family *Streptosporangiaceae* are expected to be an increasingly rich source of commercial products, notably antibiotics and enzymes. "*Microtetraspora tyrrkensis*" produces fluvirucins active against influenza A virus (Tomita et al. 1991); *Microbispora rosea* produces deoxycephalomycin B (Okazaki and Naito 1985); *Microbispora* strain SCC 1438 produces a novel fungal antibiotic (Patel et al. 1988); *Nonomuraea roseoviolacea* produces carminomicins (Nakagawa et al. 1983, 1989); *N. rubra* produces maduromycin (Fleck et al. 1978), *N. pusilla* produces actinotiocin (Tamura et al. 1973), and *N. spiralis* produces pyralomicin (Naganawa et al. 2002). Similarly, *Streptosporangium albidum* produces aculeximycin (Murata et al. 1989); *S. pseudovulgare* produces sporamycin (Komiyama et al. 1977); *S. roseum* produces maytansin-type ansamacrolactam (Hacene et al. 1998), sporangirosamycin (Gazhal and Abl El-Aziz 1993), and thiosporamycin (Celmer et al. 1978); *S. violaceochromogenes* produces platomycins

A and B (Takasawa et al. 1975) and victomycin (Kawamoto et al. 1975), and *S. vulgare* produces sporacuracins A and B (Atsushi et al. 1975). A novel anthracycline antibiotic has been isolated from *S. fragile* (Shearer et al. 1983), an antitumor antibiotic from an organism resembling *S. pseudovulgare* (Umezawa et al. 1976) and unspecified antimicrobial agents from *Microbispora indica* and *M. karnatakensis* (Rao et al. 1987).

Microbispora rosea is an excellent source of D-xylose (glucose) isomerase (Crueger and Crueger 1982), which converts D-glucose into D-fructose. The enzyme is used to produce D-fructose on a commercial scale, and its biosynthesis, purification, and immobilization, as well as its application for the production of high fructose syrup, have been the subject of many reports and patents (Crueger and Crueger 1984). Similarly, cystathionine γ-lyase has been detected in strains of Streptosporangium (Nagasawa et al. 1984). This enzyme has been shown to catalyze the α, γ-elimination reaction of L-cystathionine and also the γ-replacement of L-homoserine in the presence of various thiol compounds (Kanzaki et al. 1986a). An efficient method based on the reaction of γ-replacement has been developed (Kanzaki et al. 1986b) for the preparation of L-cystathionine, a product that may be useful, because a deficiency of this compound has been observed in the brains of homocystinuric patients (Gerritsen and Waisman 1964). The procedure allowed the total conversion of *O*-succinyl-L-homoserine and L-cysteine into L-cystathionine. Microbispora rosea also produces exoxylanases (Kusakabe et al. 1969).

Thermophilic microbisporae synthesize a wide range of enzymes that are involved in the degradation and modification of heteropolysaccharides, notably celluloses, lignocelloloses, and hemicelluloses (Henssen and Schnepf 1967; McCarthy 1987; Crawford 1988). These enzyme systems have the potential for novel application in biotechnological processes, particularly for the enzymatic generation of fermentable sugar from agricultural residues (McCarthy et al. 1988; Zimmermann 1989).

Actinomycetes have been isolated and screened by pharmaceutical companies since the pioneering work of Selman Waksman at Rutgers State University (Waksman and Lechevalier 1953). Much of this work focused on streptomycetes as these organisms grow quickly and are easily isolated on media such as starch casein (Küster and Williams 1964) and arginine-glycerol-salts agars (El-Nakeeb and Lechevalier 1963). Many species of Streptomyces have been isolated, characterized, and named, including those that produce commercially significant antibiotics, as exemplified by actinomycin from *Streptomyces antibioticus* (Waksman and Woodruff 1941), neomycin from *Streptomyces fradiae* (Waksman and Lechevalier 1949), and streptomycin from *Streptomyces griseus* (Waksman 1961).

The discovery that members of sporoactinomycete genera other than streptomycetes were the source of potentially commercial significant antibiotics led to the introduction of procedures designed to isolate "rare" and uncommon actinomycetes (Nolan and Cross 1988; Okami and Hotta 1988; Lazzarini et al. 2000).

44 The Family *Thermoleophilaceae*

Luciana Albuquerque[1] · *Milton S. da Costa*[2]
[1]Center for Neuroscience and Cell Biology, University of Coimbra, Coimbra, Portugal
[2]Department of Life Sciences, University of Coimbra, Coimbra, Portugal

Abstract
Thermoleophilaceae, a family within the order *Thermoleophilales*, embraces the genus *Thermoleophilum* with two species: *Thermoleophilum album* and *T. minutum* (Reddy and Garcia-Pichel Int J Syst Evol Microbiol 59:87–94, 2009; Zarilla and Perry Arch Microbiol 137:286–290, 1984; Zarilla and Perry 1986a). The organisms included in this order have the ability to grow at elevated temperatures, with optimum growth temperatures of around 60 °C and at the expense of *n*-alkanes with 13–20 carbons; however, these organisms are unable to assimilate any other carbon and energy sources examined. The two species of the genus *Thermoleophilum* are strictly aerobic and catalase positive. These organisms possess several polyamines, but the polar lipid and fatty acids have not been examined. These organisms were isolated from hot springs and nonthermal sources.

Taxonomy, Historical and Current

Short Description of the Order, Family, and Genus

The order *Thermoleophilales* contains one family, the *Thermoleophilaceae*. The order was proposed by Reddy and Garcia-Pichel (2009) to include the only known family *Thermoleophilaceae* (Stackebrandt 2004, 2005). The family comprises one genus, *Thermoleophilum* with two species. The type species of the genus is *Thermoleophilum album*. The type strain of *Thermoleophilum album*, HS-5^T (=ATCC 35263^T), was recovered from a hot spring in Arkansas, USA (Zarilla and Perry 1984). Strains YS-3 (=ATCC 35264), NM (=ATCC 35266), and RR-D (=ATCC 35267) are additional strains of this species. The name of the genus and of the species were, however, only validated after the name of the other species of the genus, *Thermoleophilum minutum*, had been validly published in the same issue of IJSEM (Zarilla and Perry 1986a). The species *Thermoleophilum minutum* (type strain YS-4^T = ATCC 35265^T) was also isolated and described by Zarilla and Perry (1986a). It should be noted that *T. minutum* strain, PTA-1 (=ATCC 35268), was isolated from mud at ambient temperature in North Carolina, USA. The organism was briefly named "Thermomicrobium fosteri" (Merkel et al. 1978a, b; Perry 1984; Phillips and Perry 1976).

Thermoleophilales Reddy and Garcia-Pichel 2009

Thermoleophilales (Ther.mo.le.o.phi'la.les. N.L. neut. n. *Thermoleophilum* type genus of the order; suff. *-ales* ending to denote an order; N.L. fem. pl. n. *Thermoleophilales*, the *Thermoleophilum* order).

Members of the order *Thermoleophilales* are non-spore forming. The pattern of 16S rRNA signatures consists of nucleotides at positions 52 : 359 (C-G), 63 : 104 (G-C), 70 : 98, (G-C), 127 : 234, (G-C), 139 : 224 (G-C), 144 : 178 (C-G), 291 : 309 (U-A), 370 : 391 (G-C), 408 : 434 (G-C), 580 : 776 (C-G), 590 : 649 (C-G), 600 : 638 (C-G), 657 : 749, (U-A), 670 : 736 (G-C), 681 : 709 (C-G), 823 : 877 (G-C), 906 (A), 941 : 1342 (G-C), 953 : 1228 (G-C), 954 : 1226 (G-C), 955 : 1225 (U-A), 999 : 1041 (A-U), 1051 : 1207 (G-C), 1115 : 1185 (C-G), 1118 : 1155 (C-G), 1311 : 1326 (G-C), and 1410 : 1490, (A-U). The order *Thermoleophilales* belongs to the class *Actinobacteria*. The order contains the family *Thermoleophilaceae* (Reddy and Garcia-Pichel 2009).

Thermoleophilaceae Stackebrandt 2005; emend. Zhi et al. 2009

Thermoleophilaceae (Ther.mo.le.o.phi.la.ce'a.e. N.L. neut. n. *Thermoleophilum*, type genus of the family; suff. *-aceae*, ending to denote a family; N.L. fem. pl. n. *Thermoleophilaceae*, the *Thermoleophilum* family).

The members of the sole family *Thermoleophilaceae* of the order *Thermoleophilales* stain Gram-negative, although transmission electron microscopy (TEM) demonstrates a series of layers typical of Gram-positive bacteria.

E. Rosenberg et al. (eds.), *The Prokaryotes – Actinobacteria*, DOI 10.1007/978-3-642-30138-4_203,

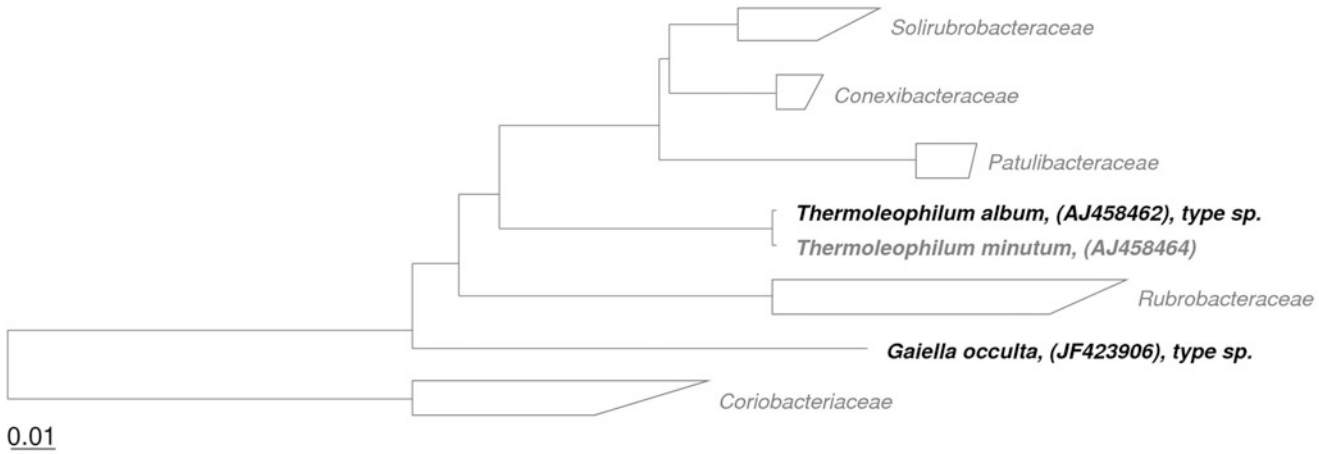

Fig. 44.1

Phylogenetic reconstruction of the family *Thermoleophilaceae* based on 16S rRNA and created using the neighbor-joining algorithm with the Jukes-Cantor correction. The sequence dataset and alignment were used according to the All-Species Living Tree Project (LTP) database (Yarza et al., 2010; http://www.arb-silva.de/projects/living-tree). The tree topology was stabilized with the use of a representative set of nearly 750 high quality type strain sequences proportionally distributed among the different bacterial and archaeal phyla. In addition, a 40 % maximum frequency filter was applied in order to remove hypervariable positions and potentially misplaced bases from the alignment. Scale bar indicates estimated sequence divergence

The organisms form rod-shaped cells. These organisms are strictly aerobic and chemoorganotrophic and contain meso-diaminopimelic acid as the diamino acid in the peptidoglycan. The type and only genus of this family is *Thermoleophilum* (Stackebrandt 2004; Zhi et al. 2009).

Phylogenetic Structure of the Family and Its Genus

The family *Thermoleophilaceae* forms a deep branching root of the phylum Actinobacteria and is most closely related to the species of the family *Solirubrobacteraceae* (88–90 % 16S rRNA gene similarity) (Albuquerque et al. 2011) (*Fig. 44.1*). Our knowledge of the species of the genus *Thermoleophilum* remains rudimentary, but it is clear that the species *T. album* and *T. minutum* cannot be distinguished from each other on the basis of the phenotypic results available although the species can be distinguished using polyacrylamide gel electrophoresis (PAGE) of whole-cell proteins. The phylogeny based on 16S rRNA sequence analysis of the two species also indicates that the organisms should be extremely closely related (99.9 % similarity); however, DNA-DNA hybridization, using [α-^{32}P]deoxycytidine triphosphate-labelled DNA method, produced values of 25–48 % indicating that these two organisms are indeed distinct from each other (Zarilla and Perry 1984, 1986a).

Phenotypic Analyses

The main features of *Thermoleophilum album* and *T. minutum* are listed in *Table 44.1*.

Thermoleophilum Zarilla and Perry 1986b

Thermoleophilum (Ther.mo.le.o'phi.lum. Gr. n. *therme*, heat; L. n. *oleum*, oil; N.L. neut. adj. *philum* (from Gr. neut. adj. *philon*), friend, loving; N.L. neut. n. *Thermoleophilum*, heat- and oil-loving microbe).

The two validly named species of the genus *Thermoleophilum* form short rod-shaped Gram-negative cells. Obligately thermophilic and capable of growth only on a narrow range of *n*-alkanes. Both species are able to assimilate *n*-alkanes with 13–20 carbons, but are not able to assimilate other alkanes, namely, shorter or longer *n*-alkanes, 1-alkanes from 12 to 19 carbons in length, cyclohexane and cycloheptane, alcohols with 12–18 carbons, and ketones from 13 to 19 carbons in length. Carbohydrates, organic acids, amino acids, yeast extract, peptone, or tryptone-yeast extract are not assimilated. The nitrogen source of the growth medium is ammonium chloride (Zarilla and Perry 1984). All strains contain meso-diaminopimelic acid (DAP) as the diamino acid of the peptidoglycan (Merkel et al. 1978a). A quaternary branched pentamine, 4,4-bis(3-aminopropyl)-1,8-diamino-4-azaoctane, is the major polyamine of the two species of this genus (Hamana et al. 1992). In *T. album* the major isoprenoid respiratory lipoquinone is a tetrahydrogenated menaquinone 7 [MK-7(H_4)], 2-methyl-3-VI,VII-tetrahydro-heptaprenyl-1,4-naphthoquinone (Collins et al. 1986). The G+C content of the DNA is around 70–71 mol%. It is noteworthy that the two validly named species of *Thermoleophilum* cannot be distinguished from each other on the basis of the phenotypic characteristics examined, except for polyacrylamide gel electrophoresis (PAGE) of whole-cell protein extracts; however, it is clear that the organisms represent two genomic species based on DNA-DNA hybridization and 16S rRNA gene analysis (Yakimov et al. 2003; Zarilla and Perry 1984, 1986a).

Isolation, Enrichment, and Maintenance Procedures

Thermoleophilum album was isolated from soil and mud samples (Zarilla and Perry 1984). The cardinal growth temperatures of the strains indicate that they possibly originate from thermal environments but several isolates were recovered from nonthermal sources. The organisms were isolated by enrichment culture techniques using mud samples taken from both thermal and nonthermal environments. Samples were obtained in the USA from thermal environments, namely, Arkansas (Hot Springs, strain HS-5^T), New Mexico (Faywood Hot Springs, strain NM), and Wyoming (Yellowstone National Park, strain YS-3) and from mud at ambient temperature at North Carolina (Roanoke Rapids, strain RR-D). The substrate for enrichment was *n*-heptadecane added at 0.1 % (v/v) to a mineral salts medium of the following composition: NH_4Cl, 1 g; $NaNO_3$, 1 g; $MgSO_4.7H_2O$, 0.2 g; $FeSO_4.7H_2O$, 1 g; Na_2HPO_4, 0.21 g; NaH_2PO_4, 0.09 g; KCl, 0.04 g; $CaCl_2$, 0.015 g; $CuSO_4.5H_2O$, 2 µg; H_3BO_3, 10 µg; $MnSO_4.5H_2O$, 10 µg; $ZnSO_4.7H_2O$, 70 µg; MoO_3, 10 µg; and deionized water 1 L. After incubation at 60 °C and repeated transfer, the organism was obtained in axenic culture by streaking on a mineral salts agar medium. The *n*-heptadecane substrate was introduced by inverting the inoculated plate and placing a drop of the hydrocarbon on the inside of the cover which vaporizes and infiltrates the inverted plate.

Thermoleophilum minutum was isolated from a hot spring in Yellowstone National Park (Wyoming, strain YS-4^T) and from mud at ambient temperature in North Carolina (Beaufort, strain PTA-1) (Zarilla and Perry 1984). The organisms were isolated using the same enrichment culture techniques used to isolate *Thermoleophilum album*.

Ecology

Habitat

The thermophilic nature of the cultivated organisms of the genus *Thermoleophilum* with an optimum growth temperature of around 60 °C and the isolation of these organisms from thermal environments argue for the colonization of hot springs with neutral pH rather than soil or mud with low temperatures. The isolation of these organisms from mud or soil environments is difficult to explain unless these organisms originate from nearly thermal areas or the soil is solar heated. The origin of long-chain *n*-alkanes is also difficult to envision in thermal springs, although alkane-utilizing bacteria have been isolated from mineral water aquifers with extremely low levels of organic nutrients (Leandro et al. 2012). The assimilation of alkanes can be viewed as a selective advantage for these organisms even when their levels in the environment are extremely low.

It is interesting to note that environclones closely related to the strains of *Thermoleophilum* have not been encountered. The most closely related 16S rRNA gene clone has a sequence of similarity of 93 % (JX240741), and the next most closely related environmental sequence has a similarity of 92 % (JF706670). The first was obtained from the Gulf of Khambhat, India, while the second sequence came from the Atacama, Chile.

45 The Family *Tsukamurellaceae*

Rüdiger Pukall
Leibniz Institute DSMZ-German Collection of Microorganisms and Cell Cultures, Braunschweig, Germany

Abstract
According to Bergey's road map of the Actinobacteria, the six families *Corynebacteriaceae*, *Dietziaceae*, *Mycobacteriaceae*, *Nocardiaceae*, *Segniliparaceae*, and *Tsukamurellacea* were displaced from the order "*Actinomycetales*" and assigned to the order *Corynebacteriales*. The family *Tsukamurellaceae* comprises solely the genus *Tsukamurella* which consists of 11 species. Representatives of these taxa share very high 16S rRNA gene sequence similarity values with exception of the type strain of *T. paurometabola* which is moderately related to *T. spongiae* and *T. soli*. Species delineation within the genus *Tsukamurella* is mainly based on DNA:DNA hybridization studies.

Taxonomy: Historical and Current

Short Description of the Family and the Genus *Tsukamurella*

Tsukamurellaceae Rainey, Ward-Rainey and Stackebrandt 1997, 486[VP], Emend. Zhi, Li, and Stackebrandt 2009, 595[VP]

Tsu.ka.mu.rel.la.ce'a.e. N.L. fem.n. *Tsukamurella* the type genus of the family; -aceae ending to denote the family; N.L. fem. pl. n. *Tsukamurellaceae*, the *Tsukamurella* family.

The family *Tsukamurellaceae* was proposed by Rainey et al. (1997) within the hierarchical classification system of the *Actinobacteria* and the family description was mainly based upon the phylogenetic position and the presence of defined 16S rRNA gene sequence signatures nucleotides. Rainey et al. defined the following 16S rRNA signatures for members of the genus *Tsukamurella* (Collins et al. 1988), the only genus within the family: at positions 70-98 (U-A), 293-304 (G-(A-U), 843 (C), 1007-1022 (G-U), and 1122-1151 (A-U). In 2009, the emended description of the family was published by Zhi et al. by extending the signature nucleotides considering all validly described species of the genus *Tsukamurella* published at that time. The pattern was specified for the following positions: 128:233 (G–C), 250 (U), 316:337 (C–G), 418:425 (C–G), 580:761 (C–G), 599:639 (C–G), 987:1218 (G–C), 1000:1040 (A–C), and 1059:1198 (C–G).

Type genus: *Tsukamurella* Collins et al. 1988, 387[VP].

Tsu.ka.mu.rel.la N.L. fem. dim n. *Tsukamurella* named in honor of Michio Tsukamura, a Japanese microbiologist.

Type species: *Tsukamurella paurometabola* corrig. (Steinhaus, 1941).

The type strain of the species was isolated from the mycetome and ovaries of *Cimex lectularis* (bedbug) by Edward

E. Rosenberg et al. (eds.), *The Prokaryotes – Actinobacteria*, DOI 10.1007/978-3-642-30138-4_189,

A. Steinberg in 1941 and was first placed into the genus *Corynebacterium* as "*Corynebacterium paurometabolum*." Analysis of *Corynebacterium paurometabolum* revealed that the strain possesses meso-diaminopimelic acid and arabinogalactan in their cell walls, but differed from the genus *Corynebacterium* by the presence of long, highly unsaturated mycolic acids, with 58–76 carbon atoms (Collins and Jones 1982). In contrast, members of *Corynebacterium* are characterized by short chain mycolic acids with 22–36 carbon atoms only.

Long, highly unsaturated mycolic acids were also detected in strain *Rhodococcus aurantiacum*, first described as *Gordonia aurantia* (Tsukamura and Mizuno 1971) and later on transferred to the genus *Rhodococcus* (Tsukamura 1974; Tsukamura and Yano 1985). Based on 16S rRNA gene sequence analysis, both strains, *R. aurantiacum* and *C. paurometabolum*, were unified in a single species and described as *Tsukamurella paurometabola* (Collins et al. 1988).

Members of the genus *Tsukamurella* are aerobic, weakly up to partially acid fast, non-motile, non-spore-forming Gram-positive bacteria. Chemo-organotrophic, catalase activity positive. Mostly characterized by straight to curved rods that occur singly, in pairs or filaments. Coccobacillary forms may also occur. Rough, dry, flat, or folded colonies are developed; sometimes edges are irregular or rhizoidal. Colonies are whitish cream colored or yellow-orange to red. Aerial hyphae are not present. The diagnostic amino acid of the type A1γ peptidoglycan is meso-diaminopimelic acid. Cell wall sugars are arabinose, galactose, but ribose and glucose can also be present. Polar lipids are diphosphatidylglycerol (DPG), phosphatidylethanolamine (PE), phosphatidylinositol (PI), and phosphatidylinositol mannosides (PIM). The predominant menaquinone is unsaturated with nine isoprene units (MK-9) for most species. MK-10, MK-8, and MK-7 may also be detectable. Mycolic acids have 58–78 carbon atoms and 1–7 double bonds, except for *T. carboxydivorans* which may have 81–95 carbon atoms. The fatty acid esters released on pyrolysis of mycolic acids have 20–22 carbon atoms. The long-chain cellular fatty acids are predominantly of the straight-chain saturated, monounsaturated, and 10-methyl branched types (*Table 45.3*). Phylogenetically, the genus is placed into the family *Tsukamurellaceae* which is in the order *Corynebacteriales*. According to Bergey's road map of the Actinobacteria, the six families *Corynebacteriaceae*, *Dietziaceae*, *Mycobacteriaceae*, *Nocardiaceae*, *Segniliparaceae*, and *Tsukamurellacea* were displaced from the order "*Actinomycetales*" and assigned to the order *Corynebacteriales*. The order *Actinomycetales* is now restricted to members of the family *Actinomycetaceae* only. DNA G+C content: 67–78 mol %. Isolated from various aquatic and terrestrial habitats as well as from clinical specimen.

Phylogenetic Structure and Molecular Analyses

At present 11 species with validly published names are included in the genus *Tsukamurella*. Representatives of these taxa share very high 16S rRNA gene sequence similarity values between 99.2 % and 99.7 %, with the exception of the type strains of the two species *T. spongiae* and *T. soli* (*Fig. 45.1*). Both strains are remotely related to *T. paurometabola*, showing similarity values of 98.4 % and 96.5 %, respectively. The 16S rRNA gene sequence of *T. soli* differs at more than 50 nucleotide positions as compared to the 16S rRNA gene sequence derived from whole genome sequencing of the *T. paurometabola* type strain.

Due to the very high relationship of the 16S rRNA gene sequences, species delineation within the genus *Tsukamurella* was mostly done by DNA:DNA hybridization (DDH). DDH studies have not been performed between all of the species published and was excluded for *T. soli*, because of the low similarity value of the 16S rRNA gene sequence. It is noteworthy that the name *T. sunchonensis* became validly published in 2008, even though the species description was

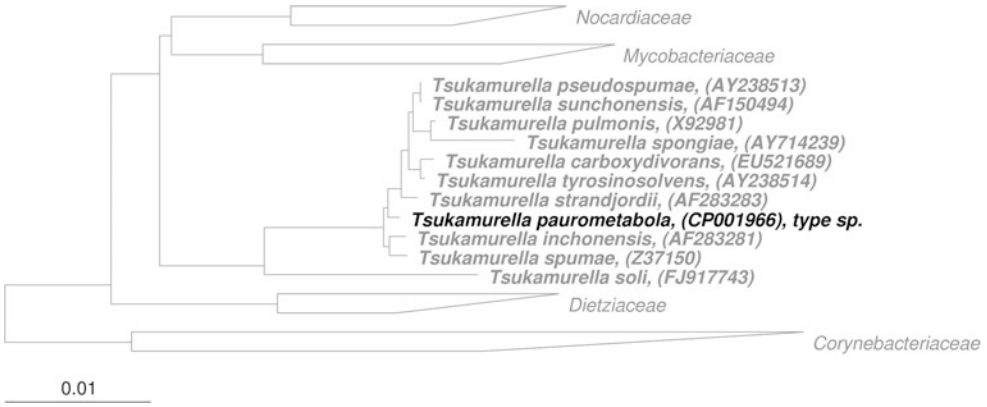

Fig. 45.1

Phylogenetic reconstruction of the family *Tsukamurellaceae* based on 16S rRNA and created using the neighbor-joining algorithm with the Jukes-Cantor correction. The sequence datasets and alignments were used according to the All-Species Living Tree Project (LTP) database (Yarza et al. 2010; http://www.arb-silva.de/projects/living-tree). The tree topology was stabilized with the use of a representative set of nearly 750 high quality type strain sequences proportionally distributed among the different bacterial and archaeal phyla. *Scale bar* indicates estimated sequence divergence

already published in 2003. As a consequence, the close relationship between *T. sunchonensis* and *T. pseudospumae* was overlooked. The 16S rRNA gene sequences of both type strains are identical, but the DNA:DNA relatedness of both strains has not yet been analyzed.

Three different techniques were applied for analysis of DNA:DNA relatedness: (1) spectrophotometrically, according to De Ley et al. 1970 (Yassin et al. 1995, 1996, 1997; Olson et al. 2007); (2) by the fluorometric microplate method (Nam et al. 2003) and (3) by dot blot hybridization (Seong et. al. 2003; Park et al. 2009). DDH studies have been performed most extensively among *T. paurometabola* DSM 20162^T and other closely related type strains of the genus. The highest DNA binding rate of 56 % was reported with strain *T. strandjordii* BAA-173^T, while all other values varied between 33 % and 11.9 % with its phylogenetic neighbors *T. inchonensis* IMMIB D-771^T, *T. pulmonis* IMMIB D13-21^T, *T. tyrosinosolvens* IMMB 13-97^T, *T. spumae* N1171^T, *T. pseudospumae* N1176^T, and *T. carboxydivorans* Y2^T. Additional data are available for other type strain combinations; the values are also summarized in *Table 45.1*. (i) according to Yassin et al. (1995, 1996, 1997): *T. pulmonis* IMMIB D13-21^T against *T. paurometabola* DSM 20162^T and *T. inchonensis* IMMIB D-771^T (44 % and 56.3 %); *T. tyrosinosolvens* IMMB 13-97^T against *T. paurometabola* DSM 20162^T, *T. inchonensis* IMMIB D-771^T, and *T. pulmonis* IMMIB D13-21^T (53.4 %, 53.5 %, and 54.7 %); (ii) *T. spongiae* K-362^T against *T. pulmonis* IMMIB D13-21^T and *T. strandjordii* BAA-173^T (48 % and 44 %) and *T. pulmonis* IMMIB D13-21^T against *T. strandjordii* BAA-173^T = 41 % (Olson et al. 2007); (iii) T. sunchonensis SCNU5^T against *T. pulmonis* IMMIB D13-21^T, *T. tyrosinosolvens* IMMB 13-97^T and *T. inchonensis* IMMIB D-771^T = 54.1 %, 55.7 % and 58.6 % (Seong et al. 2003); (iv) according to Park et al. 2009 *T. carboxydivorans* Y2^T against *T. inchonensis* IMMIB D-771^T, *T. pulmonis* IMMIB D13-21^T, *T. tyrosinosolvens* IMMB 13-97^T, *T. strandjordii* BAA-173^T, *T. spumae* N1171^T, and *T. pseudospumae* N1176^T (8.6, 60.6, 62.7, 7.9, 12.7, and 58.7).

Genome Analyses

Strain *Tsukamurella paurometabola* DSM 20162^T is the only strain of the genus from which a finished genome sequence has been generated (INSDC ID CP001966) and been published in *Standards in Genomic Sciences* (Munk et al. 2011). The genome was analyzed in course of the Genomic Encyclopedia of Bacteria and Archaea project. The 4,479,724 bp long genome also contains a 99,806 bp long plasmid, designated as pTpau 01, both with a GC content of 68.4 %. Besides 93 pseudogenes, 4,391 genes were predicted, of which 4,335 were protein-coding genes, and 56 were RNA genes: 68.7 % of the genes could be assigned to a putative function, and 68.9 % of the genes were assigned to clusters of orthologous groups (COG's). The distribution of genes into COG's functional categories shows that the highest numbers of genes are involved in transcription processes (310; 9.2 %), followed by genes coding for amino acid transport and metabolism (274; 8.1 %), lipid transport and metabolism (231; 6.8 %), carbohydrate transport and metabolism (220; 6.5 %), and energy production and conversion (217; 6.4 %). Interestingly, 172 genes (5.1 %) were found to be involved in secondary metabolite biosynthesis, transport, and catabolism. A detailed listening is given by Munk et al. (2011), but is also accessible via the Integrated Microbial Genomes platform (Markowitz et al. 2009).

The sequence of plasmid pTpau01 consists of 92 genes, but the proteins encoded from those are mainly hypothetical proteins with unknown or uncertain function. Several transposases

could be predicted as well as a putative recombinase, an abortive infection protein, a TrwC relaxase (a putative TraA-like conjugal transfer protein and CopG (RepA) responsible for regulation of the plasmid copy number). Further a putative permease of the Dif318 family has been predicted, whose function is not really known, but some proteins within this family are encoded by genes involved in arsenate/arsenite resistance. The prediction of all genes located on the plasmid is given in detail within the IMG platform (Markowitz et al. 2009).

Recently the draft genome sequence of *Tsukamurella* strain 1534 has been published by Oulmi et al. (2012). In contrast to *Tsukamurella paurometabola*, strain 1534 was originally isolated from a human sputum specimen. Four thousand and four hundred putative proteins have been predicted for strain 1534, and 89.4 % could be assigned to cluster of orthologous groups. Oulmi et al. (2012) reported that the genome of strain 1534 shared 3,037 orthologs with *Tsukamurella paurometabola* and 2 ribosomal operons have been detected for both strains.

Phages

The first phage TPA1, able to lyse *Tsukamurella paurometabola*, was isolated from activated sludge by Thomas et al. (2002). Later on, Petrovski et al. (2011) showed that this phage type could successfully be isolated over a period of more than 9 years from activated sludge plants in Australia. The authors characterized two of these phages (TPA2 and TPA3) in greater detail and found that both were identical. TPA1 and TPA2 were selected for genome sequencing and analysis revealed that both sequences were also identical, even though both phages have been isolated from different activated sludge plants. For this reason, only the complete genome sequence of phage TPA2 (NC_015210) was published. TPA2 is a polyvalent *Siphoviridae* family phage and its genome sequence contains 61.44 kb, with a GC content of 69.1 %. The NCBI database listed 79 genes for phage TPA2, but most of the proteins encoded are hypothetical. Only 30 % of the TPA2 genome is related to other phages at the DNA level. As shown by Petrovski et al. (2011), TPA2 displays a broad host range within the genus *Tsukamurella* and lyses not only *T. paurometabola*, but also most of the other species of the genus with the exception of *T. inchonensis*. On the other hand, TPA2 seems to be genus specific and was not able to lyze strains of closely related genera, like *Dietzia*, *Gordonia*, or *Rhodococcus*. Also *Mycobacteria* were not affected even though the gene organization of TPA2 was found to be similar to that of the *Mycobacterium* phage Rosebush (Petrovski et al. 2011).

The draft genome of strain *Tsukamurella* strain 1534 also contains one genetic element of 49.4 kb in size, which was identified as potential prophage, named TPA4 (Oulmi et al. 2012). Twenty-five of the 59 ORF detected encode proteins which share high identity with proteins found in the Mycobacteriophage Giles, but actually only two proteins showed high identity to the TPA2 proteins.

Phenotypic Analyses

Phenotypic properties that distinguish *Tsukamurella* species from another are indicated in ❯ *Table 45.2*. Characteristics specific for the genus are described above.

Tsukamurella paurometabola Corrig. (Steinhaus, 1941). Collins, Smida, Dorsch and Stackebrandt 1988, 387^{VP}

pau.ro.me.ta'bo.la. Gr. adj. *pauros*, little; gr. adj. *metabolos*, changeable; N.L. fem. adj. *paurometabola* little changeable.

Gram-positive, strictly aerobic slightly curved rods, but coccobacillary forms occur. Cells are 0.5–0.8 µm in diameter and 1.0–5 µm in length. Colonies are whitish to cream, small and have sometimes rhizoidal edges. Metachromic granules may be formed. Most strains are able to grow between 10 °C and 37 °C. Does not survive heat shocks at 60 °C for 15 min. Some strains may produce acid from galactose, glucose, glycerol, inositol, mannose, sucrose, and trehalose, additional properties are shown in ❯ *Table 45.2*. Acetamide and nicotinamide can be used as sole nitrogen sources, but not benzamide. Resistant to ethambutol (5 µg/mL), 5-fluorouracil (20 µg/mL), mitomycin C (10 µg/mL), and piric acid (0.2 %, w/v). Composition of the whole cellular fatty acids is listed in ❯ *Table 45.3*. Polar lipid composition is DPG, PI, PE, and PIM. The predominant menaquinone is MK-9, whereas minor amounts of MK-7, MK-8, and MK-10 are detectable. The type strain was originally deposited as DSM 20162 and ATCC 8368. Accession number of the genome sequence is CP001966.

Tsukamurella carboxydivorans Park, Kim, Park and Kim 2009, 1543^{VP}

car.bo.xy.di.vor'ans. N.L. neut. n. *carboxydum* carbon monoxide; L. part. adj. *vorans* devouring, digesting; N.L. part. adj. *carboxydivorans* digesting carbon monoxide.

Gram-positive, strictly aerobic, non-motile actinomycete. Optimal growth occurs at 30 °C, tolerates up to 6 % (w/v) NaCl. Colonies on ISP2 medium are cream to yellow. Substrates which can be used as sole carbon source are indicated in ❯ *Table 45.2*. Able to grow at lower concentrations of carbon dioxide (400 p.p.m CO). In contrast to other strains of the genus, mycolic acids have 81–95 carbon atoms. Cell wall sugars are galactose and arabinose. Whole fatty acid profile is given in ❯ *Table 45.3*. No data are available concerning the polar lipid profile or the menaquinone composition. Type strain is strain Y2^{T}.

Tsukamurella inchonensis Yassin, Rainey, Brezezinka, Burghardt, Lee and Schaal, 1995, 526^{VP}

in. cho. nen' sis. M. L. adj, *inchonensis*, referring to Inchon, the city in South Korea where the type strain was isolated.

Gram-positive, aerobic bacilli. Cells are rod-shaped and do not form spores, or aerial hyphae.

Growth on Loewenstein–Jensen medium occurs at 24 °C and 45 °C. Colonies are rough, saffron yellow to orange. Positive for the following enzyme activities: acetamidase, allantoinase, thermostable catalase, *P*-glucosidase, *P*-galactosidase, nicotinamidase, pyrazinamidase, urease, and phosphatase, but negative for arylsulfatase, benzamidase, nitrate reductase, and succinamidase activity. In addition to the substrates listed in *Table 45.2*, glucose, galactose, trehalose, sucrose, inositol, acetate, citrate, gluconate, lactate, isoamyl alcohol, 2,3 butandiol, 1,2 propandiol, and paraffin can be utilized as carbon source (Yassin et al. 1995). Resistant to streptomycin, isoniazid, ethambutol, rifampicin, *p*-aminosalicylic acid, protionamide, capreomycin, cycloserine, clindamycin, erythromycin, tetracycline, and cotrimoxazole. The cellular fatty acids are listed in *Table 45.3*. The predominant menaquinone is MK-9, but minor amounts of MK-8 and MK-10 are also detectable. Type strain: IMMIB D-771^T.

Tsukamurella pseudospumae Nam, Kim, Chun and Goodfellow, 2004, 1211[VP]

pseu.do.spu'mae. Gr. adj. *pseudes* false; L. gen. n. *spumae* of foam and specific epithet of a bacterial species; N.L. n. *pseudospumae* the false spumae, referring to the close relationship to *Tsukamurella spumae*.

Aerobic, Gram-positive, non-motile actinomycete. Does not forms spores and cells are straight to slightly curved rods. Long filaments can be formed. Grows between 10 °C and 37 °C, but not at 45 °C. Colonies on glucose-yeast extract are yellow-orange to red-orange with irregular margins. D-galactose, D-gentiobiose, D-glucose, meso-inositol, D-lactose, D-mannose, L-rhamnose, D-sucrose, D-trehalose, D-turanose, D-xylitol (1 %, w/v), amyl alcohol, butane-2,3-diol (1 %, v/v), sodium citrate, and sodium pyruvate (0.1 %, w/v) are used as sole sources of carbon. Additional phenotypic properties are shown in ➤ *Table 45.2*. Further L-phenylalanine, L-asparagine, and L-serine can be used as sole nitrogen source. Cell wall sugars are galactose and arabinose. The fatty acid composition of the type strain is shown in ➤ *Table 45.3*. No data are available concerning the polar lipid profile or the menaquinone composition. Resistant to 5-fluorouracil (20 μg/mL), bekamycin and oleandomycin (64 μg/mL), gentamicin and neomycin sulfate (32 μg/mL), clindamycin (2 μg/mL), tetracycline (10 μg/mL), vancomycin (4 μg/mL). Susceptible to chlortetracycline, ciproflaxin, and penicillin G. Type strain: N1176[T].

Tsukamurella pulmonis Yassin, Rainey, Brzezinka, Burghardt, Rifai, Seifert, Feldmann, and Schaal, 1996, 434[VP]

pul. mo' nis. L. gen. masc. n. *pulmonis*, of the lung, referring to the organ from which the bacterium was isolated.

Cells are Gram-positive, aerobic rods. Long rods may fragment at a later stage of growth into independent rods. Does not form spores or aerial hyphae. Colonies are rough and cream colored on ISP2 medium. Growth occurs between 24 °C and 37 °C. Contradictorily data are available concerning the ability to utilize various carbon sources as given by Yassin et al. (1996) and Nam et al. (2003). Differences are indicated in ➤ *Table 45.2* and marked with brackets. Cell wall sugars are arabinose and galactose. MK-9 is the predominant menaquinone, but MK-8 and MK-10 are also detectable in minor amounts. Polar lipids are DPG, PI, PIM with significant amounts of PE. Cellular fatty acids are indicated in ➤ *Table 45.3*. Resistant to streptomycin, ethambutol, rifampicin, capreomycin, and cycloserine. Type strain IMMIB D-1321[T].

Tsukamurella soli Weon, Yoo, Anandham, Schumann, Kroppenstedt, Kwon and Stackebrandt, 2010, 1670[VP]

so'li. L. neut. gen. n. *soli* of soil, the source of the type strain.

Aerobic, Gram-positive rods with 0.9–1.0 μm in diameter and 2.3–6,9 μm in length. Colonies are pearly white on R2A agar and ivory to cream colored on ISP2 medium. Colonies are dry with an irregular margin. Growth occurs between 10 °C and35 °C, tolerates up to 3 % (w/v) NaCl. In addition to the substrates listed in ➤ *Table 45.2*, D-glucose, D-mannitol, D-ribose, sucrose, inositol, *N*-acetylglucosamine, trisodium citrate, acetate, and lactic acid can be assimilated. The following enzyme activities are positive within the apiZYM test: alkaline phosphatase, esterase lipase (C8), leucine arylamidase, acid phosphatase, naphthol-AS-BI-phosphohydrolase, α-glucosidase, and β-glucosidase. Cell wall sugars are arabinose, ribose, and glucose. Polar lipids are DPG, PE, and PI. The predominant menaquinone is MK-9, minor amounts of MK-8 and MK-10 are detectable in addition. Whole cellular fatty acids composition is shown in ➤ *Table 45.3*. Type strain JS18-1[T].

Tsukamurella spongiae Olson, Harmody, Bejand, McCarthy 2007, 1480[VP]

spon'gi.ae. L. gen. n. *spongiae* of a sponge, referring to the source of isolation, a deep-water sponge.

Aerobic, Gram-positive, non-motile actinomycete. Cells are straight to slightly curved rods. Growth occurs between 25 °C and 37 °C, but not at 45 °C. In general, the colonies are dry, cream to yellow with irregular margins. Phenotypic properties are listed in ➤ *Table 45.2*. Utilizes D-galactose, D-mannose, rhamnose, D-sucrose, and D-trehalose in addition. Halotolerant (up to 4 % (w/v) NaCl), but growth is much better in media with lower NaCl concentrations. The fatty acid composition is shown in ➤ *Table 45.3*. Contains mycolic acids with 58–75 carbon atoms. No data are available concerning the polar lipid composition or the menaquinone profile. Type strain: K362[T].

Tsukamurella spumae Nam, Chun, Kim, Kim, Zakrzewska-Czerwinska, Goodfellow, 2003, 373[VP]

spu'mae, L.gen.n. *spumae* of foam denoting the presence of the organism in the foam of activated sewage sludge plants.

Aerobic, Gram-positive, non-motile actinomycete. Cells are straight to slightly curved rods, and may form longer filaments. Aerial hyphae are absent. Colonies are <5 mm on glucose-yeast extract agar, orange to red with irregular margin. Growth occurs between 25 °C and 37 °C, but the strains are not able to grow at 45 °C. Some strains grow at 10 °C, but not the type strain. Phenotypic properties are shown in ➤ *Table 45.2*. Amyl alcohol, butane-2,3-diol (1 %, v/v), sodium citrate, and sodium pyruvate (0.1 %, w/v) are used as sole sources of carbon in addition. Further L-phenylalanine, L-asparagine, and L-serine can be used as sole nitrogen source. Some strains assimilate D-arabinose, and *meso*-erythritol or hydrolyze urea. Is not able to hydrolyze aesculin. Resistant to clindamycin, and cotrimazole, but susceptible to tetracycline. Whole cellular fatty acids are indicated in ➤ *Table 45.3*. Predominant menaquinone is MK-9; minor

amounts of MK-8 and MK-10 are also detectable. No data are available concerning the polar lipid composition. Type strain N1171^T.

Tsukamurella strandjordii corrig. Kattar, Cookson, laDonna, Carlson, Stiglich, Schwartz, Nguyen, Daza, Wallis, Yarfitz, and Coyle 2001, 1474^{VP}

strandjordii N.L. gen. masc. n., of Strandjord, named in honor of Paul Strandjord, founder and chair of the Department of Laboratory Medicine, University of Washington, from 1969 to 1994.

Aerobic, Gram-positive rods. Colonies are rough, tan to yellow in color. Growth occurs between 28 °C and 35 °C, but not at 42 °C. Aerial hyphae are absent. Tolerates NaCl up to 5 % (w/v). In addition to the substrates listed in ❯ *Table 45.2*, galactose, D-glucose, D-mannose, saccharose, trehalose, D-turanose, L-fucose, gluconate, inositol, L-arabitol, arbutine, salicin, and *N*-acetylglucosamine can be utilized as carbon source. Utilization of D-fructose, maltose, and melezitose is indicated as positive by Kattar et al. (2001), but given as negative in the study of Weon et al. (2010). Resistant to erythromycin, cefatoxime, cefoxitin, azithromycin, and tobramycin, but susceptible to ciprofloxacin, imipenem, amikacin, clarithromycin, and trimethoprim-sulfamethoxazole. Cellular fatty acids are shown in ❯ *Table 45.3*. No data are available concerning the polar lipid and menaquinone composition. Type strain ATCC BAA-173^T.

Tsukamurella sunchonensis Seong, Kim, Baik, Choi, Kim, Kim and Goodfellow 2003, 88^{VP}

sun.chon.ensis. M.L. n. *sunchon* Sunchon, a city in Korea; M.L. adj. *sunchonensis* of Sunchon, Korea; referring to the place where the organism was first isolated.

Aerobic, Gram-positive long rods. Spores and aerial hyphae are absent. Growth occurs between 20 °C and 37 °C, no growth at 10 °C or 45 °C. Colonies are rough, crumbly, and yellow to orange. Utilizes sucrose, galactose, and inositol in addition to the substrates listed in ❯ *Table 45.2*. Cellular fatty acids are indicated in ❯ *Table 45.3*. The major isoprenoid quinone is MK-9. Cell wall sugars are galactose and arabinose. No data are available describing the polar lipid profile. Resistant to bacitracin and penicillin G, but susceptible to streptomycin, gentamicin, tobramycin, vancomycin, and rifampicin. Type strain SCNU5^T.

Tsukamurella tyrosinosolvens Yassin, Rainey, Burghardt, Brzezinka, Schmitt, Seifert, Zimmermann, Mauch, Gierth, Lux and Schaal 1997, 612^{VP}

ty. ro. si. no. sol' vens. Gr. masc. n. *tyros*, cheese; *tyrosine*, an amino acid; L. pres. part. *solvens*, dissolving; M. L. adj. *tyrosinosolvens*, tyrosine dissolving, referring to the hydrolysis of tyrosine which is characteristic of this species.

Aerobic, Gram-positive rods. Elongated cells with septum formation are detectable. Spores and aerial hyphae absent. Colonies are whitish to yellow in color. Growth occurs between 24 °C and 37 °C, but not at 45 °C. Phenotypic properties are indicated in ❯ *Table 45.2*. Utilizes also D-glucose, galactose, sucrose, trehalose, myo-inositol, acetate, benzoate, citrate, gluconate, adipate, isoamylalcohol, 2,3 butandiol, 1,2-propandiol, and paraffin as sole carbon source. Contradictorily data are available for utilization of L-arabinose and cellobiose. Tolerates up to 5 % NaCl. Cellular fatty acids are shown in ❯ *Table 45.3*. MK-9 is the major menaquinone, but minor amounts of MK-8 and MK-10 are detectable in addition. Polar lipids are PE, PI, PIM and DPG. Resistant to streptomycin, ethambutol, rifampicin, capreomycin and cycloserine, clindamycin, cotrimoxazole, erythromycin, and tetracycline. Type strain IMMIBD-1397^T.

Isolation, Enrichment, and Maintenance Procedures

Isolation and Enrichment

Tsukamurella paurometabola DSM 20216^T(Collins et al. 1988) was isolated from the mycetome and ovaries of the bed bug, *Cinmex lectularius* L., but additional strains were isolated from human sputum (Collins et al. 1988). The strain has originally been isolated on a semisolid medium containing proteose peptone, rabbit serum, gelatin, minced rabbit kidney, and carbohydrates (Goodfellow 2011). The strain is able to grow on complex media like nutrient agar, CASO agar incubated at 30 °C.

Tsukamurella inchonensis IMMIB D-771T (Yassin et al. 1995) was isolated from a blood culture of a patient who had ingested hydrochloric acid. The isolate was routinely cultured on Loewenstein-Jensen medium at various temperatures (24 °C, 31 °C, 37 °C and 45 °C).

Tsukamurella pulmonis IMMIB D-1321^T (Yassin et al. 1996) was isolated from sputum of a 92-year-old woman who suffered from pulmonary tuberculosis and possibly an additional mycobacterial infection. The strain was isolated from the sputum after decontamination with *N*-acetyl-L-cysteine on Loewenstein-Jensen medium, but strain IMMIB D-1321^{T}also grew well on International Streptomyces Project [ISP] medium 2), and ISP medium 3 (Shirling and Gottlieb 1966) incubated at 24–37 °C.

Tsukamurella tyrosinosolvens IMMIB D-1397^T (Yassin et al. 1997) was isolated from a 62-year-old woman who had a cardiac pacemaker implant. The strain was isolated directly from the blood culture by plating aliquots of a set of different media (blood agar, chocolate agar, brain heart infusion (BHI) agar, and Muller-Hinton agar). ISP 2 agar was also used for characterization of the colony morphology of the strain. Growth occurred after incubation at 24–37 °C.

Tsukamurella strandjordii ATCC BAA-173^T (Kattar et al. 2001) was isolated from blood cultures of a 5-year-old girl with acute myelogenous leukemia. Middlebrook 7H11 agar

was routinely used for isolation of the strain, which also is able to grow on nutrient agar, trypticase soy agar, or MacConkey agar incubated at 28–35 °C.

Tsukamurella spumae N1171^T (Nam et al. 2003) was isolated from activated sludge foam, Stoke Bardolph Water Reclamation Works, near Nottingham, UK. The strain was isolated on glucose-yeast extract agar (GYEA, Gordon and Mihm 1962) containing (g per liter) glucose 10, yeast extract 10, and agar 15 (final pH 7.2). Unlike the other isolates, the type strain (N1171^T) does not grow at 10 °C, but at 25–37 °C.

Tsukamurella pseudospumae N1176^T (Nam et al. 2004) was isolated similarly from activated sludge foam collected from Stoke Bardolph Water Reclamation Works near Nottingham, UK. Isolation was done on glucose-yeast extract agar (GYEA, Gordon and Mihm 1962), incubated at room temperature.

Tsukamurella spongiae K362^T (Olson et al. 2007) was isolated from a deep-water marine sponge collected off the coast of Curacao (the Netherlands Antilles), at a depth of 220 m. A small section of the sponge was homogenized, subsequently heat-treated (70 ° C for 15 min) and plated onto maltose-seawater agar (Olson et al. 2000). Growth occurred on marine agar, nutrient agar, or brain-heart infusion agar (BHI) after 24–48 h incubation at 25 °C.

Tsukamurella sunchonensis SCNU5^T (Seong et al. 2008) was isolated from foam collected from a full-scale activated sludge plant in Sunchon, Korea. Strain SCNU5^T was grown on glucose-yeast extract agar (GYEA), yeast extract-malt extract agar (ISP medium 2), oatmeal agar (ISP medium 3), and inorganic salts-starch casein agar (ISP medium 4, Shirling and Gottlieb, 1966) incubated at 30 °C for up to 7 days.

Tsukumarella carboxydivorans Y2^T (Park et al. 2009) was isolated from a subsurface soil sample collected from the side of a busy road at Yonsei University, Seoul, Korea. For enrichment, 20 g of soil was transferred into 500-mL flasks and incubated under 400 p.p.m. CO in air for 2 weeks at 30 °C. Two grams of the enrichment was transferred to a new 500-mL flask containing 200 mL of a standard liquid mineral medium (Park et al. 2008), supplemented with 400 p.p.m. CO in air and 0.005 % (w/v) yeast extract and incubated for 2 weeks at 30 °C on a shaker at 200 r.p.m.

One milliliter aliquots were then spread plated onto solid mineral medium supplemented with 0.2 % (w/v) glucose and incubated for 2 weeks at 30 °C under 400 p.p.m. CO in air (Hardy and King 2001). Even though the strain was isolated under low CO concentration, it was also able to grow in the mineral medium at a high concentration of CO (300,000 p.p.m.). Subculturing on tryptone soya agar (TSA) is possible.

Tsukamurella soli JS18-1^T (Weon et al. 2010) was isolated from a soil sample collected from Halla mountain, Jeju island, Republic of Korea, by the spread-plate technique on R2A agar after incubation at 30 °C for 7 days. Composition of R2A agar (g per liter) is glucose 0.5, soluble starch 0.5, casamino acids 0.5, yeast extract 0.5, peptone 0.5, sodium pyruvate 0.3, $MgSO_4 \cdot 7H_2O$ 0.05, KH_2PO_4 0.3, and agar 15 (final pH 7.2).

Maintenance

Standard procedures can be applied for members of the genus *Tsukamurella*. Serial transfer of subcultures grown on glucose-yeast extract agar slants (every 6–8 weeks) is possible. Strains can also be achieved in glycerol stocks (50 % (v/v) stored at −20 °C or for better survivability at −80 °C. For long-term storage, freeze-drying or storage in liquid nitrogen should be used. Detailed protocols are given within the Cabri guidelines, accessible at www.cabri.org.

Ecology and Pathogenicity

Tsukamurellae have been isolated from various environmental habitats as well as from clinical specimen. *T. paurometabola* strains were isolated from mycetomes and ovaries of the bed bug (*Cimex lectularius*), as well as from activated sludge. Strains of the three species *T. spumae*, *T. pseudospumae*, and *T. sunchonensis* have been isolated from activated sludge plants too (Seong et al. 2003; Nam et al. 2004). *T. spongiae* was isolated from a deep water sponge in the Netherlands Antilles (Olson et al. 2007), *T. carboxidivorans* from a subsurface soil samples (10 cm depth) collected from the side of a busy road at Yonsei University, Seoul, Korea, and *T. soli* also from a soil sample, but collected from Halla mountain, Jeju island, Republic of Korea (Weong et al 2010).

All other type strains have been isolated from clinical specimen: *T. inchonensis*, blood culture of a patient who had ingested hydrochloric acid (Yassin et al. 1995); *T. pulmonis*, sputum of a patient with pulmonary tuberculosis (Yassin et al. 1995); *T. tyrosinosolvens*, blood culture of a patient with a cardiac pacemaker implant (Yassin et al. 1997); *T. strandjordii*, blood culture from a 5-year-old girl with acute myelogenous leukemia (Kattar et al. 2001). With exception of *T. strandjordii*, these species are allocated into Risk group 2 and are generally listed as opportunistic pathogens. *T. inchonensis* and *T. pulmonis* were able to cause catheter-related bacteremia and pulmonary diseases (Yassin et al. 1995, 1996; Maertens et al. 1998; Schwartz et al. 2002), or catheter-related bloodstream infections (*T. inchonensis*; Seo et al. 2012). *T. pulmonis* and *T. tyrosinosolvens* strains were also involved in ophthalmologic infections like keratitis or conjunctivitis (Woo et al. 2003, 2009).

The human body is not the only habitat from which these clinical strains could be isolated from. Several strains have been isolated from soil and rhizosphere in addition: *T. strandjordii*, *T. tyrosinosolvens* from arsenic-resistant soil or metal tolerant rhizosphere soil (Achour et al. 2007; Becerra-Castro et al. 2012), and *T. pulmonis* from potato geocaulosphere (Weinert et al. 2010). 16S rRNA gene sequences of cultivable isolates and uncultured clones related to *Tsukamurella* sp. have been detected in several diversity studies analyzing (i) Challenger Deep sediment samples from the Mariana Trench in the Pacific Ocean (Pathom-aree et al. 2006); (ii) actinobacteria from medical plants of tropical rain forests in Xishuangbanna, China (Qin et al. 2009); (iii) the bacterial diversity from

Roopkund Glacier, India (Pradhan et al. 2010); (iv) the rhizosphere community of *Arachis hypogaea* (Haldar et al. 2011); (v) the prevalent microbiota of human forehead skin compared to forearm skin (Staudinger et al. 2011); (vi) root endophytic actinobacteria in native herbaceous plants from Korea (Kim et al. 2012); (vii) cholesterol- and deoxycholate-degrading bacteria from soil samples (Merino et al. 2013).

Application

Production of secondary metabolites by bacteria often depends on the culture conditions applied for a specific strain. Onaka et al. (2011) reported that mycolic acid containing bacteria, like *Tsukamurella*, were able to induce the biosynthesis of natural products in *Streptomyces* sp. The production of a red pigment by strain *Streptomyces lividans* TK23 was induced in coculture with strain *Tsukamurella pulmonis* TP-B0596, and Onaka et al. postulated that the mycolic acid localized within the outer cell layer may be responsible for direct interaction with the *Streptomyces* strains.

Strain *Tsukamurella paurometabola* C-924 has been used as nematocidic agent for biocontrol of nematodes. A bionematicide product of the strain is available as HerberNem™. The mechanism of action has been explained by effects of desulfurase and chitinase activities on nematodes and nematodes eggs (Mena et al. 2002).

Tsukamurella paurometabola was also considered to be one of the causal agents of foaming in activated sludge plants (Goodfellow et al. 1996) and the application of *Tsukamurella* specific bacteriophages (TPA2) as biocontrol agent (anti-foaming) offers the possibility to stabilize foams in activated sludge plants (Petrovski et al. 2011).
