Foreword

The purpose of this brief foreword is unchanged from the first edition; it is simply to make you, the reader, hungry for the scientific feast that follows. These 11 volumes on the prokaryotes offer an expanded scientific menu that displays the biochemical depth and remarkable physiological and morphological diversity of prokaryote life. The size of the volumes might initially discourage the unprepared mind from being attracted to the study of prokaryote life, for this landmark assemblage thoroughly documents the wealth of present knowledge. But in confronting the reader with the state of the art, the Handbook also defines where more work needs to be done on well-studied bacteria as well as on unusual or poorly studied organisms.

This edition of *The Prokaryotes* recognizes the almost unbelievable impact that the work of Carl Woese has had in defining a phylogenetic basis for the microbial world. The concept that the ribosome is a highly conserved structure in all cells and that its nucleic acid components may serve as a convenient reference point for relating all living things is now generally accepted. At last, the phylogeny of prokaryotes has a scientific basis, and this is the first serious attempt to present a comprehensive treatise on prokaryotes along recently defined phylogenetic lines. Although evidence is incomplete for many microbial groups, these volumes make a statement that clearly illuminates the path to follow.

There are basically two ways of doing research with microbes. A classical approach is first to define the phenomenon to be studied and then to select the organism accordingly. Another way is to choose a specific organism and go where it leads. The pursuit of an unusual microbe brings out the latent hunter in all of us. The intellectual challenges of the chase frequently test our ingenuity to the limit. Sometimes the quarry repeatedly escapes, but the final capture is indeed a wonderful experience. For many of us, these simple rewards are sufficiently gratifying so that we have chosen to spend our scientific lives studying these unusual creatures. In these endeavors, many of the strategies and tools as well as much of the philosophy may be traced to the Delft School, passed on to us by our teachers, Martinus Beijerinck, A. J. Kluyver, and C. B. van Niel, and in turn passed on by us to our students.

In this school, the principles of the selective, enrichment culture technique have been developed and diversified; they have been a major force in designing and applying new principles for the capture and isolation of microbes from nature. For me, the "organism approach" has provided rewarding adventures. The organism continually challenges and literally drags the investigator into new areas where unfamiliar tools may be needed. I believe that organism-oriented research is an important alternative to problem-oriented research, for new concepts of the future very likely lie in a study of the breadth of microbial life. The physiology, biochemistry, and ecology of the microbe remain the most powerful attractions. Studies based on classical methods as well as modern genetic techniques will result in new insights and concepts.

To some readers, this edition of *The Prokaryotes* may indicate that the field is now mature, that from here on it is a matter of filling in details. I suspect that this is not the case. Perhaps we have assumed prematurely that we fully understand microbial life. Van Niel pointed out to his students that—after a lifetime of study—it was a very humbling experience to view in the microscope a sample of microbes from nature and recognize only a few. Recent evidence suggests that microbes have been evolving for nearly 4 billion years. Most certainly, those microbes now domesticated and kept in captivity in culture collections represent only a minor portion of the species that have evolved in this time span. Sometimes we must remind ourselves that evolution is actively taking place at the present moment. That the eukaryote cell evolved as a chimera of certain prokaryote parts is a generally accepted concept today. Higher as well as lower eukaryotes evolved in contact with prokaryotes, and evidence surrounds us of the complex interactions between eukaryotes and prokaryotes as well as among prokaryotes. We have so far only scratched the surface of these biochemical interrelationships. Perhaps the legume nodule is a pertinent example of nature caught in the act of evolving the "nitrosome," a unique nitrogen-fixing organelle. The study of prokaryotes is proceeding at such a fast pace that major advances are occurring yearly. The increase of this edition to four volumes documents the exciting pace of discoveries.

To prepare a treatise such as *The Prokaryotes* requires dedicated editors and authors; the task has been enormous. I predict that the scientific community of microbiologists will again show its appreciation through use of these volumes—such that the pages will become "dog-eared" and worn as students seek basic information for the hunt. These volumes belong in the laboratory, not in the library. I believe that a most effective way to introduce students to microbiology is for them to isolate microbes from nature, that is, from their habitats in soil, water, clinical specimens, or plants. *The Prokaryotes* enormously simplifies this process and should encourage the construction of courses that contain a wide spectrum of diverse topics. For the student as well as the advanced investigator, these volumes should generate excitement.

Happy hunting!

Ralph S. Wolfe
Department of Microbiology
University of Illinois at Urbana-Champaign

Preface

During most of the twentieth century, microbiologists studied pure cultures under defined laboratory conditions in order to uncover the causative agents of disease and subsequently as ideal model systems to discover the fundamental principles of genetics and biochemistry. Microbiology as a discipline onto itself, e.g., microbial ecology, diversity, and evolution-based taxonomy, has only recently been the subject of general interest, partly because of the realization that microorganisms play a key role in the environment. The development and application of powerful culture-independent molecular techniques and bioinformatics tools has made this development possible. The fourth edition of *the Handbook of the Prokaryotes* has been updated and expanded in order to reflect this new era of microbiology.

The first five volumes of the fourth edition contain 34 updated and 43 entirely new chapters. Most of the new chapters are in the two new sections: Prokaryotic Communities and Bacteria in Human Health and Disease. A collection of microorganisms occupying the same physical habitat is called a "community," and several examples of bacterial communities are presented in the Prokaryotic Communities section, organized by Edward F. DeLong. Over the last decade, important advances in molecular biology and bioinformatics have led to the development of innovative culture-independent approaches for describing microbial communities. These new strategies, based on the analysis of DNA directly extracted from environmental samples, circumvent the steps of isolation and culturing of microorganisms, which are known for their selectivity leading to a nonrepresentative view of prokaryotic diversity. Describing bacterial communities is the first step in understanding the complex, interacting microbial systems in the natural world.

The section on Bacteria in Human Health and Disease, organized by Stephen Lory, contains chapters on most of the important bacterial diseases, each written by an expert in the field. In addition, there are separate general chapters on identification of pathogens by classical and non-culturing molecular techniques and virulence mechanisms, such as adhesion and bacterial toxins. In recognition of the recent important research on beneficial bacteria in human health, the section also includes chapters on gut microbiota, prebiotics, and probiotics. Together with the updated and expanded chapter on Bacterial Pharmaceutical Products, this section is a valuable resource to graduate students, teachers, and researchers interested in medical microbiology.

Volumes 6–11, organized by Erko Stackebrandt and Fabiano Thompson, contain 265 chapters in total on each of the ca. 300 known prokaryotic families, in some cases even higher taxa. Each chapter presents both the historical and current taxonomy of these taxa, mostly above the genus level; molecular analyses (e.g., DDH, MLSA, riboprinting, and MALDI-TOF); genomic and phenetic properties of the taxa covered; genome analyses including nonchromosomal genetic elements; phenotypic analyses; methods for the enrichment, isolation, and maintenance of members of the family; ecological studies; clinical relevance; and applications.

As in the third edition, the volumes in the fourth edition are available both as hard copies and as eReferences. The advantages of the online version include no restriction of color illustrations, the possibility of updating chapters continuously and, most importantly, libraries can place their subscribed copies on their servers, making it available to their community in offices and laboratories. The editors thank all the chapter authors and the editorial staff of Springer, especially Hanna Hensler-Fritton, Isabel Ullmann, Daniel Quiñones, Alejandra Kudo, and Audrey Wong, for making this contribution possible.

Editor-in-Chief

About the Editors

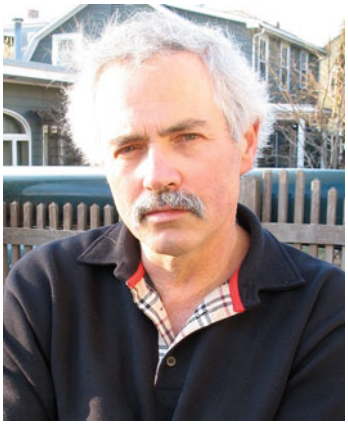
Eugene Rosenberg (Editor-in-Chief)
Department of Molecular Microbiology and Biotechnology
Tel Aviv University
Tel Aviv
Israel

Eugene Rosenberg holds a Ph.D. in biochemistry from Columbia University (1961) where he described the chemical structures of the capsules of *Hemophilus influenzae*, types B, E, and F. His postdoctoral research was performed in organic chemistry under the guidance of Lord Todd in Cambridge University. He was an assistant and associate professor of microbiology at the University of California at Los Angeles from 1962 to 1970, where he worked on the biochemistry of *Myxococcus xanthus*. Since 1970, he has been in the Department of Molecular Microbiology and Biotechnology, Tel Aviv University, as an associate professor (1970–1974), full professor (1975–2005), and professor emeritus (2006–present). He has held the Gol Chair in Applied and Environmental Microbiology since 1989. He is a member of the American Academy of Microbiology and European Academy of Microbiology. He has been awarded a Guggenheim Fellowship, a Fogarty International Scholar of the NIH, the Pan Lab Prize of the Society of Industrial Microbiology, the Proctor & Gamble Prize of the ASM, the Sakov Prize, the Landau Prize, and the Israel Prize for a "Beautiful Israel."

His research has focused on myxobacteriology; hydrocarbon microbiology; surface-active polymers from *Acinetobacter*; bioremediation; coral microbiology; and the role of symbiotic microorganisms in the adaptation, development, behavior, and evolution of animals and plants. He is the author of about 250 research papers and reviews, 9 books, and 16 patents.

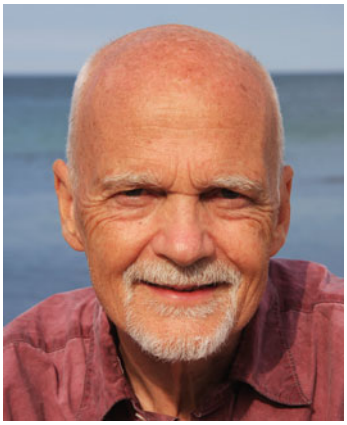
Edward F. DeLong
Department of Biological Engineering
Massachusetts Institute of Technology
Cambridge, MA
USA
and
Center for Microbial Oceanography: Research and Education
University of Hawaii, Manoa
Honolulu, HI
USA

Edward DeLong received his bachelor of science in bacteriology at the University of California, Davis, and his Ph.D. in marine biology at Scripps Institute of Oceanography at the University of California, San Diego. He was a professor at the University of California, Santa Barbara, in the Department of Ecology for 7 years, before moving to the Monterey Bay Aquarium Research Institute where he was a senior scientist and chair of the science department, also for 7 years. He has worked for the past 10 years as a professor at the Massachusetts Institute of Technology in the Department of Biological Engineering, and the Department of Civil and Environmental Engineering, and in August 2014 joined the University of Hawaii as a professor of oceanography. DeLong's scientific interests focus primarily on central questions in marine microbial genomics, biogeochemistry, ecology, and evolution. A large part of DeLong's efforts have been devoted to the study of microbes and microbial processes in the ocean, combining laboratory and field-based approaches. Development and application of genomic, biochemical, and metabolic approaches to study and exploit microbial communities and processes is his other area of interest. DeLong is a fellow in the American Academy of Arts and Science, the U.S. National Academy of Science, and the American Association for the Advancement of Science.



Stephen Lory
Department of Microbiology and Immunobiology
Harvard Medical School
Boston, MA
USA

Stephen Lory received his Ph.D. degree in microbiology from the University of California in Los Angeles in 1980. The topic of his doctoral thesis was the structure-activity relationships of bacterial exotoxins. He carried out his postdoctoral research on the basic mechanism of protein secretion by Gram-negative bacteria in the Bacterial Physiology Unit at Harvard Medical School. In 1984, he was appointed assistant professor in the Department of Microbiology at the University of Washington in Seattle, becoming full professor in 1995. While at the University of Washington, he developed an active research program in host-pathogen interactions including the role of bacterial adhesion to mammalian cells in virulence and regulation of gene expression by bacterial pathogens. In 2000, he returned to Harvard Medical School where he is currently a professor of microbiology and immunobiology. He is a regular reviewer of research projects on various scientific panels of governmental and private funding agencies and served for four years on the Scientific Council of Institute Pasteur in Paris. His current research interests include evolution of bacterial virulence, studies on post-translational regulation of gene expression in *Pseudomonas*, and the development of novel antibiotics targeting multi-drug-resistant opportunistic pathogens.



Erko Stackebrandt
Leibniz Institute DSMZ-German Collection of Microorganisms and Cell Cultures
Braunschweig
Germany

Erko Stackebrandt holds a Ph.D. in microbiology from the Ludwig-Maximilians University Munich (1974). During his postdoctoral research, he worked at the German Culture Collection in Munich (1972–1977), 1978 with Carl Woese at the University of Illinois, Urbana Champaign, and from 1979 to 1983 he was a member of Karl Schleifer's research group at the Technical University, Munich. He habilitated in 1983 and was appointed head of the Departments of Microbiology at the University of Kiel (1984–1990), at the University of Queensland, Brisbane, Australia (1990–1993), and at the Technical University Braunschweig, where he also was the director of the DSMZ-German Collection of Microorganisms and Cell Cultures GmbH (1993–2009). He is involved in systematics, and molecular phylogeny and ecology of Archaea and Bacteria for more than 40 years. He has been involved in many research projects funded by the German Science Foundation, German Ministry for Science and Technology, and the European Union, working on pure cultures and microbial communities. His projects include work in soil and peat, Mediterranean coastal waters, North Sea and Baltic Sea, Antarctic Lakes, Australian soil and artesian wells, formation of stromatolites, as well as on giant ants, holothurians, rumen of cows, and the digestive tract of koalas. He has been involved in the description and taxonomic revision of more than 650 bacteria taxa of various ranks. He received a Heisenberg stipend (1982–1983) and his work has been awarded by the Academy of Science at Göttingen, Bergey's Trust (Bergey's Award and Bergey's Medal), the Technical University Munich, the Australian Society for Microbiology, and the American Society for Microbiology. He held teaching positions in Kunming, China; Budapest, Hungary; and Florence, Italy. He has published more than 600 papers in refereed journals and has written more than 80 book chapters. He is the editor of two Springer journals and served as an associate editor of several international journals and books as well as on national and international scientific and review panels of the German Research Council, European Science Foundation, European Space Agency, and the Organisation for Economic Co-Operation and Development.

Fabiano Thompson
Laboratory of Microbiology
Institute of Biology
Center for Health Sciences
Federal University of Rio de Janeiro (UFRJ)
Ilha do Fundão
Rio de Janeiro
Brazil

Fabiano Thompson became a professor of the Production Engineer Program (COPPE-UFRJ) in 2014 and the director of research at the Institute of Biology, Federal University of Rio de Janeiro (UFRJ), in 2012. He was an oceanographer at the Federal University of Rio Grande (Brazil) in 1997. He received his Ph.D. in biochemistry from Ghent University (Belgium) in 2003, with emphasis on marine microbial taxonomy and biodiversity. Thompson was an associate researcher in the BCCM/LMG Bacteria Collection (Ghent University) in 2004; professor of genetics in 2006 at the Institute of Biology, UFRJ; and professor of marine biology in 2011 at the same university. He has been a representative of UFRJ in the National Institute of Metrology (INMETRO) since 2009. Thompson is the president of the subcommittee on the Systematics of Vibrionaceae–IUMS and an associate editor of *BMC Genomics* and *Microbial Ecology*. The Thompson Lab in Rio currently performs research on marine microbiology in the Blue Amazon, the realm in the southwestern Atlantic that encompasses a variety of systems, including deep sea, Cabo Frio upwelling area, Amazonia river-plume continuum, mesophotic reefs, Abrolhos coral reef bank, and Oceanic Islands (Fernando de Noronha, Saint Peter and Saint Paul, and Trindade).

E. Rosenberg et al. (eds.), *The Prokaryotes – Alphaproteobacteria and Betaproteobacteria*, DOI 10.1007/978-3-642-30197-1_396,

Abstract

The family *Acetobacteraceae* is taxonomically included in the order *Rhodospirillales* of the class *Alphaproteobacteria*, and 32 genera are validly described. The genera are basically classified into two groups, an acetous group and an acidophilic group, in the light of application, ecology, and phylogeny. The acetous group comprises genera in acetic acid bacteria like *Acetobacter, Gluconacetobacter, Gluconobacter, Asaia, Granulibacter, and Komagataeibacter*. The acidophilic group consists of acidophilic and neutrophilic genera like *Acidiphilium* and *Roseomonas*. In the 1960s, taxonomy of acetic acid bacteria was significantly affected by the chemotaxonomic study with G+C content of DNA, quinone systems, cellular fatty acid composition, and DNA-DNA similarity. Further, data of phylogenetic analysis based on 16S rRNA gene sequences have had a profound impact on the systematics of acetic acid bacteria and other bacteria over all. Membrane-bound dehydrogenases are responsible for the oxidation of alcohols and sugars in acetic acid bacteria. The dehydrogenases are located in the periplasmic side of the cytoplasmic membrane of the bacteria. The direct electron acceptor of the dehydrogenases is ubiquinone in the respiratory chain of the acetic acid bacteria. Production of acetic acid from ethanol and of D-gluconate, 2-keto-D-gluconate, 5-keto-D-gluconate, and 2,5-diketo-D-gluconate from D-glucose is due to the membrane-bound dehydrogenases. Acetic acid bacteria are widely distributed in alcoholic and acidic environments, and they are isolated from vinegar, wine, beer, sake, cider, fermented foods, fruits, flowers, and other alcoholic materials. *Asaia* strains are isolated from flowers and even from mosquitoes and other insects. *Granulibacter* is known for its pathogenicity for humans. Acetic acid bacteria are widely used for production of vinegar. D-Gluconic acid and keto-D-gluconic acids are produced from D-glucose by *Gluconobacter* strains, which are used in the food, pharmaceutical, and chemical industries. L-Sorbose is produced from sorbitol by *Gluconobacter* strains, which is further converted to 2-keto-L-gulonic acid as a penultimate intermediate in the industrial production of vitamin C.

Taxonomy, Historical and Current

A.ce.to.bac.te.ra'ce.ae. M. L. masc. n. *Acetobacter* the type genus of the family; *-aceae* ending to denote a family; M. L. pl. n. *Acetobacteraceae* the *Acetobacter* family.

The family *Acetobacteraceae* basically consists of two groups, an acetous group and an acidophilic group, in the light of application, ecology, and phylogeny. The former includes the so-called acetic acid bacteria, which are physiologically and biochemically homogeneous, and the latter includes other acidophilic and neutrophilic bacteria, which have heterogeneous natures physiologically and biochemically.

At the beginning of research in acetic acid bacteria, a few phenotypic characteristics were used for classification, identification, and differentiation. A brief history in the early stage on the taxonomy of acetic acid bacteria is outlined according to Asai's description (Asai 1968).

In 1894, Hansen classified acetic acid bacteria on the basis of pellicle formation and an iodine reaction. In his group I, *Bacterium aceti*, the pellicle of which was easily separable from media and not stained with iodine, and *Bacterium pasteurianum* and *Bacterium küzingianum*, the pellicles of which were easily separable from media and stained with iodine, were included. On the other hand, *Bacterium xylinum* in his group II produced thick and leathery pellicle. At that time, a few species of acetic acid bacteria were known. Beijerinck in 1898 introduced the utilization of an inorganic nitrogen source with pellicle formation and the

production of viscous colonies on sucrose-containing beer gelatin. Henneberg in 1898 considered natural habitats as a differential characteristic and used the terms of malt infusion or wort acetic acid bacteria, beer vinegar bacteria, wine vinegar bacteria, and quick vinegar bacteria. In the next year, Hoyer followed Beijerinck's classification and used a sucrose inversion for the differentiation of acetic acid bacteria. In 1916, Janke classified acetic acid bacteria on the basis of utilization of inorganic ammonium salts as a nitrogen source and acetic acid as a carbon source, along with pellicle formation, motility, and production of acid from carbohydrates. Kluyver and de Leeuw introduced the utilization of ethanol, glucose, and mannitol in 1925. Following the above classifications, biochemical and physiological characteristics were taken into account of the classification of acetic acid bacteria. Visser't Hooft in the same year used catalase, growth on Hoyer's medium, the production of D-gluconic and 5-keto-D-gluconic acids from D-glucose, and pigment formation for the classification. In 1942, Vaughn developed Visser't Hooft's system and classified acetic acid bacteria into two groups, viz., acetate oxidizers and non-acetate oxidizers. Later, the Vaughn system was dealt with in *Bergey's Manual of Determinative Bacteriology*, 7th ed., 1957. Shimwell revised the Vaughn system in 1948 and introduced the oxidation of acetic acid to carbon dioxide, the utilization of ammoniac nitrogen, the formation of leathery cellulosic pellicle on liquid medium, pigment formation, and temperature for growth. Frateur divided the genus *Acetobacter* into four groups in 1950, the *peroxydans* group, the *oxydans* group, the *mesoxydans* group, and the *suboxydans* group, based on the presence or absence of catalase, the oxidation of acetic acid, the oxidation of lactic acid, ketogenic activities, and the production of D-gluconic acid. More detailed history of classification in acetic acid bacteria can be seen in the Asai's descriptions (Asai 1968).

The generic name *Acetobacter* was first introduced for acetic acid bacteria by Beijerinck (1898). The type species of the genus was *Acetobacter aceti*. *Acetobacter pasteurianus* and *Acetobacter peroxydans* were subsequently described (Beijerinck and Folpmers 1916; Visser't Hooft 1925).

The new genus *Gluconobacter* was proposed for the acetic acid bacteria by Asai (1934, 1935), the strains of which were isolated from a variety of fruit, the new type of isolation sources. Most of isolates produced a large amount of D-gluconic acid from D-glucose and generally oxidized ethanol to acetic acid. The strains of the genus *Gluconobacter* interestingly neither assimilated nor oxidized acetic acid and were different in this respect from the strains of the genus *Acetobacter*, which oxidized acetic acid to carbon dioxide and water. In addition, the genera *Acetobacter* and *Gluconobacter* were subdivided into two subgenera, "*Euacetobacter*" and "*Acetogluconobacter*" and "*Eugluconobacter*" and "*Gluconoacetobacter*," respectively (Asai 1935). However, the new generic name *Gluconobacter* was hardly recognized, since the Asai's articles were published in Japanese.

Almost 20 years later from the publications of Asai's articles, the genus "*Acetomonas*" was proposed for strains characterized by polar flagellation and no acetate oxidation (Leifson 1954). In contrast, strains assigned to the genus *Acetobacter* had peritrichous flagellation and the capability of oxidizing acetic acid to carbon dioxide and water. The proposals of the two generic names, *Gluconobacter* and "*Acetomonas*," brought about confusion on naming of similar microorganisms (Asai and Shoda 1958; Shimwell 1958; Shimwell and Carr 1959).

However, the priority of the generic name *Gluconobacter* over the name of "*Acetomonas*" was recognized (De Ley 1961) and *Gluconobacter oxydans* was designated as the type species, because Asai (1935) did not designate the type species (De Ley 1961; Asai et al. 1964; De Ley and Frateur 1970; Buchanan 1970).

In the Approved Lists of Bacterial Names (Skerman et al. 1980), the three species *Acetobacter aceti*, *Acetobacter pasteurianus*, and *Acetobacter peroxydans* are listed in the genus *Acetobacter*, and the only one species *Gluconobacter oxydans* is listed in the genus *Gluconobacter*. The family *Acetobacteraceae* was introduced for the two genera of acetic acid bacteria (Gillis and De Ley 1980).

The two types of intermediate strains were additionally presented in acetic acid bacteria (Asai et al. 1964). One was of peritrichous flagellation, and the other was of polar flagellation. The genera *Acetobacter* and *Gluconobacter* were clearly distinguished by the presence of major ubiquinone homologues, viz., Q-9 for *Acetobacter* and Q-10 for *Gluconobacter* (Yamada et al. 1968b, 1969). Of interest was that the peritrichously flagellated intermediate strains, which were once recognized as pigment-producing strains of *Acetobacter aceti* (Carr and Shimwell 1960; Kimmit and Williams 1963), had Q-10, as found in the strains of the genus *Gluconobacter* (Yamada et al. 1968b, 1969). On the other hand, the polarly flagellated intermediate strains had Q-8, which was never found in the strains of the genera *Acetobacter* and *Gluconobacter* (Yamada et al. 1969, 1976a). The strains were later classified as a new genus and a new species, *Frateuria aurantia* (Swings et al. 1980).

The peritrichously flagellated, Q-10-equipped intermediate strains, viz., the pigment-producing strains of *Acetobacter aceti*, as well as the Q-10-equipped, nonmotile *Acetobacter xylinus* strains, were distinguished chemotaxonomically from the Q-9-equipped *Acetobacter* strains at the subgeneric level, and the subgenus *Gluconacetobacter* corrig. was proposed (Yamada and Kondo 1984). The genus *Acidomonas* was then introduced for the methanol-assimilating *Acetobacter methanolicus* strains (Urakami et al. 1989). However, the proposals of the two taxa, viz., the subgenus *Gluconacetobacter* and the genus *Acidomonas*, were not recognized (Swings 1992). The same conclusion was derived for the genus *Acidomonas* based on 16S rRNA gene sequence analysis (Sievers et al. 1994b). However, there was a different opinion that the name of *Acidomonas* was acceptable from the data obtained by 5S rRNA sequencing (Bulygina et al. 1992).

The subgenus *Gluconacetobacter* was phylogenetically discussed on the basis of the partial 16S rRNA sequences, along with the genus *Acidomonas*, and elevated to the generic level to the genus *Gluconacetobacter*, the type species of which was designated as *Gluconacetobacter liquefaciens*, with a concomitant recognition of the generic name of *Acidomonas* (Yamada et al. 1997). The genus *Gluconacetobacter* was later subdivided into two groups, viz., the *Gluconacetobacter liquefaciens* group and the *Gluconacetobacter xylinus* group, and the two groups

were suggested to be phylogenetically, phenotypically, and ecologically different from each other at the generic level (Yamada and Yukphan 2008). For the latter group, the genus *Komagataeibacter* was newly introduced with the type species, *Komagataeibacter xylinus* (Yamada et al. 2012a, b).

Thus, the four genera, *Gluconobacter*, *Acidomonas*, *Gluconacetobacter*, and *Komagataeibacter*, were additionally established for the species that were once classified in the genus *Acetobacter*. This indicates that the genus *Acetobacter* Beijerinck 1898 had an extremely large generic circumscription.

The genus *Acidiphilium* was first proposed for an acidophilic bacterium (Harrison 1981). The type species *Acidiphilium cryptum* grows at pH 1.9–5.6. However, the species of other genera such as *Roseococcus thiosulfatophilus* and *Erythrobacter longus* cannot grow at such acidic pHs but grow at pH 6–9 and 6.5–9, respectively (Yurkov 2006).

To the family *Acetobacteraceae*, 16 genera are nowadays accommodated to the acetous group, and 16 genera are accommodated to the acidophilic group.

Molecular Analyses

Phylogenetic Structure of the Family and Its Genera

The family *Acetobacteraceae* is a member of the order *Rhodospirillales* in the class *Alphaproteobacteria* (Sievers and Swings 2005a). In 1980, the genera *Acetobacter* and *Gluconobacter* were genetically separated on the basis of DNA-rRNA hybridizations and united in the family *Acetobacteraceae* (Gillis and De Ley 1980). Moreover, the genera *Acetobacter* and *Gluconobacter* were shown to constitute one large rRNA superfamily, which was shown as the alpha subclass of the *Proteobacteria* (Stackebrandt et al. 1988), later named the class *Alphaproteobacteria* (Garrity et al. 2005), together with the genera *Agrobacterium*, *Rhizobium*, *Zymomonas*, etc. On the basis of 5S rRNA gene sequencing, the genus *Acidomonas* was recognized to form an independent lineage apart from the genera *Acetobacter* and *Gluconobacter* in the family *Acetobacteraceae* (Bulygina et al. 1992). The genus *Gluconacetobacter* was phylogenetically distinguished from the genera *Acetobacter* and *Gluconobacter* by the partial 16S rRNA gene sequence analysis (Yamada et al. 1997). Meanwhile, acetic acid bacteria were indicated to relate to acidophilic bacteria including the genera *Acidiphilium*, *Acidocella*, and *Rhodopila* (Kishimoto et al. 1995; Sievers et al. 1994a). Bacteriochlorophyll *a*-containing bacteria such as the genera *Rhodopila* and *Roseococcus* were moderately related to the genus *Acidiphilium* (Yurkov et al. 1994). Therefore, the family *Acetobacteraceae* mainly consists of acetic acid bacteria, acidophilic bacteria, and bacteriochlorophyll *a*-containing bacteria.

Currently, at least 32 genera are thought to be the member of the family *Acetobacteraceae*. The phylogenetic relationships of the family *Acetobacteraceae* are shown in ❯ *Fig. 1.1*. The 30 genera except for the genera *Stella* and *Zavarzinia* form a supra-group within the order *Rhodospirillales*. This lineage is clearly and completely separated from the family *Rhodospirillaceae* with a high bootstrap value (95 % or more) by the phylogenetic tree constructed with neighbor-joining (NJ) and maximum-likelihood (ML) methods. The family *Acetobacteraceae* is divided into three major sublineages. One sublineage consists of acetic acid bacteria with 99 % of bootstrap value in the family *Acetobacteraceae*. Furthermore, the acetic acid bacteria are subdivided into three major groups: one group with the genera *Acetobacter*, *Gluconobacter*, *Neokomagataea*, and *Saccharibacter*; the second group with the genera *Asaia*, *Kozakia*, *Neoasaia*, and *Swaminathania*; and the third group with the genera *Gluconacetobacter* and *Komagataeibacter*. *Gluconacetobacter entanii* is phylogenetically affiliated with the genus *Komagataeibacter*. However, *G. entanii* was not listed as a new combination according to Rule 27 of the Bacteriological Code (Tindall et al. 2006) because the type strain of *G. entanii* was not available in any culture collection (Yamada et al. 2012b).

The genera *Acidomonas*, *Endobacter*, and *Granulibacter* form an independent sublineage each with a single species in the sublineage of the acetic acid bacteria. The second sublineage consists of acidophilic bacteria although bootstrap probability with the sublineage of the acetic acid bacteria is insufficiently supported by the phylogenetic analysis. This lineage includes the genera *Acidicaldus*, *Acidiphilium*, *Acidisoma*, *Acidisphaera*, and *Acidocella*. The third sublineage mainly consists of neutrophilic bacteriochlorophyll *a*-containing bacteria including the genera *Belnapia*, *Craurococcus*, *Humitalea*, *Paracraurococcus*, *Roseococcus*, *Roseomonas*, and *Rubritepida* with 84 % of bootstrap value. The genera *Rhodopila* and *Rhodovarius*, acidophilic phototrophic bacteria and neutrophilic bacteriochlorophyll-not-containing bacteria, respectively, form an independent lineage each with a single species in the family *Acetobacteraceae*. The phylogenetic location of the genera consisted of a single species, for instance, *Acidicaldus, Craurococcus*, *Rhodopila*, and *Saccharibacter*, was unstable due to scarce representation in the sequence dataset. The genera *Stella* and *Zavarzinia* are described as the member of the family *Acetobacteraceae* in *Bergey's Manual of Systematic Bacteriology* 2nd ed. 2005 (Garrity et al. 2005). However, the genus *Stella* is phylogenetically located near to the genera *Azospirillum* and *Skermanella* in the family *Rhodospirillaceae* on the phylogenetic tree based on 16S rRNA gene sequence. The genus *Stella* should be regarded as the member of the family *Rhodospirillaceae*. The genus *Zavarzinia* is phylogenetically located between the members of the family *Acetobacteraceae* and of the family *Rhodospirillaceae*. The phylogenetic position of the genus *Zavarzinia* is required to be discussed in detail because a bootstrap probability is insufficient at the corresponding nodes.

Genome Analyses

Approximately 20 complete and draft genome sequences of the branching within the 16S rRNA gene tree of the family *Acetobacteraceae* have been reported in public. The genome

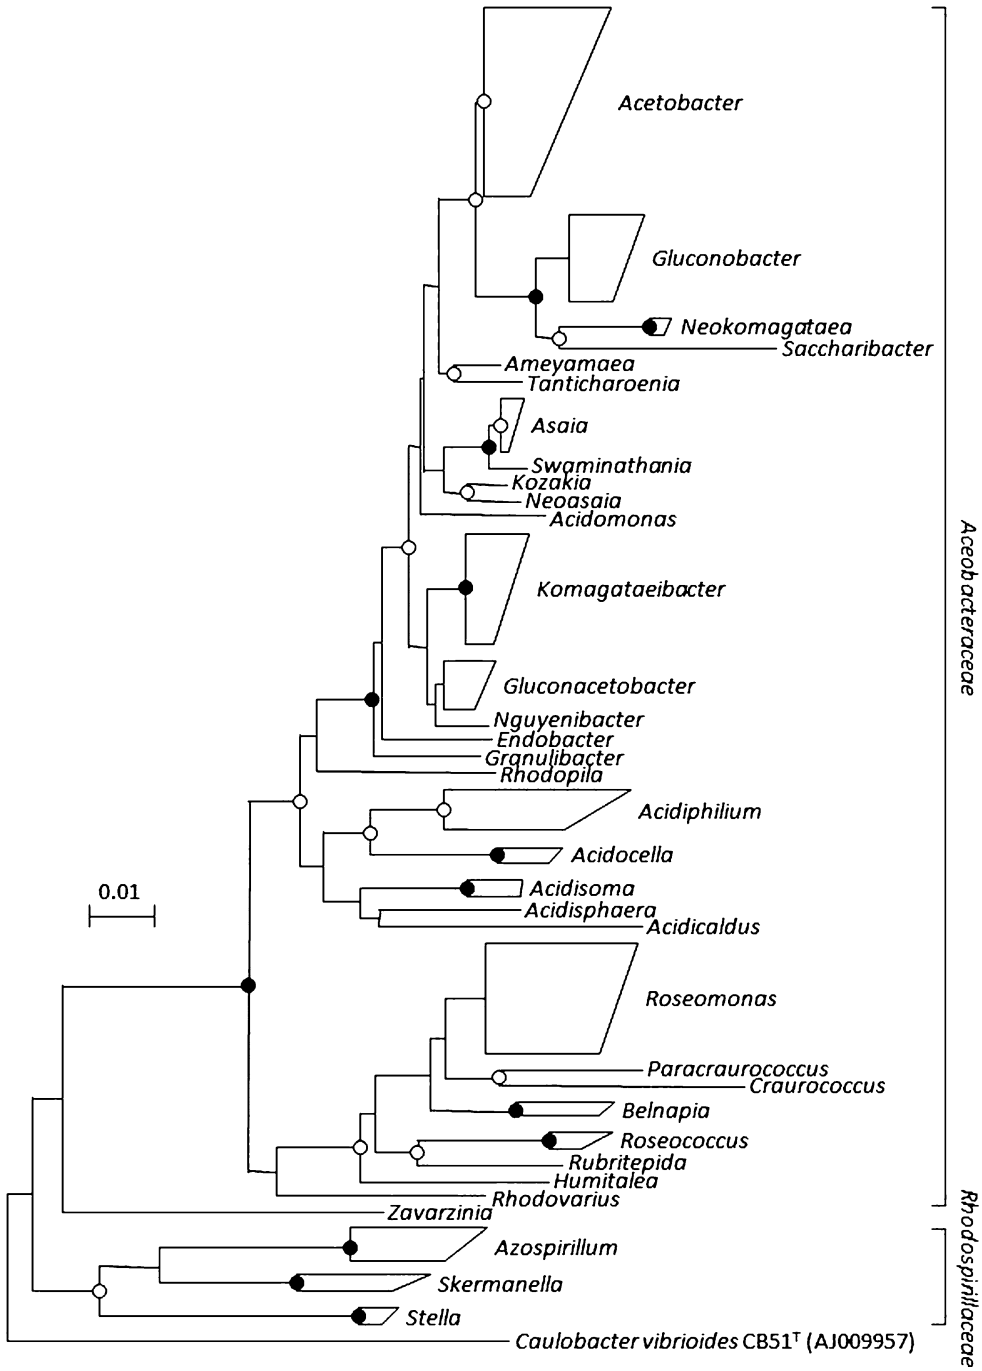

Fig. 1.1

Neighbour-joining tree of the family *Acetobacteraceae* and related bacteria based on 16S rRNA gene sequences. Phylogenetic analysis was based on alignment of 1,219 bp 16S rRNA gene sequences of 114 strains. Solid circles at branching nodes indicate supporting probabilities above 95 % by two phylogenetic analysis methods (NJ and ML), and open circles indicate probabilities above 85 % by either analysis. Bar, 0.01 substitutions per nucleotide position

of *Acetobacter aceti* NBRC 14818 is 3,577,688 bp with a G+C content of 57.3 mol% (Sakurai et al. 2011). The transcriptome profile in the *A. aceti* cells indicated that the TCA cycle (tricarboxylic acid cycle, citric acid cycle, citrate cycle) genes showed higher expression levels in the cells grown on acetate or D-glucose, and the glyoxylate pathway genes were significantly induced by ethanol or acetate. Many SOS-response gene, superoxide dismutase and catalase genes, a gene for one of type I NADH dehydrogenase, genes for bo_3-type (BO3), and cyanide-insensitive types (CIOs) for quinol oxidases were highly expressed or downregulated by acetate, ethanol, and D-glucose. These results indicate that energy conservation efficiency is fine-tuned by changing the respiratory components according to the growth conditions in the *A. aceti* cells.

Genomes of *Acetobacter pasteurianus* NBRC 3283, SKU1108, and IFO 3191 consist of 2,907,495 bp, 3,018,312 bp, and 2,888,200 bp with G+C contents of 50.7 mol%, 52.68 mol%, and 53.08 mol%, respectively, showing 100 % sequence identity by 16S rRNA gene sequence (Azuma et al. 2009; Matsutani et al. 2012). Genes involved in translation, transcription, and signal transduction are highly conserved among the each genome of these strains. Strain IFO 3191 increased mutation rates compared with the thermotolerant strains SKU1108 and NBRC 3283. Some of these genes might be correlated with the thermosensitivity of IFO 3191.

Acetobacter tropicalis SKU1100 is a thermotolerant acetic acid bacterium. The strain is able to grow above 40 °C and can perform amino acid substitutions from large to small residue and Lys to Arg in many orthologous genes compared with a mesophilic acetic acid bacterium, *A. pasteurianus* IFO 3283 (Matsutani et al. 2011). In the orthologous proteins, *A. tropicalis* SKU1100 increased the number of Arg-based salt bridges than *A. pasteurianus* IFO 3283. This fact strongly suggests that the increased number of Arg-based salt bridges may contribute to the thermotolerance of *A. tropicalis* SKU1100 because Arg-based salt bridges were reported to be an important factor for thermostability of protein structure.

Gluconacetobacter diazotrophicus Pal5 is an endophytic diazotrophic bacterium and lives in association with sugarcane plants. Its genome is composed of a circular chromosome of 3,944,163 bp with an average G+C content of 66.19 mol% and two plasmids of 16.6 and 38.8 kb, respectively (Bertalan et al. 2009). The relation to the endophytic lifestyle such as nitrogen fixation, plant growth promotion, sugar metabolism, transport systems, synthesis of auxin, and the occurrence of bacteriocins was revealed based on 3,938 coding sequences. Gene clusters for *gum*-like polysaccharide biosynthesis, *tad* pilus biosynthesis, quorum sensing, modulation of plant growth by indole acetic acid, and mechanisms involved in tolerance to acidic conditions may be related to the sugarcane endophytic and plant growth-promoting traits of *G. diazotrophicus*. An accessory component of at least 851 genes was most likely acquired by horizontal gene transfer, distributing in genome islands.

Gluconacetobacter hansenii ATCC 23769 is a model organism for cellulose biosynthesis, and its genome consists of 3,547,122 bp with a G+C content of 59 mol% (Iyer et al. 2010). The genome contains 3,351 genes, of which 3,308 are protein-encoding genes, accounting for 84 % of the genome. The genes encoding proteins involved in cellulose synthesis are in an operon consisting of *ascAB*, *acsC*, and *acsD*. The genome also contains three genes encoding diguanylate cyclase, which catalyzes the formation of cyclic di-GMP, the second messenger in bacteria that functions as an allosteric activator of cellulose synthase *AcsAB*.

The genome of *Gluconacetobacter xylinus* NBRC 3288, which is a cellulose-not-producing strain isolated from vinegar in Japan, consists of a single circular chromosome of 3,136,818 bp with a G+C content of 60.92 mol% and seven distinct plasmids (2,218–255,866 bp) (Ogino et al. 2011). The genome includes 3,195 protein-encoding ORFs, five copies of rRNA operons, and 60 genes encoding tRNAs. The genome of *G. xylinus* NBRC 3288 includes 11 genes related to cellulose synthesis within two operons. The cellulose-synthesizing operon contains the endoglucanase and the cellulose synthase catalytic subunit. On the other hand, a nonsense mutation causes splitting of *bcsB* gene that is indispensable for cellulose production. This single mutation might affect the cellulose synthesis of this strain. *Gluconacetobacter xylinus* NBRC 3288 was reidentified as *Gluconacetobacter medellinensis* NBRC 3288^{T} (= LMG 1693^{T}) (Castro et al. 2013).

Gluconobacter oxydans is known for its incomplete oxidation of a wide range of alcohols, sugars, and acids in a bioprocess. The chromosome of *G. oxydans* 621H consists of 2,702,173 bp with a G+C content of 60.8 mol% and contains 2,432 ORFs (Prust et al. 2005). In addition, five plasmids are identified that comprised 232 ORFs. *G. oxydans* 621H contains many membrane-bound dehydrogenases that are part of a strategy to thrive and to survive in nutrient-rich environments. The enzymes rapidly form sugars or sugar acids that are difficult to assimilate for the most microorganisms, whereas *G. oxydans* can easily take advantage of these substrates. The oxidized compounds are taken up and reduced in the cytoplasm, the reactions being catalyzed by a soluble set of oxidoreductases. Furthermore, incomplete oxidation of D-glucose and other aldoses leads to the formation of sugar acids and to a decrease in the pH value, thereby preventing propagation of many other microorganisms. The respiratory chain is designed to accelerate this process because proton-translocating abilities are limited. This prevents an increase in the electrochemical membrane potential that would otherwise lead to the inhibition of membrane-bound redox reactions. However, the low energy-transducing efficiency results in very low growth yields. The inability to degrade D-glucose and other sugars via the Embden-Meyerhof pathway and the incomplete citrate cycle contribute to the inadequate utilization of the substrates. Although the respiratory chain of *G. oxydans* is found to be rather simple, the organism contains many membrane-bound dehydrogenases that are critical for the incomplete oxidation of biotechnologically important substrates.

The complete genome of *Gluconobacter oxydans* H24 consists of a circular chromosome and a plasmid (Ge et al. 2013). The chromosome is composed of 3,602,424 bp with a G+C content of 56.25 mol%. The plasmid contains 213,808 bp with a G+C content of 56.14 %. There are a total of 3,732 putative ORFs (3,469 in the chromosome and 263 in the plasmid). The most significant feature of *G. oxydans* H24 is its high L-sorbose productivity. Two different membrane-bound and one cytoplasmic sorbitol dehydrogenases are identified from the genome of *G. oxydans* H24. The gene cluster responsible for the synthesis of the cofactor pyrroloquinoline quinone (PQQ) and several genes encoding sorbose dehydrogenase, sorbose reductase, sorbosone dehydrogenase, glucose dehydrogenase, and other enzymes were annotated.

The complete genome of *Gluconobacter oxydans* WSH-003 contains a single circular chromosome of 3,364,884 bp with a G+C content of 56.77 mol% (Gao et al. 2012). The draft genome harbors 3,705 predicted protein-coding sequences (CDSs); a total of 48 tRNA genes and one 16S-23S-5S rRNA are identified. The gene clusters encoding D-sorbitol dehydrogenase

and responsible for synthesis of the cofactor pyrroloquinoline quinone are identified. In addition, several genes encoding aldehyde dehydrogenase, alcohol dehydrogenase, glucose dehydrogenase, formaldehyde dehydrogenase, etc., are annotated.

The genome of *Granulibacter bethesdensis* CGDNIH1, an emerging human pathogenic acetic acid bacterium, is composed of a single circular chromosome of 2,708,355 bp with a G+C content of 59.07 mol% (Greenberg et al. 2007). Among 2,437 putative ORFs identified, 1,470 of which share sequence similarity with ORFs in the nonpathogenic but related *G. oxydans* genome. The 967 ORFs are unique to *G. bethesdensis* and potentially important for virulence, adherence, DNA uptake, and methanol utilization. Comparison of *G. bethesdensis* to other known chronic granulomatous disease (CGD) pathogens demonstrated conservation of some putative virulence factors, suggesting possible common mechanisms involved in pathogenesis in CGD. Genotyping of the four patient isolates by the use of a custom microarray demonstrated genome-wide variations in regions encoding DNA uptake systems and transcriptional regulators and in hypothetical ORFs.

The genome of *Acidiphilium* sp. PM consists of a chromosome of 3.98 Mbp with a G+C content of 68 % and nine plasmids (San Martin-Uriz et al. 2011). Metabolic construction revealed the presence of a complete Entner-Doudoroff pathway, instead of the classical Embden-Meyerhof pathway. The pentose phosphate pathway, the tricarboxylic acid cycle, and the Calvin-Benson-Bassham cycle were also found to be complete. This preliminary genome analysis revealed that *Acidiphilium* sp. PM has versatile respiratory metabolisms.

Acidocella sp. MX-AZ02 was isolated from a naturally acidic (pH 2.3) and a heavy metal-containing shallow lake. Its genome was estimated to be 3.6 Mbp with a G+C content of 64.1 mol%, and it carried 3,553 open reading frames (ORFs) (Servín-Garcidueñas et al. 2013). The genome codes for arsenic, chromium, copper, and cobalt-zinc-cadmium transporters, as well as heavy-metal sensor signal transduction histidine kinases and chaperones. Carbonic anhydrases are also encoded. The enzyme may provide to cope with the low CO_2 levels in acidic waters.

Roseomonas sp. B5 degrades *N*-acylhomoserine lactone. Its genome contains 471,409,596 bp with a mol% G+C content of 70.5 % (Chen et al. 2012). The genome includes 4,365 ORFs; 51 tRNAs, one complete rRNA operon, and one copy each of a 5S rRNA gene, 23S rRNA gene, and 16S rRNA gene are identified. One predicted protein-CDS encoding 263 amino acids shows 84 % similarity to the reported *attM* gene, and an *N*-acylhomoserine lactones (AHL)-degrading gene is detected.

Phages

A bacteriophage A-1 was isolated from *Gluconobacter oxydans* strain E and characterized to be of type A phage according to Bradley's morphological classification (Bradley 1967; Jucker and Ettlinger 1981; Robakis et al. 1985a; Schocher et al. 1979). Abnormalities in the microbial process for the oxidation of D-sorbitol to L-sorbose by *G. oxydans* were indicated to be caused by probable phage infection (Schocher et al. 1979). Two bacteriophages GW6210 and JW2040 were isolated from decaying apples using *G. oxydans* ATCC 621 and VPI 204JW, respectively (Robakis et al. 1985b). Phages GW6210 and JW2040 belonged to groups A and C of Bradley's classification, respectively. Phage GW6210 is unusually large and has a head diameter of 170 nm. Both the phages contain a double-stranded DNA. The G+C content of the DNA of phage GW6210 is 29.3 mol% (*Tm*), and the size of the genome is approximately 250–300 kb. The size of the DNA of phage JW2040 is 37 kb, and the G+C content is 56.5 mol% (Tm).

Bacteriophages were demonstrated in industrial vinegar fermentation (Sellmer et al. 1992; Stamm et al. 1989; Teuber et al. 1987). Phages with hexagonal and icosaedric heads belong to types A and C according to Bradley's classification, respectively. Seven types are morphologically identified based on head sizes, tail lengths, and diameters (Sellmer et al. 1992). Head sizes vary between 60 and 110 nm. The corresponding tail lengths ranged from 99 to 360 nm with tail diameters from 14 to 31 nm.

A bacteriophage, termed ΦAc1, infects strains of the genus *Acidiphilium*. Several of its properties were characterized (Ward et al. 1993). The virion has a lambdoid morphology and is larger than λ. The sedimentation coefficient of the virion is approximately 615S. The nucleic acid of ΦAc1 is a double-stranded DNA, approximately 102 kb in length. ΦAc1 is a temperate phage, and the plaques are turbid. ΦAc1 prophage DNA integrates into the bacterial genome during the temperate growth phase.

A prophage Acm1 was found in *Acidomonas methanolica* strains (Mamat et al. 1995). A 262-bp DNA fragment of phage Acm1 contains three very short open reading frames of 21, 24, and 36 bp. The fragment codes for the synthesis of a trans-acting RNA molecule of 97 nucleotides, designated lbi (lipopolysaccharide biosynthesis-interfering) RNA. This RNA has the ability to form intracellularly rRNA hybrid duplexes with mRNA.

Biochemical Properties

Bioenergetics

Acetic acid bacteria, the obligate aerobes, are biochemically quite unique. The Embden-Meyerhof pathway is not operative for strains assigned to the genera *Acetobacter* and *Gluconobacter*, but instead, the pentose phosphate cycle is functioning (Hauge et al. 1955; Cheldelin 1961; De Ley 1960; Asai 1968). In addition, the strains of the genus *Gluconobacter* lack the TCA cycle, differing from the strains of the genus *Acetobacter*, and the pentose phosphate cycle acts as the only terminal oxidative catabolic pathway. Glucose-6-phosphate dehydrogenase and 6-phosphogluconate dehydrogenase reduce NAD, except for NADP, in the cells of the acetic acid bacteria, and the two dehydrogenases seem to play an important role in the respiratory chain phosphorylation (Cheldelin 1961).

Acetic acid bacteria are also known to accumulate a large quantity of acetic acid from ethanol; dihydroxyacetone from glycerol; D-gluconic acid, 2-keto-D-gluconic acid, and

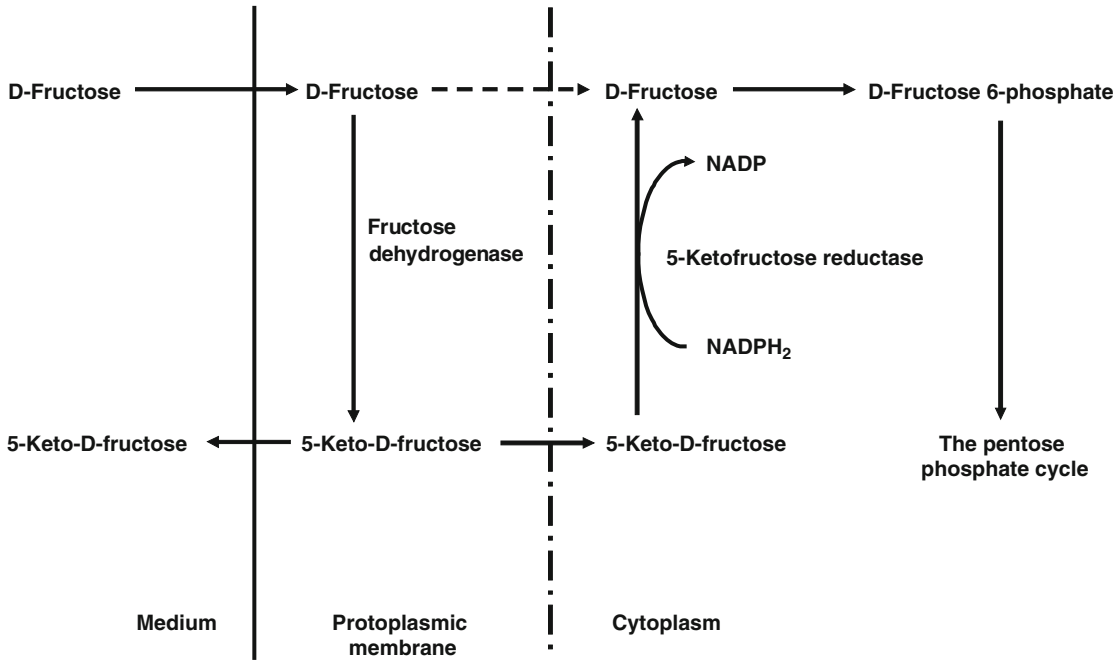

Fig. 1.2

A presumed pathway for the catabolism of D-fructose in *Gluconobacter* species. 5-Ketofructose reductase is active only for reduction, and the reverse reaction is scarcely found. The pH optimum of the reductase is 7.0 (The figure was cited from Yamada et al. (1967b))

5-keto-D-gluconic acid from D-glucose; D-fructose from D-mannitol; and L-sorbose from D-sorbitol. Such a partial or incomplete oxidation of alcohols and sugars is traditionally called "oxidative fermentation" and carried out by the membrane-bound dehydrogenases that are linked to the respiratory chain (De Ley 1960; Cheldelin 1961; Asai 1968).

The production of a large amount of dicarbonyl hexose from D-fructose was found, and the chemical structure of the product was elucidated as 5-keto-D-fructose (Terada et al. 1960). Concerning the catabolism of D-fructose and 5-keto-D-fructose in acetic acid bacteria, the existence of 5-ketofructose reductase [EC 1.1.1.124] and fructose 5-dehydrogenase [EC 1.1.99.11] was reported (Aida and Yamada 1964; Yamada et al. 1966). The membrane-bound fructose 5-dehydrogenase was supposed to be linked to ubiquinone-10 (Yamada et al. 1967a, 1968a). Within the cells of *Gluconobacter* species, the D-fructose was produced again from 5-keto-D-fructose by 5-ketofructose reductase, which was speculated to flow into the pentose phosphate cycle after the phosphorylation of D-fructose (*Fig. 1.2*; Yamada et al. 1967b; Avigad et al. 1966; Asai 1968).

In acetic acid bacteria, several kinds of membrane-bound dehydrogenases are responsible for the oxidation of alcohols and sugars (*Table 1.1*). The dehydrogenases are located in the periplasmic side of the cytoplasmic membrane of the microorganisms (Matsushita et al. 2004; Yakushi and Matsushita 2009, 2010). The direct electron acceptor of the dehydrogenases is ubiquinone in the respiratory chain of the acetic acid bacteria. Alcohol dehydrogenase [EC 1.1.5.5] was first isolated from "*Gluconobacter suboxydans*" IFO 12528 as a homogeneous state and composed of three subunits, in which a cytochrome *c* component was contained (Adachi et al. 1978). The alcohol dehydrogenase isolated from the acetic acid bacterium was then proved to contain three subunits of 72 Kd [pyrroloquinoline quinone (PQQ), heme *c*], 48 Kd (3 hemes *c*), and ~15 Kd (*Fig. 1.3*; Matsushita et al. 1994). On the other hand, glucose dehydrogenase [EC 1.1.5.2] was a monomer of 80 Kd equipped with only PQQ (Matsushita et al. 1994). Glycerol dehydrogenase [EC 1.1.99.22] exceptionally showed a wide range of substrate specificity and oxidized glycerol, D-arabitol and D-sorbitol, respectively, to dihydroxyacetone, D-xylulose, and L-sorbose under the Bertrand-Hudson law. The dehydrogenase had two subunits comprised of 80 Kd (PQQ) and ~15 Kd. Fructose 5-dehydrogenase [EC 1.1.99.11] was a trimer composed of three subunits of 67 Kd [FAD (*Table 1.1*)], 51 Kd (3 hemes *c*), and ~20 Kd (Ameyama et al. 1981; Kawai et al. 2013).

Several types of terminal oxidases were reported in the respiratory chain of acetic acid bacteria (Matsushita et al. 2004). "*Gluconobacter suboxydans*" NBRC 12528 (= IFO 12528; now *Gluconobacter oxydans*) was reported to have the respiratory chain branched to the energy-producing cytochrome *o* (bo_3), a quinol oxidase, which consisted of four nonidentical subunits and contained heme *b*, heme *o*, and copper atom as the prosthetic group, as well as to the less energy-producing cyanide-insensitive quinol oxidase (*Fig. 1.3*; Matsushita et al. 1987). The purified cyanide-insensitive quinol oxidase consisted of two nonidentical subunits, contained heme *b* and heme *d* but no Cu atom, and had the pH optimum of 5–6, in contrast to the pH optimum of 7 of cytochrome *o* (bo_3), and the apparent

Table 1.1
Membrane-bound primary dehydrogenases in acetic acid bacteria

Dehydrogenase	Substrate	Product	Subunit structure and prosthetic group	Acceptor	Species
Alcohol dehydrogenase [EC 1.1.5.5]	Ethanol	Acetaldehyde	72 Kd (PQQ/heme c), 48 Kd (3 hemes c), ~15 Kd	Ubiquinone	*'G. suboxydans'* (1) *A. aceti* (1)
Aldehyde dehydrogenase [EC 1.2.99. 7][a]	Acetaldehyde	Acetic acid	84 Kd (Iron sulfur?/ molybdopterin cytosine dinucleotide?), 49 Kd (3 hemes c), ~17Kd	Ubiquinone[b]	*'G. suboxydans'* (1) *'A. polyoxogenes'* (1), *A. europaeus* (8)
Glucose dehydrogenase [EC 1.1.5.2]	D-Glucose	D-Glucono-δ-lactone	80 Kd (PQQ)	Ubiquinone	*'G. suboxydans'* (1)
Gluconate 2-dehydrogenase [EC 1.1.99.3][a]	D-Gluconate	2-Keto-D-gluconate	64 Kd (FAD), 45 Kd (3 hemes c), ~21 Kd	Ubiquinone	*'G. dioxyacetonicus'* (1)
2-Keto-D-gluconate dehydrogenase [EC 1.1.99.4][a]	2-Keto-D-gluconate	2,5-Diketo-D-gluconate	61 Kd(FAD), 47 Kd (3 hemes c), ~25 Kd	Ubiquinone	*'G. melanogenes'* (1)
Fructose 5-dehydrogenase [EC 1.1.99. 11][a]	D-Fructose	5-Keto-D-fructose	67 Kd (FAD[c]), 51 Kd (3 hemes c), ~20 Kd	Ubiquinone	*'G. industrius'* (1, 7)
L-Sorbose 5-dehydrogenase [EC 1.1.99.12]	L-Sorbose	5-Keto-D-fructose		Ubiquinone?	*'G. suboxydans'* (2)
L-Sorbose 1-dehydrogenase [EC 1.1.99.32][a]	L-Sorbose	L-Sorbosone	58 Kd (FAD)	Ubiquinone	*G. oxydans* (1), *'G. melanogenus'* (5)
L-Sorbosone dehydrogenase	L-Sorbosone	2-Keto-L-gulonate	48 Kd?	Ubiquinone?	
Sorbitol dehydrogenase [EC 1.1.99. 21][a]	D-Sorbitol	L-Sorbose	63 Kd (FAD), 51 Kd (3 hemes c), ~17 Kd	Ubiquinone	*'G. suboxydans'* (1)
Glycerol dehydrogenase [EC 1.1.99. 22][a]	Glycerol, *meso*-Erythritol, D-Arabitol, D-Sorbitol, etc.	Dihydroxyacetone, L-Erythrose, D-Xylulose, L-Sorbose, etc.	80 Kd (PQQ), ~14 Kd	Ubiquinone	*'G. industrius'* (3), *'G. suboyxdans'* (4, 6), *Gluconobacter* (9).

For more details, see Matauahita et al. (2004), and Yakushi and Matsushita (2009, 2010)
[a]The electron acceptor was proved to be ubiquinone. Therefore, the dehydrogenases will be classified as EC class 1.1.5
[b]Unpublished data of Yakushi et al. (from Dr. Matsushita)
[c]The prothsthetic group is assumed to be FAD, but it is not proved biochemically
References: (1), Matsushita et al. (1994); (2), Sato et al. (1969b); (3), Ameyama et al. (1985); (4), Adachi et al. (2001); (5), Sugisawa et al. (1991); (6), Sugisawa and Hoshino (2002); (7), Kawai et al. (2013); (8), Thurner et al. (1997); and (9), Matsushita et al. (2003)

maximum velocity of the cyanide-insensitive quinol oxidase was much 17-fold higher than that of cytochrome *o* (bo_3) (Miura et al. 2013). The cyanide-insensitive quinol oxidase may play some important roles in the rapid oxidation of substrates under acidic growth conditions. The other types of cytochromes in acetic acid bacteria were cytochrome *a*1 (ba_3), cytochrome *d* (*bd*), and cytochrome *co* (cbb_3) (Matsushita et al. 2004). The cytochrome *a*1 is characterized as cytochrome *ba*-type ubiquinol oxidase, which consisted of four subunits and contained one mol each of heme *a*, heme *b*, and Cu atom. Interestingly, *Acetobacter aceti* IFO 3284 produced either one of the different terminal oxidases under the different culture conditions (Matsushita et al. 1990; Sievers and Swings 2005b). The cells of rough colony type of the strain predominantly produce cytochrome *a*1 (ba_3) under shaking culture, while the cells of smooth colony type of the strain predominantly produce cytochrome *o* (bo_3) under static culture.

On the oxidative fermentation of 5-keto-D-fructose from D-sorbitol by "*Gluconobacter suboxydans*" strain 1, L-sorbose and 5-keto-D-fructose were accumulated, and the biphasic

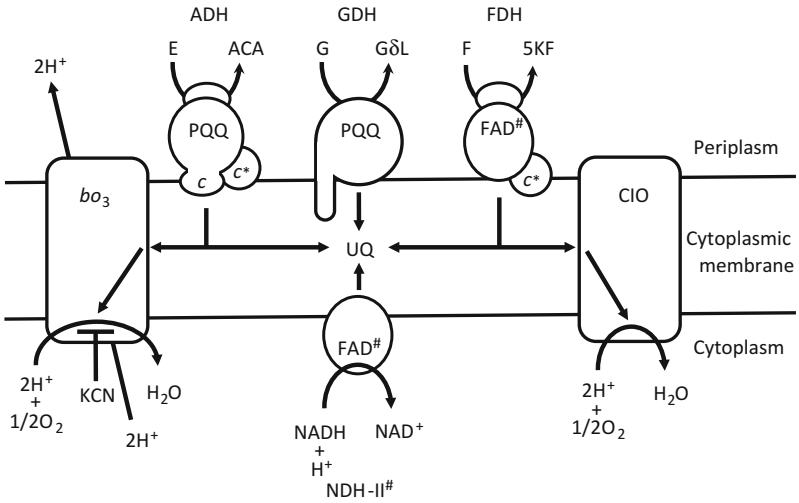

Fig. 1.3

The membrane-bound dehydrogenases and the respiratory chain of *'Gluconobacter suboxydans'*. The dehydrogenases, e.g., alcohol dehydrogenase, glucose dehydrogenase and fructose 5-dehydrogenase that contain prosthetic groups such as PQQ, FAD and heme *c* generally reduce ubiquinone, an electron acceptor. The resulting electrons are then transferred either to the energy-producing cytochrome *o* (*bo_3*), a quinol oxidase or to the less energy-producing cyanide-insensitive quinol oxidase. For more details, see the references (Matsushita et al. 2004; Yakushi and Matsushita 2009, 2010). Abbreviations: *ADH* alcohol dehydrogenase, *GDH* glucose dehydrogenase, *FDH* fructose 5-dehydrogenase, *E* ethanol, *ACA* acetaldehyde, *G* D-glucose, *GδL* D-glucono-δ-lactone, *F* D-fructose, *5KF* 5-keto-D-fructose, *FAD#* the presence of FAD is assumed but not proved biochemically, *NDH-II#* Type-II NADH dehydrogenase, which is not purified; *bo_3*, cytochrome *bo_3*; *CIO* cyanide-insensitive terminal quinol oxidase, *c* heme *c*; *c cytochrome c**

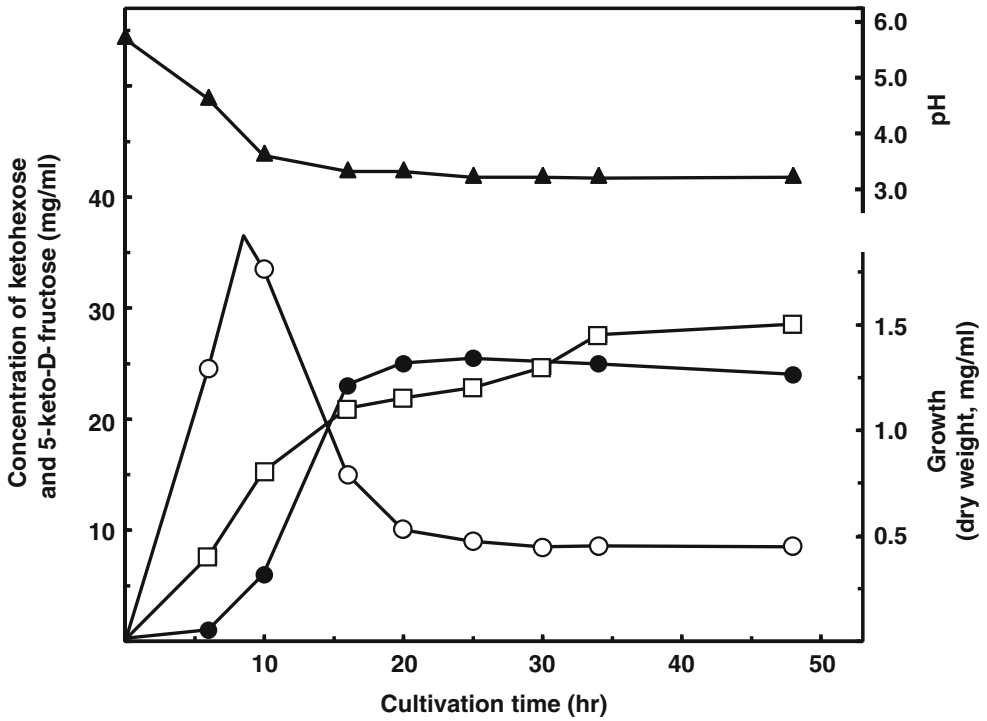

Fig. 1.4

The chemical changes during the oxidation of D-sorbitol by *'Gluconobacter suboxydans'*. '*Gluconobacter suboxydans*' strain 1 was cultured in 500 ml of a medium containing 4.0 % D-sorbitol and 2.0 % defatted soybean extract in a 5-l conical flask. The cultivation was carried out at 30 °C on a rotary shaker at 160 rpm (The figure was cited from Sato et al. (1969a). ○, L-sorbose; ●, 5-keto-D-fructose, □, growth; ▲, pH)

growth was generally seen (Fig. 1.4; Sato et al. 1969a). L-Sorbose accumulation reached the maximum 10 h later after inoculation, and then the amount of L-sorbose decreased. The production of 5-keto-D-fructose started 7 h later. After 16 h, the first growth of the organism mostly stopped, and the organism showed a temporarily stationary phase for approximately 10 h. Of the two steps of the D-sorbitol oxidation, glycerol dehydrogenase [EC 1.1.99.22] but not sorbitol dehydrogenase [EC 1.1.99.21] first appeared to function (Soemphol et al. 2008), and L-sorbose 5-dehydrogenase [EC 1.1.99.12] was secondly concerned (Sato et al. 1969b), viz., L-sorbose production from D-sorbitol and 5-keto-D-fructose production from L-sorbose. The second growth began after 25 h from inoculation. The first growth is due to the oxidations of D-sorbitol to L-sorbose and then to 5-keto-D-fructose, which seems to be coupled with the respiratory chain phosphorylation, and the second growth is assumed to be due to the reduction of 5-keto-D-fructose to D-fructose, followed by phosphorylation to D-fructose 6-phosphate and by flowing into the pentose phosphate cycle, the terminal oxidative catabolic pathway of the organism. The biphasic growth based on the oxidation of ethanol to acetic acid and then to carbon dioxide and water can be seen in vinegar production by an *Acetobacter* strain (Matsushita et al. 2004).

Nitrogen Fixation

Acetic acid bacteria capable of fixing molecular nitrogen seemed to be restricted only to those of the three genera, *Gluconacetobacter*, *Swaminathania*, and *Acetobacte*r (Pedraza 2008).

Acetobacter diazotrophicus (= *Gluconacetobacter diazotrophicus*) was first reported as a nitrogen-fixing acetic acid bacterium (Gillis et al. 1989; Cavalcante and Döbreiner 1988). Strains of the species were found inside sugarcane plant tissues. As the second examples, *Gluconacetobacter johannae* and *Gluconacetobacter azotocaptans* were found to be associated with coffee plants (Fuentes-Ramírez et al. 2001). *Swaminathania salitolerans* was described as a salt-tolerant, nitrogen-fixing, and phosphate-solubilizing bacterium (Loganathan and Nair 2004). *Acetobacter peroxydans* and *Acetobacter nitrogenifigens* were isolated, respectively, from wetland rice plants and kombucha tea (Muthukumarasamy et al. 2005; Dutta and Gachhui 2006).

Recently, *Asaia* species, including *Asaia bogorensis* and *Asaia siamensis*, were reported to have the capability of nitrogen fixation (Samaddar et al. 2011). *Nguyenibacter vanlangensis* found in rhizosphere or root of Asian rice plants showed the growth on nitrogen-free LGI medium. The strains of the species would be candidates able to fix molecular nitrogen (Vu et al. 2013).

The nitrogenase of *Gluconacetobacter diazotrophicus* was immunochemically investigated from the viewpoint of the protection against molecular oxygen (Ureta and Nordlund 2002). The nitrogenase in the organism could be protected by conformational mechanisms involving a putative FeSII protein operating when cells were subjected to sudden increases in oxygen pressure, together with increased respiration of the organism under diazotrophic condition.

Different genes involved in the N_2-fixing process and their regulation such as *nifHDK*, *nifA*, *nifB*, *nifV*, *nifE*, and *ntrBC* were identified in the nitrogenase of *Gluconacetobacter diazotrophicus* (Sevilla et al. 1997). As the results of sequence analysis, the genes were organized into eight transcriptional units, and the overall arrangement of genes was most likely that of the *nif-fix* cluster in *Azospirillum brasilense*, while the individual gene products were more similar to those in the species of *Rhizobiaceae* or in *Rhodobacter capsulatus* (Lee et al. 2000).

Swaminathania salitolerans strains reduced acetylene to ethylene and showed the expected 450-bp amplification product corresponding to *nifD* (Loganathan and Nair 2004). In the type strain of *Acetobacter nitrogenifigen*s, a 336-bp region product encoding dinitrogenase reductase, *nifH* was detected (Dutta and Gachhui 2006). Likewise, strains of *Asaia* species, including *Asaia bogorensis* and *Asaia siamensis*, were confirmed to have *nifH* (Samaddar et al. 2011).

Phenotypic Analyses

Currently, the family *Acetobacteraceae* is basically consists of two groups, an acetous group and an acidophilic group. Additionally, the genus *Frateuria* is listed in this section. The genus resembles biochemically the genera in acetic acid bacteria, but it locates in the *Gammaproteobacteria* (Swings and Sievers 2005).

The Acetous Group

Acetic acid bacteria are included in the family *Acetobacteraceae* on the basis of 16S rRNA sequence analysis, considering phenotypic and chemotaxonomic characteristics (Sievers and Swings 2005a). Thus, acetic acid bacteria can be summarized as follows: Acetic acid bacteria are Gram negative, rod-shaped, peritrichously or polarly flagellated when motile, and strictly aerobic. Catalase is positive (negative for *Acetobacter peroxydans*), and oxidase is negative. The bacteria are able to oxidize sugars, sugar alcohols, and alcohols to corresponding acids. However, phenotypic characteristics of acetic acid bacteria are diverse among the genera. Further, the table consisting of the phenotypic characteristics and species names is not always filled with data based on common characteristics (Table 1.2). Differentiation of the species based on phenotypic characteristics comes into being incomplete. Therefore, analysis of ribosomal RNA (16S rRNA and others) sequences and determination of DNA-DNA similarity are recommended for correct identification of strains. The genus *Acetobacter* has ubiquinone 9 (Q-9), but other genera have Q-10. The cellular fatty acid composition consists of $C_{18:1}\omega7c$ as a major acid and $C_{16:0}$ and $C_{14:0}$ 2-OH as minor acids (Yamada et al. 1981a; Iino et al. 2012b; Vu et al. 2013).

Several strains of acetic acid bacteria are used for the production of vinegar, gluconic acid, vitamin C, etc. The bacteria are widely distributed in vinegar and other acetous substances (wine, beer, sake, and other fermented products), fruits and sugary substances, and flowers.

G+C content of type strain			63.1					
Isolation sources	Many kinds of vinegar, Kombucha, nata de coco, cider, apple juice, beet juice, cherry	Palm brown sugar, ragi	Flower of red ginger (*Alpinia purpureus*)	Flower of lantana (*Lantana camera*), candle bush *(Senna alata*)	Rhizosphere and roots of Asian rice	Pollens of flowers	Wild rice (*Proteresia coarctata*)	Soil in Thailand
Remarks		Production of fructan from sucrose				Osmophilic. *no growth on ordinary glutamate agar, but grown on the medium supplemented with 7 % glutamate.	Fix nitrogen and solubilize phosphate	

Symbols: +, positive in most species; +w, weakly positive; +/−, positive in more than half species; −/+, negative in more than half species; v, variable; and −, negative in most species

Acetobacter Beijerinck 1898

A.ce.to.bac'ter. L. n. *acetum*, vinegar; N.L. masc. n. *bacter*, rod; N.L. masc. n. *Acetobacter*, vinegar rod.

The genus *Acetobacter* is the oldest in the history of acetic acid bacteria. The role of acetic acid bacteria could date back to the study in 1822, in which a living organism was recognized on the film formed on acetifying wine, and was named *Mycoderma* (Persoon 1822). Further, the relationship was mentioned between the film and the process of acetification and the organism was identified as *Ulvina aceti*, but it was an alga (Kützing 1837). Moreover, the relationship was established between the microbial film, oxygen, and acetification, but its microbial characteristics were failed to recognize and the organism was described as "little plant", a microscopic fungus, *Mycoderma aceti*. The results were presented in a lecture given in Orleans, which was also published as "Etudes sur la vinaigre" (Pasteur 1868). Following these studies, a cellulose-forming species *Bacterium xylinum* was described (Brown 1886), and *Bacterium aceti*, *Bacterium pasteurianum*, and *Bacterium küzingianum* were isolated from vinegar (Hansen 1894) (see Adams 1998; Asai 1968).

The following comment was described in The Index Bergeyana: [Beijerinck used the vernacular name azijnbacterien for the acetic acid bacteria. Apparently at some time before 1900 the vernacular name was rendered into neo-Latin as *Acetobacter* and finally used in publication. There is no record of its formal proposal as a genus. Kluyver (in) 1940 states: "... It is surprising that neither Beijerinck nor Hoyer proposed in their publications the creation of a new genus for the acetic acid bacteria... There can be no doubt that, in any case morally, but probably also according to the code of Botanical Nomenclature, Beijerinck is to be considered as the author of the genus *Acetobacter* as it occurs today..." The nomenclatural status of *Acetobacter* Beijerinck has been referred to the Judicial Commision of the International Commitee] (Buchanan et al. 1966). Kluyver express the same comment in the biography of Beijerinck (Kluyver 1983). The Approved Lists of Bacterial Names cited the genus *Acetobacter* as *Acetobacter* Beijerinck 1898 (Skerman et al. 1980).

Asai divided acetic acid bacteria into two genera: One group comprised the species oxidizing ethanol more actively than D-glucose and was motile with peritrichous flagella and Asai named them the genus *Acetobacter*, and the other consisted of the species oxidizing D-glucose more strongly than ethanol and was motile with polar flagella and Asai named them the genus *Gluconobacter* (Asai 1935, 1968).

Since then, the two genera have been the core in acetic acid bacteria. The genus *Acetobacter* is clearly differentiated from the genus *Gluconobacter* by quinone systems, abovementioned biochemical behaviors, and oxidation of acetate and lactate. The genus *Acetobacter* is the type genus of the family *Acetobacteraceae* (Sievers and Swings 2005b) (details are shown below in the section *Gluconobacter*).

The type species is *Acetobacter aceti* (Pasteur 1864) Beijerinck 1898. The closest neighbors are the genera *Gluconobacter, Neokomagataea*, and *Saccharibacter* (*Fig. 1.1*). Currently, the genus contains 23 species.

Acetobacter Beijerinck 1898

Cells are Gram negative, ellipsoidal to rod-shaped, measuring 0.4–1.0 by 1.2–3.0 μm, rarely longer cells. Cells occur singly or short chains and occasionally long chains. Some strains in *Acetobacter cerevisiae* produce involution forms like swollen cells. Peritrichously flagellated when motile. Exceptionally, *Acetobacter nitrogenifigens* has polar flagella. Endospores are not produced. Colonial appearance varies with cultural conditions. Generally colonies are circular, smooth, entire, convex, cream color to beige, opaque, and butyrous on glucose-yeast extract-peptone agar.

Strictly aerobic. Catalase positive (negative in *Acetobacter peroxydans*), and oxidase negative. Acetic acid is produced from ethanol. Acetate and lactate are oxidized. Usually dihydroxyacetone is not produced from glycerol, but produced by a few species. D-Gluconate and 2-keto-D-gluconate are produced from D-glucose by most of the species, and 5-keto-D-gluconate is produced by a few species. 2,5-Diketo-D-gluconate is not produced.

Generally *Acetobacter* species produce acid from a rather limited number of sugars, sugar alcohols, and alcohols. Acid production is variable with species and strains on L-arabinose, D-xylose, and D-galactose. Acid is not produced from D-fructose, lactose, maltose, melibiose, sucrose, trehalose, raffinose, D-mannitol, and sorbitol. Usually ammoniac nitrogen is not utilized. Oxidation of methanol is described by some species, but the precise test is needed (Suzuki et al. 2009). Real cellulose is not produced. The activity of nitrogen fixation is described only about *A. nitrogenifigens*.

Optimal growth temperature is around 30 °C. Most of species are able to grow at 37 °C, but not at 45 °C. They are able to grow between pH 3.5 and 8.0. Most of species are unable to grow in the presence of 30 % glucose. Growth does not occur in the presence of 10 % ethanol. The major cellular fatty acid is $C_{18:1}\omega7c$, and minor components are $C_{16:0}$, $C_{16:0}$ 2-OH, $C_{14:0}$, $C_{14:0}$ 2-OH, and $C_{19:0}$ cyclo ω8c. The major ubiquinone is Q-9. The G+C content of DNA is 53.5–60.7 mol%.

Acetobacter strains are widely distributed in vinegars, fermented foods (wine, beer, sake, nata de coco, pickles, palm wine, moromi, curd of tofu, tempeh, etc.), fruits (guava, sapodilla, star fruit, mangosteen, banana, papaya, durian, etc.), and flowers (canna, etc.). Generally, *Acetobacter lovaniensis*, *A. indonesiensis*, *A. orleanensis*, *A. pasteurianus*, and *A. tropicalis* were isolated in descending order from fermented foods, fruits, and flowers in Indonesia (Lisdiyanti et al. 2001).

Acetobacter aceti (Pasteur 1864) Beijerinck 1898

Data of this species are fragmentally recorded. Therefore, the characteristics are mainly cited from those described for the type strain of this species (Lisdiyanti et al. 2000), referring to other papers (Gosselé et al. 1983b).

Type strain: ATCC 15973^T (= CCUG 18122^T = CIP 103111^T = DSM 3508^T = ICMP 8807^T = JCM 7641^T = LMG 1261^T = LMG 1504^T = NCCB 23001^T = NBRC 14818^T = NCIMB 8621^T), isolated from beechwood

shavings of a vinegar plant. The G+C content of DNA of the type strain is 57.2 mol%.

Acetobacter cerevisiae Cleenwerck, Vandemeulebroecke, Janssens, and Swings 2002

Characteristics are the same as those described for the species (Cleenwerck et al. 2002).

Type strain: LMG 1625^T (= ATCC 23765^T = DSM 14362^T = JCM 17273^T = LMG 1625^T = NCIMB 8894^T), isolated from beer (ale) in storage at Toronto, Canada (Kozulis and Parsons 1958). The G+C content of DNA of the type strain is 57.6 mol%.

Acetobacter cibinongensis Lisdiyanti, Kawasaki, Seki, Yamada, Uchimura, and Komagata 2002

Characteristics are the same as those described for the species (Lisdiyanti et al. 2001).

Type strain: 4H-1^T (= CIP 107380^T = DSM 15549^T = JCM 11196^T = NBRC 16605^T), isolated from mountain soursop (*Annona montana*) in Indonesia. The G+C content of DNA of the type strain is 54.5 mol%.

Acetobacter estunensis (Carr 1958) Lisdiyanti, Kawasaki, Seki, Yamada, Uchimura, and Komagata 2001

Characteristics are the same as those described for the species (Lisdiyanti et al. 2000).

Type strain: NBRC 13751^T (= ATCC 23753^T = DSM 4493^T = JCM 21172^T = LMG 1626^T = NCIMB 8935^T), isolated from cider, Bristol. The G+C content of DNA of the type strain is 59.7 mol%.

Acetobacter fabarum Cleenwerck, Gonzalez, Camu, Engelbeen, De Vos, and De Vuyst 2008

Characteristics are the same as those described for the species (Cleenwerck et al. 2008).

Type strain: 985^T (= R-36330^T = DSM 19596^T = LMG 24244^T), isolated from a Ghanaian cocoa heap fermentation. The G+C content of DNA of the type strain is 57.6 mol%.

Acetobacter farinalis Tanasupawat, Kommanee, Yukphan, Muramatsu, Nakagawa, and Yamada 2011

Characteristics are the same as those described for the species (Tanasupawat et al. 2011a).

Type strain: G360-1^T (= BCC 44845^T = NBRC 107750^T = PCU 319^T), isolated from fermented rice flour. The G+C content of DNA of the type strain is 56.3 mol%.

Acetobacter ghanensis Cleenwerck, Camu, Engelbeen, De Winter, Vandemeulebroecke, De Vos, and De Vuyst 2007

Characteristics are the same as those described for the species (Cleenwerck et al. 2007).

Type strain: R-29337^T (= 430A^T = DSM 18895^T = LMG 23848^T), isolated from a traditional heap fermentation of Ghanaian cocoa beans. The G+C content of DNA of the type strain is 57.3 mol%.

Acetobacter indonesiensis Lisdiyanti, Kawasaki, Seki, Yamada, Uchimura, and Komagata 2001

Characteristics are the same as those described for the species (Lisdiyanti et al. 2000).

Type strain: 5H-1^T (= JCM 10948^T = LMG 19824^T = NBRC 16471^T = NRIC 0313^T), isolated from fruit of zirzak (*Annona muricata*) in Indonesia. The G+C content of DNA of the type strain is 53.7 mol%.

Acetobacter lovaniensis (Frateur 1950) Lisdiyanti, Kawasaki, Seki, Yamada, Uchimura, and Komagata 2001

Characteristics are the same as those described for the species (Lisdiyanti et al. 2000).

Type strain: NBRC 13753^T (=ATCC 12875^T= DSM 4491^T = JCM 17121^T = LMG 1579^T = LMG 1617^T = NCIMB 8620^T), isolated from sewage on soil by Frateur, 1929. The G+C content of DNA of the type strain is 58.6 mol%.

Acetobacter malorum Cleenwerck, Vandemeulebroecke, Janssens, and Swings 2002

Characteristics are the same as those described for the species (Cleenwerck et al. 2002).

Type strain: LMG 1746^T (= DSM 14337 = JCM 17274^T), isolated from a rotten apple in Ghent, Belgium (Gosselé et al. 1983a, b). The G+C content of DNA of the type strain is 57.2 mol%.

Acetobacter nitrogenifigens Dutta and Gachhui 2006

Characteristics are the same as those described for the species (Dutta and Gachhui 2006).

Type strain: RG1^T (= LMG 23498^T = MTCC 6912^T), isolated from kombucha tea. The G+C content of DNA of the type strain is 64.1 mol%.

Acetobacter oeni Silva, Cleenwerck, Rivas, Swings, Trujillo, Willems, and Velázquez 2006

Characteristics are the same as those described for the species (Silva et al. 2006).

Type strain: B13^T (= CECT 5830^T = LMG 21952^T), isolated from spoiled red wine of the Dão region, Portugal. The G+C content of DNA of the type strain is 58.1 mol%.

Acetobacter okinawensis Iino, Suzuki, Kosako, Ohkuma, Komagata, and Uchimura 2013

Characteristics are the same as those described for the species (Iino et al. 2012a).

Type strain: 1-35^T (= JCM 25146^T = LMG 26457^T = NRIC 0658^T), isolated from a piece of the stem of sugarcane, Okinawa, Japan. The G+C content of DNA of the type strain is 59.3 mol%.

Acetobacter orientalis Lisdiyanti, Kawasaki, Seki, Yamada, Uchimura, and Komagata 2002

Characteristics are the same as those described for the species (Lisdiyanti et al. 2001).

Type strain: 21 F-2^T (= CIP 107379^T = DSM 15550^T = JCM 11195^T = NBRC 16606^T = NRIC 0481^T), isolated from canna flower (*Canna hybrida*) in Indonesia. The G+C content of DNA of the type strain is 52.3 mol%.

Acetobacter orleanensis (Henneberg 1906) Lisdiyanti et al. 2001

Characteristics are the same as those described for the species (Lisdiyanti et al. 2000).

Type strain: NBRC 13752^T (= ATCC 12876^T = CCUG 18126^T = DSM 4492^T = JCM 7639^T = LMG 1583^T = NCCB 31003^T = NCIMB 8622^T), isolated from beer by Frateur in 1929. The G+C content of DNA of the type strain is 58.6 mol%.

Acetobacter papayae Iino, Suzuki, Kosako, Ohkuma, Komagata, and Uchimura 2013

Characteristics are the same as those described for the species (Iino et al. 2012a).

Type strain: 1-25^T (= JCM 25143^T = LMG 26456^T = NRIC 0655^T), isolated from a papaya fruit, Okinawa, Japan. The G+C content of DNA of the type strain is 60.5 mol%.

Acetobacter pasteurianus (Hansen 1879) Beijerinck and Folpmers 1916

Data of this species are fragmentally recorded. Therefore, the characteristics are mainly cited from those described for the type strain of this species (Lisdiyanti et al. 2000), referring to other paper (Gosselé et al. 1983b).

Type strain: LMG 1262^T (=ATCC 33445^T = CCUG 18125^T = CIP 103108^T = DSM 3509^T = JCM 7640^T = LMD 22.1^T = LMG 1262^T = NCCB 22001^T), isolated from beer, Netherlands. The G+C content of DNA of the type strain is 52.7 mol%.

Acetobacter peroxydans Visser't Hooft 1925

Data of this species are fragmentally recorded. Therefore, the characteristics are mainly cited from those described for the type strain of this species (Lisdiyanti et al. 2000), referring to other paper (Gosselé et al. 1983b).

Type strain: NBRC 13755^T (=ATCC 12874^T = JCM 25077^T = LMG 1635^T = NCCB 88049^T = NCCB 89009^T), isolated from ditchwater, Delft, Netherlands. The G+C content of DNA of the type strain is 60.3 mol%.

Acetobacter persici Iino, Suzuki, Kosako, Ohkuma, Komagata, and Uchimura 2013

Characteristics are the same as those described for the species (Iino et al. 2012a).

Type strain: T-120^T (= JCM 25330^T = LMG 26458^T), isolated from a peach fruit, Okinawa, Japan. The G+C content of DNA of the type strain is 58.7 mol%.

Note: The original spelling of the specific epithet, *persicus*, has been corrected on validation according to Rule 61.

Acetobacter pomorum Sokollek, Hertel, and Hammes 1998

Characteristics are the same as those described for the species (Sokollek et al. 1998).

Type strain: LTH 2458^T (= CIP 105762^T = DSM 11825^T = LMG 18848^T), isolated from a submerged cider vinegar fermentation at a factory in the southern part of Germany. The G+C content of DNA of the type strain is 50.5 mol%. *A. pomorum* DSM 11825^T did not indicate the presence of the *maxF* gene and did not grow on methanol (Suzuki et al. 2009).

Acetobacter senegalensis Ndoye, Cleenwerck, Engelbeen, Dubois-Dauphin, Guiro, Van Trappen, Willems, and Thonart 2007

Characteristics are the same as those described for the species (Ndoye et al. 2007).

Type strain: CWBI-B418^T (= DSM 18889^T = LMG 23690^T), isolated from mango fruit in Senegal (sub-Saharan Africa). The G+C content of DNA of the type strain is 56.0 mol%.

Acetobacter syzygii Lisdiyanti, Kawasaki, Seki, Yamada, Uchimura, and Komagata 2002

Characteristics are the same as those described for the species (Lisdiyanti et al. 2001).

Type strain: 9H-2^T (= CIP 107378^T = DSM 15548^T = JCM 11197^T = NBRC 16604^T = NRIC 0483^T), isolated from fruit of Malay rose apple (*Syzygium malaccense*) in Indonesia. The G+C content of DNA of the type strain is 55.3 mol%.

Acetobacter tropicalis Lisdiyanti, Kawasaki, Seki, Yamada, Uchimura, and Komagata 2001

Characteristics are the same as those described for the species (Lisdiyanti et al. 2000).

Type strain: Ni-6b^T (= JCM 10947^T = LMG 19825^T = NBRC 16470^T = NRIC 0312^T), isolated from coconut (*Cocos nucifera*) in Indonesia. The G+C content of DNA of the type strain is 55.9 mol%.

Acidomonas Urakami, Tamaoka, Suzuki, and Komagata 1989. emend. Yamashita, Uchimura, and Komagata 2004

A.ci.do.mo'nas. L. adj. *acidus*, sour, acid; L. fem. n. *monas*, a unit, monad; N.L. fem. n. *Acidomonas*, acidophilic monad.

Establishment of this genus can be traced back to the isolation of methanol-utilizing bacteria from a non-sterile fermentation process for the production of single-cell protein (SCP) from methanol with *Candida* species (Steudel et al. 1980). The strains were identified as a new species, *Acetobacter methanolicus*, on the basis of the growth on methanol and ethanol at a low initial concentration (Uhlig et al. 1986). Later, the genus *Acidomonas* was created for acidophilic, facultatively methylotrophic bacteria, with incorporating *A. methanolicus*, on the basis of DNA-DNA similarity that showed difference from those of *Acetobacter*, *Gluconobacter*, *Acidiphilium*, and *Thiobacillus* (Urakami et al. 1989).

The phylogenetic relationship of the genus *Acidomonas* to acetic acid bacteria (the family *Acetobacteraceae*) was first suggested by 5S rRNA sequencing (Bulygina et al. 1992) and subsequently confirmed by 16S rDNA sequences (Yamada et al. 1997; Boesch et al. 1998; Yamashita et al. 2004). The revival of *Acetobacter methanolicus* was once proposed (Sievers et al. 1994b), but a distant relation was recognized between the genus *Acidomonas* and other genera in the family *Acetobacteraceae* (Yamada et al. 1997, 2000; Yamashita et al. 2004).

However, this taxon was problematic because some characteristics differed from the previous descriptions (Uhlig et al. 1986; Urakami et al. 1989). Cells of *Acidomonas methanolica* had a single polar flagellum (or occasionally polar tuft flagella); this differed from a previous study that described peritrichous flagella (Yamashita et al. 2004). A few *Acidomonas methanolica* strains were available from culture collections worldwide. This low number of strains was not enough to verify the diversity of the species. Therefore, novel *Acidomonas* strains were isolated from activated sludge samples of sewage treatment plants, and the genus *Acidomonas* was recharacterized by using the new isolates and strains that were obtained from culture collections and with newly obtained 16S rDNA sequences, DNA-DNA similarities, quinone systems, and phenotypic characteristics. Thus, the genus *Acidomonas* was emended (Yamashita et al. 2004). The genus *Acidomonas* is a methanol-utilizing bacterium in the acetic acid bacteria (Suzuki et al. 2009).

The type species is *Acidomonas methanolica* (Uhlig et al. 1986) Urakami et al. 1989 emend. Yamashita, Uchimura and Komagata 2004. The genus *Acidomonas* is phylogenetically rather distant from known genera in the family *Acetobacteraceae* (*Fig. 1.1*). Currently, the genus comprises a single species, *Acidomonas methanolica*.

Acidomonas Urakami et al. 1989. emend. Yamashita et al. 2004

Cells are Gram negative and short rods with rounded ends, measuring 0.5–0.8 by 1.5–2.0 μm, and are occasionally up to 4 μm in length. Cells occur singly, in pairs, or (rarely) in short chains and are either motile with a single polar flagellum or nonmotile. Cells with polar tuft flagella are found very rarely. Endospores are not produced. Colonies are shiny, smooth, circular, convex, entire, beige to pink, and 1–3 mm in diameter on PYM agar (pH 4.5) after 5 days at 30 °C. Pellicles are produced in PYM broth, but they are not real cellulose.

Aerobic. Catalase positive. Oxidase negative. Acetic acid is produced from ethanol. Acetate is oxidized, but lactate is not or only weakly oxidized. Dihydroxyacetone is not produced from glycerol. D-Gluconate is produced from D-glucose, but 2-keto-, 5-keto-, or 2,5-diketo-D-gluconate does not accumulate in culture media. Acid is produced from L-arabinose, D-xylose, D-ribose, D-galactose, D-mannose, D-glucose, glycerol, *n*-propanol, *n*-butanol, 2-methylpropan-1-ol, ethanol, and methanol, but not from L-rhamnose, D-fructose, sucrose, maltose, lactose, raffinose, trehalose, D-mannitol, inositol, D-sorbitol, dulcitol, or soluble starch. Production of acid from D-arabinose, D-ribose, melibiose, and 2-methylpropan-1-ol varies with strains. Methanol, ethanol, D-glucose, D-mannose, glycerol, and succinic acid are utilized as sole sources of carbon, but D-fructose, L-arabinose, maltose, trehalose, inositol, and D-mannitol are not utilized. Pantothenic acid is an essential requirement for growth. Urease negative.

Growth occurs in the presence of 30 % glucose and 0.35 % acetic acid. Growth occurs at the same extent between pH 3.0 and 8.0; acidotolerant. Growth occurs at 30 °C, but not at 45 °C.

Major cellular fatty acids are $C_{18:1}$ and $C_{16:0}$, and major hydroxyl acids are $C_{16:0}$ 2-OH and $C_{16:0}$ 3-OH. Major ubiquinone is Q-10. The G+C content of DNA ranges from 62 to 63 mol%.

The type strain was isolated from a non-sterile fermentation process for the production of single-cell protein (SCP) from methanol with *Candida* species. *Acidomonas* strains were most abundantly isolated from activated sludge samples, but not from vegetables, fruit, decayed wood and leaves, manure, and paddy soil (Yamashita et al. 2004).

Acidomonas methanolica Urakami, Tamaoka, Suzuki, and Komagata 1989. emend. Yamashita, Uchimura, and Komagata 2004

Characteristics are the same as those described for the emended genus (Yamashita et al. 2004). The type strain: MB 58^T (= DSM 5432^T = IMET 10945^T = JCM 6891^T = LMG 1668^T = NRIC 0498^T), isolated from a non-sterile fermentation process for the production of single-cell protein (SCP) from methanol with *Candida* species. Cells of the type strain are nonmotile, and the G+C content of DNA is 62 mol%.

Ameyamaea Yukphan, Malimas, Muramatsu, Takahashi, Kaneyasu, Potacharoen, Tanasupawat, Nakagawa, Hamana, Tahara, Suzuki, Tanticharoen, and Yamada 2010

A.me.ya.ma'e.a. N. L. fem. n. named after Dr. Minoru Ameyama, Professor Emeritus of Yamaguchi University, Yamaguchi, Japan, who contributed studies of acetic acid bacteria, especially their biochemical and systematic studies.

Ameyamaea strains were isolated from the flowers of red ginger (*Alpinia purpurea*) collected in Chiang Mai, Thailand. They are motile with polar flagella. The strains intensely oxidize acetate to CO_2 and water and weakly oxidize lactate. Gene restriction analysis of 16S rRNA with two restriction endonucleases, TaqI and Hin6I, discriminates the strains from those of other genera in acetic acid bacteria. Thus, the genus *Ameyamaea* was established (Yukphan et al. 2009).

The type species is *Ameyamaea chiangmaiensis* Yukphan et al. 2010. The closest neighbor is the genus *Tanticharoenia* (Fig. 1.1). Currently, the genus contains a single species, *Ameyamaea chiangmaiensis*.

Ameyamaea Yukphan et al. 2010

Cells are Gram negative, rod-shaped, measuring 0.6–0.8 by 1.0–1.8 μm, and motile with polar flagella. The strains grow on glutamate agar (weakly positive) and mannitol agar. Colonies are creamy and smooth with entire margin on glucose-ethanol-peptone-yeast extract-calcium carbonate agar.

Acetic acid is produced from ethanol. Acetate is intensely oxidized to carbon dioxide and water, but lactate is weakly oxidized. Dihydroxyacetone is weakly produced from glycerol. 2-Keto-D-gluconate and 5-keto-D-gluconate are produced from D-glucose.

Acid is produced from D-glucose, D-mannose, D-galactose, D-xylose, D-arabinose (weakly positive), L-arabinose, L-rhamnose, *meso*-erythritol, glycerol (weakly positive), melibiose, and ethanol, but not from D-fructose, L-sorbose, D-mannitol, D-sorbitol, dulcitol, maltose, lactose, sucrose, or raffinose. Growth occurs on D-glucose, D-mannose (very weakly positive), D-galactose, D-xylose, L-arabinose, L-rhamnose, D-fructose, L-sorbose, D-mannitol, D-sorbitol, dulcitol, *meso*-erythritol, glycerol, and melibiose (very weakly positive), but not on D-arabinose, maltose, lactose, sucrose, raffinose, or ethanol. Growth is weak on methanol. Ammoniac nitrogen is very weakly assimilated in the presence of D-glucose, D-mannitol, or ethanol as a carbon source. A water-soluble brown pigment is not produced on glucose-peptone-yeast extract-calcium carbonate agar.

Growth occurs in the presence of 0.35 % acetic acid (w/v). Growth does not occur on 30 % D-glucose (w/v). A major isoprenoid quinone is Q-10. The G+C content of DNA is 66.0–66.1 mol% G+C, with a range of 0.1 mol%.

Ameyamaea chiangmaiensis Yukphan, Malimas, Muramatsu, Takahashi, Kaneyasu, Potacharoen, Tanasupawat, Nakagawa, Hamana, Tahara, Suzuki, Tanticharoen, and Yamada 2010

Characteristics are the same as those described for the species (Yukphan et al. 2009). The type strain is AC04^T (= BCC 15744^T = NBRC 103196^T), isolated from a flower of red ginger (*Alpinia purpurea*) in Chiang Mai, Thailand. The G+C content of DNA of the type strain is 66.0 mol%.

Asaia Yamada, Katsura, Kawasaki, Widyastuti, Saono, Seki, Uchimura, and Komagata 2000

A.sa'i.a. N.L. fem. n. named after Prof. Toshinobu Asai, a Japanese bacteriologist who contributed to the systematics of acetic acid bacteria.

Asaia strains were first isolated from flowers of orchid tree (*Bauhinia purpurea*) and plumbago (*Plumbago auriculata*) and fermented glutinous rice in Indonesia. The strains produced no or only limited amounts of acetic acid from ethanol and did not grow in the presence of 0.35 % acetic acid. Further, they were distant from the known genera in the family *Acetobacteraceae* on the basis of 16S rRNA gene sequences. Therefore, the bacterial strains were classified in a new genus, *Asaia*, on the basis of phenotypical characteristics and the phylogenetic position. The type strain was named *Asaia bogorensis* after the isolation site, Bogor, Indonesia (Yamada et al. 2000).

Since the description of *A. bogorensis*, *A. siamensis* (Katsura et al. 2001), *A. krungthepensis* (Yukphan et al. 2004b), *A. lannensis* (Malimas et al. 2008c), *A. spathodeae*

Table 1.3
Differential characteristics of *Asaia* species

	A. bogorensis	*A. astilbis*	*A. krungthepensis*	*A. lannensis*	*A. platycodi*	*A. prunellae*	*A. siamensis*	*A. spathodea*

Symbols: +, positive in most strains; w, weakly positive; v, variable with strains; and −, negative in most strains

(Kommanee et al. 2010), *A. astilbis* (Suzuki et al. 2010), *A. platycodi* (Suzuki et al. 2010), and *A. prunellae* (Suzuki et al. 2010) have been reported to date. *Asaia* strains were isolated not only from tropical countries, Indonesia, Thailand, and the Philippines, but also from a temperate region, Japan. Therefore, *Asaia* species are thought to be cosmopolitan. Further, the strains were isolated from clinical specimens and an Asian malarial mosquito vector, *Anopheles stephensi* (Favia et al. 2007). Species in the genus *Asaia* are barely differentiated with phenotypic characteristics; no or little production of acetic acid from ethanol, the growth in the presence of 0.35 % acetic acid, the growth on 30 % glucose, the acid production from a considerable number of sugars and sugar alcohols, and the production of pink to red colonies on agar plates would be possible features. DNA-DNA similarity and 16S rRNA gene sequences are reliable for the identification of the species. Possible differential characteristics are shown in *Table 1.3*.

The type species is *Asaia bogorensis* Yamada et al. 2000. The closest neighbor is the genus *Swaminathania* (*Fig. 1.1*). Currently, the genus *Asaia* comprises eight species.

Asaia Yamada et al. 2000

Cells are Gram negative, rod-shaped, measuring 0.4–1.0 by 1.0–2.5 (rarely 4.5) μm, and motile with peritrichous or lateral flagella. Endospores are not produced. Colonies are smooth, entire, raised, shiny, and light brown, pink to dark pinkish on GYP or GESA. Grows on glutamate agar and mannitol agar.

Aerobic. Catalase positive. Oxidase negative. Produces no or a limited amount of acetic acid from ethanol. Oxidizes acetate and lactate to carbon dioxide and water. Production of dihydroxyacetone from glycerol is generally positive. Produces 2-keto-D-gluconate and 5-keto-D-gluconate from D-glucose, but not 2,5-diketo-D-gluconate. Acid is produced from D-glucose, D-galactose, D-fructose, and other sugars and sugar alcohols, but not from lactose or maltose (with an exception). Grows on D-glucose, D-fructose, and D-mannitol, but not on lactose. Ammoniac nitrogen is assimilated on D-glucose and D-mannitol.

Grows on 30 % glucose, but not in the presence of 0.35 % acetic acid. Growth occurs between 10 °C and 30 °C, but not at 37 °C. However, *Asaia prunellae* is able to grow at 37 °C. Growth occurs between pH 3.0 and 8.5. Major cellular fatty acids are $C_{18:1}\omega7c$ and $C_{16:0}$ (*Asaia spathodeae*). Major quinone is Q-10. The G+C content of DNA is 58.6–61.0 mol%.

Asaia strains are isolated from a variety of such flowers as orchid tree, plumbago, astilbe, Asian dayflower, heliconia, spider lily, balloon flower, self-heal, crown flower, ixora, African tulip tree, etc.

Asaia bogorensis Yamada, Katsura, Kawasaki, Widyastuti, Saono, Seki, Uchimura, and Komagata 2000

Characteristics of the species are the same as those described for the species (Yamada et al. 2000).

Type strain: 71^T (= JCM 19569^T = NRIC 0311^T), isolated from orchid tree (*Bauhinia purpurea*) in Bogor, Indonesia. The G+C content of DNA of the type strain is 60.2 mol%.

Asaia astilbis Suzuki, Zhang, Iino, Kosako, Komagata, and Uchimura 2010

Characteristics of the species are the same as those described for the species (Suzuki et al. 2010).

Type strain: T-6133^T (= DSM 23030^T = JCM 15831^T), isolated from astilbe (*Astilbe thunbergii* var. *congesta*), Yamanashi, Japan. The G+C content of DNA of the type strain is 58.9 mol%.

Note: The original spelling of the specific epithet, *astilbes* (sic), has been corrected on validation according to Rule 61.

Asaia krungthepensis Yukphan, Potacharoen, Tanasupawat, Tanticharoen, and Yamada 2004

Characteristics of the species are the same as those described for the species (Yukphan et al. 2004b).

Type strain: AA08^T (= BCC 12978^T = NBRC 0535^T = TISTR 1524^T), isolated from a heliconia flower (*Heliconia* sp.) in Bangkok, Thailand. The G+C content of DNA of the type strain is 60.3 mol%.

Asaia lannensis Malimas, Yukphan, Takahashi, Kaneyasu, Potacharoen, Tanasupawat, Nakagawa, Tanticharoen, and Yamada 2008

Characteristics of the species are the same as those described for the species (Malimas et al. 2008c).

Type strain: AB92^T (= BCC 15733^T = NBRC 102526^T), isolated from a flower of spider lily (*Crinum asiaticum*) in Chiang Mai, Thailand. The G+C content of DNA of the type strain is 60.8 mol%.

Note: The specific epithet, *lannaensis* (sic), has been corrected on validation according to Rule 61.

Asaia platycodi Suzuki, Zhang, Iino, Kosako, Komagata, and Uchimura 2010

Characteristics of the species are the same as those described for the species (Suzuki et al. 2010).

Type strain: T-683^T (= JCM 25414^T = DSM 23029^T), isolated from balloon flower (*Platycodon grandiflorum*) in Akita, Japan. The G+C content of DNA of the type strain is 60.0 mol%.

Asaia prunellae Suzuki, Zhang, Iino, Kosako, Komagata, and Uchimura 2010

Characteristics of the species are the same as those described for the species (Suzuki et al. 2010).

Type strain: T-153^T (= DSM 23028^T = JCM 25354^T), isolated from self-heal (*Prunella vulgaris*) in Akita, Japan. The G+C content of DNA of the type strain is 58.9 mol%.

Asaia siamensis Katsura, Kawasaki, Potacharoen, Saono, Seki, Yamada, Uchimura, and Komagata 2001

Characteristics of the species are the same as those described for the species (Katsura et al. 2001).

Type strain: S60-1^T (= JCM 10715^T = NBRC 16457^T = NRIC 0323^T), isolated from a flower of crown flower (*Calotropis gigantea*), in Bangkok, Thailand. The G+C content of DNA of the type strain is 59.3 mol%.

Asaia spathodeae Kommanee, Tanasupawat, Yukphan, Malimas, Muramatsu, Nakagawa, and Yamada 2010

Characteristics of the species are the same as those described for the species (Kommanee et al. 2010).

Type strain: GB23-2^T (= BCC 36458^T = NBRC 105894^T = PCU 307^T), isolated from a flower of the African tulip (*Spathodea campanulata*) in Thailand. The G+C content of DNA of the type strain is 59.7 mol%.

Endobacter Ramírez-Bahena, Tejedor, Martín, Valázques, and Peix 2013

En.do.bac'ter. Gr. pref. *endo* within; N.L. masc. n. *bacter* a rod; *Endobacter* a rod isolated from the inside of a root nodule of *Medicago sativa*.

An *Endobacter* strain was isolated from a surface-sterilized alfalfa (*Medicago sativa*), as an endophyte, in Zamora, Spain. The results of *recA* gene analysis supported the classification of the strain in a new genus in the family *Acetobacteraceae*. Further, ITS fragment analysis showed the phylogenetic divergence of the strain with respect to other species in the family *Acetobacteraceae*. The results of *recA* gene and ITS fragment analysis of the strain agreed with those from 16S rRNA gene sequence analysis and supported the strain in a member of a new genus

within the family *Acetobacteraceae*. Thus, the genus *Endobacter* was established (Ramírez-Bahena et al. 2013).

The type species is *Endobacter medicaginis* Ramírez-Bahena et al. 2013. The genus *Endobacter* is phylogenetically rather distant from known genera in the family *Acetobacteraceae* (Fig. 1.1). Currently, the genus contains a single species, *Endobacter medicaginis*.

Endobacter Ramírez-Bahena et al. 2013

Cells are Gram negative and coccid to rod-shaped. Motile with subpolar flagella. Colonies are white and mucoid on YMA agar. Growth occurs on glutamate agar and mannitol agar.

Aerobic. Catalase positive. Oxidase negative. Urease negative. Acetate and lactate are not oxidized. Acetic acid is produced from ethanol. Dihydroxyacetone is produced from glycerol. Acid is produced from D-xylose, D-glucose, glycerol, and ethanol, but not from lactose, maltose, sucrose, dulcitol, D-mannitol, or D-sorbitol. Ammoniac nitrogen is assimilated on D-glucose.

Growth occurs between 20 °C and 37 °C with an optimum temperature for growth of 28 °C. Optimal pH for growth ranges from 5.0 to 7.0, but the growth occurs at pH 3.5.

Major cellular fatty acids are $C_{18:1}$ ω7*c* (39.94 %), $C_{19:0}$cyclo ω8*c* (12.15 %), and $C_{16:0}$ (13.40 %). The lipid profile consists of diphosphatidylglycerol, phosphatidylethanolamine, two aminophospholipids, three aminolipids, four glycolipids, two phospholipids, and one lipid. Major quinone is Q-10. The G+C content of DNA of the type strain is 60.3 mol%.

An *Endobacter* strain was isolated from a surface-sterilized nodule of alfalfa (*Medicago sativa*), Spain.

Endobacter medicaginis Ramírez-Bahena et al. 2013

Characteristics of the species are the same as those described for the species (Ramírez-Bahena et al. 2013).

Type strain: M1MS02^T (= CECT 8088^T = LMG 26838^T), isolated from a surface-sterilized nodule of alfalfa (*Medicago sativa*), Spain. The G+C content of DNA of the type strain is 60.3 mol%.

Gluconacetobacter Yamada, Hoshino, and Ishikawa 1998

Glu.con.a.ce.to.bac'ter. N. L. n. *acidum gluconicum*, gluconic acid; L. n. *acetum*, vinegar; N.L. masc. n. *bacter*, rod; N.L. masc. n. *Gluconacetobacter*, gluconate-vinegar rod.

The genus *Gluconacetobacter* Yamada et al. 1998 (*Gluconoacetobacter* [sic]) was introduced into the family *Acetobacteraceae* by the elevation of the subgenus *Gluconacetobacter* (ex Asai 1935) Yamada and Kondo 1984 on the basis of partial 16S rRNA sequences with the type species of *Gluconacetobacter liquefaciens* (Asai 1935) Yamada et al. 1998 (Yamada et al. 1997). Thus, five *Acetobacter* species, *Acetobacter diazotrophicus*, *A. europaeus*, *A. hansenii*, *A. liquefaciens*, and *A. xylinus*, were transferred to the genus *Gluconacetobacter* as new combinations.

Further, *Gluconacetobacter liquefaciens*, *G. diazotrophicus*, and newly described *Gluconacetobacter sacchari* were positioned distantly from *Gluconacetobacter xylinus*, *G. europaeus*, and *G. hansenii* by 16S rRNA sequence similarities, and two groups were suggested in the genus *Gluconacetobacter* (Franke et al. 1999). The two groups or two subclusters were recognized in the genus *Gluconacetobacter* according to phylogenetic analyses based on 16S rRNA sequences and phenotypical and ecological point of view (Dellaglio et al. 2005; Lisdiyanti et al. 2006; Yamada and Yukphan 2008; Yamada et al. 2012a). The two groups were referred to as the *Gluconacetobacter liquefaciens* group and the *Gluconacetobacter xylinus* group in the genus *Gluconacetobacter*.

Differentiation between *G. liquefaciens* strains and *G. xylinus* strains was beforehand reported based on the G+C content of DNA, DNA-DNA similarity, and oxidation products from D-glucose (Navarro and Komagata 1999). In addition, the two groups were confirmed by multilocus analyses of housekeeping genes, *dnaK*, *groEL*, and *rpoB* as well (Cleenwerck et al. 2010). Consequently, the genus *Gluconacetobacter* was divided into two genera, the genus *Gluconacetobacter* for the *Gluconacetobacter liquefaciens* group and a new genus *Komagataeibacter* for the *Gluconacetobacter xylinus* group with 12 new combinations on the basis of the taxonomic characteristics (Yamada et al. 2012b). Some species have the activity of nitrogen fixation. Further, *Gluconacetobacter asukensis* and *G. tumulicola* were isolated from the Kitora Tumulus in Japan (Tazato et al. 2012).

The type species is *G. liquefaciens* (Asai 1935) Yamada et al. 1998. The closest neighbors are the genera *Komagataeibacter* and *Nguyenibacter* (Fig. 1.1). Currently, the genus *Gluconacetobacter* comprises seven species.

Gluconacetobacter Yamada et al. 1998

Cells are Gram negative, ellipsoidal to rod-shaped, measuring 0.5–0.8 by 1.0–3.0 μm, and motile with peritrichous flagella when motile. Occurring singly or in pairs (*Gluconacetobacter azotocaptans* and *G. johannae*). Long involution forms are found (*G. diazotrophicus*). Colonial color is light brown to brownish (*G. azotocaptans* and *G. johannae*). Growth occurs on glutamate agar and mannitol agar.

Aerobic. Catalase positive. Oxidase negative. Acid is produced from ethanol. Oxidizes acetate and lactate. A few species produce dihydroxyacetone from glycerol. 2-keto-D-gluconate is produced from D-glucose. Most of species produce 2,5-diketo-D-gluconate, and a few species produce 5-keto-D-gluconate. Acid is produced from D-glucose, D-fructose, and sucrose. Growth occurs on D-fructose, D-glucose, sucrose, D-mannitol, and

ethanol, but not on methanol. Ammoniac nitrogen is used as a sole nitrogen source. Most of the species produce water-soluble pigment(s). Most of the species have the activity of nitrogen fixation.

Most of the species grow on 30 % D-glucose. Growth occurs between 15 °C and 30 °C, but not at 37 °C. Optimum growth temperature is around 30 °C. Growth occurs between pH 3.0 and 6.8 (*G. asukensis* and *G. tumulicola*). Optimum growth pH is about 5.5 and no growth at pH 7.0 (*G. diazotrophicus*). Major cellular fatty acid is $C_{18:1}$ ω7*c*. A major quinone is Q-10. The G+C content of DNA ranges from 58 to 65 mol%.

Gluconacetobacter strains are isolated from vinegar, fruits, dried fruits, rhizosphere of coffee plants, pink sugarcane mealybug, and even in a tumulus in Japan.

Gluconacetobacter liquefaciens (Asai 1935) Yamada et al. 1998

The characteristics of this species are rather fragmentally described. Following papers are relating to phenotypical characteristics (Asai et al. 1964; Gosselé et al. 1983a), quinone systems (Yamada and Kondo 1984), the G+C content of DNA (Navarro and Komagata 1999), and methanol utilization (Suzuki et al. 2009).

Type strain: Asai G-1^T (= ATCC 14835^T = CCUG 18124^T = CIP 103109^T = DSM 5603^T = JCM 17840^T = LMG 1381^T = LMG 1382^T = NBRC 12388^T = NCCB 76052^T), isolated from dried persimmon. The G+C content of DNA of the type strain is 64.9 mol%.

Gluconacetobacter asukensis Tazato, Nishijima, Handa, Kigawa, Sano, and Sugiyama 2012

Characteristics are the same as those described for the species (Tazota et al. 2012).

Type strain: K8617-1-1b^T (= JCM 17772^T = NCIMB 14759^T), isolated from a brown viscous gel on the northeast area of the ceiling in the stone chamber of the Kitora Tumuli in Asuka village, Nara Prefecture, Japan. The G+C content of DNA of the type strain is 65.4 mol%.

Gluconacetobacter azotocaptans Fuentes-Ramírez, Bustillos-Cristales, Tapia-Hernández, Jiménez-Salgado, Wang, Martínez-Romero, and Caballero-Mellado 2001

The characteristics are the same as those described for the species (Fuentes-Ramírez et al. 2001).

Type strain: CFN-Ca54^T (= ATCC 700988^T = CIP 107161^T = DSM 13594^T), isolated from the rhizosphere of coffee plants. The G+C content of DNA of the type strain is 64.0 mol%.

Gluconacetobacter diazotrophicus (Gillis et al. 1989) Yamada, Hoshino, and Ishikawa 1998

The characteristics are the same as those described for the species (Gillis et al. 1989).

Type strain: PA 5^T (= ATCC 49037^T = CCUG 37298^T = CIP 103539^T = DSM 5601^T = LMG 7603^T = NCCB 89154^T), isolated from roots and stems of sugarcane in Alagoas, Brazil. The G+C content of DNA of the type strain is 61 mol%.

Gluconacetobacter johannae Fuentes-Ramírez, Bustillos-Cristales, Tapia-Hernández, Jiménez-Salgado, Wang, Martínez-Romero, and Caballero-Mellado 2001

The characteristics are the same as those described for the species (Fuentes-Ramírez et al. 2001).

Type strain: CFN-Cf55^T (= ATCC 700987^T = CIP 107160^T = DSM 13595^T), isolated from the rhizosphere of coffee plants. The G+C content of DNA of the type strain is 57.95 mol%.

Gluconacetobacter sacchari Franke, Fegan, Hayward, Leonard, Stackebrandt, and Sly 1999

The characteristics are the same as those described for the species (Franke et al. 1999).

Type strain: SRI 1794^T (= CIP 106693^T = DSM 12717^T), isolated from the leaf sheath of sugarcane and from the pink sugarcane mealybug. The G+C content of DNA of the type strain is 65 mol%.

Gluconacetobacter tumulicola Tazato, Nishijima, Handa, Kigawa, Sano, and Sugiyama 2012

The characteristics are the same as those described for the species (Tazato et al. 2012).

Type strain: K5929-2-1b^T (= JCM 17774^T = NCIMB 14760^T), isolated from a black viscous substance in a plaster hole at the center of the ceiling in the stone chamber of the Kitora Tumulus in Asuka village, Nara Prefecture, Japan. The G+C content of DNA of the type strain is 64.7 mol%.

Gluconobacter Asai 1935

Glu.co.no.bac'ter: N.L. n. *acidum gluconicum*, gluconic acid; N.L. masc. n. *bacter*, rod; N.L. masc. n. *Gluconobacter* gluconate rod.

The generic name *Gluconobacter* appeared for the first time in 1935 by Asai. He focused isolation sources of acetic acid bacteria on a various kinds of fruit and others. As a result, 67 isolates were classified into two groups: One group consisted of the isolates from

fruit and oxidized D-glucose more vigorously than ethanol; and the other group comprised the isolates from vinegar and related materials and oxidized ethanol more actively than D-glucose. The two groups differed clearly from each other on the oxidation of acetate and growth temperature as well. The former was named the genus *Gluconobacter* and the latter the genus *Acetobacter* (Asai 1935). Asai's study showed an important thing, which the genus *Gluconobacter* was established on the basis of biochemical characteristics different from those of the genus *Acetobacter*, and the isolation sources of acetic acid bacteria were focused on the other materials than vinegar and related alcoholic materials. However, his study did not become widely known in the West because his papers were written in Japanese.

Subsequently Leifson proposed the division of acetic acid bacteria into two genera, *Acetobacter* and "*Acetomonas*," on the basis of flagellation and oxidation of acetate and lactate (Leifson 1954). Surprisingly the genera *Gluconobacter* and "*Acetomonas*" agreed to each other on taxonomic characteristics. Later, De Ley and Frateur concluded after detailed investigation in 1970 that the genus *Gluconobacter* was validly and legitimately published 19 years before Leifson (De Ley and Frateur 1970). Thus, the name of *Gluconobacter* was listed in Approved Lists of Bacterial Names 1980 (Skerman et al. 1980). The genus *Gluconobacter* with ubiquinone 10 (Q-10) was distinguished from the genus *Acetobacter* with Q-9 (Yamada et al. 1968b; Yamada et al. 1969). This criterion is still useful for the differentiation of both the genera. In general, the species in the genus *Gluconobacter* is divided into two groups based on the G+C content of DNA and nutritional requirement: The species with the high G+C content of DNA around 60 mol% require pantothenic acid for growth, and the species with the low G+C content of DNA around 55 mol% do not require pantothenic acid. This relationship shows a good correlation with the phylogenetic relationship based on the analysis of 16S rRNA gene sequences and 16S-23S rRNA gene ITS sequences (Tanasupawat et al. 2011b).

The type species is *Gluconobacter oxydans* (Henneberg 1897) De Ley 1961. The closest neighbors are the genera *Neokomagataea* and *Saccharibacter* (Fig. 1.1). Currently, the genus *Gluconobacter* comprises 13 species.

Gluconobacter Asai 1935

Cells are Gram negative, ellipsoidal to rod-shaped, measuring 0.4–1.2 by 1.0–3.0 μm, and polarly flagellated when motile. Colonies are smooth, raised to convex, entire, and glistening on agar media containing ethanol-glucose-yeast extract-$CaCO_3$. Some strains produce pink-colored colonies. Growth occurs on mannitol agar, but not on glutamate agar.

Strictly aerobic. Catalase positive. Oxidase negative. Acetic acid is produced from ethanol. Acetate and lactate are not oxidized. Dihydroxyacetone is produced from glycerol. 2-Keto-D-gluconate and 5-keto-D-gluconate are produced from D-glucose. Some strains produce D-gluconate, and a few strains produce 2,5-diketo-D-gluconate. Acid is produced from L-arabinose, D-xylose, D-fructose, D-galactose, D-glucose, D-mannose, melibiose, D-mannitol, glycerol, and ethanol, but not from lactose or dulcitol. Acid production varies with species from D-arabinose, L-sorbose, L-rhamnose, maltose, sucrose, raffinose, L-arabitol, *meso*-erythritol, D-mannitol, and *meso*-ribitol. Growth occurs on D-glucose and D-mannitol, but does not on lactose or maltose. Growth on other sugars and sugar alcohols differs with the species. Growth on *meso*-ribitol and L-arabitol was once used for differentiation of *Gluconobacter oxydans* from *Gluconobacter cerinus* and *Gluconobacter frateurii* (Mason and Claus 1989; Katsura et al. 2002; Sievers and Swings 2005d). However, this relation is not clear because some strains show a weak or very weak reaction toward one of the polyols. The production of water-soluble pigment is found in the strains of *G. oxydans*, *G. kanchanaburiensis*, *G. sphaericus*, *G. uchimurae*, and *G. wancherniae*. Strains in several species require nicotinic acid for growth.

Optimum temperature for growth is between 25 °C and 30 °C. Majority of species grow at 35 °C, and a few species grow at 37 °C. Optimum pH for growth is around pH 5.5. Majority of species grow at pH 3.0 or 3.5. Major cellular fatty acid is $C_{18:1}\omega7c$. Major ubiquinone is Q-10. The G+C content of DNA ranges from 54.0 to 61.5 mol%.

Gluconobacter strains are isolated from a variety of fruits, including kaki (persimmon), jujube, peach, a variety of citrus fruits, strawberry, cherry, apple, apricot, grape, fig, etc., and flowers and other sugar-rich environments.

Gluconobacter oxydans (Henneberg 1897) De Ley 1961

The characteristics are the same as those described for the species (Asai et al. 1964; Gosselé et al. 1983a; Katsura et al. 2002; Mason and Claus 1989; Sievers and Swings 2005d; Tanaka et al. 1999; Yamada and Akita 1984). Characterization of *Gluconobacter oxydans* is rather fragmentally, and the description of the species is needed to be compiled from data based on detailed research.

Type strain: ATCC 19357^T (= CCUG 18132^T = CIP 103106^T = DSM 3503^T = DSM 7145^T = ICMP 12533^T = JCM 7642^T = LMG 1408^T = NBRC 14819^T = NCCB 75005^T = NCIMB 9013^T), isolated from beer by J. G. Carr. The G+C content of DNA of the type strain is 60 mol%.

Gluconobacter albidus (ex Kondo and Ameyama 1958) Yukphan, Takahashi, Potacharoen, Tanasupawat, Nakagawa, Tanticharoen, and Yamada 2005

The characteristics are the same as those described for the species (Yukphan et al. 2004a).

Type strain: NBRC 3250^T (= BCC 14434^T = JCM 20271^T), isolated from a flower of dahlia by Kondo and Ameyama (1958). The G+C content of DNA of the type strain is 60.0 mol%.

Gluconobacter cerinus (ex Asai 1935) Yamada and Akita 1984 emend. Katsura et al. 2002

The characteristics are the same as those described for the species (Yamada and Akita 1984; Katsura et al. 2002).

Type strain: NBRC 3267^T (= ATCC 19441^T = CIP 103150^T = DSM 9533^T = DSM 9534^T = LMG 1368^T = NRRL B-4241^T), isolated from cherry (*Prunus* sp.). The G+C content of DNA of the type strain is 56 mol%.

Gluconobacter frateurii Mason and Claus 1989

The characteristics are the same as those described for the species (Mason and Claus 1989; Katsura et al. 2002; Tanaka et al. 1999).

Type strain: Kondo 40^T (= ATCC 49207^T = CIP 104735^T = DSM 7146^T = LMG 1365^T = NBRC 3264^T), isolated from strawberry (*Fragaria ananassa*). The G+C content of DNA of the type strain is 55 mol%.

Gluconobacter japonicus Malimas, Yukphan, Takahashi, Muramatsu, Kaneyasu, Potacharoen, Tanasupawat, Nakagawa, Tanticharoen, and Yamada 2009

The characteristics are the same as those described for the species (Malimas et al. 2009b).

Type strain: Kondo 7^T (= BCC 14458^T = NBRC 3271^T), isolated from a fruit of Chinese bayberry. The G+C content of DNA of the type strain is 56.4 mol%.

Gluconobacter kanchanaburiensis Malimas, Yukphan, Lundaa, Muramatsu, Takahashi, Kaneyasu, Potacharoen, Tanasupawat, Nakagawa, Suzuki, Tanticharoen, and Yamada 2009

The characteristics are the same as those described for the species (Malimas et al. 2009a).

Type strain: AD92^T (= BCC 15889^T = NBRC 103587^T), isolated from a spoiled fruit of jackfruit (*Artocarpus heterophyllus*). The G+C content of DNA of the type strain is 59.5 mol%.

Gluconobacter kondonii Malimas, Yukphan, Takahashi, Kaneyasu, Potacharoen, Tanasupawat, Nakagawa, Tanticharoen, and Yamada 2007

The characteristics are the same as those described for the species (Malimas et al. 2007).

Type strain: Kondo 75^T (= BCC 14441^T = NBRC 3266^T), isolated from strawberry. The G+C content of DNA of the type strain is 59.8 mol%.

Gluconobacter nephelii Kommanee, Tanasupawat, Yukphan, Malimas, Muramatsu, Nakagawa, and Yamada 2011

The characteristics are the same as those described for the species (Kommanee et al. 2011).

Type strain: RBY-1^T (= BCC 36733^T = NBRC 10606^T = PCU 318^T), isolated from rambutan (*Nephelium lappaceum*). The G+C content of DNA of the type strain is 57.2 mol%.

Gluconobacter roseus (ex Asai 1935) Malimas, Yukphan, Takahashi, Muramatsu, Kaneyasu, Potacharoen, Tanasupawat, Nakagawa, Tanticharoen, and Yamada 2008

The characteristics are the same as those described for the species (Malimas et al. 2008a).

Type strain: Asai G-2^T (= BCC 14456^T = JCM 20293^T = NBRC 3990^T), isolated from a fruit of kaki (persimmon, *Diasporas kaki*). The G+C content of DNA of the type strain is 60.5 mol%.

Gluconobacter sphaericus (Ameyama 1975) Malimas, Yukphan, Takahashi, Muramatsu, Kaneyasu, Potacharoen, Tanasupawat, Nakagawa, Tancharoen, and Yamada 2008

The characteristics are the same as those described for the species (Ameyama 1975; Malimas et al. 2008b).

Type strain: NBRC 12467^T (= BCC 14448^T = CIP 106061^T = LMG 1414^T), isolated from fresh grapes by Ameyama. The G+C content of DNA of the type strain is 59.5 mol%.

Gluconobacter thailandicus Tanasupawat, Thawai, Yukphan, Moonmangmee, Itoh, Adachi, and Yamada 2004

The characteristics are the same as those described for the species (Tanasupawat et al. 2004).

Type strain: F-149 T (= BCC 14116^T = JCM 12310^T = NBRC 100600^T = PCU 225^T = TISTR 1533^T), isolated from a flower of Indian cork tree (*Millingtonia hortensis*), Bangkok, Thailand. The G+C content of DNA of the type strain is 55.8 mol%.

Gluconobacter uchimurae Tanasupawat, Kommanee, Yukphan, Moonmangmee, Muramatsu, Nakagawa, and Yamada 2011

The characteristics are the same as those described for the species (Tanasupawat et al. 2011b).

Type strain: ZW160-2^T (= BCC 14681^T = NBRC 100627^T =PCU 264^T), isolated from rakam fruit (*Salacca wallichiana*). The G+C content of DNA of the type strain is 60.5 mol%.

Gluconobacter wancherniae Yukphan, Malimas, Lundaa, Muramatsu, Takahashi, Kaneyasu, Tanasupawat, Nakagawa, Suzuki, Tanticharoen, and Yamada 2010

The characteristics are the same as those described for the species (Yukphan et al. 2010).

Type strain: AC42^T (= BCC 15775^T = NBRC 103581^T), isolated from unknown seed. The G+C content of DNA of the type strain is 56.6 mol%.

Granulibacter Greenberg, Porcella, Stock, Wong, Conville, Murray, Holland, and Zelazny 2006

Gra.nu.li.bac'ter. L. n. *granulum*, grain; N. L. masc. n. *bacter*, rod; N.L. masc. n. *Granulibacter*, a rod that causes granules or granuloma formation.

A *Granulibacter* strain was first isolated from cervical and supraclavicular lymph nodes of a chronic granulomatous disease (CGD) patient in Bethesda, USA. This organism was subsequently isolated from the same patient and then from other two CGD patients (Greenberg et al. 2006a). The strains were characterized by a multilocus analysis on the 16S rRNA gene, the internal transcribed spacer (ITS) region, and the RecA protein, and they were assigned with a new genus *Granulibacter* in the family *Acetobacteraceae* (Greenberg et al. 2006b). Further, the organism was isolated from a child with CGD (López et al. 2008). The genome sequence of a *G. bethesdensis* strain was determined, in which methanol dehydrogenase genes were recognized (Greenberg et al. 2007; Greenberg et al. 2010). However, the strain grew poorly on methanol compared with that of *Acidomonas methanolica*.

The type species is *Granulibacter bethesdensis* Greenberg et al. 2006. This genus is phylogenetically rather independent from other genera in the family *Acetobacteraceae* (*Fig. 1.1*). Currently, the genus contains a single species, *Granulibacter bethesdensis*.

Granulibacter Greenberg et al. 2006

Cells are Gram negative, coccobacillus to rod-shaped, and nonmotile. Colonies are convex, entire, smooth, and yellow (nondiffusible) on a modified glucose-yeast extract-$CaCO_3$. Growth occurs on glutamate agar and on mannitol agar.

Strictly aerobic. Catalase positive. Oxidase negative. Little acetic acid is produced from ethanol. Lactate and acetate are oxidized to carbon dioxide and water, but the activity of the latter is weak. Dihydroxyacetone is not produced from glycerol. Acid is produced from D-glucose and ethanol and variably from glycerol (weak or a negative reaction), but not from D-mannitol, D-sorbitol, dulcitol, lactose, sucrose, maltose, or D-xylose. Methanol can be used as a sole carbon source. Ammoniac nitrogen is assimilated on glucose medium. Urease variable.

High concentration of glucose [e.g., 5 % (w/v) glucose] is preferable for growth. Optimum temperature for growth is 35–37 °C. Growth does not occur at 42 °C. Optimum pH for growth is pH 5.0–6.5. Growth occurs at pH 3.5. The major cellular fatty acids are a straight-chain unsaturated acid ($C_{18:1}\omega7c$) and saturated acid ($C_{16:0}$). A cyclopropane acid ($C_{19:0}$ cyc. 11–12) is contained in a relatively high concentration. A major quinone is Q-10 (Yukphan et al. 2009). The G+C content of DNA is 59.1 mol%.

Granulibacter strains are isolated from lymph nodes of CGD patients.

Granulibacter bethesdensis Greenberg, Porcella, Stock, Wong, Conville, Murray, Holland, and Zelazny 2006

Characteristics are the same as those described for the species (Greenberg et al. 2006b). The type strain: CGDNIH1^T (= ATCC BAA-1260^T = DSM 17861^T), isolated from lymph node culture from a granulomatous disease patient in Bethesda, MD, USA, in 2003. The G+C content of DNA of the type strain is 59.1 mol%.

Komagataeibacter Yamada, Yukpan, Vu, Muramatsu, Ochaikul, Tanasupawat, and Nakagawa 2013

Ko.ma.ga.ta.e.i.bac'ter. N. L. fem. n. *Komagataea*, Komagata (the name of a Japanese microbiologist); N.L. masc. n. *bacter*, a rod; N.L. masc. n. *Komagataeibacter*, a rod, which is named in honor of Dr. Kazuo Komagata, Professor of The University of Tokyo, Japan, who contributed to the bacterial systematics, especially acetic acid bacteria.

The genus *Gluconacetobacter* Yamada et al. 1998 (*Gluconoacetobacter* [sic]) was divided into two genera, the genus *Gluconacetobacter* and the genus *Komagataeibacter*, on the basis of 16S rRNA gene analysis and phenotypic characteristics, and 12 species in the previous *Gluconacetobacter* were transferred to the genus *Komagataeibacter* as new combinations (Yamada et al. 2012b) (see *Gluconacetobacter*). In addition, *Gluconacetobacter kakiaceti* (Iino et al. 2012b), *Gluconacetobacter medellinensis* (Castro et al. 2013), and *Gluconacetobacter maltaceti* (Slapšak et al. 2013) were described. The three species were included into the genus *Komagataeibacter* on the basis of the phylogenetic relationships (Yamada 2014).

The type species is *Komagataeibacter xylinus* (Brown 1886) Yamada, Yukphan, Vu, Muramatsu, Ochaikul, Tanasupawat and Nakagawa 2013. The closed neighbors are the genera *Gluconacetobacter* and *Nguyenibacter* (Fig. 1.1). Currently, this genus comprises 13 species.

Komagataeibacter Yamada et al. 2013

Cells are Gram-negative rods, measuring 0.5–0.8 by 1.0–3.0 μm, occurring singly, in pairs, or in chains. Nonmotile (a *K. xylinus* strain is motile with peritrichous flagella) (Asai et al. 1964). Colonies are circular, smooth, or rough, raised to convex or umbonate, entire, glistening, and white-creamy to beige. Growth occurs on glutamate agar and mannitol agar. *K. kakiaceti* strains do not grow on glutamate agar.

Aerobic. Catalase positive. Oxidase negative. Acetic acid is produced from ethanol. Acetate and lactate are oxidized to carbon dioxide and water. Dihydroxyacetone is generally produced from glycerol. D-Gluconate, 2-keto-D-gluconate, and/or 5-keto-D-gluconate is produced from D-glucose, but 2,5-diketo-D-gluconate is not produced. *K. kakiaceti* strains do not produce ketogluconates. Acid is produced from L-arabinose, D-xylose, D-galactose, D-glucose, and ethanol, but not from L-sorbose, D-fructose, D-mannitol, lactose, maltose, or D-sorbitol. Growth occurs on D-fructose, D-glucose, maltose, sucrose, and D-mannitol, but not on lactose. Ammoniac nitrogen is generally assimilated on D-mannitol. Cellulosic materials are produced by the strains of *K. xylinus* and other species. A water-soluble brown pigment is not produced on glucose-yeast extract-calcium carbonate medium. γ-Pyrone compounds are not produced.

Growth occurs in the presence of 0.35 % acetic acid (v/v) in general. Some species require acetic acid for growth. Growth occurs at pH 3.0. A major cellular fatty acid is $C_{18:1}\omega7c$. Additionally, *K. rhaeticus* shows the presence of $C_{14:0}$ 2-OH and $C_{16:0}$ 2-OH. A major quinone is Q-10. The G+C content of DNA ranges from 58 to 64 mol%.

A number of strains of this genus are isolated from acetous materials including a variety of vinegar, kombucha, fruits, and a variety of fruit juice.

Komagataeibacter xylinus (Brown 1886) Yamada, Yukphan, Vu, Muramatsu, Ochaikul, Tanasupawat, and Nakagawa 2013

Characteristics of this species are rather fragmentally described. Following papers are relating to phenotypical characteristics (Gosselé et al. 1983a; Lisdiyanti et al. 2006; Navarro and Komagata 1999; Sievers and Swings 2005c; Yamada 1983), quinone systems (Yamada et al. 1976b), cellular fatty acid composition (Yamada et al. 1981a), and the G+C content of DNA (Navarro and Komagata 1999). The G+C content of the type strain is 62 mol%. A few strains of this species produce cellulose from sugars, but cellulose-less strains are known (Yamada 1983).

Type strain: NCIMB 11664^T (= BCC 49175^T = DSM 6513^T = JCM 7644^T = LMG 1515^T = NBRC 15237^T), isolated from mountain-ash berry by Prof. G. Bertrand. The G+C content of DNA of the type strain is 62 mol%.

Gluconacetobacter entanii Schüller, Hertel, and Hammes 2000

Characteristics are the same as those described for the species (Schüller et al. 2000).

Type strain: LTH 4560^T (= BCRC 17196^T = DSM 13536^T = LMG 20950^T = LMG 21788^T), isolated from submerged high-acid industrial vinegar fermentations. The G+C content of DNA of the type strain is 58 mol%.

The type strain is not available in any culture collection (Yamada et al. 2012b). Therefore, this species cannot be listed as a new combination according to Rule 27 of the Bacteriological Code (Tindall et al. 2006).

Komagataeibacter europaeus (Sievers, Sellmer, and Teuber 1992) Yamada, Yukphan, Vu, Muramatsu, Ochaikul, Tanasupawat, and Nakagawa 2013

Characteristics are the same as those described for the species (Sievers et al. 1992).

Type strain: DES11^T (= BCC 36446^T = DSM 6160^T = JCM 16935^T), isolated from a submerged culture vinegar generator at a factory in Esslingen in the southern part of Germany. The G+C content of DNA of the type strain is not recorded. The range of the species is described from 56.2 to 57.3 mol%.

Komagataeibacter hansenii (Gosselé, Swings, Kersters, Pauwels, and De Ley 1983) Yamada, Yukphan, Vu, Muramatsu, Ochaikul, Tanasupawat, and Nakagawa 2013

Characteristics are the same as those for the species (Gosselé et al. 1983b; Lisdiyanti et al. 2006).

Type strain: NCIMB 8746^T (= BCC 6318^T = DSM 5602^T = JCM 7643^T = LMG 1527^T = NBRC 14820^T), isolated from a local vinegar in Jerusalem, Israel. The G+C content of DNA of the type strain is 59 mol%.

Komagataeibacter intermedius (Boesch, Trček, Sievers, and Teuber 1998) Yamada, Yukphan, Vu, Muramatsu, Ochaikul, Tanasupawat, and Nakagawa 2013

Characteristics are the same as those for the species (Boesch et al. 1998; Yamada 2000).

Type strain: TF2^T (= DSM 11804^T = JCM 16936^T = BCC 36447^T = LMG 18909^T), isolated from a commercially available tea fungus beverage (kombucha) in Switzerland. The G+C content of DNA of the type strain is 61.55 mol%.

Gluconacetobacter kakiaceti Iino, Suzuki, Tanaka, Kosako, Ohkuma, Komagata, and Uchimura 2012

Characteristics are the same as those described for the species (Iino et al. 2012b).

Type strain: G5-1^T (= JCM 25156^T = LMG 26206^T = NRIC 0798^T), isolated from a traditional Japanese kaki vinegar. The G+C content of DNA of the type strain is 63.6 mol%.

Gluconacetobacter maltaceti Slapšak, Cleenwerck, De Vos, and Trček 2013

The characteristics are the same as those described for the species (Slapšak et al. 2013).

Type strain: Walker strain A^T (= LMG 1529^T = NBRC 14815^T = NCIMB 8752^T), isolated from malt vinegar brewery acetifier. The G+C content of DNA of the types strains is 62.5 mol%.

Gluconacetobacter medellinensis Castro, Cleenwerck, Trček, Zuluaga, De Vos, Caro, Aguirre, Putaux, and Gañán 2013

Characteristics are the same as those described for the species (Castro et al. 2013).

Type strain: Kondo 51^T (= LMG 1693^T = NBRC 328^T), isolated from vinegar. The G+C content of DNA of the type strain is 60.7 mol%.

Komagataeibacter nataicola (Lisdiyanti, Navarro, Uchimura, and Komagata 2006) Yamada, Yukphan, Vu, Muramatsu, Ochaikul, Tanasupawat, and Nakagawa 2013

Characteristics are the same as those described for the species (Lisdiyanti et al. 2006).

Type strain: LMG 1536^T (= BCC 36443^T = JCM 25120^T = NRIC 0616^T), isolated from nata de coco in the Philippines. The G+C content of DNA of the type strain is 62 mol%.

Komagataeibacter oboediens (Sokollek, Hertel, and Hammes 1998) Yamada, Yukphan, Vu, Muramatsu, Ochaikul, Tanasupawat, and Nakagawa 2013

Characteristics are the same as those described for the species (Sokollek et al. 1998; Yamada 2000).

Type strain: LTH 2460^T (= BCC 36445^T = DSM 11826^T = JCM 16937^T = LMG 18849^T), isolated from a submerged red wine vinegar fermentation at a factory in the southern part in Germany. The G+C content of DNA of the type strain is 59.9 mol%.

Komagataeibacter rhaeticus (Dellaglio, Cleenwerck, Felis, Engelbeen, Janssens, and Marzotto 2005) Yamada, Yukphan, Vu, Muramatsu, Ochaikul, Tanasupawat, and Nakagawa 2013

Characteristics are the same as those described for the species (Dellaglio et al. 2005).

Type strain: DST GL02^T (= BCC 36452^T = DSM 16663^T = JCM 17122^T = LMG 22126^T), isolated from apple juice in South Tyrol region, Italy. The G+C content of DNA of the type strain is 63.4 mol%.

Komagataeibacter saccharivorans (Lisdiyanti, Navarro, Uchimura, and Komagata 2006) Yamada, Yukphan, Vu, Muramatsu, Ochaikul, Tanasupawat, and Nakagawa 2013

Characteristics are the same as those described for the species (Lisdiyanti et al. 2006).

The type strain: LMG 1582^T (= BCC 36444^T = JCM 25121^T = NRIC 0614^T), isolated from beet juice in Germany in 1927. The G+C content of DNA of the type strain is 61 mol%.

Komagataeibacter sucrofermentans (Toyosaki, Kojima, Tsuchida, Hoshino, Yamada, and Yoshinaga 1996) Yamada, Yukphan, Vu, Muramatsu, Ochaikul, Tanasupawat, and Nakagawa 2013

Characteristics are the same as those described for the species (Toyosaki et al. 1995; Cleenwerck et al. 2010).

Type strain: LMG 18788^T (= BCC7227^T = DSM 15973^T = JCM 9730^T), isolated from a cherry. The G+C content of DNA of the type strain is 62.7 mol%.

Komagataeibacter swingsii (Dellaglio, Cleenwerck, Felis, Engelbeen, Janssens, and Marzotto 2005) Yamada, Yukphan, Vu, Muramatsu, Ochaikul, Tanasupawat, and Nakagawa 2013

The characteristics are the same as those described for the species (Dellaglio et al. 2005).

Type strain: DST GL01^T (= BCC 36451^T = DSM 16373^T = JCM 17123^T = LMG 22125^T), isolated from apple juice in South Tyrol region, Italy. The G+C content of DNA of the type strain is 61.7 mol%.

Kozakia Lisdiyanti, Kawasaki, Widyastuti, Saono, Seki, Yamada, Uchimura, and Komagata 2002

Ko.za'ki.a. N. L. fem. n. named after Kozaki, to honor the Japanese microbiologist Michio Kozaki, Professor Emeritus of Tokyo University of Agriculture, in recognition of his contributions to the study of microorganisms in tropical regions, especially Southeast Asia.

Kozakia strains were isolated from palm brown sugar and ragi (a starter for fermentation in southeastern Asia) collected in Indonesia by an enrichment culture approach for acetic acid bacteria. They were tentatively identified as *Gluconacetobacter* (Yamada et al. 1999). Later, the strains were included in a new genus *Kozakia*, which was established on phenotypic and chemotaxonomic characteristics, DNA-DNA similarity, and 16S rRNA sequences (Lysdiyanti et al. 2002). The strains produced a large amount of mucous polysaccharide from a sucrose-containing medium. The polysaccharide was determined as fructan (Jakob et al. 2013).

The type species is *Kozakia baliensis*. The closest neighbor is the genus *Neoasaia* (Fig. 1.1). Currently, the genus contains a single species, *Kozakia baliensis*.

Kozakia Lisdiyanti et al. 2002

Cells are Gram negative, rod-shaped, measuring 0.6–0.8 by 2.0–3.0 μm, and nonmotile. Growth occurs on mannitol agar, but not on glutamate agar. Nonpigmented.

Strictly aerobic. Catalase positive. Oxidase negative. Acetic acid is produced from ethanol. Acetate and lactate are oxidized to carbon dioxide and water, but the activity is weak. Dihydroxyacetone is produced from glycerol. D-Gluconate, 2-keto-D-gluconate, and 5-keto-D-gluconate are produced from D-glucose, but 2,5-diketo-D-gluconate is not produced. Acid is produced from L-arabinose, D-xylose, D-glucose, D-galactose, D-mannose, melibiose, raffinose, *meso*-erythritol, glycerol, and ethanol, but not from L-rhamnose, D-fructose, L-sorbose, lactose, D-mannitol, D-sorbitol, or dulcitol. Acid production from D-arabinose and sucrose is variable depending on the strain. Methanol is not utilized. Ammoniac nitrogen is not assimilated on D-glucose, mannitol, and ethanol medium without vitamins. Levan-like mucous substance(s) is produced from sucrose or D-fructose. Water-soluble brown pigment(s) is not produced from D-glucose or on $CaCO_3$-containing agar slants. γ-Pyrone is produced from D-fructose but not from D-glucose. Gelatinase, H_2S, indole, or ammonia is not produced from L-arginine, and nitrate is not reduced.

Growth is not inhibited by 0.35 % acetic acid at pH 3.5. Growth does not occur on 30 % D-glucose. Growth occurs at pH 3.0 and 30 °C. Major ubiquinone is Q-10. The G+C content of DNA is from 56.8 to 57.2 mol%.

Kozakia strains are isolated from palm brown sugar and ragi.

Kozakia baliensis Lisdiyanti, Kawasaki, Widyastuti, Saono, Seki, Yamada, Uchimura, and Komagata 2002

Characteristics are the same as those described for the species (Lisdiyanti et al. 2002).

Type strain: Yo-3^T (= DSM 14400^T = JCM 11301^T = NBRC 16664^T= NRIC 0488^T), isolated from palm brown sugar collected in Bali, Indonesia in 1996. The G+C content of DNA of the type strain is 57.2 mol%.

Neoasaia Yukphan, Malimas, Potacharoen, Tanasupawat, Tanticharoen, and Yamada 2006

Ne.o.a.sa'i.a. Gr. adj. *neos*, new; N. L. fem. n. *Asaia*, a bacterial name; N.L. fem. n. *Neoasaia*, a new *Asaia*.

A *Neoasaia* strain was isolated from a flower of red ginger (*Alpinia purpurata*) collected in Chiang Mai, Thailand, by the use of a glucose-ethanol-acetic acid (0.3 %, w/v) medium at pH 3.5. The strain was assigned with the new genus *Neoasaia*, which was established on 16S–23S rRNA internal transcribed spacer (ITS) region sequences (Yukphan et al. 2005).

The type species is *Neoasaia chiangmaiensis*. The closest neighbor is the genus *Kozakia* (Fig. 1.1). Currently, this genus contains a single species, *Neoasaia chiangmaiensis*.

Neoasaia Yukphan et al. 2006

Cells are Gram negative, rod-shaped, measuring 0.8–1.0 by 1.0–2.0 μm, and nonmotile. Colonies are smooth, raised, entire, shiny, and pink. Growth occurs on glutamate agar and mannitol agar.

Aerobic. Acetic acid is produced from ethanol. Acetate and lactate are not oxidized. Dihydroxyacetone is weakly produced from glycerol. 2-Keto-D-gluconate and 5-keto-D-gluconate are produced from D-glucose. Acid is produced from D-arabinose (weakly positive), L-arabinose, D-xylose, L-rhamnose (weakly positive), D-fructose (delayed), D-galactose, D-glucose, D-mannose, melibiose, sucrose, raffinose, dulcitol (weakly positive), *meso*-erythritol, D-mannitol (weakly positive), D-sorbitol (delayed), glycerol, and ethanol, but not from L-sorbose, lactose, or maltose.

Growth occurs in a liquid medium containing D-arabinose (weakly positive), L-arabinose, L-sorbose, D-xylose, D-fructose, D-galactose, D-glucose, D-mannose (weakly positive), sucrose, raffinose, dulcitol, *meso*-erythritol, D-mannitol, D-sorbitol, and glycerol, but not from L-rhamnose, lactose, maltose, melibiose,

or ethanol. Ammoniac nitrogen is hardly assimilated in the presence of D-glucose or D-mannitol as a carbon source. A water-soluble brown pigment is not produced on a glucose-peptone-yeast extract-$CaCO_3$ medium, and a levan-like polysaccharide is not produced on a sucrose medium. However, the production of fructan is reported by *Neoasaia chiangmaiensis* NBRC 101099 (Jakob et al. 2013).

Growth occurs on 30 % D-glucose (w/v) and in the presence of 0.35 % acetic acid (w/v), but not in the presence of 1.0 % KNO_3 (w/v). Major cellular fatty acids are $C_{18:1}$ ϖ7c and $C_{16:0}$. Major ubiquinone is Q-10. The G+C content of DNA is 63.1 mol% G+C.

Neoasaia strains are isolated from red ginger (*Alpinia purpurata*).

Neoasaia chiangmaiensis Yukphan, Malimas, Potacharoen, Tanasupawat, Tanticharoen, and Yamada 2006

Characteristics are the same as those described for the species (Yukphan et al. 2005).

The type strain: AC28^T (= BCC 15763^T = NBRC 101099^T), isolated from a flower of red ginger (*Alpinia purpurata*) in Chiang Mai, Thailand, in September 2002. The G+C content of DNA of the type strain is 63.1 mol%.

Neokomagataea Yukphan, Malimas, Muramatsu, Potacharoen, Tanasupawat, Nakagawa, Tanticharoen, and Yamada 2011

Ne.o.ko.ma.ga.ta'ea. N. L. fem. n. new Komagata, named after Dr. Kazuo Komagata, a Japanese microbiologist who contributed to bacterial systematics and phylogeny, especially of acetic acid bacteria.

Two *Neokomagataea* strains were isolated from flowers collected in Thailand. One strain was isolated from a flower of lantana (*Lantana camera*) by the use of an enrichment culture medium containing 2.0 % glucose. The other strain was isolated from a flower of candle bush (*Senna alata*) by the use of an enrichment culture medium containing 10 % glucose. In phylogenetic trees based on 16S rRNA gene sequences, the two strains formed an independent cluster in the family *Acetobacteraceae*. The two isolates were able to grow in the range between 1.0 % and 30 % glucose. Therefore, the isolates are osmotolerant but not osmophilic. A new genus *Neokomagataea* was proposed, and two species, *Neokomagataea thailandica* and *N. tanensis*, were described on the basis of the difference of the G+C content of DNA and acid production from melibiose and raffinose (Yukphan et al. 2011).

The type species is *Neokomagataea thailandica*. The closest neighbor is the genus *Saccharibacter* (❯ *Fig. 1.1*). Currently, this genus contains two species, *N. thailandica* and *N. tanensis*.

Neokomagataea Yukphan et al. 2011

Cells are Gram-negative rods, measuring 0.6–0.8 by 1.0–1.6 μm, and nonmotile. Colonies are smooth, entire, and creamy on glucose-ethanol-peptone-yeast extract-calcium carbonate agar. Growth occurs on glutamate agar or mannitol agar.

Acetic acid is weakly produced from ethanol. Acetate and lactate are not oxidized. Dihydroxyacetone is not produced from glycerol. 2-Keto-D-gluconate, 5-keto-D-gluconate, and 2,5-diketo-D-gluconate are produced from D-glucose. Acid is produced from L-arabinose (weakly), D-xylose, D-fructose, D-glucose, D-galactose (weakly), and sucrose, but not from D-arabinose, D-mannose, lactose, maltose, melibiose, raffinose, dulcitol, *meso*-erythritol, D-mannitol, D-sorbitol, glycerol, or ethanol (*N. tanensis* produces acid from melibiose and raffinose).

Growth occurs on L-rhamnose (weakly), D-glucose, and sucrose, but not on D-arabinose, L-arabinose, L-sorbose, D-xylose, D-fructose, D-galactose, D-mannose, lactose, maltose, melibiose, raffinose, dulcitol, *meso*-erythritol, D-mannitol, D-sorbitol, glycerol, or ethanol (*N. tanensis* grows on raffinose). Methanol is not utilized as a carbon source. Ammoniac nitrogen is assimilated on D-glucose (very weakly) or ethanol as a source of carbon (*N. tanensis* does not grow on D-glucose, D-mannitol, or ethanol). Water-soluble brown pigment is not produced.

Growth occurs on between 1.0 % and 30 % D-glucose (w/v). Osmotolerant. Growth does not occur in the presence of 0.35 % acetic acid (w/v) or in the presence of 1.0 % or 2.0 % NaCl (w/v) or 1.0 % KNO_3 w/v. Major cellular fatty acids are $C_{18:1}$ϖ7c, $C_{18:1}$2OH, and $C_{18:0}$. The major quinone is Q-10. The G+C content of DNA is 51.2–56.8 mol% (the G+C content of DNA of the type strain *N. thailandica* is 56.8 mol%, and that of *N. tanensis* is 51.2 mol%).

Neokomagataea strains are isolated from a flower of lantana (*Lantana camera*) and a flower of candle bush (*Senna alata*).

Neokomagataea thailandica Yukphan, Malimas, Muramatsu, Potacharoen, Tanasupawat, Nakagawa, Tanticharoen, and Yamada 2011

Characteristics are the same as those described for the species (Yukphan et al. 2011).

The type strain: AH11^T (= BCC 25710^T = NBRC 106555^T), isolated from a flower of lantana (*Lantana camera*) at Tan Island, Hat Khanom-Mu Ko Thale Tai National Park, Nakhon Si Thammarat, Thailand in 2007. Does not produce acid from melibiose and raffinose. The G+C content of DNA of the type strain is 56.8 mol%.

Neokomagataea tanensis Yukphan, Malimas, Muramatsu, Potacharoen, Tanasupawat, Nakagawa, Tanticharoen, and Yamada 2011

Characteristics are the same as those described for the species (Yukphan et al. 2011).

The type strain: AH13^T (= BCC 25711^T = NBRC 106556^T), isolated from a flower of candle bush (*Senna alata*) at Tan Island, Hat Khanom-Mu Ko Thale Tai National Park, Nakhon Si Thammarat, Thailand in 2007. Produces acid from melibiose and raffinose. The G+C content of DNA of the type strain is 51.2 mol%.

Nguyenibacter Vu, Yukphan, Chaipitakchonlatarn, Malimas, Muramatsu, Bui, Tanasupawat, Duong, Nakagawa, Pham, and Yamada 2013

Ngu.ye.ni.bac'ter. N.L. masc. n. *Nguyenius* Nguyen (the name of a famous Vietnamese microbiologist); N. L. masc. n. *bacter*, a rod; N.L. masc. n. *Nguyenibacter* a rod, which is named in honor of Dr. Dung Lan Nguyen, Professor, Institute of Microbiology and Biotechnology, Vietnam National University – Hanoi, Hanoi, Vietnam – who contributed to the study of microorganisms, especially of strains isolated in Vietnam.

Two *Nguyenibacter* strains were isolated by an enrichment culture with N_2-free medium (Cavalcante and Döbreiner 1988) from the rhizosphere and roots of Asian rice collected in Vietnam. The results of 16S rRNA gene sequence and so-called partial 16S rRNA gene 800R-region sequence analyses supported the strains in a member of a new genus within the family *Acetobacteraceae*. Thus, the genus *Nguyenibacter* was established (Vu et al. 2013).

The type species is *Nguyenibacter vanlangensis*. The closest neighbor is the genus *Gluconacetobacter* (Fig. 1.1). Currently, this genus consists of a single species, *Nguyenibacter vanlangensis*.

Nguyenibacter Vu et al. 2013

Cells are Gram-negative rods, measuring 0.6–0.8 by 1.0–1.6 μm. Motile with peritrichous flagella. Colonies are smooth, entire, transparent, and creamy to brownish. Growth occurs on glutamate agar and mannitol agar.

Aerobic. Catalase positive. Oxidase negative. Acetic acid is not produced from ethanol. Acetate is oxidized to carbon dioxide and water, but lactate is not oxidized. Dihydroxyacetone is not produced from glycerol. 2-Keto-D-gluconate and 5-keto-D-gluconate are produced from D-glucose. Acid is produced from L-arabinose, D-xylose, D-fructose, D-galactose (weakly), D-glucose, maltose, melibiose, sucrose, and raffinose (weakly), but not from D-arabinose, L-sorbose, L-rhamnose, lactose, dulcitol, *myo*-inositol, D-mannitol, D-sorbitol, glycerol, or ethanol. Growth occurs on L-arabinose (weakly), L-sorbose (weakly), D-xylose (weakly), D-fructose (weakly), D-galactose, D-glucose, maltose, melibiose (weakly), sucrose, raffinose, D-mannitol (weakly), D-sorbitol (weakly), and glycerol, but not from D-arabinose, L-rhamnose, lactose, dulcitol, *myo*-inositol, or ethanol. Ammoniac nitrogen is utilized on D-mannitol, but not on D-glucose or ethanol. Growth occurs on N_2-free medium. γ-Pyrone compound is weakly produced. Water-soluble pigment is produced. Levan-like polysaccharides are produced from sucrose.

Growth occurs weakly on 30 % glucose and weakly in the presence of 0.35 % acetic acid. Growth does not occur on 1.0 % KNO_3. Major cellular fatty acid is $C_{18:1}\varpi7c$. Major quinone is Q-10. The G+C content of DNA ranges from 68.1 to 69.4 mol%.

Nguyenibacter strains were isolated from the rhizosphere and roots of Asian rice collected in Vietnam.

Nguyenibacter vanlangensis Vu, Yukphan, Chaipitakchonlatarn, Malimas, Muramatsu, Bui, Tanasupawat, Duong, Nakagawa, Pham, and Yamada 2013

Characteristics are the same as those described for the species (Vu et al. 2013).

The type strain: TN01LGI^T (= BCC 54774^T = NBRC 109046^T = VTCC-B-1198^T), isolated from the rhizosphere of Asian rice collected at Long Thanh Trung Commune, Hoa Thanh District, Tay Ninh Province, Vietnam. The G+C content of DNA of the type strain is 69.4 mol%.

Saccharibacter Jojima, Mihara, Suzuki, Yokozeki, Yamanaka, and Fudo 2004

Sac.cha.ri.bac'ter. L. neut. n. *saccharum* or *saccharon*, a kind of sugar; N. L. masc. n. *bacter*, rod; N. L. masc. n. *Saccharibacter*, a sugar rod, a rod that grows well in a sugar-rich environment.

Saccharibacter strains were isolated from the pollen of flowers in Japan by the use of an enrichment medium containing 20 % glucose, as producers of xylitol that is a promising low-calorie sweetener. They have rather unusual characteristics for the acetic acid bacteria, such as a negligible or weak capacity to produce acetic acid from ethanol and an osmophilic growth profile. The osmophilic growth property distinguishes the strains from other acetic acid bacteria. Major cellular fatty acids are a 2-hydroxy acid ($C_{16:0}$2-OH) and an unsaturated straight-chain acid ($C_{18:1}\varpi7c$). Phylogenetic analyses of the 16S rRNA gene sequences demonstrated that the isolates formed a new cluster within the family *Acetobacteraceae* in the *Alphaproteobacteria*. The genus *Saccharibacter* was established on the basis of unique biochemical characteristics and phylogenetic profile (Jojima et al. 2004).

The type species is *Saccharibacter floricola*. The closest neighbor is the genus *Neokomagataea* (Fig. 1.1). Currently, this genus contains a single species, *Saccharibacter floricola*.

Saccharibacter Jojima et al. 2004

Cells are Gram negative and straight rods, measuring 0.8–1.0 by 2.5–4.0 μm, and nonmotile. Endospores are not produced.

Colonies are circular, entire, and pale in color on YGP agar. Growth occurs on mannitol and glutamate agar supplemented with 7 % (w/v), but not on glutamate agar supplemented with 1 % (w/v). No growth occurs on ordinary mannitol agar and glutamate agar.

Strictly aerobic. Chemoorganotrophic. Catalase positive. Oxidase negative. Produces negligible or very little acetic acid from ethanol. Acetate is not oxidized to carbon dioxide and water, and lactate is weakly oxidized. Dihydroxyacetone is not produced from glycerol. D-Gluconic acid, 2-keto-D-gluconic acid, and 5-keto-D-gluconic acid are produced from D-glucose. Acid is produced from L-arabinose, D-xylose, D-glucose, D-galactose, D-mannose, melibiose, sucrose, and mannitol, but not from D-arabinose, L-rhamnose, raffinose, D-sorbitol, dulcitol, glycerol, or ethanol. Production of acid from L-sorbose is variable. Methanol is not utilized. Ammoniac nitrogen is not assimilated on Hoyer-Frateur medium with glucose, mannitol, or ethanol. Cellulosic pellicles and water-soluble mucous substances are not produced. Not pigmented.

Growth occurs in the glucose range between 2 % and 40 % (w/v), with an optimum around 10 % (w/v). High glucose concentration [e.g., 10 % (w/v) glucose] is preferable for the growth. Osmophilic. No growth occurs in 0.35 % acetic acid (v/v) at pH 3.5. Temperature for growth ranges from 20 °C to 33 °C and the optimum around 25–30 °C. The growth pH ranges from pH 4.0 to 7.5, and the optimum pH is around pH 5.0–7.0. No growth is observed above pH 8.0 or below pH 4.0. The major cellular fatty acids are $C_{16:0}$ 2-OH (31.1–41.0 %) and $C_{18:1}$ ϖ7*c* (22.0–29.8 %). The major quinone is Q-10. The G+C content of DNA is between 52 and 53 mol%.

Saccharibacter strains are isolated from pollens of flowers.

Saccharibacter floricola Jojima, Mihara, Suzuki, Yokozeki, Yamanaka, and Fudo 2004

Characteristics are the same as those described for the species (Jojima et al. 2004).

The type strain: S-877^T (= AJ 13480^T = DSM 15669^T = JCM 12116^T), isolated from pollen collected in Kanagawa Prefecture, Japan. The G+C content of DNA of the type strain is 52.3 mol%.

Swaminathania Loganathan and Nair 2004

Swa.mi.na.tha'nia. N. L. fem. n. after Swaminathan, Indian biologist, the father of the Green Revolution in India.

Swaminathania strains were isolated from the rhizosphere, roots, and stems of salt-tolerant, mangrove-associated wild rice (*Porteresia coarctata* Tateoka) in Pichavaram, Tamil Nadu, India, with nitrogen-free, semisolid LGI medium at pH 5.5 (Cavalcante and Döbreiner 1988) supplemented with 250 mM NaCl. Phylogenetic analysis based on 16S rRNA gene sequences showed that these strains were related to the genera *Acidomonas*, *Asaia*, *Acetobacter*, *Gluconacetobacter*, *Gluconobacter*, and *Kozakia*. The strains were able to fix nitrogen and solubilize phosphate in the presence of NaCl. Based on overall analysis of the tests and comparison with the characteristics of the members of the family *Acetobacteraceae*, a novel genus *Swaminathania* was established (Loganathan and Nair 2004).

The type species is *Swaminathania salitolerans*. The closest neighbor is the genus *Asaia* (Fig. 1.1). Currently, this genus contains a single species, *Swaminathania salitolerans*.

Swaminathania Loganathan and Nair 2004

Cells are Gram negative and straight rods with round ends, measuring approximately 0.7–0.9 by 1.9–3.1 μm, and motile with peritrichous flagella. Colonies are initially yellowish, becoming dark orange later on, smooth, and raised, with entire margin on LGI medium (Cavalcante and Döbreiner 1988). Growth occurs on mannitol agar and glutamate agar.

Aerobic. Catalase positive. Oxidase negative. Acetic acid is produced from ethanol in neutral and acidic conditions. Glucose is oxidized to acetic acid. Acetate and lactate are oxidized to carbon dioxide and water, but the activity was weak. Acid is produced from L-arabinose, D-galactose, D-glucose, D-mannose, sorbitol, glycerol, and ethanol, but not from L-rhamnose or D-mannitol. Methanol is not utilized. Water-soluble brown pigments are produced on D-glucose- and $CaCO_3$-containing agar plates and GYC agar medium. Brown pigmentation is observed on yeast extract-, D-glucose-, and $CaCO_3$-containing medium. Gelatin and starch are not hydrolyzed. The strains are able to fix nitrogen, which is determined by acetylene reduction assay and PCR amplification of *nifD* gene. Solubilization of phosphate is recognized, which is determined by spotting on Pikovskaya medium and generation of clearing zones (Pikovskaya 1948).

Good growth occurs in the presence of 0.35 % acetic acid at pH 3.5 and 3 % NaCl using 1 % KNO_3 as a nitrogen source.

Major cellular fatty acids are $C_{18:1}$ ϖ7c/ϖ9t/ϖ12t (30.41 %), $C_{13:1}$ AT 12-13 (0.53 %), and $C_{19:0}$ cyclo ϖ8c (11.84 %). The major quinone is Q-10. The G+C content of DNA is between 57.6 and 59.9 mol%.

Swaminathania strains are isolated from mangrove-associated wild rice (*Porteresia coarctata* Tateoka).

Swaminathania salitolerans Loganathan and Nair 2004

Characteristics are the same as those described for the species (Loganathan and Nair 2004).

The type strain: PA51^T (= LMG 21291^T = MTCC 3852^T), isolated from mangrove-associated wild rice in Pichavaram, Tamil Nadu, India. The G+C of DNA of the type strain is 59.9 mol%.

Tanticharoenia Yukphan, Malimas, Muramatsu, Takahashi, Kaneyasu, Tanasupawat, Nakagawa, Suzuki, Potacharoen, and Yamada 2008

Tan.ti.cha.ro.e'nia. N. L. fem. n. named after Dr. Morakot Tanticharoen, National Center for Genetic Engineering and Biotechnology (BIOTEC), National Science and Technology Development Agency (NSTDA), Pathum Thani, Thailand, who contributed to studies of acetic acid bacteria and especially to their systematic study.

Tanticharoenia strains were isolated from soil collected at Sakaerat, Nakhon Ratchasima, in Thailand by an enrichment approach with glucose-ethanol-acetic acid medium. Those are included within a lineage comprising the genera *Asaia*, *Kozakia*, *Swaminathania*, *Neoasaia*, *Acetobacter*, *Gluconobacter*, and *Saccharibacter* in a phylogenetic tree based on 16S rRNA gene sequences but formed a quite different and independent cluster. The strains did not oxidize acetate and lactate and grew on 30 % glucose (w/v). A new genus, *Tanticharoenia*, was established on the basis of biochemical activities and the phylogenetic position (Yukphan et al. 2008).

The type species is *Tanticharoenia sakaeratensis*. The closest neighbor is the genus *Ameyamaea* (Fig. 1.1). Currently, this genus comprises a single species, *Tanticharoenia sakaeratensis*.

Tanticharoenia Yukphan et al. 2008

Cells are Gram negative, rod-shaped, measuring 0.6–0.8 by 1.0–1.6 μm, and nonmotile. Colonies are creamy and smooth with entire margin when grown on glucose-ethanol-peptone-yeast extract-calcium carbonate agar. Growth occurs on glutamate agar (weakly positive) and mannitol agar.

Acetic acid is produced from ethanol. Acetate and lactate are not oxidized. Dihydroxyacetone is produced from glycerol. 2-Keto-D-gluconate, 5-keto-D-gluconate, and 2,5-diketo-D-gluconate are produced from D-glucose. Acid is produced from L-arabinose, D-xylose, D-fructose (weakly positive), D-galactose, D-glucose, D-mannose, melibiose, sucrose (weakly positive), raffinose (weakly positive), *meso*-erythritol, glycerol, and ethanol, but not from D-arabinose, L-sorbose, L-rhamnose, lactose, maltose, dulcitol, D-mannitol, or D-sorbitol. Growth occurs on D-arabinose, D-xylose, D-fructose, D-glucose, D-galactose, *meso*-erythritol, D-mannitol, D-sorbitol, glycerol, or sucrose, but not on D-arabinose, L-sorbose, L-rhamnose, D-mannose, lactose, maltose, melibiose, raffinose, dulcitol, or ethanol. Ammoniac nitrogen is not assimilated in the presence of D-glucose, D-mannitol, or ethanol as a carbon source. Growth does not occur on methanol. A water-soluble brown pigment is intensely produced on glucose-peptone-yeast extract-calcium carbonate agar.

Growth occurs in the presence of 0.35 % acetic acid (w/v), but not of 1 % KNO_3. Growth occurs on 30 % D-glucose (w/v). The major quinone is Q-10. The G+C content of DNA ranges from 64.5 to 65.6 mol%.

Tanticharoenia strains are isolated from soil.

Tanticharoenia sakaeratensis Yukphan, Malimas, Muramatsu, Takahashi, Kaneyasu, Tanasupawat, Nakagawa, Suzuki, Potacharoen, and Yamada 2008

Characteristics are the same as those described for the species (Yukphan et al. 2008).

Type strain: AC37^T (= BCC 15772^T = NBRC 103193^T), isolated from soil collected at Sakaerat, Nakhon Ratchasima, Thailand. The G+C content of the type strain is 65.6 mol%.

The Acidophilic Group

The acidophilic group is said aerobic phototrophic bacteria in another way (Yurkov 2006). Photosynthesis in purple bacteria has been widely assumed to be an anaerobic metabolic process, active in light and anaerobic conditions. However, bacteriochlorophyll (BChl) *a* was found in aerobic heterotrophic bacteria in spite of no growth of the bacteria in anaerobic and phototrophic conditions (Sato 1978; Harashima et al. 1978). The properties of BChl-protein complexes in aerobic phototrophic bacteria were shown to be similar to those in typical anaerobic photosynthetic bacteria although photochemical reactions supported only under aerobic conditions (Yurkov and Beatty 1998). The majority of the aerobic phototrophic bacteria are phylogenetically associated with the member of the class *Alphaproteobacteria*. Among the aerobic phototrophic bacteria, the acidophilic group belonging to the family *Acetobacteraceae* has heterogeneous natures as shown in Table 1.4, e.g., acidophilic to slightly alkaliphilic, mesophilic to moderately thermophilic, and phototrophic or non-phototrophic. The acidophilic group mostly consists of the species with being catalase positive and oxidase positive, which differs from the acetous group.

Acidicaldus Johnson, Stallwood, Kimura, and Hallberg 2006

A.ci.di.cal'dus. N. L. n. *acidum* an acid; N. L. adj. *caldus*, warm; a (moderately) thermophilic acid-requiring microorganism.

Acidicaldus strains are facultatively anaerobic, moderately thermophilic, acidophilic bacteria and were isolated from acidic geothermal springs and soils in Yellowstone National Park, Wyoming (Johnson et al. 2003, 2006). Those formed an independent lineage near the genus *Acidisphaera* in a phylogenetic tree based on 16S rRNA gene sequences but formed an independent lineage (Fig. 1.1). Currently, this genus contains a single species, *Acidicaldus organivorus*.

Acidicaldus Johnson et al. 2006

Cells are Gram negative, non-sporulating, motile, and rod-shaped. Obligately heterotrophic, acidophilic, and moderately thermophilic. Facultative anaerobes, growing by ferric iron

Table 1.4

respiration in the absence of oxygen. Colonies are round to convex and off-white. Bacteriochlorophyll (BChl) *a* and carotenoids are absent.

Grows on simple organic compounds such as sugars and small molecular weight alcohols, but aliphatic acids inhibit growth at millimolar concentrations. Capable of dissimilatory oxidation of elemental sulfur, but not of autotrophic growth on sulfur in organic-free media. The G+C content of the genomic DNA is ca. 72 mol%. The type species is *Acidicaldus organivorus*.

Acidicaldus organivorus Johnson, Stallwood, Kimura, and Hallberg 2006

The characteristics of the species are the same as those described for the species (Johnson et al. 2006).

Type strain: Y008^T (= ATCC BAA-1105^T = DSM 16953^T), isolated from acidic geothermal springs and soils in Yellowstone National Park, Wyoming. The G+C content of DNA of the type strain is 71.8 ± 0.9 mol%.

Acidiphilium Harrison 1981 emend. Kishimoto, Kosko, Wakao, Tano, and Hiraishi 1996

A.ci.di.phi.li'um. N.L. n. *acidum* (from L. adj. *acidus*, sour), an acid; N.L. neut. adj. *philum* (from Gr. neut. adj. *philon*), friend, loving; N.L. neut. n. *Acidiphilium*, acid lover.

Acidiphilium strains are aerobic, mesophilic, acidophilic bacteria and were isolated from acidic drainage waters and mine refuse from mines (Harrison 1981; Kishimoto and Tano 1987; Lobos et al. 1986; Wakao et al. 1988; Wichlacz and Unz 1981). The closest neighbor is the genus *Acidocella* (*Fig. 1.1*). Currently, this genus contains six species.

Acidiphilium Harrison 1981

Cells are Gram negative, non-sporulating, and rod-shaped, 0.6–3.8 μm long. Motile or nonmotile; motile cells have one polar flagellum or two lateral flagella. Aerobic. Chemoorganotrophic or heterotrophic, mesophilic, and acidophilic. Colonies are white to cream, yellow, pink, red, or brown.

Catalase positive. Oxidase variable. Some strains form BChl *a* and carotenoid. Sugars, sugar alcohols, organic acids, and amino acids are used as a carbon and energy sources. Sodium acetate inhibits the growth of some strains.

The major cellular fatty acid is $C_{18:1}$. The major quinone is Q-10. The G+C content of the genomic DNA is between 63 and 70 mol%. The type species is *Acidiphilium cryptum*.

Acidiphilium cryptum Harrison 1981

The characteristics of the species are the same as those described for the species (Harrison 1981).

Type strain: Lhet2^T (= ATCC 33463^T = DSM 2389^T = JCM 21277^T = NBRC 14242^T =NCIMB 11690^T), isolated from a culture of *Thiobacillus ferrooxidans* from coal mine water in Pennsylvania. The G+C content of DNA of the type strain is 69.8 mol%.

Acidiphilium acidophilum (Harrison 1981) Hiraishi, Nagashima, Matsuura, Shimada, Takaichi, Wakao, and Katayama 1998

The characteristics of the species are based on information from the previous data (Guay and Silver 1975; Harrison 1983; Hiraishi et al. 1998; Katayama-Fujimura et al. 1982, 1983, 1984; Mason et al. 1987; Norris et al. 1986; Pronk et al. 1990).

Type strain: ATCC 27807^T (= CIP 104483^T = DSM 700^T), isolated from an iron-oxidizing culture of *Thiobacillus ferrooxidans*. The G+C content of DNA of the type strain is 63.5 mol%.

Acidiphilium angustum Wichlacz, Unz, and Langworthy 1986

The characteristics of the species are the same as those described for the species (Wichlacz et al. 1986).

Type strain: KLB^T (= ATCC 35903^T = NCCB 86036^T), isolated from acidic waters discharged from abandoned coal mines in central Pennsylvania. The G+C content of DNA of the type strain is 67 mol%.

Acidiphilium multivorum Wakao, Nagasawa, Matsuura, Matsukura, Matsumoto, Hiraishi, Sakurai, and Shiota 1995

The characteristics of the species are the same as those described for the species (Wakao et al. 1994).

Type strain: AIU 301^T (= DSM 11245^T = JCM 8867^T = NBRC 100785^T = NBRC 100883^T), isolated from pyritic acid mine drainage. The G+C content of DNA of the type strain is 69.8 mol%.

Acidiphilium organovorum Lobos, Chisolm, Bopp, and Holmes 1986

The characteristics of the species are the same as those described for the species (Lobos et al. 1986).

Type strain: ATCC 43141^T (= NCCB 86037^T), isolated from a *Thiobacillus ferrooxidans* culture. The G+C content of DNA of the type strain is 64 mol%.

Acidiphilium rubrum Wichlacz, Unz, and Langworthy 1986

The characteristics of the species are the same as those described for the species (Wichlacz et al. 1986).

Type strain: OP^T (= ATCC 35905^T), isolated from acidic waters discharged from abandoned coal mines in central Pennsylvania. The G+C content of DNA of the type strain is 63 mol%.

Acidisoma Belova, Pankratov, Detkova, Kaparulina, and Dedysh 2009

A.ci.di.so'ma. M.L. n. *acidum* in acid; Gr. neut. n. *soma* body; M.L. neut. n. *Acidisoma* an acid(-requiring) body.

Acidisoma strains are aerobic, mesophilic, and acidophilic and were isolated from acidic Sphagnum-dominated tundra and Siberian wetlands in Russia (Belova et al. 2009). The strains phylogenetically belong to the class *Alphaproteobacteria* but were distantly related to the type strains of acidophilic bacteria: *Acidisphaera rubrifaciens* (93.4–94.3 % 16S rRNA gene sequence identity), members of the genera *Acidiphilium* (91.3–93 %), and *Acidocella* (91.8–92.4 %). The closest neighbors are the genera *Acidisphaera* and *Acidicaldus* (Fig. 1.1). Currently, this genus contains two species.

Acidisoma Belova et al. 2009

Cells are Gram negative, non-sporulating, nonmotile, and coccobacilli. Strictly aerobic, chemoorganotrophic, psychrotolerant, and moderately acidophilic. Colonies are circular, smooth, convex slimy, and white to cream and pinkish.

Catalase positive. Oxidase positive. BChl *a* is absent. Sugars, polyalcohols, and some organic acids are used as carbon sources. The major cellular fatty acid is cyclo $C_{19:0}\omega 8c$. The major quinone is Q-10. The major polar lipids are phosphatidylcholine, diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylglycerol, and unknown aminolipids. The G+C content of the genomic DNA is between 60 and 62 mol%. The type species is *Acidisoma tundrae*.

Acidisoma tundrae Belova, Pankratov, Detkova, Kaparulina, and Dedysh 2009

The characteristics of the species are the same as those described for the species (Belova et al. 2009).

Type strain: WM1^T (= DSM 19999^T = VKM B-2488^T), isolated from an acidic oligotrophic Sphagnum-dominated wetland in the Vorkuta region of northern Russia. The G+C content of DNA of the type strain is 61.9 mol%.

Acidisoma sibiricum Belova, Pankratov, Detkova, Kaparulina, and Dedysh 2009

The characteristics of the species are the same as those described for the species (Belova et al. 2009).

Type strain: TPB606^T (= DSM 21000^T = VKM B-2487^T), isolated from the Sphagnum peat bog Bakchar in the Tomsk region of western Siberia. The G+C content of DNA of the type strain is 60.5 mol%.

Acidisphaera Hiraishi, Matsuzawa, Kanbe, and Wakao 2000

A.ci.di.sphae'ra. M.L. n. *acidum* an acid; M.L. fem. n. *sphaera* a sphere; M.L. fem. n. *Acidisphaera* acid-requiring coccoid microorganism.

Acidisphaera strains are aerobic, mesophilic, and acidophilic and produce BChl *a*. The strains were isolated from surface water and sediment from an acidic hot spring and pyritic mine drainage (Hiraishi et al. 2000). Those were phylogenetically clustered in the acidophilic group which includes the genera *Acidiphilium* and *Rhodopila*. The closest neighbor is the genus *Acidicaldus* with 93.4 % of 16S rRNA gene sequence similarity (Fig. 1.1). Currently, this genus contains a single species, *Acidisphaera rubrifaciens*.

Acidisphaera Hiraishi et al. 2000

Cells are Gram negative, non-sporulating, nonmotile, and cocci or coccobacilli, 0.8–1.2 μm long. Obligately aerobic, chemoorganotrophic, facultative photoorganotroph mesophilic, and obligately acidophilic. Colonies are circular, smooth, convex, and salmon-pink to red.

Catalase positive. Oxidase positive. Produces Bchl *a* and carotenoid. The major quinone is Q-10. The G+C content of the genomic DNA is between 69.1 and 69.8 mol%. The type species is *Acidisphaera rubrifaciens*.

Acidisphaera rubrifaciens Hiraishi, Matsuzawa, Kanbe, and Wakao 2000

The characteristics of the species are the same as those described for the species (Hiraishi et al. 2000).

Type strain: HS-AP3^T (= JCM 10600^T), isolated from surface water from an acidic hot spring in Hakone, Kanagawa Prefecture, Japan. The G+C content of DNA of the type strain is 69.3 mol%.

Acidocella Kishimoto, Kosako, Wakao, Tano, and Hiraishi 1995

A.ci.do.cel'la. Gr. n. *acidum* an acid; L. fem. n. *cella* a cell; N.L. fem. n. *Acidocella*, acid (-requiring) cell.

Acidocella strains are aerobic, mesophilic, and acidophilic. The strains were isolated from acidic mine drainage and mud (Kishimoto and Tano 1987; Wichlacz et al. 1986). *Acidocella* was distinguished from *Acidiphilium* by 16S rRNA gene sequence analysis with less than 94.2 % similarity (Kishimoto et al. 1995). The closest neighbor is the genus *Acidiphilium* (Fig. 1.1). Currently, this genus contains three species.

Acidocella Kishimoto et al. 1995

Cells are Gram negative, non-sporulating, and rod-shaped, 1.0–1.8 μm long. Motile or nonmotile; motile cells have a polar flagellum. Strictly aerobic. Chemoorganotrophic. Mesophilic. Acidophilic. Colonies are circular, smooth, opaque, and white to pale light brown. Catalase positive. Oxidase negative. BChl and carotenoids are absent.

The major cellular fatty acid is $C_{18:1}$. The major quinone is Q-10. The G+C content of the genomic DNA is between 63 and 70 mol%. The type species is *Acidocella facilis*. The G+C content of the genomic DNA is between 58.7 and 65.6 mol%.

Acidocella facilis (Wichlacz, Unz and Langworthy 1986) Kishimoto, Kosako, Wakao, Tano, and Hiraishi 1996

The characteristics of the species are the same as those described for the species (Kishimoto et al. 1995; Wichlacz et al. 1986).

Type strain: PW2^T (= ATCC 35904^T = NCCB 86038^T), isolated from acidic waters discharged from abandoned coal mines in central Pennsylvania. The G+C content of DNA of the type strain is 65 mol%.

Acidocella aluminiidurans Kimoto, Aizawa, Urai, Ve, Suzuki, Nakajima, and Sunairi 2010

The characteristics of the species are the same as those described for the species (Kimoto et al. 2010).

Type strain: AL46^T (= NBRC 104303^T = VTCC-D9-1^T), isolated from a waterweed, *Panicum repens*, grown in a highly acidic swamp (pH 3) at an actual acid sulfate soil area of Vietnam. The G+C content of DNA of the type strain is 65.6 mol%.

Acidocella aminolytica (Kishimoto, Kosako, and Tano 1994) Kishimoto, Kosako, Wakao, Tano, and Hiraishi 1996

The characteristics of the species are the same as those described for the species (Kishimoto et al. 1993, 1995).

Type strain: 101^T (= ATCC 51361^T = DSM 11237^T = JCM 8796^T), isolated from acidic mine drainage. The G+C content of DNA of the type strain is 58.7 mol%.

Belnapia Reddy, Nagy, and Garcia-Pichel 2006

Bel.na'pi.a. N.L. fem. n. *Belnapia* after J. Belnap, in honor of her contributions to the study of biological soil crusts (BSCs).

Belnapia strains are aerobic, mesophilic, neutrophilic, and facultatively fermentative. The strains were isolated from biological soil crusts, forest soil, and grass soil (Jin et al. 2012, 2013; Reddy et al. 2006). Those were phylogenetically distantly related BChl-producing bacteria *Paracraurococcus ruber* (<94.9 %), *Craurococcus roseus* (<92.2 %), and *Roseococcus thiosulfatophilus* (<92.3 %) and non-BChl-producing bacteria *Roseomonas rosea* (<94.9 %), *Roseomonas gilardii* (<94.2 %), and *Roseomonas mucosa* (<93.8 %). Currently, this genus contains three species.

Belnapia Reddy et al. 2006

Cells are Gram negative, non-sporulating, nonmotile, and cocci. Aerobic, facultative fermentative, mesophilic, and neutrophilic. Colonies are circular, smooth or rough, convex, and red to pink. Catalase positive. Oxidase variable. BChl is absent, and carotenoid is produced.

The major cellular fatty acids are $C_{18:1}\omega7c/C_{18:1}\omega6c$ and $C_{16:0}$. The major quinone is Q-9. The G+C content of the genomic DNA is between 70 and 75 mol%. The type species is *Belnapia moabensis*.

Belnapia moabensis Reddy, Nagy, and Garcia-Pichel 2006

The characteristics of the species are the same as those described for the species (Reddy et al. 2006).

Type strain: CP2C^T (= ATCC BAA-1043^T = DSM 16746^T), isolated from biological soil crusts in the Colorado Plateau, USA. The G+C content of DNA of the type strain is 75 mol%.

Belnapia rosea Jin, Liu, Wei, Li, Zhang, and Yu 2012

The characteristics of the species are the same as those described for the species (Jin et al. 2012).

Type strain: CPCC 100156^T (= DSM 23312^T = CGMCC 1.10758^T), isolated from a forest soil from Hainan Island, South China. The G+C content of DNA of the type strain is 70.3 mol%.

Belnapia soli Jin, Lee, No, Ko, Kim, Ahn, and Oh 2013

The characteristics of the species are the same as those described for the species (Jin et al. 2013).

Type strain: PB-K8^T (= JCM 18033^T = KCTC 23765^T), isolated from grass soil in Daejeon, Republic of Korea. The G+C content of DNA of the type strain is 72.1 mol%.

Craurococcus Saitoh, Suzuki, and Nishimura 1998

Cra.u.ro.coc'cus. Gr. adj. *crauros* fragile; Gr. n. *coccus* a grain, berry; M.L. masc. n. *Craurococcus* fragile coccus.

A Craurococcus strain is aerobic, mesophilic, neutrophilic, and heterotrophic and contains BChl. The strain was isolated from soil (Saitoh and Nishimura. 1996). Phylogenetic analysis revealed that *Craurococcus* formed a distinct lineage with *Paracraurococcus ruber* (94.2 %) in the class *Alphaproteobacteria*.

Craurococcus Saitoh et al. 1998

Cells are Gram negative, nonmotile, and cocci, 0.8–2.0 μm in size. Aerobic, heterotrophic, mesophilic, and neutrophilic. No growth occurs anaerobically in the light. Colonies are irregular and pink. Catalase positive. Oxidase positive. BChl *a* is present. Currently, this genus contains a single species, *Craurococcus roseus*.

The major cellular fatty acid is $C_{18:1}$. The major quinone is Q-10. The G+C content of the genomic DNA is 70.5 mol%. The type species is *Craurococcus roseus*.

Craurococcus roseus Saitoh, Suzuki, and Nishimura 1998

The characteristics of the species are the same as those described for the species (Saitoh et al. 1998).

Type strain: NS130^T (= CIP 105707^T = JCM 9933^T), isolated from soil. The G+C content of DNA of the type strain is 70.5 mol%.

Humitalea Margesin and Zhang 2013

Hu.mi.ta'le.a. L. n. *humus* soil; L. fem. n. *talea* a rod, stick; N.L. fem. n. *Humitalea* a rod from soil.

Humitalea strain is aerobic, mesophilic, and neutrophilic and produces BChl. The strain was isolated from soil (Margesin and Zhang 2013). The strain was phylogenetically related to members of the genera *Roseococcus* and *Rubritepida* (<92.8 %) but formed a distinct lineage in the family *Acetobacteraceae* (Fig. 1.1). Currently, this genus contains a single species, *Humitalea rosea*.

Humitalea Margesin and Zhang 2013

Cells are Gram negative, nonmotile, and rod-shaped, 1.4–1.7 μm long. Obligately aerobic, mesophilic, and neutrophilic. Colonies are smooth, round, glossy, convex, circular with entire margins, and pale pinkish. Catalase positive. Oxidase positive. BChl *a* is present.

The major cellular fatty acids are $C_{18:1}\omega7c$ and $C_{16:1}\omega7c$/iso-$C_{15:0}$ 2-OH. The major polar lipids are phosphatidylglycerol, diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylchloline, and unidentified aminolipids. The G+C content of the genomic DNA is 68.2 mol%. The type species is *Humitalea rosea*.

Humitalea rosea Margesin and Zhang 2013

The characteristics of the species are the same as those described for the species (Margesin and Zhang 2013).

Type strain: W37^T (= CIP 110261^T = LMG 26243^T), isolated from soil. The G+C content of DNA of the type strain is 68.2 mol%.

Paracraurococcus Saitoh, Suzuki, and Nishimura 1998

Pa.ra.cra.u.ro.coc'cus. Gr. Prep. *Para* like, along side of; Gr. adj. *crauros* fragile; Gr. n. *coccus* a grain, berry; M.L. masc. n. *Paracraurococcus* coccus like *Craurococcus*.

Paracraurococcus strains are aerobic, mesophilic, neutrophilic, and heterotrophic and contain BChl. The strains were isolated from soil (Saitoh and Nishimura. 1996). Phylogenetic analysis revealed that *Paracraurococcus* formed a distinct lineage with *Craurococcus roseus* (94.2 %) in the class *Alphaproteobacteria* (Fig. 1.1). Currently, this genus contains a single species, *Paracraurococcus ruber*.

Paracraurococcus Saitoh et al. 1998

Cells are Gram negative, nonmotile, and cocci, 0.8–1.5 μm in size. Aerobic, heterotrophic, mesophilic, and neutrophilic. No growth occurs anaerobically in the light. Colonies are irregular and red. Catalase positive. Oxidase positive. BChl *a* is present.

The major cellular fatty acid is $C_{18:1}$. The major quinone is Q-10. The G+C content of the genomic DNA is 70.3–71.0 mol%. The type species is *Paracraurococcus ruber*.

Paracraurococcus ruber Saitoh, Suzuki, and Nishimura 1998

The characteristics of the species are the same as those described for the species (Saitoh et al. 1998).

Type strain: NS89^T (= CIP 105708^T = JCM 9931^T), isolated from soil. The G+C content of DNA of the type strain is 70.3 mol%.

Rhodopila Imhoff, Trüper, and Pfennig 1984

Rho.do.pi'la. Gr. n. *rhodon* rose; M.L. fem. n. *pila* ball or sphere; M.L. fem. n. *Rhodopila* red-colored spherical bacterium.

A *Rhodopila* strain is anaerobic, mesophilic, acidophilic, and phototrophic and produces BChl. The strain was isolated from the acidic water and sludge sample from a warm sulfur spring of pH 3.0 near the Gibbon River in the Yellowstone Park, Wyoming, USA (Pfennig 1974). The strain was once named *Rhodopseudomonas globiformis* but reidentified as *Rhodopila globiformis* on the basis of amino acid sequence of cytochromes *c*, DNA-rRNA hybridization, 16S rRNA oligonucleotide catalogs, and major components of the polar lipids (Imhoff et al. 1984; Pfennig and Trüper 1983). Currently, this genus contains a single species, *Rhodopila globiformis*.

Rhodopila Imhoff, Trüper et al. 1984

Cells are Gram negative, spherical to ovoid, 1.6–1.8 µm in diameter, and motile by means of a polar flagellum. Photoheterotrophic, growing either anaerobically in the light or microaerobically in the dark. Mesophilic and acidophilic. Cells growing anaerobically in the light are red, and those growing microaerobically are pink. BChl *a* and carotenoids are present.

The major cellular fatty acids are $C_{18:1}$ and $C_{16:0}$. The G+C content of the genomic DNA is 66.3 mol%. The type species is *Rhodopila globiformis*.

Rhodopila globiformis (Pfennig 1974) Imhoff et al. 1984

The characteristics of the species are the same as those described for the species (Pfennig 1974; Imhoff et al. 1984).

Type strain: 7950^T (= ATCC 35887^T = DSM 161^T = LMG 4312^T), isolated from the acidic water and sludge sample from a warm sulfur spring at the Gibbon River, Yellowstone Park, Wyoming, USA. The G+C content of DNA of the type strain is 66.3 mol%.

Rhodovarius Kämpfer, Busse, Rosselló-Mora, Kjellin, and Falsen 2004

Rho.do.va'ri.us. Gr. n. *rhodon*, the rose; L. adj. *varius*, diverse, varied; M.L. masc. n. *Rhodovarius*, the varying red-colored one.

A *Rhodovarius* strain is aerobic, mesophilic, and neutrophilic. The strain was isolated from a Rodac medium during a routine industrial hygiene control (Kämpfer et al. 2004). The strain was formed a phylogenetically distinct lineage in the class *Alphaproteobacteria* (Fig. 1.1). Currently, this genus contains a single species, *Rhodovarius lipocyclicus*.

Rhodovarius Kämpfer et al. 2004

Cells are Gram negative and short rods, 1.0–1.2 µm long. Long filaments are formed in liquid culture. Strictly aerobic, chemoorganotrophic, mesophilic, and neutrophilic. Colonies are red. Catalase positive. Oxidase positive. BChl is absent, but carotenoids are present.

The major cellular fatty acids are cyclo $C_{19:0}\omega 8c$ and cyclo $C_{17:0}$. The major quinone is Q-10. The major polar lipids are phosphatidylglycerol, phosphatidylethanolamine, phosphatidyl di-methylethanolamine, phosphatidylcholine, and unknown aminolipids. The G+C content of the genomic DNA is 72.4 mol%. The type species is *Rhodovarius lipocyclicus*.

Rhodovarius lipocyclicus Kämpfer, Busse, Rosselló-Mora, Kjellin, and Falsen 2004

The characteristics of the species are the same as those described for the species (Kämpfer et al. 2004).

Type strain: CCUG 44693^T (= CIP 108310^T), isolated from Rodac medium during a routine industrial hygiene control submitted to CCUG for identification. The G+C content of DNA of the type strain is 72.4 mol%.

Roseococcus Yurkov, Stackebrandt, Holmes, Fuerst, Hugenholtz, Golecki, Gad'on, Gorlenko, Kompantseva, and Drews 1994

Ro.se.o.coc'cus. M.L. adj. *roseus* rose, pink; Gr. n. *coccus* sphere or spheroidal shape; M.L. masc. n. *Roseococcus* pink spherical bacterium.

Roseococcus strains are aerobic, mesophilic, slightly alkaliphilic, and facultatively photoheterotrophic and produce BChl. The strains were isolated from freshwater cyanobacterial mat of a thermal alkaline sulfide spring and a low-mineralized steppe soda lake (Boldareva et al. 2009; Yurkov et al. 1994). Those were phylogenetically moderately related to *Rubritepida flocculans* with less than 95.0 % 16S rRNA gene sequence similarity. Currently, this genus contains two species.

Roseococcus Yurkov et al. 1994

Cells are Gram negative, cocci or short rods, 1.2–1.7 µm long, and motile by means of a single polar flagellum. Obligately aerobic, chemoorganotrophic, facultatively photoheterotrophic, mesophilic, and neutrophilic to alkaliphilic. Colonies are pinkish. BChl *a* and carotenoids are present.

The major cellular fatty acid is $C_{18:1}\omega 7c$. The G+C content of the genomic DNA is between 69.1 and 70.4 mol%. The type species is *Roseococcus thiosulfatophilus*.

Roseococcus thiosulfatophilus Yurkov, Stackebrandt, Holmes, Fuerst, Hugenholtz, Golecki, Gad'on, Gorlenko, Kompantseva, and Drews 1994

The characteristics of the species are the same as those described for the species (Yurkov et al. 1994).

Type strain: RB3^T (= ATCC 700004^T = DSM 8511^T), isolated from freshwater cyanobacterial mat of a thermal alkaline sulfide spring. The G+C content of DNA of the type strain is 70.4 mol%.

Roseococcus subuntuyensis Boldareva, Tourova, Kolganova, Moskalenko, Makhneva, and Gorlenko 2009

The characteristics of the species are the same as those described for the species (Boldareva et al. 2009).

Type strain: SHET^T (= DSM 19979^T = VKM B-2453^T), isolated from the low-mineralized steppe soda lake (Eastern Siberia). The G+C content of DNA of the type strain is 69.1 mol%.

Roseomonas Rihs, Brenner, Weaver, Steigerwalt, Hollis, and Yu 1998

Ro.se.o.mo'nas M.L. adj. *roseus* rosy, rose colored, or pink; Gr. n. *monas* a unit; M.L. n. *Roseomonas*, a pink-pigmented bacterium.

Roseomonas strains are aerobic, mesophilic, neutrophilic, and chemoorganotrophic. The genus *Roseomonas* is associated with pathogenic for humans, causing bacteremia, wound, urinary tract, and other infections, usually as a secondary or opportunistic pathogens. *Roseomonas* strains are isolated from the blood and cervix of patients, air, drinking water, water of estuary and pond, soil, and freshwater sediment. The closest neighbors are the genera *Paracraurococcus* and *Craurococcus* (*Fig. 1.1*). Currently, this genus contains 16 species and 2 subspecies.

Roseomonas Rihs et al. 1998

Cells are cocci, coccobacilli, or rod-shaped, 0.6–3.0 μm long. Motile or nonmotile; motile cells have one polar flagellum. Gram negative, non-sporulating, aerobic, chemoorganotrophic, mesophilic, and neutrophilic. Colonies are white, yellow, orange, or pink. Catalase positive. Oxidase variable.

The major cellular fatty acid is $C_{18:1}$ 2-OH. The major quinone is Q-10. The major polar lipids are diphosphatidylglycerol, phosphatidylglycerol, phosphatidylethanolamine, phosphatidylcholine, and/or unidentified aminolipids. The G+C content of the genomic DNA ranges 65–73 mol%. The type species is *Roseomonas gilardii*.

Roseomonas gilardii subsp. *gilardii* (Rihs, Brenner, Weaver, Steigerwalt, Hollis, and Yu 1998) Han, Pham, Tarrand, Rolston, Helsel, and Levett 2003

The characteristics of the species are the same as those described for the species (Han et al. 2003; Rihs et al. 1993). *R. gilardii* corresponded to *Roseomonas* genomospecies 1 defined by Rihs et al. (1998) and Wayne et al. 1987).

Type strain: 5424^T (= ATCC 49956^T = CCUG 33005^T = CIP 104026^T), isolated from potable water around 1980. The G+C content of DNA of the type strain is 67.6 mol%.

Roseomonas gilardii subsp. *rosea* Han, Pham, Tarrand, Rolston, Helsel, and Levett 2003

The characteristics of the species are the same as those described for the subspecies (Han et al. 2003).

Type strain: MDA5605^T (= ATCC BAA-691^T = NCTC 12390^T), isolated from a patient's blood in 1999.

Roseomonas aerilata Yoo, Weon, Noh, Hong, Lee, Kim, Kwon, and Go 2008

The characteristics of the species are the same as those described for the species (Yoo et al. 2008).

Type strain: 5420S-30^T (= DSM 19363^T = KACC 12521^T), isolated from air sampled at an urban site in Suwon city, Republic of Korea. The G+C content of DNA of the type strain is 72.1 mol%.

Roseomonas aerophila Kim, Weon, Ahn, Hong, Seok, Whang, and Kwon 2013

The characteristics of the species are the same as those described for the species (Kim et al. 2013).

Type strain: 7515 T-07^T (= KACC 16529^T = NBRC 108923^T), isolated from air sampled in the Taean region, Republic of Korea. The G+C content of DNA of the type strain is 73.0 mol%.

Roseomonas aestuarii Venkata Ramana, Sasikala, Takaichi, and Ramana 2010

The characteristics of the species are the same as those described for the species (Venkata Ramana et al. 2010).

Type strain: JC17^T (= CCUG 57456^T = KCTC 22692^T = NBRC 105654^T), isolated from estuary water in India. The G+C content of DNA of the type strain is 66.2 mol%.

Roseomonas aquatica Gallego, Sánchez-Porro, García, and Ventosa 2006

The characteristics of the species are the same as those described for the species (Gallego et al. 2006).

Type strain: TR53^T (= CECT 7131^T = JCM 13556^T), isolated from drinking water. The G+C content of DNA of the type strain is 68.6 mol%.

Roseomonas cervicalis Rihs, Brenner, Weaver, Steigerwalt, Hollis, and Yu 1998

The characteristics of the species are the same as those described for the species (Rihs et al. 1993). *R. cervicalis* is corresponded *Roseomonas* genomospecies 2 defined by Rihs et al. (1998) and Wayne et al. (1987).

Type strain: E7107^T (= ATCC 49957^T = CIP 104027^T), isolated from the cervix of a woman in New Jersey in 1980. The G+C content of DNA of the type strain is 70.6 mol%.

Roseomonas frigidaquae Kim, Baik, Park, Rhee, Oh, and Seong 2009

The characteristics of the species are the same as those described for the species (Kim et al. 2009).

Type strain: CW67^T (= JCM 15073^T = KCTC 22211^T), isolated from a cooled water from an oxygen-producing plant in Gwangyang, Republic of Korea. The G+C content of DNA of the type strain is 69.5 mol%.

Roseomonas lacus Jiang, Dai, Wang, Zhou, and Liu 2006

The characteristics of the species are the same as those described for the species (Jiang et al. 2006).

Type strain: TH-G33^T (= CGMCC 1.3617^T = JCM 13283^T), isolated from freshwater lake sediment. The G+C content of DNA of the type strain is 71.9 mol%.

Roseomonas ludipueritiae (Kämpfer, Andersson, Jäckel, and Salkinoja-Salonen 2003) Sánchez-Porro, Gallego, Busse, Kämpfer, and Ventosa 2009

The characteristics of the species are the same as those described for the species (Kämpfer et al. 2003; Sánchez-Porro et al. 2009).

Type strain: 170/96^T (= CIP 107418^T = DSM 14915^T), isolated from non-water-damaged building material of a children's day-care center. The G+C content of DNA of the type strain is 65.8 mol%.

Roseomonas mucosa Han, Pham, Tarrand, Rolston, Helsel, and Levett 2003

The characteristics of the species are the same as those described for the species (Han et al. 2003).

Type strain: MDA5527^T (= ATCC BAA-692^T = CCUG 48654^T = NCTC 13291^T), isolated from patient's blood in 1999.

Roseomonas pecuniae Lopes, Espírito-Santo, Grass, Chung, and Morais 2011

The characteristics of the species are the same as those described for the species (Lopes et al. 2011).

Type strain: N75^T (= CIP 110074^T = LMG 25481^T), isolated from the surface of a 50 Euro cent copper-alloy coin. The G+C content of DNA of the type strain is 72.5 mol%.

Roseomonas riguiloci Baik, Park, Choe, Kim, Moon, and Seong 2012

The characteristics of the species are the same as those described for the species (Baik et al. 2012).

Type strain: 03SU10-P^T (= JCM 17520^T = KCTC 23339^T), isolated from freshwater from Woopo wetland in Gyeongnam Province, Republic of Korea. The G+C content of DNA of the type strain is 68 mol%.

Roseomonas rosea (Kämpfer, Andersson, Jäckel, and Salkinoja-Salonen 2003) Sánchez-Porro, Gallego, Busse, Kämpfer, and Ventosa 2009

The characteristics of the species are the same as those described for the species (Kämpfer et al. 2003; Sánchez-Porro et al. 2009).

Type strain: 173/96^T (= CIP 107419^T = DSM 14916^T), isolated from non-water-damaged building material of a children's day-care center. The G+C content of DNA of the type strain is 68.9 mol%.

Roseomonas stagni Furuhata, Miyamoto, Goto, Kato, Hara, and Fukuyama 2008

The characteristics of the species are the same as those described for the species (Furuhata et al. 2008).

Type strain: HS-69^T (= DSM 19981^T = JCM 15034^T = KCTC 22213^T), isolated from pond water of Nomori Pond in Shizuoka, Japan. The G+C content of DNA of the type strain is 72.0 mol%.

Roseomonas terrae Yoon, Kang, Oh, and Oh 2007

The characteristics of the species are the same as those described for the species (Yoon et al. 2007).

Type strain: DS-48^T (= JCM 14592^T = KCTC 12874^T), isolated from soil. The G+C content of DNA of the type strain is 69.3 mol%.

Roseomonas vinacea Zhang, Yu, Wang, Liu, Sun, Jiang, Zhang, and Li 2008

The characteristics of the species are the same as those described for the species (Zhang et al. 2008).

Type strain: CPCC 100056^T (= CCM 7468^T = KCTC 22045^T), isolated from a soil from the Qinghai-Tibet Plateau, northwest China. The G+C content of DNA of the type strain is 67.3 mol%.

Rubritepida Alarico, Rainey, Empadinhas, Schumann, Nobre, and Da Costa 2002

Ru.bri.te'pi.da. L. adj. *rubrus* red; L. adj. *tepidus* warm; N.L. fem. adj. *Rubritepida* the red-warm one.

Rubritepida strains are aerobic, moderately thermophilic, and neutrophilic and produce BChl *a*. The strains were isolated from a hot spring (Alarico et al. 2002). The strain was phylogenetically most closely related to *Roseococcus thiosulfatophilus* with 93.2 % of 16S rRNA gene sequence similarity (Fig. 1.1). Currently, this genus contains a single species, *Rubritepida flocculans*.

Rubritepida Alarico et al. 2002

Cells are Gram negative, short rods, 1.4–1.7 μm long, and motile by means of a single polar flagellum. Strictly aerobic, chemoorganotrophic, moderately thermophilic, and slightly alkaliphilic. Colonies are red. Catalase positive. Oxidase positive. BChl *a* and carotenoids are present.

The major cellular fatty acids are $C_{16:0}$ and $C_{18:1}\varpi 7c$. The major quinone is Q-9. The major polar lipids are phosphatidylcholine, phosphatidylethanolamine, phosphatidylglycerol, diphosphatidylglycerol, and two unidentified aminolipids. The G+C content of the genomic DNA is 70.2 mol%. The type species is *Rubritepida flocculans*.

Rubritepida flocculans Alarico, Rainey, Empadinhas, Schumann, Nobre, and Da Costa 2002

The characteristics of the species are the same as those described for the species (Alarico et al. 2002).

Type strain: H-8^T (= ATCC BAA-385^T = DSM 14296^T), isolated from the hot spring at Egerszalók in Hungary. The G+C content of DNA of the type strain is 70.2 mol%.

Stella Vasilyeva 1985

Stel'la. L. fem.n. *stella* star, denoting the star-shaped morphology of the cells.

Stella strains are aerobic, mesophilic, and neutrophilic. The strains were isolated from soils, freshwater sediments, sewage and sludge, and horse manure (Vasilyeva 1985). Currently, this genus contains two species. *Stella* is phylogenetically affiliated to the family *Rhodospirillaceae* on the phylogenetic tree based on 16S rRNA gene sequence as shown in phylogenetic analysis (Fig. 1.1), but described in this chapter.

Stella Vasilyeva 1985

Cells are Gram negative, flat, six-pronged stars, 0.7–3.0 μm in diameter, and nonmotile. Aerobic or microaerophilic, chemoorganotrophic, mesophilic, and neutrophilic to slightly alkaliphilic. Catalase positive. Oxidase positive. The G+C content of the genomic DNA ranges from 69.3 to 73.5 mol%. The type species is *Stella humosa*.

Stella humosa Vasilyeva 1985

The characteristics of the species are the same as those described for the species (Vasilyeva 1985).

Type strain: AUCM B-1137^T (= ATCC 43930^T = DSM 5900^T = VKM B-1137^T), isolated from virgin chernozem on a layer, Krasnodar region, USSR. The G+C content of DNA of the type strain is 72.7 mol%.

Stella vacuolata Vasilyeva 1985

The characteristics of the species are the same as those described for the species (Vasilyeva 1985).

Type strain: 229^T (= ATCC 43931^T = DSM 5901^T = INM 229^T = VKM B-1552^T), isolated from sewage sludge from pig farm, Leningrad region, USSR. The G+C content of DNA of the type strain is 73.5 mol%.

Zavarzinia Meyer, Stackebrandt, and Auling 1994

Za.var.zi'ni.a. N.L. fem. n. *Zavarzinia*, named for Georgi Alexandrovich Zavarzin, the Russian microbiologist who with his co-workers made the first thorough investigation of mesophilic, Gram-negative carboxydotrophic strains.

A *Zavarzinia* strain was isolated from mud of the Moskva River (Meyer et al. 1993). The strain had been once allocated to the genus *Pseudomonas* but was allocated as a member of the class *Alphaproteobacteria* due to their quinone, polyamine, fatty acid patterns and the signature oligonucleotides in their 16S rRNA gene catalogs (Auling et al. 1988; Meyer et al. 1993). Currently, this genus contains a single species, *Zavarzinia compransoris*. The phylogenetic position of *Zavarzinia* is unclear in the order *Rhodospirillales* as shown in phylogenetic analysis (*Fig. 1.1*) but is described in this chapter.

Zavarzinia Meyer et al. 1994

Cells are Gram negative, rod-shaped, 1.0–1.8 μm long, and motile by means of a single polar flagellum. Colonies are very thin and translucent. Catalase positive. Organic acids and amino acids are used as sole carbon and energy sources.

The major cellular fatty acid is $C_{18:1}$. The major quinone is Q-10. The G+C content of the genomic DNA is 66.1 mol%. The type species is *Zavarzinia compransoris*.

Zavarzinia compransoris Meyer, Stackebrandt, and Auling 1994

The characteristics of the species are the same as those described for the species (Meyer et al. 1993).

Type strain: Z-1155^T (= ATCC 51430^T = CCUG 15334^T = DSM 1231^T = LMG 5821^T = LMG 8357^T), isolated from mud of the Moskva river. The G+C content of DNA of the type strain is 66.1 mol%.

A Genus in the *Gammaproteobacteria*

Frateuria Swings, Gillis, Kersters, De Vos, Gosselé and De Ley 1980 emend. Zhang 2011

Fra.teur'i, a. N. L. fem. n. *Frateuria*, named after Joseph Frateur (1903–1974), eminent Belgian microbiologist.

Four strains of acetic acid bacteria were isolated from lily flowers (*Lilium aurantum*), and the strains produced brown pigment on the media containing glucose and calcium carbonate, oxidized D-glucose to D-gluconic acid, produced a large amount of acid from pentoses, and utilized ammonium salt. These characteristics resembled those of acetic acid bacteria, and the strains were named "*Acetobacter aurantium*" (sic) (Kondo and Ameyama 1958). Later, the strains were regarded as an intermediate type between the genera *Acetobacter* and *Gluconobacter* on the basis of different phenotypic characteristics from those of both genera and tentatively named "polarly flagellated intermediate strains" (Asai et al. 1964). Additional strains were isolated from rose (*Rose hybrida*), saffron (*Crocus sativus*), and ladybell (*Adenophora triphylla*) and recognized polar flagellation and a negative response to gelatin liquefaction (Ameyama and Kondo 1967). Further, three other strains were obtained from raspberry (*Rubus parvifolius*) and recognized polar flagellation, growth on mannitol and glutamate agar, oxidation of acetate and lactate, and the production of dihydroxyacetone from glycerol (Yamada et al. 1976a). Prior to the work, quinone systems of the polarly flagellated intermediate strains were found to be Q-8, which is clearly different from Q-9 of the genus *Acetobacter* and Q-10 of the genus *Gluconobacter* (Yamada et al. 1969).

Recharacterization of "*A. aurantium*" was carried out for the strains obtained from IFO by phenotypic characteristics, protein electrophoreogram, and DNA-rRNA hybridization. As a result, positive reactions were found for oxidation of lactate but not for that of acetate, for the production of dihydroxyacetone from glycerol, for the production of 2-keto-D-gluconate and 2,5-diketo-D-gluconate from D-glucose but not 5-keto-D-gluconate, and for the production of H_2S, and negative reactions were found for gelatin liquefaction and oxidation of acetate. Further, the strains were circumscribed by the protein electrophoreogram and DNA-rRNA hybrids, and a new genus and a new species *Frateuria aurantia* were established with phenotypic characteristics (Swings et al. 1980; Swings and Sievers 2005).

Cellular fatty acid composition of acetic acid bacteria was determined, and the peculiar composition was recognized for *Frateuria aurantia* strains. The representatives of the genera *Acetobacter* and *Gluconobacter* contained the straight-chain unsaturated acid of $C_{18:1}$ as a major constituent. In contrast, *Frateuria aurantia* strains had *iso*-branched saturated acid of *i*-$C_{15:0}$ as a main component (Yamada et al. 1981a). This discriminates the genus *Frateuria* from the genera *Acetobacter* and *Gluconobacter* and the other genera in acetic acid bacteria. Further, DNA base composition and DNA-DNA similarity were determined for acetic acid bacteria. *Frateuria aurantia* strains showed a range of 62.8–65.8 mol% of G+C content of DNA and were discriminated on the basis of DNA-DNA similarity from the other members of the genera *Acetobacter*, *Gluconobacter*, and *Pseudomonas* (including *Pseudomonas maltophilia*, now *Stenotrophomonas maltophilia*) (Yamada et al. 1981b). On the basis of the differences in a major isoprenoid quinone comprising Q-8 and a major *iso*-branched saturated fatty acid comprising *i*-$C_{15:0}$, the *Frateuria* strains were said to be "pseudoacetic acid bacteria" (Yamada 1979; Yamada et al. 1981a; Lisdiyanti et al. 2003a).

Further, 16 *Frateuria aurantia* strains were isolated from fruits of mango, rambai, jackfruit, and kemaris and coconut flower collected in Indonesia. The isolates were determined for phenotypic characteristics, DNA base composition, DNA-DNA similarity, quinone systems, cellular fatty acid composition, and phylogenetic relationships on the basis of 16S rRNA sequences (Lisdiyanti et al. 2003a). The cellular fatty acid composition and quinone systems were confirmed the same as those previously reported (Yamada et al. 1969, 1981a). The DNA base composition on the new isolates fell into a range of the composition as previously reported (Swings et al. 1980; Yamada et al. 1981b). Phylogenetic analysis with 16S rRNA sequences revealed the allocation of the isolates and the reference strains of *F. aurantia* to the *Gammaproteobacteria*.

Recently, a membrane-bound, pyrroloquinoline quinone (PQQ)-dependent alcohol dehydrogenase (ADH) was purified from *Frateuria aurantia* LMG 1558, and its similarity to ADH of *Gluconacetobacter europaeus* V3 (LMG 18494) (*Alphaproteobacteria*) was found. The similarity of ADH over the class suggests the possibility of horizontal gene transfer between two groups of genera (Trček and Matsushita 2013).

Problematic features were solved with the recharacterization of the new isolates, which were the oxidation of acetate, ketogenesis, the utilization of ammoniac nitrogen, and the production of H_2S (Lisdiyanti et al. 2003a). In conclusion, acetate was not oxidized as the previous study (Swing et al. 1980), and a more reliable method was needed for the test of ketogenesis. Ammoniac nitrogen was utilized when D-mannitol was served as a carbon source, but not ethanol or D-glucose. The production of H_2S was reported to be useful for differentiation of the genus *Frateuria* from the other genera in acetic acid bacteria (Swing et al. 1980). When the production of H_2S was tested with lead acetate paper strips, the isolates and reference strains of *F. aurantia* blackened the tip of the lead acetate paper strips, and *Pseudomonas* and *E. coli* strains did as well. However, all the abovementioned strains showed a negative response with TIS agar. The lead acetate paper strips were much more sensitive than TIS agar and would give a false-positive reaction. Therefore, the production of H_2S was not recognized for applicable to differentiation of the genus *Frateuria* from the other genera in acetic acid bacteria (Lisdiyanti et al. 2003a). *Frateuria terrea* was described, and the description of the genus *Frateuria* was emended (Zhang et al. 2011). Type species is *Frateuria aurantia*. Currently, the genus comprises two species, *F. aurantia* and *F. terrea*.

Frateuria Swings et al. 1980 emend. Zhang 2011

Cells are Gram negative, rod-shaped, measuring 0.4–0.8 by 0.8–2.0 μm, singly or in pairs, motile with a single polar or subpolar flagellum when motile (*F. terrea* shows a subpolar flagellum). Endospores are not produced. Luxuriant growth on glucose-yeast extract-$CaCO_3$ agar. Colonies are flat or circular, and medium turns to brown. Grows on glutamate agar and mannitol agar.

Aerobic. Catalase positive or negative (*F. terrea* is for negative). Oxidase negative or positive (*F. terrea* is for positive). Oxidizes lactate but not acetate. Production of dihydroxyacetone from glycerol is generally positive. Produces D-gluconate, 2-keto-D-gluconate, and 2, 5-diketo-D-gluconate from D-glucose, but not 5-keto-D-gluconate. Acid is produced from D-arabinose, L-arabinose, D-ribose, D-xylose, L-rhamnose, D-fructose, D-galactose, D-glucose, D-mannose, glycerol, and ethanol, but not from L-sorbose, sucrose, D-mannitol, or D-sorbitol. Growth does not occur on methanol. Assimilates ammoniac nitrogen with mannitol. Produces water-soluble brown pigment. No growth in the presence of 0.35 % acetic acid. Growth occurs on 20 % D-glucose, at 34 °C, and at pH 3.5. A major cellular fatty acid is *iso*-$C_{15:0}$. A major quinone is Q-8. The G+C content is from 62 to 64 mol %. *Frateuria* strains are isolated from flowers of lily, rose, ladybell, and coconut and fruits of mango, rambai, and jackfruit.

Frateuria aurantia Swings, Gillis, Kersters, De Vos, Gosselé, and De Ley 1980

Characteristics are the same as those described for the species (Swings et al. 1980; Lisdiyanti et al. 2003a).

Type strain: G-6^T (= Kondô 67 = ATCC 33424 = DSM 6220 = NBRC 3245 = LMG 1558), isolated from flowers of lily. The G+C content of DNA of the type strain is 63 mol%.

Frateuria terrea Zhang, Liu, and Liu 2011

Characteristics are the same as those described for the species (Zhang et al. 2011).

Type strain: VA24^T (= CGMCC 1.7053 = NBRC 104236), isolated from forest soil of the Changbai Mountains, Heilongjiang Province, China. The G+C content of DNA of the type strain is 67.4 mol%.

Isolation, Enrichment, and Maintenance Procedures

Sugary and alcoholic materials are widely used for isolation of acetic acid bacteria. Recently, many acetic acid bacteria are found in a wide variety of natural environments, and the kinds of isolation sources greatly increased (see the sections of the respective species concerned and the ecology).

A medium for the enrichment procedure and isolation of acetic acid bacteria, designated as the medium with pH 3.5 (Yamada et al. 1999), is composed of 1.0 % glucose, 0.5 % ethanol (99.8 %) v/v, 0.3 % peptone, 0.2 % yeast extract, and 0.01 % cycloheximide and adjusted pH to 3.5 with a diluted hydrochloric acid solution. LGI medium is used for isolation of acetic acid bacteria capable of fixing atmospheric nitrogen (Cavalcante and Döbereiner 1988). The medium contains 10.0 % sucrose, 0.06 % KH_2PO_4, 0.02 % K_2HPO_4, 0.02 % $MgSO_4$, 0.002 % $CaCl_2$, 0.001 % $FeCl_3$, and 0.0002 % Na_2MoO_4 and adjusted pH to 6.0. When microbial growth is found in the LGI medium; the culture is transferred to the medium with pH 3.5 (Vu et al. 2013). The culture in the medium with pH 3.5 is streaked onto agar plates to obtain candidates of acetic acid bacteria. The medium is composed of 2.0 % glucose, 0.5 % ethanol (99.8 %) v/v, 0.3 % peptone, 0.3 % yeast extract, 0.7 % calcium carbonate (precipitated), and 1.5 % agar (Yamada et al. 1976a, 1999). Colonies dissolving calcium carbonate on the agar plates are picked up and transferred onto the agar slants with the same composition as the agar plates. The cultures are preserved for the further study. The isolates are examined again for the growth in the medium with pH 3.5.

Enrichment culture approach and selective isolation of acetic acid bacteria can be done by changing the medium composition, especially the carbon source. In fact, strains of *Asaia bogorensis*, *Asaia siamensis*, and *Asaia krungthepensis* were first isolated with D-sorbitol or dulcitol as a carbon source instead of D-glucose (Yamada et al. 2000; Katsura et al. 2001; Yukphan et al. 2004b).

Four to six kinds of media were employed for the enrichment culture (Lisdiyanti et al. 2003b; Huong et al. 2007; Suzuki et al. 2010). The medium with pH 4.5 is also useful for isolation of acetic acid bacteria (Yamada et al. 1976a; Tanasupawat et al. 2004).

The genera *Acetobacter*, *Gluconobacter*, *Gluconacetobacter*, *Asaia*, and *Komagataeibacter* are not monotypic and include 8–20 more species. Brief identification can be predicted at the genus level from the combination of oxidation of acetate and lactate and production of acetic acid from ethanol (Yamada and Yukphan 2008).

Acetobacter strains show a deep blue color fast and clearly on the oxidation of acetate and lactate (Asai et al. 1964). On the other hand, *Gluconobacter* strains show a clear yellow color in the acetate and lactate oxidation tests. In *Gluconacetobacter* and *Komagataeibacter* strains, the color change to blue is not so vigorous compared with that of *Acetobacter* strains. The two conventional tests described above are very useful particularly when a large number of isolates are classified or identified routinely at the generic level. *Gluconacetobacter* and *Komagataeibacter* strains can be discriminated from each other by the production of a water-soluble brown pigment and cell motility. *Gluconacetobacter* strains generally produce a water-soluble brown pigment and are motile. In contrast, *Komagataeibacter* strains do not produce the pigment and are nonmotile. *Asaia* strains show no or little acetic acid production from ethanol, differing from the above four genera, and the color change is very slow on the oxidation of acetate and lactate.

Aerobic phototrophic bacteria in the acidophilic group can be isolated by the enrichment procedure, which are preferable to be under similar conditions to isolation sources (Yurkov 2006).

Most acetic acid bacteria and their relatives can be generally maintained at 4 °C for 1 month on agar slants containing the appropriate medium. Long-term preservation of acetic acid bacteria and related organisms can be achieved by lyophilization or by storage in liquid nitrogen or by cryoconservation at −80 °C with low-temperature refrigerators and appropriate cryoprotectants (Kersters et al. 2006).

Ecology

The genera *Acetobacter* and *Gluconobacter* were the core genera in acetic acid bacteria for a long time. Members of the genus *Acetobacter* have niches in alcoholic and acidic environments, and they are isolated from vinegar, wine, beer, sake, cider, fruits, and other alcoholic materials. The main substance of vinegar is acetic acid, and its concentration ranged from approximately 4 % to 6 %. Malt vinegar contains 4.3–5.9 % of acetic acid, cider vinegar 3.9–9.0 %, wine vinegar 4.4–7.4 %, spirit vinegar 11.5–12.5 %, rice vinegar 4.00–5.24 %, and Balsamic vinegar 6.25–14.88 % (Adams 1998). By contrast, the members of the genus *Gluconobacter* are isolated from sugary materials, fruits, flowers, foods, and other sources. However, the concept of acetic acid bacteria has extended to all of the bacteria in the family *Acetobacteraceae*. Consequently, sources of the bacteria become diversified, and the sources have extended beyond the limits (see the section of Phenotypic Analyses).

Sources of Isolation

Members of the genus *Gluconobacter* were first isolated from kaki (*Diospyros kaki* Thunb.) and other fruits (Asai 1934), and isolation sources extend to a variety of flowers and fruits (Kondo and Ameyama 1958). The genus *Komagataeibacter* is separated from the genus *Gluconacetobacter* and has niches in acetous materials such as a variety of vinegar, kombucha, and fruit juice. *Gluconacetobacter* strains were reported to be isolated from vinegar, fruits, dried fruits, rhizosphere of coffee plants, pink sugarcane mealybug, and even in a tumulus in Japan.

Asaia strains are widely distributed in such flowers as orchid tree, plumbago, astilbe, Asian dayflower, heliconia, spider lily, balloon flower, self-heal, crown flower, ixora, and African tulip tree. Further, an *Asaia* strain was isolated from spoiled fruit-flavored bottle water (Moore et al. 2002). *Acidomonas methanolica* strains were abundantly isolated from activated sludge samples, but not from vegetables, fruits, decayed wood and leaves, manure, and paddy soil (Yamashita et al. 2004).

Strains of the genera *Ameyamaea*, *Neoasaia*, and *Neokomagataea* were isolated from a variety of flowers. A *Tanticharoenia sakaeratensis* strain was isolated from soil. An osmophilic acetic acid bacterium, *Saccharibacter floricola*, was isolated from pollens in Japan.

Flora of Acetic Acid Bacteria in Southeast Countries

The study of distribution of acetic acid bacteria is rather limited to certain sources, and systematic research is sporadically reported. However, microbiologists are interested in acetic acid bacteria in the tropical region from the viewpoint of the diversity of the bacteria. For example, the microbiological study was conducted on microflora of acetic acid in Indonesia. In this study, 64 strains of acetic acid bacteria were isolated from flowers, nata de coco, brown sugar, fruits, ragi, and mash of soybean paste collected in Indonesia. An enrichment medium was used, which consisted of 1 % glucose, 0.5 % ethanol, 0.3 % acetic acid, 1.5 % peptone, 0.8 % yeast extract, and 100 ppm cycloheximide (adjusted pH to 3.5 with diluted hydrochloric acid). The isolates were classified on the basis of cell morphology, quinone systems, oxidation of acetate and lactate, DNA base composition, and DNA-DNA hybridization, and *Acetobacter* strains accounted for 70 %, *Gluconacetobacter* strains 13 %, and *Gluconobacter* strains 17 % (Yamada et al. 1999). This led to the further study of the diversity of acetic acid bacteria and resulted in the descriptions of five new species, *Acetobacter indonesiensis*, *A. tropicalis*, *A. syzygii*, *A. cibinongensis*, and *A. orientalis*, of which strains were isolated from flowers, fruits, and fermented foods collected in Indonesia; and three new

combinations, *Acetobacter orleanensis*, *A. lovaniensis*, and *A. estunensis*, were described, of which strains were reference strains (Lisdiyanti et al. 2000, 2001).

Further, a survey was carried out on acetic acid bacteria in Thailand, and 40 strains were isolated from 23 kinds of fruits and other samples. Of the 40 strains isolated, 31 strains were identified as *Acetobacter pasteurianus*, three strains as *A. orientalis*, and six strains as *Gluconacetobacter liquefaciens* (Seearunruangchai et al. 2004). In addition, 13 strains were isolated from 12 kinds of flowers collected in Thailand, and nine strains were identified as *Asaia bogorensis*, two strains as *A. siamensis*, and two strains as *A. krungthepensis* (Yukphan et al. 2006). Moreover, of 44 Thai isolates from flowers and fruits, 16 strains were identified as *Gluconobacter oxydans* and six strains as *G. frateurii*, and the rests were remained unidentified (Huong et al. 2007).

Besides the above studies, 26 strains of acetic acid bacteria were isolated from 13 kinds of fruits including apple, banana, guava, Kaffier lime, longan, mango, Manila tamarind, muskmelon, peach, plum mango, sapodilla, and sugar apple and four other samples collected at markets in Bangkok and other sites in Thailand. The isolates were identified as *Acetobacter tropicalis* (one strain), *A. orientalis* (four strains), *A. pasteurianus* (five strains), *A. syzygii* (one strain), *A. ghanensis* (three strains), *Gluconobacter frateurii* (four strains), *G. japonicus* (six strains), *Gluconobacter* sp. (one strain), and *Asaia* sp. (one strains) based on phenotypic characterization, 16S rRNA sequence analysis, and 16S-23S rRNA gene internal spacer (ITS) restriction analysis (Tanasupawat et al. 2009). So far as reported, a considerable number of genera and species of acetic acid bacteria are expected to be in fruits and flowers in the tropical region.

A Comprehensive Survey of Acetic Acid Bacteria in Southeast Asia

As mentioned above, acetic acid bacteria show a wide distribution in various kinds of vinegar, wine, beer, cider, sake, a variety of fruits and flowers, fermented foods, and environments. Nevertheless, a few comprehensive studies were conducted in the environmental and ecological points of view. The distribution of the acetic acid bacteria was studied in the light of isolation sources, the sources from three different countries, Indonesia, Thailand, and the Philippines, and different enrichment media. A total of 331 strains including 196 new isolates and 135 strains previously reported were subjected to the study of the diversity of acetic acid bacteria (Lisdiyanti et al. 2003b).

First, the diversity of acetic acid bacteria is described from the viewpoint of isolation sources. Of 331 isolates, 118 strains were isolated from fermented foods, followed by 98 strains from fruits, and 99 strains from flowers. At the generic level, 83 *Acetobacter* strains were obtained from fermented foods, followed by 60 from fruits. Most of *Gluconobacter* strains were isolated from fruits and flowers, followed by fermented foods. Interestingly, *Asaia* strains were mostly isolated from flowers. *Asaia bogorensis* strains were mostly isolated from flowers as well (*Table 1.5*).

Secondly, of 331 isolates, 208 strains were isolated from Indonesian samples, followed by 51 strains from Thai samples and 72 strains from the Philippine samples (*Table 1.6*; Lisdiyanti et al. 2003b). This figure does not indicate the relevance to the specialty of the country because the number of the samples varies with country to country.

Thirdly, enrichment media were designed for isolation (*Table 1.7*; Lisdiyanti et al. 2003b). Medium I (ME I) is good for a wide variety of acetic acid bacteria. Medium V (ME V) is designed for isolation of *Acidomonas* because it contains methanol as a carbon source. Medium VI (ME VI) is prepared for isolation of *Asaia* strains (Suzuki et al. 2010), which will be mentioned below. Of 331 isolates of acetic acid bacteria, 139 were isolated with EM I, followed by 103 with EM II, 38 with EM III, 34 with EM IV, and 17 with ME V (*Table 1.8*; Lisdiyanti et al. 2003b). EM I is appropriate for isolation of *Acetobacter* strains because it contains both D-glucose and ethanol as carbon sources. Members of *Gluconacetobacter* and *Kozakia* are also enriched with EM I, and EM II is suitable for isolation of the genus *Gluconobacter* as well. EM II and EM IV are good for isolation of *Asaia* strains because D-sorbitol and dulcitol serve carbon sources for *Asaia*. Further, *Asaia* and *Frateuria* strains are not enriched with EM I and EM III because acetic acid inhibits the growth of those bacteria. No *Acidomonas* strains are isolated even with EM V in which methanol is supplied. Modification of the enrichment media is helpful for the isolation of targeted microorganisms in nature.

Fourthly, the relevancy was discussed between the species isolated and detailed isolation sources (*Table 1.9*; Lisdiyanti et al. 2003b). *Acetobacter* strains are isolated from fermented foods such as palm vinegar, palm wine, nata de coco, and pickles as well as fruits such as guava, mango, zirzak, etc. It is worthy of remark that *Acetobacter pasteurianus* strains were isolated only from fermented foods such as palm vinegar, palm wine, rice wine, pickles, water of nata de coco, fermented rice, and tape cassava. Further, *A. pasteurianus* strains are not isolated from fruits and flowers. Most of the *Gluconobacter* strains inhabit fruits and flowers. *Gluconacetobacter* strains are mostly found in nata de coco. This tells us that acetic acid bacteria have particular niches for each genus and even for each species.

Flora of Acetic Acid Bacteria in Japan

The genus *Asaia* was assumed to be a genus with specific niches in the tropical countries because the *Asaia* species had been isolated flowers and fruits in the tropics. Therefore, a survey was made on the bacterial flora of acetic acid bacteria in Japan, particularly focusing on *Asaia* strains (Suzuki et al. 2008). Japan extends approximately 3,000 km from the north to south and covers isolation sites from Hokkaido in the northern area to Okinawa in the southern area. Two media are used: Medium I (ME I) is designed for isolation of diverse acetic acid bacteria, and Medium VI (ME VI) is aimed to isolate *Asaia* strains, which contains D-sorbitol and dulcitol as

Table 1.5
Diversity of acetic acid bacteria relevant to isolation sources

		Sources

		0	**13**	**3**	**0**	**16**
Total		**118**	**98**	**99**	**16**	**331**

Reproduced and modified data of Lisdiyanti et al. (2003b)

sources of carbon (*Table 1.7*). Thus, 345 strains were isolated from 776 samples consisting of 684 from flowers, 58 from fruits, and 34 from fermented foods (Suzuki et al. 2008).

The isolates were classified into the genera *Acetobacter*, *Gluconobacter*, *Gluconacetobacter*, *Asaia*, *Saccharibacter*, and *Frateuria* based on phenotypic characteristics, 16S rRNA sequence analysis, and DNA-DNA hybridization (Suzuki et al. 2008). *Asaia* strains are most abundantly isolated, followed by *Acetobacter* strains, *Gluconobacter* strains, and *Gluconacetobacter*. A few strains of the genera *Saccharibacter* and *Frateuria* are isolated (*Table 1.10*). No *Acidomonas* strains are found. The *Asaia* strains are obtained by the use of ME VI and from flowers as expected (*Table 1.10*). Further, acetic acid bacteria are distributed evenly across Japan (*Fig. 1.5*). In addition, the strains are isolated from Akita, Niigata, Tokyo, and Yamanashi located in the temperate zone in Japan. Three new species of the genus *Asaia* were identified based on the characterization of the isolates from flowers collected in the northern area (Suzuki et al. 2010). Consequently, the genus *Asaia* is not a particular acetic acid bacterium, and members of the genus are distributed widely and not limited to tropical countries. Thus, the genus can be said to be a cosmopolitan bacterium. Besides, *Acetobacter*, *Gluconobacter*, and *Gluconacetobacter* strains are isolated by the use of ME I and from fermented foods, followed by fruits, and flowers, as shown in "A comprehensive survey of acetic acid bacteria in Southeast Asia." The abovementioned figures indicate that a variety of isolation sources and enrichment media are essential for the study of distribution of targeted microorganisms.

Insects

Mosquitoes

A mosquito, *Anopheles stephensi*, is a vector of *Plasmodium* sp., the pathogen of Asian malaria. The total number of cases of malaria is estimated to be 300–500 million in the world, and two

to three million deaths are caused by malaria. Approximately 90 % of malaria occurs in Africa. Therefore, malaria is the most important disease of the tropical parasite disease. In the above circumstances, *Asaia* strains were found in *Anopheles stephensi* and dominated the microflora of the mosquito. Therefore, 16S rRNA gene libraries were made from DNA of the abdomen of the laboratory-fed mosquitoes. Analysis of the 16S rRNA gene sequence revealed that the libraries dominated with sequences related to the genus *Asaia*, which showed more than 90 % of nucleotide identity with those of *Asaia bogorensis* and *Asaia siamensis*. Further, *Asaia* strains were isolated from *Anopheles stephensi* bodies, with $9.8 \times 10^{4-5}$ cells/individual (Favia et al. 2007). Thus, *Asaia* strains are recognized to be normally associated with larvae and adults of A*nopheles stephensi*. A green fluorescent protein (Gfp)-tagged *Asaia* strain effectively logged in male and female reproductive organs and salivary glands, which are sites crucial for *Plasmodium* sp. development and transmission. Further, *Asaia* strains were found to transmit from the mother to offspring and undergo paternal transmission to the progeny (Damiani et al. 2008; Favia et al. 2007).

In addition, *Asaia* strains were present in the body of the mosquito *Aedes aegypti*, which is a vector of yellow fever and dengue fever, and in the leafhopper *Scaphoideus titanus*, which is a vector of grapevine flavescence dorée phytoplasma. Cross-colonization patterns of the body of *Aedes aegypti*, *Anopheles stephensi*, and *Scaphoideus titanus* were recognized with *Asaia* strains isolated from *Anopheles stephensi* or *Aedes aegypti*. This indicated the cross-colonization in insects of phylogenetically distant genera and orders (Crotti et al. 2009).

Further, the ability of *Asaia* strains was recognized in colonizing Afro-tropical malaria vector *Anopheles gambiae* mosquitoes (Damiani et al. 2010). In addition, 281 *Asaia* strains were isolated from *Anopheles stephensi*, *Anopheles gambiae*, *Aedes aegypti*, and *Aedes albopictus* and clustered into two groups, one clustering with *Asaia krungthepensis* and the other clustering *Asaia bogorensis* (Chouaia et al. 2010). Wild *Aedes*

albopictus and *Aedes aegypti* mosquito specimens were collected in three different regions in Madagascar. Culturing methods and denaturing gradient gel electrophoresis (DGGE) and sequencing of the *rrs* amplicons revealed *Proteobacteria* and *Firmicutes* as major phyla. Isolated genera were dominated by *Bacillus*, followed by *Acinetobacter*, *Agrobacterium*, and *Enterobacter*. Common DGGE bands belonged to *Acinetobacter*, *Asaia*, *Delftia*, *Pseudomonas*, *Enterobacteriaceae*, and uncultured *Gammaproteobacteria* (Zouache et al. 2011).

Further, prevalence of the bacteria in *Aedes albopictus* was surveyed in field populations in Madagascar, and both genera were detected at relatively high frequencies, 46 % of *Asaia* and

Table 1.10

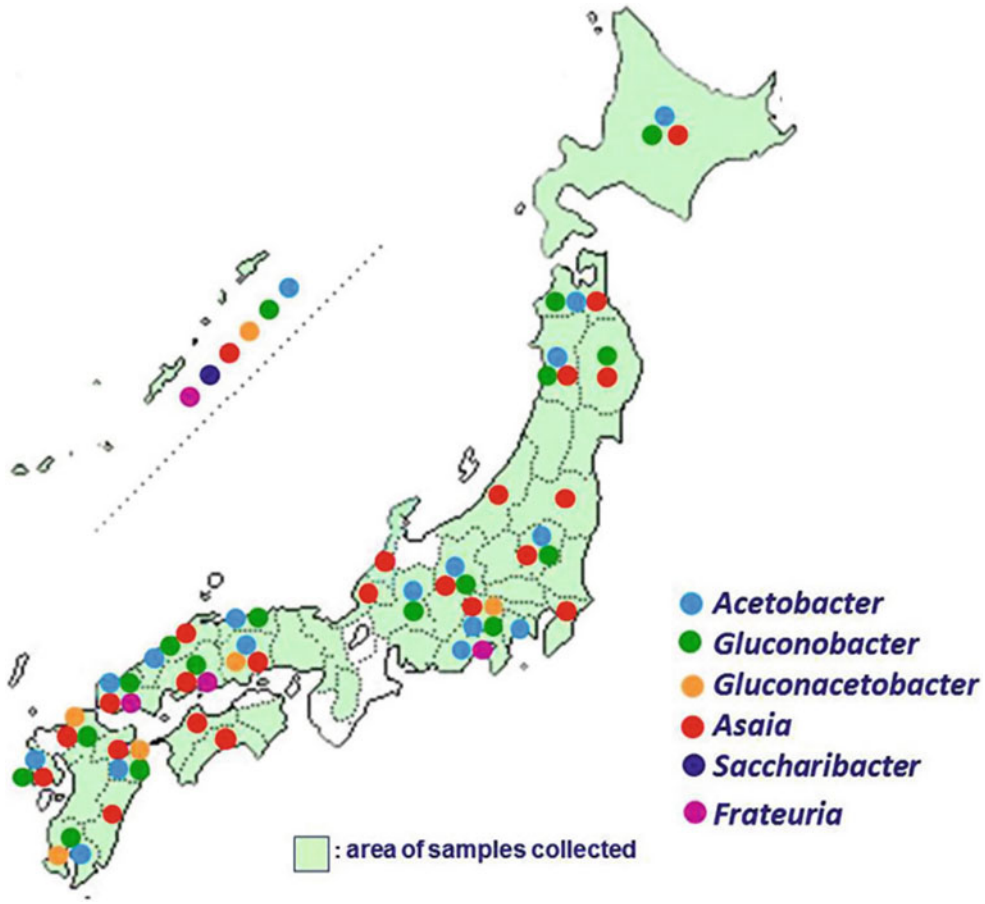

Fig. 1.5
Distribution of acetic acid bacteria in Japan Suzuki et al. (2008)

74 % of *Acinetobacter*. The prevalence of the genus *Acinetobacter* correlated with mosquito gender and the prevalence of the genus *Asaia* with the interaction between mosquito gender and the sampling sites. Male mosquitoes were more infected than female mosquitoes for each bacterial genus (Minard et al. 2013a). This study emphasizes the need to gain a global view on the bacterial partners on the mosquito vectors. Since the genus *Asaia* was regarded as tools for control of mosquito-borne disease, particularly malaria, *Asaia* spp. have been investigated on circulating among humans. All human sera and whole blood samples were negative for *Asaia* spp. This suggested that *Asaia* spp. bacteria could be regarded as opportunistic

pathogens and could be utilized as a malaria control in the future (Epis et al. 2012).

A review entitled "Diversity and function of bacterial microbiota in the mosquito holobiont" was presented (Minard et al. 2013b). According to the review, bacterial phyla and genera found in *Culicidae* mosquitoes are recorded as follows: *Proteobacteria*, 73 genera; *Bacteroidetes*, 11 genera; *Actinobacteria*, 17 genera; *Firmicutes*, *Tenericutes*, and *Fusobacteria*, 16 genera; *Cyanobacteria*, 2 genera; and *Deinococcus* and *Thermus*, 1 genus each. In addition, the genera *Asaia* and *Gluconobacter* are isolated from *Aedes*, *Anopheles*, *Culex*, and *Mansonia* mosquitoes, the genus *Acetobacter* from *Aedes* and *Mansonia* mosquitoes, and the genus *Roseomonas* from *Aedes* and *Anopheles* mosquitoes.

Flies

Drosophila melanogaster (fruit fly) is widely used in research in genetics and developmental biology. In view of bacterial community in the fly, adult flies were collected from 11 sites in the USA, and the DNAs from bacteria were isolated from male flies at each of the 11 different locations. Bacterial 16S rRNA gene sequences libraries recovered were compared, and the bacteria from these sequences were grouped into 74 different taxa, spanning the phyla *Proteobacteria*, *Bacteroidetes*, and *Firmicutes*. In addition, many groups were found in the genus *Gluconacetobacter* in the order *Alphaproteobacteria* (Corby-Harris et al. 2007). However, conflicts are reported on the bacterial taxa, particularly the genera *Gluconobacter* and *Gluconacetobacter*, which were found in *Drosophila* samples. The samples were collected around the world, and after extraction of DNA, the 16S rDNA PCR amplification and sequencing were done. As a result, the family *Acetobacteraceae* was not a major family, and both the groups were not detected in the samples (Chandler et al. 2011).

Further, commensalism with microorganisms in gut of the *Drosophila* has attracted attention to biologists. In the light of interests, bacteria were examined by DGGE fingerprints of PCR-amplified 16S rRNA fragments for the midgut of reared wild-type flies and Cad-RNAi flies that carried the *UAS-Cad-RNAi* construct to mimic the loss of function via RNA interference (RNAi). *Lactobacillus plantarum*, *Lactobacillus brevis*, and *Acetobacter pomorum* were commonly detected in both the wild-type flies and Cad-RNAi flies. However, a bacterium in the family *Acetobacteraceae* EW911 (*A911*) [a dominant commensal member in wild-type flies, controls, 1.5×10^5 colony-forming units (CFUs) per gut] was markedly diminished and maintained at very low level in the *Cad-RNAi* gut (900 CFUs per gut), whereas *Gluconobacter* sp. EW707 (*G707*) (a minor commensal member in the control gut, 800 CFUs per gut) emerged as a dominate commensal in the *Cad-RNAi* gut (1.7×10^4 CFUs per gut) (Ryu et al. 2008).

Olive fruit fly (olive fly, *Bactrocera oleae*) is one of the major pests of the olive tree. Wild specimens of *B. oleae* collected in field as pupae from 10 locations in Greece and a population reared at the laboratory were used for study. Bacterial 16S rRNA gene libraries revealed the presence of several bacterial taxa associated with this insect, among which *Acetobacter tropicalis* was dominant. Using an *A. tropicalis*-specific PCR assay, the bacterium was detected in all insects originating from laboratory stocks or field collected. *A. tropicalis* was successfully established in cell-free medium, and typing analyses, carrying out on a collection of isolates, revealed that differed strains are present in fly populations (Kounatidis et al. 2009).

Mealybug

Pink sugarcane mealybug (*Saccharococcus sacchari*) is common to all countries that grow sugarcane and almost the extensive species of mealybug found on commercially grown sugarcane. A small number of acetic acid bacteria were isolated from pink sugarcane mealybugs and were identified as *Gluconobacter oxydans* (Ashbolt and Inkerman 1990). In addition, *Gluconacetobacter sacchari*, *G. liquefaciens*, and *G. diazotrophicus* strains were isolated from pink sugarcane mealybugs collected in Australia and Hawaii (Franke et al. 1999).

Bee

Honeybees (*Apis mellifera*) are domesticated bees reared in apiaries and are used for producing honey and for pollination commercial crops. Isolation of *Gluconobacter* strains was attempted with enrichment approach from not only 411 samples, mostly bees, but also flowers visited bees, honey, and other materials from the hive and some wasps in three regions in Belgium. As a result, 53 strains were isolated, and the strains were studied based on phenotypic characteristics. Further, the strains were classified into two groups, Group A and Group B with polyacrylamide gel electrophoresis of soluble cell proteins. As a result, 37 strains in Group A were identified as "*Gluconobacter oxydans* subsp. *suboxydans*" (now *Gluconobacter oxydans*) and 15 strains in Group B as a member of the genus *Gluconobacter* (Lambert et al. 1981). Bacteria associated with worker adults of two subspecies of *Apis mellifera* in Southern Africa, *Apis mellifera capensis* and *Apis mellifera scutellata*, were screened by analysis with high-fidelity PCR of 16S rRNA sequences. As a result, the genus *Gluconacetobacter* was detected in the abdomen of the workers with the genera *Lactobacillus*, *Bifidobacterium*, *Serratia*, and three other genera (Jeyaprakash et al. 2003).

In addition, the structural diversity of bacteria found in the gut of three different bee species, *Apis mellifera carnica* (honeybee), *Bombus terrestris* (bumblebee), and *Osmia bicornis* (red mason bee), was studied for understanding how specific insects select for their own bacterial communities. The bees were collected at a flowering oilseed rape field for three successive years

in Germany. Total DNA was extracted from gut materials, and the bacterial diversity was analyzed by genetic profiling with single-strand conformation polymorphism of PCR-amplified partial 16S rRNA gene sequences. Sequencing of the PCR products revealed a dominance of *Alphaproteobacteria*, *Betaproteobacteria*, *Gammaproteobacteria*, *Bacteroidetes*, and *Firmicutes* in all bee species. Further, *Gluconobacter* sp. was exclusively detected in adults of *Apis mellifera* collected in 2001 (Mohr and Tebbe 2006).

Leafhopper

Flavescence dorée (FD) is a grapevine disease that afflicts several wine production area in Europe. FD is caused by "*Candidatus* Phytoplasma vitis" and the insect vector of a leafhopper, *Scaphoideus titanus*, which is widespread in vineyards. Focusing on *Asaia* sp. and *S. titanus*, the association with the bacteria and the leafhopper was studied in the light of better understanding of a possible role of the bacteria.

S. titanus adult individuals were collected in vineyards with heavy symptoms of FD from different area in Piedmont region in Italy. Further, feeds that were fed on 300 µl of sucrose 5 % in TE pH 8.0 with or without rifampicin (200 µg ml^{-1}) were used in order to simulate the natural situation of insects feeding on plant. Quantitative real-time PCR was performed on insects or feeds DNA with appropriate primers.

Data demonstrated that *Asaia* sp. was a significant part of the insect microflora. The distributing pattern of the bacteria inside the insect body was investigated through the use of *Asaia* expressing a green fluorescent protein. *Asaia* strain SF2.1 tagged with Gfp was able to colonize efficiently salivary glands and female and male reproduction organs of *S. titanus* (Crotti et al. 2008).

Plant Hopper

The brown plant hopper (brown rice plant hopper, *Nilaparvata lugens*) is a monophagous insect herbivore of rice. The insect feeds on rice plants, sucks sap from the rice leaf sheath, and makes rice plant dry out. This gives a serious damage to rice crops. Since little was known about bacteria in *N. lugens*, the bacteria are examined.

Insects from three populations of *N. lugens* were used, which were maintained at Wuhan University in China, and designated biotypes 1, 2, and 3. Three rice varieties were used for the biotypes: TMC (a susceptible variety) for biotype 1, Mudgo (carrying the resistance gene to *N. lunges*, *Bph1*) for biotype 2, and ASD 7 (carrying resistance gene to *N. lunges*, *Bph2*) for biotype 3.

DNA was isolated from individual insects and used for construction of 16S rRNA gene libraries. 16S rRNA gene sequences were amplified from three biotype libraries. The restriction patterns of the PCR products were examined by ARDRA using *Hha*I, *Hae*II, and *Rsa*I and then sequenced. Resulted restriction patterns were assigned to four phyla, *Proteobacteria* (72 %), *Firmicutes* (11 %), *Actinobacteria* (11 %), and *Bacteroidetes* (11 %). *Asaia* was detected only in biotype 2 and located in front of the ovipositor sheath in biotype 2 females (Tang et al. 2010).

Medical and Clinical Specimens

Recently, acetic acid bacteria draw attention of medical and clinical microbiologists (see the section of pathogenicity of acetic acid bacteria). A Gram-negative rod was isolated from cervical and lymph nodes of a patient with the chronic granulomatous disease (CGD). The rod-shaped bacterium was identified as a new genus and a new species, *Granulibacter bethesdensis*. Introducing the bacterial strain into mouse models of CGD brought about evidence that the organism cause similar disease in the patient, and the organisms was re-isolated from the mouse. This is the first evidence with the pathogenicity of acetic acid bacteria (Greenberg et al. 2006a, b).

Prior to the establishment of the genus *Granulibacter*, *Asaia bogorensis* strains were isolated from the peritoneal dialysis fluid of a patient with a medical history of end-stage renal disease (Snyder et al. 2004) and from the blood of a man with a history of intravenous drug abuse (Tuuminen et al. 2006). These cases suggest the potential opportunistic pathogen of *Asaia bogorensis*. Further, *Asaia lannensis* strains were isolated from a bloodstream infection on a child with cancer and bone transplantation (Abdel-Haq et al. 2009), and *Gluconobacter* spp. were isolated from human blood and sputa (Alauzet et al. 2010). In addition, an *Acidomonas methanolica* strain was isolated from an excised lymph node of a boy with chronic granulomatous disease (Chase et al. 2012). *Roseomonas* strains were isolated from human blood, cerebrospinal fluid, sputum, genitourinary site, and other clinical specimens (Gilardi and Faur. 1984; Wallace et al. 1990; Struthers et al. 1996; Han et al. 2003).

Pathogenicity, Clinical Relevance

Acetic acid bacteria play roles in vinegar production, and the oldest record on vinegar would date back to 5,000 B.C. Babylonian people are said to prepare vinegar from juice or sap of date palm, date wine, and raisin wine by acetous fermentation (Conner and Allgeier 1976). However, it is only 150 years ago that Pasteur made clear the role of acetic acid bacteria in vinegar production. The bacteria can be said to be the genus *Acetobacter* in modern bacterial taxonomy. They grow well in acidic conditions and produce acetic acid from ethanol. Further, *Acetobacter* strains are widely distributed in nature, particular in vinegar, wine, beer, sake, and other alcoholic materials, and the members of some other genera in acetic acid bacteria are found in a variety of fruits, flowers, and sugary materials.

Therefore, the pathogenicity of acetic acid bacteria to humans has been ignored entirely until recently. Acetic acid bacteria clearly differ from generally known bacteria of medical and clinical importance in the light of growth responses and phenotypes

and further in phylogenetic relationships. Advances in bacterial taxonomy on acetic acid bacteria, particularly 16S rRNA sequence analysis, brought about rearrangement of classification of all the bacteria, and acetic acid bacteria were allocated in the family *Acetobacteraceae*. Thus the bacteria other than typical acetic acid bacteria are allocated in the family, and a number of new genera have come into being described. More recently, acetic acid bacteria have been isolated from clinical specimens, and the pathogenicity is recognized in the genus *Granulibacter*. Sources and routes of infection of acetic acid bacteria are still unknown, but removal of the suspected indwelling device is suggested (Alauzet et al. 2010). In addition, acetic acid bacteria are resistant to almost all antibiotics and establishment of susceptibility guidelines are required for clinicians. Therefore, acetic acid bacteria draw attention to medical and clinical microbiologists as newly emerging opportunistic pathogens.

Granulibacter bethesdensis

Scientists in an American group isolated a novel Gram-negative rod from cervical and supercervical lymph nodes of a patient with the chronic granulomatous disease (CGD). The disease is a rare inherited disease of the phagocyte NADPH oxidase system, which leads to defective production of superoxide and hydrogen peroxide. Normally, the phagocyte kills bacteria and fungi ingested by reactive oxygen compounds produced, but the phagocyte of the patient with the disease is unable to kill the bacteria and fungi because of deficiency of the phagocyte. Therefore, the patient with the disease suffers from recurrent life-threatening infection with bacteria and fungi. The scientists attempted to make clear the pathogenicity of the strains and introduced the bacteria into mouse models of CGD. As a consequence, they obtained evidence that the organism causes the similar disease in the patient, and the organism was re-isolated from the mouse. Therefore, Koch's postulates were fulfilled as a new pathogen (Greenberg et al. 2006a).

Further, this organism was isolated from the same patient three more times, and a similar Gram-negative rod was isolated from other two patients. The group was unable to identify the strains by conventional methods and commercial identification kits at that time. Therefore, the scientists employed phylogenetic analysis of 16S rRNA sequence, IT region, and *RecA* protein-encoding gene. Thus, they identified the bacterium as a new genus and a new species and named them *Granulibacter bethesdensis* in the family *Acetobacteraceae* (Greenberg et al. 2006b).

The *Granulibacter bethesdensis* strains have phenotypic characteristics common to acetic acid bacteria, produce acid from D-glucose and ethanol, and oxidize lactate and acetate weakly. Further, the strains prefer high concentrations of D-glucose (e.g., 5 % of D-glucose) and grow on glutamate agar and mannitol agar. Interestingly, they assimilate methanol (Greenberg et al. 2006b). Further, genomic sequences revealed genes relevant to methanol utilization. Therefore, *Granulibacter* strains have the characteristics of both acetic acid bacteria and facultative methylotrophs (Greenberg et al. 2007). This study should be emphasized as the first case to evidence the pathogenicity of acetic acid bacteria. In addition, more cases of *Granulibacter* infections are reported (Greenberg et al. 2010), and other case of the isolation of this bacterium was described in Spain from a child patient with CGD (López et al. 2008) (detailed characteristics of the genus *Granulibacter* are shown in the Section of Phenotypic Analyses).

Asaia bogorensis

Scientists at the University of Pennsylvania isolated a bacterium from the peritoneal dialysis fluid of a patient with a medical history of end-stage renal disease secondary to diabetes mellitus, but they were unable to identify the organism by conventional biochemical tests. Therefore, the scientists performed 16S rRNA gene sequencing of the organism and identified it as *Asaia bogorensis*. They concluded that the organism from multiple samples made it unlikely that the organisms represented a contaminant and may cause peritonitis (Snyder et al. 2004).

Other case was presented on *Asaia bogorensis* as well. A man with a history of intravenous drug abuse was transferred to University of Helsinki Hospital, Finland, who was suspected to have systemic infection. A Gram-negative rod was isolated from his blood and not identified by conventional routine tests and commercial identification systems. However, this bacterium was identified as *Asaia bogorensis* on the basis of 16S rRNA gene analysis (Tuuminen et al. 2006).

These reports suggest the potential opportunistic pathogens of *Asaia bogorensis*. Both groups of Pennsylvania University and Helsinki University emphasized the usefulness of sequencing of 16S rRNA gene for the identification of unusual bacteria from the clinical specimen.

Asaia lannensis

Following the isolation of *Asaia bogorensis*, Gram-negative bacilli were isolated from a bloodstream infection on a child with cancer and bone marrow transplantation. However, the bacteria were unable to be identified with commercial identification systems but were identified as *Asaia lannensis* according to 16S rRNA gene sequencing. This would be the first case of bacteremia caused by *Asaia lannensis* (Abdel-Haq et al. 2009).

Further, two cases of nosocomial infection with *Asaia lannensis* were reported. Case 1 is of a 15-month-old female and Case 2 is of a 5-year-old female both with congestive heart failure due to idiopathic dilated cardiomyopathy. In Case 1, the patient was presumed to have bacteremia. Isolates from blood cultures of both patients showed the same micro- and macroscopic features. The organisms were strictly aerobic, catalase positive, and oxidase negative and produced acid from D-xylose, D-glucose, and D-mannitol. However, three commercial identification systems failed to identify the bacteria, and the bacteria were identified as *Asaia lannensis* according to 16S rRNA gene sequencing (Juretschko et al. 2010).

Acetobacter cibinogensis and *Acetobacter indonesiensis*

The genus *Acetobacter* is one of the typical genera in acetic acid bacteria, and the member of this genus has been isolated from vinegar, wine, beer, cider, and other alcoholic materials. However, a strain of *Acetobacter cibinogensis* was isolated from blood samples of a man who had been receiving chronic hemodialysis for end-stage renal failure and had intravenous drug use. Two samples were drawn through a subclavian catheter and through the arteriovenous fistula. A Gram-variable rod was isolated. The strain grew on 0.7 % calcium carbonate agar plates with 7 % ethanol (pH 3.5) and cleared calcium carbonate. Commercial identification systems failed to identify it. Therefore, 16S rRNA gene sequencing was employed, and the sequence matched with *Acetobacter cibinogensis* (Gouby et al. 2007). In other case, Gram-negative, catalase-positive, and oxidase-negative bacilli were isolated from sputum samples of a man with cystic fibrosis. Commercial identification systems failed to identify the bacteria. However, a strain of the bacteria was identified by matching the sequence of 16S rRNA gene with that of *Acetobacter indonesiensis* (Bitter et al. 2008).

Gluconobacter spp.

Members of the genus *Gluconobacter* are widely distributed in fruits and flowers. However, several strains were found in human blood and sputa (Alauzet et al. 2010). A Gram-negative rod was isolated from peripheral blood samples of a male patient with a history of intravenous drug abuse. Conventional methods and commercialized systems failed to identify it. However, the strain was identified as *Gluconobacter* sp. by sequencings of 16S rRNA gene, 16S-13S tRNA gene, and *dnaK* gene. In other case, four Gram-negative, catalase-positive, and oxidase-negative rods were isolated from sputa of a boy suffering from cystic fibrosis (CF). Phenotypic identification was unsuccessful for the strains, but the strains were identified as *Gluconobacter* spp. according to the above molecular means. In addition, a Gram-negative, catalase-positive, and oxidase-negative strain was isolated from the sputum of a girl with CF. The strain was not identified by phenotypic methods while identified as *Gluconobacter* sp. by the molecular means. In addition, strains of *Gluconobacter* spp. were isolated from bloodstream infection associated with endocardial lesions in a female intravenous drug abuser (Bassetti et al. 2013). However, the abovementioned *Gluconobacter* strains were unable to be identified at the level of species.

Acidomonas methanolica

The genus *Acidomonas* comprises one species, *Acidomonas methanolica*, which is a known methanol-utilizing acetic acid bacterium. Until now, the strains are most abundantly isolated from sewage samples (Yamashita et al. 2004). However, an *Acidomonas methanolica* strain was isolated from an excised lymph node of a boy with chronic granulomatous disease (CGD). Identification was carried out by sequencing 16S rRNA gene. *Acidomonas methanolica* is described to be a pathogen associated with adenitis in the patient with CGD (Chase et al. 2012).

Roseomonas spp.

The genus *Roseomonas* includes Gram-negative coccobacilli characterized by pink-pigmentation and their inability to utilize methanol as a carbon source (Rihs et al. 1993). Strains of this genus have since been isolated from human blood, cerebrospinal fluid, sputum, genitourinary site, and other clinical specimens (Gilardi and Faur 1984; Wallace et al. 1990; Struthers et al. 1996; Han et al. 2003). Cases of catheter-related bacteremia due to *Roseomonas gilardii* and *Roseomonas mucosa* were reported (Alcalá et al. 1997; Vasallo et al. 1998; Bard et al. 2010). Further, blood isolates were obtained from patients with clinically significant underlying disease who had central venous catheters in place, and the majority was associated with polymicrobial catheter infections (Lewis et al. 1997). Cases of peritonitis caused by *Roseomonas gilardii* and *Roseomonas fauriae* were reported in patients undergoing continuous ambulatory peritoneal dialysis (Sandoe et al. 1997; Bibashi et al. 2000). In addition, peritonitis caused by *Roseomonas mucosa* was reported in an adolescent infected with HIV on continuous cycling peritoneal dialysis (Boyd et al. 2012). *Roseomonas* species were reported to have an overall low pathogenic potential for humans, but the species, in particular *R. gilardii*, may be significant pathogens in persons with underlying medical complications (Struthers et al. 1996). A case of chronic postoperative endophthalmitis due to *Roseomonas* spp. was reported, which might result in misdiagnosis and delayed treatment and caused ocular damage and severe visual loss. This was related to a case with postoperative endophthalmitis secondary to *Roseomonas* infection (Chen et al. 2009). Natural reservoir of *Roseomonas* strains is not known. However, the isolates from water were described (Rihs et al. 1993), and domestic water supplies were noticed for *Roseomonas* infection (Sandoe et al. 1997; Bibashi et al. 2000). In addition, *Roseomonas vinacea* was isolated from a soil sample collected from the Qinghai-Tibet Plateau, China (Zhang et al. 2008).

Application

Vinegar

The word "vinegar" is derived from "vin," "aigre," and "vinaigre" in French, literally meaning "sour wine" (Kersters et al. 2006). In the past, wine making and vinegar preparation were always linked. As early as 4000 B.C., vinegar was already mentioned in Babylonian writings, as a product of the date palm, the culture of which was highly developed (Nickol 1979). In Babylon, "fruit honey," viz., sugary syrup made from figs, apricots, grapes, and dates, was used in the kitchen and for

the preparation of wine (Kersters et al. 2006). After the process of wine making was completed, the extracted dates, together with their stones, were used for making a drink composed of a kind of lemonade and vinegar. Vinegar was also a side product, mostly as the unwanted material, in beer brewing. Originally, beer, wine, and vinegar were homemade (4000–3000 B.C.), but later they were prepared in breweries (3000–2000 B.C.). The Babylonian and the Assyrian breweries started mixing barley and dates. Raisin wine and raisin vinegar also became very popular in Babylon from approximately 1000 B.C.

In the Greek settlements in Southern Italy, wine production and trade were important from the eighth century B.C. The Roman took over the Greek knowledge of vine growing and wine making. In Rome, good cooking was an art for the rich, who eagerly accepted the Greek cooking heritage. For example, one of the principal characteristics of the classical Latin taste was its preference for sweet sour (honey vinegar) combinations (André 1961). Uncooked vegetables were eaten with a sort of French dressing ("vinaigrette"), the *acetaria* (Kersters et al. 2006). Several kinds of vinegar were known, e.g., *acetum piperatum*, vinegar containing pepper; *oxygarum*, made from vinegar, garum, and herbs; *oxymeli*, made by boiling vinegar, honey, water, and salt; and *oxysporium*, vinegar containing spices (André 1961).

In ancient China, vinegar seemed to be produced from fruit in the later Shang or Yin period (c. 1300–1046 B.C.) (Yanagida 1990a). In the subsequent Zhou period (1046–256 B.C.), the vinegar was widely used among noblemen. According to a Chinese old book, alcoholic beverages were mainly produced from grains. The vinegar seemed to be produced first from huángjiŭ (a yellow-colored alcoholic beverage), which is at present made from rice and widely brewed. In the old China, there were three kinds of saccharification methods for making alcoholic beverages. The first was by *Aspergillus oryzae*, the second was by *Rhizopus* species, and the third was by the use of malt. However, the malt technique for brewing was lost before the Tang period (A.D. 618–907) except for candy making, for which malt is still utilized in the Chinese countryside (Yanagida 1990a). In the Yuan period (A.D. 1271–1368), there was a record that vinegar was made by *Monascus* species.

In Japan, the sake brewing technique using rice koji by *Aspergillus oryzae* was supposed to come from China in the third century. In China, however, the technique appeared to be already developed in the third century B.C. (Ohtsuka 1990). Sake or rice wine is easily spoiled and turns to rice vinegar. In the Nara period (710–794), the rice vinegar was brewed extensively in Japan. In the middle to late Edo period (c. 1693–1868), many kinds of "sushi" were made using rice vinegar or sake lees vinegar (Ohtsuka 1990).

In Asian countries, the rice vinegar is also produced in Thailand (Yanagida 1990b). In the Philippines, coconut vinegar is particularly made from fermented coconut water. Sugarcane vinegar, which is made from either sugarcane juice or molasses, is most popular also in the Philippines. When the sugarcane vinegar is produced from molasses, the fermented material is distilled, and the resulting alcohol is adequately diluted to be subjected to vinegar fermentation (Yanagida 1990b). Chinese black vinegar is an aged product, which is made from rice, wheat, millet, and sorghum or their combinations. A lighter form of black vinegar is made from rice in Japan. It is called "kurosu" and used as a healthful drink. Date vinegar is produced from dates and a traditional product of the Middle East.

The first commercial vinegar process used wooden casks, and the wine was oxidized on the surface of the liquid by the mother of the vinegar, which contained the acetic acid bacteria (Kersters et al. 2006). The vinegar process was known as the Orleans process or the French method. In Japan, the commercial production of vinegar started in the middle Edo period (around 1690) (Masai 1980). The raw materials were rice, sake, and sake lees. The lees is a by-product of the sake production. Up to the end of World War II, the surface fermentation in wooden shallow trays was the most common process in Japan (Masai 1980). In the traditional fermentation of rice vinegar in Japan, strains with more than 99 % similarity to *Acetobacter pasteurianus* in 16Sr RNA gene sequence analysis dominated all the stages of fermentation, indicating that appropriate strains were spontaneously established almost pure cultures during a century of the fermentation (Nanda et al. 2001).

The German method or the quick process was first introduced from Germany at the beginning of the nineteenth century (Kersters et al. 2006). The system was composed of the generator, consisting of a tank packed with beechwood shavings. Wine was dropped at the top and allowed to trickle through the generator. The acetic acid bacteria grow on the surface of the beechwood shavings and catalyze the oxidation of ethanol to acetic acid. Air is introduced from the holes of the bottom of the tank.

In addition to the surface culture of acetic acid bacteria for vinegar production, the submerged fermentation processes were introduced. After World War II, the techniques for penicillin production were extensively developed. The techniques were applied to vinegar production. The acetator, which was composed of a stainless tank equipped with the aeration and the cooling systems, was put on the market in 1954 by Frings, Germany (Yanagida 1990c). The cavitator of Yeoman, USA, was also utilized for submerged vinegar fermentation. On the other hand, the acetic acid bacteria useful for producing high-acid vinegar were isolated, viz., "*Acetobacter polyoxogenes*," *Acetobacter europaeus* (= *Komagataeibacter europaeus*), and *Gluconacetobacter entanii* (Entani et al. 1985; Sievers et al. 1992; Schüller et al. 2000). The combination of such submerged fermentations and the different types of acetic acid bacteria made possible to produce vinegar with high acidity.

Recently, the quorum-sensing system was investigated for *Gluconacetobacter intermedius* (= *Komagataeibacter intermedius*) NCI 1051 and its mutants (Iida et al. 2008a, b, 2009). Acetic acid production was intensely enhanced with either the *glnI*: :Km mutant harboring pMV24 or the *gltA*::Km mutant harboring pMV24, in comparison with the wild-type strain NCI 1051 which also harbored the plasmid vector pMV24. The final yields of acetic acid with the mutants were twice, when compared with the wild-type strain (Iida et al. 2009).

Alcoholic Beverages

Starting in the Pasteur's time, it was known that acetic acid bacteria were involved in the acetification of wine (Vallery-Radot 1924). The microbiologists at that time already knew that these bacteria could be isolated from the pellicle that formed on wine when it was exposed to air. They were also aware of the fact that the acetification required oxygen (Behrens 1896; Fuhrmann 1905; Wermischeff 1893). The high alcohol tolerance of acetic acid bacteria was already observed. Many acetic acid bacteria were isolated from wine must, but not from either intact or injured grapes (Fuhrmann 1905). *Acetobacter pasteurianus* (75 % of the isolated strains) and *A. aceti* (19 %) strains were isolated from wines in southern France (Dupuy 1957). Acetic acid bacteria were present in about half of the samples of ripe grapes, and they multiplied on injured grapes (Peynaud and Domercq 1961).

Gluconobacter strains occurred profusely on ripe grapes of the Bordeaux region (73 % of all strains isolated), whereas *Acetobacter* and *Pseudomonas* strains constituted, respectively, only 12 and 15 % of the isolates (Blackwood et al. 1969). *Gluconobacter* strains were present on intact and injured grapes but not during the fermentation. The ketogenesis by *Gluconobacter* strains on grapes led to a higher requirement for SO_2 in the sulfitation process. *Gluconobacter* but no *Acetobacter* strains were isolated from dried and mature grapes and vines (Passmore and Carr 1975). *G. oxydans* strains were isolated from grapes (Ameyama 1975). *G. oxydans* was reported as the dominating acetic acid bacteria in fresh grape must, and *A. pasteurianus* and *Gluconacetobacter liquefaciens* were dominated during the fermentation process in South Africa (Du Toit and Lambrechts 2002).

Palm wine is a typical tropical beverage from the fermentation of sugary palm sap and a whitish, effervescent, acidic alcoholic beverage, which is the product of a mixed alcoholic, lactic acid, and acetic acid fermentation. It is popular beverages in Africa, South America, and the Far East. As a first step, the sugar of the sap is fermented to ethanol within 8–12 h by *Zymomonas* strains and yeasts, thus creating a medium highly suitable for the development of acetic acid bacteria. A rather complex flora was present in palm wines (Swings and De Ley 1977). During palm sap fermentation, the acetic acid bacteria appear after 2–3 days. Acetic acid bacteria utilizing D-glucose and/or sucrose might be present in earlier stages of the palm sap fermentation (Okafor 1975). *Acetobacter* species were isolated from palm wines (Faparusi 1973; Okafor 1975) and from the immature spadix of the palm tree (Faparusi 1973). *A. pasteurianus, A. lovaniensis, A. indonesiensis,* and *A. tropicalis* were isolated from palm wine (Simonart and Laudelout 1951; Lysdiyanti et al. 2003b) and *Gluconacetobacter xylinus* from the leaflets of the palm tree and the surrounding air (Faparusi 1973). *Gluconobacter oxydans* was found on the floret of the palm tree, in the tap hole, and in palm sap (Faparusi 1973, 1974).

Acetic acid bacteria occasionally cause deterioration of alcoholic beverage. *Acetobacter pasteurianus* strains were isolated from hiochi sake samples with the smell of acetic acid, applying "hiochi" to sake altered after fermentation, clarification, and pasteurization (Takahashi 1907). *Acetobacter* infection in tequila was described, which occurred in developed cloudiness upon standing and seasonally during summer (Greene and Breazeale 1952).

Cocoa Fermentations

Cocoa is one of many foods that need microbial fermentation or microbial curing for flavor development. The main reason for the fermentation of cocoa is to induce biochemical transformation within the cacao beans that leads to the formation of the color, the aroma, and the flavor of precursors of cocoa. These properties are further developed during drying, roasting, and final processing of the well-fermented cocoa beans to produce cocoa powder and chocolate (Hansen et al. 1998; Thompson et al. 2001; Cleenwerck et al. 2007; Romero-Cortes et al. 2012).

Of the microbial flora in the fermentation, yeasts, lactic acid bacteria, acetic acid bacteria, and spore-forming bacteria were identified (Schwan and Wheals 2004). During the fermentation of cocoa beans, yeasts dominate for the first 24 h. Since the pulp of cocoa beans disappears and acetic acid bacteria start to dominate, the temperature rises to 50 °C, and the resulting heat and the resulting acid are due to chemical reactions in the cocoa beans known as the microbial fermentation or the microbial curing (Schwan 1998). The effect of acetic acid produced and rise in temperature cause the death of the seed embryo as well as the end of fermentation (Cleenwerck et al. 2007). In the cocoa fermentation process, *Acetobacter ghanensis* and *Acetobacter tropicalis* strains were reported (Cleenwerck et al. 2007; Romero-Cortes et al. 2012).

Cocoa wine is made by fermentation of cocoa seeds and is a popular drink in Nigeria (Bassir 1968; Kersters et al. 2006). The cocoa beans are ground and boiled in sugared water and allowed to cool to approximately 50 °C, before inoculum is added. The alcohol concentration of the cocoa wine is 9.5–11.6 % and is significantly higher than that of palm wine (Bassir 1968). *Acetobacter* and *Gluconobacter* strains were isolated from cocoa wine (Bassir 1968). To improve the reliability and quality of the cocoa fermentation process, a defined and mixed starter culture including *Acetobacter* and *Gluconobacter* strains was successfully used (Schwan 1998).

Nata

Nata is a white- to creamy-colored gelatinous or agar-like film grown on surface of juice made from coconut, pineapple, sugarcane, or other fruit wastes in the Philippines, Thailand, Indonesia, and other Southeast Asian countries. Nata de coco is produced from coconut water or coconut milk. The following ingredients are added to coconut water: to be final concentrations 2 % of glacial acetic acid; 15 % of sucrose; 0.5 % of ammonium dihydrogen phosphate, giving pH 5.0–5.5; and 10 % of 48 h culture inoculum. After fermentation at 28–31 °C

for 12–15 days, 5–7 cm-thick layer of bacterial cellulose is formed. Washing it with water and removing acetic acid, the film is cut into cubes. Nata de coco is a popular dessert in the Southeast Asian countries (Campbell-Platt 1987) and was once exported to other countries (Librero and Tidon 1994). Mother liquor in which acetic acid bacteria inhabit can be used (Librero and Tidon 1994). Cultures of *Komagataeibacter xylinus* (*Gluconacetobacter xylinus*) were considered a major cellulose-producing bacterium. Analysis of 16S rRNA sequence revealed that *K. xylinus and K. hansenii* (*Gluconacetobacter hansenii*) concerned with the production of nata de coco (Bernardo et al. 1998). In addition, *A. pasteurianus*, *A. orleanensis*, *A. lovaniensis*, *Gluconobacter oxydans*, and *G. frateurii* strains were also found in the process of nata production (Lysdiyanti et al. 2003b).

Kombucha and "Tea Fungus"

Kombucha is a slightly acidulous and effervescent beverage obtained by the fermentation of sugared black tea with a symbiotic culture of acetic acid bacteria and yeasts. Several names have been given to the beverage and the organisms responsible for acetic acid fermentation of tea infusions: kombucha, tea fungus, miracle fungus, fungus of charity, fungus of a long life, remedy for immortality, Ma Gu, Chinese or Japanese fungus, Japanese or Indian tea fungi, Hongo, Haipao, Teeschwamm, Teekwasspilz, indischer Weinpilz, Wunderpilz, and Wolgapilz (Dinslage and Ludorff 1927; Stadelmann 1957; Kraft 1959; Abadie 1962). These names, often referring to a fungus, are confusing, in fact, which mean an association of yeasts with acetic acid bacteria, forming a thick film on the surface of a tea infusion.

Kombucha and Japanese tea fungus were cited as follows: The Japanese word "kombu" describes an edible fungus (*Laminaria japonica*) that is used for the production of tea (Japanese "cha" = tea) (Caesar 1990; Mayser et al. 1995). However, kombu (*Laminaria japonica*) is a kind of seaweeds in Japanese but not "edible fungi," and "cha" means tea. "Kombucha" in Japanese is a powdery material produced from the dried seaweed (*Laminaria japonica*) and a small amount of sodium chloride. It has been used as a drink and a seasoning in Japan. Therefore, "kombucha" in Japanese clearly differs from kombucha used in Europe and the USA.

Approximately one hundred years ago, the tea fungus was already used in Japan, China, and India; then in Russia, Poland, and the Baltic States starting in about 1915; in the Balkan, Germany, and Eastern Europe in about 1925; and in Spain, Italy, France, and Switzerland in about 1955 (Kraft 1959).

Recipes of kombucha are almost identical to one another. One example is shown (Teoh et al. 2004). The tea medium was prepared traditionally by boiling 1 l of distilled water, 100 g white sugar, and 5.4 g black tea leaves for 5 min and allowing the mixture to steep for 15 min. The sweetened tea was strained to remove the leaves, during transfer to a sterile glass jar (2 l). Once cooled to the ambient laboratory temperature (20–22 °C), the tea was inoculated with the kombucha culture (pellicle). At the completion of the first fermentation, the pellicle, covering the entire surface area of the liquor, was used to inoculate the next (second) fermentation. During subsequent fermentations, a "daughter" pellicle similar to that of the "parent" was used as the inoculum. For each of the second and subsequent fermentations, 100 ml of beverage was added from the previous fermentation, in addition to the pellicle. For each fermentation, the jar was covered with paper towel, secured with rubber band. Fermentation was conducted in a temperature-controlled laboratory (20–22 °C) for up to 14 days. The pH of the beverage decreased rapidly within the first 24 h., decreasing to pH 2.2 by the completion of fermentation.

Hermann (1928a, b) isolated "*Bacterium gluconicum*" (*Gluconobacter oxydans*) and "*Bacterium xylinus*" (*Komagataeibacter xylinus*) from kombucha. *Acetobacter xylinum* (*Komagataeibacter xylinus*) (Sievers et al. 1995), *Acetobacter aceti* and *A. pasteurianus* (Liu et al. 1996), *Acetobacter intermedius* (*Komagataeibacter intermedius*) (Boesch et al. 1998), *Acetobacter nitrogenifigens* (Dutta and Gachhui 2006), and *Gluconoacetobacter kombuchae* (Dutta and Gachhui 2007; later reidentified as *Gluconacetobacter hansenii*, Cleenwerck et al. 2009) have also been identified in kombucha beverage. The following yeasts have been identified in kombucha: the genera *Brettanomyces*, *Zygosaccharomyces* and *Saccharomyces* (Mayser et al. 1995); *Saccharomyces cerevisiae*, *Zygosaccharomyces bailii*, and *Brettanomyces bruxellensis* (Liu et al. 1996); and *Zygosaccharomyces kombuchaensis, Z. bailii*, *Z. bisporus*, and *Pichia fluxuum* (Kurtzman et al. 2001).

Kombucha was made with pure cultures of *Acetobacter* sp. NRRL B-2357 and two yeast strains, NRRL Y-4810 (later identified *as Zygosaccharomyces kombuchaensis*; Kurtzman et al. 2001) and NRRL Y-4882 (later identified as *Pichia fluxuum*; Kurtzman et al. 2001) (Hesseltine 1965). When all three organisms were used together, normal fermentation occurred. The fermentation with three organisms appeared to be exactly similar to that which occurred when the original culture was used, which contained a number of a few different organisms. When an *Acetobacter* strain was used alone, a film formed with some gas. When the yeasts were used singly or in combination, no film was formed. When the three microorganisms were used in combination, a thicker film was formed rapidly, no gas accumulated, and a typically normal fermentation occurred.

The process during kombucha fermentation was described (Sievers et al. 1995). *Zygosaccharomyces* yeasts in kombucha converted sucrose into D-glucose and D-fructose. D-Fructose was metabolized prior to D-glucose. Further, D-glucose and D-fructose were turned to ethanol and carbon dioxide. *Acetobacter xylinus* produced acetic acid from ethanol and D-gluconic acid from D-glucose. The pH value of kombucha decreased during fermentation from pH 3.75 to 2.42. Sucrose was completely hydrolyzed after 40 days, and D-fructose was entirely metabolized. After 20 days, 7.0 g/l of ethanol was produced, and after 40 days, 2.0 g/l of alcohol remained. Further, 28.4 g/l acetic acid was

D-Glucose → D-Sorbitol → L-Sorbose → Diacetone-L-sorbose → Diacetone-2-keto-L-gulonic acid → L-Ascorbic acid

Fig. 1.6
The Reichstein-Grüssner process for the production of L-ascorbic acid. The biological oxidation of D-sorbitol to L-sorbose is catalyzed by *G. oxydans*. The other processes are no biological steps

D-Sorbitol → L-Sorbose → L-Sorbosone → 2-Keto-L-gulonic acid → L-Ascorbic acid

Fig. 1.7
The conversion of D-sorbitol to 2-keto-L-gulonic acid by *G. oxydans*. The conversion of 2-keto-L-gulonic acid to L-ascorbic acid is a no biological step to yield vitamin C

produced after 40 days, and 13.5 g/l gluconic acid remained. In the first period (6–8 days), the taste of kombucha was fruit-sour-like; with prolonged incubation, the tea fungus developed a vinegar-like taste. The liquid portion is used for a drink. Nata de coco is basically the same as kombucha, and a cellulose pellicle is taken for a dessert.

The claimed health effects of kombucha have been discussed (Dufresne and Farnworth 2000; Greenwalt et al. 2000).

Production of D-Gluconate and Keto-D-gluconates

D-Gluconic acid and its lactone, salts, and keto-forms have a wide range of applications in the food, pharmaceutical, and chemical industries. *Gluconobacter* strains oxidize D-glucose and D-gluconic acid to keto-D-gluconic acids (2-keto-D-gluconic acid, 5-keto-D-gluconic acid, and 2,5-diketo-D-gluconic acid). 2-Keto-D-gluconate and 5-keto-D-gluconate are interesting precursors for isoascorbic acid synthesis and tartaric acid production, respectively (Klasen et al. 1992). 2,5-Diketo-D-gluconate can be converted to 2-keto-L-gulonic acid as a penultimate intermediate in the industrial production of vitamin C.

Production of L-Sorbose and Vitamin C

Gluconobacter strains are used for the oxidative conversion of D-sorbitol to L-sorbose, which is an important intermediate in the production of L-ascorbic acid (vitamin C) (estimated world production, more than 100,000 t per year at the time of writing). Vitamin C is important for human and animal nutrition and is used as an antioxidant in the food industry. It is currently produced by the Reichstein-Grüssner process, involving a series of chemically based unit operations and a single biological oxidative step, where D-sorbitol is regioselectively oxidized to L-sorbose by a membrane-bound D-sorbitol dehydrogenase of *G. oxydans* (Fig. 1.6). D-Sorbitol is obtained by electrolytic or catalytic reduction of D-glucose.

The overall practical yield of the Reichstein process, with the recent advances in chemical engineering, was thought to be approximately 50 % (Boudrant 1990). The effects of cross-linking agents, such as glutaraldehyde and polyethyleneimine on L-sorbose production by immobilized *G. oxydans* cells, were studied (Park et al. 1998). The theoretically maximal productivity of the biological oxidative step was achieved by using a *G. oxydans* mutant that was selected under conditions of substrate inhibition (De Wulf et al. 1996).

Several strategies including recombinant DNA technologies are being developed to shift the synthesis of ascorbic acid from chemical procedures to purely bioconversion routes, where the synthesis of 2-keto-L-gulonic acid is a key intermediate (Deppenmeier et al. 2002). Some *Gluconobacter* strains convert D-sorbitol to 2-keto-L-gulonic acid via L-sorbosone. The 2-keto-L-gulonic acid can be converted nonbiologically to L-ascorbic acid (Fig. 1.7; Hoshino et al. 1990; Saito et al. 1997).

Overexpression of the L-sorbose dehydrogenase and the L-sorbosone dehydrogenase genes in *G. oxydans* resulted in improved yields of 2-keto-L-gulonic acid (Saito et al. 1997). In this respect, the application of *Ketogulonigenium* strains belonging to the family *Rhodobacteraceae* may open new perspectives for the biological conversion of L-sorbose to 2-keto-L-gulonic acid (Urbance et al. 2001).

Production of Dihydroxyacetone and Acetylmethylcarbinol

Dihydroxyacetone is used as a cosmetic tanning agent and as an intermediate for the synthesis of various organic chemicals and surfactants. The oxidation of glycerol to dihydroxyacetone by *G. oxydans* strains is catalyzed by a membrane-bound PQQ-dependent glycerol dehydrogenase (Claret et al. 1994) and can be optimized by using immobilized *G. oxydans* cells (Tkac et al. 2001). Similarly *Gluconobacter* strains can be used to oxidize 2,3-butanediol to acetylmethylcarbinol.

Synthesis of 1-Deoxynojirimycin and Miglitol

1-Deoxynojirimycin and its *N*-substituted analog *N*-hydroxyethyl-1-deoxynojirimycin (miglitol) are strong inhibitors of α-glucosidases and are used for the treatment of

D-Glucos → 1-Amino-D-sorbitol → 6-Amino-L-sorbose → 1-Deoxynojirimycin

D-glucose → *N*-Hydroxyethyl-1-amino-D-sorbitol → *N*-Hydroxyethyl-6-amino-L-sorbose → *N*-Hydroxyethyl-1-deoxynojirimycin (miglitol)

Fig. 1.8

Synthesis of 1-deoxynojirimycin and miglitol from D-glucose. The conversions of 1-amino-D-sorbitol to 6-amino-L-sorbose and of *N*-hydroxyethyl-1-amino-D-sorbitol to *N*-hydroxyethyl-6-amino-L-sorbose are the regioselective oxidation by a *G. oxydans* strain. The other conversion are no biological steps. The first step is a chemical reductive amination of D-glucose and the last step is a chemical stereoselective ring closure

non-insulin-dependent diabetes (Campbell et al. 2000). The industrial production of these compounds follows a combined biotechnological-chemical synthesis, whereby a *G. oxydans* strain plays a key role in the oxidation of 1-aminosorbitol derivatives (Fig. 1.8; Deppenmeier et al. 2002). Because *Gluconobacter* strains cannot grow on aminopolyols, whole resting cells (grown on sorbitol) have to be used for this biotransformation process (Schledel 2000).

Gluconobacter as Biosensor

The cells and enzymes of *G. oxydans* find applications as biosensors for the estimation of the concentrations of various aldoses, polyalcohols, ethanol, glycerol, etc. (Lusta and Reshetilov 1998; Macauley et al. 2001; Tkac et al. 2000, 2001).

2 The Family *Anaplasmataceae*

Eugene Rosenberg
Department of Molecular Microbiology and Biotechnology, Tel Aviv University, Tel Aviv, Israel

Abstract
The family *Anaplasmataceae* is in the order *Rickettsiales* that includes the four genera *Anaplasma*, *Ehrlichia*, *Neorickettsia*, and *Wolbachia*, all of which are small Gram-negative pleomorphic cocci and obligatory intracellular bacteria. The *Rickettsiales* are most often cited as the alphaproteobacterial subgroup from which mitochondria arose.

Anaplasmataceae is a family in the order *Rickettsiales* that includes the four genera *Anaplasma*, *Ehrlichia*, *Neorickettsia*, and *Wolbachia*, all of which are small Gram-negative pleomorphic cocci and obligatory intracellular bacteria (Dumler et al. 2001; Williams et al. 2007). The *Rickettsiales* are most often cited as the alphaproteobacterial subgroup from which mitochondria arose (Fitzpatrick et al. 2006).

The genus *Wolbachia* is of particular interest due to its ubiquitous distribution and many different evolutionary interactions. It is one of the world's most common parasitic microbes and is possibly the most common reproductive parasite in the biosphere. As many as 70 % of all insect species are estimated to be potential hosts (Kozek and Rao 2007). Its interactions with its insect hosts are often complex and in some cases have evolved to be mutualistic rather than parasitic. Some host species cannot reproduce, or even survive, without *Wolbachia* infection (Zimmer 2001). The genomes of several *Wolbachia* strains show substantial differences at some rapidly evolving regions of the genome, primarily associated with prophage and repetitive elements (Duplouy et al. 2013). These genes include a number that have been recently horizontally transferred from phylogenetically distant bacterial taxa.

The ability of *Wolbachia* to spread through cytoplasmic incompatibility and render mosquitoes resistant to a variety of human pathogens (Moreira et al. 2009) has instigated the development of *Wolbachia*-based strategies for both suppression and replacement of disease vector populations (Hoffmann et al. 2011). Recently this effort has been extended to anopheles malaria vector mosquitoes, which are not naturally infected by *Wolbachia* spp. (Bian et al. 2013).

The genus *Anaplasma* comprises obligate intracellular rickettsial pathogens that are biologically transmitted by ticks (Telford et al. 1996). They target circulating blood cells of wild and domestic animals, as well as of humans, and are of global veterinary and human health importance. The type species, *Anaplasma marginale*, has been studied intensively (Kocan et al. 2000) and can be grown in cell lines derived from the tick *Ixodes scapularis* (Munderloh et al. 1994; Dyachenko et al. 2013). The complete genome sequence of *A. marginale*, the most prevalent tick-borne livestock pathogen worldwide, has been published (Brayton et al. 2005).

The obligate intracellular bacterium *Ehrlichia chaffeensis* that resides in mononuclear phagocytes is the etiologic agent of the emerging human disease monocytotropic ehrlichiosis (Thomas et al. 2010). *Ehrlichia* are round or ovoid Gram-negative bacteria and form a characteristic vacuole-contained microcolony (morula) in macrophages (Popov et al. 1998). *Ehrlichia* are transported between cells through the host cell filopodia during initial stages of infection, whereas in the final stages of infection, the pathogen ruptures the host cell membrane and spreads from cell to cell (Thomas et al. 2010). Complete genome sequencing revealed that the *Ehrlichia canis* genome consists of a single circular chromosome of 1,315,030 bp predicted to encode 925 proteins, 40 stable RNA species, 17 putative pseudogenes, and a substantial proportion of noncoding sequences (Mavromatis et al. 2006).

Discovered in 1984, *Neorickettsia* (formerly *Ehrlichia*) *risticii* is an obligate intracellular bacterium and the causative agent of Potomac horse fever (Rikihisa and Perry 1984). It was determined that *N. risticii* has similar genetic, antigenic, and morphologic characteristics to *Neorickettsia helminthoeca* (Pretzman et al. 1995), which were the major reasons it, as well as *Neorickettsia* (formerly *Rickettsia*, *Ehrlichia*) *sennetsu*, was regrouped into the genus *Neorickettsia* (Dumler et al. 2001).

E. Rosenberg et al. (eds.), *The Prokaryotes – Alphaproteobacteria and Betaproteobacteria*, DOI 10.1007/978-3-642-30197-1_413,

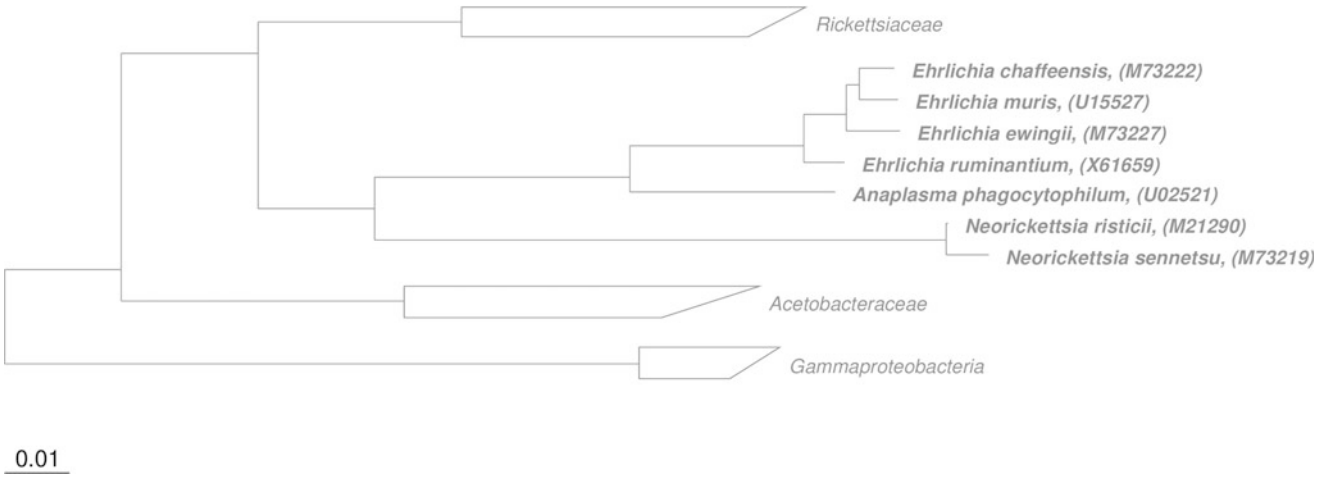

Fig. 2.1

Phylogenetic reconstruction of isolates belonging to the family *Anaplasmataceae* based on 16S rRNA and created using the neighbor-joining algorithm with the Jukes-Cantor correction. The sequence datasets and alignments were used according to the All-Species Living Tree Project (*LTP*) database (Yarza et al. 2010; http://www.arb-silva.de/projects/living-tree). The tree topology was stabilized with the use of a representative set of nearly 750 high-quality type strain sequences proportionally distributed among the different bacterial and archaeal phyla. In addition, a 40 % maximum frequency filter was applied in order to remove hypervariable positions and potentially misplaced bases from the alignment. *Scale bar* indicates estimated sequence divergence

The identification of Neorickettsia proteins is now achievable with the availability of. The whole genome sequences of both the type strain (Miyayama) of *N. sennetsu* (Hotopp et al. 2006) and the type strain (Illinois) of *N. risticii* (Lin et al. 2009) are available (*Fig. 2.1*).

Abstract
Bartonellaceae is a family within the order *Rhizobiales* in the sub-class of *Alphaproteobacteria* which contains only the genus *Bartonella*. They are fastidious, facultative intracellular, slow-growing, gram-negative, slightly curved bacilli that cause a wide range of diseases in humans and animals, some species being zoonotic. Clinical manifestations in humans include Carrión's disease, trench fever, cat scratch disease, bacteremia with fever, bacillary angiomatosis and peliosis, endocarditis, and neuroretinitis. Colony morphology varies from clear to smooth white and rough tan. Several species embed in the agar. They are typically inert biochemically; the organisms are usually catalase and oxidase negative and aerobic, and they do not produce acid from carbohydrates. Some species are motile. The genus *Bartonella*, to date, contains 29 species and 3 subspecies. Most *Bartonella* species have successfully adapted to survival in specific domestic or wild mammals. Blood-sucking arthropod vectors are often involved. Clinical presentation generally depends on both the infecting *Bartonella* species and the immune status of the infected individual. *Bartonella* species are susceptible to many antibiotics in vitro; however, in vivo antibiotic susceptibilities do not correlate well for a number of antibiotics.

E. Rosenberg et al. (eds.), *The Prokaryotes – Alphaproteobacteria and Betaproteobacteria*, DOI 10.1007/978-3-642-30197-1_251,

Taxonomy, Historical and Current

Short Description of the Family

Bartonellaceae (*Bar.to.nel.la' ce.ae.* M.L. fem. n. *Bartonella*, type genus of the family; suff. *-aceae*, ending to denote a family; N.L. fem. pl. n. *Bartonellaceae*, the *Bartonella* family; Gieszczykiewicz, 1939 emend. Brenner et al. 1993).

Type genus: *Bartonella* Strong, Tyzzer and Sellards 1915 emend. Birtles, Harrison, Saunders, and Molyneux 1995.

Phylogenetically, the family of *Bartonellaceae* is a member of the order *Rhizobiales*, class *Alphaproteobacteria* (subgroup 2) in the phylum Proteobacteria. The family contains only the genus *Bartonella* (type genus) (Birtles et al. 1995; Strong et al. 1915). The phylogenetic relationship of *Bartonella* to other *Alphaproteobacteria* indicates that they have a close evolutionary homology with the members of the genera *Brucella*, *Agrobacterium*, and *Rhizobium* (Brenner et al. 1993). These four genera have similar characteristic, such as the fact that they evolve toward a parasitic or mutualistic association, being *Bartonella* spp. and *Brucella* spp. intracellular parasites of mammalian cells, whereas *Agrobacterium* and *Rhizobium* species can parasitize or mutualistically associate with plant cells, respectively (Minnick and Anderson 2006). In addition, none of these bacteria are obligate parasites, and all can be cultivated in vitro.

The family *Bartonellaceae* suffered a major taxonomic reorganization in the 1990s. For decades, since the description of *Bartonella bacilliformis* in 1909 by Alberto L. Barton (1909), this species was the sole member of the genus *Bartonella*. However, in 1992, on the basis of DNA relatedness data, previous 16S rRNA sequence data, guanine-plus-cytosine contents, and phenotypic characteristics, Brenner and colleagues proposed that the genus *Rochalimaea* should be united with the genus *Bartonella* in the family *Bartonellaceae* (Brenner et al. 1993). The name *Bartonella* was retained as the genus name since it had nomenclatural priority over the name *Rochalimaea*. As a result, new combinations for the *Rochalimaea* species were created: *Bartonella quintana* comb. nov., *Bartonella vinsonii* comb. nov., *Bartonella henselae* comb. nov., and *Bartonella elizabethae* comb. nov. (Brenner et al. 1993). This reclassification also resulted in the transfer of these organisms from the family *Rickettsiaceae* to the family *Bartonellaceae*, which included *Bartonella bacilliformis*. In addition, the family *Bartonellaceae* has been removed from the order *Rickettsiales*, a group that originally included *Anaplasmataceae*, *Rickettsiaceae*, and *Bartonellaceae*. Later, in 1995, based upon DNA relatedness data and phenotypic characteristics, it was proposed that the genera *Grahamella* and *Bartonella* should be unified and that the latter name should be retained (Birtles et al. 1995). *Bartonella talpae* comb. nov. and *Bartonella peromysci* comb. nov., new combinations for former *Grahamella* species, were created, and three new *Bartonella* species were described: *Bartonella grahamii* sp. nov., *Bartonella taylorii* sp. nov., and *Bartonella doshiae* sp. nov. In effect, these reclassifications eliminated the previous genera *Rochalimaea* and *Grahamella*. In 1996, *Bartonella vinsonii* subsp. *berkhoffii* subsp. nov. was designated a new subspecies, *Bartonella vinsonii* subsp. *vinsonii* subsp. nov. renamed (formerly *B. vinsonii*) (Kordick et al. 1996), and *Bartonella clarridgeiae* sp. nov. characterized as a new species (Lawson and Collins 1996). In 1998, *Bartonella tribocorum* sp. nov. was isolated from the blood of wild rats and characterized (Heller et al. 1998). On a sequence, *Bartonella koehlerae* sp. nov. (Droz et al. 2000), *Bartonella alsatica* sp. nov. (Heller et al. 1999), and *Bartonella vinsonii* subsp. *arupensis* subsp. nov. (Welch et al. 2000) were isolated and added to the growing list of *Bartonella* species and subspecies. In the year 2000, *Bartonella birtlessi* sp. nov. was isolated from small mammals (*Apodemus* spp.) and received the name after Richard J. Birtles, whose studies have contributed to an improved understanding of the taxonomy of the genus (Bermond et al. 2000). Also in the same decade, *Bartonella schoenbuchensis* sp. nov. (Dehio et al. 2001), *Bartonella bovis non* (formerly called *Bartonella weissi* or *Bartonella weissii*), *Bartonella capreoli* sp. nov. (Bermond et al. 2002), and *Bartonella chomelii* sp. nov. were isolated (Maillard et al. 2004). New species were later added with the identification of *Bartonella rattaustraliani* sp. nov. (Gundi et al. 2009), *Bartonella queenslandensis* sp. nov. (Gundi et al. 2009), *Bartonella coopersplainsensi* sp. nov. (Gundi et al. 2009), *Bartonella japonica* sp. nov. (Inoue et al. 2010), *Bartonella silvatica* sp. nov. (Inoue et al. 2010), and *Bartonella rochalimae* sp. nov. (Eremeeva et al. 2012). Recently, in 2013, *Bartonella jaculi* sp. nov., *Bartonella callosciuri* sp. nov., *Bartonella pachyuromydis* sp. nov., and *Bartonella acomydis* sp. nov. were isolated from wild Rodentia (Sato et al. 2013) and increased the list of species compromising the genus *Bartonella*. According to the *List of Prokaryotic Names with Standing in Nomenclature* (*LPSN*, 2014), the genus *Bartonella*, to date, contains 29 species and 3 subspecies. Further growth in the number of species and subspecies in the genus is thus expected to occur in the future.

It is noteworthy that some *Bartonella* organisms are considered *Candidatus*, a category used for describing prokaryotic entities for which more than a mere sequence is available but for which characteristics required for description according to the *Bacteriological Code* (1990 Revision) are lacking. These include "*Candidatus* Bartonella ancashi" (Blazes et al. 2013), "*Candidatus* Bartonella antechini" (Kaewmongkol et al. 2011a), "*Candidatus* Bartonella bandicootii" (Kaewmongkol et al. 2011b), "*Candidatus* Bartonella mayotimonensis" (Lin et al. 2010), "*Candidatus* Bartonella merieuxii" (Chomel et al. 2012), "*Candidatus* Bartonella thailandensis" (Saisongkorh et al. 2009), "*Candidatus* Bartonella washoensis subsp. cynomysii" (Bai et al. 2008), and "*Candidatus* Bartonella woyliei" (Kaewmongkol et al. 2011).

According to the Second Edition of *Bergey's Manual of Systematic Bacteriology*, the family *Bartonellaceae* is metabolically diverse and includes aerobic organisms. The Gram staining of these bacteria is negative and is not acid fast. The morphology is characterized by small coccobacilli that may be beaded or filamentous and <3 μm in their greatest diameter. Erythrocytic forms stain lightly with many aniline dyes but distinctly with

Giemsa stain after methanol fixation. Some species have polar flagella although most are nonmotile. Organisms are cultivable, but highly fastidious, in vitro, on blood-enriched bacteriological media (Welch 2005).

Clinical manifestations in humans and the vectors and reservoirs associated with each of the currently recognized species and subspecies of *Bartonella*, as well as discovery and first cultivation date are described in *Table 3.1*.

Molecular Analyses

Phylogenetic Structure of the Family and Its Genus

The *Bartonellaceae* family consists of closely related bacteria grouped into a single genus (*Fig. 3.1*). Molecular approaches are the most contemporary tools used to classify organisms and study their evolutionary relationships. These analyses are based on the variability of the sequences of certain genes, especially those encoding RNA molecules. The use of well-defined secondary structure in the identification of homologous residues (i.e., the alignment process) is an important advantage of the RNA sequences as compared with the genes encoding other proteins. To perform a phylogenetic study of prokaryotes, comparative analysis of *16S rDNA* (Woese 1987; Ludwig and Schleifer 1999) is considered the gold standard. Because of the high degree of *16S rDNA* sequence conservation, the phylogenetic differentiation at the species level is low. Thus, the use of this molecular marker in differentiating groups of closely related organisms, such as species of the genus *Bartonella*, can be a limiting factor (Fox et al. 1992; Suksawat et al. 2001; Houpikian and Raoult 2001a). This has led to problems in the identification of medically important bacteria of *Bartonella* genus when the molecular diagnosis was based on the 16S rDNA gene. Other genes have been successfully used to increase the sensitivity and specificity of analytical methods for the detection of these *Bartonella* species.

Alternative genes that may be used for phylogenetic purposes should be both highly conserved (i.e., housekeeping genes) and sufficiently variable to allow species identification (Olsen and Woese 1993). Useful alternative genes include a 17 kDa antigen gene (Sweger et al. 2000), *flaA* (Sander et al. 2000), *gltA* (Birtles and Raoult 1996; Roux et al. 2000; Houpikian et al. 2001), *htrA* (Anderson and Neuman 1997), *ftsZ* (Ehrenborg et al. 2000), and *groEL* (Marston et al. 1999), as well as the 16S and 23S rDNA internally transcribed spacer sequences (Jensen et al. 2000; Birtles et al. 2000). However, when used to infer the phylogenetic relationships within the genus *Bartonella*, these sequences suggested convicting relationships.

The *gltA* and 16S–23S genes are often used to classify bacterial species, especially those of the genus *Bartonella*. The trees generated from the *16S rDNA* gene have an improved resolution, but many of them lack statistical support (Birtles and Raoult 1996; Roux and Raoult 1995; Jensen et al. 2000). Phylogenetic trees derived from *ITS* gene for the *Bartonella* species showed reliable organizations, similar to derived trees of *groEL* gene (Houpikian and Raoult 2001a). Several studies have demonstrated the importance of the *groEL* gene as a molecular marker sensitive and valuable for determining phylogenetic relationships of bacteria species (Viale et al. 1994). Several bacteria species of *Bartonella* genus known to date have been classified by Zeaiter et al. (2002) using *groEL* gene sequences. In the same study, the *groEL* gene was used for subtyping of *B. henselae* and *B. quintana* isolates. Zeaiter et al. (2002) compared phylogenetic trees derived from 16S rDNA sequences; it was confirmed that this gene was unable to resolve the relationships within the genus *Bartonella* as most branches lacked statistical support, and only one reliable cluster was established by *B. elizabethae* and *B. tribocorum*. In contrast, trees generated using *groEL* sequences were much more informative. All three phylogenetic analysis methods provided similar and reliable topologies.

According Houpikian and Raoult (2001b), the sequences of protein-coding genes have been used for evolutionary inferences for being more conserved at the species level, but highly variable between species. Furthermore, these sequences may be analyzed by amino acid sequence as well as genomic level for improved reliability (Birtles and Raoult 1996; Marston et al. 1999; Birtles et al. 2000). In the literature, there is no consensus about the use of hypervariable region of the ITS gene as indicator of molecular evolution (Birtles et al. 2000; Roux and Raoult 1995). Nevertheless, the ability of a specific sequence to produce meaningful phylogenetic data can only be appreciated after comparison and reconstruction inferable, by assessing the statistical support of the resulting branching order. Thus, only the *16S rDNA*, *ITS*, *gltA*, and *groEL* are routinely used for phylogenetic studies. Use of other genes is hampered by the lack of *Bartonella* sequences.

Six clusters were consistently identified after genotyping studies based on phylogenetic information from the 16S rDNA, ITS, groEL, and gltA genes of *Bartonella* species (i.e., clusters which were statistically supported to at least two different genes). The cluster formed by *B. bacilliformis* (group A) is the only one that diverges from the others relatively well with 100 % bootstrap values for the 16S rDNA, ITS, groEL, and gltA genes. This divergence is also supported by differences in colony morphology, requirements for growth, fatty acid composition, protein, and antigenic structure (Anderson et al. 1995; Birtles and Raoult 1996; Marston et al. 1999; Birtles et al. 1991). Levels of similarity for amino acid sequences of ftsZ proteins, as well as for nucleotide sequences of *ribC* genes, are low between *B. bacilliformis* and other *Bartonella* species, supporting its divergent position (Bereswill et al. 1999; Kelly et al. 1998). *Bartonella clarridgeiae* may also be a divergent species (group B) according to *ITS* and *groEL* analyses. Strains of *Bartonella* sp. associated with cats in the Netherlands and the USA have a close phylogenetic relationship with *B. clarridgeiae* based on analyses of 16S rDNA gene. Studies have suggested that *B. clarridgeiae* and *B. bacilliformis* have a close phylogenetic relationship, since these species are flagellated, but statistical

support is lacking for such organization (Kosoy et al. 1997; Marston et al. 1999; Jensen et al. 2000). The third group (group C) is formed by *B. quintana* and *B. henselae*; the cluster is supported by bootstrap values >90 % with trees derived from *gltA* and *groEL* genes. Studies indicate that *B. henselae* and *B. quintana* are two species closely related; these studies were based on the high degree of conservation between *ftsZ* homologues, *ribC* proteins, and 17 kDa antigens (Bereswill et al. 1999; Kelly et al. 1998; Sweger et al. 2000). *Bartonella koehlerae* is a species more closely related to *B. henselae* based on a comparison of *16S rDNA* and *gltA* gene sequences.

Group D is formed by *Bartonella* species associated with rats and mice captured in Peru and the USA. This phylogenetic group was determined from the analysis of the *gltA* gene (Birtles et al. 1999; Kosoy et al. 1997; Ellis et al. 1999b; Birtles and Raoult 1996). Group D may be divided into two subgroups, one of which includes *Bartonella* species associated with mice, and the second subgroup includes species associated with rats. Phylogenetic studies have revealed a strong association between *B. vinsonii* subsp. *vinsonii* and *B. vinsonii* subsp. *berkhoffii* (group E) with sequences of *ITS*, *groEL*, and *gltA* genes, but not for the sequences of the *16S rDNA* gene (Kordick et al. 1996). The position of this *B. vinsonii* cluster relative to other *Bartonella* species remains unclear. The sixth group (F) is obtained with *16S rRNA*, *ITS*, *gltA*, *and groEL* gene sequence comparisons. Like group D, it contains rodent-associated organisms. *B. elizabethae*, *B. grahamii*, and *B. tribocorum* cluster into this clade, together with uncharacterized strains found in mice and rats from the USA, Peru, and Europe (Birtles et al. 1999; Ellis et al. 1999a; Birtles et al. 1994). Within group F, *B. elizabethae* clusters with isolates from Peruvian rats in a separate subclade supported by *gltA*

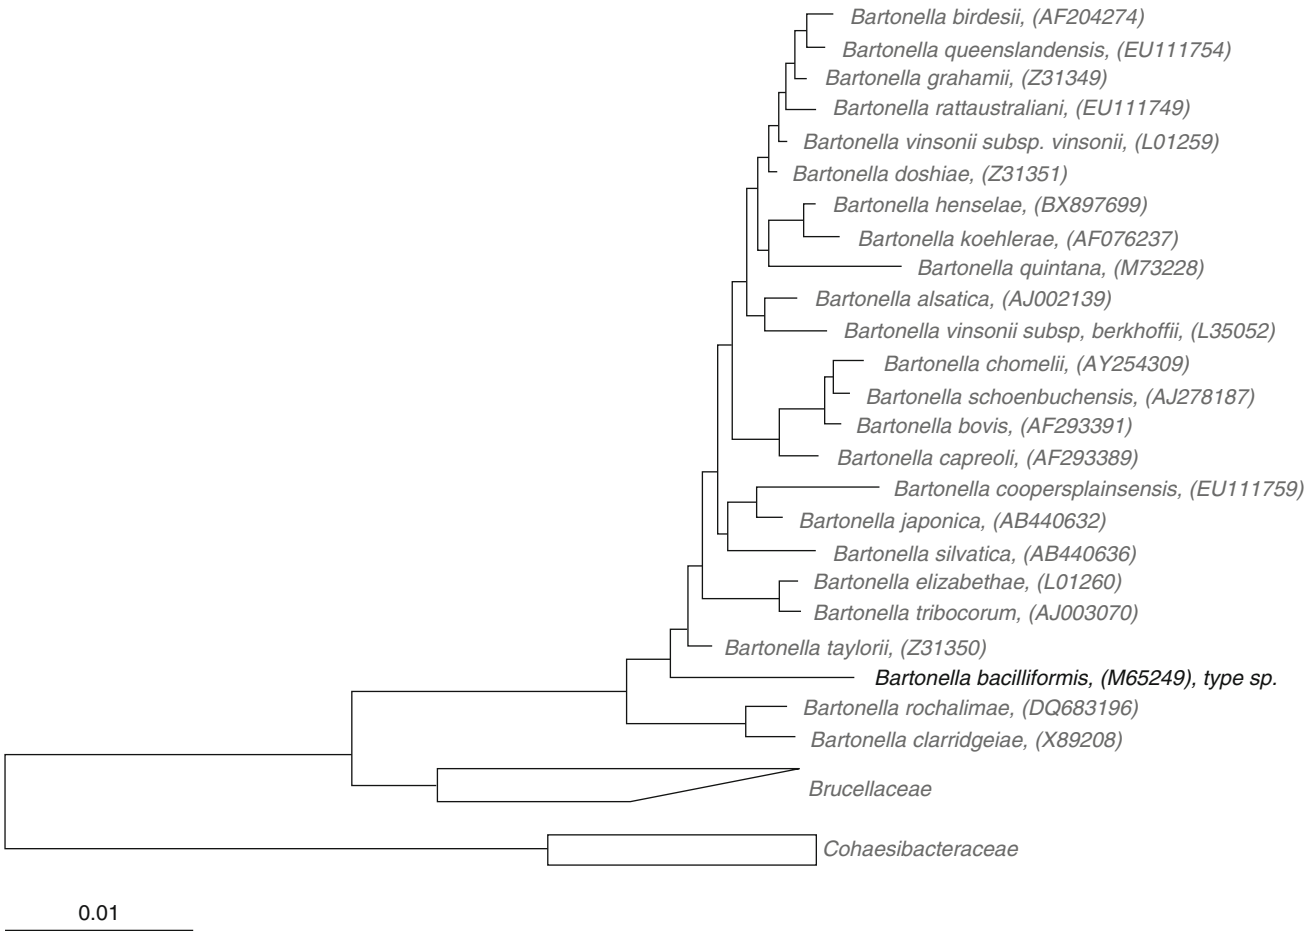

Fig. 3.1
Phylogenetic relationships of the organisms belong to *Bartonellaceae* family in relation of *Cohaesibacteraceae* and *Brucellaceae* families, based on the DNA sequences. The numbers of GenBank access are positioned right of the specie name

analysis. The taxonomic position of other species and strains, mainly *B. taylorii*, *B. doshiae*, and *B. alsatica*, could not be consistently determined on the basis of genetic sequence data available.

The phylogeny of *Bartonella* species remains confusing, and it is likely that this may be exacerbated as new isolates of *Bartonella* continue to be made in large numbers from mammal populations (Chang et al. 2000; Birtles and Raoult 1996; Birtles et al. 2000). Although 16S rDNA-based phylogenetic studies give little information on evolutionary processes occurring within the genus *Bartonella*, studies using comparisons of *ITS*, *gltA*, *and groEL* sequences have enabled six distinct evolutionary clades to be identified within the genus. As multiple gene data sets have been shown to be useful in determining the precise molecular relationships between genera and species (Marston et al. 1999), comparisons of the sequences of the ribC, the ftsZ, and the 17 kDa antigen genes might be used to improve the understanding of the evolutionary process. This will specifically help in the identification of lateral gene transfer, which occurs more commonly in intracellular pathogens (Doolittle 1999).

The phylogenetic data available for *Bartonella* species suggest that a phenomenon of coevolution occurred between the bacteria and their reservoir hosts. This host specificity may be partially offset by concomitant vector specificity. As a consequence of the restricted geographical distribution of their hosts and vectors, geographically distant *Bartonella* species may have evolved separately. It would be interesting to combine genetic classifications with phenotypic data sets such as duration of experimental bacteremia (Lucey et al. 1992) to better understand the natural history of *Bartonella* species and their association with specific mammal hosts and to confirm the apparent divisions identified within the genus.

Genome Analysis

According to the genome project database of the NCBI (http://www.ncbi.nlm.nih.gov/genomes/lproks.cgi), eight genomes of *Bartonella* species have been sequenced completely: *Bartonella quintana* RM-11, *Bartonella bacilliformis* KC583, *Bartonella henselae* str. Houston-1, *Bartonella vinsonii* subsp. *berkhoffii* str. Winnie, *Bartonella grahamii* as4aup, *Bartonella clarridgeiae* 73,

Table 3.2

***Bartonella* species with completely sequenced genome**

Bacteria	Genome	G + C %	Proteins	Genes	Reference/GenBank
Bartonella quintana RM-11	One chromosome (1,59 Mb)	38.8	1,203	1,251	NC_005955.1
Bartonella bacilliformis KC583	One chromosome (1,45 Mb)	38.2	1,283	1,374	NC_008783.1

Source: http://www.ncbi.nlm.nih.gov/genome/?term=Bartonella

Bartonella tribocorum CIP 105476, and *Bartonella australis* Aust/NH1 (Table 3.2). In other 14 species, the genome was partially sequenced: *Bartonella birtlesii* LL-WM9, *Bartonella elizabethae* ATCC 49927, *Bartonella bovis* 91–4, *Bartonella tamiae* Th239, *Bartonella doshiae* ATCC 700133, *Bartonella washoensis* 085–0475, *Bartonella schoenbuchensis* m07a, *Bartonella rochalimae* ATCCBAA-1498, *Bartonella queenslandensis* AUST/NH15, *Bartonella rattaustraliani* AUST/NH4, *Bartonella koehlerae* C-29, *Bartonella alsatica* IBS 382, *Bartonella taylorii* 8TBB, *Bartonella melophagi* K-2C, and *Bartonella rattimassiliensis* 15908. Only the *B. grahamii* and *B. tribocorum* species have plasmids.

Seubert et al. (2003a) was first to isolate and molecularly characterize the pBGR1, the first native plasmid isolated from the genus *Bartonella*. Cloning and sequencing revealed a 2725-bp cryptic plasmid comprising two open reading frames of considerable length, which were designated rep and mob. The regions containing rep and mob are separated by 140-bp inverted repeat sequences and display a difference in G+C content from one another. A 1435-bp SacI-BclI fragment containing the rep gene is sufficient to mediate replication in the species *B. henselae* and *B. tribocorum*.

Comparative genomics studies revealed that *Bartonella* species related to rodents have a higher of copy number of genes related with factors linked to adaptability to their host when compared with *Bartonella* species human-specific. These gene clusters are located in a highly dynamic region of 461 kb. A microarray designed for the *B. grahamii* genome was utilized to observe a massive, putatively phage-derived run-off replication of this region (Berglund et al. 2009). These authors identified a novel gene transfer agent, which packages the bacterial genome, with an overrepresentation of the amplified DNA, in 14 kb pieces. This is the first observation associating the products of run-off replication with a gene transfer agent. Because of the high concentration of gene clusters for host-adaptation proteins in the amplified region and since the genes encoding the gene transfer agent and the phage origin are well conserved in *Bartonella* (Berglund et al. 2009). There is the hypothesis that these systems are driven by selection. Berglund et al. (2009) proposed that the coupling of run-off replication with gene transfer agents promotes diversification and rapid spread of host-adaptability factors, facilitating host shifts in *Bartonella*.

The complete genome sequence of *B. tribocorum* was determined by shotgun sequencing. It was functionally identified 97 pathogenicity genes by signature-tagged mutagenesis (Saenz et al. 2007). In core genome (1,097 genes) 81 pathogenicity genes were identified which belong to the radiating lineage inferred from genome comparison of *B. tribocorum*, *B. henselae*, and *B. quintana*. Sixty-six pathogenicity genes are present in *B. bacilliformis*, and one has been lost by deletion. The 14 pathogenicity genes specific for the radiating lineage encode two laterally acquired type IV secretion systems, suggesting that these systems have a role in host adaptability.

Genomic comparison studies were performed between *B. quintana* and *B. henselae*, where a high degree of similarity was observed. The main differences were observed in genomic islands encoding filamentous hemagglutinin that are specific to *B. henselae*. Genomic reduction observed in *B. quintana* reminds that found in *Rickettsia prowazekii* (Alsmark et al. 2004). Both genomes are reduced versions of chromosome I from the highly related pathogen *Brucella melitensis*. Flanked by two rRNA operons is a segment with similarity to genes located on chromosome II of *B. melitensis*, suggesting that it was acquired by integration of megareplicon DNA in a common ancestor of the two *Bartonella* species. Comparisons of the vector–host ecology of these organisms suggest that the utilization of host-restricted vectors is associated with accelerated rates of genome degradation and may explain why human pathogens transmitted by specialist vectors are outnumbered by zoonotic agents, which use vectors of broad host ranges (Alsmark et al. 2004).

The experimentally characterized genes in *B. quintana*, *B. henselae*, and *B. tribocorum* are those coding for the type IV (VirB, Trw) and type V (adhesins, autotransporters) secretion systems. The VirB system translocates effector proteins into the cytoplasm of endothelial cells, thereby mediating antiapoptotic activity and angiogenic reprogramming (Schulein and Dehio 2002; Schulein et al. 2005; Schmid et al. 2006), whereas the Trw system is required for invasion of erythrocytes (Seubert et al. 2003b) and displays diversifying selection on the pilus proteins (Nystedt et al. 2008). The *Bartonella* adhesin (BadA) is involved in binding to endothelial cells, autoaggregation, and mediates a proangiogenic response in *B. henselae* (Kaiser et al. 2008; Riess et al. 2004). The homologous proteins in *B. quintana* have essentially the same function and are required for bloodstream infection but have been termed Vomps (variably expressed outer membrane proteins) since they have been shown to undergo sequence and expression variation in a monkey model system (Zhang et al. 2004; Schulte et al. 2006; Mackichan et al. 2008). Less is known about the autotransporters; however, they are known to be upregulated during infection of endothelial cells (Seubert et al. 2002) and may be involved in adhesion to host cells (Litwin et al. 2007).

Several of the genes for secretion systems are located in a dynamic region of the genome, up to several hundred kb in size, which is thought to have originated by the integration of an auxiliary replicon (Alsmark et al. 2004). DNA from this region was highly amplified in *B. henselae* upon prolonged growth (Lindroos et al. 2006). Microarray hybridizations suggested bidirectional replication starting from a region encoding a few phage genes (Lindroos et al. 2006). A similar phenomenon has also been observed in lambdoid phages of Salmonella (Frye et al. 2005) and has been termed escape replication or run-off replication. It has been suggested to arise from defects in prophage excision (Frye et al. 2005; Fukasawa et al. 1978). Despite the replication of large amounts of the bacterial chromosome, the prophage that induced escape replication in Salmonella produced phage particles that only contained phage DNA (Frye et al. 2005).

Bacteriophage particles have been identified in several species of *Bartonella* (Umemori et al. 1992; Anderson et al. 1994; Barbian and Minnick 2000; Chenoweth et al. 2004b; Maggi and Breitschwerdt 2005), and growth experiments have suggested phage induction and lysis of *B. henselae* cells as they enter stationary phase (Chenoweth et al. 2004a). While the morphology of the bacteriophage particles differed slightly—phages from *B. bacilliformis* and *B. vinsonii* ssp. *berkhoffii* were tailed, whereas those from *B. henselae* and *B. Quintana* lacked tails—they all contained 14 kb linear, double-stranded DNA, packaged in a round to icosahedral head of 40–80 nm in size (Anderson et al. 1994; Barbian and Minnick 2000; Maggi and Breitschwerdt 2005). No one has been able to fully characterize the 14 kb band; however, it has been suggested to consist of random or heterogeneous bacterial DNA (Anderson et al. 1994; Barbian and Minnick 2000; Maggi and Breitschwerdt 2005).

Alsmark et al. (2004) identified 128 pseudogenes and extensively degraded gene sequences in *B. henselae* (excluding 23 tandem duplication remnants), as compared with 175 fragmented genes in *B. quintana*. As many as 67 pseudogenes in *B. quintana* are represented by intact orthologs in *B. henselae*, where they code for proteins with basic metabolic functions. In contrast, only six *B. henselae* pseudogenes are present as intact genes in *B. quintana*, a few of which are found in the operon *fatBCD* that codes for proteins involved in iron transport. As many as 57 and 75 pseudogenes in *B. quintana* and *B. henselae* represent degraded fragments of genes present in the phage and the islands.

Phenotypic Analyses

The main features of members of genus *Bartonella* are listed in *Table 3.3*, as well as morphological, physiological and molecular characteristics differentiating species within the genus. As *Bartonella* are phenotypically similar, characterization and differentiation of species is extremely reliant on genotypic and phylogenetic methods.

Bartonella, Strong et al. 1915. Emend. Brenner et al. 1993 Emend. Birtles et al. 1995

Bar.to.nel'Ia. M.L. dim. ending *-ella;* M.L. fem. dim. n. *Bartonella* named after Alberto L. Barton, who described these organisms in 1909, after studying the agent of Carrion's disease.

Cells are gram-negative, slightly curved bacillus (0.5–0.6 × 1.0 μm). They are not acid fast and stain satisfactorily with Romanowsky or Giemsa stain. Warthin–Starry silver staining of fixed tissue sections reveals bacilli in clusters. They may be seen in stained blood films appearing as rounded or ellipsoidal forms or as slender, straight, curved, or bent rods, occurring singly or in groups. They characteristically occur in chains of several segmenting organisms, sometimes swollen at one or both ends and frequently beaded. In the tissues, they are situated within the cytoplasm of endothelial cells as isolated elements or are grouped in rounded masses. Intraerythrocytic forms occur in the blood of humans, felines, small rodents, birds, fish, and other animals. In cultures, the cells may be very autoadherent. Some species are motile since they possess unipolar flagella. Electron microscope examination showed multiple unipolar flagella in species such as *B. capreoli* and *B. rochalimae*. In *B. bacilliformis*, motility is achieved by means of 1–10 polar flagella, although a small number of cells appear to have subpolar or lateral flagella. The presence of pili is associated with the marked adherence. They are highly fastidious organisms and may be cultivated on media enriched with blood components in the presence of air or 5 % CO_2. The optimal incubation temperature varies from 20 °C to 37 °C after prolonged incubation (7–21 days). Optimum pH for growth is between pH 7.1 and 7.8. No growth on MacConkey agar nutrient agars. Succinate, pyruvate, and glutamine or glutamate, but not glucose, can be utilized as sources of energy for *B. quintana* and *B. bacilliformis*. Colony morphology varies from clear to smooth white and rough tan. Several species embed in the agar.

Symbols: + positive, – negative, *w* weakly positive, *v* variable (only some isolates have the characteristic)

Cocultivation with an endothelial cell line can also be performed. They are usually catalase and oxidase negative and aerobic. They are typically inert biochemically, with no acid or gas production from amygdalin, L-arabinose, dextrin, dukitol, fructose, D-galactose, D-glucose, inulin, lactose, maltose, D-mannitol, D-mannose, raffinose, L-rhamnose, salicin, sucrose, trehalose, or D-xylose. However, *B. bovis* and *B. capreoli* are able to hydrolyze trehalose and have trypsin-like activity and glycyl arylamidase activity, but no pyrrolidonyl arylamidase activity, as *B. birtlessi*, *B. japonica*, and *B. silvatica* also have glycyl arylamidase activity, but no pyrrolidonyl arylamidase activity. Additionally, *B. doshiae* and *B. grahamii* are able to hydrolyze butyrin (albeit weakly), and *B. doshiae* exhibits pyrazinamidase activity. *B. tribocorum* presents ability to hydrolyze trypsin but not proline and tributyrin. Gelatin is not liquefied. Esculin is not hydrolyzed. H_2S is not detected with lead acetate. Some species are Voges–Proskauer positive (*B. doshiae*, *B. grahamii*, *B. taylorii*). *B. henselae*, *B. coopersplainsensis*, *B. rattaustraliani*, and *B. queenslandensis* are readily stained with Gimenez stain. *Bartonella* species contain greater than 50 % $C_{18:1}$ isoacids, 16–25 % $C_{18:0}$, and 16–22 % $C_{16:0}$, with minor amounts of $C_{13:1}$ and $C_{17:0}$ fatty acids. *B. henselae* lack cellular fatty acids $C_{15:0}$ and $C_{12:0}$, which are present in isolates of *B. vinsonii* and *B. bacilliformis*, respectively. *B. quintana* can be differentiated from most *B. henselae* isolates by amounts of $C_{18:0}$. *B. elizabethae* has cellular fatty acid composition similar to *B. vinsonii* and includes $C_{15:0}$ (not found in *B. henselae* and *B. quintana*) and larger amounts of $C_{17:0}$ (21 %), than *B. henselae* (3 %), *B. quintana* (1 %), and *B. vinsonii* (9 %). *B. elizabethae* also contains smaller amounts of cellular fatty acid $C_{16:0}$ than other species. DNA G+C content varies from 37 to 41 mol%. *Bartonella* species have been distinguished by the concatenated sequence of its 16SrRNA, *ftsZ*, *gltA*, *groEL*, *ribC*, *rpoB* genes, and ITS region, by the total protein profiles in SDS-PAGE, by the banding patterns in the ERIC-PCR, as well as by whole DNA hybridization and some species by the unique mammalian host.

The type species is *Bartonella bacilliformis* (Strong et al. 1913, 1915). As mentioned before, the genus contains 29 species and 3 subspecies, in which etymology, total DNA G+C content, type strain, and *GenBank* accession number are outlined below.

Bartonella acomydis, Sato et al. 2013

a.co'my.dis. N.L. gen. n. *acomydis* of *Acomys*, isolated from *Acomys russatus*.

The mol % G+C of the DNA is 37.2 (based on the *ftsY* gene sequence).

Type strain: KS2-1^T (=JCM 17706^T = KCTC 23907^T), KS7-1 (=JCM 17707 = KCTC 23908)

GenBank accession number (16S rRNA): AB602533

Bartonella alsatica, Heller et al. 1999

al.sa'ti.ca. L. adj. *alsaticus* from Alsace, the region in the eastern part of France near the Rhine River where the wild rabbits were trapped and where the strains were isolated and identified.

The mol % G+C of the DNA is 37 (capillary electrophoresis method).

Type strain: IBS 382^T (CIP 105477^T).

GenBank accession number (16S rRNA): AJ002139

Bartonella bacilliformis, Strong et al. 1913, Strong et al. 1915

ba.cil.li.for'mis. L. dim. n. *bacillus*, a small staff, rodlet; L. adj. suffix *-formis -is -e* (from L. n. *forma*, figure, shape, appearance)-like, in the shape of; N.L. fem. adj. *bacilliformis*, rod shaped.

The mol % G+C of the DNA is 39 (T_m).

Type strain: KC583 (=Herrer 020/F12,63 = ATCC 35685)

GenBank accession number (16S rRNA): M65249

Bartonella birtlesii, Bermond et al. 2000

birt.les'i.i. M.L. gen. n. *birtlesii* of Richard J. Birtles, whose studies have contributed to an improved understanding of the taxonomy of the *Bartonella* genus.

The mol % G+C of the DNA is not determined.

Type strain: IBS 325^T (=CIP 106294^T = CCUG 44360^T)

GenBank accession number (16S rRNA): AF204274

Bartonella bovis, Bermond et al. 2002 Non Donatien and Lestoquard 1934

Bo'vis. L. gen. n. *bovis* of the ox.

OBS: *Bartonella weissi* or *Bartonella weissii* have no standing in nomenclature, and this species must be designated as *Bartonella bovis* Bermond et al. 2002.

The mol % G+C of the DNA is 38.

Type strain: 91-4^T (=CIP 106692^T = CCUG 43828^T)

GenBank accession number (16S rRNA): AF293391 and AF293394 (gltA)

Bartonella callosciuri, Sato et al. 2013

cal.lo.sci'u.ri. N.L. gen. n. *callosciuri* of *Callosciurus*, isolated from *Callosciurus notatus*.

The mol % G+C of the DNA is 35.5 (based on the *ftsY* gene sequence).

Type strain: BR11-1^T (=JCM 17709 T = KCTC 23909 T)

GenBank accession number (16S rRNA): AB602530

Bartonella capreoli, Bermond et al. 2002

ca.pre.o'li. L. gen. n. *capreoli* of the roe deer.

The mol % G+C of the DNA is 38.

Type strain: IBS 193^T (=CIP 106691^T = CCUG 43827^T)

GenBank accession number (16S rRNA): AF293389 and AF293392 (gltA)

Bartonella chomelii, Maillard et al. 2004

cho.mel'i.i. N.L. gen. n. *chomelii* in honor of Bruno B. Chomel, who was the first to experimentally demonstrate the transmission of *B. henselae* by fleas in cats and to isolate *B. bovis* from domestic cattle. His studies on *Bartonella* infection in animals contributed to an improved understanding of epidemiology and vectors of *Bartonella*-associated disease in animals.

The mol % G+C of the DNA is not determined.
Type strain: A828^T(CIP 107869^T)
GenBank accession number (16S rRNA): AY254309

Bartonella clarridgeiae, Lawson and Collins 1996

clar.ridge'i.a.e. M.L. fem. adj. *clarridgeiae* named in honor of Jill E. Clarridge III, the microbiologist who first isolated the organism in Houston, Texas.

The mol % G+C of the DNA is not determined.
Type strain: Houston-2 cat (ATCC 51734)
GenBank accession number (16S rRNA): X89208

Bartonella coopersplainsensis, Gundi et al. 2009

coo.pers.plain.sen'sis. N.L. fem. adj. *coopersplainsensis* pertaining to Coopers Plains, Queensland, the name of the area where the rat was trapped from which the type strain was isolated.

The mol % G+C of the DNA is not determined.
Type strain: AUST/NH20^T (=CIP 109064^T = CCUG 52174^T = CSUR B619^T)
GenBank accession number (16S rRNA): EU111759

Bartonella doshiae, Birtles et al. 1995

do'shi.ae. N. L. gen. n. *doshiae*, of Doshi, named after Nivedita Doshi, whose technical skills have been central to the work on *Legionella* and *Bartonella* at the Central Public Health Laboratory.

The mol % G+C of the DNA is 41(T_m).
Type strain: R18 (=ATCC 7000133 = NCTC 12862)
GenBank accession number (16S rRNA): Z31351

Bartonella elizabethae (Daly et al. 1993), Brenner et al. 1993

e.liz'a.beth.e.a. N.L. fem. adj. *elizabethae*, named after Saint Elizabeth's Hospital, Brighton, MA., where the organism was isolated.

The mol % G+C of the DNA is 41 (T_m).
Type strain: F9251 (=B91-002005 = ATCC 49927)
GenBank accession number (16S rRNA): LO1260

Bartonella grahamii, Birtles et al. 1995

gra.ham'i.i. N. L. gen. n. *grahamii*, of Graham, named after G. S. Graham-Smith, who observed similar organisms, subsequently named *Grahamella*, in the blood of moles in 1905.

The mol % G+C of the DNA is 40 (T_m).
Type strain: V2 (=ATCC 7000132 = NCTC 12860)
GenBank accession number (16S rRNA): Z31349

Bartonella henselae (Regnery et al. 1992), Brenner et al. 1993

hen'.sel.a.e. N. L. gen. n. *henselae* is named in honor of Diane M. Hensel, who isolated many of the original strains detected in bacteremic patients from Oklahoma.

The mol % G+C of the DNA is 41 (T_m).
Type strain: Houston 1 (=G5436 = ATCC 49882)
GenBank accession number (16S rRNA): M73229

Bartonella jaculi, Sato et al. 2013

ja'cu.li. N.L. gen. n. *jaculi* of *Jaculus*, isolated from *Jaculus orientalis*.

The mol % G+C of the DNA is 37.4 (based on the *ftsY* gene sequence).
Type strain: OY2-1^T (=JCM 17712^T = KCTC 23655^T) and OY5-1 (=JCM 17713 = KCTC 23656)
GenBank accession number (16S rRNA): AB602527

Bartonella japonica, Inoue et al. 2010

ja.po'ni.ca. N.L. fem. adj. *japonica* of Japan, where the host rodent, the small Japanese field mouse (*Apodemus argenteus*), from which the strain was isolated.

The mol % G+C of the DNA is 40.1.
Type strain: Fuji 18-1^T (=JCM 15567^T = CIP 109861^T)
GenBank accession number (16S rRNA): AB440632

Bartonella koehlerae, Droz et al. 2000

koeh'ler. ae. N. L. fem. adj. *koehlerae*, in honor of Jane E. Koehler, who was the first to isolate *Bartonella* species from bacillary angiomatosis lesions and whose studies of *B. quintana* and *B. henselae* isolates from human immunodeficiency virus-infected patients have contributed to an improved understanding of the molecular epidemiology, reservoirs, and vectors of *Bartonella*-associated disease in humans.

The mol % G+C of the DNA is not determined.
Type strain: C-29 (=ATCC 700693)
GenBank accession number (16S rRNA): AF076237

Bartonella pachyuromydis, Sato et al. 2013

pa.chy.u.ro'my.dis. N.L. gen. n. *pachyuromydis of Pachyuromys*, isolated from *Pachyuromys duprasi.*

The mol % G+C of the DNA is 35.7 (based on the *ftsY* gene sequence).
Type strain: FN15-2^T (=JCM 17714 T = KCTC 23657 T) and FN18-1 (=JCM 17715 = KCTC 23911)
GenBank accession number (16S rRNA): AB602531

Bartonella peromysci (Ristic and Kreier 1984), Birtles et al. 1995

pe.ro.mys' ci. M.L. gen. n. *peromysci*, of *Peromyscus* a genus of mice.

The mol % G+C of the DNA is unknown.
Type strain: No type strain available.
GenBank accession number (16S rRNA):

Bartonella queenslandensis, Gundi et al. 2009

queens.lan.den'sis. N.L. fem. adj. *queenslandensis* referring to Queensland, the Australian state where the rats were trapped from which the first strains were isolated.

The mol % G+C of the DNA is not determined.
Type strain: AUS^T/NH12^T (=CIP 109057^T = CCUG 52167^T = CSUR B617^T), AUST/NH5 (=CIP 109052 = CCUG 52162 = CSUR B614), AUST/NH8 (=CIP 109053 = CCUG 52163 = CSUR B615), AUST/NH11 (=CIP 109056 = CCUG 52166 = CSUR B616), and AUST/NH15 (=CIP 109060 = CCUG 52170 = CSUR B618).
GenBank accession number (16S rRNA): EU111754

Bartonella quintana (Schmincke 1917), Brenner et al. 1993

quin.ta' na. M.L. fem. adj. *quintana* fifth, referring to 5-day fever and the clinical disease produced by the species.

The mol % G+C of the DNA is 40 (T_m).
Type strain: ATCC VR-358 (=CIP 107027)
GenBank accession number (16S rRNA): M73228

Bartonella rattaustraliani, Gundi et al. 2009

ratt.aus.tra.li.a'ni. N.L. n. *Rattus* zoological name of a genus of rat; N.L. adj. *australianus* Australian; N.L. gen. n. *rattaustraliani* of an Australian rat, from which the first strains were isolated.

The mol % G+C of the DNA is not determined.
Type strain: AUST/NH4^T (=CIP 109051^T = CCUG 52161^T = SUR B609^T). Other isolates are AUST/NH9 (=CIP 109055 = CCUG 52164 = CSUR B610), AUST/NH10 (=CIP 109054 = CCUG 52165 = CSUR B611), AUST/NH14 (=CIP 109059 = CCUG 52169 = CSUR B612), and AUST/NH18 (=CIP 109063 = CCUG 52173 = CSUR B613).
GenBank accession number (16S rRNA): EU111749

Bartonella rochalimae, Eremeeva et al. 2012

ro.cha.li.ma'e. N.L. gen. masc. n. *rochalimae*, of Rochalima, named in honor of Henrique da Rocha Lima, an early Brazilian investigator of the etiology of rickettsial diseases.

The mol % G+C of the DNA is not determined.
Type strain: BMGH (=ATCC BAA-1498 = DSM 25050)
GenBank accession number (16S rRNA): DQ683196

Bartonella schoenbuchensis, Dehio et al. 2001

schoen.buch'i.i. N.L. gen. n. *schoenbuchii* from Schönbuch, a nature park near Tubingen in southwest Germany where most of the roe deer analyzed were shot.

The mol % G+C of the DNA is not determined.
Type strain: R1^T NCTC 13165^T and DSM 13525^T
GenBank accession number (16S rRNA): AJ278187

Bartonella silvatica, Inoue et al. 2010

sil.va'ti.ca. L. fem. adj. *silvatica* of the forest where the host rodent, the large Japanese field mouse (*Apodemus speciosus*), from which the strain was isolated, was captured.

The mol % G+C of the DNA is 40.4.
Type strain: Fuji 23-1^T (=JCM 15566^T = CIP 109862^T)
GenBank accession number (16S rRNA): AB440636

Bartonella talpae (Ristic and Kreier 1984), Birtles et al. 1995

tal' pae. M.L. gen. n. *talpae* of *Taipa*; M.L. fem. n. a genus of moles.

The mol % G+C of the DNA is unknown.
Type strain: No type strain available.
GenBank accession number (16S rRNA): Not available

Bartonella taylorii, Birtles et al. 1995

tay.lor'i.i. N. L. gen. n. *taylorii*, of Taylor, named after A. G. Taylor, whose foresight led various microbiologic studies at the Central Public Health Laboratory.

The mol % G+C of the DNA is 41 (T_m).

Type strain: M6 (=NCTC 12861)
GenBank accession number (16S rRNA): Z31350

Bartonella tribocorum, Heller et al. 1998

tri.bo.co'rum. L. n. gen. pl. *Triboci* named after the tribes mentioned by Caesar (51 BC) in his *Commentarii de Bello Gallico*, which were living in the region near the Rhine River in the eastern France. Wild rats, from which the two strains were isolated, were trapped there.

The mol % G+C of the DNA is 38 (capillary electrophoresis).
Type strain: IBS 506^T (=CIP 105476^T)
GenBank accession number (16S rRNA): AJ003070

Bartonella vinsonii, (Weiss and Dasch 1982), Brenner et al. 1993, Kordick et al. 1996

vin.so'ni.i. N.L. gen. n. *vinsonii*, of Vinson, named in honor of J. William Vinson who, with Henry S. Fuller, originally demonstrated that *Bartonella vinsonii* subsp. *vinsonii* (*Rochalimaea vinsonii*) could be grown on blood agar.

Bartonella vinsonii subsp. *vinsonii* Weiss and Dasch 1982; Kordick et al. 1996

The mol % G+C of the DNA is 41(T_m).
Type strain: ATCC VR-152 (strain Baker = CCUG 30453 = CIP 103738)
GenBank accession number (16S rRNA): L01259

Bartonella vinsonii subsp. *arupensis*, Welch et al. 2000

a.rup.en.'sis. N.L. fem. adj. *arupensis*, from Associated Regional and University Pathologists, Inc., in Salt Lake City, Utah, the laboratory where the type strain was initially characterized.

The mol % G+C of the DNA is not determined.
Type strain: OK 94–513 (5 = ATCC 700727)
GenBank accession number (16S rRNA): U71322

Bartonella vinsonii subsp. *berkhoffii*, Kordick et al. 1996

berk.hof'fi.i. N. L. gen. n. *berkhoffii*, of Berkhoff, in honor of Herman A. Berkhoff, a veterinary microbiologist whose research encompasses a wide spectrum of veterinary pathogens and who contributed to the study of *Bartonella* infection in domestic animals that led to the recognition of this subspecies.

The mol % G+C of the DNA is not determined.
Type strain: 93-CO1 (=ATCC 51672)
GenBank accession number (16S rRNA): L35052

Isolation, Enrichment, and Maintenance Procedures

The specimen sources of most isolates of *Bartonella* are blood and tissue (e.g., liver, spleen, lymph node, and skin). Specimens collected early in the clinical course are preferred, especially those obtained from lymph nodes biopsy from patients with suspected of cat scratch disease. Late-stage, suppurative lymph nodes may not yield organisms. Tissue specimens should be homogenized and plated on culture medium. Lysis-centrifugation methods may be used to enhance recovery of these bacteria from blood specimens (Koehler et al. 1992; Lucey et al. 1992; Larson et al. 1994). However, lysis-centrifugation is said to be prone to contamination due to extensive manipulation, including centrifugation and specimen separation. If storage of the specimens is necessary, they should be kept frozen. The blood collected in tubes containing EDTA can be plated after 26 days at –65 °C with no loss of sensitivity (Brenner et al. 1997). Freeze-thawing of a blood sample prior to direct plating has also been used (Varela et al. 1969; Regnery et al. 1992; Larson et al. 1994; Maggi et al. 2005a, b) and may enhance recovery, especially when blood is collected with heparin. Since *Bartonella* produce little or no CO_2 during growth, detection of these bacteria in automated blood culture systems (e.g., BACTEC; Bacti/Albert, etc.) may be problematic. However, species have been isolated using BACTEC 460 blood culture bottles (Lucey et al. 1992; Daly et al. 1993; Larson et al. 1994), BACTEC NR-660 infrared CO_2 detection system (Spach et al. 1993; Larson et al. 1994), and Septi-Chek biphasic system (Lucey et al. 1992; Larson et al. 1994).

Member of the genus *Bartonella* spp. has been isolated by plating onto an appropriate media (including agar, semisolid media, and broth) or by cultivation in cell culture. Cell culture methods are performed with shell vials containing a human endothelia cell monolayer (e.g., ECV 304 cell line) or other cell types (e.g., Vero cells, HeLa cells, L292 cells) (Drancourt et al. 1995; Koehler et al. 1992; Raoult et al. 1994; Zbinden et al. 1995). Vero E6 and L-929 (mouse fibroblasts) mammalian cell lines, for example, have been successfully utilized to culture *Bartonella* species (Chmielewski et al. 2007). Previous works have suggested that under mammalian cell culture-based conditions, cell coculture is important for *B. quintana* growth (Battisti and Minnick 2008); however, when the medium is modified to incorporate insect cell culture-based medium, coculturing with mammalian cells is no longer needed. Lynch et al. (2011) compared three culturing methodologies for *B. henselae*, *B. elizabethae*, *B. quintana*, *and B. tamiae*: showing that combination of mammalian and insect cell culture-based media (MS10 medium) are able to achieve peak growth comparable to that achieved with the insect cell culture-based medium alone (S10 medium) at 35 °C but that at 37 °C the MS10 medium performed significantly better for both *B. tamiae* and *B. quintana*. Data suggest that mammalian cell coculture is not necessary for growth of laboratory-adapted Bartonella strains; however, the combination medium is still able to support mammalian cell culture, which may remain an important variable during initial isolation of Bartonella from biological samples. Bovine endothelial cell line (i.e., CPA cells, ATCC cell line # 207) has also been used to isolate with success *B. henselae* and *B. quintana* from biopsies of bacillary angiomatosis lesions (Koehler et al. 1992). In addition, *B. quintana* has been isolated from the blood using ECV 304 cells (a continuous human endothelial cell line) (Drancourt et al. 1995).

Broth-based systems generally tend to have lower sensitivity for the isolation of *Bartonella* species (Spach et al. 1995). However, broth-enrichment recovery of *B. henselae* from human and cat blood has also been performed with a defined medium containing RPMI 1640 (a tissue culture liquid medium) supplemented with hemin, amino acids, and pyruvate (Wong et al. 1995). Combining the subculture of blood culture broth into shell vials has been reported to increase sensitivity for recovery (La Scola and Raoult 1999). The alphaproteobacteria growth medium (BAPGM) has also been used to isolate *Bartonella* species (Welch et al. 1992; Houpikian and Raoult 2002; Eremeeva et al. 2007; Kosoy et al. 2008). This is a modified formulation of liquid medium designed to support insect cells and requires sheep blood supplementation. It should be mentioned that BAPGM followed by PCR might provide a complimentary diagnostic approach for the isolation and identification of potentially fastidious bacteria from the blood and tissue samples. Another modified insect cell culture-based medium (Schneider's medium) capable of supporting *B. henselae*, *B. quintana*, and B. *vinsonii* was also described, without the requirement of whole-blood supplementation (Riess et al. 2008).

Agar-based culture methods include culture on heart infusion agar containing 5 % horse or rabbit blood. Blood-supplemented BHI, trypticase soy, and Columbia agars and enriched chocolate agar may also support growth (Lappin et al. 2008). For optimal recovery, the medium should be as freshly as possible prepared. Didi et al. (2013) compared strategies for the identification of *B. henselae* and outlined that growth can be obtained on biphasic medium, tryptic soy broth, trypticase soy agar with 5 % sheep blood, and brain–heart infusion agar, although colony morphology varied. Selective medium are not available, and media containing antimicrobial agents should not be used (Koneman et al. 2006). Growth is dependent on humid (>40 %), microaerophilic conditions (5–10 % CO_2) at temperatures ranging for most species between 35 °C and 37 °C (Maurin et al. 1997; La Scola et al. 2001; Rolain et al. 2004). The fastidious nature of these organisms requires that precaution be taken to minimize delayed attempts of isolation. *Bartonella* species grow slowly on blood agar, and primary isolates appear after 12–14 days on average (Jacomo et al. 2002), although it has been reported that primary isolation can take up to 45 days (Maurin et al. 1994). Subcultured colonies have been found to appear after only 3–5 days (Jacomo et al. 2002). Most *Bartonella* species do not grow under anaerobic conditions, at temperatures of 25 or 42 °C, or in the absence of hemin and CO_2. *B. bacilliformis*, however, is exceptional, in that this species favors a lower growth temperature (25–28 °C) and does not require supplemental CO_2 for growth (Koneman et al. 2006).

On primary isolation, *Bartonella* species appear usually initially as white, or gray-whitish, small (average 1–2 mm in diameter) adherent colonies that vary in shape and size. Some strains of *B. henselae*, *B. quintana*, and *B. elizabethae* may pit the agar surface during growth. Colonies of most of the species are smooth, although *B. birtlessi* colonies are rough. Characteristically, *B. henselae* colonies are white, dry, adherent, "cauliflower-like," embedded in the agar, and morphologically heterogenous. With multiple passages, the colonies become less dry, less adherent, and larger. Also, colonies of *B. schoenbuchensis* appear in primary culture within 4–6 days as firm adherent, deeply invaginated, "cauliflower-like" colonies which upon passaging may switch to a more rapidly growing, shiny, and smooth colony phenotype (Dehio et al. 2001). Colonies of *B. elizabethae* resemble *B. henselae* except that weak or partial hemolysis may be noted around colonies growing on heart infusion agar with 5 % rabbit blood (Daly et al. 1993).

According to the Second Edition of *Bergey's Manual of Systematic Bacteriology*, viability of cultures can usually be maintained by passage on blood or chocolate agar at biweekly intervals. Cultures are best maintained during storage at −70 °C in a blood- or hemoglobin-containing medium. Long-term storage is best accomplished by lyophilization. Retrieval of viable cultures that have been lyophilized may be enhanced by suspending dried cells in a blood–broth mixture followed by culture on fresh blood agar media (Welch 2005).

B. acomydis—isolated from the blood of golden spiny mouse (*Acomys russatus*). All the animals were imported to Japan as pets from Egypt, Thailand, and the Netherlands. Growth occurred on heart infusion agar plates (Difco™, Difco Laboratories, Inc., subsidiary of Becton, Dickinson and Company) containing 5 % defibrinated rabbit blood (HIA) at 35 °C in a moist atmosphere under 5 % CO_2 after 14 days of incubation. Also cultured on rabbit blood–chocolate HIA plates for 14 days at 35 °C in a moist atmosphere under 5 % CO_2 with H_2O_2 on a glass slide (Sato et al. 2013).

B. alsatica—the type strain (IBS 382^T) was isolated from the blood of wild rabbit (*Oryctolagus cuniculus*) caught in warrens in Alsace, France. Growth occurred on Columbia agar base containing 5 % defibrinated rabbit blood after 10-day postinoculation, and culture was detectable in Bactec Peds Plus liquid medium supplemented with Bacto Fildes enrichment (Difco Laboratories, Inc., subsidiary of Becton, Dickinson and Company) after 4 weeks. Incubation was performed at 35 °C in a moist atmosphere containing 5 % CO_2 (Heller et al. 1999).

B. bacilliformis—on isolation, type strain KC583 grew slowly (3–5 days), without hemolysis, on heart infusion agar with 5 % rabbit blood. Growth is best at 25 °C, weak at 35 °C, and absent at 42 °C (Brenner et al. 1991).

B. birtlesii—was isolated from the blood of small mammals belonging to the genus *Apodemus* in France and the UK. Growth occurred on Columbia base agar plates containing 5 % fresh, defibrinated rabbit blood at 35 °C in a moist atmosphere containing 5 % CO_2. Primary culture of type strain IBS325^T was obtained after 10-day incubation and subcultured after 6-day culture in the same conditions (Bermond et al. 2000).

B. bovis* Bermond et al. *non Donatien and Lestoquard 1934—was isolated from the blood samples collected from domestic cows belonging to a herd of dairy cattle located in Bissy, 50 km south of Paris, France. For isolation, the blood samples were thawed before plating and centrifuged at 1,800 g for 60 min. After centrifugation, the pellets were plated onto Columbia base agar plates (Difco Laboratories, Inc., subsidiary

of Becton, Dickinson and Company) containing 5 % fresh defibrinated rabbit blood. The plates were incubated at 35 °C in a moist atmosphere containing 5 % CO_2. Primary culture of type strain 91-4^T was obtained after 10-day incubation and subcultured after 4-day culture in the same conditions (Bermond et al. 2002).

B. callosciuri—isolated from the blood of plantain squirrel (*Callosciurus notatus*). Animals were imported to Japan as pets from Egypt, Thailand, and the Netherlands. Growth occurred on heart infusion agar plates (Difco Laboratories, Inc., subsidiary of Becton, Dickinson and Company) containing 5 % defibrinated rabbit blood (HIA) at 35 °C in a moist atmosphere under 5 % CO_2 after 14 days of incubation. Also cultured on rabbit blood–chocolate HIA plates for 14 days at 35 °C in a moist atmosphere under 5 % CO_2 with H_2O_2 on a glass slide (Sato et al. 2013).

B. capreoli—isolated from the blood of wild roe deer (*Capreolus capreolus*) captured in Chize forest conservation hunting area (western France). For isolation, blood samples were centrifuged at 1,800 g for 60 min and the pellets plated onto Columbia base agar plates (Difco Laboratories, Inc., subsidiary of Becton, Dickinson and Company) containing 5 % fresh defibrinated rabbit blood. The plates were incubated at 35 °C in a moist atmosphere containing 5 % CO_2. Primary culture of type strain (IBS 193^T) was obtained after 10 days of incubation, while subculture was obtained after 6 days, at 35 °C in a moist atmosphere containing 5 % CO_2 (Bermond et al. 2002).

B. chomelii—was isolated from blood domestic cows in two regions in France (Loire-Atlantique and Nord departments). For isolation, blood samples were thawed, centrifuged at 1,800 g for 75 min, and then plated onto agar plates containing 5 % fresh defibrinated rabbit blood. Incubation was held at 35 °C in a moist atmosphere containing 5 % CO_2. The type strain A828^T and A12.90 isolate grew slowly, in which primary culture were obtained after 10 days incubation and subculture after 6 days culture. Although it grows on rabbit blood and sheep blood agar plates, a higher efficiency was observed on rabbit blood agar plates (Maillard et al. 2004).

B. clarridgeiae—was first isolated from a kitten which belonged to a patient with cat scratch disease and from whom *B. henselae* had been isolated (Lawson and Collins 1996).

B. coopersplainsensis—isolated from the blood of wild rat of the species *Rattus leucopus*, which were trapped in Queensland, Australia. Good growth was observed on Columbia agar with 5 % sheep blood in a 5 % CO_2 atmosphere at 35 °C, after 20 days (Gundi et al. 2009).

B. doshiae—the type strain R18 was isolated from the blood of *Microtus agrestis*. It was cultivated on Columbia blood agar containing 10 % whole fresh horse blood. Plates were incubated at 37 °C in a moist atmosphere containing 5 % CO_2 (Birtles et al. 1995).

B. elizabethae—the type strain F9251 was isolated from a patient with endocarditis after the blood was drawn for culture into BACTEC 460 blood culture medium (Johnson Laboratories, Towson, Md.) and subcultured onto blood and chocolate agar and incubated for 14 days in an atmosphere of 5 % CO_2. Grows well on semisolid heart infusion agar supplemented with rabbit blood, on which it produced incomplete hemolysis.

B. grahamii—the type strain V2 was isolated from the blood of *Clethrionomys glareolus*. It was cultivated on Columbia blood agar containing 10 % whole fresh horse blood, with best growth at 37 °C in a moist atmosphere containing 5 % CO_2 (Birtles et al. 1995).

B. henselae—the type strain is Houston 1 (=G5436 = ATCC 49882) and was isolated from the blood of a febrile, 40-year-old human immunodeficiency virus-positive man. Optimal growth occurs on enriched medium with erythrocytes. Colonies were observed after 9–15 days of incubation at 35 °C in a 5 % CO_2, humidified atmosphere or at 30 °C in air; optimal growth does not occur anaerobically (Slater et al. 1990). Subsequent passages demonstrated more rapid growth (Regnery et al. 1992; Brenner et al. 1993). A second genotype among *B. henselae* isolates involved in cat scratch disease and endocarditis was identified in 1996 by Drancourt and colleagues. As so, *B. henselae* was divided into two geno-/serogroups: *B. henselae* Houston, 16S type I, and *B. henselae* Marseilles, 16S type II (Bergmans et al. 1996; Drancourt et al. 1996).

B. jaculi—isolated from the blood of wild-captured greater Egyptian jerboas (*Jaculus orientalis*) that were imported to Japan as pets from Egypt, Thailand, and the Netherlands. Growth occurred on heart infusion agar plates (Difco Laboratories, Inc., subsidiary of Becton, Dickinson and Company) containing 5 % defibrinated rabbit blood (HIA) at 35 °C in a moist atmosphere under 5 % CO_2 after 14 days of incubation. Also cultured on rabbit blood–chocolate HIA plates for 14 days at 35 °C in a moist atmosphere under 5 % CO_2 with H_2O_2 on a glass slide (Sato et al. 2013). The two strains, OY2-1^T (type strain) and strain OY5-1, were isolated from the same source (Sato et al. 2013).

B. japonica—the type strain, Fuji 18-1^T (=JCM 15567^T = CIP 109861^T), was isolated from the blood of the small field mice *Apodemus argenteus*, captured in the Mount Fuji forest in Japan. Growth was performed on heart infusion agar plates (Difco Laboratories, Inc., subsidiary of Becton, Dickinson and Company) containing 5 % (w/v) defibrinated rabbit blood at 35 °C with 5 % CO_2 (14 days) (Inoue et al. 2010).

B. koehlerae—two strains, C-29 (type strain) and C-30, were isolated from the blood of a healthy kitten during a prevalence study of *B. henselae* in domestic cats in the greater San Francisco Bay area of northern California. Optimal growth on chocolate agar, and primary colonies were observed after 14 days of incubation at 35 °C in a CO_2-enriched environment. Chocolate agar should be prepared with hemoglobin powder and GC agar base (Acumedia Manufacturers, Inc., Baltimore, Md.) and supplemented with 10 ml of IsoVitalex (Becton Dickinson). Usually fails to produce any growth on heart infusion agar supplemented with 5 % rabbit blood (Droz et al. 2000).

B. pachyuromydis—isolated from the blood of fat-tailed gerbil (*Pachyuromys duprasi*), imported to Japan as pets from Egypt, Thailand, and the Netherlands. Growth occurred on heart infusion agar plates (Difco Laboratories, Inc., subsidiary

of Becton, Dickinson and Company) containing 5 % defibrinated rabbit blood (HIA) at 35 °C in a moist atmosphere under 5 % CO_2 after 14 days of incubation. Also cultured on rabbit blood–chocolate HIA plates for 14 days at 35 °C in a moist atmosphere under 5 % CO_2 with H_2O_2 on a glass slide. The type strain (FN15-2^T) and strain FN18 were isolated from the same source (Sato et al. 2013).

B. queenslandensis—the type strain AUS^T/NH12^T was isolated from the blood of a wild rat belonging to the genus *Melomys* during mammal surveys carried out in Queensland, Australia. Other isolates belonging to the species, isolated from the blood of rats, are AUST/NH5 from *Rattus tunneyi*, AUST/NH8 from *Rattus fuscipes*, AUST/NH11 from *Rattus conatus*, and AUST/from *Rattus leucopus*. Good growth was observed on Columbia agar with 5 % sheep blood in a 5 % CO_2 atmosphere at 37 °C (Gundi et al. 2009).

B. quintana—in 1961, Vinson and Fuller reported the first successful cultivation of the agent of trench fever on cell-free media using blood-enriched agar. The authors went on to fulfill Koch's postulates by inducing trench fever in human volunteers following their inoculation with suspensions of the isolated organisms. The report also emphasized that different clinical manifestations of trench fever were observed in different volunteers inoculated with the same strain.

B. rattaustraliani—the type strain AUST/NH4^T was isolated from the blood of a wild rat of the species *Rattus tunneyi* which were trapped in Queensland, Australia. Other isolates are AUST/NH9 from *Uromys caudimaculatus*, AUST/NH10 from *Rattus leucopus*, AUST/from *Rattus conatus*, and AUST/NH18 from *Melomys* sp. Growth was observed on Columbia agar with 5 % sheep blood in a 5 % CO_2 atmosphere at 37 °C (Gundi et al. 2009).

B. rochalimae—the type strain BMGH was isolated from a 43-year-old woman with splenomegaly, fever, and anemia, which had recently traveled to Peru. Grows on fresh defibrinated rabbit blood agar at 35 °C in a candle extinction jar (Eremeeva et al. 2012).

B. schoenbuchensis—type strain R1^T was isolated from the blood of a 4-month-old female wild roe deer which was shot in a nature park near Tubingen in southwest Germany. For isolation, the blood which was preserved at −80 °C was thawed and streaked onto the blood agar plates made with a Columbia agar base supplemented with 5 % defibrinated sheep blood. Incubation of the plates was performed at 37 °C in a moist atmosphere containing 5 % CO_2. Primary cultured appeared within 4–6 days (Dehio et al. 2001).

B. silvatica—the type strain Fuji 23-1^T was isolated from the blood of *Apodemus speciosus* mice captured in the Mount Fuji forest in Japan. Growth on heart infusion agar plates (Difco Laboratories, Inc., subsidiary of Becton, Dickinson and Company) containing 5 % (w/v) defibrinated rabbit blood at 35 °C with 5 % CO_2 for 14 days (Inoue et al. 2010).

B. taylorii—the type strain M6 was isolated from the blood of small woodland mammals (*Apodemus* spp.) in the UK. Cultivated on Columbia blood agar containing 10 % whole fresh horse blood. Plates inoculated were incubated for up to 10 days at 30 °C in a moist atmosphere containing 5 % CO_2 (Birtles et al. 1995).

B. tribocorum—type strain IBS 506^T was isolated from wild rats (*Rattus norvegicus*) trapped in a wetland conservation area near the Rhine River, in the eastern part of France. For isolation, the blood was streaked without prior centrifugation onto the blood agar plates made with a Columbia agar base with 5 % defibrinated rabbit blood. Incubation of plates was performed at 35 °C in a moist atmosphere containing 5 % CO_2 (Heller et al. 1998).

Bartonella vinsonii* subsp. *arupensis—the type strain is OK 94–513 (5 = ATCC 700727) and was isolated from a 62-year-old bacteremic cattle rancher. Growth occurred on heart infusion agar in the presence of X factor and on Columbia agar supplemented with 5 % defibrinated sheep blood at 35 °C in 5–10 % CO_2, after 5–7 days (Welch et al. 2000).

Bartonella vinsonii* subsp. *berkhoffii—the type strain 93-CO1 was isolated from a dog with valvular endocarditis. The Isolate appeared following 8 days of incubation at 35 °C in the presence of 5 % CO_2, on trypticase soy agar supplemented with 5 % rabbit blood. Subcultures grew vigorously within 4 days. Did not grow on heart infusion agar supplemented with X factor (Kordick et al. 1996).

Bartonella vinsonii* subsp. *vinsonii—the type strain ATCC VR-152 was isolated from voles by Baker (1946). Grows on heart infusion agar supplemented with X factor (Kordick et al. 1996).

Ecology

Habitat

The species belonging to the genus *Bartonella* have been isolated and detected in a wild range of animal species. Potential animal reservoirs include cats, dogs, rodent, rabbits, ruminants, and sea mammals, as well as wild animals including wild cats, coyotes, deer, elk, and foxes. At least three species have been identified as major human pathogens, and their disease syndromes and treatment recommendation are described below. An additional seven species, including two other subspecies have been associated with disease in humans. Finally, currently nineteen species and one subspecies have been isolated from animals, and most remain of uncertain pathogenicity (*Table 3.1*). Additionally, some species have been associated with disease in animals, such as cats and dogs. The adaptation of *Bartonella* spp. to a broad range of mammalian hosts, as well as vectors which transmit these bacteria, is representative of the complexity of the ecological diversity of members of the *Bartonella* genus.

Considering host ecology, with the exception of *B. bacilliformis* and *B. quintana*, which are classified as "specialists" because humans are the only reservoirs, most *Bartonella* species are referred to as "generalists" because they are able to infect and persist in numerous animal hosts. Although *B. quintana* has been categorized as a "specialist," there is evidence to support the possibility that this species

may have adapted the means to utilize another mammalian species, the domestic cat, as a reservoir host (Breitschwerdt et al. 2007; Drancourt et al. 1996; La et al. 2005). In contrast to other vector-borne diseases which are typically limited to one host, many *Bartonella* species have the ability to be transmitted from a reservoir host to an accidental host. The establishment of a primary reservoir host for *Bartonella* spp. is key because it allows for persistent infection at a high level of bacteremia for a prolonged period of time in a host, permitting uptake by blood-feeding arthropods and subsequent transmission to other hosts. Accordingly, prolonged bacteremia in clinically normal reservoir hosts is considered common (Chomel et al. 2003, 2009; Jacomo et al. 2002). Cats appear to be the primary mammalian reservoir for the important zoonotic specie, *B. henselae*, and also for *B. clarridgeiae* and *B. koehlerae* (Chomel et al. 2004). Coyotes and dogs are considered mammalian reservoirs for *B. vinsonii* subsp. *berkhoffii* and foxes, coyotes, and dogs for *B. rochalimae* (Chomel et al. 2003; Henn et al. 2009a, b). Other examples of reservoir hosts include cattle, which appears to be the mammalian reservoir for *B. bovis* (Bermond et al. 2002). Infection of a single host animal with more than one *Bartonella* species has been reported in cats, dogs, cattle, and wild mammals (Cherry et al. 2009; Diniz et al. 2007; Gurfield et al. 1997; Telfer et al. 2007). Additionally, coinfection with multiple genetic types of *B. henselae* or *B. vinsonii* subspecies *berkhoffii* is reported for cats and dogs, respectively (Duncan et al. 2007; Gurfield et al. 1997).

Transmission of *Bartonella* to humans occurs through an insect vector for most *Bartonella* species. The list of vectors and potential vectors associated with transmission includes flies, flees, ticks, lice, and mites (*Table 3.1*). *B. quintana* is carried by human body lice (*Pediculus humanus*) and human hosts form the reservoir (Chang et al. 2001; Roux and Raoult 1995). *B. bacilliformis* has humans as the only reservoir host, and the sand fly, *Lutzomyia verrucarum*, is the transmitting vector. Transmission of *B. henselae* in cats has typically been associated with the cat flea (*Ctenocephalides felis*) via fleas acquiring *B. henselae* during a blood meal from an infected carrier and then later regurgitating infected saliva while feeding on an uninfected individual (Guptill 2003). Feline intraspecies transmission is regarded as vector-borne, and several studies have failed to demonstrate either seroconversion or bacteremia in uninfected cats living in prolonged association with infected cats but in an ectoparasite-free environment (Bradbury and Lappin 2010; Chomel et al. 1996; Guptill 2003; Kordick and Breitschwerdt 1998). Direct transmission between cats experimentally has also failed (Chang et al. 1999). In cats, the presence of arthropod vectors appears to be necessary for horizontal disease transmission (Abbott et al. 1997; Guptill 2003). Experimental studies have shown that fleas and intradermal inoculation of flea feces can spread the infection between cats. It is supported by the fact that transmission is reduced or absent when fleas are controlled. Domestic dogs are reported to be accidental hosts for *B. henselae*, and as in cats, intraspecies transmission is believed to rely on arthropod vectors (Chang et al. 1999; Guptill 2003). Transmission to humans is known to occur via dog bites, and oral swabs of dogs have confirmed at least four *Bartonella* species (*B. henselae*, *B. quintana*, B. *vinsonii* subsp. *berkhoffii*, and *B. bovis*) (Chomel et al. 2006; Duncan et al. 2007; Skerget et al. 2003). Humans have been assumed to acquire *B. henselae* infection when flea fecal material is introduced through the skin via a cat scratch or cat or dog bite (Skerget et al. 2003). Recent evidence suggests that iatrogenic transmission to humans via accidental needle stick may occur, as well as perinatal transmission (Breitschwerdt et al. 2010; Oliveira et al. 2010). It has also been suggested, but not proven, that fleas may be able to transmit *B. henselae* directly to humans (Center for Food Security and Public Health 2005).

Ticks have been proposed as vectors for transmission of *Bartonella* species among cats, humans, dogs, and other mammalian hosts (Bergmans 1996; Cotte et al. 2008; Pappalardo et al. 1997; Slater et al. 1990; Welch et al. 1999). *B. henselae* and other *Bartonella* spp. were detected by PCR in questing ticks (Chang et al. 2001, 2002; Sanogo et al. 2003). Transstadial transmission of *B. henselae* has been demonstrated in *Ixodes ricinusticks* (Cotte et al. 2008). However, the role of ticks is still unknown.

Pathogenicity, Clinical Relevance

Analysis of the species belonging to the genus *Bartonella* indicates the presence of human and animal pathogenic species/strains, although information about the pathogenicity for several species remains uncertain to date. Despite the large spectrum of antibiotic sensibility among the species, clinical use of antimicrobial agents in vivo are dependent on the infection (disease) caused by *Bartonella* species.

Human- and Animal-Related Pathogenicity

Bartonella spp. are facultative intracellular pathogens that employ a unique stealth infection strategy comprising immune evasion and modulation, intimate interaction with nucleated cells, and intraerythrocytic persistence. Infections with *Bartonella* are ubiquitous among mammals, and many species can infect humans either as their natural host or incidentally as zoonotic pathogens (*Table 3.1*). Upon inoculation into a naive host, the organism first colonizes a primary niche that is widely accepted to involve the manipulation of nucleated host cells in the microvasculature. Consistently, in vitro researches have demonstrated that *Bartonella* harbors an ample arsenal of virulence factors to modulate the response of such cells, gain entrance, and establish an intracellular niche (Dehio 2004; Harms and Dehio 2012). Subsequently, the bacteria are seeded into the bloodstream where they invade erythrocytes and give rise to a typically asymptomatic intraerythrocytic bacteremia. Residing intraerythrocytically allows the bacteria to evade the host's immune system and thus chronically infect the host (Greub and Raoult 2002). While this course of infection is characteristic for natural hosts, zoonotic infections or the

infection of immunocompromised patients may alter the path of *Bartonella* and result in considerable morbidity. The probability of infection is heightened in immunosuppressed transplant patients, chemotherapy patients, and patients who suffer from immunosuppressive disorders such as HIV/AIDS (Tappero et al. 1993).

Since *Bartonella* spp. resides within the red blood cells of the host, the transmissibility of the bacteria is greatly facilitated. Disease in the reservoir host, depending on the adaptation level to the host and *Bartonella* species, varies from an asymptomatic or subclinical to clinical manifestations with low morbidity and limited mortality, or even to life-threatening severe disease (Chomel et al. 2009). Besides erythrocytes, endothelial cells represent another major target cell type for *Bartonella*, and studies have shown that there is a phenomenon of host restriction. As so, when humans are the reservoir host, such as for *B. bacilliformis* and *B. quintana*, clinical manifestations result from both intraerythrocytic bacteremia and endothelial cell association (Chomel et al. 2003; Dehio 2001; Dehio and Sander 1999). On the other hand, other *Bartonella* species, for which humans are not the natural reservoir, tend to cause persistent bacteremia only in immunodeficient individuals, and in this case without evidence for intraerythrocytic localization, as typically observed in the reservoir host. For these zoonotic infections, the severity of the clinical presentation correlates well with the status of the host's immune system and often reflects a close association with proliferating endothelial cells (Dehio 2001; Dehio and Sander 1999; Resto-Ruiz et al. 2003).

Although, several studies have detected *Bartonella* sp., other than *B. bacilliformis* within erythrocytes (Mehock et al. 1998; Rolain et al. 2002), which ones may also localize and persist within vascular endothelial cells (Dehio 2001), the exact localization of *Bartonella* species in mammalian hosts has not been completely determined. *Bartonella* have a strong tendency to stick or clump together in tissues and in culture and also to stick to, and penetrate, red blood cells and endothelial cells. The ability to adhere to each other, as well as to the membranes of red blood cells and endothelial cells, leads to the wide and varied tissue pathogenesis observed in cats, dogs and people. Pili and a protein called deformin are probably responsible for the sticky properties (Xu et al. 1995). *Bartonella* proteins stimulate endothelial cells to proliferate causing neovascularization or angiogenesis, as well as an outpouring of inflammatory cytokines which recruit inflammatory cells such as lymphocytes, plasma cells, and macrophages. Studies upon virulence factors of *Bartonella* species suggest that they include adhesins, heme acquisition/utilization mechanisms, type IV secretion systems, outer membrane proteins, and a low-potency lipopolysaccharide, among others (Dehio 2004; Minnick and Battisti 2009; Harms and Dehio 2012). The T4SS Trw has been identified in *B. henselae* and *B. quintana* and is believed to be important in erythrocyte and endothelial cell invasion (Minnick and Battisti 2009; Dehio 2008). The VirB/VirD4T4SS, investigated in *B. henselae*, has important effects including activation of nuclear factor kappa B, leading to the release of proinflammatory or proangiogenic cytokines and inhibition of apoptosis of colonized endothelial cells (Dehio 2008; Minnick and Battisti 2009). It should be mentioned that the source of inoculum may substantially influence the pathogenicity of the disease. A synopsis of pathogenicity factors of *Bartonella* spp. and their function is highlighted below (*Table 3.4*), as reviewed by Dehio (2004) and Harms and Dehio (2012).

Several studies have indicated the lack of immune protection following *Bartonella* infection (Arvand et al. 2008; Kordick et al. 1995) and consequently relapsing bacteremia, such as 454 days for *B. henselae* or *B. clarridgeiae* (Kordick et al. 1999). Relapsing bacteremia may be facilitated by antigenic variation or by localization to the so-called "privileged" sites such as within erythrocytes or other host cells. In vitro studies indicate that *Bartonella* spp. can also infect professional macrophages, including dendritic cells, microglial cells, monocytes, and tissue macrophages (Chomel et al. 2009; Schulein et al. 2001; Muñana et al. 2001). In addition, experimental infection of dogs with *B. vinsonii* subsp. *berkhoffii* induced immunosuppression, characterized by sustained suppression of peripheral blood CD81 lymphocytes, accompanied by an altered cell surface phenotype and an increase in CD41 lymphocytes in the peripheral lymph nodes (Pappalardo et al. 2000, 2001). Studies have also demonstrated lack of or incomplete cross-protection among *Bartonella* isolates, likely due to genetic variation (Guptill et al. 2004). Experimentally infected cats became immune to challenge infection with homologous strains of *Bartonella*, but there is a lack of protection against reinfection with heterologous isolates (Greene et al. 1996; Yamamoto et al. 1997). Considering humoral immunity, the antibody response to acute experimental infection of *B. henselae* or *B. clarridgeiae* is similar to other diseases, with antibodies IgM being detected within 1 week followed by a rise in IgG 1–2 weeks later. Although some studies suggest that antibody titer may correlate with bacteremia, this association is unreliable for clinical use (Pressler 2006).

A wide spectrum of diseases has been described following *Bartonella* infection. Clinical disease ranges from painless lymphadenopathy to large cervical abscesses (Kabeya et al. 2002; Seubert et al. 2002; Ridder et al. 2005; Rie et al. 2003). Lymph nodes most commonly involved are those ones localized in the axilla, neck, and groin regions (Marakaki et al. 2003; Dyachenko et al. 2005). Although rare, serious diseases such as encephalopathy, pulmonary disease, pneumonia, neuroretinitis, endocarditis, aseptic meningitis, and osteomyelitis may complicate *Bartonella* infections, even in immunocompetent individuals (Ciervo et al. 2005; Ridder et al. 2005; Loa et al. 2006). In immunocompromised patients, disseminated and systemic infections such as fever, bacillary angiomatosis, and bacillary peliosis may occur (Harms and Dehio 2012; Johnson et al. 2003). In severe cases, HIV-positive patients develop cerebral lesions (Spach et al. 1992; Muñana et al. 2001) and dementia associated with relapsing *B. henselae* bacteremia (Lucey et al. 1992; Schwartzmann et al. 1995; Muñana et al. 2001). However, the pathogenesis and dysfunction of central nervous system is not fully understood (Muñana et al. 2001). Other diseases include meningoencephalitis, stellar retinitis, Parinaud's oculoglandular syndrome, erythema nodosum,

Table 3.4
Virulence factors of *Bartonella* spp.

Virulence factor(s)	Direct functions(s)	Contribution(s) to pathogenesis
Autotransporters	Unknown, cohemolysin activity (CAMP-like factor autotransporter)	Unknown
Deformin	Formation of invaginations in erythrocyte membranes	Enabling erythrocyte invasion
Filamentous hemagglutinins	Unknown	Unknown
Flagellation	Motility; mechanical force	Binding to and invasion of erythrocytes
Hemin-binding proteins (Hbps)	Hemin-binding, fibronectin binding (HbpA)	Host cell adhesion? Formation of a heme surface layer (antioxidant barrier? Nutritive reservoir?)
Invasion-associated locus (ial), encoding IalA and IalB	Unknown	Invasion of erythrocytes
Lipopolysaccharides	Invisibility to Toll-like receptor 4 (TLR4), antagonizing TLR4 signaling	Immune evasion and immunomodulation
OMP43 (outer membrane protein of *Bartonella*)	Fibronectin binding, host cell binding	Host cell adhesion?
Outer membrane proteins	Activation of NF-kB signaling, host cell adhesion	Secretion of monocyte chemoattractant protein 1 (MCP-1) and upregulation of E-selectin and ICAM-1 (as part of proangiogenic signaling?)
Secreted factor (GroEL heat shock protein)	Unknown, activation of Ca2+ signaling?	Inhibition of apoptosis and mitogenic stimulation of host cells
Trimeric autotransporter adhesins (i.e., *Bartonella* adhesin A of *B. henselae*, "variably expressed outer membrane of *B. quintana*)	Bacterial autoaggregation, attachment to extracellular matrix, host cell binding via β1-integrins, activation of hypoxia-inducible factor 1 (HIF-1) and NF-Kb, inhibition of macrophage phagocytosis	Stable integration with host cell as basis for further manipulation, secretion of proangiogenic cytokines
Trimeric autotransporters or the VirB/D4 type IV secretion system (T4SS), *Bartonella* effector proteins	Inhibition of apoptosis, proinflammatory activation, modulation of angiogenesis, invasome formation	Setup and control of intracellular niche
Trw type IV secretion system	Adhesion to erythrocyte surface	Enabling erythrocyte invasion
Unknown factor (probably surface protein)	Activation of cellular signaling via β1-integrins	Triggering host cell invasion in course of invasome formation

arthritis, pulmonary nodules, myelitis, granulomatous hepatitis, and lesions of almost every organ system (Anderson and Neuman 1997; Giladi et al. 2001; Greub and Raoult 2002).

Carrión's Disease and Verruga Peruana: The classical course of infection with *B. bacilliformis* is known as Carrion's disease and consists of Oroya fever as the acute phase with hemolytic anemia and a subsequent chronic phase hallmarked by multiple vasoproliferative lesions on the skin (verruga peruana for "Peruvian wart"). This infection is also known as Carrion's disease after Daniel Carrion, a Peruvian medical student in whom the disease developed after inoculating himself with material from an infectious lesion. The disease is considered endemic in South America, particularly in Peru (Maguina 1998), Colombia (Alexander 1995), Ecuador, Chile, and Guatemala (Sanchez et al. 2012), and it has afflicted travelers visiting the region. The first phase, Oroya fever, involves invasion of human erythrocytes and results in an often severe acute hemolytic anemia, and life-threatening septicemia usually develops (Chang et al. 2001; Houpikian and Raoult 2002). The second phase, verruga peruana, involves infection and prominent proliferation of endothelial cells, resulting in characteristic skin eruptions of papules and nodules (Anderson and Neuman 1997). These papules are often inflamed and bleed, and osteoarticular pain usually occurs in association with these vascular lesions (Rolain et al. 2004). However, atypical pathological angiogenesis during the verruga peruana cases involving other organs such as the spleen has been reported (Lydy et al. 2008). People are still the only known reservoirs of *B. bacilliformis*, and they serve as sources of infection for sand flies, which are the vectors of the disease. The devastating hemolytic anemia during Oroya fever is a critical difference between the pathologies of *B. bacilliformis* and the other *Bartonella* species, since severe

morbidity and severe hemolytic anemia are not usually observed with modern species. Mortality during Oroya fever ranges from close to zero in the case of hospitalized patients receiving antibiotic treatment to up to 88 % in untreated cases (Pachas 2000). Approximately 70 % of patients suffering from Oroya fever develop complications of the disease, of which approximately half are of an infectious cause and half of a noninfectious nature. Noninfectious complications such as fever, anorexia, or an altered mental status have been suggested to be primarily a consequence of systemic infection (Maguina et al. 2001). Secondary infections may occur during Oroya fever and contribute prominently to morbidity and mortality by provoking septicemia, most often with *Salmonella* (Pachas 2000; Maguina et al. 2001). However, it is known today that this classical course of Carrion's disease is not the only possible outcome of a *B. bacilliformis* infection, since natives in the areas of endemicity exhibit a significant baseline of asymptomatic bacteremia and suffer from Oroya fever relatively rarely, but they frequently develop verruga peruana without prior hemolytic anemia (Harms and Dehio 2012).

***B. quintana* Infections**: Trench fever, also known as 5-day fever, Wolhynia fever, or Quintan fever, is caused by *B. quintana* and is distributed throughout the world (Roux and Raoult 1999). Although symptoms vary between patients, the disease usually present mild to moderately severe fever (for up to 8 days, concurrent with the onset of erythrocyte infection), chills, malaise, myalgia, and leg pains and is especially prominent in the tibia (Maurin et al. 1997; Rolain et al. 2004). The acute signs usually resolve spontaneously, but recurrences of the disease may occur (Kostrzewski 1949). Occasionally, splenomegaly and a maculopapular rash resembling the rose spots of typhoid fever may develop (Strong 1918). Many of the infected individuals do not suffer from disease but develop a chronic asymptomatic, bacteremic carrier state (Raoult et al. 2001). Trench fever occurred in millions of troops in World War I, but with the introduction of louse control measures by armed forces, the disease was thought no longer to be a threat (Maurin and Raoult 1996). However, *B. quintana* has recently reemerged as a contemporary disease, in which manifestations include "urban" trench fever and several new disease manifestations including endocarditis and, specifically in HIV patients, a vasoproliferative disorder called bacillary angiomatosis. Major risk factors for acquiring *B. quintana* infections nowadays include poor living conditions, chronic alcoholism, and HIV-positive individuals (Jacomo et al. 2002). The vasoproliferative infection is usually progressive and fatal unless treated by antibiotic therapy (Bass et al. 1997).

Cat scratch Disease (CSD): Studies have shown that *B. henselae* Houston-1 strain constitutes the primary etiologic agent of CSD. However, *B. henselae* Marseille strain, *B. clarridgeiae*, *B. koehlerae*, and *B. grahamii* have also been identified as agents of the disease in limited cases (Kordick et al. 1997; Lamas et al. 2008; Margileth and Baehren 1998; Oksi et al. 2013; Windsor 2001). CSD has a worldwide distribution and is probably the most common zoonotic human infection caused by *Bartonella* spp. nowadays. Regional lymphadenopathy is the main clinical manifestation of CSD, associated with the nodes draining the site of the cat scratch and preceded by localized lesions with redness, swelling, and pustules also appearing at the site of initial inoculation. Lymph nodes usually regress in size over a period of weeks or months, but the lymphadenitis may become suppurative in 10 % of patients. However, atypical manifestations with involvement of various organs such as the eyes, liver, spleen, central nervous system, skin, and bones may occur including malaise, fatigue, myalgia and arthralgia, weight loss, splenomegaly, and Parinaud's oculoglandular syndrome (Dehio 2004). Encephalopathy and neuroretinitis are less common complications of CSD (Bass et al. 1997). Typically, the course of CSD is benign as it is observed in immunocompetent hosts, in whom the pathological response is granulomatous, suppurative, extracellular and intracellular, generally self-limited, and without bacteremia (Bass et al. 1997; Carithers 1985; Zangwill et al. 1993). However, severe immunosuppression, particularly secondary to HIV, as well as organ transplantation, is associated with disseminated and often tissue-invasive forms of CSD which have the potential to be life-threatening (Black et al. 1986). Manifestations in such patients include bacillary angiomatosis, hepatitis peliosis, endocarditis, and persistent or relapsing fever in association with bacteremia (Chomel et al. 1996; Higgins et al. 1996) Although CSD may occur in people of any age, most patients are under 18 years of age, perhaps because children are more likely to have close and rough contact with cats. The incidence of CSD is seasonal, with most cases occurring in August to October in northern temperate areas (Carithers 1985).

Endocarditis: *B. quintana*, *B. henselae*, *B. elizabethae*, *B. vinsonii* subsp. *berkhoffii*, *B. vinsonii* subsp. *arupensis*, *B. koehlerae*, and *B. alsatica* are known to cause infective endocarditis (Johnson et al. 2003; Lepidi et al. 2008). Several studies suggest that previous valve lesions predispose an individual to endocarditis with nonhuman *Bartonella* species, with *B. quintana* endocarditis being more frequently diagnosed in patients without previous heart diseases (Jacomo et al. 2002). *Bartonella*-caused endocarditis often requires valve replacement surgery, and since it is generally indolent and culture negative, delays in diagnosis contribute to a higher death rate than other forms of endocarditis (Rolain et al. 2004). Prescription of an aminoglycoside appears to be critical in the outcome of endocarditis (Jacomo et al. 2002). Endocarditis caused by *Bartonella* has been reported in both immunocompetent and immunosuppressed individuals (Minnick and Anderson 2006).

Bacillary Angiomatosis (BA) and Bacillary Peliosis (BP): BA and BP are vasoproliferative disorders that occur particularly in immunocompromised patients with *Bartonella* infections seen most commonly in patients with advanced HIV (Perkocha et al. 1990; Tappero et al. 1993; Dehio 2005). It is characterized by cutaneous manifestations of vascular tumors of the skin and subcutaneous tissues, including single or multiple discolored cutaneous nodules, hyperpigmented lichenoid plaques, and subcutaneous nodules with the potential to ulcerate (Conrad 2001; Klotz et al. 2011; Koehler and Tappero 1993). BA cutaneous

lesions may resemble pyogenic granulomas, Kaposi's sarcoma, lichenoid violaceous plaques, or verruga peruana (Koehler and Tappero 1993). A multicellular inflammatory infiltrate with polymorphonuclear lymphocytes that display leukocytoclastic characteristics is present in BA (Cockerell and LeBoit 1990). Both *B. quintana* and *B. henselae* are the species responsible for this manifestation (Chang et al. 2001; Houpikian and Raoult 2001b; Johnson et al. 2003; Stoler et al. 1983). BA lesions can also involve the bone marrow, liver, spleen, or lymph nodes. Risk factors for BA include exposure to infected cats or cat fleas (Koehler et al. 1994). The BP is caused by *B. henselae* and is considered by several researchers as the visceral manifestation of BA. It is characterized by vascular proliferation in single or multiple organs, including liver, spleen, and lymph nodes, which results in the formation of blood-filled cysts (Rolain et al. 2004; Slater et al. 1992; Tappero et al. 1993). Gastrointestinal distress, fever, and chills may accompany peliosis, and the syndrome may occur alone or in combination with BA or bacteremic syndrome (Minnick and Anderson 2006). BP can produce hepatomegaly and may result to an increase in the activity of liver enzymes and also death due to liver failure (Perkocha et al. 1990). Typically, patients with tuberculosis, advanced cancers, or those utilizing anabolic steroids are considered most prone to develop BP (Koehler et al. 1992, 1997).

***Bartonella* Species in Felines**: Natural infection of cats with five *Bartonella* species (*B. henselae*, *B. clarridgeiae*, *B. koehlerae*, *B. quintana*, and *B. bovis)* has been reported, although feline infection with species other than *B. henselae* and *B. clarridgeiae* is rarely reported (Guptill 2010). Nevertheless, pathogenesis of *Bartonella* infection, including the localization of the organism, in these hosts is not completely understood until nowadays (Guptill 2010; Jacomo et al. 2002; O'Reilly et al. 1999; Rolain et al. 2004). *B. henselae* and *B. clarridgeiae* bacteremia is usually asymptomatic, and the disease is strain dependent (Chenoweth et al. 2004a, b; Johnson et al. 2003; Koehler et al. 1994). *Bartonella* spp. are responsible for chronic bacteremia in kittens and adult cats, which may remain bacteremic for several months, or even years, without ever becoming symptomatic (Chomel et al. 1999). Most of the cats naturally infected with *B. henselae* do not show any clinical manifestation; however, some of them can demonstrate only mild clinical signs which are self-limiting (Stutzer and Hartmann 2012). Several studies have suggested a link between infection and clinical signs such as endocarditis, pyogranulomatous myocarditis and diaphragmatic myositis (Varanat et al. 2012), central nervous system diseases (Leibovitz et al. 2008), uveitis, conjunctivitis (Ketring et al. 2004) and possibly stomatitis, and various urinary tract disorders (Glaus et al. 1997). Additionally, clinical signs reported in cats inoculated with *B. henselae* include swelling at the site of inoculation, fever, lethargy, anorexia, myalgia, anemia, lymphadenopathy, and reproductive failure (Guptill et al. 1999; Kordick and Breitschwerdt 1997; O'Reilly et al. 1999). It should be mentioned, however, that establishing causal associations between clinical conditions and a pathogen like *Bartonella* that has a high prevalence in the reservoir host population is difficult. The likelihood that some clinical conditions have multiple causes must also be considered, particularly in cats with exposure to arthropod vectors (Guptill 2010).

***Bartonella* Species in Dogs**: Infection in dogs may be associated with *B. clarridgeiae*, *B. elizabethae*, *B. henselae*, *B. vinsonii subspecies berkhoffii*, *B. quintana*, and *B. rochalimae* (Boulouis et al. 2005; Breitschwerdt et al. 1995, 2002; Chomel et al. 2001, 2003; Henn et al. 2009a; Kelly et al. 2006; Kordick et al. 1996; Mexas et al. 2002). *Bartonella henselae* and *B. vinsonii* subspecies *berkhoffii* are currently believed to be the most common *Bartonella* infections in dogs (Skerget et al. 2003). A wide variety of clinical signs for *Bartonella* infection in dogs have been reported, including polyarthritis, cutaneous vasculitis, endocarditis, myocarditis, cardiac arrhythmias, epistaxis, peliosis hepatitis, and granulomatous inflammatory diseases in several organs (Breitschwerdt et al. 1995; Cadenas et al. 2008; Chomel et al. 2001, 2003; Cockwill et al. 2007; Henn et al. 2009a; Pasavento et al. 2005; Saunders and Monroe 2006). Endocarditis appears to be the clinical condition with the strongest association with *Bartonella* in dogs, and most of the cases are attributable to *B. vinsonii* subsp. *berkhoffii* (Guptill 2010). Thrombocytopenia, anemia, neutrophilic leukocytosis, and eosinophilia are the most commonly detected in dogs seropositive for *B. vinsonii* subsp. *berkhoffii* (Breitschwerdt et al. 2004). The role of dogs as reservoirs of *Bartonella* spp. is less clear than it is for cats because domestic dogs are more likely to be final, clinically affected hosts.

Other *Bartonella* Species: Numerous rodents are known to have intraerythrocytic *Bartonella* bacteremias, and in the past years, some have been associated with human disease, while others remain unknown. As mentioned before, *B. elizabethae*, which naturally infects rats (Ellis et al. 1999b), has been associated with endocarditis (Daly et al. 1993), as well as *B. vinsonii* spp. a*rupensis* (mice) which was isolated from a bacteremic patient with fever (Welch et al. 1999). Additionally, *B. grahamii* naturally infects rats and other rodents (Ellis et al. 1999; Koesling et al. 2001) and may cause neuroretinitis in humans (Kerkhoff et al. 1999). Other *Bartonella* species that infect small woodland mammals and herbivores and domesticated animals are of uncertain pathogenicity, including *B. birtlesii* (mouse), *B. bovis (ruminant)*, *B. capreoli* (roe deer), *B. doshiae* (rodent), *B. peromysci* (rodent), *B. schoenbuchensis* (roe deer), *B. talpae* (rodent), *B. taylorii* (rodent), *B. tribocorum* (rodent), *B. vinsonii* subsp. *vinsonii* (Canadian vole agent), *B. jaculi*, *B. callosciuri*, *B. pachyuromydis*, and *B. acomydis* (wild Rodentia).

Antibiotic Sensitivity

The antibiotic sensitivity is variable among the genus *Bartonella*, and the in vitro and in vivo antibiotic susceptibilities of *Bartonella* do not correlate well for a number of antibiotics; for instance, penicillin has no efficacy in vivo, despite the very low minimal inhibitory concentration (MIC) observed in vitro. Evaluation of susceptibilities to antibiotics has been performed either in the presence of eukaryotic cells or without cells, i.e., in axenic media. Determination of antibiotic susceptibility in

axenic media has been carried out either with solid media enriched with 5–10 % sheep or horse blood or with liquid media (Maurin et al. 1995; Rolain et al 2004).

Generally, *Bartonella* spp. display high levels of in vitro susceptibility to antibacterial agents. Agar dilution testing shows resistance only to fosfomycin, colistin, and vancomycin (Maurin et al. 1995). The highest sensitivity is observed to ketolides such as telithromycin, macrolides, particularly doxycycline, clarithromycin, and rifampin, as well as amoxicillin, cefotaxime, azithromycin, clarithromycin, gentamicin, tetracycline, minocycline, and deftriaxone (Bass et al. 1998; Dörbecker et al. 2006; Maurin and Raoult 1993). However, macrolide-resistant strains of *Bartonella* are reported, and studies suggest that these may arise as a result of animals being treated with macrolide antibiotics (Biswas et al. 2006). Additionally, resistance to azithromycin has been reported in vitro (Biswas et al. 2010). There is a considerable variability in the susceptibilities of isolates to the fluoroquinolones, and only the aminoglycosides (gentamicin, tobramycin, and amikacin) are found to be bactericidal (Jacomo et al. 2002). *B. bacilliformis* is resistant in vivo to neosalvarsan and to other arsenical compounds in general. It is sensitive to penicillin, streptomycin, chloramphenicol, and oxytetracycline. When grown with penicillin, the organism produces L forms (Sharp 1968). *B. henselae*, *B. quintana*, and *B. elizabethae* are susceptible to the macrolides azithromycin, clarithromycin, dirithromycin, erythromycin, and roxithromycin based on testing in Vero cell cultures (Ives et al. 1997). Results of a recent study showed good in vitro efficacy of pradofloxacin against *B henselae* (Biswas et al. 2010), although natural fluoroquinolone resistance in *Bartonella* isolates have been reported (Angelakis et al. 2008). Recently, specific antibiotic resistance mutations have been characterized in *B. henselae* (azithromycin, gentamicin, enrofloxacin, and ciprofloxacin), *B. quintana*, and B. *bacilliformis* (erythromycin, rifampicin, and ciprofloxacin) (Biswas et al. 2006, 2007, 2010; Biswas and Rolain 2010; Habib et al. 2009; Rolain et al. 2004; Meghari et al. 2006). Resistance in vitro to doxycycline or amoxicillin has not yet been induced (Guptill 2010). The results of susceptibility testing with *Bartonella* spp. were demonstrated in a review published by Rolain and colleagues (2004) (❯ *Table 3.5*).

Recommendations for the treatment of human *Bartonella* infections are summarized in ❯ *Table 3.6* according to the data available from several studies (Biswas and Rolain 2010; Rolain et al. 2004; Pérez-Martinez et al. 2010; Prutsky et al. 2013). Antibiotic susceptibilities are not routinely tested in clinical isolates as susceptibility studies often fail to predict response to therapy (Hammoud et al. 2008).

Penicillin G, chloramphenicol, tetracycline, and erythromycin have been used for the treatment of Oroya fever. Treatment with these drugs produces rapid defervescence, with disappearance of the organisms from the blood, usually within 24 h (Bass et al. 1997). However, because many patients suffer from secondary infections, especially salmonellosis and infections caused by other enteropathogenic bacteria, chloramphenicol has become the recommended antibiotic therapy (Rolain et al. 2004). Nevertheless, in some patients, simultaneous treatment with another antibiotic (especially a beta-lactam compound) is recommended (Maguina et al. 2001). Trimethoprim–sulfamethoxazole, macrolides (roxithromycin), and fluoroquinolones (norfloxacin and ciprofloxacin) have also been used successfully in some patients (Maguina 1998). Although, verruga peruana is caused by the same bacterium that causes Oroya fever, chloramphenicol is an ineffective treatment for this eruptive stage of infection with *B. bacilliformis* (Maguina 1998). The treatment used in this case has traditionally been streptomycin (15–20 mg/kg of body weight intramuscularly [i.m.] once daily) for 10 days, although rifampin may also be used (Maguina et al. 2001). Meta-analysis showed that there is no difference between them (Prutsky et al. 2013). However, failures of rifampin treatment have been reported, as well as resistance. Ciprofloxacin at 500 mg p.o. twice daily for 7–10 days has also been used with success for the treatment of adults with multiple eruptive-phase lesions, as has azithromycin (Maguina and Gotuzzo 2000).

Considering trench fever, recommendation for patients with the acute form of *B. quintana* bacteremia relies on gentamicin (3 mg/kg of body weight i.v. once daily for 14 days) in combination with doxycycline (200 mg p.o. daily) for 28 days. Rifampin resistance was readily induced in *B quintana*, and it is recommended that people with *Bartonella* infections should not be treated with rifampin alone (Biswas et al. 2008).

Agents that have been used in therapy of cat scratch disease include azithromycin and rifampin. A placebo-controlled clinical study showed that azithromycin caused an 80 % decrease in lymph node volume in 7 of 14 azithromycin-treated CSD patients during the first 30 days of observation (Bass et al. 1998). However, Rolain et al. (2004) and Prutsky et al. (2013) pointed out that it is not clear that antibiotic therapy is useful for the treatment of CSD in immunocompetent patients, and because antibiotic therapy adds the risk of adverse drug reactions and the generation of resistant flora, the current recommendation for the mild to moderately ill immunocompetent patient with CSD is not antibiotic treatment, being azithromycin used only in patient with extensive lymphadenopathy. Considering complicated CSD (retinitis, encephalopathy, and visceral forms), the combination of doxycycline with rifampin should be used (Reed et al. 1998). However, it remains unclear whether the antibiotic treatment of a localized disease reduces the risk of the development of a systemic disease.

Bartonella infections causing bacillary angiomatosis (BA), bacillary peliosis (BP), and endocarditis have been treated with a variety of antibiotics, including trimethoprim–sulfamethoxazole, doxycycline, erythromycin, ciprofloxacin, rifampin, gentamicin, clarithromycin, and azithromycin (Rolain et al. 2004). Nowadays, however, it is not recommended to use fluoroquinolones, trimethoprim–sulfamethoxazole, or narrow-spectrum cephalosporins for the treatment of BA or BP. Studies have demonstrated that treatment of BA and BP with oral doxycycline (100 mg twice daily) has been consistently successful (Koehler and Tappero 1993). The drug of choice for the treatment of BA is erythromycin, in which patients intolerant of erythromycin can be treated with doxycycline (Koehler 1995).

Table 3.5

Minimal inhibitory concentration (MIC) for *Bartonella* sp. strains determined by the agar dilution technique with Columbia agar supplemented with 5 % horse blood

Vancomycin	2–8	8–16	4–8	8	8

Note that the in vitro MICs correlate poorly with the in vivo efficacies of antibiotics in patients with *Bartonella*-related infections, and thus, these MICs should not be used for the selection of antibiotics for patient treatment. MICs are the concentrations at which there is complete inhibition of growth. *Abbreviations*: *ND* not determined, *TMP-SMX* trimethoprim–sulfamethoxazole

No statistically significant difference was observed in treatment with erythromycin or doxycycline (Prutsky et al. 2013). BP responds more slowly than cutaneous BA to treatment. Considering *Bartonella* endocarditis, a retrospective study using aminoglycosides with either a beta-lactam or other antibiotics (vancomycin, doxycycline, rifampin, or co-trimoxazole) demonstrated that patients receiving an aminoglycoside were more likely to recover fully and, if they were treated for at least 14 days,

Table 3.6

Recommendations for the treatment of infections caused by *Bartonella* spp. for humans

Disease	Adults	Children
Carrion's disease Oroya fever	Chloramphenicol at 500 mg p.o. or i.v. QID for 14 days and another antibiotic (a beta-lactam is preferred) Or ciprofloxacin at 500 mg p.o. BID for 10 days	Chloramphenicol at 50–75 mg/kg/day p.o. or i.v. divided into four doses for 14 days and another antibiotic (a beta-lactam is preferred) Or ciprofloxacin in children 7–12 years 250 mg p.o. BID for 10 days Or doxycycline + gentamicin
Carrion's disease Verruga peruana	Doxycycline + gentamicin Or streptomycin at 15–20 mg/kg/day i.m. for 10 days Or rifampin at 10 mg/kg/day p.o. for 14–21 days 10 days	Rifampin at 10 mg/kg/day p.o. for 14 days (maximum total daily dose of 600 mg/day)
Trench fever or chronic bacteremia with *B. quintana*	Doxycycline at 200 mg p.o. QD for 4 weeks and gentamicin 3 mg/kg i.v. QD for 2 weeks	Unknown
Typical CSD	No recommendation	No recommendation
	For patients with extensive lymphadenopathy, consider azithromycin at 500 mg p.o. on the first day and 250 mg p.o. on days 2–5 as a single daily dose	For patients with extensive lymphadenopathy, consider azithromycin at 10 mg/kg p.o. on day 1 and 5 mg/kg p.o. on days 2–5 as a single daily dose
Retinitis	Doxycycline at 100 mg p.o. BID for 4–6 weeks and rifampin at 300 mg p.o. BID for 4–6 weeks	Unknown
Bacillary angiomatosis (BA)	Erythromycin at 500 mg p.o. QID for 3 months Or doxycycline at 100 mg p.o. BID for 3 months	Erythromycin 40 mg/kg/day p.o. divided in four divided doses (maximum total daily dose, 2 g/day) for 3 months
Bacillary peliosis (BP)	Erythromycin at 500 mg p.o. QID for 4 months Or doxycycline at 100 mg p.o. BID for 4 months	Erythromycin 40 mg/kg/day p.o. divided in four divided doses (maximum total daily dose, 2 g/day) for 4 months
Endocarditis	Suspected *Bartonella*, culture negative: Gentamicin at 3 mg/kg/day i.v. for 14 days and ceftriaxone at 2 g i.v. or i.m. QD for 6 weeks with or without doxycycline at 100 mg p.o. or i.v. BID for 6 weeks	Unknown
	Documented *Bartonella*, culture positive: Doxycycline at 100 mg p.o. BID for 6 weeks and gentamicin at 3 mg/kg/day i.v. for 14 days	

Abbreviations: BID, twice a day; QD, once a day; QID, four times a day

were more likely to survive (Raoult et al. 2003). These data strongly support the use of aminoglycoside therapy for at least 14 days for patients with suspect of *Bartonella* sp. endocarditis. Additionally, it is recommended that patients with suspected (but culture negative) *Bartonella* endocarditis receive treatment with gentamicin for the first 2 weeks and ceftriaxone with or without doxycycline (Habib et al. 2009; Raoult et al. 2003; Prutsky et al. 2013).

Considering feline bartonellosis, documenting clearance of *Bartonella* infections through antibiotic treatment is difficult because of the relapsing nature of the bacteremia. Treatment seems to require long-term (at least 4–6 weeks) antibiotic administration. No regimen of antibiotic treatment has been proved effective for definitively eliminating *Bartonella* infections in cats (Greene et al. 1996; Guptill 2010; Regnery et al. 1996). Enrofloxacin (3.5–11.4 mg/kg given by mouth every 12 h) treatment for 28 days appeared to be efficient for *B. henselae* or *B. clarridgeiae* (Kordick et al. 1997). However, enrofloxacin causes retinal degeneration and blindness in some cats when administered at more than 5 mg/kg/day, and use of a higher dose is contraindicated. In addition, doxycycline seems to clear *B. henselae* or *B. clarridgeiae* infection in cats, in which higher doses (e.g., 50 mg/cat by mouth every 12 h for 1 week) may be more likely to be effective (Greene et al. 1996; Kordick et al. 1997). Other antibiotics have also been tested (erythromycin, amoxicillin, amoxicillin/clavulanic acid, tetracycline hydrochloride) and proven to decrease the level of bacteremia in treated cats, although cats were not followed by a prolonged period of treatment (Guptill 2010). Rifampin should not be used alone because resistance develops quickly (Biswas et al. 2008); however, combination with doxycycline has been recommended. Azithromycin has been widely used to treat feline *Bartonella* infections, but there are no data from controlled studies to support this practice, and its efficacy may be limited (Guptill 2010). Additionally, azithromycin is not recommended as a first-line antibiotic for cats and dogs, due to the rapid development of resistance when compared to several other antibiotic classes. Considering that there are differences in antibiotic treatment protocols and that routine treatment of asymptomatic feline *Bartonella* infections may induce resistant strains, the treatment

is recommended only for cats showing clinical signs of disease, and doxycycline may be the antibiotic of choice (Guptill 2010). Experimental and clinical evidence in treatment of cats and dogs supports the lack of efficacy for doxycycline, particularly when given for periods of, at least, 4 weeks at 5 mg/kg every 12 h (i.e., the recommended dose and treatment period for canine ehrlichiosis). Thus, the combination of doxycycline and amikacin would be a reasonable initial antibiotic combination to treat canine or feline endocarditis cases. For long-term therapy, doxycycline and enrofloxacin should be considered, until other antibiotics or antibiotic combinations are proven to be effective. Ciprofloxacin has less favorable MICs compared to enrofloxacin and pradofloxacin, and because of variable intestinal absorption following oral administration, ciprofloxacin is not recommended for treatment of bartonellosis in dogs (Diniz et al. 2009). For canine cases with central nervous system involvement, doxycycline and rifampin in combination have been used successfully.

Application

There are very few evidence in the literature involving directly application of *Bartonella* species. However, some of them are used for serological diagnosis of species which cause important disease in humans. Several serodiagnostic methods, including Western blotting, enzyme-linked immunosorbent assay (ELISA), and indirect immunofluorescent antibody (IFA) assay, have been proposed (Chomel et al. 1995; Chamberlin et al. 2000; Matsuoka et al. 2013; Regnery et al. 1992; Tea et al. 2003). IFA assay is most commonly used for routine clinical diagnosis of Bartonella infections, using fixed bacterial cells cocultured with Vero cells on a slide as the antigen. Commercial kits are also available for the diagnosis of *B. henselae* (e.g., MRL Diagnostics) and *B. quintana* (e.g., Focus technologies, USA) (Seki et al. 2006; Zbinden et al. 1997). However, cross-reactivity with other species has been reported (Maurin et al. 1997; McGill et al. 1998; Regnery et al. 1992). Recombinant antigens, such as immunoreactive protein P26 of *B. henselae*, have also been used in ELISAs, resulting in a more sensitive test than *B. henselae* type I outer membrane proteins (Chenoweth et al. 2004b; Feng et al. 2009). Accordingly, use of a recombinant B. henselae 17-kDa antigen (the r17-kDa antigen) was used for the development of an IgG and an IgM capture-based ELISA for the detection of *B. henselae* infections, with good results of sensitivity and specificity (Anderson et al. 1995; Loa et al. 2006; Hoey et al. 2009). Recently, Matsuoka and colleagues (2013) reported that synthetic peptides HbpB2 (hemin-binding protein B) and HbpD3 (hemin-binding protein D) might be suitable for developing serological tools for differential diagnosis of *B. quintana* infections. Additionally, the potential application of affinity-purified recombinant Pap31 in ELISA for the diagnosis of *B. bacilliformis* infection has been demonstrated (Taye et al. 2005).

The development of a vaccine to prevent feline infection is warranted to reduce the prevalence of infection in the feline population and consequently to decrease the potential for zoonotic transmission. Several antigenic *B. henselae* proteins have been described, including the recombinant immunoreactive protein P26 of *B. henselae*, but to date, no effective protection has been achieved (Anderson et al. 1995; Feng et al. 2009; Kabeya et al. 2003; Werner et al. 2006).

Acknowledgments

The support of CNPq, FAPERJ and Federal Rural University of Rio de Janeiro is greatly acknowledged. The authors wish to thank Dr. Rosangela Zacarias Machado (UNESP/FCAV/Brazil) for stimulating first studies on *Bartonella* spp., as well as the M.Sc. and Ph.D. students Aline Tonussi da Silva, Andresa Guimarães, and Juliana Macedo Raimundo for review of the text and Dr. Vera Lucia Divan Baldani (EMBRAPA/Agrobiologia) for suggestions in the topics phenotypic analyses and isolation procedures.

Abstract
To date there are only 18 established species in the family *Beijerinckiaceae* and only 12 if outgroup members are not taken into account. This small number does not impede to consider them quite interesting from the metabolic and evolutionary point of view since it encompasses from obligate methanotrophs to chemoorganoheterotrophs, plus examples of the intermediate states: facultative methylotrophs and facultative methanotrophs. Nitrogen fixation is another remarkable trait of the family, enabling them to thrive in habitats in which other potential sources of nitrogen are scarce. Their global distribution is wide, with a preference for acidic soils of tropical regions (in the case of *Beijerinckia*) or of temperate and even polar regions in the case of *Methylocapsa*, *Methylocella*, *Methyloferula*, *Methylorosula*, and *Methylovirgula*.

Taxonomy, Historical and Current

The family *Beijerinckiaceae* belongs to the order *Rhizobiales* within the *Alphaproteobacteria* (Garrity et al. 2005). At the time of its proposal contained the genera *Beijerinckia*, *Chelatococcus*, *Methylocapsa*, and *Methylocella* and was described as a metabolically diverse family of aerobic bacteria capable of forming poly-β-hydroxybutyrate granules and fixing nitrogen (*Beijerinckia* and *Methylocella*). To date, four more genera have been formally described within this family: *Camelimonas*, *Methyloferula*, *Methylorosula*, and *Methylovirgula*. However, the phylogenetic analysis taking into account the newly described taxa (also within neighboring families) reveals that two of the eight genera, namely, *Camelimonas* and *Chelatococcus*, occupy an uncertain position close to *Bosea* spp. (family *Bradyrhizobiaceae*) and *Microvirga* (family *Methylobacteriaceae*) (◉ *Fig. 4.1*).

From the historical point of view, there is a clear separation in the taxonomic activity of the different genera. The type genus, *Beijerinckia*, named to honor the Dutch pioneering microbiologist Martinus Willem Beijerinck (1851–1931), has deep roots (Starkey and De 1939; Derx 1950a). There is account of intense research going on for decades concerning isolation of *Beijerinckia* sp. from different habitats and characterization by different methods (Becking 2006) and its beneficial role as nitrogen fixers. However, studies become infrequent after the nineties and there is only one species description of *Beijerinckia* in this century (Oggerin et al. 2009). For the other genera it is just the opposite since all descriptions appeared from 2000 on with the only exception of *Chelatococcus asaccharovorans* (Auling et al. 1993). The push of knowledge in recent times, and not only taxonomic, has been especially important in the case of the methanotrophic and methylotrophic aerobic bacteria of the genera *Methylocapsa*, *Methylocella*, *Methyloferula*, *Methylorosula*, and *Methylovirgula*, whose ecological importance and interest for understanding evolutionary processes go beyond the possibilities of this chapter.

Members of the family *Beijerinckiaceae* include chemoorganoheterotrophs, facultative methylotrophs, facultative methanotrophs, and obligate methanotrophs (◉ *Table 4.1*). The ability to utilize multicarbon compounds is variable but is generally broader in the chemoorganoheterotrophs, then facultative methylotrophs, and then facultative methanotrophs. Other important aspects related with C_1 compounds metabolism such as the carbon assimilation pathway or the type of methane monooxygenase, in those species affected, are additional sources of variability (◉ *Table 4.1*).

E. Rosenberg et al. (eds.), *The Prokaryotes – Alphaproteobacteria and Betaproteobacteria*, DOI 10.1007/978-3-642-30197-1_255,

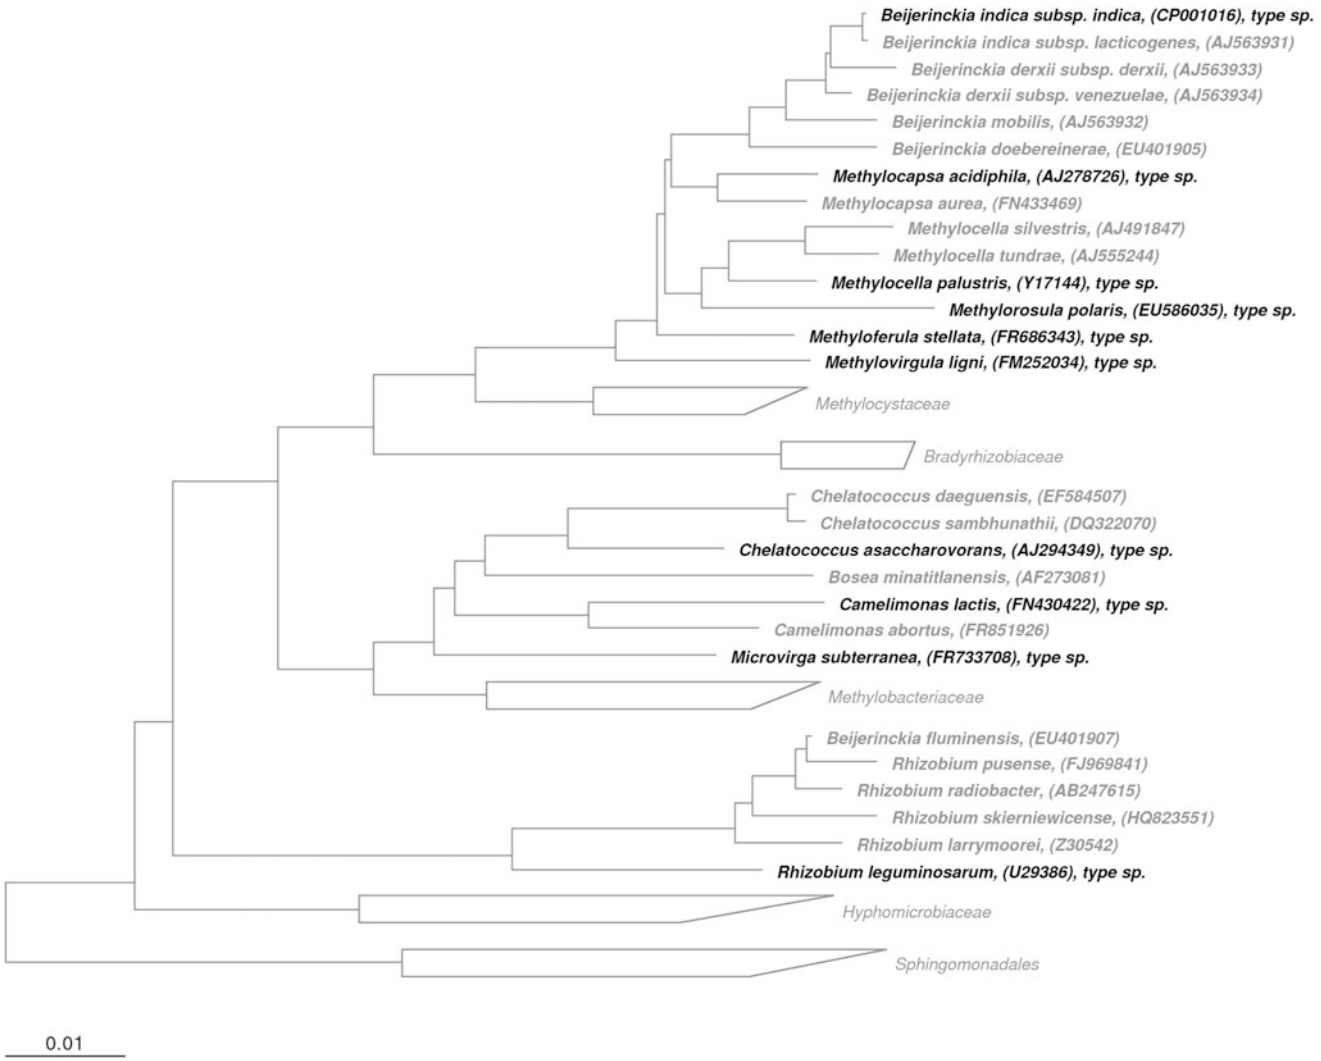

Fig. 4.1

Phylogenetic reconstruction of the family *Beijerinckiaceae* based on 16S rRNA and created using the neighbor-joining algorithm with the Jukes–Cantor correction. The sequence data sets and alignments were used according to the All-Species Living Tree Project (*LTP*) database (Yarza et al. 2010; http://www.arb-silva.de/projects/living-tree). The tree topology was stabilized with the use of a representative set of nearly 750 high-quality type strain sequences proportionally distributed among the different bacterial and archaeal phyla. In addition, a 40 % maximum frequency filter was applied in order to remove hypervariable positions and potentially misplaced bases from the alignment. Scale bar indicates estimated sequence divergence

Formation of poly-β-hydroxybutyrate granules is still a general trait, followed by exopolysaccharide production and nitrogen-fixing activity, with one and two exceptions known, respectively. Unfortunately, these three traits have not been determined in all species, and the main data gap occurs in the uncertain position genera *Camelimonas* and *Chelatococcus*, with no or only partial data, respectively (*Table 4.1*). In contrast, some of the characteristics determined in them (e.g., polyamine pattern or polar lipid composition) have not been explored in the other genera and therefore comparison is not possible. If we leave aside these two genera, the DNA G+C content is 55–63 mol %, a range that could well fit for a single genus.

All members of the family *Beijerinckiaceae* are aerobic but *C. daeguensis* and *C. sambhunathii* can also grow anaerobically with nitrate (Panday and Das 2010; Yoon et al. 2008). Growth factor requirements have been only reported in two species, *C. asaccharovorans* (Auling et al. 1993) and *M. ligni* (Vorob'ev et al. 2009).

During the course of a research project with free-living nitrogen-fixing bacteria, Oggerin et al. (2009) confirmed that strains *B. fluminensis* UQM 1685^T and *B. fluminensis* CIP 106281^T had the same origin but did not descend from the nomenclatural type of the species since they exhibit important phenotypic and genotypic differences

[c]Reported for *Camelimonas lactis* but not for *C. abortus*

when compared with the descriptions of *B. fluminensis* or any of the other species of the genus *Beijerinckia*. As a matter of fact, they were identified as *Rhizobium radiobacter* (Fig. 4.1). All other available equivalent strains (DSM 2327^T and CCUG 53676^T) were confirmed too as *R. radiobacter* (Oggerin et al. 2011). Subsequent attempts to find older deposits of the type strain, hopefully derived from the original isolate, or other existing strains of *B. fluminensis* that could be proposed as a neotype strain were fruitless, and the bibliographic search of the key publications (Döbereiner and Ruschel 1958; Hilger 1965; Skerman et al. 1980; Thompson and Skerman 1979) did not provide enough traceability or hints to locate such biological material. According to Rule 18c of the International Code of Nomenclature of Bacteria (Lapage et al. 1992), if a suitable replacement type strain or a neotype cannot be found or proposed, respectively, within 2 years of the publication of the request for an opinion (Oggerin et al. 2011), the Judicial Commission of the International Committee on Systematic of Prokaryotes is entitled to place the name *Beijerinckia fluminensis* on the list of rejected names. The next foreseeable meeting of the Judicial Commission is during the celebration of the 14th International Congress of Bacteriology and Applied Microbiology to be held in Montreal, Canada, from July 27 to August 1, 2014.

Subspeciation has only been proposed in the genus *Beijerinckia*, namely, in the species *B. derxii* and *B. indica* (Thompson and Skerman 1979).

Molecular Analyses

DDH

To the best of our knowledge, DDH methods have never been reported in the genus *Beijerinckia*, in spite of having the largest number of species, not in the monospecific genera *Methyloferula*, *Methylorosula*, and *Methylovirgula*. In the remaining four genera of the family *Beijerinckiaceae*, we find several examples.

Thus, the proposal of *Chelatococcus asaccharovorans* as novel genus and species (Auling et al. 1993) was based on two strains, TE1 and TE2^T, that could not be discriminated by DDH. However, much lower values (less than 30 %) were obtained against other nine nitrilotriacetate (NTA)-utilizing strains that were proposed in the same study as *Chelatobacter heintzii* gen. nov., sp. nov. For about 15 years, the genus contained one single species, but recently it was enlarged twice and in both cases DDH was considered necessary. The mean value obtained between

C. daeguensis K106^T and *C. asaccharovorans* DSM 6462^T was 13 % (Yoon et al. 2008), whereas *C. sambhunathii* HT4^T displayed 52 and 20 % to *C. daeguensis* CCUG 54519^T and *C. asaccharovorans* DSM 6462^T, respectively (Panday and Das 2010).

The description of *Methylocapsa acidiphila* (Dedysh et al. 2002) included the DDH value between the type strain B2^T and *Methylocella palustris* K^T (7 %). However, in the description of the second species of the genus, *M. aurea* (Dunfield et al. 2010), this information was absent.

In the case of the genus *Methylocella*, DDH was included in the proposal of the second and third species: *M. silvestris* BL2^T was confronted to *M. palustris* K^T resulting in 21–22 % values (Dunfield et al. 2003) and, later on, *M. tundrae* T4^T was hybridized to *M. silvestris* BL2^T and *M. palustris* K^T resulting in values of 36 and 27 %, respectively.

When proposing *Camelimonas lactis* as new genus and species based on strains M-2040^T, M 1973, and M 1878-SK2, Kämpfer et al. (2010) performed DDH experiments and obtained relatedness values among them ranging from 89 % to 100 %. The three strains where also confronted to *Chelatococcus asaccharovorans* DSM 6462^T and *Chelatococcus daeguensis* CCUG 54519^T resulting in values from 22.3 % to 49.2 % and 18.5 % to 49.6 %, respectively (reciprocal measurements included). Later, the proposal of the second species of the genus *Camelimonas* was supported by DNA–DNA relatedness values of 18.0 % and 13.6 % (reciprocal analysis) between *C. abortus* UK34/07-5^T and *C. lactis* M 2040^T (Kämpfer et al. 2012).

Molecular Phylogenetic Markers

An important metabolic ability in many *Beijerinckiaceae*, as has been already mentioned, is dinitrogen fixation that allows them to thrive in environments depleted in available nitrogen compounds. The sequences of *nifH* and *nifD* gene fragments from representatives of the genera *Methylocella*, *Methylocapsa*, *Beijerinckia*, together with some outgroup methanotrophs have been used to withdraw phylogenetic relationships (Dedysh et al. 2004b). The trees constructed for the inferred amino acid sequences of *nifH* and *nifD* were highly congruent. The phylogenetic relationships among methanotrophs in the NifH and NifD trees also agreed well with the corresponding 16S rRNA-based phylogeny, but two discrepancies were found. One suggested that an ancient event of lateral gene transfer was responsible for the aberrant branching of *Methylococcus capsulatus*. On the other hand, the identity values of NifH and NifD sequences between *Methylocapsa acidiphila* B2^T and representatives of *Beijerinckia* were clearly higher (98.5 % and 96.6 %, respectively) than would be expected from their 16S rRNA-based relationships. This can be taken as an indication that these two bacteria originated from a common acidophilic dinitrogen-fixing ancestor and were subject to similar evolutionary pressure with regard to nitrogen acquisition. This interpretation is corroborated by the observation that, in contrast to most other diazotrophs, *M. acidiphila* and *Beijerinckia* spp. are capable of active growth on nitrogen-free media under fully aerobic conditions.

In addition to these genes, the key genes of C_1 metabolism have also been widely used as phylogenetic and functional markers in a number of taxonomic and ecologic studies (Berestovskaya et al. 2012; Dedysh et al. 1998b, 2000, 2001b, 2002, 2004a; Dunfield et al. 2003, 2010; Lau et al. 2013; McDonald and Murrell 1997a, b; Vorob'ev et al. 2009; Vorobev et al. 2011).

The first step of bacterial methane oxidation is catalyzed by methane monooxygenase (MMO), which occurs in two forms: a membrane-bound or particulate (pMMO) and a cytoplasmic or soluble (sMMO). Virtually all known methanotrophs except perhaps, the *Methylocella* species, possess pMMO that consists of three membrane-associated polypeptides encoded by *pmoC*, *pmoA*, and *pmoB* (McDonald and Murrell 1997b; Murrell et al. 2000; Pacheco-Oliver et al. 2002). In addition to pMMO, several methanotrophs possess sMMO. The enzyme from strains belonging to *Methylosinus*, *Methylocystis*, and *Methylococcus* has been thoroughly studied, and the nucleotide sequence of the sMMO gene cluster *mmoX*, *mmoY*, *mmoB*, *mmoZ*, *mmoC*, and *mmoD* appears to be highly conserved (Trotsenko and Khmelenina 2005). The *pmoA* gene encoding a 26-kDa subunit that harbors the active site of the pMMO and *mmoX* gene coding for α-subunit of the sMMO hydroxylase component has been used as appropriate gene markers for the occurrence of the enzymes in various methanotrophs.

Methanol dehydrogenase (MDH), the second enzyme involved in methane oxidation, is present in all Gram-negative methylotrophs including methane and methanol utilizers, and *mxaF* is an appropriate indicator gene for their occurrence in the natural environment (McDonald and Murrell 1997a). Its potential as a functional and phylogenetic marker for methanotrophs has been recently addressed (Lau et al. 2013). This gene codes for the large α-subunit of methanol dehydrogenase and is highly conserved among distantly related methylotrophic species in the alpha-, beta-, and gammaproteobacteria. Topology tests revealed that *mxaF* and 16S rRNA genes of methanotrophs do not show congruent evolutionary histories. Moreover, the *mxaF* gene has poor resolving power for methanotrophs within the *Beijerinckiaceae* (genera *Methylocapsa*, *Methylocella*, and *Methyloferula* in this study), although it performed well for the families *Methylocystaceae* and *Methylococcaceae*. The polyphyletic nature seen for the *Beijerinckiaceae* and the fact that it includes obligate and facultative methylotrophs give rise to various hypothesis: (i) methanotrophy arose once in the group and was lost by some methylotrophic taxa, (b) methanotrophy arose separately in more than one taxon in the group, and/or (c) multiple occurrences of horizontal gene transfers have occurred in the common ancestor of methanotrophic *Beijerinckiaceae*. It therefore is difficult to ascertain whether microorganisms with *mxaF* gene sequences placed near the polyphyletic *Beijerinckiaceae* genera *Methylocapsa*, *Methylocella*, and *Methyloferula* are indeed methanotrophic.

Genomic Data

The first two complete genome sequences to be published in the family came in 2010, both obtained from type strains of separate species and genera.

On one hand, *Methylocella silvestris* BL2^T (Chen et al. 2010) was a judicious choice since it brought as well the first genome available for an alphaproteobacterial methanotroph. Moreover, the organism itself is interesting because it was the first fully authenticated example of facultative methanotroph growing not only on methane and other one-carbon (C_1) substrates but also on some compounds containing carbon–carbon bonds, such as acetate, pyruvate, propane, and succinate (Dedysh et al. 2005a). The genome is a circular chromosome of 4.31 Mbp (CP001280) and a G+C content of 63.1 mol%. In total, 3,917 candidate genes were predicted and 99 pseudogenes were found. Functionality was assigned to 67.9 % of the genes, while 30.9 % of the genes could not be assigned any known function. All tRNA-encoding regions were identified, and two identical rRNA operons were found (Chen et al. 2010). In agreement with previous knowledge of the metabolic capabilities of the organism, the genome analysis permitted to conclusively verify (i) the absence of any *pmoCAB* genes encoding a pMMO enzyme that is present in all other genera of methanotrophs and (ii) the presence of a complete operon encoding sMMO (*mmoXYBZDC*), a complete operon encoding methanol dehydrogenase (*mxaFJGIRSACKLDEH*), and all genes necessary for fixation of methane-derived carbon via the serine cycle. Genes encoding key enzymes in both the tetrahydrofolate and the tetrahydromethanopterin-mediated formaldehyde oxidation pathways were found. Acetate kinase- and phosphotransacetylase-encoding genes are present, allowing acetate to be fed into the tricarboxylic acid (TCA) cycle. Genes encoding glyoxylate bypass enzymes (i.e., isocitrate lyase and malate synthase), essential for bacteria growing on C_2 compounds, were also identified. A full gene set encoding enzymes of the TCA cycle is also present, including genes encoding α-ketoglutarate dehydrogenase, which are lacking in some methanotrophs. Interestingly, a gene cluster encoding di-iron-containing multicomponent propane monooxygenase is also present (Chen et al. 2010).

On the other hand, *B. indica* subsp. *indica* ATCC 9039^T was also a wise choice for its phylogenetic proximity yet different metabolism. Its genome consists of a chromosome of 4,170,153 bp and two plasmids of 181,736 and 66,727 bp (CP001016, CP001017, and CP001018, respectively). There are a total of 3,982 open reading frames predicted, of which 3,784 are predicted protein-coding genes and 2,695 (70 %) have been assigned a predicted function (Tamas et al. 2010). There are 134 pseudogenes, 52 tRNA genes, and three operons each containing 16S, 23S, and 5S rRNA genes. The G+C content is 57.0 % (56 % and 54 % in the plasmids). The initial analysis (Tamas et al. 2010) revealed that this strain lacks phosphofructokinase, the key enzyme of the Embden–Meyerhof pathway. Instead, it uses the Entner–Doudoroff or pentose phosphate pathway to catabolize sugars, which is typical of free-living *Rhizobiales*. The majority of the genes involved in N_2 fixation are clustered in two genomic islands (10 and 51 kb), with the notable exception of the *nifS* gene encoding cysteine desulfurase. *B. indica* is a metabolically versatile bacterium capable of growth on a variety of organic acids, sugars, and alcohols, while *M. silvestris* is a highly specialized methanotrophs capable of growth on very few substrates (Dedysh et al. 2005a). However, their genome sizes (4.17 vs. 4.30 Mbp, respectively) and the numbers of predicted protein-encoding genes (3,788 vs. 3,917, respectively) are remarkably similar. A BLAST analysis indicated that the 57 % of the genes in the genome of *B. indica* have homologues in *M. silvestris* (Tamas et al. 2010). Some key pathways of one-carbon metabolism (such as the tetrahydromethanopterin and serine pathways of formaldehyde metabolism) that are present in *M. silvestris* appear to be absent or incomplete in *B. indica*, which confirms previous experiments showing that the organism is incapable of methylotrophic growth (Dedysh et al. 2005b). However, an operon encoding a putative propane monooxygenase homologous to soluble propane/methane monooxygenases of *M. silvestris* BL2^T was identified. More in-depth comparison of these genomes will help elucidate what defines their distinct lifestyles.

Meanwhile three more genomic sequences (scaffolds or contigs) have become available. One corresponds to *Chelatococcus* sp. GW1, a crude-oil degrading strain that has 5.21 Mb and a G+C content of 68.7 mol%. The other two are from the types of two obligate methanotrophs, *Methylocapsa acidiphila* B2^T and *Methyloferula stellata* AR4^T, with sizes of 4.10 and 4.24 Mb and G+C contents of 61.8 and 59.5 mol%, respectively. This expands considerably the possibilities of performing comparative genome analyses for the study and understanding of methanotrophy.

Using a combination of proteomic, biochemical, and genetic approaches, the identification and characterization of trimethylamine (TMA) monooxygenase gene (*tmm*) from *M. silvestris* have been reported (Chen et al. 2011). This enzyme is an example of bacterial flavin-containing monooxygenase, a system much better studied in eukaryotes and with many important physiological functions. It contained the conserved sequence motif and typical flavin adenine dinucleotide and nicotinamide adenine dinucleotide phosphate-binding domains. It was highly expressed in TMA-grown *M. silvestris* and absent during growth on methanol. Indeed, the ability to use TMA as a sole carbon and/or nitrogen source is directly linked to the presence of *tmm* in the genomes as shown by recombination and mutagenesis experiments. Close homologues of *tmm* occur in many *Alphaproteobacteria*, in particular *Rhodobacteraceae* (marine *Roseobacter* clade) and the marine SAR11 clade (*Pelagibacter ubique*). It is highly abundant in the metagenomes of the Global Ocean Sampling expedition, and it has been estimated that 20 % of the bacteria in the surface ocean contain *tmm*, playing an important role in the global carbon and nitrogen cycles (Chen et al. 2011).

By comparing the genomes of the generalist organotroph *B. indica*, the facultative methanotroph *M. silvestris*, and the obligate methanotroph *M. acidiphila*, Tamas et al. (2014) obtained the first insights into the evolution of the family *Beijerinckiaceae*

[a]Negative or weak and only in young cultures

Fatty acid methyl ester profiles of *B. indica* LMG 2817^T, *B. doebereinerae* LMG 2819^T, and *B. mobilis* LMG 3912^T were obtained by Oggerin et al. (2009). The only major fatty acid was C18:1 ω7c accounting 86.0–92.4 %. C16:0 was the only minor fatty acid present in all three strains (at amounts between 2.8 and 6.9 %), the rest being present only in one or two strains and representing up to 7.0 % of the total composition: C17:0 iso, C18:0, C16:1 and/or C15:0 iso 2-OH, and C17:1 iso and/or anteiso

and into the trade-offs required for a specialist methanotrophic lifestyle compared with a generalist chemoorganotrophic lifestyle. Thus, highly resolved phylogenetic construction based on 29 universally conserved genes demonstrated that the *Beijerinckiaceae* forms a monophyletic cluster with the *Methylocystaceae* (each represented by three genomes in this study), the only other family of alphaproteobacterial methanotrophs. For methanotrophy and methylotrophy genes, a vertical inheritance pattern within these families could be seen. At the same time, many lateral gene transfer events were detected in the genome of *B. indica* for genes encoding carbohydrate transport and metabolism, energy production and conversion, and transcriptional regulation, suggesting that they have been acquired recently. *B. indica* also had a larger abundance of transporter elements, particularly periplasmic-binding proteins and major facilitator transporters. Thus, the authors conclude that the most parsimonious scenario for the evolution of methanotrophy in the *Alphaproteobacteria* is that it occurred only once, when a methylotroph acquired methane monooxygenases via lateral gene transfer. This was supported by a compositional analysis suggesting that all methane monooxygenases in *Alphaproteobacteria* methanotrophs are foreign in origin. Some members of the *Beijerinckiaceae* subsequently lost methanotrophic functions and regained the ability to grow on multicarbon energy substrates. According to that, *B. indica* is a recidivist multitroph, the only known example of a bacterium having completely abandoned an evolved lifestyle of specialized methanotrophy (Tamas et al. 2014).

Phenotypic Analyses

Beijerinckia

Formally, the description of the genus is that of Derx (1950a), although some traits have been studied later (Becking 2006; Kennedy 2005). *Beijerinckia* species are nonsymbiotic, aerobic, chemoheterotrophic bacteria with the ability to fix atmospheric dinitrogen. They utilize a wide range of multicarbon compounds, but sugars are the preferred growth substrates. Members of this genus are straight or slightly curved rods with rounded ends containing polar lipoid bodies (PHB). Cells occur singly or appear as dividing pairs. Individual cells measure 0.5–2.0 × 1.6–4.5 μm (*Table 4.2*), although larger misshapen cells can also be seen. Cysts (enclosing one cell) and capsules (enclosing several cells) may occur in some species. Gram negative. Motile by peritrichous flagella or nonmotile. Aerobic, having a strictly respiratory type of metabolism. N_2 is fixed under aerobic or microaerobic conditions. Growth occurs between 10°C and 35 °C (optimal 20–30 °C); no growth occurs at 37 °C. Growth occurs between pH 3.0 and 10.0. Liquid cultures can become a highly viscous, semitransparent mass; in

some species the whole medium becomes opalescent and turbid, and adhering slime is not produced. On agar media, especially under N_2-fixing conditions, copious slime is produced and giant colonies with a smooth, folded, or plicate surface develop; some strains form slime having a more granular consistency. Catalase positive. Glucose, fructose, and sucrose are utilized by all strains and oxidized to CO_2. No growth occurs on peptone medium. Glutamate is utilized poorly or not at all. Negative for indole production. The G+C of the DNA is 54.4–60.7 mol%.

The chemical structure of the water-soluble polysaccharide, CV-70, produced by one strain of *Beijerinckia* sp. was defined applying different analytical methods. Glucose, galactose, and fucose were identified as the components in the CV-70 polysaccharide, in a 3:1:3 ratio (Scamparini et al. 1997).

A recent study (Jendrossek et al. 2007) has shown that the location of poly-3-hydroxybutyrate granules in *B. indica* and other bacteria is nonrandom. The early stages of formation were examined by confocal laser scanning fluorescence microscopy of Nile red-stained cells and by transmission electron microscopy. Cells of this species harbored one PHB granule at each cell pole, often close to or even in physical contact with the cytoplasmic membrane.

As methanotrophy was being uncovered in the family *Beijerinckiaceae* and given the close phylogenetic distance between *Beijerinckia* and the new genera, and the fact that some of the new species were facultative and not obligate methanotrophs, it became more imperative to check for C_1 metabolism in the genus *Beijerinckia*. Dedysh et al. (2005b) tested five type strains of different *Beijerinckia* species/subspecies (*B. mobilis* DSM 2326^T, *B. indica* subsp. *indica* ATCC 9039^T, *B. indica* subsp. *lacticogenes* DSM 1719^T, *B. derxii* subsp. *derxii* DSM 2328^T, and *B. derxii* subsp. *venezuelae* DSM 2329^T) for their ability to grow on methanol as the sole carbon and energy source in either nitrogen-free medium or supplemented with KNO_3. The only species capable of growth on methanol was *B. mobilis*. Growth occurred under a wide range of methanol concentrations ranging from 0.01 % to 3 % (vol/vol) and was optimal between 0.05 % and 0.5 % (vol/vol) CH_3OH. Growth was obtained under both nitrogen-fixing and nitrogen-sufficient conditions and could be maintained continuously without loss of viability. The enzymatic activities in the metabolism of methanol and glucose have been measured (Smirnova et al. 2005) confirming that *B. mobilis* possesses all the enzymes necessary for oxidation of methanol to CO_2 via formaldehyde and formate coupled with the ribulose bisphosphate (RuBP) pathway of C_1 assimilation. Therefore, *B. mobilis* is a facultative chemoautotrophic methylotroph that in addition to growth on C_1-reduced compounds (methanol and formate) has the ability to use a wide range of multicarbon substrates. These studies also demonstrate that there is more metabolic versatility within representatives of the genus *Beijerinckia* than was previously thought. Although methylotrophic autotrophy could be attributed to only one species of this genus, future studies may extend the number of *Beijerinckia* species capable of C_1 metabolism. In this sense, it is important to mention that *B. doebereinerae* (Oggerin et al. 2009) was described after the publication of these studies and occupies a position that is intermediate between *B. mobilis* and *Methylocapsa* spp. (Fig. 4.1).

Camelimonas

Cells of *Camelimonas* (Kämpfer et al. 2010) are Gram-negative, nonmotile, nonspore-forming rods, approximately 2 µm long and 1 µm wide. Oxidase-positive, showing an oxidative metabolism. Good growth occurs on R2A agar, TSA, PYE agar, and nutrient agar at 25–30 °C. Beige, translucent, and shiny colonies with entire edges are formed within 24 h, with a diameter of about 2 mm. The characteristic peptidoglycan diamino acid is meso-diaminopimelic acid. The predominant compound in the polyamine pattern is spermidine, and sym-homospermidine is absent. The quinone system is ubiquinone Q-10. The polar lipid profile includes the major compounds phosphatidylcholine and diphosphatidylglycerol and moderate amounts of phosphatidylethanolamine, phosphatidylglycerol, an unidentified glycolipid, and two unidentified aminolipids. The major fatty acids are C19:0 cyclo ω8c, C18:1 ω7c, and C16:0, with C18:0 3-OH as the major hydroxylated fatty acid. The G+C content of the DNA of the type strain of the type species is 65 mol%.

The genus contains two species, *C. lactis* (type species) and *C. abortus*, that can be differentiated according to the traits in Table 4.3.

Chelatococcus

Description of the genus *Chelatococcus* is based on Auling et al. (1993) and the emendation by Yoon et al. (2008). Cells are cocci

Table 4.4
Differential traits between *C. asaccharovorans* (Auling et al. 1993), *C. daeguensis* (Yoon et al. 2008), and *C. sambhunathii* (Panday and Das 2010)

	C. asaccharovorans	*C. daeguensis*	*C. sambhunathii*
Cell morphology	Cocci	Rods	Rods

pH optimum for growth	7.0–8.0	7.0–7.5	7.5–8.0

or rods (Table 4.4). Gram negative. Nonmotile. Obligately aerobic. Optimal growth temperature is 35–37 °C and temperature range for growth is 4–41 °C. Poly-β-hydroxybutyrate is accumulated within the cells. Utilization of the metal-chelating nitrilotriacetic acid (NTA) as sole source of carbon, nitrogen, and energy is positive or negative. Ubiquinone Q-10 is present. The major fatty acids are C18:1 ω7c and C19:0 cyclo ω8c. Major polar lipids are phosphatidylcholine, phosphatidylglycerol, phosphatidylethanolamine, two aminolipids, and two unidentified phospholipids. Major polyamines are sym-homospermidine, spermidine, and putrescine. The DNA G+C content is 63.3–68.3 mol%.

The type species, *C. asaccharovorans*, requires one or more vitamins (Auling et al. 1993), whereas growth factors are not needed by the two other established species of the genus. Besides the typical Gram-negative cell envelope (cytoplasmic membrane, murein layer, and outer membrane), *C. asaccharovorans* is surrounded by an additional proteinaceous S-layer approximately 15 nm wide.

There are some traits of the genus description, not formally emended though, that are discrepant in *C. daeguensis* and *C. sambhunathii*. These include temperature growth range (20–50 °C on both species), anaerobic growth with nitrate (both species), and motility (*C. sambhunathii* has one polar flagellum).

Methylocapsa

The description of *Methylocapsa* is that of Dedysh et al. (2002) later emended by Dunfield et al. (2010). Gram-negative, curved coccoids or thick curved rods (Table 4.5) that occur singly or in conglomerates, but do not form rosettes. Surrounded by an extracellular polysaccharide matrix (the etymologic meaning of the genus name is methyl-using cell covered by a capsule). Reproduce by normal cell division. Nonmotile. Produce intracellular poly-β-hydroxybutyrate granules. Resting cells are *Azotobacter* type cysts. Cells are not lysed by 2 % SDS. Cells possess a well-developed intracytoplasmic membrane system of type III which appears as stacks of membrane vesicles packed in parallel on only one side of the cell membrane. Strictly aerobic. Possess pMMO and do not express sMMO. Moderately acidophilic and mesophilic. Prefers dilute media of low salt content. Some members of the genus are obligate utilizers of C_1 compounds via the serine pathway, while others are also capable of growth on acetate, but sugars are not utilized. Does not contain the ribulose monophosphate and ribulose bisphosphate enzymes. Tricarboxylic acid cycle is complete. Capable of atmospheric nitrogen fixation. The major cellular fatty acid is C18:1 ω7c and the major phospholipids are phosphatidylglycerols. The G+C content is 61.4–63.1 mol%.

Methylocella

The isolation of acidophilic methane-oxidizing bacteria from northern peat wetlands (Dedysh et al. 1998a) paved the way for the description of the new genus and species *Methylocella palustris* (Dedysh et al. 2000). Two more species proposals followed, *M. silvestris* (Dunfield et al. 2003) and *M. tundrae* (Dedysh et al. 2004a), each time including an emendation of the genus description. Several characteristics of the genus make

Table 4.5
Differential traits between *M. acidiphila* (Dedysh et al. 2002) and *M. aurea* (Dunfield et al. 2010)

	M. acidiphila	*M. aurea*
Cell morphology	Curved coccoids	Thick curved rods
Cell size	0.5–0.8 × 0.8–1.2 μm	0.7–1.2 × 1.8–3.1 μm
Growth on solid media	Not achieved	Yellow colonies
Carbon sources	Methane and methanol (obligate methanotrophy)	Methane, methanol, formate, and acetate (facultative methanotrophy)
pH range for growth (optimal)	4.2–7.2 (5.0–5.5)	5.2–7.2 (6.0–6.2)
Temperature range for growth (optimal)	10–30 °C (20–24 °C)	2–33 °C (25–30 °C)
Growth in nitrogen-free medium under fully aerobic conditions	+	–
Growth inhibited by NaCl (w/v)	0.5 %	0.3 %

it unique compared with other methanotrophic bacteria. Representatives of this genus do not contain an intracytoplasmic membrane system like that in all other known methanotrophs and appear to possess only a soluble form of methane monooxygenase (sMMO).

Methylocella spp. are Gram-negative, polymorphic rods or ovoids that are 0.6–1.0 μm wide by 1.0–2.5 μm long with rounded ends. Produce large, highly refractile, intracellular poly-β-hydroxybutyrate granules. Reproduce by normal cell division. Cells occur singly or in irregularly shaped aggregates, but do not form rosettes. Nonmotile. Encapsulated. Cells are not lysed by 2 % SDS. Cells lack an extensive ICM system typical of both type I and type II methanotrophic bacteria but contain a vesicular membrane system composed of singular flattened or ovoid vesicles connected to the cytoplasmic membrane. Possess sMMO. The temperature range for growth is 4–30 °C with an optimum at 15–25 °C; no growth occurs at 37 °C. Growth occurs between pH 4.2 and 7.5. Highly sensitive to salt stress; prefer diluted media with a low salt content. Utilize C_1 compounds via the serine pathway. Do not contain the enzymes of the ribulose monophosphate and ribulose bisphosphate pathways. The tricarboxylic acid cycle is complete. Fix atmospheric nitrogen via an oxygen-sensitive nitrogenase. The major phospholipid fatty acids are 18:1 ω7c acids. The G+C content of the DNA is 60–63 mol%.

The intact phospholipid profiles of *M. palustris* using liquid chromatography/electrospray ionization/mass spectrometry (Fang et al. 2000) revealed it has a preponderance of phosphatidylmethylethanolamine phospholipids with C18:1 fatty acids. The relative abundance of C18:1 is one of the features that help to discriminate species of the genus (*Table 4.6*).

Methylocella species are considered the first fully authenticated examples of facultative methanotrophs (Dedysh et al. 2005a). In addition to methane and methanol, they can utilize as well multicarbon compounds, such as acetate, pyruvate, succinate, malate, and ethanol. This ability does not include other compounds tested, urea, glucose, fructose, sucrose, lactose, galactose, xylose, sorbose, maltose, raffinose, arabinose, ribose, lactate, oxalate, citrate, mannitol, or sorbitol, but clearly provides a competitive advantage in natural environments where methane production is temporally heterogeneous due to fluctuations in temperature, water content, and water table level (Segers 1998). The molecular regulation of methane oxidation in *M. silvestris* $BL2^T$ during growth on methane and acetate has been assessed (Theisen et al. 2005).

Methyloferula

Shortly after the description of *Methylovirgula* (Vorob'ev et al. 2009), another genus of rosette-forming bacteria was proposed in the family *Beijerinckiaceae*. *Methyloferula* (Vorobev et al. 2011), an obligate methanotroph, was described as Gram-negative, aerobic, colorless, nonmotile rods that occur singly or are arranged in rosettes and misshapen cell clusters. Reproduce by irregular fission. Colonies are small, circular, and smooth. The colony color varies from white to cream. Produce poly-β-hydroxybutyrate. Mesophilic and moderately acidophilic. Prefer dilute media of low salt content. Obligate utilizers of methane and methanol; the latter is the preferred growth substrate. Possess only a soluble MMO. Positive to RubisCO activity. Capable of atmospheric nitrogen fixation. The major fatty acid is 18:1 ω7c. The major quinone is Q-10. The G+C content of the DNA is 55.6–57.5 mol%.

The type species *M. stellata* is the only one of the genus to date. Its cells are 0.4–0.65 μm wide and 1.1–3.0 μm long. Carbon sources include methane and methanol. Grows optimally at methanol concentrations of 0.5–1 %. Nitrogen sources (0.05 %, w/v) include ammonia, nitrate, urea, and yeast extract. Capable of growth at pH 3.5–7.2 (optimum pH 4.8–5.2) and at 4–33 °C (optimum 20–23 °C). NaCl inhibits growth at concentrations above 0.7 % (w/v).

Methylorosula

Methylorosula (Berestovskaya et al. 2012) is described as Gram-negative rods that are not capable of nitrogen fixation. Aerobic, facultative methylotrophic bacteria.

Table 4.6
Differential traits between *M. palustris* (Dedysh et al. 2000), *M. silvestris* (Dunfield et al. 2003), and *M. tundrae* (Dedysh et al. 2004a). Substrate utilization from (Dedysh et al. 2005a)

	M. palustris	*M. silvestris*	*M. tundrae*
Cell morphology	Straight or curved short rods	Straight or curved short rods	Curved ovoids
Macrocapsule (slimy colonies)	+	+	–
pH range for growth (optimal)	4.5–7.0 (5.5)	4.5–7.0 (5.5)	4.2–7.5 (5.5–6.0)
Temperature range for growth (optimal)	10–28 °C (20 °C)	4–30 °C (15–25 °C)	5–30 °C (15 °C)
Growth inhibited by NaCl (w/v)	0.5 %	0.8 %	0.8 %
Concentration range of methanol (v/v) utilization	0.01–0.1 %	0.01–5 %	0.01–2 %
Substrate utilization			
Formate	–	–	w
Methylamine	w	+	+
Fatty acids (%)			
16:1 ω7t	5.8	0	0
17:0 cyclo	0	0	5.0–6.5
18:1 ω7c	78.6	82.2	59.2–61.7
19:0 ω8c cyclo	0	0	7.9–13.6

Chemoorganoheterotrophic. Use the RuBP pathway for carbon assimilation. The dominant cellular fatty acid is C18:1 ω7c.

M. polaris is the type species, and only species thus far, of the genus. Its cells are long, bipolar rods (0.5–0.6 × 1.3–4.5 μm) that are single or form rosettes. Reproduces by irregular fission. Young cells are motile by means of a subpolar flagellum. Forms pale, non-translucent slimy (mucoid) colonies with an uneven edge. Resting cells are not known. After 2 weeks of growth on methanol at 20 °C, colonies are 1.5–2.0 mm in size. Utilizes C_1 compounds, methanol and methylamines, sugars, polysaccharides, sugar alcohols, and amino acids as a carbon and energy source. The temperature and pH ranges for growth are 4–30 °C (optimum, 20–25 °C) and pH 4.0–7.8 (optimum, pH 5.5–6.0), respectively. NaCl is not required for growth and is tolerated up to a concentration of 2.0 % (w/v). The major fatty acid is C18:1 ω7c. The DNA G+C content of the type strain is 65.2 mol%.

Methylovirgula

The genus *Methylovirgula* (Vorob'ev et al. 2009) contains Gram-negative, aerobic, colorless, nonmotile, thin rods that occur singly or are arranged in rosettes and misshapen cell clusters. Reproduce by binary fission. Colonies are small, circular, smooth, and convex. The colony color varies from white to cream. Produce poly-β-hydroxybutyrate. Obligately acidophilic and mesophilic. Prefer dilute media of low salt content. Restricted facultative methylotrophs. Assimilate methanol-derived carbon via the RuBP pathway. Capable of atmospheric nitrogen fixation. The major phospholipid fatty acid is C18:1 ω7c, and the major phospholipids are phosphatidylethanolamine, phosphatidylcholine, and phosphatidylglycerols. The major quinone is Q-10. The G+C content of the DNA varies between 61.8 and 62.8 mol%.

The type and only species is *M. ligni*, whose cells are 0.3–0.65 μm wide and 1.2–2.5 μm long. Resting cell forms are absent. Carbon sources include methanol, ethanol, pyruvate, and malate. Grows optimally at methanol concentrations of 0.5–1 %. Nitrogen sources used (at 0.05 %, w/v) include ammonia, nitrate, and yeast extract. Growth factors are required. Capable of growth at pH 3.1–6.5 (optimum pH 4.5–5.0) and at 4–30 °C (optimum 20–24 °C). NaCl inhibits growth at concentrations above 0.7 % (w/v).

Enrichment, Isolation, and Maintenance Procedures

Strategies for enrichment and isolation are different depending on the metabolism and physiology considered.

Beijerinckia spp. are chemoheterotrophic diazotrophs, mesophilic, able to grow on a wide range of pH (including values as low as 3.0 units), and known to show a preference for sugars as carbon sources. Complex media such as peptone medium are even inhibitory and yield no growth. Thus, nitrogen-free media with low pH are considered selective for members this genus. A simple formulation used in early studies (Becking 1961; Derx 1950a, b) contains (g/l of distilled water) glucose, 20.0; KH_2PO_4, 1.0; and $MgSO_4 \cdot 7H_2O$, 0.5 (pH is adjusted to 5.0). Aeration is important to inhibit the development of nitrogen-fixing anaerobes. So, instead of using tubes, the medium can be poured as thin layers (2–3 mm) into Petri dishes. Approximately 0.5 g of soil per plate can be used as inoculum. This provides also the necessary trace elements. For water samples, for example,

irrigation water, larger inocula might be needed to compensate the much lower presence of *Beijerinckia* in this type of habitat. Enrichment can be then approached mixing the water sample with sterile double-strength medium before dispensing the dishes as before. Samples collected from the phyllosphere can be immersed in the enrichment medium for the same purpose. Recommended incubation is at 30 °C for 2 or more weeks. Positive enrichments cultures can be streaked on the following isolation nitrogen-free, mineral agar medium (Becking 2006) that contains (g/l of distilled water) glucose, 20.0; K_2HPO_4, 0.8; KH_2PO_4, 0.2; $MgSO_4 \cdot 7H_2O$, 0.5; $FeCl_3 \cdot 6H_2O$, 0.025; $Na_2MoO_4 \cdot 2H_2O$, 0.005; $CaCl_2$, 0.05; and agar 15.0 (pH is adjusted to 6.9) that can also be used for routine maintenance. Development of exopolysaccharide, a common trait of *Beijerinckia*, can be easily recognized by the slimy appearance of the colonies or by the viscosity of liquid-aged cultures. An easy confirmation step is plating on peptone medium because *Beijerinckia* will not develop, whereas other free-living diazotrophs such as *Azotobacter* or *Azomonas* will grow readily.

Camelimonas have been isolated from two different farm animals in different countries but using very similar media. Strains *C. lactis* M 2040^T, M 1973, and M 1878-SK2 were initially cultivated on *Brucella* agar (Difco) from milk of different camels of a camel milk production farm in the United Arab Emirates during routine bacteriological testing for *Brucella* species in 2008 (Kämpfer et al. 2010). *C. abortus* UK34/07-5^T was initially cultured on Farrell's medium (Farrell 1974) from placental tissue following a case of abortion in a Holstein–Friesian cow in Derbyshire, UK, in 2007 (Kämpfer et al. 2012). Farrell's medium was manufactured using a *Brucella* medium base (CM0169; Oxoid) and a Brucella selective supplement (SR0209E; Oxoid). So, it seems that an adequate formulation is (g/l of distilled water) peptone, 10.0; "Lab-Lemco" powder, 5.0; glucose, 10.0; NaCl, 5.0; and agar, 15.0 (pH 7.5). Antibiotic combinations used as selective supplements for *Brucella* can also favor the growth of *Camelimonas* sp., as occurred with *C. abortus*. In both cases, the classical methods for identification of *Brucella* species failed because they are phenotypically very distinct. Subcultivation was done in tryptone soy agar (Kämpfer et al. 2010, 2012) and other common general media can be also employed.

The two strains that served for the description of ***Chelatococcus*** *assacharovorans* were isolated with a batch enrichment procedure using nitrilotriacetic acid (NTA) as the only source of carbon, energy, and nitrogen (Egli 1988). However, they were not as easily enriched as members of the genus *Chelatobacter*. The fact that the optimal growth temperature of *Chelatococcus* strains (35–37 °C) is considerably higher than that of *Chelatobacter* strains, together with their resistance to vancomycin, was proposed to enrich for *Chelatococcus* when using NTA as the only source of carbon and nitrogen for growth (Egli and Auling 2005). However, the next two species of the genus, each based on a single strain, were obtained following a more general approach. *C. daeguensis* K106^T (Yoon et al. 2008) was isolated from wastewater of a textile dye works in Korea, by means of the standard dilution-plating technique on trypticase soy agar (TSA; Difco) at 30 °C. *C. sambhunathii* HT4^T (Panday and Das 2010) was retrieved from sediment of an Indian hot spring that was inoculated into a 250 ml conical flask containing 50 ml nutrient broth (Difco) and incubated on a shaker at 200 r.p.m. and 45 °C. After 2 days incubation, the contents of the flasks were serially diluted and plated onto nutrient agar medium (Difco) and incubated at 37 °C for 4 days, after which colonies were picked and purified by repeated streaking on the same medium. Interestingly, *C. sambhunathii* HT4^T showed a nutritional pattern closer to *C. asaccharovorans* than to *C. daeguensis* (Table 4.4) and was also able to grow on NTA as single carbon, nitrogen, and energy source although it had not been used for the enrichment and isolation.

Methylocapsa, ***Methylocella***, and ***Methyloferula*** are methanotrophs, either facultative or obligately, that can be cultivated using liquid or solid mineral media with methane as growth substrate (Dedysh and Dunfield 2011). Facultative methanotrophic species can utilize multicarbon compounds, but its use for isolation or even maintenance is not recommended since these substrates give a selective advantage to chemoorganoheterotrophs that will contaminate and surpass the methanotrophic cultures. Two media have been successfully applied for the enrichment and isolation of most strains of these three genera:

- Nitrogen-free medium M2 (Dedysh et al. 1998b) containing (in grams per liter of distilled water) KH_2PO_4, 0.04; $MgSO_4 \cdot 7H_2O$, 0.02; and $CaCl_2 \cdot 2H_2O$, 0.004, with the addition of 0.1 % (by volume) of a trace elements stock solution containing (in grams per liter) EDTA, 5; $FeSO_4 \cdot 7H_2O$, 2; $ZnSO_4 \cdot 7H_2O$, 0.1; $MnCl_2 \cdot 4H_2O$, 0.03; $CoCl_2 \cdot 6H_2O$, 0.2; $CuCl_2 \cdot 5H_2O$, 0.1; $NiCl_2 \cdot 6H_2O$, 0.02; and Na_2MoO_4, 0.03. The initial pH of the medium can be adjusted with concentrated phosphoric acid from 6 to 3.
- Dilute nitrate mineral salts (DNMS) medium (Dunfield et al. 2003) containing (in grams per liter of distilled water) KNO_3, 0.2; $MgSO_4 \cdot 7H_2O$, 0.2; $Na_2HPO_4 \cdot 12H_2O$, 0.143; KH_2PO_4, 0.054; and $CaCl_2 \cdot 6H_2O$, 0.04 and containing 1 mM NaH_2PO_4/Na_2HPO_4 buffer (pH 5.8).

For growth in liquid medium, screw cap serum bottles are used with a headspace/liquid space ratio of 4:1. After inoculation, the bottles are sealed with silicone rubber septa, and methane is added aseptically using a syringe equipped with a disposable filter (0.22 μm) to achieve a 15–20 % mixing ratio in the headspace. Bottles can be incubated on a rotary shaker (120 r.p.m.) at 20–25 °C. Solid media are prepared adding agar or gellan gum as solidifying agents (15 g per liter). These media are incubated in closed vessels or desiccators containing air supplemented with (v/v) CH_4 (10–30 %) and CO_2 (5 %) and can be used for maintenance.

Of course, other formulations are possible (Vorobev et al. 2011; Dedysh and Dunfield 2011) with variations in the presence or the amount of minerals and/or adjusted pH. Initial incubation times are long (up to 2 months). Methanotrophic cultures are frequently contaminated by heterotrophic bacteria that survive on metabolic by-products of methanotrophs. The presence of only a few satellite cells in a culture may lead to false

conclusions regarding substrate utilization, and several early reports of facultative methanotrophy are likely attributable to impure cultures. Another recurring mistake is the misidentification of non-methanotrophic facultative methylotrophs as facultative methanotrophs. Valuable advice on how to differentiate and identify facultative and obligate methanotrophs, not necessarily members of the family *Beijerinckiaceae*, is given by Dedysh and Dunfield (2011).

Media based on methane as carbon source are not suited for the facultative methylotrophic genera ***Methylorosula*** and ***Methylovirgula*** because they lack MMO. But actually, the three strains that conformed *Methylorosula polaris* (Berestovskaya et al. 2012) were isolated from acidophilic, methanotrophic enrichments obtained from *Sphagnum* peat of three tundra wetland sites of Northern Russia. Cell suspensions of these enrichments were spread onto medium 2A (Berestovskaya et al. 2002) agar plates, containing 2 % (w/v) agar (Difco) and amended with 0.5 % methanol as the sole carbon source. Mineral medium 2A had been specially developed to cultivate microorganisms from ultrafresh habitats due to its low mineralization (mg/l): NH_4SO, 500; $MgCl_2$, 40; KH_2PO_4, 70; and a solution of microelements, 1 ml/l (Berestovskaya et al. 2002). In the case of *Methylovirgula ligni*, each of the two strains that served for its description was recovered from a nutrient-rich, although diluted, medium. One of them, designated medium W5, had the following composition (per liter of demineralized water): NaCl, 1 g; yeast extract, 0.1 g; 2-[*N*-morpholino]ethane sulfonic acid (MES) as a buffering compound, 1.95 g; and agar, 20 g. Medium T5 contained (per liter) NaCl, 1 g; trypticase soy broth (Oxoid), 3 g; MES, 1.95 g; and agar, 20 g. Attempts to maintain both strains on their respective isolation media proved they were not suited for optimal growth and a slightly modified medium M2 (designated medium MM2) resulted in good development of the strains when methanol was provided as a growth substrate. Thus, further maintenance and cultivation experiments with these bacteria were performed using medium MM2 of the following composition (mg per liter distilled water): $(NH_4)_2SO_4$, 200; KH_2PO_4, 100; $MgSO_4$, 50; $CaCl_2 \cdot 2H_2O$, 20; yeast extract, 10; and methanol, 0.5 % (v/v) (pH 4.8–5.2). For growth in liquid media, 500 ml screw-capped serum bottles were used with a headspace/liquid space ratio of 4:1. After inoculation, methanol was added aseptically to the cultures, and the bottles were capped with silicone rubber septa to prevent loss of methanol by evaporation. Bottles were incubated on a rotary shaker (120 r.p.m.) at 24 °C.

In addition to periodic transfer using the maintenance media referred above, members of the family can be successfully maintained using the common long-term preservation protocols and techniques, that is, lyophilization and deep freezing of cell suspensions in the presence of lyo-/cryoprotectants. The possibility of preserving *Beijerinckia* cultures by encapsulation using a spray drier, for use in biotechnological processes in the production of biopolymers, has been addressed (Boza et al. 2003). Among different wall (coating) malt dextrin presented the greatest stability with respect to fermentative activity, although the glucose-encapsulated cells showed the highest percentage of viability during spray drying and during the storage period.

Ecology

Members of the type genus ***Beijerinckia*** are commonly found as free-living bacteria in acidic soils and also in plant rhizosphere and phyllosphere environments. The earliest recorded isolations (Becking 2006) are from a Malaysian quartzite soil (pH 4.5) by Altson (1936), from a Dacca, Bangladesh, soil (pH 4.9), and from a soil of Insein, Burma (pH 5.2), by Starkey and De (1939), although considered at that time *Azotobacter* spp. Later it was found to be widely distributed in the more acidic soils of mainly tropical regions, and it was also isolated from neutral and slightly alkaline soils and outside the tropics. In a large soil survey covering 392 soils of worldwide distribution, *Beijerinckia* was found in some temperate and subtropical soils of Europe (former Yugoslavia), South Africa, India, China, and Japan (Becking 1959, 1961). Other authors mention its isolation from other nontropical soils, i.e., from an acidic volcanic ash soil of Sendai, Tohoku District, Japan (lat. 38°N) (Suto 1954, 1957); from some Indian nontropical soils (up to lat. 27–30°N) (Barooah and Sen 1959); in some subtropical and nontropical soils in Australia (lat. 15–43°S) (Tchan 1953; Thompson 1968; Thompson and Skerman 1979); and in two soils of Egypt (Kharga Oasis, lat. 25°N) (Vančura et al. 1965). In addition, it was isolated from some Pacific Northwest soils in North America (Snake River Plain, Idaho, USA; lat. 44°N), from soil of the Squamish Bay Area, British Columbia, Canada (lat. 50°N) by Anderson (1966). Also, Jordan and McNicol (1978) reported the isolation of *Beijerinckia* from three sites of a permanently cold, high Arctic soil (Devon Island, Northwest Territories; lat. 75°N).

Distribution in the more tropical soils of the African continent was largely explored. In addition to the South African soils already mentioned (Becking 1959, 1961) *Beijerinckia* was observed to occur in soils of Zimbabwe (Meiklejohn 1968), Ivory Coast (Kauffmann and Toussaint 1951a, b), Sudan (Hegazi and Ayoub 1979), Sierra Leone, Nigeria, Ethiopia, Uganda, Kenya, Tanzania, and Congo/Zaire (Becking 1961). *Beijerinckia* was also found in many soil samples of South America: Argentina (Amor Asunción et al. 1980), Trinidad Island, Surinam, Venezuela, Bolivia, and Brazil (Becking 1961).

Decades of research on the biological nitrogen fixation in graminaceous plants in Brazil (Baldani and Baldani 2005) have provided many insights on ecology of *Beijerinckia*. It was demonstrated that the size of the populations was related to vegetation, physical, and chemical characteristics of the soil (Döbereiner and Castro 1955). Further studies on the occurrence of this genus in soil of several Brazilian States (Rio de Janeiro, São Paulo, Pernambuco and Paraná) led to the description of *B. fluminensis* (Döbereiner and Ruschel 1958). Analysis of 158 samples collected in different regions of Brazil showed that this species occurred predominantly in soils where sugarcane was cultivated (Döbereiner 1959a) and a direct influence of

the plant on the development of the bacteria was suggested (Döbereiner 1959b). Additional studies showed that roots as well as leaves and stems had a positive influence on *Beijerinckia* populations. This was influenced by the exudation of substances into the soil by the roots during rainfall (Döbereiner and Alvahydo 1959). The population of *Beijerinckia* was much more pronounced in the rhizoplane region (refers to the soil adherent to the root surface) than in the rhizosphere. In addition, it was shown that removal of the aerial part of the plant significantly reduced the population of bacteria in both the rhizoplane and rhizosphere regions (Döbereiner 1961). Rice plants grown in greenhouse and inoculated with *Beijerinckia* showed the establishment of the bacteria as well as an increase in the yield (Döbereiner and Ruschel 1961). The measurement of the nitrogenase activity in roots of sugarcane, thanks to the introduction of acetylene reduction methodology, showed that it was much higher than that observed in the rhizosphere and in soil between the plant rows. *B. indica* was the most abundant bacterial species in both roots and soil samples (Döbereiner et al. 1972). Quantification of nitrogen fixation in sugarcane based on the extrapolation of the nitrogenase activity data indicated a contribution of 50 kg N/ha/year to the soil/plant system (Döbereiner et al. 1973).

Concerning habitats other than soil, Ruinen (1956, 1961) found *Beijerinckia* as a regular component of the phyllosphere of tropical plants. Diem et al. (1978) have used the fluorescent antibody technique to study the behavior of a *Beijerinckia* isolate in the rhizosphere and seed region (spermosphere) of rice seedlings in Camargue (France). Also in rice, Karkhanis and Tikhe (1980) and Karkhanis (1987) reported not only its presence in the rhizosphere but also its intracortical occurrence within the rice root. Murty (1984) measured nitrogenase activities on the leaf surfaces of different varieties of cotton (*Gossypium hirsutum* L. and *G. herbaceum* L.) plants, and *Beijerinckia* sp. was observed to be the predominant nitrogen-fixing microorganism in the phyllosphere of these varieties.

Jackson and Denney (2011) studied the annual and seasonal variation in the phyllosphere bacterial community associated with leaves of the southern Magnolia (*Magnolia grandiflora*) using multivariate analysis of denaturing gradient gel electrophoresis profiles of 16S rRNA gene fragments. Temporal changes had a much greater variation than leaf to leaf. This was confirmed by sequencing and analysis of 16S rRNA gene clone libraries generated for each sample date. All phyllosphere communities were dominated by *Alphaproteobacteria*, with a reduction in the representation of *Beijerinckiaceae* related to *B. indica* and *M. silvestris* during the summer and a concurrent increase in the *Methylobacteriaceae* being the most significant seasonal change.

The knowledge about the ecology of ***Camelimonas*** is limited to the information of the habitat from where the two species described were isolated: milk of camels at a camel milk production farm in the United Arab Emirates for *C. lactis* (Kämpfer et al. 2010) and placental tissue following a case of abortion in a Holstein–Friesian cow in the UK for *C. abortus* (Kämpfer et al. 2012). This limitation does not occur with ***Chelatococcus***; the type species *C. asaccharovorans* was isolated from wastewater and soil in Switzerland (Auling et al. 1993), but its ubiquitous distribution in surface waters and sewage treatment plants was shown by immunofluorescence (Wilberg et al. 1993). *C. daeguensis* was indeed isolated from wastewater, in this case, from textile dye works in the Republic of Korea (Yoon et al. 2008), while *C. sambhunathii* originated from a hot spring sediment in India (Panday and Das 2010). In addition to water, soils can also be inhabited by *Chelatococcus*. In a recent study (Fredrickson et al. 2008) dealing with bacterial cultures obtained from irradiated soils in Washington (USA), 6 out of 47 were identified as *Chelatococcus* sp. For extremely ionizing radiation-resistant bacteria, survival has been attributed to protection of proteins from oxidative damage during irradiation, with the result that repair systems survive and function with far greater efficiency during recovery than in sensitive bacteria. The relationship between survival of dry climate soil bacteria and the level of cellular protein oxidation induced by desiccation was examined. Desiccation-resistant isolates accumulated high intracellular manganese and low iron concentrations compared to sensitive bacteria. In vivo, proteins of desiccation-resistant bacteria were protected from oxidative modifications that introduce carbonyl groups in sensitive bacteria during drying. Members of *Chelatococcus* have also been identified among other genera present in the headbox water of a paper machine in Canada (Prince et al. 2009), using an amplified ribosomal DNA restriction analysis.

Acidic wetlands, particularly *Sphagnum* peat bogs, from different sites of Russia and forest soils from Germany, Russia, and the Netherlands were the habitats from where the species of ***Methylocapsa***, ***Methylocella***, ***Methyloferula***, ***Methylorosula***, and ***Methylovirgula*** were originally isolated (Berestovskaya et al. 2012; Dedysh et al. 2000, 2002, 2004a; Dunfield et al. 2003, 2010; Vorob'ev et al. 2009; Vorobev et al. 2011).

Wetlands with peat-forming soils (peatlands) provide habitat for anaerobic archaeal methanogens that produce CH_4 under strictly anoxic conditions, usually below the water table. In contrast aerobic methane-oxidizing bacteria (methanotrophs) are active primarily above the water table in aerated portions of the soil and play an important role in wetlands by limiting CH_4 emissions to the atmosphere. Given the global scope of bogs, the number of molecular studies of methanotrophs in these sites is still small. Gupta et al. (2012) investigated the active methanotroph community in two contrasting North American peatlands, a nutrient-rich sedge fen and nutrient-poor *Sphagnum* bog using in vitro incubations and DNA stable-isotope probing (DNA-SIP) with ^{13}C–CH_4. This approach avoids cultivation biases or issues associated with facultative methanotrophs such as members of the genus *Methylocella* being active, but not necessarily using CH_4 as a substrate. Rates of CH_4 oxidation were slightly, but significantly, faster in the bog, and methanotrophs belonged to the class *Alphaproteobacteria* and were similar to other methanotrophs of the genera *Methylocystis*, *Methylosinus*, and *Methylocapsa* or *Methylocella* detected in, or isolated from, European bogs. The fen had a greater phylogenetic diversity of organisms that had

assimilated ^{13}C, including methanotrophs from both the *Alpha-* and *Gammaproteobacteria* classes and other potentially non-methanotrophic organisms that were similar to bacteria detected in a UK and Finnish fen. Based on similarities between bacteria in North American sites and those in Europe, including Russia, it was concluded that site physicochemical characteristics rather than biogeography controlled the phylogenetic diversity of active methanotrophs and that differences in phylogenetic diversity between the bog and fen did not relate to measured CH_4 oxidation rates (Gupta et al. 2012). Using a different approach, fluorescent in situ hybridization with 16S rRNA targeted oligonucleotide probes; Dedysh et al. (2003) detected *Methylocystis* spp. as the numerically largest methanotroph group in peat from Siberia and Germany, followed by *Methylocapsa acidiphila* and *Methylocella palustris*. *M. acidiphila* was enumerated in both samples at greater than 10^5 cells g^{-1} of peat. This accounted for 5 % and 2 % of total methanotroph cells detected by FISH in peat from Siberia and Germany, respectively. In contrast, the population sizes of *M. palustris* were significantly different in *Sphagnum* peat from West Siberia (10^6 cells g^{-1} of peat) and northern Germany (10^4 cells g^{-1} of peat). But, the possibility that some unknown species of acidophilic *Methylocella* and *Methylocapsa* escaped detection by FISH with the available set of oligonucleotide probes cannot be excluded. Besides, these values refer to single-time, single peat soil depth sample measurements. Significant variations in methanotroph community structure and abundance might occur in different subsites and depths as well as on a seasonal scale. In addition, some environmental factors (variation in temperature, aeration conditions, substrate availability) might also have a strong impact on population dynamics of different methanotrophs in acidic peatlands. Indeed, a previous study at Bakchar bog, Plotnikovo field station in west Siberia, 56°N, 82°E, revealed *M. palustris* as predominant methanotroph well above *Methylocystis* (Dedysh et al. 2001a).

Radajewski et al. (2002) applied DNA-SIP to characterize the active methylotroph populations in microcosms in an oak (*Quercus petraea*) forest soil (pH 3.5) collected from the Gisburn Forest Experiment, UK. The microcosms were exposed to $^{13}CH_3OH$ or $^{13}CH_4$ and distinct ^{13}C-labeled DNA fractions were resolved from total community DNA by CsCl density gradient centrifugation. Subsequent analysis of amplified 16S rRNA sequences from these ^{13}C-DNA revealed bacteria related to the genera *Methylocella*, *Methylocapsa*, *Methylocystis*, and *Rhodoblastus*. Enrichments targeted towards the active proteobacterial CH_3OH utilizers were successful, although none of these bacteria were isolated into pure culture. Chen et al. (2008) investigated the active methanotroph community in heather (*Calluna*)-covered moorlands and *Sphagnum-*/*Eriophorum*-covered UK peatlands. Direct extraction of mRNA from these soils facilitated detection of expression of methane monooxygenase genes, which revealed that particulate methane monooxygenase, and not soluble methane monooxygenase, was probably responsible for CH_4 oxidation in situ, because only *pmoA* transcripts (encoding a subunit of particulate methane monooxygenase) were readily detectable. Differences in methanotroph community structures were observed between both habitats. In *Calluna*-covered moorlands, in addition to *Methylocella* and *Methylocystis*, a unique group of peat-associated type I methanotrophs (*Gammaproteobacteria*) and a group of uncultivated type II methanotrophs (*Alphaproteobacteria*) were also found. The *pmoA* sequences of the latter were only distantly related to *Methylocapsa* and also to the RA-14 group of methanotrophs, which are believed to be involved in oxidation of atmospheric CH_4. Soil samples were also labeled with $^{13}CH_4$, and subsequent analysis of the ^{13}C-labeled phospholipid fatty acids showed that C16:1 ω7, C18:1 ω7, and C18:1 ω9 were the major labeled fatty acids. Since C18:1 ω9 is not a major fatty acid of any established species of methanotroph, it suggests the presence of novel species in this peatland. The *Sphagnum-*/*Eriophorum*-covered gullies were dominated by *Methylocystis*, but *Methylocella*- and *Methylocapsa*-related species were also present.

Corsican pine (*Pinus nigra*) roots colonized by the ectomycorrhizal (ECM) fungi, *Suillus variegatus* and *Tomentellopsis submollis*, were examined analyzing the diversity of bacterial nitrogenase genes (*nifH*) present and their mRNA transcription (Izumi et al. 2006). DNA-derived *nifH* PCR products were obtained from all samples, but only a few reverse transcription PCRs for *nifH* mRNA were successful, suggesting that nitrogenase genes were not always transcribed. Putative nitrogenase amino acid sequences revealed that more than half of the *nifH* products were derived from methylotrophic bacteria, such as *Methylocella* spp.

Methanotroph abundance was analyzed in control and long-term nitrogen-amended pine and hardwood soils in Massachusetts, USA (42°13′N, 72°11′W) using rRNA-targeted quantitative hybridization (Lau et al. 2007). Family-specific 16S rRNA and *pmoA*/*amoA* genes were analyzed via PCR-directed assays to elucidate methanotrophic bacteria inhabiting soils undergoing atmospheric methane consumption. Quantitative hybridizations suggested methanotrophs related to the family *Methylocystaceae* were one order of magnitude more abundant than *Methylococcaceae* and more sensitive to nitrogen addition in pine soils. 16S rRNA gene phylotypes related to known *Methylocystaceae* and acidophilic methanotrophs and *pmoA*/*amoA* gene sequences, including three related to the upland soil cluster *Alphaproteobacteria* (USCalpha) group, were detected across different treatments and soil depths. The result suggested that methanotrophic members of the *Methylocystaceae* and *Beijerinckiaceae* may be the candidates for soil atmospheric methane consumption (Lau et al. 2007).

Landfills are also a suitable habitat for methanotrophs with important ecological implications. The identity of active methanotrophs in Roscommon (Ireland) landfill cover soil, a slightly acidic peat soil, was assessed by DNA-SIP (Cébron et al. 2007). Landfill cover soil slurries were incubated with ^{13}C-labeled methane and under either nutrient-rich nitrate mineral salt medium or water. 16S rRNA gene analysis revealed that the cover soil was mainly dominated by Type II methanotrophs closely related to the genera *Methylocella* and *Methylocapsa* and to *Methylocystis* species. These results were supported by analysis

of *mmoX* genes in ^{13}C-DNA. Analysis of *pmoA* gene diversity indicated that a significant proportion of active bacteria were also closely related to the Type I methanotrophs, *Methylobacter*, and *Methylomonas* species. Phylogenetic analysis of mRNA recovered from the soil indicated that *Methylobacter*, *Methylosarcina*, *Methylomonas*, *Methylocystis*, and *Methylocella* were actively expressing genes involved in methane and methanol oxidation. Transcripts of *pmoA*, but not *mmoX*, were readily detected by reverse transcription polymerase chain reaction (RT-PCR), indicating that particulate methane monooxygenase may be largely responsible for methane oxidation in situ (Chen et al. 2007).

Another study (Han et al. 2009), involving 16S rRNA gene and functional gene clone libraries and microarray analyses using *pmoA*, investigated the methanotroph community structure in alkaline soil from a Chinese coal mine. This environment contained a high diversity of methanotrophs, including the type II *Methylosinus* and *Methylocystis*, type I *Methylobacter*, *Methylosoma*, *Methylococcus*, and a number of as yet uncultivated methanotrophs. In order to identify the metabolically active methane-oxidizing bacteria from this alkaline environment, DNA-SIP experiments using $^{13}CH_4$ were carried out. This showed that both type I and type II methanotrophs were active, together with methanotrophs related to *Methylocella*, which had previously been found only in acidic environments. This finding opened the question if *Methylocella* species are widely distributed in nature and not restricted to acidic environments. The affirmative answer came through another study (Rahman et al. 2011) employing a real-time quantitative PCR method and primers targeting *Methylocella mmoX*.

Application

Beijerinckia have received attention due to their plant growth-promoting properties (Miyasaka et al. 2003; Thuler et al. 2003) and for their abundant production of exopolysaccharide with potential biotechnological uses (Scamparini et al. 1997).

Nitrogen-fixing bacteria are probably among the most extensively studied soil microorganisms. Several genera of free-living, N_2-fixing bacteria occur in high numbers in the rhizosphere, rhizoplane, and phyllosphere, and *Beijerinckia* is one of the most notable genera. Inoculation of rice seeds with *Beijerinckia* showed that this genus is able to multiply in the soil, establishing itself in large numbers and reducing the number of other competing microorganisms (Döbereiner and Ruschel 1961). It has been observed (Miyasaka et al. 2003) that *B. derxii* maintains an increasing nitrogenase-specific activity during the stationary growth phase. To verify the destination of the nitrogen fixed during this phase, intra- and extracellular nitrogenated contents were analyzed. Organic nitrogen and amino acids were detected in the supernatant of the cultures. An increase in intracellular content of both nitrogen and protein occurred. Cytoplasmic granules indicated the presence of arginine. The ability of a non-diazotrophic bacterium (*Escherichia coli*) to use *B. derxii* proteins as a source of nitrogen was observed concomitantly with *E. coli* growth. This suggested that *B. derxii* contributes to the environment by both releasing nitrogenated substances and accumulating substances capable of being consumed after its death. Moreover, the ability of *B. derxii* to release certain plant growth regulators (indoleacetic acid, ethylene and polyamines) and amino acids into the growth medium has also been addressed (Thuler et al. 2003). The production of those substances was compared using cultures in which nitrogenase was active (N-free medium) and cultures in which nitrogenase was repressed (combined-N cultures) and with and without agitation. Total indoleacetic acid production was higher in agitated, N-free cultures, but specific production was greater in combined-N cultures under agitation. Putrescine and spermidine were detected under all conditions tested. Ethylene was produced in both N-free and combined-N cultures. Although a greatest diversity of amino acids was released in N-free cultures, it is important that production of growth regulators was not inhibited under conditions where nitrogenase was inactive, and so are independent activities. The fact that indoleacetic acid was released by *B. derxii* in three of the four tested conditions suggests that it is likely to be produced in the rhizosphere and therefore influence plant growth. The diversity of amino acids released by *B. derxii* was higher than that observed for *B. indica* (Pati et al. 1994) but in lower concentrations. The high concentration of glutamic acid detected under all conditions tested suggests that *B. derxii* actively excretes amino acids as the CFU number remained stable in N-free medium under agitation. The excretion of amino acids may be seen as a way for the bacteria to maintain a low intracellular N level, necessary for active N_2 fixation. However, this phenomenon may be particularly advantageous to the naturally surrounding environment where these amino acids may be directly assimilated and incorporated into the proteins of plants and a number of other living organisms. The growth-promoting effect of *B. mobilis* and *Clostridium* sp. cultures isolated from the pea rhizosphere on some agricultural crops was studied (Polianskaia et al. 2002). Seed soaking in bacterial suspensions followed by the soil application of the suspensions or their application by means of foliar spraying was found to be the most efficient method of bacterization. The application of both bacteria in combination with mineral fertilizers increased the crop production by 1.5–2.5 times. The study of the population dynamics of *B. mobilis* by genetic marking showed that it quickly colonized the rhizoplane of plants.

It is important to mention that a number of research articles that appeared between 1973 and 1996 dealing with *Beijerinckia* able to degrade polycyclic aromatic hydrocarbons such as anthracene, biphenyl, dibenzofuran, and phenanthrene, among others, correspond indeed to a different organism. The original strain, isolated from a polluted stream, is designated as B1 or Bwt and its mutant B8/36 (Gibson et al. 1973), but a polyphasic study concluded that it is a member of *Sphingomonas yanoikuyae* (Khan et al. 1996). It is interesting to note that two independent studies, employing apparently other isolates of *Beijerinckia*, do also claim polycyclic aromatic hydrocarbon degradative activity. One is strain *B. mobilis* 1f isolated from a soil contaminated

with creosote (Surovtseva et al. 1999), and the other one is a strain of *B. indica* proposed as a biomaterial for aerobic biofilm barriers for the removal of phenanthrene from groundwater (Lim et al. 2010).

As for the production of EPS, Lee et al. (2007) have characterized the water-soluble extracellular polysaccharide produced by *B. indica*, heteropolysaccharide-7 or PS-7, a gellan-like biopolymer. It is composed of β-D-glucose, α-L-rhamnose, and β-D-galacturonic acid in a molar ratio of approximately 5:1:1.3. The aqueous solution of PS-7 is highly viscous and shows high thermal stability over the temperature range from 4 °C to 93 °C. This PS-7 dispersion is stable in the wide pH range from 3.0 to 12.0 as well. The PS-7 dispersion shows distinct pseudoplastic behavior, which means the viscosity of PS-7 dispersion decreases as the shear rate increases. In the presence of cationic or polyvalent ions at high pH, PS-7 dispersion easily produced a gel matrix. Unique chemical structure and physical properties of PS-7 make them to be useful for a wide range of applications to the oil industries and potentially to dripless water-based latex well-joint cement adhesives and textile printing.

Chelatococcus has been considered for a number of applications mostly related with biodegradation and bioremediation. Aminopolycarboxylic acids are used in a broad range of household products and industrial applications to control the solubility and precipitation of metal ions. The two most widely used are ethylenediaminetetraacetate (EDTA) and nitrilotriacetate (NTA). Because their application is mostly water-based, they are disposed off in wastewater from where they reach the environment if not sufficiently well eliminated. A number of NTA- and EDTA-degrading bacterial strains have been isolated. The NTA-degrading genera *Chelatobacter* and *Chelatococcus* appear to be well represented in most aerobic environments, and their key enzymes involved in NTA and EDTA catabolism have been studied in considerable detail (Egli 2001).

Also related with environment protection but this time through waste treatment is the recent report of an effective candidate for simultaneous nitrification and denitrificaton at high temperature (Yang et al. 2013). Strain, *Chelatococcus daeguensis* TAD1, isolated from the biofilm of a biotrickling filter at a coal-fired power plant in China has the ability to denitrify at 50 °C under aerobic condition without accumulation of nitrite, nitric oxide, and nitrous oxide and with nitrogen gas as its terminal product. It can utilize not only nitrate and nitrite but also ammonium at this temperature. The denitrification genes were identified (*napA*, *nirK*, *cnorB*, and *nosZ*) and sequenced. Heterotrophic nitrification and aerobic denitrification by one single organism has attractive advantages over the two-step process involving anaerobic denitrification because of its easy operation, cost benefit, and relatively accelerated rate.

Another thermophilic member of the genus *Chelatococcus*, strain E1 isolated from a compost sample, is capable of low-molecular-weight polyethylene degradation, and this activity has been thoroughly assessed in a recent study (Jeon and Kim 2013).

In the field of energy production and diversification of strategies with less environmental concerns, the biotransformation of coal into a cleaner fuel is being explored to extend the utilization of coal-derived biofuels as an alternative source of energy. This requires isolation of microbes with the capability to degrade complex coal into simpler substrates to support methanogenesis in the coal beds. For that purpose aerobic bacteria able to solubilize and utilize coal as the sole source of carbon were searched in samples from an Indian coal bed (700 m depth). Two isolates fulfilling these requirements, strains BHU2 and BHU6, were characterized and identified as *Chelatococcus* spp. (Singh and Tripathi 2011).

Polyhydroxybutyrate (PHB) production by *Chelatococcus* has also been approached. Ibrahim and Steinbüchel (2010) examined different fermentation strategies that were employed for the cultivation of *Chelatococcus* sp. strain MW10, a new PHB-accumulating thermophilic bacterium, with the aim of achieving high-cell-density growth and high PHB productivity. Enhanced cultivation was achieved by a cyclic fed-batch fermentation technique (42 l scale), and maximal productivity (16.8 ± 4.2 g/l) was obtained during the second cycle. Strain MW10 has the advantage of accumulating PHB using cheap media made with renewable resources (Ibrahim et al. 2010), but also being a moderate thermophile can help to reduce the costs of bioreactor operation since cooling is not required during the exothermic fermentation process.

Motivated by the need to establish an economical and environmentally friendly methanol control technology for the pulp and paper industry, a bench-scale activated carbon biofiltration system was developed (Babbitt et al. 2009) that supported a diverse community of methanol-degrading bacteria, with high similarity to species in the genera *Methylophilus*, *Hyphomicrobium*, and ***Methylocella***. The system was evaluated for its performance in removing methanol from an artificially contaminated air stream and characterized for its bacterial diversity over time, under varied methanol loading rates, and in different spatial regions of the filter. The biofilter system, composed of a novel packing mixture, provided an excellent support for growth and activity of methanol-degrading bacteria, resulting in approximately 100 % methanol removal efficiency for loading rates of 1–17 g/m3 packing/h, when operated both with and without inoculum containing enriched methanol-degrading bacteria. Although bacterial diversity and abundance varied over the length of the biofilter, the populations present rapidly formed a stable community that was maintained over the entire 138-day operation of the system and through variable operating conditions, as observed by PCR–DGGE methods that targeted all bacteria as well as specific methanol-oxidizing microorganisms.

Abstract
Bradyrhizobiaceae is a family of *Rhizobiales* order into the *Alphaproteobacteria* class that presents 12 genera including the type genus *Bradyrhizobium*. Phylogenetic analyses based on 16S rRNA sequences evoke a versatile family presenting a broad taxonomic affiliation with organisms from different environments like soil, plant, or animal hosts. Bacteria are pleomorphic with predominance of rod-shaped form. There is a diversity of phenotypic, metabolic, and ecological properties associated with each genus, and their participation in biogeochemical cycles is of extreme importance. Biological nitrogen fixation particularly performed by *Bradyrhizobium* is one of the most important ecological properties with potential application in agriculture, besides other diazotrophic members. In addition, the genus *Afipia* is clinically relevant once *A. felis* is a human pathogen causing the cat scratch disease. A lot of members of *Bradyrhizobiaceae* already had their genome completely sequenced which in turn corroborates their taxonomic classification. Considering that, taxonomy into *Bradyrhizobiaceae* will become better illustrated with advances in genomic projects applied to other members of this family.

Taxonomy: Historical and Current

The traditional nomenclature of *Rhizobium* was first modified when the new genus *Bradyrhizobium* was described by Jordan (1982), which included all nitrogen-fixing bacteria (NFB) that have symbiotic associations with soybean plants, and the nomenclature is still based on physiological traits that are different from the other rhizobia. Advances in molecular methods for phylogenetic analysis, particularly those based on 16S rRNA gene sequences, have led to the creation of the family *Bradyrhizobiaceae*, which includes NFB genera of subclass α of *Proteobacteria* with different traits, but which have similar slow growth rates (5–6 days) in A1EG culture medium (Garrity et al. 2005; Turner and Young 2000). The family contains 12 genera, including the type genus *Bradyrhizobium* (derived from the Latin term *bradus*, meaning slow growing) (Garrity et al. 2005; Euzéby 2006).

Strains belonging to the rhizobial groups diverged even before the emergence of legumes. The symbiotic genes arose later in one or more strains and diversified themselves as they propagated by lateral gene transfer between different genera and strains (Kaneko et al. 2000; Hirsch et al. 2001; Galibert et al. 2001; Moulin et al. 2004). The divergence between bradyrhizobia and the fast-growing rhizobia (*Rhizobium*, *Sinorhizobium*, and *Mesorhizobium*) dates between 507 and 553 MYA (million years ago), as estimated by the divergence times of sequences using molecular clocks (Turner and Young 2000). Complex events during the evolution of genomes involved gene recruitment from paralogs, gene duplication, and lateral and vertical gene transfer, as shown by taxonomic studies based mainly on the diversity of 16S rRNA sequences, glutamine synthetases, nodulation genes (*nod*), and nitrogen fixation genes (*nif*) (Turner and Young 2000; Moulin et al. 2004; Parker 2012). Despite the high sequence diversity, *Bradyrhizobium* strains reveal a monophyletic character with few exceptions, particularly for photosynthetic Bradyrhizobia (Moulin et al. 2004).

In contrast to many NFB strains that interact with legumes, *Bradyrhizobium* does not group symbiotic genes in larger plasmids, but has a chromosomal symbiotic island (SI) that groups the genes related to nodulation and biological nitrogen fixation (BNF) (Kaneko et al. 2002). The high degree of genotypic plasticity in this genus associated with SI recombination may have contributed to the high degree of adaptation and selective advantage in this genus (Kaneko et al. 2002; Parker 2012).

Small genetic alterations can have strong pleiotropic effects on the phenotype. Thus, systematics based only on phenotype can lead to confused, divergent, or skewed results (Bécquer 2004). It is unfeasible to explain the genetic diversity of microorganisms according to one criterion alone. Modern polyphasic taxonomy (Colwell 1970; Zakhia and de Lajudie 2006) recommends combining genotypic and phenotypic information that

An erratum to this chapter can be found at

E. Rosenberg et al. (eds.), *The Prokaryotes – Alphaproteobacteria and Betaproteobacteria*, DOI 10.1007/978-3-642-30197-1_253,

integrates several cellular levels, including DNA, RNA, and other macromolecules and expressed traits, such as proteins and their activities, fatty acids, and chemotaxonomic markers. In this context, several techniques are employed and contribute to a more stable classification. Among them, sequencing the gene encoding the small ribosomal subunit 16S rRNA revolutionized bacterial taxonomy. Polyphasic taxonomy is therefore an example of maintaining traditional and modern, classical, and molecular techniques for microbial characterization because all genotypic, phenotypic, and phylogenetic information is included in its analysis (Bécquer 2004; Cohan and Perry 2007). Rhizobia are clearly polyphyletic, as there are no phylogenetic branches that contain only this group and no other bacteria (Young 1996; Bécquer 2004). When only considering *Bradyrhizobium*, polyphasic taxonomy already has consensus problems between the phenotypic and phylogenetic data (Young et al. 1991; Dupuy et al. 1994; Ladha and So 1994; Zakhia and de Lajudie 2001).

Currently, the family *Bradyrhizobiaceae* in particular demonstrates a marked effect of phylogenetic analysis based on 16S rRNA sequences (Garrity et al. 2005) (*Fig. 5.1*). In addition to the genus *Bradyrhizobium*, the following other genera comprise the family *Bradyrhizobiaceae*: *Afipia*, *Agromonas*, *Balneimonas*, *Blastobacter*, *Bosea*, *Nitrobacter*, *Oligotropha*, *Rhodoblastus*, *Rhodopseudomonas*, *Salinarimonas*, and *Tardiphaga*. The taxonomy in *Bradyrhizobiaceae* became quite confusing and makes this family one of the most distinct in terms of including genera that are quite phenotypically diverse and that exhibit extreme physiological and ecological characteristics.

Despite genetic, biochemical, physiological, and ecological characteristics being important to better elucidate the taxonomic classification in *Bradyrhizobiaceae*, particularly in this case, we still suggest that complete genome sequencing and comparative genomics seem to be the best alternatives in these cases. Given the advances in DNA sequencing techniques on a large scale, this trend can be seen as a common practice in bacteria that have small genomes and not complex genomes like those of eukaryotes.

Molecular Analyses

Currently, the family *Bradyrhizobiaceae* consists of 11 genera, as defined by 16S rRNA gene phylogenetic analysis (Garrity et al. 2005; Okubo et al. 2013), while considering that the inclusion of genus *Nitrobacter* is out of accordance with the Rules of the Bacteriological Code (1990 Revision) (Parte, 2014). However, these genera have high phenotypic, metabolic, and ecological diversity, including organisms that can fix nitrogen, photosynthetic organisms, organisms that employ aerobic and/or anaerobic respiration, organisms that are important in the sulfur cycle, and even organisms that are human pathogens.

The classification of the microorganisms in the family *Bradyrhizobiaceae*, with regard to genera, was recently altered, mainly due to the use of more effective molecular methods and comparison of genomic sequences or complete genomes. Sequencing of the *Agromonas oligothophica* genome (the only species in the genus *Agromonas*) showed that this species can be classified as a bacterium belonging to the genus *Bradyrhizobium* and oligotrophic *Bradyrhizobium* species (Okubo et al. 2013). Similarly, a new genus within the family *Bradyrhizobiaceae* was isolated and determined from this species, the genus *Salinarimonas* (Liu et al. 2010), whose species is *Salinarimonas rosea*, and more recently the genus *Tardiphaga*, whose species is *Tardiphaga robiniae* (De Meyer et al. 2012).

Currently, a large number of *Bradyrhizobiaceae* strains have had their complete and/or draft genome sequence deciphered according to the Genomes Online Database (Pagani et al. 2012). Indeed, genome sequencing is a powerful tool for investigating the biology of the bacterial world. In particular, for nitrogen fixation symbionts, genomic sequencing research during the last decades has yielded several insights regarding the molecular genetics and physiology of these organisms. For instance, it is well known that most of the genes related to nitrogen fixation and interaction with the plant host are located in specific genomic islands, known as symbiosis islands. In general, the genomic island forms syntenic groups of multiple accessory genes encoding a diverse set of functions and characteristics, most of which are associated with adaptation and virulence (Juhas et al. 2009). These genomic islands are acquired by lateral gene transfer (LGT) events, such as bacterial conjugation and are often inserted into various tRNA genes (Juhas et al. 2009). Conversely, to form functional nodules, some *Bradyrhizobiaceae*, such as *B. japonicum* USDA 110, use a type III secretion system to transport bacterial effector proteins into the cytoplasm of target eukaryotic cells (Tsukui et al. 2013). Indeed, some of the essential genes related to type III secretion systems are also found on symbiotic islands (Kaneko et al. 2002, 2011). Symbiosis islands have been very well explored in previous years by classical molecular analysis and more recently, due to the revolution generated by the genomics era, by sophisticated bioinformatics approaches, such as sequence comparison and analysis of the bias of nucleotide patterns and composition along the entire chromosome. However, the impact of symbiosis island transfer on symbiotic relationships is not well understood (Parker 2012). Recently, using Bayesian and comparative approaches, Parker (2012) concluded that symbiotic specificity is complex and difficult to characterize by only analyzing genomic data from the public databases. In this same study, Parker also observed that the host impact on symbiont population structure falls on different genomic regions and that the symbiosis islands are transferred across chromosomal lineages with few impacts to the bacterial genetic structure in other portions of the genome (Parker 2012). Therefore, we are just beginning to understand the evolutionary mechanisms related to these islands in the *Bradyrhizobiaceae* genera.

Moreover, other *Bradyrhizobiaceae* species do not carry these islands and are related to roles other than nitrogen-fixing activities. For instance, the *Afipia* genera is related to human diseases, *Rhodopseudomonas* and *Rhodoblastus* are related to phototropism in non-sulfur environments, *Bosea* is a commensal inhabitant of legume plants, and *Nitrobacter* and *Oligotropha* are chemolithoautotrophic microorganisms. The genetic traits

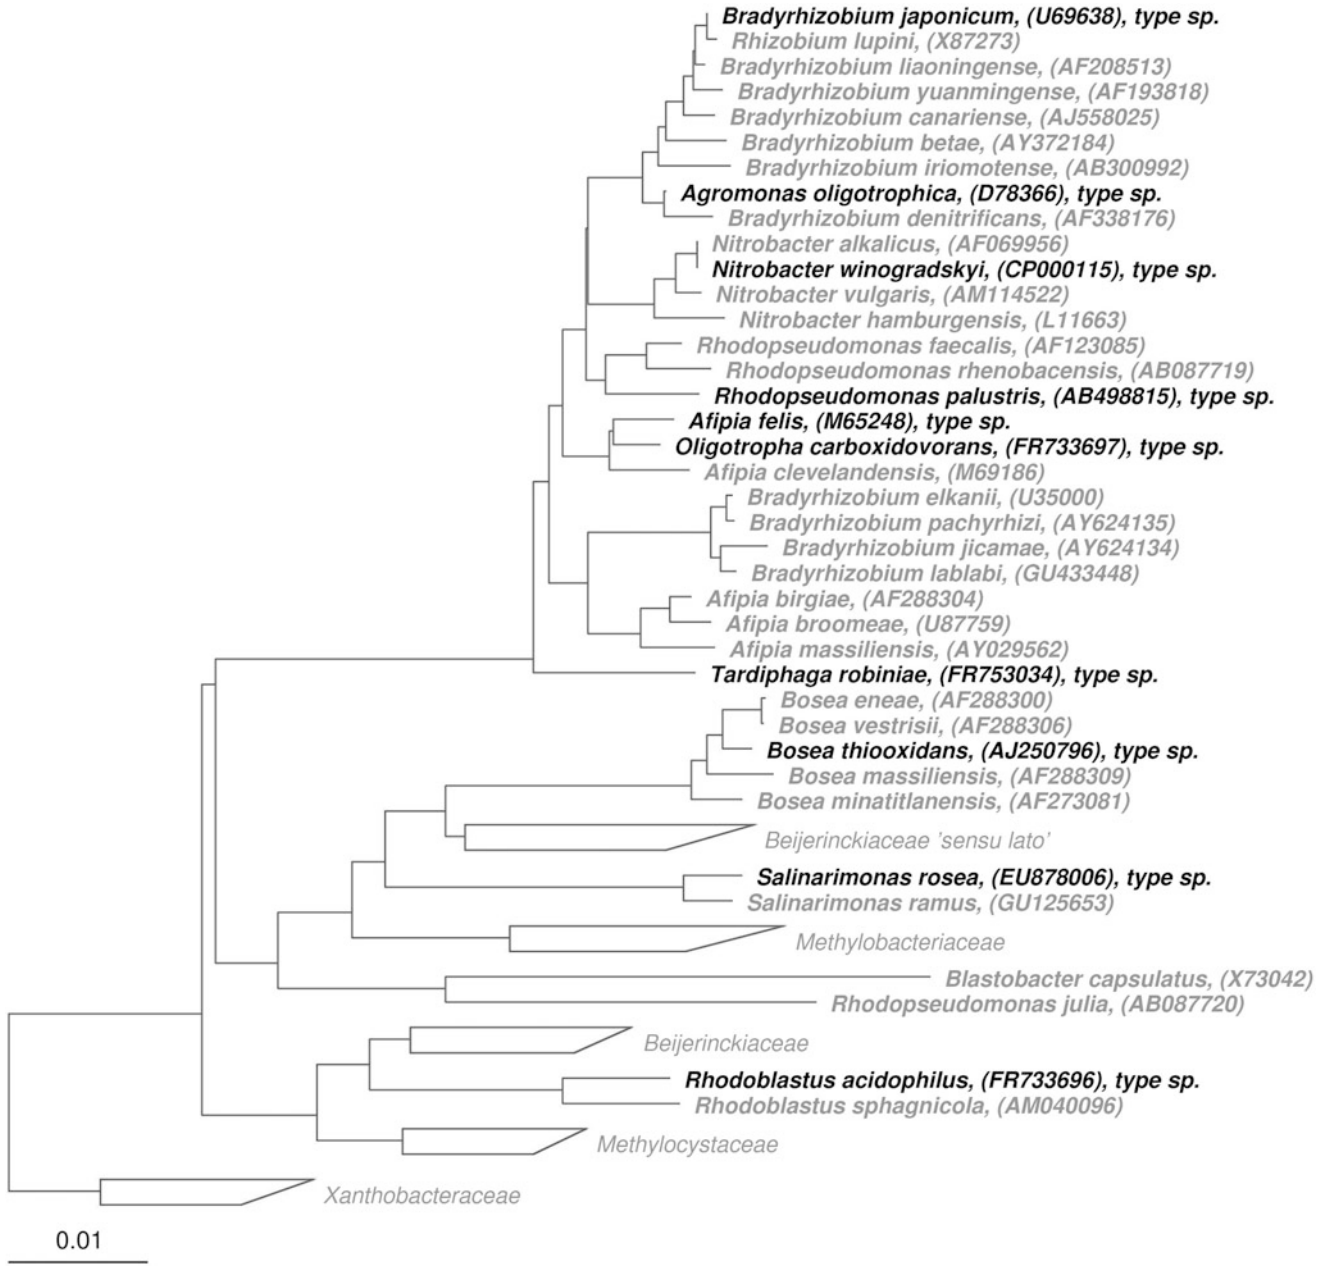

Fig. 5.1

Phylogenetic reconstruction of the family *Bradyrhizobiaceae* based on 16S rRNA and created using the neighbor-joining algorithm with the Jukes–Cantor correction. The sequence datasets and alignments were used according to the All-Species Living Tree Project (*LTP*) database (Yarza et al. 2010, http://www.arb-silva.de/projects/living-tree). The tree topology was stabilized with the use of a representative set of nearly 750 high-quality type strain sequences proportionally distributed among the different bacterial and archaeal phyla. In addition, a 40 % maximum frequency filter was applied in order to remove hypervariable positions and potentially misplaced bases from the alignment. Scale bar indicates estimated sequence divergence

related to each genus cited above are specific for their location on the chromosome and their genes. For most of these microorganisms, different research groups around the world in recent years have made and are indeed making efforts to generate the genome sequence for these organisms, with the main goal being to achieve these genetic traits and also to catalog the microbiological diversity of our planet. Currently, study and comparisons of the genome sequence using molecular and bioinformatics approaches, such as DNA–DNA hybridization and 16S rRNA and housekeeping gene phylogeny, indicate that the *Bradyrhizobiaceae* group is indeed genetically quite heterogeneous.

In this study, we will present and compile the major findings and features of the sequenced type strains of the

Table 5.1

Genome structure and architecture of the sequenced type strains of *Bradyrhizobiaceae*. The genomic information used to fill this table was collected from the GenBank and IMG databases and the literature. The absence of information regarding one of the selected features does not mean that these particular feature do not exist on the type strain considered in this table

Bradyrhizobiaceae family. Each type strain described will be mainly focused on what advantages the genomic sequence has brought to the knowledge of biology and also implications for ecology and agriculture. In particular, we will focus on genome structure and architecture and symbiosis and genomic islands. An overview of the main strains considered in this review, summarizing the major genomic features, is presented in *Table 5.1*, and the following subtopics are explored based on the literature and the public genomic databases, such as GenBank, Integrated Microbial Genomes (IMG), and PATRIC (PathoSystem Resource Integration Center) (Schueller et al. 2007).

B. japonicum USDA 6. The soybean symbiont *B. japonicum* species exhibits a remarkable genetic diversity, and the strain USDA6 is an effective nitrogen-fixing bacterium and is considered the prototype strain of this species (Kaneko et al. 2011). In summary, the complete genome sequence was deciphered in 2011, having 9.2 Mb, and composed of a unique chromosome encoding 8,826 open reading frames (Kaneko et al. 2011) (*Table 5.1*). Comparative genomics against the closely related

strain, *B. japonicum* USDA 110, showed a high degree of identity and collinearity between both chromosomes and indicated that the major differences are due to three genomic rearrangements related to a large symbiosis island (Kaneko et al. 2011). Genomic analysis also indicates that the symbiosis island was split by large-scale genome rearrangements in three regions called Locus A, Locus B, and Locus C, accounting for a total of 860 kb of its genome (Kaneko et al. 2011). Indeed, the nitrogen fixation gene cluster (*nif*/*fix*) is located in the midst of this disrupted symbiosis island (Kaneko et al. 2011). Furthermore, at least 67 insertion sequences are located inside these loci of symbiosis islands (Kaneko et al. 2011), suggesting that the transposition mediated by insertion sequences may have contributed to the genomic rearrangements and thus to differences found in the collinearity between *B. japonicum* USDA 6 and *B. japonicum* USDA 110. Moreover along with the symbiosis island loci, an additional 15 varieties of typical GIs not associated with nitrogen fixation and with duplicated portions of tRNA genes at both ends were identified, which account for up to 592 laterally transferred genes (Kaneko et al. 2011). Therefore, a considerable proportion of laterally acquired elements carrying important genes related to soybean interaction, adaptation, and fitness are very common among *B. japonicum* species. It is noteworthy that *Bradyrhizobium* sp. S23321, which was isolated from paddy field soil, is unable to nodulate in siratro, a legume often used for testing the Nod factors, and interestingly shows a strong collinearity with *B. japonicum* USDA 6 and B. japonicum USDA 110 (Okubo et al. 2012). Genomic analysis strongly suggests that *Bradyrhizobium* sp. S23321 did not acquire the required symbiosis island present in both *B. japonicum* strains by horizontal gene transfer and instead carries a photosynthetic system, indicating the capacity to adapt to a wide range of environments (Okubo et al. 2012). These observations indicate that lateral gene transfer acts as a central player in the evolution of genome architecture in this group of important nitrogen-fixing bacteria.

A. felis ATCC 53690. The human intracellular, lymph node isolated, and putative etiologic agent of cat scratch disease, *A. felis* ATCC 53690, is an organism that is very difficult to isolate (Birkness et al. 1992). Although only a few reports indicate successful isolation and maintenance of the bacterium on artificial medium (Birkness et al. 1992), this organism has been studied since the early 1990s but only partially sequenced by the Broad Institute through the Human Microbiome Project (HMP) initiative in 2012. According to the Integrated Microbial Genomes Database (IMG), only 122 genes are putative products of LGT events, and only 1 gene and no genes code for viruses and transposase functions, respectively. This finding suggests a genome with no pressure for LGT events and with no extra chromosomal elements. This observation may be investigated in detail in future works. Indeed the HMP is underway, and insights into the role of *A. felis* should be revealed in the coming years.

A. oligotrophica S58. This bacterium, formally known as *Bradyrhizobium oligotrophicum*, is a soil-dwelling and nitrogen-fixing oligotroph that is capable of growing in extra-low-nutrient conditions (Okubo et al. 2013). Its complete genome sequence was recently deciphered and interestingly lacks the presence of important nitrogen-fixing landmarks, such as the symbiosis island and nodABC genes. Conversely, *A. oligotrophica* S58 carries nitrogen fixation and photosynthesis gene clusters and is able to nodulate *Aeschynomene indica*, an aquatic legume plant, in the absence of the Nod factor (Okubo et al. 2013). Inoculation experiments also suggested an endophytic lifestyle of *A. oligotrophica* S58 in rice plants (Okubo et al. 2013). Interestingly, both *A. oligotrophica* S58 and *Bradyrhizobium* sp. S23321 lack a typical symbiosis island (Okubo et al. 2013). Therefore, it is believed that key molecules for the Nod factors independent of symbiosis are also key components for maintaining basic cellular functions of *A. oligotrophica* S58, thus indicating that bradyrhizobial purine derivatives would be a key component for triggering the process of nodule formation (Okubo et al. 2013; Masson-Boivin et al. 2009).

B. thiooxidans DSM9653. The *Bosea thiooxidans* species was originally isolated from agricultural soils in India and also found as a commensal inhabitant of legume nodules in Tunisia, but it was not capable of inducing nodule formation (Das et al. 1996; Zakhia et al. 2006). The phenotypic traits of the genus *Bosea* are related to cellular fatty acid and substrate utilization. Unfortunately, there is no full-length or draft genome sequence determined yet for *B. thiooxidans* type strain DSM9653. However, different strains of *B. thiooxidans* have had nearly full-length portions of the 16S rRNA and nitrogenase genes, as well as other housekeeping genes such as *rpoB*, *gyrB*, *atpD*, *recA*, *dnaK*, and *nifH* genes, sequenced and added to the public databases for comparative studies. These sequenced genes have been used for phylogenetic studies in the last few years, which confirmed that the *Bosea* genus is near the *Salinarimonas* genus, according to the *Bradyrhizobiaceae* tree.

S. rosea DSM 21201. *S. rosea* DSM 21201 was isolated from Moxie, Yunnan, Southwest China. The genome sequence was deciphered as a permanent draft in 2013 by an initiative created by the DOE Joint Genome Institute, which has the aim to determine the genome sequence of 1,000 type strains from DSMZ and ATCC repositories and to create an encyclopedia of type strains in order to fill phylogenetic gaps and generate reference genomes. Genomic comparisons indicate that the closest relative is strain 69-29, which was isolated from sediments of the Guanting Reservoir in China and shares at least 98 % identity based on 16S rRNA sequence comparisons (Liu et al. 2010). Although a partial genome sequence is available, there is no published comparative genomic study available in the literature, and this species remains to be investigated in the very near future by the scientific community.

Nitrobacter winogradskyi Nb-255. The third member of the *Bradyrhizobiaceae* for which the genome has been fully sequenced is the nitrite-oxidizing bacteria, *N. winogradskyi* Nb-255, which is a facultative chemolithoautotrophic microorganism that fixes carbon dioxide as its source of carbon (Starkenburg et al. 2006). The genome sequence that was determined in 2006 indicated an important set of gene clusters related to nitrite oxidation and reduction to nitric oxide and to

autotrophy capabilities that are mostly mediated by type I ribulose-1,5-bisphosphate carboxylase–oxygenase (RuBisCO) via the Calvin–Benson–Bassham (CBB) cycle (Starkenburg et al. 2006). Previous studies based on DNA–DNA hybridization of *coxA*, *coxB*, and *coxC* genes revealed that cytochrome c oxidase genes are organized in a repeated gene cluster (Berben 1996). Cell motility is guaranteed by structural and regulatory genes necessary for flagellar synthesis and function in response to environmental changes (Starkenburg et al. 2006). Genomic comparisons based on 16S rRNA show that *N. winogradskyi* Nb-255 is 98 % and 95 % identical to *Bradyrhizobium japonicum* USDA110 and *Rhodopseudomonas palustris* CGA009, respectively (Starkenburg et al. 2006). Two-thirds of the predicted proteins in *N. winogradskyi* Nb-255 have the highest degree of sequence identity to homologs in *B. japonicum* and *R. palustris* (Starkenburg et al. 2006). For instance, at least 85 genes are closely related to *N. europaea* and encode transposases, a multicopper oxidase/cytochrome cluster, glycolate oxidase, sulfite reductase, and siderophore receptors (Starkenburg et al. 2006), thus suggesting an exchange of genetic material by lateral gene transfer events (Starkenburg et al. 2006). Moreover, several integration events mediated by the lateral gene transfer mechanism were identified and account for up to 276 of the coding sequences, whereas the insertion sequence and phage-like regions appear to be the most prevalent mobile genetic elements found in *N. winogradskyi* Nb-255, and they present a potential role for *Nitrobacter* evolution (Starkenburg et al. 2006).

Oligotropha carboxidovorans (Strains OM4 and OM5). Isolated from wastewater in Göttingen, Germany, the chemolithoautotrophic bacteria *O. carboxidovorans* is capable of using carbon monoxide and carbon dioxide hydrogen and also has the capability for heterotrophic growth under appropriate environmental conditions (Paul et al. 2008; Meyer et al. 1993). The genomes of strains OM4 and OM5 were sequenced in 2011 (Paul et al. 2008). These genome sequences revealed that the main differences between these strains were related to acquisition of an 8 kb prophage-like region and a 53 kb region encoding a dissimilatory nitrate reduction (*narGHJI*), nitrous oxide reduction (*nosRZDFYL*), transporters, and biosynthesis proteins in the OM5 strain (Paul et al. 2008). The corresponding 53 kb region in OM4 is formed of phage-related genes, transposases, pseudogenes, and only a single copy of the *narI* gene (Paul et al. 2008), suggesting that the lateral gene transfer events generate by mobile genetic elements, such as temperate phages, are the key agents of genome evolution and differentiation in these strains.

Rhodoblastus acidophilus DSM137T. The purple, non-sulfur bacteria *R. acidophilus* is adapted to acidic aquatic environments and has properties that are considered unique to the genus *Rhodoblastus* (Imhoff 2001). For instance, DNA–DNA hybridization against the closely related bacterium *Rhodopseudomonas palustris* indicates that there is less than 15 % similarity between these strains (Imhoff 2001). Moreover, 16S rRNA comparisons also support that *R. acidophilus* is quite different from the *Rhodopseudomonas* genera (Ivanova et al. 1988). In spite of the absence of full-length or draft genome sequences deposited in the public databases, several sequences of 16S rRNA and nitrogen-fixing genes from different strains of *R. acidophilus* are available in the public databases for evolutionary and functional studies.

R. palustris ATCC 17001. The phototrophic, purple, non-sulfur bacteria *R. palustris* has had several strains completely sequenced in the last few years according to the Genome Online Database (Pagani et al. 2012), whereas the genome sequence of the type strain ATCC 17001 is in progress by an initiative coordinated by the University of Washington. In general, the non-type and different strains of *R. palustris* harbor a unique replicon, ranging from 4.8 to 5.7 Mb and encoding from 4,500 to 5,200 proteins. The only exception is strain CGA009, which harbors a small plasmid of 8.4 kb. Therefore, molecular analyses based on 16S rRNA, internal transcribed spacer (ITS), *puf* genes, and DNA–DNA hybridization indicate that *R. palustris* is genetically quite heterogeneous within the genus. Only in the year 2009 was *R. palustris* considered a novel species of the genus *Rhodopseudomonas* (Okamura et al. 2009).

Phenotypic Analyses

Among the genera of this family, there are still many isolates that are not fully classified or characterized; some have phenotypic traits similar to species already described but without molecular support, and others have similar molecular traits but are biologically different. In addition, there are defined genera with species that have still not been obtained from pure cultures, for example, the type species of the genus *Blastobacter* (*B. henricii*).

The type species of each genus from family *Bradyrhizobiaceae* (Table 5.1) were used for comparative phenotypic analysis in this family. The general morphological, cultural, and metabolic characteristics of this large family are shown in Tables 5.2 and 5.3, which are exclusively based on the characteristics of the type species from each genus currently belonging to the family *Bradyrhizobiaceae* and were mostly obtained from texts described by Garrity et al. (2005) and updated as needed.

All species of the family *Bradyrhizobiaceae* are characterized as Gram-negative bacteria, rod shaped, and irregular or not, with sizes ranging from 0.5 to 1.3 μm wide by 1 to 5 μm long. Species of the genus *Rhodoblastus* stand out for having the largest size on average (Table 5.2). All exhibit mobility provided by the presence of one or two polar or subpolar flagella.

In the genus *Bradyrhizobium*, bacteria are small and rod shaped in young cultures, but these bacteria become pleomorphic (swollen and elongated) in older cultures or under adverse conditions. The different species of the genus *Bradyrhizobium* characteristically form symbiotic nodules on the roots of tropical legumes (Leguminosae), in which the bacteria live as nitrogen-fixing symbionts. *Bacteroides* are rod shaped and slightly swollen, but not branched or highly distorted. Both forms have poly-β-hydroxybutyrate granules, and *Bacteroides* also exhibit polyphosphate inclusions. Bacterial cells of this genus are characterized by a bifurcated division that results in Y-shaped cells in culture. In solid culture medium containing arabinose, yeast extract, or gluconate (Kuykendall 1987; Kuykendall et al. 1988),

Table 5.2

Morphological and molecular characteristics for type species of *Bradyrhizobiaceae*

Genera	*Bradyrhizobium*	*Afipia*	*Agromonas*	*Blastobacter*	*Bosea*	*Nitrobacter*	*Oligotropha*	*Rhodoblastus*	*Rhodopseudomonas*	*Salinarimonas*	*Tardiphaga*
Morphology	Rods (0.5–0.9 × 1.2–3.0 μm)	Rods (0.5 × 1.0 μm)	Irregular rod shape, bent, branched, and/or budding rods (0.6–1.0 × 2.0–7.0 μm)	Ovoid rods, wedge or club shaped (rosette formation), slightly curved, and occasionally branched (0.5–1.0 × 1.0–4,5 μm)	Rods (0.55 × 1.4–1.6 μm)	Pleomorphic rod or pear shaped (0.5–0.9 × 1.0–2.0 μm)	Rod shaped, slightly curved (0.4–0.7 × 1.0–3.0 μm). Star-shaped aggregates (rosettes) by polar pili and excreted slime	Rod shaped (1.0–1.3 × 2.0–5.0 μm)	Rod shaped (0.6–0.9 × 1.2–2.0 μm)	Rod shaped (0.4–1.0 × 1.2–1.45 μm)	Rod shaped, 0.4–0.6 μm by 1.2–2.2 μm
Cell division	*Bradyrhizobium* cells swell and branch (changing to a Y shape) in culture	Not determined	Cell division is by irregular budding and/or elongation pinching	Reproduce by budding at the poles or laterally; the cells are often attaching to form rosettes	Not determined	Cells reproduce by budding or binary fission	Reproduce by budding and sessile division	Polar ground, budding and asymmetric cell division, sessile	Polar ground, budding and asymmetric cell division, tube, or sessile. Formation of prosthecae and rosette-like cell aggregates	Not determined	Not determined
Capsule and special internal structures	Poly-β-hydroxybutyrate granules	None	Cytoplasm compartmentalization by invagination and growth of the cytoplasmic membrane	Capsule in some species. Reproduce by budding at the poles or laterally, form rosettes	None	Intracytoplasmatic membranes as a polar cap of flattened vesicle Inner side of wall and cytoplasmic and intracytoplasmic membranes are covered with a particles from 8 to 10 nm of the nitrite oxidoreductase enzyme	None	Internal photosynthetic membranes underlying and parallel to the cytoplasmatic membrane	Internal photosynthetic membranes underlying and parallel to the cytoplasmatic membrane	None	None

Table 5.3

Cultural, biochemical, and biological characteristics associated with each genus

Genera	*Bradyrhizobium*	*Afipia*	*Agromonas*	*Blastobacter*	*Bosea*	*Nitrobacter*	*Oligotropha*	*Rhodoblastus*	*Rhodopseudomonas*	*Salinarimonas*	*Tardiphaga*
Colony size, appearance, and color	>1.0 mm (5–6 days incubation), circular, opaque (rarely translucent), white and convex	0.5–1.5 mm opaque, gray white, glistening, and convex with smooth edges	<0.5 mm, colorless/white, punctiform, pulvinate	*B. henricii* characteristic was observed only in an enrichment culture	Round, circular, smooth, mucoid, and cream colored	Growth on agar surface is limited	Colony is white or cream colored. Colony size is variable	Colony/culture is red to orange-red colored	Colony/culture is brown-red to red colored	Colonies are circular, entire, convex, and pink. with 2.5 mm diameter	Colonies are white, smooth, and round; have a diameter smaller than 0.3 mm; and are convex with entire margins
Optimal temperature	25–30 °C (maximum growth temperature 33–35 °C)	30 °C (not growth at/or above 42 °C)	25–27 °C	10–46 °C	30–32 °C (range 20–37 °C)	28–30 °C (range 5–37 °C)	30 °C	25–30 °C	30–37 °C	28–30 °C (range 15–37 °C)	28 °C. (range 15 °C–33 °C)
Optimal pH	pH 6–7 Acid tolerant	pH 6,8	Not determined	6.8–7.8	7.5–8.0 (range 6.0–9.0)	7.5–8.0	Not determined	5.5–6.0	6.9 (range 5.5–8.5)	7.0–8.0 (range 6.0–9.0)	Not determined
Metabolic and cultural characteristics	Aerobic	Aerobic	Aerobic and oligotrophic	Aerobic, heterotrophic	Aerobic	Aerobic but also capable of anaerobic respiration with nitrate	Aerobic and some strains can denitrify	Chemotrophic (microoxic and oxic conditions)	Chemotrophic (microoxic and oxic conditions)	Anaerobic facultative	Aerobic
	Chemoorganotrophic Does not grow in medium with 2 % NaCl	Has non-fermentative metabolism and grows in various common media	Grows under conditions of low organic carbon supply, fixes nitrogen under microaerobic conditions	Grows in low-nutrient medium	Chemolithoheterotrophic	Lithoautotrophic and chemoorganotrophic	Facultatively chemoorganotrophic	Photoheterotrophic (anoxic conditions and light)	Photoheterotrophic (anoxic conditions and light)	Halotolerant, grows in NaCl concentration 0–5 % (optimum, 3 %, w/v)	Very slow-growing bacteria showing visible growth after 7 days on aerobic incubated R2A and 10 times diluted
	Does not absorb Congo red from a yeast extract–mannitol mineral salts; the colonies are colorless or very faintly pink	Grows well in BCYE medium without NaCl and does not grow in medium with 6% NaCl		Some species can grow chemolithotrophically with hydrogen	Reduced sulfur in the presence of organic carbon	Grows in mineral liquid medium containing nitrite and in the dark or with organic C and N without nitrite	Colony formation is slower in solid medium (1–4 weeks) than in broth (generation time varies from 15 to 20 hs with 20 % CO)	Photoautotrophic growth (with hydrogen as electron donor; sulfide and thiosulfate can't be used) Sulfate is used as a sulfur source	Photoautotrophic growth (with hydrogen, sulfide, or thiosulfate as electron donor) Sulfate is used as a sulfur source		TSA

Table 5.3 (continued)

Genera	*Bradyrhizobium*	*Afipia*	*Agromonas*	*Blastobacter*	*Bosea*	*Nitrobacter*	*Oligotropha*	*Rhodoblastus*	*Rhodopseudomonas*	*Salinarimonas*	*Tardiphaga*
Main carbon source	Uses several carbohydrates and organic acids as a carbon source	Several – common agar and broth media (heart infusion with blood, trypticase soy with blood, tryptone glucose yeast extract and BCYE)	Ferulic, p-coumaric, and p-anisic acid with organic nutrients in the medium	Alcohol, sugars, organic acids, and some amino acids	Uses several monosaccharides, organic acids, and amino acids	Carbon dioxide (oxic conditions with nitrite)	CO (energy and carbon assimilation by Calvin cycle)	Carbon sources are several organic acids (but not sugars or sugar alcohol), methanol, and ethanol	Benzoate, pyruvate, formate acetate, fumarate, lactate, butyrate, and some sugar alcohol such as mannitol and glycerol	Sugar, amino acid, and organic acids	Don't use glucose for oxidation, utilization of citrate and gluconate
						Pyruvate, formate acetate (without nitrite)	Salts of pyruvate, formate, glyoxylate, and other organic acids; sugars and amino acids may be used by some strains				
Main nitrogen source	Ammonium salts, nitrate, and amino acids as nitrogen source	Not determined	Ammonium Sulfate in the presence of O_2 and N_2 in microaerophilic conditions	Ammonium, nitrate, urea, yeast extract casein hydrolyzed	Glutamate, glutamine, and aspartate	Peptone and yeast extract in heterotrophic medium without nitrite	Urea, ammonia, nitrite, and nitrate (exception when CO is the substrate)	Ammonia, dinitrogen, and amino acids	Several nitrogen sources (ammonia, guanine, xanthine amino acids, cytidine, citosyne, and others	Nitrate is reduced to nitrite	Not determined
					Neither ammonia nor nitrate or urea serves as nitrogen source			Complex nutrients (yeast extract) do not increase the growth			Positive for nitrate reduction
N_2 fixation	Yes, in symbiosis with root of leguminous plants or free-living state under special conditions	No	Yes, under microaerobic conditions	No, may reduce nitrate to nitrite	Denitrification occurs with gas production under microaerobic conditions with malate, succinate, glucose, and sucrose	No	No	Nitrogenase has been found in all species	Nitrogenase shows a "switch-off" effect by ammonia and some organic compounds	No	No
C assimilation	No	No	No	Some species when grown on methanol or methylated amines	No	Yes, under oxic conditions and in the presence of nitrite	Carbon monoxide oxidation can occur in some strains and it is assimilated in the Calvin cycle	Yes, under anoxic conditions	Yes, under anoxic conditions	No	No

Bradyrhizobium colonies are characterized by being opaque, rarely translucent, white, and convex; can have a granular aspect; and are never larger than 1 mm in diameter after incubation for 5–6 days. In liquid medium, turbidity only appears after 3–4 days, and the generation time of these species is calculated to be between 9 and 18 h. These traits were responsible for the name of this bacterial group, with slower growth than another group of symbiotic nitrogen-fixing bacteria, the genus *Rhizobium* from the family *Rhizobiaceae*.

Bacteria of the genus *Afipia* appear to be related to human infections, as *A. felis* was isolated or detected by PCR in the lymph nodes of patients with cat scratch disease (CSD), although the bacterium *Bartonella henselae* is considered a causative agent of CSD. The isolation and history of other species of the genus *Afipia* suggest that these bacteria may act as opportunistic pathogens in humans. Morphologically, bacteria belonging to the genus *Afipia* are straight rods and Gram-negative, do not form clusters or chains, and have one or two polars, subpolar, or lateral flagella easily visualized by the Ryu method (Ryu 1937; Weyant 1995). In BCYE medium, *Afipia* bacterial colonies have diameters ranging from 0.5 to 1.5 mm after 72 h of culture at 30 °C, have gray to white coloring, and are glistening, convex, and opaque with smooth edges.

The genus *Agromonas*, described by Ohta and Hattori (1983) and represented by a single species, *Agromonas oligotrophica*, is characterized by having irregular shapes of bent, branched, or budding rods and compartmentalization of the cytoplasm by invagination of the cytoplasmic membrane and growth. This bacterium shows poly-β-hydroxybutyrate granules and produces a fluorescent pigment. The colonies on solid media are small, colorless or white, punctiform, and pulvinate. However, in 2013, a comparison of 16S rRNA gene sequences and housekeeping gene sequence analysis, phenotypic characterization, and DNA–DNA hybridization led Ramírez-Bahena et al. (2013) to propose reclassification of *Agromonas oligotrophica* within the genus *Bradyrhizobium* as *Bradyrhizobium oligotrophicum*.

Rosette formation is a marked morphological trait of species from the genus *Blastobacter*. These bacterial species are ovoid rod, wedge, or club shaped; slightly curved; and occasionally branched. Cells generally reproduce by budding at the poles or laterally, with the cells attaching to form rosettes. A great difficulty in the study of the *Blastobacter* strains is the absence of a pure culture for the type species *B. henricii*, whose description was performed only by examination of an enrichment culture (Zavarzin 1961). Nevertheless, currently there are five species described for this genus, which have been isolated from water samples and activated sludge (Hirsch and Müller 1985; Doronina et al. 1983; Loginova and Trotsenko 1979).

The genus *Bosea* is characterized by cells with a bacillary shape and a single polar flagellum; the colonies are round, circular, smooth, mucoid, and cream colored in a medium containing an organic substrate supplemented with sodium thiosulfate. Various morphological, biochemical, and molecular traits (DNA–DNA hybridization analysis) determined the isolation of four more species in this genus, *B. eneae*, *B. vestrisii*, *B. massiliensis*, and *B. minatitlanensis* (La Scola et al. 2003; Ouattara et al. 2003), and the additional isolates *Bosea lupine*, *Bosea lathyri*, *and Bosea robiniae* were determined by multilocus analysis techniques (De Meyer and Willems 2012).

Nitrobacter is a genus described by Winslow et al. (1917) and amended by Watson (1971); this genus is morphologically described as being pleomorphic rod or pear shaped. The cells are characterized by the presence of intracytoplasmic membranes as a polar cap of flattened vesicles. The cell wall differs from that found in other Gram-negative bacteria. The inner side is more electron dense than the outer because it has densely packed particles of nitrite oxidoreductase enzyme (Spieck et al. 1996, 1998; Meincke et al. 2004). Poly-β-hydroxybutyrate, glycogen and polyphosphates granules, and (in some species) carboxysomes can be observed in the cytoplasm. Cells normally reproduce by budding (Holt et al. 1994), and growth on an agar surface is limited (Markowitz et al. 2012).

Bacteria belonging to the genus *Oligotropha* are rod shaped and slightly curved, form star-shaped aggregates by polar pili, and excrete slime, especially in the post-exponential and stationary growth phases. Reproduction is by budding and sessile division. Colonies are white or cream colored and are visible on agar plates after 1–4 weeks, depending on the medium. *Oligotropha carboxidovorans* is the sole species representative of the genus *Oligotropha* and has had its genome sequenced by Paul et al. (2010).

Rhodoblastus is a *Bradyrhizobiaceae* genus characterized by rod-shaped cells. Daughter cells originate from polar growth as sessile buds at the pole opposite the flagella; there are no tubes or filaments between the original and the new cell. When the daughter cell reaches the size of the mother cell, division occurs by constriction, and clusters can form. These cells form colonies that are red to orange-red colored, and this color also can be observed in broth culture. The bacteria have internal photosynthetic membranes underlining and parallel to the cytoplasmic membrane. They produce photosynthetic pigments, such as bacteriochlorophyll *a* and carotenoids. The type species from this genus is *Rhodoblastus acidophilus* (previously named *Rhodopseudomonas acidophila*), but another species was recently proposed, *Rhodoblastus sphagnicola* (Kulichevskaya et al. 2006). In contrast to *R. acidophilus*, this new species is not capable of aerobic growth in the dark, has no spirilloxanthin among the carotenoids, and differs in its pattern of substrate utilization. The value for DNA–DNA hybridization between the two strains is only 22 %.

Bacteria from the genus *Rhodopseudomonas* are very similar to *Rhodoblastus*, but in this genus the cells are smaller. The species are characterized by asymmetric cells during cell division and formation of prosthecae and rosette-like cell aggregates. The mother cell produces a slender prosthecae 1.5–2.0 times the length of the original cell at the opposite pole from the flagella. Rosette or cluster formation occurs mainly in older cultures. The colonies or culture suspensions are brown-red or red colored. Similar characteristics can be observed in all species from this genus. They produce photosynthetic pigments, such as bacteriochlorophyll *a* and carotenoids of the spirilloxanthin series.

The newest genus from the *Bradyrhizobiaceae* family, the genus *Salinarimonas*, was proposed by Liu et al. (2010), and the genus *Tardiphaga* was proposed by De Meyer et al. (2012). The type species from *Salinarimonas* is *S. rosea* and another species, *S. ramus*, was defined (Cai et al. 2011). These bacteria have a rod shape, and the colonies formed after 5 days under optimal conditions are circular, entire, convex, and pink-colored. The type species from *Tardiphaga*, which has only one isolated species, *Tardiphaga robiniae*, is an aerobic, nonmotile, rod-shaped bacterium with a very slow growth rate that was isolated from *Robinia pseudoacacia* root nodules.

Guanine–cytosine content is an important attribute of bacterial genomes. It has been used to scan the basic makeup of the genome, as well as to understand coding sequence evolution. The variety in GC content is great in bacterial genomes. The percentage composition can range from 25 % to 75 % for GC richness among species (Table 5.2), but it is highly constrained and constant in a single species. However, this trait does not have a classificatory value for the levels of bacterial family and genus due to its large variation. The GC content in *B. henricii* is unknown, but this parameter ranges from 59 % to 69 % for other species of the genus. In contrast, the DNA GC content among all of the genera ranges from 59 % to 71 %, and the genus *Afipia* has the highest variation in this parameter (7.5 %). All of the species studied from the genera belonging to the family *Bradyrhizobiaceae* can be considered C+G-rich bacteria, which may relate to their mesophilic characteristics (Zheng and Wu 2010).

A wide diversity of behaviors can also be observed in the culture and biochemical characteristics of genera from the family *Bradyrhizobiaceae* (Table 5.3). The optimal pH for most species is between 6 and 7, with some acid tolerance occurring in *Bradyrhizobium*, and *Salinarimonas*, *Nitrobacter*, and *Rhodopseudomonas* can even grow in basic medium with a pH close to 8. The pH range for *Agromonas*, *Oligotropha*, and *Tardiphaga* has not yet been determined. The growth temperature for these bacteria ranges from 25 to 30 °C, where *Blastobacter* species exhibit greater extremes and can adapt to temperatures from 10 to 46 °C.

In in vitro culture, the size and shape of the colonies are also characteristic of each genus, and the colonies are usually circular and translucent but with different colorations: *Bradyrhizobium* colonies are characteristically white, *Afipia* have gray-white colonies, *Bosea* and *Oligotropha* have cream-colored colonies, and the colonies from *Rhodoblastus* and *Rhodopseudomonas* have orange-red-brown color and the color of colonies are pink. The type species *Nitrobacter* should be highlighted because it has limited growth in solid mineral medium. *N. winogradskyi* was described as a bacterium that forms small colonies that are yellowish white in color, although other species of the genus that were recently isolated have an orange color (Zare et al. 2012). In contrast within the genus *Blastobacter*, its type species *Blastobacter henricii* has been observed only in enrichment cultures, and thus the colony morphology cannot be determined. Other species from the genus *Blastobacter* have colorless to yellow colonies that become brownish when older.

Regarding the metabolic characteristics observed in genera from the family *Bradyrhizobiaceae*, this bacterial group comprises organisms with high diversity in the strategies for obtaining energy, carbon sources, and electrons needed for their development. The vast majority of species are aerobic, i.e., use oxygen as a final electron acceptor in the oxidative processes of obtaining energy (*Bradyrhizobium*, *Afipia*, *Agromonas*, *Blastobacter*, *Bosea*). Bacteria from the genera *Nitrobacter* and *Oligotrophica* are aerobic, but can survive anaerobically under specific conditions. In contrast, there are bacteria that preferentially develop in low-oxygen or anaerobic environments (*Rhodoblastus*, *Rhodopseudomonas*, and *Salinarimonas*).

Bacteria from the genus *Bradyrhizobium* are chemoorganotrophic, using a range of carbohydrates and salts from organic acids as carbon sources, but do not use cellulose or starch, and produce alkaline reactions on mineral salts medium with mannitol or other sugars. In this medium, the *Bradyrhizobium* strains lack the ability to absorb Congo red, and the colonies observed under this condition are colorless white or very faintly pink. This is a differential medium because most other soil bacteria produce red colonies under this condition. Ammonium salts (nitrates preferably) and some amino acids can be used as nitrogen sources. This organism may enter through the root hairs of tropical and temperate zone leguminous plants (Fabaceae) and induce nodule formation. In the nodule, the bacteria live as symbionts where they are able to fix nitrogen. Some strains exhibit hydrogenase activity with the soybean host and thus are more efficient in symbiotic nitrogen fixation (Maier 1981; Vauclare et al. 2013).

The main metabolic trait of *Agromonas oligotrophica*, currently classified as *Bradyrhizobium oligotrophicum* (Okubo et al. 2013), is its ability to grow in an environment that is poor in carbon. Important carbon sources in culture medium for this bacterium include the following organic acids: ferulic acid, p-coumaric acid, and p-anisic acid (Ohta 2000). The main nitrogen source in the presence of oxygen is ammonium sulfate, but this bacterium has the ability to fix nitrogen in microaerobic environments. Despite these data, metabolic knowledge about this bacterial species is still scarce, although it appears to be important for the degradation of organic matter and nutrient cycling in environments with low levels of this material considering its isolation site (rice paddy soils).

Afipia is a *Bradyrhizobiaceae* genus that is related to cat scratch disease, and it is a facultative intracellular bacterium. This bacterium has a non-fermentative and aerobic metabolism; it grows well on buffered charcoal yeast extract (BCYE) agar and nutrient broth without NaCl or less than 6 % of this salt. The bacteria from this genus grow well in several common medias, but generally these medias must be supplemented with heart infusion or blood. Some strains have the ability to reduce nitrate. *Afipia* bacteria do not produce acid with carbohydrate; they are positive for oxidase, urease, and litmus milk alkalinization.

Bacteria from the genus *Blastobacter* are aerobic and heterotrophic. They grow in low-nutrient medium, and they can use many alcohols, sugars, organic acids, or some amino

acids as carbon and energy sources. Ammonium, nitrate, urea, peptone, yeast extract, or casein hydrolysate may be utilized as nitrogen sources. These bacteria may reduce nitrate to nitrite or denitrify. Some species of these bacteria grow chemolithotrophically with hydrogen, and some species may fix CO_2 reductively when grown on methanol or methylated amines (Loginova and Trotsenko 1979). Because a culture of the type species *Blastobacter henricii* has never been isolated, the genus is characterized mainly by morphological traits, as budding cell division, which is not a phylogenetically useful characteristic and is observed in several genera from the *Alphaproteobacteria* class. Several authors have demonstrated a high degree of heterogeneity in species of the genus *Blastobacter* with respect to their phenotype and molecular phylogeny. Analysis of the 16SrRNA sequences of some species from the *Blastobacter* genus has determined that these species are in polyphyletic positions in the *Alphaproteobacteria* class (Sly and Hugenholtz 2005; Doronina et al. 1996); therefore, the taxonomy of the genus *Blastobacter* needs revision (Doronina and Trotsenko 2003).

Species from the genus *Bosea* are characterized as being aerobic and chemolithoheterotrophic bacteria, capable of obtaining energy from the oxidation of reduced sulfur compounds. Ammonia, urea, and nitrate cannot serve as nitrogen sources, and instead the type species of this genus, *B. thiooxidans*, uses glutamate, glutamine, and aspartate as sources of this element. Heterotrophic growth can be caused by organic compounds, such as glucose, fructose, sorbose, xylose, pyruvate, rhamnose, ribose, arabinose and galactose, citrate, gluconate, succinate, malate and acetate, glutamine, proline, aspartic acid, cysteine, serine, asparagine, alanine, and lysine. Under microaerobic conditions, denitrification occurs with gas production in GYM medium (glutamate–yeast extract–mineral salts medium) containing malate, succinate, glucose, or sucrose as a carbon source.

Nitrobacter grows lithoautotrophically or chemoorganotrophically, occurs in aerobic and microaerophilic atmospheres where organic matter is mineralized, and it is capable of anaerobic respiration. Under anaerobic conditions, nitrate is reduced to nitrite, nitric oxide, and nitrous oxide. Nitrobacter cells are facultative lithoautotrophs that obtain energy from the oxidation of nitrite to nitrate when the main carbon source is carbon dioxide. In the absence of nitrite, pyruvate, formate, and acetate can serve as energy and carbon sources. During mixotrophic growth, nitrite is oxidized first, followed by the oxidation of organic material. Under lithoautotrophic and mixotrophic conditions, bacteria have a generation time of 8–14 h, and under heterotrophic conditions, the generation time is 70–100 h.

The type species from the genus *Oligotropha*, *O. carboxidovorans*, is an obligately aerobic, facultative autotrophic bacterium. It is a chemolithoautotrophic bacterium that is capable of utilizing carbon monoxide, carbon dioxide, and hydrogen. It is also capable of heterotrophic growth under appropriate environmental conditions. It can utilize as its sole source of carbon and energy organic acids such as acetate, lactate, pyruvate, succinate, fumarate, I.-malate, formate, and crotonate. It cannot utilize sugars, amino acids, or citrate. Starch, tween, agar, gelatine, and polyhydroxybutyrate are not hydrolyzed. Nitrates are reduced to nitrites. It grows autotrophically at the expense of either carbon monoxide or hydrogen plus carbon dioxide. The carbon monoxide-oxidizing activity is bound to a small particle fraction, does not reduce NAD(P), and is only present in cells grown on $CO + O_2$. Hydrogenase is membrane bound, does not reduce NAD(P), and is present in cells grown on $H_2 + O_2 + CO_2$, $CO + O_2$, and pyruvate + O_2. *O. carboxidovorans* may have practical utility for bioenergy production. This species is capable of utilizing syngas, which is a mixture of CO, CO_2, and H_2 that results from gasification of organic wastes, for chemolithoautotrophic growth. Microbial fermentation of this gas mixture could serve as a source for biofuels.

The genus *Rhodoblastus* prefers photoheterotrophic growth with a number of organic carbon sources under anoxic conditions and light. Photoautotrophic growth is possible with hydrogen as an electron donor under anoxic conditions. In the dark and under microoxic or oxic conditions, organic carbon sources are acetate, propionate, butyrate, lactate, pyruvate, fumarate, malate, succinate, valerate, formate, methanol, and ethanol; these cells do not use sugars, sugar alcohols, glutamate, and other amino acids. As a sulfur source, it uses only sulfate, and for nitrogen ammonia, dinitrogen and some amino acids can be used. Recently, studies with new *Rhodoblastus acidophilus* isolates support the observation that few species of acidophilic purple bacteria appear to exist in nature. These isolates, in addition to methanol and ethanol, can grow on several other primary alcohols, results that were not reported in the original species description (Kempher and Madigan 2012).

Cells from the *Rhodopseudomonas* genus can live under aerobic, microaerobic, and anaerobic conditions. They exhibit photoautotrophic grow with hydrogen, sulfide, or thiosulfide as an electron donor. In the light and under anoxic conditions, the cells can grow photoheterotrophically, and under microoxic and oxic conditions, *Rhodopseudomonas* have chemotrophic growth. When necessary, the carbon source can be formate, acetate, pyruvate, lactate, malate, succinate, fumarate tartrate, gluconate, ethanol, or butyrate. Glucose, fructose, citrate, methanol, arginine, and glutamate are not used, and p-aminobenzoic acid and sometimes biotin are required as growth factors. Sulfate is the sole sulfur source. Nitrogenase shows no activity in medium with ammonia or some organic nitrogen compounds, and these cells can use several nitrogen compounds as a nitrogen source (amino acids, di- and trimethylamine, guanine, uric acid, and xanthine).

One of the newest genera from the *Bradyrhizobiaceae* family, *Salinarimonas*, is characterized as a facultative anaerobe; it was isolated under anaerobic conditions, but is able to grow well under aerobic conditions. *Salinarimonas* is halotolerant and must grow in medium supplemented with 0–5 % NaCl. These cells can use several organic compounds as carbon and nitrogen sources (Liu et al. 2010; Cai et al. 2011).

Another recently determined genus in this family is the genus *Tardiphaga* (de Meyer et al. 2012). The type species from this genus is *Tardiphaga robiniae*, which is characterized as an

aerobic bacterium that grows slowly on R2A at 28 °C. It can be distinguished from the other genera by positive nitrate reduction, positive β-glucosidase hydrolase, negative D-mannitol assimilation, and negative malate assimilation, as well as its use of capric acid. This species is negative for lysine and ornithine decarboxylase, tryptophan deaminase, and production of acetoin.

Isolation, Enrichment, and Maintenance Procedures

Bradyrhizobium species are common soil inhabitants, but the strains are difficult to isolate directly from this habitat. The isolation from symbiotic strains in the soil requires the use of trap hosts, a leguminous plant from which nodules are selected for isolation. *Bradyrhizobium* strains cause nodule production in *Glycine* (soybean), *Vigna* (cowpea), and *Macroptilium* (siratro), so these leguminous plants can be used as a trap hosts. The nodules with a small portion of root attached must first be surface sterilized (5–60 min in 3 % H_2O_2 or 5 % commercial hypochlorite) and washed in sterile water. The nodule is crushed in a small drop of sterile 0.05 % peptone or 0.1 M phosphate solution. A loopful of the suspension must be streaked onto surface plates with yeast extract–mannitol agar (YMA medium) (Vincent 1970), and the plate incubated at 28 °C for 3 or more days. The agar medium for initial isolation should contain 0.002 % actidione to avoid fungal contamination. Well-isolated, white, mucoid, glistening, hemispheric colonies are restreaked onto fresh plates for subsequent confirmation, which requires reinfection of the original host under aseptic conditions, and reisolation. The maintenance of *Bradyrhizobium* species consists of several procedures. These bacteria persist on YMA slants in tightly closed screw-capped tubes for more than 5 years at 4 °C. A suitable maintenance medium is A1EG (Kuykendall 1987) or arabinose-enriched (0.1 % yeast extract) gluconate (Kuykendall et al. 1988). Long-term storage at −20 °C or −80 °C is recommended using turbid suspensions from fresh broth cultures mixed with equal volumes of sterile 80 % glycerol in water. Lyophilized cultures stored at 4 °C remain viable for at least 25 years (Kuykendall 2005).

Agromonas oligothophica (the only species from the genus *Agromonas*) and the species *Bradyrhizobium oligotrophicum*, which was recently classified as belonging to the genus *Bradyrhizobium* (Okubo et al. 2013), are widely distributed in nature and share the ability to grow on low-nutrient media. Isolation of these strains is performed on plates with NB medium diluted 1/100. After 1 week to 1 month, the colonies must be tested for sensitivity to nutrients on NB medium without dilution. The cells can be maintained in screw-capped tubes with 1/100 NB medium at room temperature for 3–4 years. Another method for maintenance is the suspension of cells in 20 % glycerol and freezing at −80 °C.

Although no selective media have yet been described for the growth of *Afipia* strains, these strains can be grown at 30–32 °C under aerobic conditions on a variety of media, including nutrient broth, brain–heart infusion, heart infusion, chocolate, potato dextrose, trypticase soy, and BCYE agar. The isolation of *Afipia felis* strains was performed by grinding lymph nodes tissues in phosphate buffered and cultivation on brain–heart infusion or HeLa cell monolayers (English et al. 1988; Brenner et al. 1991). For long-term preservation of *Afipia* strains, it is necessary to mix freshly grown cells with 20 % glycerol or defibrinated rabbit blood and freeze at −70 °C. These strains can be maintained for the short term (less than 1 year) in a semisolid motility medium deep in tightly closed screw-capped tubes at room temperature (Weyant et al. 1995).

Low-nutrient medium containing glucose, peptone, and yeast extract (Stalwy 1981) is used for isolation or enrichment of *Blastobacter* strains from environmental samples or water. Enrichment may be performed by incubating samples at 18–23 °C for 1–3 weeks. Mineral salts medium with 1 % methanol at 30 °C for 7 days was used to isolate *Blastobacter viscosus* (Loginova and Trotsenko 1979). Cultures may be preserved in sucrose peptone broth containing 10 % glycerol by cryogenic storage or freeze-drying in glucose peptone medium with horse serum.

The *Bosea* genus is represented by *Bosea thiooxidans*. To isolate this strain, it is necessary to enrich the soil sample on medium containing sodium thiosulfate, sodium sulfide, and S° for 10 days. Then, the soil is incubated for 2 days in another mineral salt broth with sodium thiosulfate or sodium sulfide and yeast extract. The bacterial colonies can be obtained by culturing on salt–thiosulfate–yeast extract agar by incubation at 30 °C for 4 days. The cultures can be maintained on mixed substrate agar or Luria agar at 4 °C for 2 months or mixed in growth medium with 15 % glycerol and stored at −20 °C for approximately 1 year. For long-term preservation, lyophilization is the best method (Das 2005).

Mineral medium containing nitrite is used to isolate bacteria that oxidate nitrite. If these bacteria have lithotrophic, mixotrophic, or heterotrophic growth, the medium used needs to have different components (Watson and Waterbury 1971; Bock et al. 1983). An interesting summary of the composition of these media can be obtained from *Bergey's Manual of Systematic Bacteriology* (Garrity et al. 2005), where the composition of media for lithoautotrophic (terrestrial and marine), mixotrophic, and heterotrophic nitrite oxidizers is shown. For isolation, enrichment cultures must be incubated for one to several months in the dark. These cells are sensitive to oxygen, so growth on the agar surface is limited. *Nitrobacter* can survive in liquid medium at 17 °C for approximately 4 months. These cells can be stocked for one or more years by freezing in liquid nitrogen with a buffer containing sucrose or histidine or freeze-drying.

The enrichment and isolation of bacteria from the genus *Oligotropha* and other carbon monoxide-oxidizing microorganisms is performed in a mineral medium with CO as an energy source and CO_2 as the sole carbon source under aerobic conditions. Alternatively, enrichment may be carried out under anoxic conditions in the presence of an electron acceptor. In this case, the culture is performed in mineral medium under an

atmosphere composed of 5 % CO_2, 10 % O_2, and 85 % CO or 5 % CO_2, 45 % CO, and 50 % air. The culture is incubated for approximately 1 month (with or without shaking) at 30 °C in the dark. Every 2 weeks, subcultures must be done, and a sample must be streaked onto an agar plate with mineral medium supplemented with pyruvate. The plate has to be maintained in the same atmosphere. Slow-growing colonies (appear after 1 week) with a morphology consistent with these colonies and cells are evidence of axenic culture.

The media used for isolation, enrichment, and maintenance of *Rhodoblastus* and *Rhodopseudomonas* species are the same as that used to isolate other purple sulfur bacteria (Imhoff et al. 1994). A succinate mineral medium with pH 5.2 is selective for *Rhodoblastus acidophilus*. Benzoate is the carbon source that is generally used for enrichment of *Rhodopseudomonas palustris*. The *Rhodoblastus* and *Rhodopseudomonas* species can be preserved in liquid nitrogen, by lyophilization, or in a freezer at −80 °C (Imhoff 2005).

Bacteria from the genus *Salinarimonas* can be isolated on marine agar 2216 (MA; Difco) or seawater agar (ASW), as described by Cai et al. (2011) and Eguchi et al. (1996), respectively. The culture is cultivated at 28 to 30 °C under aerobic or anaerobic conditions. It can be maintained on MA slants at 4 °C and stored in a 20 % glycerol suspension at −80 °C (Liu et al. 2010).

The newest genus described from *Bradyrhizobiaceae*, *Tardiphaga*, was isolated and is maintained with a group of rhizobia associated with indigenous legumes. This bacterium was isolated in YMA medium from surface-sterilized root nodules. All YMA plates were incubated at 28 °C, and the isolates were stored in 15 % glycerol + YMA broth tubes at −20 °C (De Meyer et al. 2011).

Ecology

The ecological diversity observed in *Bradyrhizobiaceae* reflects the genetic, phenotypic, and metabolic diversity present in the family. The different bacteria isolated from soil, water, or hosts may or may not be able to perform fixation and/or other pathways of nitrogen assimilation, carbon assimilation, photosynthesis, aerobic or anaerobic respiration, and even pathogenicity in humans (Garrity et al. 2005).

The ability to use different nitrogen sources in their metabolism (*Table 5.3*) makes all genera of the family, except for *Afipia*, important components of the biogeochemical nitrogen cycle. Nitrogen is the fourth most common element in many biomolecules, and its cycle in soils is one of the most studied (Philippot and Germon 2005). Microorganisms are essential components in different processes that maintain the balance between reduced and oxidized nitrogen forms, ranging from ammonia (−3) to nitrate (+5). Nitrogen cycle fluxes are primarily driven by nitrogen fixation and mineralization through ammonification and nitrification (Robertson and Groffman 2007).

Nitrobacter participates in nitrogen mineralization and immobilization from organic matter, generating nitrate (NO_3^-), which is one of the main nitrogen forms used by most microorganisms and plants. Nitrification is performed via oxidation reactions to assimilate CO_2 and separates the bacteria into two groups based on their ability to oxidize ammonia into nitrite and oxidize nitrite into nitrate (De Boer and Kowalchuk 2001; Gubry-Rangin et al. 2010). *Nitrobacter* species ($NO_2^- \rightarrow NO_3^-$) are important obligatory chemooligotrophic nitrifiers (*Table 5.3*) in soils and allow for complete oxidation of NH_4^+ when combined with actions performed by members of the genus *Nitrosomonas* (Nitrosomonadaceae) ($NH_4^+ \rightarrow NO_2^-$) (Sundermeyer-Klinger et al. 1984; Zhu and Carreiro 1999; Philippot and Germon 2005).

In contrast, *Salinarimonas* and *Tardiphaga* exhibit nitrate reduction ability, generating nitrite under anaerobic conditions. This transformation is an important step in producing ammonia through a process called dissimilatory reduction of nitrate into ammonia. In the absence of oxygen, this process is important for maintaining functional respiratory activity and is an alternative mechanism for denitrification in the soil (Robertson and Groffman 2007).

Denitrification allows the nitrogen to return to the atmosphere, its main reservoir on the planet, by reducing nitrate to gasses, such as NO, N_2O, and N_2. Denitrifying bacteria have representatives from genera *Bosea* and *Blastobacter* (*Table 5.3*). This process occurs under anaerobic conditions because nitrate is a less efficient electron acceptor than oxygen. In some soils, denitrification occurs after the pores are saturated by flooding, which prevents oxygen diffusion and is the main point of the cycle in which the fixed nitrogen reenters the atmosphere as N_2 gas (Tiedje 1988; Čuhel et al. 2010).

Despite the enormous amount of nitrogen in the atmosphere, soil, and water, more than 99 % is present in the form of N_2 gas and unavailable for almost all living organisms on Earth (Herridge et al. 2008). Bacteria belonging to the genera *Bradyrhizobium*, *Agromonas*, *Rhodoblastus*, and *Rhodopseudomonas* are able to directly fix atmospheric nitrogen. These bacteria form a restricted group of microorganisms called biological nitrogen fixers and can perform this process via oxygen-sensitive nitrogenase enzyme complex activity. BNF may or may not occur exclusively in free-living bacteria in soil or water, under specific culture conditions in vitro, and/or in symbiosis with host plants (Garrity et al. 2005). In these processes, N_2 is reduced to ammonia (NH_3), which can be incorporated into the bacterial biomass or supplied to host plants when in symbiosis (Bottomley and Myrold 2007). BNF is important, as it reduces gaseous nitrogen by breaking its triple bond, converting it into inorganic reactive forms, and contributing to an input on the order of 100–175 million tons (Tg) of N per year on the planet (Bottomley and Myrold 2007). The anthropogenic action related to BNF adds another 50–70 million tons (Tg) per year of N used in agriculture (Herridge et al. 2008; Lindström et al. 2010).

BNF is only performed by prokaryotic species, and the NH_3 produced may be assimilated into inorganic nitrogen forms that comprise macromolecules or may be converted into NO_2^- and NO_3^- by nitrifying bacteria. NO_3^- can thus enter

Table 5.4
Examples of host plants associated with *Bradyrhizobium*

Bradyrhizobium species	Host plant
B. japonicum	*Glycine max, Glycine soja, Macroptilium atropurpureum, Lupinus* spp., *Arachis hypogaea, Aeschynomene americana, Rhynchosia minima, Crotalaria hyssopifolia, Bryaspis lupulina, Sesbania rostrata, Chamaecrista* sp., *Cassia absus, Acacia* spp.
B. elkanii	*Glycine max, Glycine soja, Parasponia, Cajanus cajan, Tephrosia purpúrea, Abrus stictosperma, Faidherbia albida, Aeschynomene uniflora, Aeschynomene afraspera, Astragalus canadensis, Faidherbia albida*

into organic metabolism through its reduction into NH_4^+ and assimilation into amino acids by bacteria, fungi, and plants, in addition to serving as an electron acceptor for denitrifying bacteria (Crawford et al. 2000). Thus, all biological processes associated with the nitrogen cycle together contribute to the balance and use of inorganic and organic nitrogen forms associated with different microorganisms, plants, and animals.

Pathogenicity: Clinical Relevance

In the family *Bradyrhizobiaceae*, pathogenicity is associated with the genus *Afipia*. *A. felis*, the cat scratch disease (CSD) bacillus, was first detected in the lymph nodes of human patients with the disease (English et al. 1988; Bergman et al. 1995; Brenner et al. 1991). CSD, also known as cat scratch fever, is a bacterial infection that affects the lymph nodes that drain the inoculation sites and usually develops in patients with a history of cat scratches or bites (Regnery and Tappero 1995). The disease develops as a chronic, localized lymphadenopathy in infected young people, while some immunocompetent patients develop severe systemic diseases or other atypical manifestations, which include oculoglandular syndrome, encephalitis, neuroretinitis, pneumonia, osteomyelitis, erythema nodosum, arthralgia, arthritis, and thrombocytopenic purpura (Carithers 1985; Abbasi and Chesney 1995; Marra 1995; de Kort et al. 2006).

Bartonella henselae is actually considered the main etiologic agent of CSD (Bergman et al. 1995; Regnery and Tappero 1995). Species of the genus *Afipia* can act as opportunistic pathogens capable of surviving in phagosomes by inhibiting the fusion of phagosomes with lysosomes (Schueller et al. 2007). *A. felis* strains are resistant to a wide variety of antimicrobial agents, which include many beta-lactams, ciprofloxacin, and tetracycline, and are susceptible to aminoglycosides and imipenem. *A. clevelandensis* and *A. broomeae* share a similar susceptibility pattern but are more resistant to aminoglycosides. *Afipia* genomospecies 1 and 2 are the most resistant, including all the antibiotics tested, whereas genomospecies 3 is the most sensitive, exhibiting susceptibility to all classes of antibiotics cited except for cefoperazone, cefotoxin, and ceftazidime (Garrity et al. 2005).

Application

Symbiotic nitrogen fixation with bacteria of genus *Bradyrhizobium* is one of the most important aspects of agroecosystem sustainability. In many parts of the world, soybean crops are one of the most relevant examples of the importance of symbiotic associations with bradyrhizobia, in which inoculants are applied to the soil (Lindström et al. 2010). BNF associated with cultivable plants is not only beneficial to them but also provides sustainability of crop development and is related to mitigation of greenhouse gas emissions because it can replace nitrogen fertilizers produced at a high cost of CO_2-generating fossil resources (Boddey et al. 2009).

Plants are considerably varied in acquiring and assimilating nitrogen compounds from the soil, according to their dependency and variation, where NO_3^- is the predominant form. In the case of plants hosting symbiotic N-fixers, this process occurs via endosymbionts hosted in root nodules (Reddy et al. 1997; Hirsch et al. 2001; Lindström et al. 2010). Inoculation of legumes with rhizobia is perhaps one of the oldest agri-biotechnological management strategies, and recognition of its importance dates back to 1888, when M. Beijerinck confirmed that a

microorganism, later identified as a bacterium, was responsible for the formation of root nodules in legumes (Crawford et al. 2000).

There are a variety of host plants associated with different *Bradyrhizobium* species strains (› *Table 5.4*). However, from an applied point of view, the following strains stand out for their ability to nodulate soybean (*Glycine max*): *B. japonicum* (Kaneko et al. 2011) and *B. elkanii* (de Souza et al. 2012). Well-established strains of these two species are available for formulation of commercial inoculants for soybean, and the search for more efficient strains and those adapted to each country's specific agrarian conditions is a constant concern.

Another important biotechnological aspect of bacteria belonging to the family *Bradyrhizobiaceae* is the ability that some species have to produce substances with great biotechnological applications, such as water-soluble extracellular polysaccharides (exopolysaccharides, EPSs). Many species of bacteria possess this ability, and biological EPSs provide protection from various environmental insults, such as desiccation, predation, and the effects of antibiotics (Donot et al. 2012). However, the interest in EPSs has increased considerably in recent years because these compounds are candidates for many commercial applications. Numerous types of exopolysaccharides have already been described (Castellane and Lemos 2007; Monteiro et al. 2012; Mota et al. 2013; Radchenkova et al. 2013; Silvi et al. 2013).

However, only three EPSs (i.e., dextran, xanthan, and gellan gums) have been successfully adopted for industrial purposes (Donot et al. 2012; Prajapati et al. 2013). Bacteria from the genera *Bradyrhizobium* and *Rhizobium* are ESP producers that exhibit important characteristics for use in diverse industrial sectors and bioremediation, although this is still not entirely applied on the commercial scale (Bomfeti et al. 2011). Similarly, these bacteria can also produce another polymer of biotechnological relevance, polyhydroxybutyrate (PHB), the most common representative of polyhydroxyalkanoates (PHA). PHAs are biopolymers that accumulate as carbon sources in many microorganisms, usually when essential nutrients, such as nitrogen or phosphorus, are available in limiting concentrations, as well as in the presence of excess carbon sources. The PHB microbial polyester has unique physicochemical properties, such as thermoplasticity, biodegradability, and biocompatibility (Kapritchkoff et al. 2006). Because of these properties, it could be used to make plastic packages, suture ties, bone prostheses, and medicine capsules. Rhizobia is not yet used for PHB industrial production, but Paganeli et al. (2011) demonstrated that some strains are potential candidates for this purpose because they can be produced in large quantities from inexpensive carbon sources.

6 The Family *Brucellaceae*

Peter Kämpfer[1] · *Steffen Wohlgemuth*[2] · *Holger Scholz*[3]
[1]Institute of Applied Microbiology, Justus-Liebig-University Giessen, Giessen, Germany
[2]Institut für Angewandte Mikrobiologie, Justus-Liebig-Universität Giessen, Giessen, Germany
[3]Institut für Mikrobiologie der Bundeswehr, Abteilung Bakteriologie und Toxinologie, Munich, Germany

Abstract
The family *Brucellaceae* comprises the type genus *Brucella* and six further genera, namely, *Crabtreella, Daeguia*, *Mycoplana*, *Ochrobactrum*, *Paenochrobactrum*, and *Pseudochrobactrum*, phylogenetically members of the order *Rhizobiales* within the class *Alphaproteobacteria*. Organisms are Gram-negative and have a rod-shaped morphology with varying length, occasionally motile, do not produce spores, and have an aerobic respiratory type of metabolism. The majority of *Brucella* species have been isolated from animals and occasionally humans, whereas the species belonging to the other genera have been predominantly isolated from environmental sources such as sludge, soil, and water and only rarely from human or animal sources. *Brucella* species of the *B. melitensis* type (*B. melitensis, B. abortus*, *B. suis, B. ovis, B. neotomae*, *B. canis*, and B. *ceti*, considered by some taxonomists as one species, because of their high genetic relatedness) are the causal agents of Brucellosis, a severe disease of animals and man by comparative genetic analyses, it has been demonstrated that the family *Brucellaceae* especially the genus *Brucella* is genetically highly related to plant symbionts/pathogens, such as *Agrobacterium*, *Rhizobium*, and *Mesorhizobium*, and also to animal pathogens such as *Bartonella*.

Several *Ochrobactrum* species are opportunistic living organisms, which cycle from soil-rhizoplane to immunocompromised humans/animals; however, the species of the *Brucella melitensis* group live as intracellular primary parasites that do not require predisposing conditions and are capable to cycle directly from animal to animal.

Taxonomy, Historical, and Current

Short Description of the Family

Bru.cel.la'ce.ae. M.L. fem. n. *Brucella* type genus of the family; *-aceae* ending to denote family; M.L. fem. pl. n. *Brucellaceae* the *Brucella* family. The description is an emended version of the description given in *Bergey's Manual*, 2nd edition.

Phylogenetically a member of the order *Rhizobiales* within the class *Alphaproteobacteria*. The family contains the type genus *Brucella* (Meyer and Shaw 1920). In addition, six further genera, namely, *Crabtreella* (Crabtree and McCoy 1967; emended by Xie and Yokota 2006), *Daeguia* (Yoon et al. 2008), *Mycoplana* (Gray and Thornton 1928; emended by Urakami et al. 1990), *Ochrobactrum* (Holmes et al. 1988), *Paenochrobactrum* (Kämpfer et al. 2010), and *Pseudochrobactrum* (Kämpfer et al. 2006), are currently recognized. Organisms are Gram negative and have a rod-shaped

E. Rosenberg et al. (eds.), *The Prokaryotes – Alphaproteobacteria and Betaproteobacteria*, DOI 10.1007/978-3-642-30197-1_299,

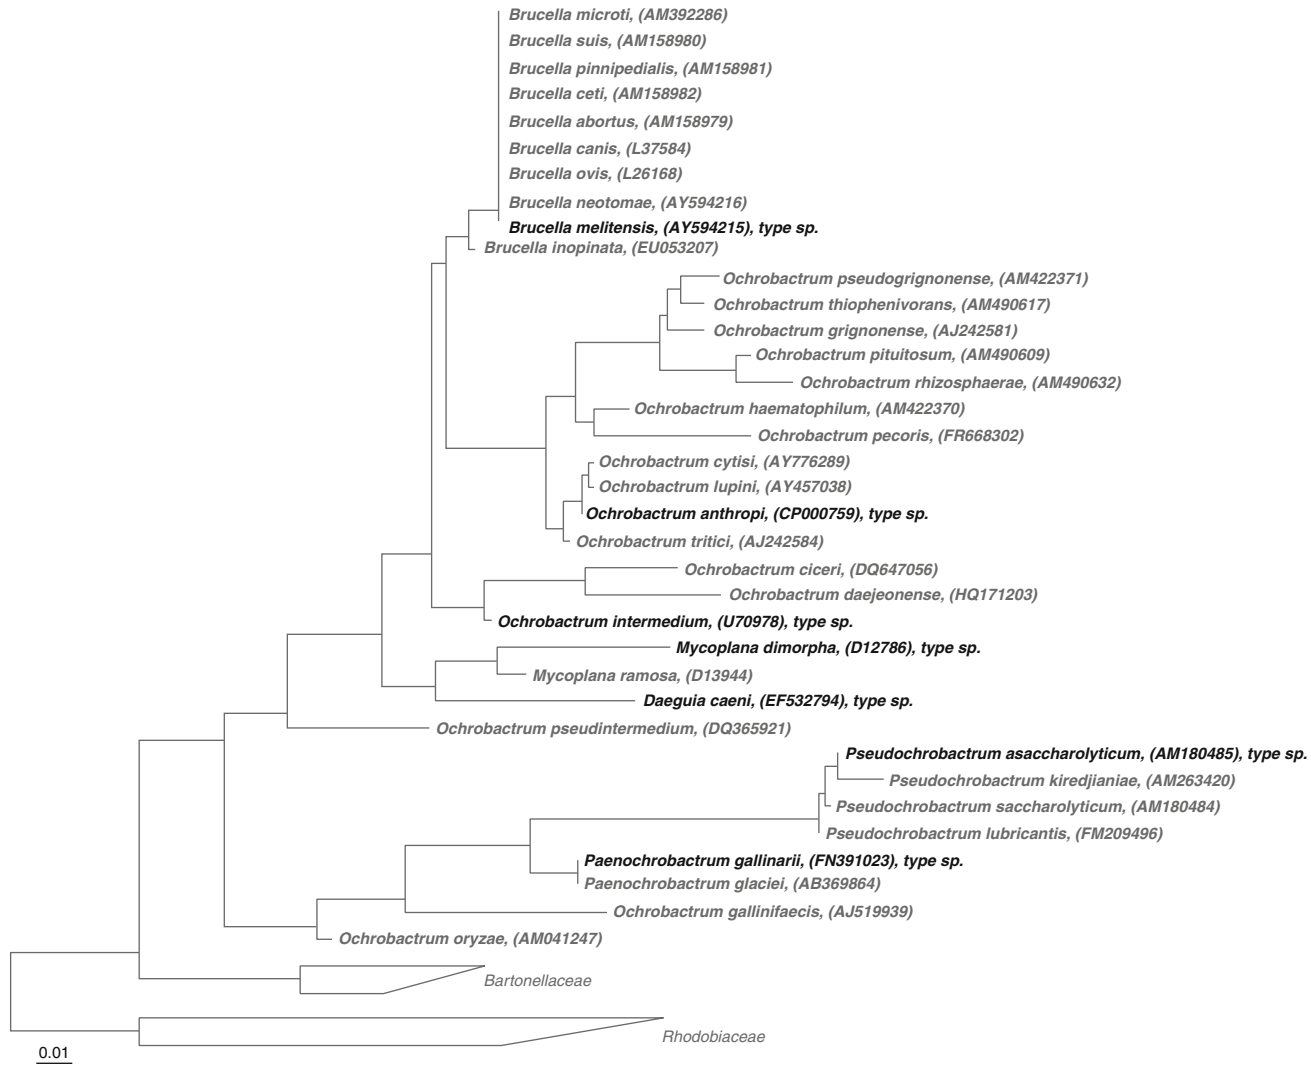

Fig. 6.1

Phylogenetic reconstruction of the family *Brucellaceae* based on 16S rRNA and created using the maximum likelihood algorithm PhyML (Guindon et al. 2010). The sequence dataset and alignment were used according to the All-Species Living Tree Project (LTP) database (Yarza et al. 2010; http://www.arb-silva.de/projects/living-tree). Representative sequences from closely related taxa were used as out-groups. Scale bar indicates estimated sequence divergence

morphology with varying length. Do not form spores. Cells are motile by means of one to several lateral or peritrichous flagella; nonmotile species occur among the genera *Brucella*, *Paenochrobactrum*, and *Pseudochrobactrum*. Aerobic, with a respiratory type of metabolism. Major fatty acids are $C_{16:1}$, $C_{18:0}$, $C_{18:1}$, and $C_{18:1}$ $\omega 7c$; other fatty acids such as $C_{14:0}$, $C_{14:0}$ 3-OH, $C_{16:0}$, $C_{16:0}$ 3-OH, and $C_{19:0}$ cyclo $\omega 8c$ may also be present. The predominant polar lipids are phosphatidylcholine, phosphatidylethanolamine, phosphatidylglycerol, and diphosphatidylglycerol. The major ubiquinone system is Q-10. The mol % G+C content of the DNA lies between 49.7 and 65.3 %. Usually found in environmental sources such as sludge, soil, and water. Some species belonging to *Brucella* and *Ochrobactrum* have been predominantly isolated from human clinical samples.

Phylogenetic Structure of the Family and Its Genera

By comparative 16S rRNA gene analysis, DNA–DNA hybridization studies, and genome sequencing analysis, it has been demonstrated that the family *Brucellaceae* especially with the genus *Brucella* is genetically related to plant symbionts/pathogens such as *Agrobacterium*, *Rhizobium*, and *Mesorhizobium* (Paulsen et al. 2002) as well as to animal pathogens such as *Bartonella* (O'Connor et al. 1991; Brenner et al. 1993) within the class of *Alphaproteobacteria* and the order *Rhizobiales*.

A phylogenetic tree is shown in *Fig. 6.1*.

The genus *Brucella* consists of genetically highly related organisms. By means of DNA–DNA hybridization studies, it has been shown that all *Brucella* species share DNA–DNA

reassociation values >90 % (Hoyer and Mccullou 1968a, b; Verger et al. 1985; De Ley et al. 1987), which is in agreement with the single species concept (accepted limit for bacterial species delineation is 70 % DNA–DNA similarity). Also based on the information that *Brucella* species cannot be differentiated by 16S rRNA gene sequencing, it has been proposed to classify all *Brucella* species as biovars of a single species, *Brucella melitensis* (Verger et al. 1985). Nevertheless, recent molecular data are in support of the classical delineation into nomenspecies and biovars, which were defined earlier on the basis of phenotypic characteristics and host preference (Michaux-Charachon et al. 1997). The ten species that are currently recognized by the Subcommittee on Taxonomy of *Brucella* are *B. melitensis*, *B. abortus*, *B. suis, B. ovis, B. neotomae*, *B. canis*, B. *ceti*, B. *pinnipedialis, B. microti*, and B. *inopinata* (http://www.the-icsp.org/subcoms/Brucella.htm#taxa).

Investigation of the taxonomic neighborhood of *Brucella* by DNA–DNA hybridization led to the conclusion that *Brucella* and *Achromobacter* CDC Group Vd strains are closely related, belonging to the same rRNA superfamily IV (De Ley et al. 1987). Later, the genus *Ochrobactrum* was constituted on the basis that *Achromobacter* CDC Group Vd strains were distinct from the genus *Achromobacter* but also displayed less than 30 % DNA–DNA similarity with *Brucella* strains. *Ochrobactrum anthropi* was constituted as the single species of this novel genus (Holmes et al. 1988).

Additional analysis of *O. anthropi* strains by a polyphasic approach identified a subset of strains with a very high relatedness to *Brucella* with 16S rRNA gene sequence similarities of >98.5 %. However, these strains clearly differed in their protein patterns, Western blot profiles, and serology. Based on this finding, a new species *Ochrobactrum intermedium* was established, which name should reflect the intermediate position between *Ochrobactrum* and *Brucella* (Velasco et al. 1998). Even though these two genera share strong genetic similarities, they differ strongly in their biological characteristics (see *Table 6.1*). While *Ochrobactrum* are opportunistic organisms, which cycle from soil-rhizoplane to immunocompromised humans/animals, *Brucella* live as intracellular primary parasites that do not require predisposing conditions and are capable to cycle directly from animal to animal (Moreno and Moriyon 2006). In addition to *O. anthropi* and *O. intermedium*, 14 more species, such as *O. grignonense*, *O. tritici* (Lebhun et al. 2000), *O. cytisi* (Zurdo-Pineiro et al. 2007), and *O. oryzae* (Tripathi et al. 2006), have recently been described and included in the genus.

The genus *Mycoplan*a was first placed within the family *Mycobacteriaceae* in the order *Actinomycetales* on the basis of phenotypic characteristics (Gray and Thornton 1928). A detailed characterization of *Mycoplana bullata* and *Mycoplana dimorpha* was performed by Urakami et al. (1990) and two new species, *M. ramosa* and *M. segnis*, were proposed. More recent 16S rRNA similarity analyses revealed that the genus is paraphyletic. With the two species *M. dimorpha* and *M. ramosa*, *Mycoplana* represents a separate branch closely related to the genera *Brucella* and *Ochrobactrum* within the *Brucellaceae*. The two former *Mycoplan*a species *M. bullata* and *M. segnis* were placed in the emended genera of *Brevundimonas* and *Caulobacter*, respectively (Abraham et al. 1999).

Phylogenetic analysis and chemotaxonomic studies of *Zoogloea ramigera* strain ATCC 19623 (Crabtree and McCoy 1967) indicated a close relationship to the *Alphaproteobacteria* and distance to the genus *Zoogloea*. As a consequence, a new genus *Crabtreella* was constituted within the *Brucellaceae*, and *Z. ramigera* was reclassified as the type species *Crabtreella saccharophila* (Xie and Yokota 2006).

The genus *Pseudochrobactrum* was constituted on the basis of 16S rRNA sequence similarity and chemotaxonomic analysis of two newly isolated Gram-negative rod-shaped oxidase-positive bacteria (Kämpfer et al. 2006). 16S rRNA sequence analysis displayed that the two organisms belong to the *Alphaproteobacteria*, with similarities less than 95 % to established species within the genera *Bartonella*, *Brucella*, and *Ochrobactrum*. Even though both bacteria displayed highest 16S rRNA gene sequence similarity to members of *Brucella*, phenotypic characteristics (including chemotaxonomic features) were more similar to those of members of the genus *Ochrobactrum*. By *recA* sequence comparison, DNA–DNA hybridization, and biochemical analysis, it was possible to clearly differentiate the two strains from each other and all known *Ochrobactrum* species. As a result, the new genus *Pseudochrobactrum* with the two species *Pseudochrobactrum asaccharolyticum* (type species) and *Pseudochrobactrum saccharolyticum* was constituted. In addition, two more species, *P. lubricantis* and *P. kiredjianiae*, have been described (Kämpfer et al. 2007, 2009).

More recently, polyphasic analysis of a newly isolated bacterial strain K107^T has led to the constitution of the genus *Daeguia* with classification of *Daeguia caeni* K107^T as the single type species (Yoon et al. 2008). *D. caeni* K107^T displays 16S rRNA gene sequence similarity values of 94.7–97.1 % with respect to members of the genera *Brucella*, *Mycoplana*, *Ochrobactrum*, and *Pseudochrobactrum*. In addition, it could be differentiated from phylogenetically related genera by *recA* gene analysis, phenotypic properties, and fatty acid profiles.

The genus *Paenochrobactrum* was newly generated after analysis of a bacterial isolate Sa25^T, which could be clearly placed in the vicinity of the *Brucella–Ochrobactrum–Pseudochrobactrum* group by 16S rRNA gene and *recA* sequencing and with *Pseudochrobactrum glaciei* KMM 3858^T being the closest relative (Kämpfer et al. 2010). Due to the fact that strain Sa25^T and *P. glaciei* KMM 3858^T form a distinct lineage in the 16S rRNA gene sequence-based phylogenetic tree and that this separate position is supported by unique characteristics of their polar lipid profiles and polyamine patterns, the novel genus *Paenochrobactrum* was proposed with *Paenochrobactrum gallinarii* strain Sa25^T as the type species and reclassification of *Pseudochrobactrum glaciei* as *Paenochrobactrum glaciei* KMM 3858^T.

Phenotypic Analyses

The main characteristics of the members of the family *Brucellaceae* are listed in *Table 6.1*.

Brucella (Meyer and Shaw 1920, 173[AL])

Bru.cel'la. L. dim. ending-*ella*; M.L. fem n. *Brucella* named after Sir David Bruce, who first recognized the organism causing undulant (Malta) fever.

Cells are Gram-negative nonspore-forming cocci, coccobacilli, or short rods with a size of 0.5–0.7 x 0.6–1.5 μm and occur singly and, less frequently, in pairs, short chains, or small groups. Nonmotile. True capsules are not formed. Do not usually display true bipolar staining. Colonies are transparent, raised, and convex, with an entire edge and a smooth, shiny surface when grown on serum-dextrose agar or other clear media. They appear in a pale honey color by transmitted light. Smooth strains produce a distinctive lipopolysaccharide (LPS) and perosamine synthetase. Nonsmooth variants of the smooth species exist, but stable nonsmooth nomenspecies with a characteristic host range do also occur. Growth occurs between 20 °C and 40 °C with an optimum growth temperature at 37 °C. Optimum pH for growth is between 6.6 and 7.4. Many strains require supplementary CO_2 for growth, especially for primary isolation. Cells are aerobic, having a respiratory type of metabolism and a cytochrome-based electron transport system with oxygen or nitrate as the terminal electron acceptor. Generally oxidase positive, but negative strains occur. Catalase and urease positive, except *B. ovis* which is usually urease negative. Nitrate reduction occurs. Voges–Proskauer test is usually negative, except for *B. inopinata* and *B. microti* which are positive for the production of acetyl methylcarbinol. Methyl red test is negative. Do not form indole. The major fatty acids are $C_{14:0}$, $C_{16:1}$, $C_{18:0}$, and $C_{18:1}$. Phosphatidylcholine is the predominant polar lipid; phosphatidylglycerol and diphosphatidylglycerol are also present as major phospholipids. Phosphatidyl ethanolamine, phosphatidyl serine, and cardiolipin are present in minor amounts. The ubiquinone system is Q-10. Chemoorganotrophic. For most strains, complex media containing several amino acids, nicotinamide, thiamine, iron, and magnesium ions are required; some strains may be induced to grow on minimal media containing an ammonium salt as the sole nitrogen source. Growth is improved by serum or blood, but hemin (X factor) and nicotinamide adenine dinucleotide (NAD: V factor) are not necessary. Acid production does not occur from carbohydrates in conventional media, except for *B. neotomae*. No liquefaction of inspissated serum or gelatine. No hemolysis. Organisms are intracellular parasites, contagious to a wide range of animal species including humans. The mol% G+C content of the DNA is 57.9–59.0. The type species is *Brucella melitensis* (Hughes 1893), Meyer and Shaw 1920, 179 (*Streptococcus melitensis* Hughes 1893, 235). Differential characteristics of the classical *Brucella* species are shown in *Table 6.2*. More detailed informations on the genus *Brucella*, including phenotypic characteristics, genetics, and pathology of Brucellosis, can be found in the comprehensive study of Moreno and Moriyon (2006).

Crabtreella Xie and Yokota 2006, 623[VP]

Crab.tre'el.la. N.L. fem. n. *Crabtreella* named after Dr K. Crabtree, the American microbiologist who isolated the type strain of the type species.

The type strain of the type species is *Crabtreella saccharophila* ATCC 19623[T] after reclassification of *Zoogloea ramigera* ATCC 19623[T], which was initially isolated from sludge (Crabtree and McCoy 1967). Currently the genus description is based on only one species. The description is based on the data compiled by Unz (1971) and Xie and Yokota (2006). Cells are Gram-negative, straight rods with rounded, blunt, or tapered ends. Cells have a size of 0.6–0.9 x 1.5–2.0 μm with one to several laterally attached flagella. Zoogloea formation is absent. Colonies are straw colored, glistening, circular, and raised when grown on CY agar. The optimum growth temperature is 28–30 °C, with slow growth at 10 °C and no growth at 45 °C. Optimum growth at pH 7.0–7.5 with no growth at pH 4.5 or 9.6. Growth occurs in the presence of 3 % (w/v) NaCl, but not at 6 % NaCl. PHB is accumulated. Catalase and oxidase positive, but urease negative. H_2S is generated in a peptone-cysteine-sulfated medium. Indole is not produced. Nitrate reduction is absent. The predominant fatty acid is $C_{18:1}$. The major hydroxy fatty acids produced are $C_{14:0}$ 3-OH, $C_{16:0}$ 3-OH, and $C_{18:0}$ 3-OH. The predominant ubiquinone is Q-10. Hydrolyses tyrosine agar with formation of brown pigment. Utilizes acetate, fumarate, malate, oxalacetate, pyruvate, arginine, asparagine, aspartate, citrulline, glutamate, histidine, ornithine, tyrosine, ammonia, *n*-propanol, ethanol, *n*-butanol, and ethanol, but not citrate, benzoate, or *m*-toluate. Arginine dihydrolase is present. Tributyrin is hydrolyzed. Acid is produced oxidatively from arabinose, fructose, ethanol, glucose, glycerol, mannitol, rhamnose, ribose, sucrose, and xylose, but no acid is formed from inulin or starch. The mol % G + C content of the DNA is 65.3 %.

Daeguia Yoon, Kang, Park and Oh 2008, 170[VP]

Dae.gu'i.a. N.L. fem. n. *Daeguia* pertaining to Daegu, the location of the textile dye works from which the type strain of the type species was isolated.

The type strain of the type species is *Daeguia caeni* K107[T] and was isolated from sludge collected from the wastewater treatment plant of textile dye works in Deagu, Korea (Yoon et al. 2008). Currently the genus description is based on only one species. Cells are aerobic, Gram-negative, nonspore-forming rods with a size of 0.4–0.6 x 0.7–2.0 μm. Colonies are grayish yellow, circular, convex, smooth, glistening, and 1.0–1.5 mm in diameter after incubation at 37 °C on TSA for 2 days. Growth occurs at 15–55 °C with an optimum at 30–37 °C and at pH 5.0–9.0 with an optimum at pH 7.0–8.0. Grows in the presence of 0–4 % (w/v) NaCl (optimum 0.5–1.0 %). The strain displays 16S rRNA gene sequence similarity values of

94.7–97.1 % with respect to members of the genera *Brucella*, *Mycoplana*, *Ochrobactrum*, and *Pseudochrobactrum*. The *recA* gene (550 nt) exhibits sequence similarity values of 77.6–84.5 % with respect to the genera *Brucella*, *Mycoplana*, *Ochrobactrum*, and *Pseudochrobactrum*. The predominant fatty acid is $C_{18:1}$ *ω7c*; a significant amount of $C_{18:1}$ 2-OH is produced. The major ubiquinone is Q-10. Urease negative. No nitrate reduction occurs. H_2S and indole are not produced. Assimilation of glucose, mannose, *N*-acetylglucosamine, inositol, adonitol, and phenylacetate. Adipate is weakly assimilated, but no assimilation of aesculin, amygdalin, D-arabinose, D-arabitol, L-arabitol, arbutin, caprate, cellobiose, citrate, dulcitol, erythritol, D-fucose, L-fucose, gentiobiose, gluconate, glycogen, inulin, 2-ketogluconate, 5-ketogluconate, lactose, D-lyxose, malate, melezitose, melibiose, methyl α-D-mannoside, methyl α-D-glucoside, methyl β-D-xyloside, raffinose, salicin, starch, sorbose, D-tagatose, turanose, xylitol, and L-xylose. Hypoxanthine is hydrolyzed, but aesculin, casein, gelatin, starch, tyrosine, urea, xanthine, and Tween 20, 40, 60, and 80 are not. Alkaline phosphatase, acid phosphatase, esterase (C4), esterase lipase (C8), leucine arylamidase, and naphthol-AS-BI-phosphohydrolase are present, but arginine dihydrolase, cystine arylamidase, lysine decarboxylase, ornithine decarboxylase, tryptophan deaminase, valine arylamidase, lipase (C14), α-fucosidase, α-galactosidase, β-galactosidase, β-glucuronidase, α-glucosidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, trypsin, and α-chymotrypsin are absent. The organism is susceptible to carbenicillin, cephalothin, chloramphenicol, gentamicin, kanamycin, neomycin, novobiocin, streptomycin, and tetracycline, but not to ampicillin, lincomycin, oleandomycin, penicillin G, or polymyxin B. The mol % G + C content of the DNA of the type strain of the type species is 57.0 %.

Mycoplana Gray and Thornton 1928, 82^{AL} emend. Urakami, Oyanagi, Araki, Suzuki and Komagata 1990, 439

My.co.pla'na. Gr. *Mykes* fungus; Gr. *plane* a wandering; M.L. fem. n. *Mycoplana* fungus wanderer.

Cells are Gram-negative and nonspore-forming curved or irregular rods with rounded ends and a size of 0.5–0.8 x 2.0–3.0 μm. The cells form branching filaments prior to fragmentation into irregular rods and occur singly or rarely in pairs. Motile by means of peritrichous flagella. Occur in soil. Colonies have a white to light yellow color and are not mucous. Good growth on standard culture media at 30 °C and between pH 6.0 and 8.0, but not at 42 °C and in the presence of 3 % (w/v) NaCl. Cells are aerobic, nonfermentative, with a strictly respiratory type of metabolism. Catalase, oxidase, and urease are produced. Voges–Proskauer is positive, but the methyl red test is negative. H_2S and indole are not formed. The predominant fatty acids are $C_{18:1}$, in large

amounts, $C_{16:0}$, and $C_{16:1}$. The major hydroxy fatty acid produced is $C_{14:0}$ 3-OH. The major ubiquinone is Q-10; small amounts of Q-9 and traces of Q-11 are also detected. Hydrolysis of gelatin and starch does not occur. Denitrification is negative, and litmus milk is not changed. Ammonia is produced. The cells accumulate granules of poly-β-hydroxybutyrate, and some have the ability to decompose aromatic compounds, such as phenol and *m*-cresol. A water-soluble fluorescent pigment is not formed on King A or King B media. Cells utilize many different compounds as sole as sole carbon sources. Currently the genus description is based on four species. In the original description of the genus (Gray and Thornton 1928), *Mycoplana* produced no acid from carbohydrates. This is inconsistent with the emended description (Urakami et al. 1990), where strains of *M. dimorpha* and *M. ramosa* have been shown to form acid oxidatively from L-arabinose, D-fructose, D-galactose, D-glucose, D-mannose, D-xylose, D-mannitol, D-sorbitol, and glycerol, but not from inositol, lactose, maltose, sucrose, trehalose, and soluble starch. The mol % G + C content of the DNA is between 63 and 65 %. The type species is *Mycoplana dimorpha* (Gray and Thornton 1928, 82 emend. Urakami et al. 1990, 440).

Ochrobactrum Holmes, Popoff, Kiredjian and Kersters 1988, 412[VP]

O.chro.bac'trum. Gr. adj. *ochros* pale, colorless; Gr. neut n. *baktron* a staff or stick; M.L. neut. n. *Ochrobactrum* a colorless rod.

Gram-negative rods with parallel sides and rounded ends with a size of 1.0 x 1.5–2.0 µm; shorter oval forms, 1.0–1.5 µm in length, may occur. Cells usually occur singly and are motile by means of peritrichous flagella. Colonies are < 0.5 mm in diameter, circular, smooth, low convex, moist, glistening, translucent, and butyrous and have an entire edge after incubation on nutrient agar for 24 h at 37 °C. Pigment is not produced. Growth occurs on MacConkey agar. Optimum growth temperature is between 20 °C and 37 °C. Few strains grow at 42 °C, and while clinical strains have not been reported to grow at 5 °C, environmental isolates will grow at 4 °C. Occur in human clinical specimens, also in soil samples and wheat roots. Cells are obligately aerobic, having a strictly respiratory type of metabolism. Catalase and oxidase positive. Indole is not produced. Nitrate reduction occurs. Urease usually positive, but ornithine decarboxylase (ODC) negative. Predominant fatty acids are $C_{18:1}$ ω7c, and $C_{19:0}$ cyclo ω8c (Kämpfer et al. 2011). The major ubiquinone is Q-10. Chemoorganotrophic, utilizing a variety of amino acids, organic acids, and carbohydrates as carbon sources. Acid is produced from arabinose, glucose, ethanol, fructose, rhamnose, and xylose. Substrate utilization patterns of various *Ochrobactrum* type strains are shown in Table 6.3. Clinical strains have been reported to be resistant to ampicillin, amoxicillin and clavulanic acid, aztreonam, cefamandole, cefonicid, cefoperazone, cefoxitin, cefsulodin, ceftazidime, cefuroxime, cephalothin, chloramphenicol, erythromycin, fosfomycin, kanamycin, mezlocillin, pipemidic acid, piperacillin, pristinamycin, streptomycin, and ticarcillin but have been shown to be susceptible to amikacin, cefoperazone, ceftriaxone, ciprofloxacin, gentamicin, imipenem, netilmicin, nalidixic acid, pefloxacin, rifampicin, tetracycline, and vancomycin; most are also susceptible to moxalactam. The mol % G+C content of the DNA is between 56 % and 59 %. The type species is *Ochrobactrum anthropi* (Holmes et al. 1988, 412).

Paenochrobactrum Kämpfer, Martin, Lodders, Jäckel, Huber, Schumann, Langer, Busse, Scholz 2010, 60[VP]

Pae'no.chro.bac'trum. L. adv. *Paene* nearly, almost; N.L. neut. n. *Ochrobactrum* a bacterial genus name; N.L. masc. n. *Paenochrobactrum* almost *Ochrobactrum.*

Cells are Gram-negative, nonmotile, nonspore-forming rods, approximately 2.0 µm long. On the basis of 16S rRNA gene sequence analysis, most closely related to the genera *Brucella*, *Ochrobactrum*, and *Pseudochrobactrum.* Currently the genus description is based on two species. Cells are oxidase positive, showing an oxidative metabolism. The predominant fatty acids are $C_{18:1}$ ω7c and $C_{19:0}$ cyclo *ω8c.* The major polar lipids are phosphatidylcholine, phosphatidylethanolamine, phosphatidylglycerol, diphosphatidylglycerol, phosphatidylmonomethylethanolamine, unknown aminolipid AL1, and moderate or minor amounts of unknown polar lipids L1 and L2. In addition, an aminolipid that stretches over a long range in the first chromatographic dimension (stretched aminolipid) is detectable. The predominant ubiquinone is Q-10. The polyamine pattern exhibits the major compound putrescine and moderate to large amounts of spermidine while sym-homospermidine is absent. *P. gallinarii* Sa25^T and *P. glaciei* KMM 3858^T are positive for the hydrolysis of L-alanine, *p*-nitroanilide (*p*NA), and L-proline *p*NA and weakly positive for hydrolysis of bis-*p*-nitrophenyl (*p*NP) phosphate, but do not hydrolyze aesculin, *p*NP-β-D-galactopyranoside, *p*NP-β-D-glucuronide, *p*NP-α-D-glucopyranoside, *p*NP-β-D-glucopyranoside, *p*NP-phosphorylcholine, *p*NP-phenylphosphonate, and 2-deoxythymidine-59-*p*NP phosphate. Both strains assimilate acetate and L-alanine, but no assimilation of adonitol, *p*-arbutin, cellobiose, D-gluconate, maltitol, maltose, *myo*-inositol, D-mannitol, α-melibiose, D-sorbitol, salicin, trehalose, putrescine, L-leucine, L-phenylalanine, L-tryptophan, 3-hydroxybenzoate, *trans*-aconitate, adipate, citrate, itaconate, mesaconate, phenylacetate, suberate, azelate, and 4-hydroxybenzoate occurs. Table 6.4 shows assimilation of different substrates by *P. gallinarii* Sa25^T and *P. glaciei* KMM 3858^T. The type strain of the type species is *Paenochrobactrum gallinarii* Sa25^T and has a mol% G + C content of the DNA of 49.7 % (Kämpfer et al. 2010).

Pseudochrobactrum Kämpfer, Rosselló-Mora, Scholz, Welinder-Olsson, Falsen, Busse 2006, 1825[VP]

Pseud.och.ro.bac'trum. (Gr. adj. *pseudes* false; N.L. neut. n. *Ochrobactrum* a bacterial genus name; N.L. neut. n. *Pseudochrobactrum* false *Ochrobactrum*).

Cells are Gram-negative, nonmotile, nonspore-forming rods, approximately 2.0 μm long. The *recA* gene exhibits sequence similarity to species of *Ochrobactrum* (81 %), *Brucella* (80 %), and *Bartonella* (76 %). Currently the genus description is based on four species. Negative for a *Brucella abortus*- and *Brucella melitensis*-specific antigen (according to the assay of Baily et al. 1992). Cells are oxidase positive, showing an oxidative metabolism. Optimum growth temperature is between 25 °C and 30 °C. The major fatty acids produced are $C_{18:1}$ ω7*c* and moderate amounts of $C_{18:0}$ and $C_{19:0}$ cyclo ω8*c*. The predominant polar lipids are phosphatidylcholine, phosphatidylethanolamine, phosphatidylmonomethylethanolamine, phosphatidylglycerol, and diphosphatidylglycerol. In addition,

moderate amounts of phosphatidyldimethylethanolamine and unknown aminolipid AL1 and small amounts of unknown phospholipid PL1 and five unknown lipids (L1–L5) are detected. The major ubiquinone is Q-10. The polyamine pattern exhibits the major compounds putrescine and spermidine and small amounts of 1,3-diaminopropane and spermine. All *Pseudochrobactrum* strains are positive for hydrolysis of L-alanine-*p*NA and L-proline-*p*NA and weakly hydrolyze bis-*p*NP-phosphate, but do not hydrolyze *p*NP-β-D-galactopyranoside, *p*NP-β-D-glucuronide, *p*NP-α-D-glucopyranoside, *p*NP-β-D-glucopyranoside, *p*NP-phosphorylcholine, *p*NP-phenylphosphonate, 2-deoxythymidine-5′-*p*NP-phosphate, and aesculine. All strains are positive for assimilation of L-alanine, L-proline, L-serine, acetate, and oxoglutarate, but do not assimilate adonitol, *p*-arbutin, D-cellobiose, D-gluconate, i-inositol, D-maltose, D-maltitol, D-mannitol, α-D-melibiose, D-sorbitol, salicin, D-trehalose, putrescine, L-leucine L-phenylalanine, L-tryptophan, trans-aconitate, adipate, azelate, citrate, itaconate, mesaconate, phenylacetate, suberate, 3-hydroxybenzoate, and 4-hydroxybenzoate. *Table 6.5* shows assimilation of different substrates by *Pseudochrobactrum* type strains. The type strain of the type species is *Pseudochrobactrum asaccharolyticum* CCUG 46016^T and has a mol% G + C content of the DNA of 50.9 % (Kämpfer et al. 2006).

Molecular Analyses

All *Brucella* species are genetically highly related to each other, exhibiting sequence similarity values of 98–100 % in aligned genomic regions (core genomes). In fact, with the exception of *B. inopinata*, all *Brucella* species have identical 16S rRNA and *recA* gene sequences and show only few variations in most housekeeping genes. Thus, the population structure is clonal and *Brucella* represents a monophyletic genus. Because of this close genetic relatedness, DNA–DNA hybridization cannot be used for species differentiation. However, despite this close genetic relatedness, the various species show species-specific and to some extent even biovar-specific clustering in high-resolution molecular typing assays, such as multilocus sequence typing (MLST) or multilocus sequence analysis (MLSA). More recently, whole genome sequencing (WGS) and the resulting global genome-wide single-nucleotide polymorphism (SNP) analysis have become available to study phylogeny, evolution, host specificity, and pathogenicity of the genus *Brucella* at the highest level possible.

Species Delineation

Accurate species delineation can be achieved by conventional multiplex polymerase chain reaction (PCR) targeting species-specific genes, SNP analysis, MLST, or MLSA. The last approach is also suitable for phylogenetic reconstructions, owing to the highly clonal evolution of the different species and in particular to study *Brucella* at the strain level which is important for molecular epidemiologic studies, e.g., outbreak investigations.

PCR-Based Methods

One of the first PCR assays to differentiate among *Brucella* species was the so-called Abortus–Melitensis–Ovis–Suis (AMOS) PCR, developed by Bricker and Halling (1994). This PCR uses a single reverse primer, targeting the *Brucella*-specific insertion element IS*711*, and four different forward primers, each specific for a given species as estimated by testing representative isolates. Species are differentiated on the basis of different PCR fragment sizes. This assay distinguishes *B. melitensis*, *B. abortus*, *B. ovis*, and *B. suis*. The disadvantage of this PCR is that not all species can be identified (i.e., *B. canis* and *B. neotomae*) and that some biovars within a given species give negative results.

In 2006 a new conventional multiplex PCR (Bruce-ladder), using eight primer pairs in a single reaction, was developed by Garcia-Yoldi and colleagues (Garcia-Yoldi et al. 2006). Later, this PCR was enhanced, to cover novel species such as *B. microti* and *B. inopinata* and to differentiate between *B. ceti* and *B. pinnipedialis* (Mayer-Scholl et al. 2010). However, differentiation at the biovar level, or below, is not possible (*Fig. 6.2*). Consequently, PCR assays that allow discrimination among biovars within a given species were developed. The most recent

multiplex PCR assay to differentiate among *B. suis* biovars 1 to 5 (Suis-ladder) was developed by López-Goñi et al. (2011).

To date, at least 400 reports have been published dealing with various PCR-based methods for *Brucella* detection and differentiation. For details on PCR-based assays, see Yu and Nielsen (2010).

Specific High-Resolution Assays

Multilocus Variable Number of Tandem Repeat Analysis

The MLVA assays take advantage of array-length variations in tandem repeats. Owing to the availability of whole genome sequences, tandem repeats can be readily identified and tested for polymorphism. Most tandem repeats have been evaluated, essentially by three groups (Bricker, Vergnaud, Whatmore, and colleagues), and tens of polymorphic loci have been identified. Different selections of such loci, used in MLVA assays, have been proposed to suit different purposes.

The first MLVA assay, named "HOOF-Prints" (hypervariable octameric oligonucleotide fingerprints), was developed by Bricker et al. in 2003 (Bricker et al. 2003). The *Brucella* genome contains a family of tandem repeats sharing the repeat unit "AGGGCAGT." Eight highly variable such loci, present in most *Brucella* species, were selected for use in the HOOF-Print assay. Variations of the repeat numbers at each locus can easily be investigated by amplifying the corresponding regions and subsequent gel electrophoresis or preferably capillary electrophoresis given the short repeat unit size. This selection of tandem repeats has a very high discriminatory power and can be useful for local outbreak investigations.

With the HOOF-Print assay, a reliable tool to study the relationship of human cases and outbreak dynamics became available for the first time (Valdezate et al. 2007). However, it cannot provide a species assignment owing to the high level of homoplasy (see below) at these loci.

Indeed, high-resolution markers allow the discrimination of individual strains and therefore can be used for trace-back analyses and epidemiological studies in outbreak scenarios. A high discriminatory power is desired when investigating an outbreak with very limited geographical and temporal distribution, and highly variable loci will then be preferred. However, rapidly evolving VNTR markers often suffer from homoplasy,

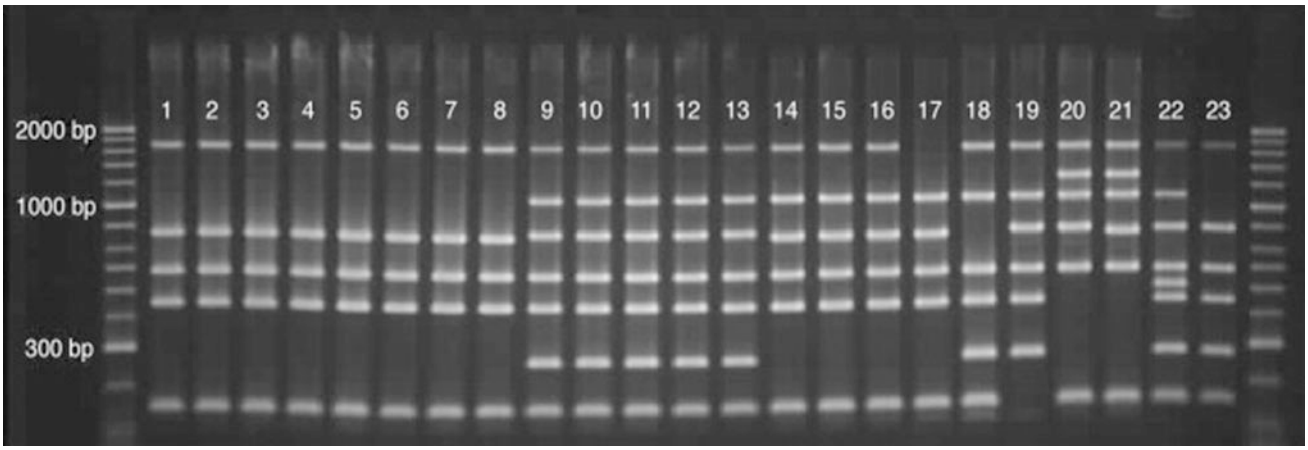

Fig. 6.2

i.e., the appearance of the same genetic alteration in two or more branches of a phylogenetic tree. These phenomena can disrupt and confound the accurate phylogenetic placement of some isolates within an MLVA cluster and prevent accurate species-level designation.

A stronger phylogenetic signal and different selections of loci are needed when looking for species identification. Practical considerations (cost) also need to be taken into account. Although tens of VNTRs have been described in *Brucella* and are potentially useful, the number of loci in an MLVA assay should be kept to a minimum. Because the HOOF-Print MLVA assay could not be used for identification purposes at the species level, additional selections of tandem repeats were subsequently proposed (*Table 6.6*).

The MLVA15$_{Orsay}$ and MLVA16$_{Orsay}$ selection (Le Fleche et al. 2006) and/or their subpanels are currently the most commonly used, according to the literature, probably because of the existence of an accessible internet database which contains MLVA16 data from 1,492 isolates (see: http://mlva.u-psud.fr/brucella/ accessed 10 December 2012).

The MLVA16$_{Orsay}$ assay is divided in two different panels: one with a low discriminatory index that allows quick allocation to a major branch and species and a second panel with VNTR markers of high discriminatory power, suitable for outbreak investigations, some of which are used in the HOOF-Print assay (*Table 6.5*). A minimum spanning tree based on MLVA16$_{Orsay}$ data from 1,925 isolates is shown in *Fig. 6.3*.

Whereas MLVA is a highly efficient tool for clustering strains, it is not a phylogenetic tool because rapidly evolving VNTR markers often suffer from homoplasy. However, clusters can be easily connected upon a phylogenetic backbone, as soon as a subset of representative strains have been analyzed by both MLST (see below) and MLVA.

Given the clonal evolution of the main *Brucella* species, phylogeny makes sense, and phylogenetic investigations can conveniently be used to define lineages. In fact, MLST is probably the tool most commonly used in current phylogenetic investigations of *Brucella*.

Multilocus Sequence Typing of Single-Nucleotide Polymorphisms

The conventional MLST approach uses sequence divergence in housekeeping genes. About 7–9 housekeeping genes are commonly analyzed in order to obtain a reasonable balance between the acceptable identification power, time, and cost for the strain typing. From each housekeeping gene, approximately 450–500 base pairs (bp) are amplified by PCR, followed by DNA sequencing and subsequent comparative sequence analysis. Each unique sequence is assigned a specific allele number, and alleles are combined into an allelic profile and further assigned to a specific sequence type (ST). New alleles result in a new combination and therefore in a novel sequence type.

Because accumulated changes occur slowly and are regarded as selectively neutral, the MLST approach is a reliable tool for the overall characterization of microbial populations and the investigation of phylogenetic relationships. However, the slow molecular clock rate and the limited number of genes do not allow in-depth phylogenetic reconstructions and analysis of local epidemiological studies. Thus, unlike MLVA, MLST is of little value for outbreak investigations.

In 2006 Whatmore et al. developed an MLST assay based on nine different loci (Whatmore et al. 2006). Of the nine loci, seven correspond to classical housekeeping genes. The remaining two loci target the *omp25* gene and an intergenic region, respectively, resulting in more discriminatory power. Nine loci are sequenced, totalling almost 4,400 bp or 0.1 % of the genome. Owing to clonal evolution and congruence of the phylogeny of individual loci, these data are usually analyzed as MLSA in which the sequence

HOOF-designations are from Bricker et al. 2003; "Bruce" are from Le Flèche et al., 2006 (48), "VNTR" are from Whatmore et al. 2006 (49), "BruceVNTR" are from Tiller et al. 2009 (50); *HGDI* (Hunter–Gaston diversity index): discriminatory power

[a]The primers for BruceVNTR3 amplify simultaneously VNTR5A and VNTR5B

[b]Bruce19 was initially published by Le Flèche et al., 2006 as a 6 bp repeat unit VNTR. However due to a secondary internal deletion in the array, present in some lineages, it is considered as a 3 bp repeat unit for allele calling consistency purposes

from all nine loci is concatenated. Such a tree is shown in Fig. 6.4.

In a comprehensive study, Whatmore and colleagues investigated 160 *Brucella* isolates belonging to all known species and biovars (Whatmore et al. 2007). The assay grouped *B. abortus*, *B. melitensis*, *B. ovis*, and *B. neotomae* as well-separated clusters according to their species affiliation. *B. suis* biovars 1 to 4 also clustered together but demonstrated higher intraspecies heterogeneity when compared with the other species. *B. suis* biovar 5 formed a separated lineage. The ten *B. ovis* isolates, although from different geographical regions, were represented by a single sequence type. The *B. canis* strains grouped in proximity to *B. suis* biovars 3 and 4 but were distinguishable by a different sequence type. *Brucella* isolates from marine mammals also grouped as a separated cluster.

The results of that study confirmed the close proximity of *B. suis* biovars 3 and 4 with *B. canis* and the separate position of *B. suis* biovar 5, already suggested by phenotypic assays and molecular methods. On the basis of these results, the authors concluded that this assay can be used to provide a strong phylogenetic backbone for the *Brucella* genus.

Real-Time Polymerase Chain Reaction Assays of Single-Nucleotide Polymorphisms

The MLST technique requires amplification of the corresponding target genes by PCR, followed by double-strand DNA sequencing of the products and subsequent sequence analysis. The overall procedure is expensive and time consuming. Consequently, a new platform for the rapid detection of SNPs was developed.

Based on the results from MLST, Gopaul et al. developed a rapid assay to distinguish the major *Brucella* clades using the minor groove binder real-time PCR technology (Gopaul et al. 2008). For each allele, a highly specific 5′ labeled, 3′ minor groove binding (MGB) TaqMan probe was designed. The assay was evaluated by testing over 300 isolates of *Brucella*. Almost at the same time, a similar approach to distinguish among the various *Brucella* species was developed by Foster et al. (2008). However, it is important to keep in mind that assays based on typing selected SNPs are highly biased. They collapse tree branches along linear trees.

Whole Genome Sequencing and Global Analysis of Single-Nucleotide Polymorphisms

The first two genome sequences available were from *B. melitensis* 16 M and *B. suis* 1330 (DelVecchio et al. 2002; Paulsen et al. 2002). From genome sequencing analysis, in particular the genome of *B. suis* 1330, it became evident that *Brucella* shares extensive genetic similarity with some plant pathogens and microbes that live symbiotically with plants, such as *Agrobacterium, Rhizobium*, and *Mesorhizobium* (Paulsen et al. 2002). Paulsen et al. found that a total of 1,902 *B. suis* ORFs were conserved in all three genomes of *M. loti*, *S. meliloti*, and *A. tumefaciens*, and 2,408 *B. suis* 1330 ORFs were conserved in at least one of these three genomes. In addition to gene sequence conservation, *B. suis* 1330 chromosome 1 shares extensive regions of gene synteny (gene order) with the *M. loti* chromosome, whereas chromosome 2 does not. Instead, chromosome 2 possesses a cluster of plasmid-like replication genes similar to plasmid replication genes from *Agrobacterium* Ti plasmids and plasmids from other organisms including *Rhizobium* spp. (Paulsen et al. 2002).

Detailed sequence analysis revealed the existence of an intact beta-ketoadipate pathway in *B. suis* 1330 (Paulsen et al. 2002) and also in *B. microti* (Audic et al. 2009). This pathway, which enables the bacterium to break down plant-derived aromatic compounds and lignin monomers, is widely distributed and highly conserved in soil bacteria and fungi, including *Pseudomonas putida*, *Acinetobacter calcoaceticus*, *Agrobacterium tumefaciens*, and *Rhodococcus erythropolis* (Harwood and Parales 1996). Therefore, it seems likely that some *B. suis* strains can persist and even might multiply in the environment. Various studies have been performed to confirm this hypothesis. In a study, carried out by the US Environmental Protection Agency (EPA), the persistence of *B. suis* biotype 1 strain Battelle BRU163 on various outdoor materials was evaluated. *B. suis* persisted as long as 28 days (longest period tested) on various matrices (aluminum, wood, glass, soil) under low and moderate temperatures without UV light (report see: EPA/600/R-10/026; April 2010; www.epa.gov/ord). Thus, it seems likely that *Brucella* has evolved from a soil/plant-associated ancestral bacterium, and speculatively, at least some strains of *B. suis* and *B. microti* may be have a replicative life cycle outside of a mammalian host. Sequencing of the *B. abortus* field isolate 9–941 in 2005 (Halling et al. 2005) and comparison to the genome sequences of *B. melitensis* 16 M and *B. suis 1330* revealed a striking similarity, with nearly identical genetic content and gene organization.

In 2009 the genome sequence of *B. microti*, originally isolated from the common vole in the Czech Republic, was published (Audic et al. 2009). Although *B. microti* is metabolically very active displaying numerous metabolic reactions that are absent from all classical *Brucella* species (Scholz et al. 2008; Al Dahouk et al. 2012), the genome sequence of *B. microti* is almost identical to that of *Brucella suis* 1330 with an overall sequence identity of 99.84 % in aligned regions (Audic et al. 2009). Hence, the authors concluded that the different phenotype is rather a matter of differential gene regulation than based on the presence of additional genes in the chromosome of *B. microti*.

In 2011 the first genome sequence of a *Brucella* strain isolated from a marine mammal, *Brucella pinnipedialis* B2/94, was published (Audic et al. 2011).

To date, a total of 40 *Brucella* genomes have been sequenced, with an average size of 3.3 MB ranging from

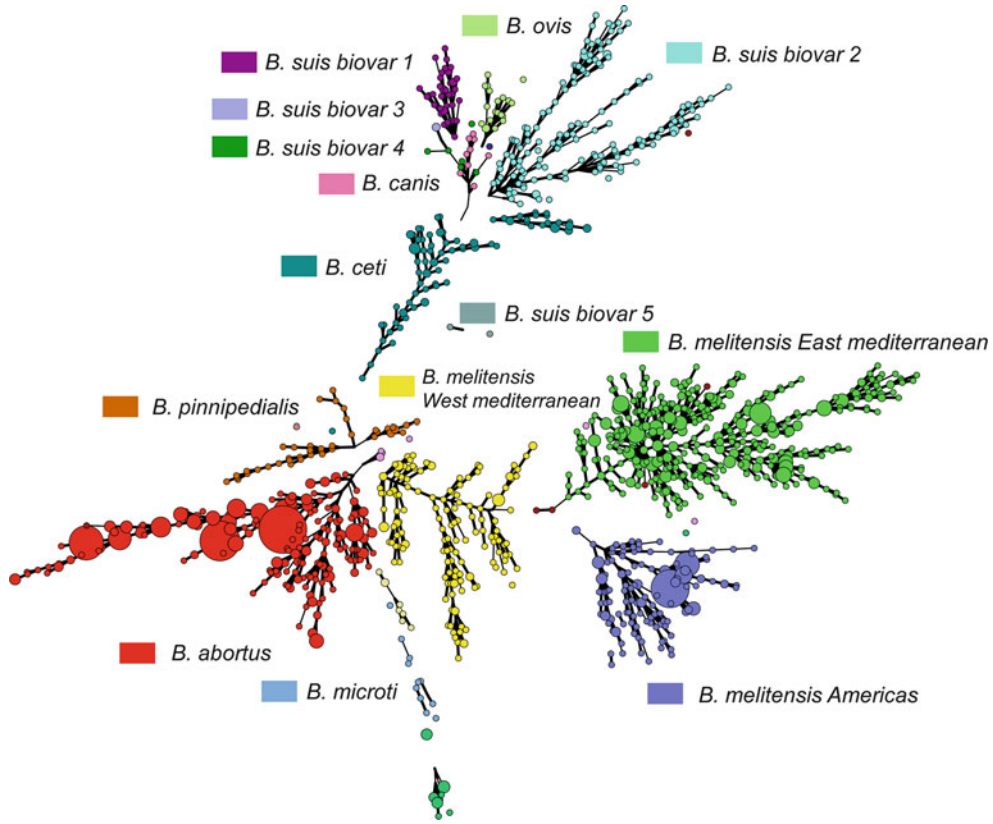

Fig. 6.3

Minimum spanning tree based on MLVA15Orsay data from 1925 isolates, the majority being compiled from the literature. Branch length up to 3 are shown. The figure illustrates how MLVA can be used to draw the image of a population at low cost and then pick the rare isolates (shown with different *colors*) with long branches for whole genome draft sequencing (Figure provided by G.Vergnaud)

3.11 MB (*Brucella* sp. NF2653) to 3.4 MB (*B. pinnipedialis* B2/94). The average number of annotated genes per genome is 3,524, ranging from 3,325 (*Brucella* sp. 83/13) to 3,709 (*B. ceti* Cudo) (Sobral and Wattam 2011). With the exception of *B. suis* biovar 3, which consists of a single 3.15 MB chromosome, all other so far sequenced *Brucella* genomes are composed of two chromosomes. Plasmids are absent in all *Brucella* sequenced so far. To date, there has been no comparative analysis including all 40 genomes; however, two comparative studies have recently been published covering 10 and 37 *Brucella* genomes, respectively (Wattam et al. 2009; Bohlin et al. 2010).

Wattam et al. (2009) analyzed the genomes of *Brucella* strains that have recently been described as atypical *Brucella* because of their different phenotype compared with the classical *Brucella* species. These analyses included stain BO1 (*B. inopinata*), isolated from a breast implant infection of a 71-year-old woman (De et al. 2008); strain BO2, isolated from a patient with obstructive pneumonia in Australia (Tiller et al. 2010a); and two strains, 83–13 and NF2653, isolated from Australian rodents (Tiller et al. 2010b). They found that the atypical strains grouped separately from the classical *Brucella* species but markedly closer to them as *Ochrobactrum*, the genetically closest genus in the family *Brucellaceae*, suggesting the atypical strains as true members of the genus *Brucella* – at least from a genetically point of view. Furthermore, all so far sequenced atypical *Brucella* strains, including *B. inopinata* and *B. microti*, harbor the *Brucella*-specific genetic marker *bcps*31 (31 KDa surface protein) and the insertion element (IS) *IS711*, confirming their affiliation to the genus *Brucella*. Wattam et al. (2009) also found a set of genes specific for each group, respectively, or genes which are absent in one of the groups. In fact, the atypical *Brucella* strains harbor unique regions not found in the classic *Brucella* genomes and vice versa. A recent genome study, carried out by Bohlin and colleagues (Bohlin et al. 2010), compared a set of *Brucella* species with closely related bacteria, such as *Ochrobactrum* and *Agrobacterium*, using base compositional- and proteome-based methods. Both methods were in good agreement with the current *Brucella* taxonomy but demonstrated that *Brucella* species are characterized by extremely high levels of nucleotide similarity and yet vary in microbial and disease phenotypes as well as in pathogenicity and host preference.

Draft whole genome sequencing is increasingly being used in replacement of MLST and large-scale SNP typing because it is an unbiased approach and provides an incomparable wealth of data, at a cost which is now getting closer to that

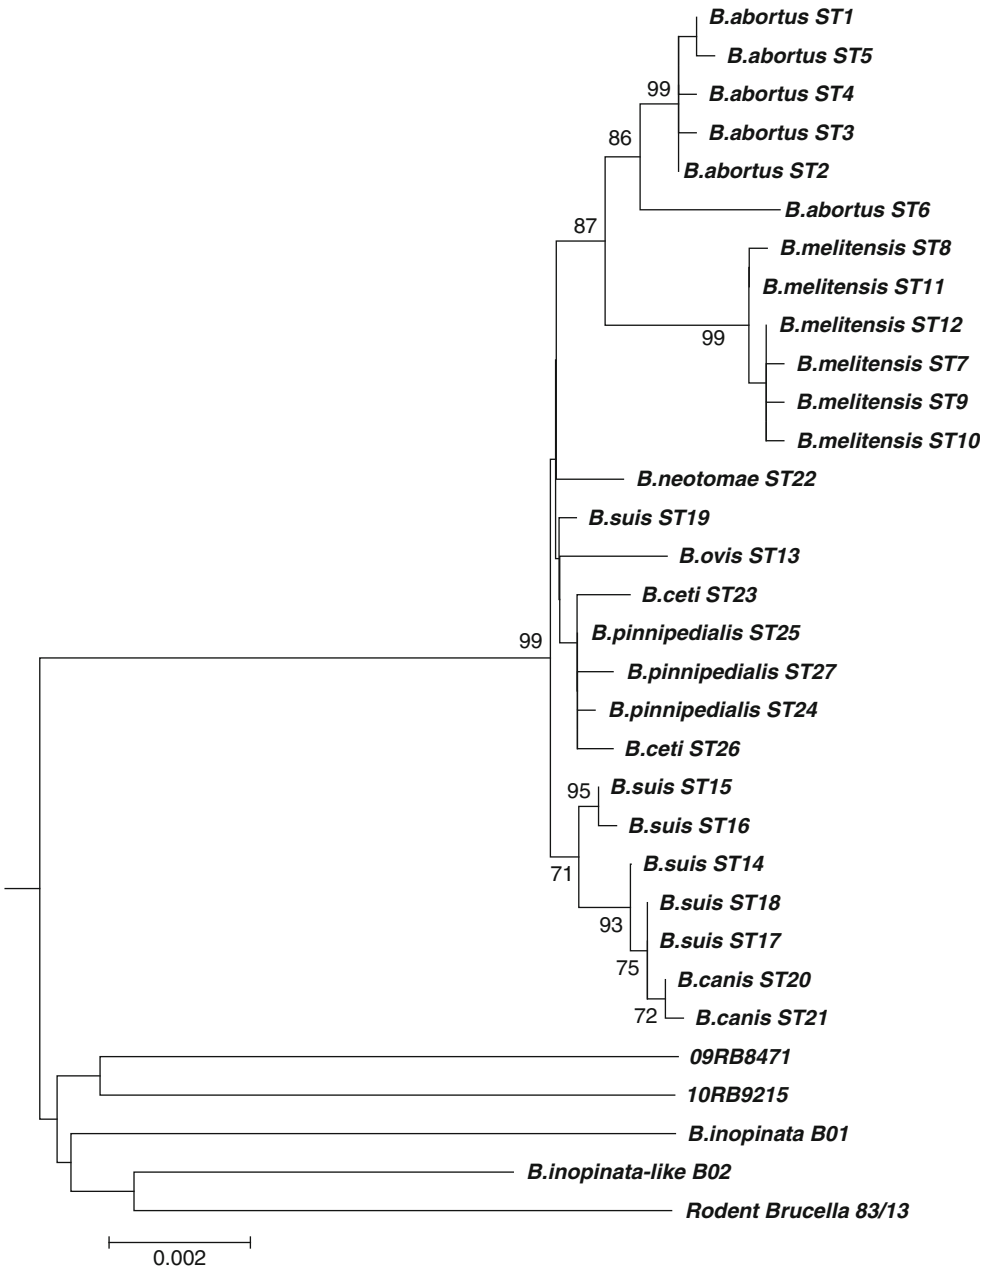

Fig. 6.4

Relationships among the *Brucella* complex based on eight loci MLSA. The extended *Brucella* group, including *B. inopinata*, the rodent isolate 83/13, strain BO2, and the two isolates (09RB8471 and 09RB9215) from African bullfrogs cluster separately from the core *Brucella*. Sequences were concatenated and the phylogenetic tree constructed using the neighbor-joining approach. Numbers at nodes correspond to proportions of 100 resamplings that support the topology shown with only values >70 % indicated. Bar = number of substitutions per nucleotide position (Figure provided by AM Whatmore)

of the previously described assays. Hundreds of isolates are currently being sequenced and analyzed at draft level for whole genome SNP discovery (O'Callaghan and Whatmore 2011). Compared with MLSA, this will provide much higher resolution. From the resulting information, it will be possible to devise specific SNP assays that efficiently complement MLVA typing and clustering analysis when necessary (Foster et al. 2009).

Phages

A major criterion for species definition of *Brucella* is their susceptibility to phages. Over twenty *Brucella* phages have been isolated from various sources such as *Brucella*-infected animals, blood, milk, fetuses and from the bacteria themselves (Moreno and Moriyon 2006). Based on their host specificity, *Brucella* phages may be classified into seven

distinct groups with numbers that reflect the order they were isolated or developed (Corbel and Banai 2005). The characteristics of the main *Brucella* phages are shown in Table 6.7. Due to their narrow host range, phages are valuable for the identification of *Brucella* at the genus and, combined with other test, even at the species level. Although phage typing mainly provides a precise result, some *Brucella* strains may display variation from the standard lysis pattern. This is predominantly the case for *B. melitensis* strains, which can be classified into subtypes according to their susceptibility pattern for Bk_2, Iz_1, and Wb phages (Corbel 1987, 1989). More detailed information on *Brucella* phages can be found at Corbel and Banai (2005) and Moreno and Moriyon (2006).

MALDI-TOF Analysis

Despite the close genetic relatedness, it is possible to differentiate the various *Brucella* species using matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF-MS). In a recent study, Lista et al. (2011) investigated 170 *Brucella* strains covering all classical *Brucella* species. Identification was possible at the species level.

Isolation, Enrichment, and Maintenance Procedures

Detailed information on isolation and culture of *Brucella* can be found at Corbel and Banai (2005) and Moreno and Moriyon (2006). *Brucella* has been classified as a risk group 3 microorganism and should be handled with the appropriate precautions. *Brucella* may be isolated from clinical specimens such as any tissue or secretion. The material which will most likely yield positive cultures includes abortion material (amniotic fluid, fetal gastric contents, fetal lung, fetal liver, placenta cotyledon, and vaginal discharge), accessory glands, bone marrow, lymph nodes, mammary gland, uterus, seminal vesicles, testes and epididymides, or other organs with local lesions, as well as body fluids like blood, colostrum, milk, and semen (Corbel and Banai 2005).

To isolate *Brucella* from samples where contaminating bacteria are expected, a selective isolation medium is advised. Most smooth strains of *Brucella* can be isolated with SDA supplemented with the antibiotic formulation of Farrell (1974), yet this medium might inhibit growth of *B. canis* and *B. ovis*. These two species may be isolated from contaminated material by using SDA supplemented with 10 % (v/v) heated horse serum and VCN-F inhibitor (BBL) or modified Thayer–Martin medium (Brown et al. 1971). These media have shown to be less selective compared to Farrell's SDA; therefore, it is recommended to dilute heavily contaminated material, such as semen, in 5–10 volumes of sterile isotonic solution and subsequently filter it through a membrane filter (0.8 µm pore size) before plating. Inoculated plates should be incubated at 37 °C under an air atmosphere supplemented with 5–10 % (v/v) CO_2. Incubation with CO_2 supplementation can be omitted when isolation of a CO_2-independent *Brucella* species is being attempted. Direct inoculation of heavily infected materials onto selective media generally leads to a satisfactory isolation of *Brucella*, even if contaminating bacteria are present. Uncontaminated sample materials may be plated directly on to SDA plates.

When the concentration of *Brucella* in the sample is expected to be low, as it is the case for body fluids such as blood, milk, or semen, enrichment procedures should be employed. To enrich *Brucella* in milk, samples should be incubated at 4 °C, leading to concentration of *Brucella* cells in the cream layer, which can then be cultured. Enrichment of *B. canis* in blood of tissue material may be achieved by inoculation of the yolk sacs of 6–8-day-old chicken embryos. Yolk from eggs with dead embryos is plated onto SDA or other suitable media. Cell wall-defective forms of *Brucella* may be enriched by culturing blood, solid tissue, and synovial fluid samples on SDA supplemented with 20 % (v/v) horse serum and with the antibiotic formulation of Farrell (1974). The inoculated plates should be incubated for at least 2 weeks and be inspected for microcolonies under a stereomicroscope.

Another way to enrich for *Brucella* is either by growth in a liquid enrichment medium or by intramuscular injection of the sample material into guinea pigs followed by subsequent culturing of the spleen tissue past 4 weeks. However, enrichment in guinea pigs is only presumably being successful with virulent strains of *B. abortus*, *B. melitensis*, and *B. suis*. Enrichment cultures can be carried out using a two-phase culturing system established by Castañeda (1947). The system contains a liquid phase, which consists of SDB supplemented with the antibiotic formulation of Farrell (1974) and 25 % (w/v) trisodium citrate, and a solid phase containing SDA with 2.5 % (w/v) agar. At first, the liquid phase is inoculated with the sample, and bottles are then incubated at 37 °C under air atmosphere (supplemented with CO_2, if required). Every 2–3 days, an aliquot of the liquid phase is poured over the solid phase. Bottles are re-incubated for up to 6 weeks or until colonies start to grow on the solid phase, whichever is sooner. For enrichment cultures of *B. canis* and *B. ovis*, the antibiotic formulation can be substituted by VCN-F inhibitor.

Short time maintenance of *Brucella* cultures can be achieved by streaking them onto SDA slants. Following incubation at 37 °C for 72 h under air atmosphere (supplemented with 10 % CO_2 (v/v), if required), the slants are sealed and stored at 4 °C. Subculturing has to be repeated at intervals of 6–8 weeks. However, for long-term preservation of *Brucella* strains, this procedure is insufficient, as these tend to alter their characteristics when subcultered repeatedly.

Cultures of *Brucella* may be maintained appropriately for long-term periods by vacuum drying. The strains are incubated on SDA slants at 37 °C for 72 h under air (+ 10 % CO_2 (v/v), if required). The culture is then washed off the slants and suspended in sterile rabbit serum to reach a final concentration of about 10^{10} bacteria/ml. Aliquots of 0.1 ml are filled into sterile

tubes sealed with cotton-wool plugs and are stored over phosphorus pentoxide in a desiccator kept at 4 °C. The desiccator has to be evacuated on a daily basis until a stable pressure of 0.05-mmHg is reached. Finally, the tubes are sealed under vacuum in glass ampoules including a small quantity of silica gel. Preserved this way, *Brucella* cultures may stay viable for several years.

In addition, *Brucella* cultures may be preserved adequately by freeze-drying. General instructions for this procedure have been provided by Lapage et al. (1970), and further details about the technique are given by Boyce and Edgar (1966).

Storage of *Brucella* cultures in liquid nitrogen is another option for preservation, yielding to a higher degree of viable cells compared to vacuum drying or freeze-drying (Davies et al. 1973). *Brucella* are incubated on SDA slants at 37 °C for 72 h under air (+10 % CO_2 (v/v), if required). The culture is then suspended in single-strength Bacto-glutamate medium to give a dense suspension. The bacterial suspension is left alone at 4 °C for 1 week, and then aliquots of 1 ml are filled into sterile glass screw-capped vials. Finally, the vials are placed in the vapor phase or are directly immersed in the liquid nitrogen.

Isolation of *Crabtreella saccharophila* (*Zoogloea ramigera* ATCC 19623^T) from sludge was initially described by Crabtree and McCoy (1967): flocs obtained from activated sludge samples are gently washed several times in sterile phosphate buffer (pH 7.2), then collected by sedimentation and decantation to free them from floating cells and debris. The washed flocs are further homogenized and subsequently used to inoculate arginine broth (arginine 0.05 %, K_2HPO_4 0.2 %, KH_2PO_4 0.1 %, $MgSO_4$ x 7 H_2O 0.02 %, biotin and vitamin B_{12} 2 µg/ml each). Penicillin G (2–5 units/ml) is added to the medium to inhibit contaminating Gram-positive bacteria. Cultures are incubated under gentle agitation at 30 °C for 12–24 h. Following incubation, cells in the enrichment culture are homogenized once more, and suitable dilutions are plated on trypticase soy (0. 5 %) agar. Colonies of selected isolates are re-inoculated in arginine broth and in flocculation test medium (arginine broth + 5 % glucose). Flocculation in the glucose medium but not in the plain broth indicates selection of the right isolates, which may be further purified. Isolates can be maintained on trypticase soy (0. 5 %) agar slants with transfer every 6 months.

Daeguia caeni was isolated from sludge of a wastewater treatment plant by using standard dilution plating techniques (Yoon et al. 2008). Diluted samples are plated on trypticase soy agar and incubated aerobically at 30 °C. Isolates can be further cultured in trypticase soy broth. Special maintenance procedures have not been reported. Organisms may be maintained for short time periods on trypticase soy agar slants.

Isolation of *Mycoplana* strains has been originally described by Gray and Thornton (1928): inoculate 0.5–1 g of soil sample in 100 ml of a mineral salt solution containing 0.05–0.1 % phenol or 0.05 % *m*-cresol. If growth is observed, transfer the culture into a new flask of the same medium. *Mycoplana* strains can be isolated by further plating and purification on agar medium.

It is possible to maintain *Mycoplana* cultures on most common media. Good growth occurs in nutrient broth, PYG broth and peptone water, and on soil media, when cultures are incubated aerobically at 30 °C. Cultures may be kept for short periods at room temperature or at 4 °C. Subculturing should be repeated every week, although longer storage of cultures is possible when stored at 4 °C. Long-term maintenance can be achieved by freezing at −80 °C, storage in liquid nitrogen, or lyophilization. If organisms are frozen, cultures with a high cell density should be used and cryoprotective agents such as DMSO or 10 % glycerol should be added.

For the isolation of *Ochrobactrum*, no special procedures are necessary. Cultures may be maintained for several months on Dorset egg medium slants (Barrow and Feltham 1993) in a screw-capped bottle stored at 4 °C. Longtime preservation may be achieved by lyophilization or by suspension of an 18-h-old agar slant culture in a small tube containing defibrinated rabbit blood, which is then frozen in a mixture of alcohol and dry ice prior to storage at −50 °C.

Paenochrobactrum gallinarii was isolated from air collected in a duck barn (Kämpfer et al. 2010). Bioaerosol samples are collected on gelatine filters. Filters are dissolved and decimally diluted in isotonic NaCl. Subsequently, tryptone soy agar plates are inoculated with an aliquot of each dilution and incubated at 25 °C. Isolates may be picked from the plates inoculated with liquid of the first decimal dilution. Further subcultivation may be performed aerobically on TSA at 28 °C for 48 h.

Paenochrobactrum glaciei has been recovered from sea ice (Romanenko et al. 2008). The sea ice sample is collected in a sterile flask together with a small quantity of sterile sea water. The sample is stored for 2 days at 15 °C and melted carefully. An aliquot of melting sea ice is inoculated onto a marine 2216 agar plate and incubated for 1 week at 15 °C. Subcultivation of isolates may be performed on marine 2216 agar or in marine broth, trypticase soy agar or trypticase soy broth, and R2A agar aerobically at 28 °C. Long-term maintenance may be achieved by storage of cells at −80 °C in liquid marine broth supplemented with 30 % (v/v) glycerol.

Isolation of various *Pseudochrobactrum* strains has been described by Kämpfer et al. (2006, 2007, and 2009). Most strains have been isolated from industrial samples by inoculation on blood agar, nutrient agar, or standard plate count agar, following aerobically incubation at 30–37 °C. Subculturing may be performed on tryptone soy agar at 28 °C for 48 h. Growth occurs also on MacConkey and R2A agar when incubated at 30 °C. Longtime maintenance procedures have not been reported so far but may be achieved by freezing of the culture together with a cryoprotective agent at −80 °C.

Ecology

Habitat

The main habitat of organisms belonging to the *Brucellaceae* seems to be environmental habitats such as soil and water.

Table 6.7
Characteristics of the main *Brucella* phages

Group	Phage-type strain	Origin	Propagating strain	Host lysis	Other features
1	Tb	Isolated from liquid manure of a cowshed in Tbilisi (Russia)	*B. abortus* 544 and S19	*B. abortus*, *B. inopinata*, *B. neotomae*, *B. microti*, *B. suis*, some *B. pinnipedialis* strains	Does not lyse rough mutants
2	Fi 75/13	Obtained from *B. abortus* culture in Firenze (Italy)	*B. abortus* S19	*B. abortus*, *B. neotomae*, *B. suis*	Does not lyse rough mutants. Plating efficiency is to some extend higher on *B. abortus* strains
3	Wb	Obtained from *B. suis* culture in Weybridge (England)	*B. abortus* S19, *B. suis* 1330	*B. abortus*, *B. ceti*, *B. neotomae*, *B. suis, B. pinnipedialis*, some *B. melitensis* strains	Does not lyse rough mutants
4	Bk_2	Obtained by plating phage Bk_0 on *B. melitensis* 16 M in Berkley (USA)	*B. melitensis* Isfahan and 16 M	*B. abortus*, *B. neotomae*, *B. suis, B. melitensis*	Relative of phage Bk_1 Does not lyse rough mutants
5	R/C	Obtained from phage R/O by serial propagation on *B. canis* RM 6/66	*B. canis* RM 6/66 and Mex.51	*B. canis*, *B. ovis*, rough *B. abortus*, and some rough *B. melitensis* mutant strains	Does not lyse smooth *Brucella* strains. Relative of phage R/M, which lyses some *B. melitensis* strains
	R/M	Obtained from phage R/C by serial propagation on *B. melitensis* 115	*B. melitensis* 115	Some rough *B. melitensis* strains	Genetically unstable. Reported to be more consistently lytic for rough *B. melitensis*
6	Iz_1	Isolated from goat and sheep feces in Izatnagar (India)	*B. abortus* S19, *B. melitensis* 16M and 115	*B. abortus*, *B. ceti*, *B. neotomae*, *B. suis, B. melitensis*, *B. pinnipedialis*	Lysis of all smooth *Brucella*. Also lysis of rough *B. abortus*, *B. suis, B. melitensis*
7	Np	Obtained from atypical B. abortus strains in Nepean (Canada)	*B. abortus* S19	*B. abortus*, *B. neotomae*	Does not lyse rough mutants

Adapted from Moreno and Moriyon (2006)

However, mammalian animals including humans present a reservoir for various *Brucella* species, whereas they may also be present in the environment. Several species especially of the genus *Pseudochrobactrum* have been isolated from industrial environments, while some species belonging to the genera *Brucella* and *Ochrobactrum* have been predominantly found in human clinical samples.

Even though *Brucella* species are cultivated in vitro without problems, under natural conditions, they behave as obligate intracellular pathogens and do not seek for an existence apart from their animal hosts. Nevertheless, they are capable to persist for longer times in the environment, such as in soil or surface water, under the appropriate humidity, low temperature conditions (between 2 and 8 °C), and when protected from sun light. *Brucella* species are distributed worldwide and can infect various hosts, whereas the host range of a specific *Brucella* species may be enormous. The common natural hosts for *B. melitensis* are goats and sheep, but other mammals like cattle, humans, and pigs may also be infected (Corbel and Banai 2005). For *B. abortus*, cattle has been described as the natural host. Yet, *B. abortus* has been found to persist in various other hosts, such as camels, dogs, elk, goats, horses, pigs, sheep, yaks (Crawford et al. 1990), and humans (Arimi et al. 2005; Swai and Schoonman 2009). Biovars 1, 2, and 3 of *B. suis* naturally infect pig. In addition, all biovars of *B. suis*, except for biovar 2, are pathogenic for humans. Other species, such as dogs, horses, and rodents, may also serve as hosts (Corbel and Banai 2005). Under certain conditions, *Brucella* is also capable to replicate within lice, fleas, ticks, and worms, which may serve as vectors for transmission to mammalian hosts (Moreno and Moriyon 2006). Another group of *Brucella* species has been isolated from marine mammals initially designated as *B. maris*. These marine mammalian *Brucella* isolates have a host preference for either the order *Cetacea* (whales, dolphins, and porpoises) or *Pinnipedia* (seals, sea lions, and walruses) (Thakur et al. 2012). Instead of the designation *B. maris*, 7 novel species have recently been described. These include *B. delphini*, *B. phoecoenae*, *B. ceti*, *B. pinnipedialis*, and *B. phocae*, with dolphins, porpoises, cetaceans, and seals as their preferred hosts, respectively (Corbel and Banai 2005; Foster et al. 2007).

The two *Mycoplana* species *M. dimorpha* and *M. ramosa* were both isolated from soil (Gray and Thornton 1928). The same applies to several species of the genus *Ochrobactrum*: *O. grignonense* has been isolated from a French soil, and *O. tritici* has been isolated from wheat root (Lebhun et al. 2000); *O. oryzae* originated from surface-sterilized seeds and plant tissue from

deep-water rice cultivated in Suraha Tal Lake in northern India (Tripathi et al. 2006); another species *O. cytisi* was recovered from nodules of common broom growing in a Spanish soil (Zurdo-Pineiro et al. 2007). Strains of *O. intermedium* have been isolated from French soil (Holmes et al. 1988) and chromium-contaminated soil from India (Kavita and Keharia 2012); other *O. intermedium* strains are from human blood (Velasco et al. 1998). *Ochrobactrum pseudintermedium* has been isolated from human clinical samples (Teyssier et al. 2007). The most predominant isolates from human clinical samples are strains of *O. anthropi*, which have been recovered from human blood, wounds, urogenital tracts or urine, respiratory tracts, and feces; a few strains have also been reported from environmental sources like activated sludge, biofilm in water supply lines, soil, and the termite gut (Holmes et al. 1988; Laura et al. 1996; Kuhnigk and Konig 1997).

Paenochrobactrum have so far only been isolated occasionally from environmental samples. *P. gallinarii* was isolated from air of a duck barn (Kämpfer et al. 2010), and *P. glaciei* was isolated from a sea ice sample from the Sea of Japan (Romanenko et al. 2008).

Pseudochrobactrum species have been isolated more often especially from various industrial environments. *P. lubricantis* was isolated from a water-mixed metal-working fluid (Kämpfer et al. 2009), and *P. kiredjianiae* has been recovered from a seafood-processing plant sample in New Zealand (Kämpfer et al. 2007). *P. saccharolyticum* was isolated from industrial glue, whereas *P. asaccharolyticum* originates from a knee aspirate of a 66-year-old man (Kämpfer et al. 2006).

The habitat of members of the monospecific genera and of those species for which only a single strain, the type strain, is available must be considered tentative.

Pathogenicity and Clinical Relevance

Brucella species are pathogens that cause infections in a wide range of animals and in humans. Generalized infections with an initial bacteremic phase are often followed by localization in the reproductive organs and reticuloendothelial system. In vivo, organisms grow intracellular and may survive within immune cells such as monocytes and granulocytes. Infection may involve any organ or body system, causing a variety of lesions. Infections in the natural host are generally mild and seldom lethal. Clinical manifestations occur mainly in the pregnant animal, were abortion is often a result of placental and fetal infection. *Brucella* may also be excreted in the milk after localization in the mammary tissue. In general, all main species of meat- and milk-producing domesticated animals are susceptible to *Brucella* infections and act therefore as possible sources of human infection (Corbel and Banai 2005).

Human infections are caused by direct or indirect contact with infected animals or by ingestion of contaminated milk or meat products. A transmission from person-to-person hardly ever takes places and does not play a role in the natural history of the disease. *B. melitensis* is responsible for the majority of severe infections, followed by *B. suis*. Milder infections are generally associated with *B. abortus* and *B. canis*. Organisms may enter the body via the gastrointestinal or respiratory mucosa or via percutaneous penetration. The pathogenesis is thought to be analogous to the disease progression in experimental animals, with an initial bacteremic phase of variable duration causing proliferation of the organisms in lymphoid tissue, which is in a few cases followed by localization in specific organs. The infection can have a complete subclinical progression, or it may cause a subacute or acute febrile sickness. If not treated appropriate with adequate antibiotic therapy, the infection may persist for several months and can be accompanied by drastic complications like arthritis, endocarditis, meningoencephalitis, orchitis, and spondylitis. *Brucella* infection stimulates both antibody production and cell-mediated immunity. The prevailing antigen in the serological response is LPS. However, immunological response to a number of proteins can also develop. More detailed information is given by Young and Corbel (1989) and Madkour (2000).

O. anthropi has been isolated from a variety of human clinical specimens, predominantly from cases of bacteremia (Gransden and Eykyn 1992; Kern et al. 1993) but also of pancreatic abscess (Appelbaum and Campbell 1980), necrotizing fasciitis (Brivet et al. 1993), and puncture wound osteochondritis of the foot (Barson et al. 1987). In most cases, it seems that *O. anthropi* is community acquired; moreover catheters have been suggested as a pathogenic niche for this organism (Gransden and Eykyn 1992). It may be pathogenic in immunocompromised or critically ill patients, with or without indwelling catheters. Even though it can cause serious clinically infections, it appears to have a relatively low virulent potential (Corbel and Banai 2005). Most strains display a multiple resistance to a variety of antibiotics, being only susceptible to aminoglycosides, fluoroquinolones, imipenem, and trimethoprim–sulfamethoxazole. Monotherapy with an appropriate aminoglycoside has yielded a good clinical response in the treatment of bacteremia. However, despite determining in vitro susceptibility to imipenem in initial isolates, treatment of patients with this agent failed to eradicate the organism. Due to the unpredictable susceptibility pattern, choice of antibiotics should be based on susceptibility tests for each isolate. In addition, multidrug therapy may be advised (Kern et al. 1993).

O. intermedium may also cause infections in immunocompromised patients; however, case reports are limited. The organism has so far been isolated from two cases of bacteremia, from a liver transplanted patient (Moller et al. 1999) as well as from a patient with bladder cancer (Apisarnthanarak et al. 2005). It may also be possible that certain infections believed to be caused by *O. anthropi* were actually caused by *O. intermedium*, since both organisms cannot be easily differentiated by biochemical tests. Nevertheless, both organisms may be discriminated by genotypic methods, and their antibiotic resistance to colistin and polymyxin B, with susceptibility of *O. anthropi* and resistance of *O. intermedium*, isolates to both antibiotics (Velasco et al. 1998; Moller et al. 1999).

So far there is no comprehensive data on the pathogenic potential of other organisms belonging to the *Brucellaceae*.

Acknowledgments

The excellent and comprehensive treatise of Moreno and Moriyon from the 2nd edition of *The Prokaryotes* is still highly recommended for a more deep study on classical approaches in the biology of *Brucella*.

Abstract
The family *Caulobacteraceae* comprises Gram-negative, aerobic, or facultatively anaerobic, rod-shaped, and motile bacteria which do not form spores. Although *Caulobacteraceae* have first been recognized because of their unusual cell morphology and cell cycle, their genera harbor both prosthecate or non-prosthecate species. Prosthecate cells often attach to surfaces with the prostheca at one end and forming polarly flagellated swarming cells at the other end. Prostheca of several cells may form rosettes. The species are chemo-organotrophic, some species require peptone or B vitamins and amino acids. Some species denitrify. All species have alkaline phosphatase activity, but none of α-glucuronidase, α-mannosidase, or α-fucosidase. In most species, the major isoprenoid quinone is Q-10. Main polar lipids are α-D-glucopyranosyl diacylglycerol, α-D-glucopyranuronosyl diacylglycerol, 6-phosphatidyl-α-D-glucopyranosyl diacylglycerol (but lacking in *Asticcacaulis*), and phosphatidylglycerol. Members of the family have been isolated from freshwater, soil, sea water, plants, animals, and humans. The family is a member of the *Alphaproteobacteria* Garrity et al. 2006 and comprises the type genus *Caulobacter* Henrici et Johnson 1935, emend. Abraham et al. 1999 and the genera *Brevundimonas* Segers et al. 1994, emend. Abraham et al., 1999, *Asticcacaulis* Poindexter 1964 and *Phenylobacterium* Lingens et al. 1985, emend. Oh et Roh, 2012. The species live in very diverse habitats, mostly aquatic, but also in soil, at the surfaces of eukaryotes. The temperature range of these habitats is moderate, but some species also thrive at low temperatures. Few species are pathogens. Because of their life cycle, most species are associated with surfaces where they form biofilms.

Taxonomy: Historical and Current

The first report on the isolation of a species of the *Caulobacteraceae* appeared more than a century ago (Loeffler 1890). The strain could not be assigned to a known taxon and was named "*Vibrio* (*?*) *spermatozoides*," but even then, its unusually low nutrient requirements were noticed. Almost half a century later, Henrici and Johnson (1935) described the genus *Caulobacter* with *Caulobacter vibrioides* as the type species. Henrici and Johnson did not isolate *Caulobacter vibrioides*, and

E. Rosenberg et al. (eds.), *The Prokaryotes – Alphaproteobacteria and Betaproteobacteria*, DOI 10.1007/978-3-642-30197-1_259,

therefore, a type strain was not named. Poindexter (1964) enlarged the monotypic genus considerably by describing nine species and two subspecies, thereafter adding *C. variabilis* (Poindexter 1989). Strain CB51 was proposed as the neotype strain of *C. vibrioides* (Poindexter and Lewis 1966). At that time, the taxonomy of the species of the genus was based almost exclusively on the characteristic morphology and mode of reproduction (Poindexter 1981b). They are dimorphic, prosthecate bacteria in which reproduction occurs by binary fission and results in the separation of two cells that are morphologically distinct from each other. The prosthecate cell is sessile, being nonmotile, and, possessing at least one elongated, cylindrical appendage, a prosthecum (Staley 1968). The other cell is motile by one polar flagellum. The mode of reproduction of the dimorphic, prosthecate bacteria is unique and helps to disperse the population at each generation, thereby minimizing competition among siblings for resources. This enables these bacteria to exist in oligotrophic habitats (Poindexter 1981a) and to tolerate prolonged starvation. In 1964, Poindexter described the genus *Asticcacaulis* harboring species with prostheca but attaching to substrate with holdfasts at the cell poles and not at the prosthecum (Poindexter 1964).

In 1973 Krassilnikov and Belyaev described eight additional species (*Caulobacter robiginosus, C. rutilus, C. glutinosus, C. kusnezovii, C. rossi, C. flexibilis, C. metschnikovii*, and *C. fulvus*) and five subspecies (*C. vibrioides ssp. luridus, C. bacteroides ssp. modicus, C. bacteroides ssp. podsolicum, C. bacteroides ssp. creteus*, and *C. variabilis ssp. albus*) (Krassilnikov and Belyaev 1973). These taxa, however, were not validly described because no type strains were given. Consequently, the species described by Krassilnikov and Belyaev in 1973 were all not accepted in the Approved Lists. They were discussed by Poindexter (1981a) but otherwise largely ignored probably also due to the fact that the publication of Krassilnikov and Belyaev was in Russian.

The phylogenetic position of *Caulobacter crescentus* within the *Alphaproteobacteria* was first deduced from 5S rRNA sequences (Stackebrandt et al. 1988). First hints that not all prosthecate bacteria may belong to a single genus came from analyses of a large set of strains which revealed differences between freshwater and marine caulobacteria (Anast and Smit 1988). The differences between these two groups could be substantiated by a phylogenetic analysis using 16S rRNA gene sequences of several *Caulobacter* isolates (Stahl et al. 1992). This study revealed, for the first time, that *Caulobacter* actually forms two different lineages, one comprising mainly the freshwater and brackish water *Caulobacter* spp. and the other the true marine species. Surprisingly, the study also showed that the non-prosthecate *Brevundimonas diminuta* (Segers et al. 1994) clusters with the group of freshwater *Caulobacter* spp. The 16S rDNA sequences of *Mycoplana segnis* and *Mycoplana bullata* also fell in the freshwater *Caulobacter-Brevundimonas* cluster, thus confirming that the presence of a prosthecum is not a sufficient criterion for taxonomy (Yanagi and Yamasato 1993). The diversity of more than 70 strains of *Caulobacter*, *Brevundimonas*, and *Mycoplana* was evaluated using lipid analysis, 16S rRNA gene sequences, and profiling of the 16S-23S rRNA gene interspacer (ITS) regions and comparison of these results with physiological data. As a consequence, the descriptions of the genera *Caulobacter* and *Brevundimonas* were emended and a number of *Caulobacter* species were transferred to the genus *Brevundimonas* (Abraham et al. 1999). *Mycoplana bullata* was found to belong to the genus *Brevundimonas, Caulobacter crescentus* to be conspecific with *C. vibrioides*, and *Mycoplana segnis* was transferred to *Caulobacter* as *C. segnis*.

Phenylobacterium, for many years a monospecific genus consisting of a degrader of xenobiotics, was found to be closely related with *Caulobacter* and the prosthecate species *Phenylobacterium conjunctum* was described (Abraham et al. 2008). Currently, the family *Caulobacteraceae* comprises the genera *Caulobacter*, *Asticcacaulis*, *Brevundimonas*, and *Phenylobacterium*. Within the family only the genus *Asticcacaulis* exclusively contains prosthecate species; the other genera habor both prosthecate and non-prosthecate species.

Description of *Caulobacteraceae*

Caulobacteraceae (Cau.lo.bac.te.ra′ceae. N.L. fem. n. *Caulobacter* type genus of the family; -aceae ending to denote a family; N.L. fem. pl. n. *Caulobacteraceae* the *Caulobacter* family).

Gram-negative, rod-shaped bacteria. Motile. Do not form spores. Cells are either prosthecate or non-prosthecate. Prosthecate cells often attach to surfaces with the prostheca at one end and form polarly flagellated swarming cells at the other end. Prostheca of several cells may form rosettes. Chemoorganotrophic. Some species require peptone or B vitamins and amino acids. Aerobic or facultatively anaerobic. Some species denitrify. All species have alkaline phosphatase activity but none of α-glucuronidase, α-mannosidase, or α-fucosidase. In most species, the major isoprenoid quinone is Q-10. Main polar lipids are α-D-glucopyranosyl diacylglycerol, α-D-glucopyranuronosyl diacylglycerol, 6-phosphatidyl-α-D-glucopyranosyl diacylglycerol (but lacking in *Asticcacaulis*), and phosphatidylglycerol. Members of the family have been isolated from freshwater, soil, sea water, plants animals, and humans. The family is a member of the *Alphaproteobacteria* Garrity et al. 2006 and comprises the type genus *Caulobacter* Henrici et Johnson 1935, emend. Abraham et al. 1999 and the genera *Brevundimonas* Segers et al. 1994, emend. Abraham et al., 1999, *Asticcacaulis* Poindexter 1964 and *Phenylobacterium* Lingens et al. 1985, emend. Oh et Roh, 2012.

Molecular Analyses

DNA-DNA hybridizations between strains of *Caulobacteraceae* (Moore et al. 1978) revealed a diversity to their genomes which is high compared to the diversity of their 16S rRNA gene

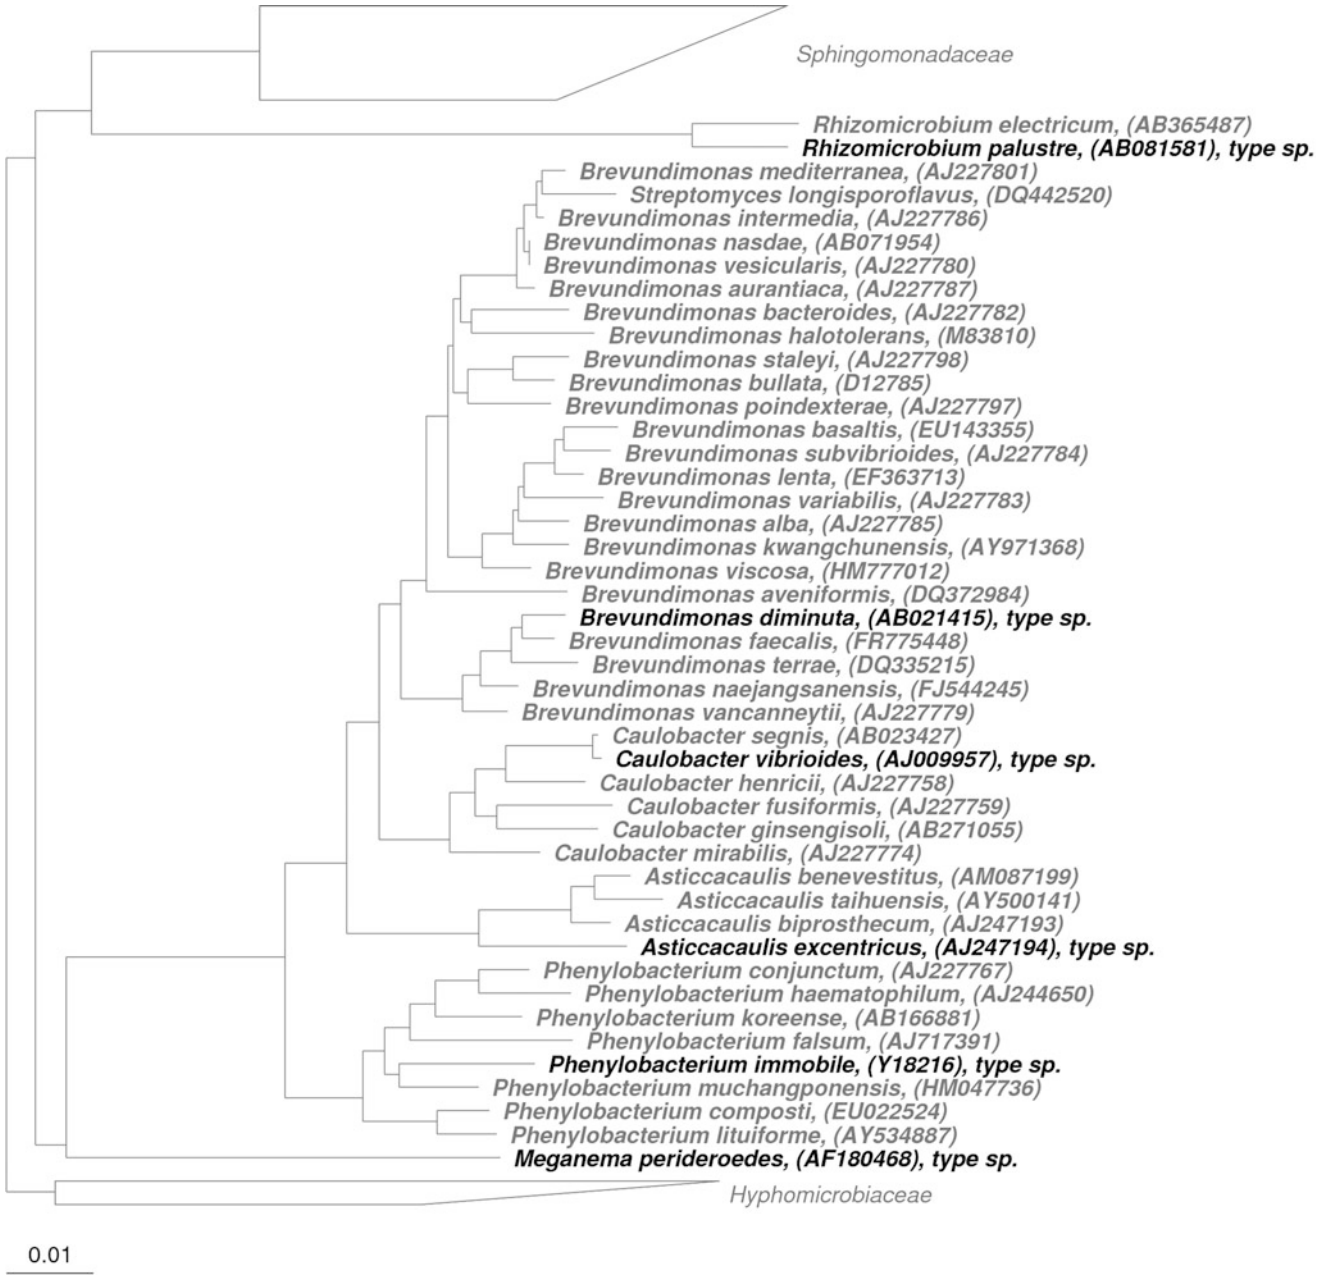

Fig. 7.1

Phylogeny of *Caulobacteraceae* based on their 16S rRNA gene sequences. For comparison, the closest related families are also shown

sequences. This results in DNA-DNA hybridizations below 70 % similarity for strains with otherwise almost identical 16S rRNA gene sequences, as has been reported, e.g., for *Caulobacter vibrioides* and *C. segnis* (Abraham et al. 1999). A similar tendency has been found in such an analysis for *Brevundimonas bacteroides* isolates (Ariskina 1995). *Caulobacteraceae* comprises four different genera, *Caulobacter*, *Brevundimonas*, *Asticcacaulis*, and *Phenylobacterium*, which are well resolved in phylogenetic trees based on the 16S rRNA sequences of their type strains (*Fig. 7.1*).

Whole-Genome Analyses

The completion of the first complete genome of a *Caulobacter* strain was carried out with *Caulobacter crescentus* (= *C. vibrioides*) CB15 in 2001 (Nierman et al. 2001). At that time, the genome of *C. vibrioides* CB15 was the first publicly available from a free-living *Alphaproteobacteria*. The final version of the genome was deposited in the GenBank database (accession no. AE005673 or NC_002696). The complete genome sequence of *C. vibrioides* CB15 was determined to be 4,016,947

base pairs in a single circular chromosome, encoding 3,767 genes. By means of this accomplishment, the genome of the probably most prevalent organism specially adapted to survive in nutrient-poor aquatic and marine habitats was determined and annotated. Consequently, the complete and detailed description of the genetic circuitry at the genome level of the *Caulobacter* cell cycle; which controls the processes of differentiation, growth, and progression of their cycle, established the basis for exploring and understanding the biology of this group of bacteria, at the molecular level. The detailed genome analysis showed that the *C. vibrioides* genome encoded for up to 105 of two-component signaling proteins, a number significantly high. It is well known that these systems, together with DNA methylation, are of interest from the point of view of the regulatory mechanisms implied in cell cycle.

Moreover, through the comprehensive analysis of the annotated genome sequence, numerous gene clusters were pointed out coding for proteins needed for the subsistence of the microorganism in oligotrophic habitats. The repertoire for this environmental survival includes genes for chemotaxis, outer membrane channel function, biodegradation of aromatic compounds, the use of plant-derived carbon sources by microorganisms as growing substrates, and several bacteria sigma factors involved in the regulation of extracytoplasmic functions (termed as ECF or extracytoplasmic functions). This heterogeneous subfamily group of alternative sigma factors is assumed to be involved in the regulation of the gene expression in response to a variety of conditions, including stress. Thus, as a result of the data obtained from the annotated genome analysis, it could be concluded that *C. vibrioides* is well provided with the ability to respond to a wide range of environmental fluctuations.

More recently, the genome of *C. vibrioides* has been used to point out evidences for close relationships between two dimorphic prosthecate bacteria, comparing *C. vibrioides* with *Hyphomonas neptunium* (Badger et al. 2006); and for the establishment of the genetic basis of laboratory adaptation in *C. vibrioides* (Marks et al. 2010). Interestingly, the comparison between the genomes of *H. neptunium* ATCC 15444^{T} and *C. vibrioides* CB15 revealed some unexpected results and found that both strains share more proteins than does *H. neptunium* with the on the basis of 16S rRNA gene phylogeny more closely related species, *Silicibacter pomeroyi*. This fact may perhaps be a demonstration that genome comparison could be an important approach to confirm or reclassify the phylogeny of microorganisms, like the genus *Hyphomonas*, although we have shown that the observed dissimilarity between phylogenies based on the 16S and the 23S rRNA genes was simply caused by the lack of available 23S rRNA gene sequences (see the chapter 12: The Family *Hyphomonadaceae* in this edition). Phylogenetic trees using the currently available sequences of these two rRNAs are consistent and do not show the disparity observed by Badgers et al.

Combining whole-genome sequencing with classical molecular approaches, the genetic basis underlying the multiple derived phenotypes between two closely related *C. vibrioides* strains, CB15 and NA1000, was characterized through genome comparison. Both strains had a common ancestor but have evolved marked phenotypic differences while having been cultured over more than 50 years in the laboratory environment (Marks et al. 2010). *Caulobacter vibrioides* NA1000 was described as a spontaneous mutant of *C. vibrioides* CB15, and is routinely used worldwide because it can easily be synchronized, allowing for studies related to the bacterial cell cycle. The changes detected in that study aiming to determine the mechanisms underlying adaptation to laboratory are related to growth rate, mucosity, adhesion, sedimentation, phage susceptibility, and stationary-phase survival. The work demonstrated that the rapid adaptation of *C. vibrioides* to the laboratory environment occurred in both strains and was characterized by few genetic changes. These changes encompassed non-synonymous mutations, non-coding regulatory changes, the acquisition of new genes, and inactivation of already existing genes, each with a large phenotypic effect (Marks et al. 2010). This study underlines once more the reasons why *C. vibrioides* is an excellent system to study the nature of selection and phenotypic microevolution in prokaryotes during colonization of new environments.

In addition to the whole-genome sequencing projects described above, pointing toward characterization and annotation of the different protein-coding sequences, a remarkable study focusing on the characterization of the essential genome of *C. vibrioides* was performed (Christen et al. 2011). The essential genome of *C. vibrioides* includes not only protein-coding sequences but also structural elements, non-coding RNAs, and regulatory sequences. The study was done basically by applying hypersaturated transposon mutagenesis followed by high-throughput DNA sequencing to determine the transposon insertion sites. The obtained essential genome for *C. vibrioides* was of 492,941 bp in size, covering 12.19 % of its entire genome. This proposed essential genome for *Caulobacter vibrioides* or even for most *Caulobacter* species comprised up to 1,012 features, including 480 open reading frames (ORFs), 402 regulatory elements, and 130 non-coding sequences. Remarkably, 38 % of the essential protein-coding sequences were absent in most species not belonging to the *Alphaproteobacteria* evaluated and 10 % were unique to *Caulobacter*. The results reported in this study included also the identification of those promoter elements essential for the cell-cycle–regulated genes. An interesting conclusion refers to the location of the essential elements, which seems to be preferentially positioned near both origin and terminus of the *Caulobacter* chromosome.

Besides the leading coverage in the literature or in the databases genomic projects of *C. vibrioides* had, other *Caulobacteraceae* genome projects are either completed or running. *Table 7.1* summarizes the information related to genome projects for *Caulobacteraceae* publicly available in databases. For example, the U.S. Department of Energy (DOE) Joint Genome Institute (JGI) is trying to gain further insights into the biological and environmental activities of oligotrophs in general, but *Caulobacter* isolates in particular, through the comparison of genomes of species from each of the major *Caulobacter* habitats. For this reason, and in addition to the genomic DNA sequence already mentioned about *C. vibrioides* CB15, the genomic DNA

sequences of *Maricaulis maris* MCS10 (GenBank accession nº CP000449), a stalked, biofilm-forming marine bacterium of the *Hyphomonadaceae* family, and *Caulobacter* sp. strain K31, a groundwater isolate, were both generated at JGI. Through comparative genome analyses of these microorganisms, it is expected to obtain information related to the specific functions of each, i.e., the pangenome adaptations may be revealed for each natural niche.

The complete list of *Caulobacteraceae* microorganisms for which complete genome sequences currently exist includes *Phenylobacterium zucineum* HLKI which was isolated from the human leukemia cell line K562 (Luo et al. 2008). This facultative intracellular bacterium maintains, unlike other known intracellular pathogens, a stable association with the host cell without affecting the growth and morphology of the latter. The detailed genome analysis revealed the fundamental basis for this strain to invade and persistently survive in human cells. The relationship between *P. zucineum* and *C. vibrioides* was determined on the basis of comparative genome analysis (Luo et al. 2008). Although the genome size and protein number of *P. zucineum* (4.37 Mb, 3,529 proteins respectively) were similar to those of *C. vibrioides* (4.02 Mb, 3,737 proteins), no significant synteny was found between both genomes. The largest synteny block was about 30 kb, coding for 24 proteins. The conservation region with the largest number of proteins was an operon coding for 27 ribosomal proteins. Moreover, both species share only 57.8 % of the orthologous proteins. Probably related to functional elements involved in the efficient response to environmental changes, the genome of *P. zucineum* contains abundant two-component signal transduction proteins, transcriptional regulators, and the largest number of heat shock response proteins when compared with 5 *Alphaproteobacteria* and 93 bacteria (Luo et al. 2008). Interestingly, the *P. zucineum* genome contains also information on features involved in the adaptation of *P. zucineum* to the intracellular lifestyle, like genes crucial for the defense against oxidative stress or the use of protein-bound iron, e.g., siderophore transporter systems, to cope with the low intracellular levels of iron not appropriate to support bacterial life. Finally, the comparative analysis of cell-cycle genes between *C. vibrioides* and *P. zucineum* also indicated that the CtrA regulon (which controls the transcription of 95 genes involved in the cycle) is well conserved, with 93.07 % and 89.88 % amino acid and nucleotide sequence identities respectively.

Other strains of *Caulobacteraceae* currently used for comparative genome analysis include *Brevundimonas diminuta* 470-4, an isolate obtained from the human oral cavity and proposed as reference genome for the Human Microbiome (NCBI BioProject PRJNA67195). The data generated from the whole-genome shotgun assembly of *B. diminuta* 470-4 consists of 168 contigs (GenBank accession nº AMFA00000000.1), comprising 3,506 protein sequences. Similarly, the genomes of a group of uncharacterized isolates from a population of *Caulobacter*, which are clearly distinct from currently recognized species, are sequenced. One of these uncharacterized isolates is *Caulobacter* sp. AP07 (BioProjects at NCBI PRJNA171682 and PRJNA83031); for which a genome assembly of 326 contigs is

available at the GenBank (accession nº AKKF00000000.1). The assembly comprises a genome size of 5.62 Mb, from which 5,311 genes were detected (5,260 protein sequences). The *Caulobacter* sp. AP07 strain has been proposed for Plant-Microbe Interfaces (PMI) projects focusing on the study of the dynamic interface that exists between plants, microbes, and the common environment that they do occupy. Furthermore, *Caulobacter* sp. JGI 0001010-J14 (BioProject PRJNA169806), JGI 0001013-D04 (BioProject PRJNA169803), and JGI 0001013-O16 (BioProject PRJNA169704) have been proposed as grand challenge to perform single cell sequencing at the rhizosphere.

Comparative analyses of the actually existing and the new upcoming genome sequences will not only provide a multitude of insights into the genomic and physiological diversities in the *Caulobacteraceae*, but will also aid researchers in exploring and advancing through new trends on traditional subjects such as the prokaryotic cell cycle, morphogenetic regulatory genes, and systems. Continuing with the acquisition and deeper understanding of the information obtained from the genomes of these organisms is expected to shed light on the potential for practical applications of the *Caulobacteraceae*.

Phenotypic Analyses

All species are chemo-organotrophic and have a respiratory, never a fermentative metabolism. Cells usually possess prostheca, but a number of species do not. The prosthecate cells undergo a remarkable and complex cell cycle. The motile swarmer cells become sessile forming prostheca and attach to surfaces by a holdfast. The cell cycle is completed by binary fission of the prosthecate cell forming again a new swarmer cell. The morphogenesis of *Caulobacteraceae*, especially of *Caulobacter crescentus*, now *Caulobacter vibrioides* (Abraham et al. 1999), has been studied in detail and the main features of the regulation process have been revealed; however, many details are still unclear (Kirkpatrick and Viollier 2012).

The Prosthecum

Most species of the family *Caulobacteraceae* produce cells with filiform extensions of the cell, devoid of reproductive function, the prosthecum (Gr. n. *prosthece*, appendage). The prosthecum does not contain DNA, ribosomes, and cytoplasmic material (Poindexter and Cohen-Bazire 1964). The length of the prosthecum depends on the availability of nutrients but also on phosphate concentration. By growing cells under phosphate limitation, it has been demonstrated that the prosthecum is synthesized at the junction of the prosthecum with the cell (Schmidt and Stanier 1966). The extended prosthecum under phosphate limitation points to a role of the prosthecum as nutrient scavenger (Poindexter 1984). The nutrient transport into the prosthecum has been studied by several groups, and it was found that free glucose accumulated within the prosthecum at a concentration 60–200 times higher than the surrounding concentration. Glucose transport into prostheca was stereospecific for D-glucose and neither methyl α-D-glucopyranoside nor 2-deoxyglucose was transported (Larson and Pate 1976). Amino acids are also actively transported into the prosthecum, and three different transport systems could be identified. The G system transported all 20 amino acids tested, while the P system transported seven amino acids, including proline, and the A system only glutamate and aspartate (Tam and Pate 1985). Two-dimensional gel (2D gel) electrophoresis of the proteome of the prosthecum showed that the prosthecum is mostly free of cytoplasmic proteins and has a protein composition very similar to that of the cell membrane. Several TonB-dependent receptors, two OmpA family proteins, two alkaline phosphatases, 3-phytase and a putative ToIC protein were identified, corroborating the view that the prosthecum plays a role in nutrient uptake (Ireland et al. 2002).

In many *Caulobacter* and *Asticcacaulis* species, crossbands have been observed in the prosthecum. In the case of *Asticcacaulis*, these crossbands consist of a series of concentric rings and can be digested by lysozyme (Schmidt and Swafford 1975). These crossbands differ from the ones found in *Caulobacter*. While the *Brevundimonas bacteroides* and *Caulobacter vibrioides* crossbands are restrictions, undivided septation was detected in *Asticcacaulis excentricus* and *A. biprosthecum* (Poindexter and Hagenzieker 1981). A band it added to the *Caulobacter* prosthecum during each cell cycle allowed the determination of cell age (Poindexter and Staley 1996) and in situ reproductive rate of *Caulobacter* (Poindexter et al. 2000). The cell division protein FtsZ is needed for the formation of these crossbands, and it is also needed for proper prosthecum formation (Divakaruni et al. 2007).

The Holdfast

Many *Caulobacteraceae* species stick to surfaces with the aid of a holdfast. The holdfast sits at the tip of the prosthecum in the prosthecate *Caulobacter*, *Brevundimonas*, and *Phenylobacterium* species, but in *Asticcacaulis* species, the holdfast is located at the cell pole. In *Caulobacter vibrioides*, the holdfast is composed both of protein and polysaccharide. It can be labeled by wheat germ agglutinin lectin, indicating the presence of *N*-acetylglucosamine. It also reacts with chitinase which cleaves β-1 → 4 linkages; therefore, the polysaccharide of the holdfast has some β-1 → 4-linkages (Merker and Smit 1988). Biophysically the holdfast can be seen as a gel-like substance possessing an impressive adhesiveness (Tsang et al. 2006). Such an immense stickiness is important for the ecology of *Caulobacter* and *Brevundimonas* species living, e.g., in fast running creeks (Zhang et al. 2010).

The holdfasts of other *Caulobacteraceae* have been characterized, and they contain a variety of polysaccharides (MacRae and Smit 1991), differing from those of *Maricaulis* species

(Merker and Smit 1988). The holdfasts of *Caulobacter henricii* and *C. vibroides* have α-linked *N*-acetylgalactosamine and *N*-acetylglucosamine while the *Brevundimonas subvibroides* holdfast contains α-linked mannose, α-linked fucose, and *N*-acetylgalactosamine. The holdfasts of all prosthecate *Caulobacteraceae* species examined bind cationic gold, suggesting that the polysaccharides of the holdfast are negatively charged (Merker and Smit 1988). The variation in sugar composition and holdfast structure may cause also differences in the stickiness to various substrata allowing *Caulobacteraceae* to attach to surfaces with different physicochemical properties depending on the specific environment they colonize and minimizing competition. An intriguing phenomenon concerning the selectivity of *Caulobacter* attachment was observed: While the holdfast sticks to a wide variety of materials and surfaces, it never sticks to *Caulobacter* cells. Assumptions that the presence of an S-layer is responsible for this selectivity proved to be wrong because also in S-layer-lacking mutants, no holdfasts were found attached to the cells of such mutants.

The S-layer

Paracrystalline protein surface arrays, S-layers, were identified on many Bacteria and Archaea. Their functions are diverse, e.g., they are virulence factors, protective against predators, a depository for surface-exposed enzymes, shape-determining agents, and crystallization points for mineral formation (Beveridge et al. 1997). More than 30 years ago, proteins arranged in a precisely ordered crystalline array forming an S-layer were found on *C. vibrioides* cells (Smit et al. 1981). They are formed by the RsaA protein with the length of 1,026 amino acids in the case of *C. vibrioides* CB15A which is not cleaved during export (Gilchrist et al. 1992). The extreme N-terminus of the protein directs its export but is not essential for secretion (Bingle et al. 1996). The RsaA protein is secreted by a type I secretion mechanism involving an ABC transporter protein (Awram and Smit 1998) and two outer membrane proteins (Toporowski et al. 2004). For all *Caulobacteraceae* strains forming S-layers, such a type I excretion system has been detected (Iuga et al. 2004). Staining of the S-layer proteins revealed distinct *de novo* biosynthesis at the region of cell division and at the prosthecum during the cell cycle of *C. vibrioides* (Smit and Agabian 1982).

When the S-layer proteins of several cauliform freshwater isolates were extracted by treatment with HEPES (*N*-2-hydroxyethylpiperazine-*N*′-2-ethanesulfonic acid) buffer at pH 2, for most strains, S-layer proteins were found. This method likely disrupted calcium-mediated bonds which were re-established after addition of calcium but not magnesium or strontium, allowing recrystallization of the proteins. From 35 strains out of 42 strains producing an S-layer, a single characteristic protein could be isolated, ranging in size from 100 to 193 kDa. A specific S-layer-associated oligosaccharide was detected in all S-layer-producing strains (Walker et al. 1992; Awram and Smit 2001). However, not in all examined *Caulobacteraceae* isolates S-layer proteins were found, and they were absent in *Brevundimonas poindexterae* FWC40^T, *Brevundimonas staleyi* FWC43^T, (Abraham et al. 2010), *Caulobacter mirabilis* FWC 38^T and *Phenylobacterium conjunctum* FWC21^T (Abraham et al. 2008).

The Shape of the Cell

Cell shape seems to be an important advantage for the survival of *Caulobacteraceae*, also highlighted by a dramatic change in cell shapes at the late stationary phase. Cell shape is controlled in *Caulobacteraceae* as in most rod-shaped bacteria by the murein cluster *mre* (Ingerson-Mahar and Gitai 2012). In *Caulobacter vibrioides*, MreB is an actin-like protein, essential for cell shape during growth (Gitai et al. 2004) and prosthecum elongation (Wagner et al. 2005). Transcript and protein levels of MreB remain constant throughout the cell cycle, but MreB is localized during the cell cycle. MreB forms a cytoplasmic spiral which condenses into a ring at the mid-cell during cell division similar to FtsZ (Lam et al. 2006). MreB maintains its position in the cell by polymerizing new monomers at one end of the polymer and cleaving old monomers from the other end (Kim et al. 2006). Other proteins from the *mre* operon also contribute to cell shape and two of them, MreC and PBP2, interact and form also spirals of polymers which are offset from the MreB spirals. They also play a role in cell wall synthesis (Divakaruni et al. 2005), and MreB and MreD polymers are responsible for the organization of murein biosynthetic enzymes (White et al. 2010). Two different cytoskeletal proteins of the group of bactofilins are also present in *Caulobacter vibrioides*. They form a sheet-like structure covering the membrane around the prosthecate cell pole and mediate polar localization of a peptidoglycan synthase involved in prosthecum morphogenesis again connecting cell shape and cell wall synthesis in *Caulobacter* (Kühn et al. 2010). A model developed from electron cryotomography data on sacculi of *Caulobacter vibrioides* showed that a single layer of linked glycan strands encircles the cell in a disorganized hoop-like fashion. From this model follows that peptidoglycan cannot determine cell shape but requires factors like the cytoskeletal filaments to guide peptidoglycan synthesis and control cell shape (Gan et al. 2008).

Responsible for the curved form of *Caulobacter vibrioides* cells is the protein crescentin, as has been demonstrated in deletion mutants (Ausmees et al. 2003). Crescentin is a remarkable protein because it resembles intermediate filaments only known from metazoa. It is a coiled coil-rich protein with essential domains similar to the tripartite architecture of intermediate filament proteins (Cabeen et al. 2011), it assembles into 10-nm wide filaments without the requirement of cofactors and it forms a higher-order helical structure localized along the concave side of the cell (Ausmees 2006). With the aid of modern superresolution microscopy, the three-dimensional superstructures of the polymers could recently be visualized and confirmed (Lew et al. 2011).

The Life Cycle of *Caulobacteraceae*

The characteristic form of *Caulobacter* cells and their dimorphism led to the recognition of a distinct cell cycle (review by Curtis and Brun 2010). The swarmer cell carries a flagellum and pili at a single pole. This cell is incapable of DNA replication, and its role is dispersal of the strain for which it is motile and possesses chemotaxis. After some time, the flagellar pole of the swarmer cells undergoes differentiation and secretes a polysaccharide adhesin. This adhesin, also called the holdfast, mediates the surface attachment of the cell. The next step in the cell cycle is the loss of the pili and the flagellum and the formation of a prosthecum, a thin extension of the cell envelope. Only this prosthecate cell is able to reproduce, forming swarmer cells which closes the cell cycle (Brown et al. 2009). Their cell cycle, especially their asymmetric cell division, made *Caulobacter* species a model system for bacterial development. Synchronization of the cell cycle to study morphogenesis of *Caulobacteraceae* can easily be achieved by separating swarmer cells from prosthecate cells by centrifugation in a density gradient (Evinger and Agabian 1977). Almost all studies were done with *Caulobacter crescentus* which is synonym to *C. vibrioides* (Abraham et al. 1999).

How is this life cycle coordinated? One key element is the strict control of DNA replication which occurs only once per cell cycle (Marczynski 1999) and that is during the transition of the swarmer cell to the prosthecate cell (Marczynski and Shapiro 1992). Responsible for the control of DNA replication is the transcription factor CtrA. Global transcription analyses of *Caulobacter vibrioides* revealed that the transcription of 553 genes, i.e., 19 % of the genome, varied with the cell cycle. A single regulatory factor, CtrA, is involved in the control of 26 % of these genes; hence, CtrA has been dubbed the master regulator (Laub et al. 2000). CtrA is a response regulator and binds in the phosphorylated form CtrA∼P to 5 sites at the chromosomal origin silencing the origin in swarmer cells (Quon et al. 1998). Interestingly, this function of CtrA is required for the cell cycle in rich media but is not important in minimal media (Bastedo and Marczynski 2009). Nevertheless, CtrA is essential for the cell because it binds to about 95 promoters on the chromosome, regulating their activities (Laub et al. 2002).

A rather complex network is active during the cell cycle to ensure that CtrA is only active when it is needed. The histidine kinases, PlecC and DivJ, are localized in the predivisional cell at opposite cell poles. While DivJ phosphorylates the response regulators DivK and PleD, PleC is a phosphatase for DivK∼P and inhibits the formation of PleD∼P. In the swarmer cell, PleC is localized at the flagellated pole and cleaves DivK∼P which stabilizes CckA and CtrA∼P. When the swarmer cell differentiates to the prosthecate cell, PleC delocalizes and DivJ is synthesized and bound to the prosthecate pole. Here Div J phosphorylates DivK and the formed DivK∼P migrates to the flagellar pole of the predivisional cell where it delocalized CckA, stopping the phosphorylation of CtrA, allowing the initiation of chromosome replication (Lam et al. 2003).

In order to initiate DNA replication, CtrA, resp. CtrA∼P, has to be deactivated. Probably because of the essential role of CtrA, regulation is achieved at several levels, including dephosphorylation, hydrolysis, and repression of transcription. Phosphorylation of CtrA is controlled by CckA, a hybrid histidine kinase/response regulator (Jacobs et al. 2003). CckA is present throughout the entire cell cycle but is not evenly distributed in the cell. It becomes localized to the swarmer cell pole before cell division (Jacobs et al. 1999), a characteristic essential for proper temporal activation of CtrA. Depletion of CckA leads to a decrease of CtrA∼P but also to destabilization of CtrA. To achieve this, CckA uses a phospho-relay by transferring the phosphate to ChpT (Biondi et al. 2006) which transfers it further either to CtrA or CpdR. CdpR is a response regulator and localizes the ATP-dependent protease ClpXP to the prosthecate pole, where phosphorylated CpdR cannot target ClpXP (Iniesta et al. 2006). Here regulation by dephosphorylation and proteolysis of CtrA are connected because ClpXP degrades CtrA (Jenal and Fuchs 1998). The consequence is that when CckA is active, it activates CtrA by phosphorylation and prevents its degradation by inactivating CpdR again by phosphorylation. For DNA replication, initiation CckA is inactivated which leads to a lack of phosphorylation, both of CtrA and of CpdR, and this results in CtrA inactivation, both due to a lack of phosphorylation and proteolysis by CpdR.

It underlines the importance of CtrA that *Caulobacter vibrioides* has a third mechanism of controlling CtrA. This mechanism is based on epigenetics by controlling DNA expression via methylation. In *C. vibrioides* and probably other *Caulobacteraceae*, DNA methylation is performed by the CcrM methylase which is essential for the viability of the cells (Zweiger et al. 1994). CcrM is active in the monomeric form but dimerizes in solution, probably to resist proteolysis by the Lon protease (Shier et al. 2001). CcrM is active only shortly before cytokinesis in the predivisional cell and was found preferentially in the prosthecate cell (Reuter and Shapiro 1987). This is achieved by a spike of *ccrM* transcription which overcomes temporarily the degradation rate of CcrM by Lon and this is also under the control of CtrA (Reisenauer et al. 1999). The *ctrA* gene has the weak P_1 and the strong P_2 promoter (Domian et al. 1999). The promoter P_1 is only active in the hemimethylated form and is regulated by GcrA (Holtzendorff et al. 2004). Therefore, when GcrA is active and the chromosome has been duplicated past the *ctrA* gene, *ctra* expression increases steadily. The formed CtrA∼P represses promoter P_1 and activates the stronger P_2 promoter, leading to a strong burst of CtrA. The high concentration of CtrA is then able to bring CcrM synthesis to a level where it overcomes degradation of CcrM by Lon. The now abundant CcrM methylates the newly synthesized DNA only when CtrA is present which also binds to the replication origin, blocking reinitiation. The outcome of this regulation cascade is that due to the dependence of CcrM on the presence of CtrA, the chromosome is only replicated once per cell cycle.

Before DNA replication is initiated the chromosomal origin is localized at the site where the prosthecate pole of the *C. vibrioides* cell will be located. One copy of a newly replicated locus is immediately segregated to its new location at the future swarmer cell while the other remains in the prosthecum cell section (Viollier et al. 2004). To start replication, the initiator protein DnaA is required. DnaA is an essential replication factor, and 40 genes were shown to be DnaA-dependent (Hottes et al. 2005). DnaA binds to two different types of DnaA boxes, the two G-boxes with moderate affinity and five W-boxes with weak affinities for DnaA. DnaA and CtrA compete for binding at the chromosomal origin and activate or repress replication at different stages of the cell cycle (Taylor et al. 2011). This is achieved by a tight control of DnaA level, being the highest in prosthecate cells (Cheng and Keiler 2009). DnaA activity is dependent on ATP-binding, and as a consequence, hydrolysis of ATP deactivates DnaA. DnaA activates HdaA expression, shutting itself down by promoting the formation of its own inhibitor (Grünenfelder et al. 2001). The replisome-associated protein HdaA stimulates ATPase activity and acts therefore as a DnaA inhibitor (Collier and Shapiro 2009).

Chromosome replication is also regulated at the level of RNA. Here the hybrid tRNA-mRNA, called tmRNA, encoded by the *ssrA* gene, plays a key role. The main function of tmRNA is to release ribosomes that are blocked by mRNAs without a stop codon by adding the SsrA degradation tag at the C-terminal end of these incomplete proteins. One domain of tmRNA is folded into an alanyl-tRNA-like structure and is loaded by alanyl-tRNA synthetase, and its 3′ end does not contain an anticodon but encodes the degradation tag that is added to the C-terminal end of incomplete proteins (Keiler 2007). The small protein SmpB interacts with tmRNA by increasing its stability and interaction with the ribosome. This mechanism is used in *Caulobacter vibrioides* to regulate protein biosynthesis and changes of tmRNA concentrations over the cell cycle (Keiler and Shapiro 2003). It is produced in swarmer and predivisional cells. A burst in transcription of the ssrA promoter leads to high levels of tmRNA during the swarmer to prosthecate cell transition while tmRNA is rapidly degraded in prosthecate cells. The cell-cycle regulation of tmRNA stability is controlled by the degradation by the 3–5′ exoribonuclease RNase R on the one hand and the stabilization by the SmpB protein on the other hand (Hong et al. 2005). RNase R degrades tmRNA, but its level is relatively constant during the cell cycle, indicating that the cell-cycle variation in tmRNA is not caused by the regulation of RNase R expression but by the level of SmpB. SmpB stabilizes and selectively protects tmRNA from degradation by RNase R. SmpB abundance dramatically increases together with tMRNA during the swarmer to prosthecate cell differentiation, and SmpB is rapidly degraded again together with tmRNA in prosthecate cells (Keiler and Shapiro 2003). Therefore, the cell-cycle-dependent fluctuation of tmRNA is mediated by the protective action of SmpB against RNase R degradation. This model has been confirmed by fluorescent in situ hybridization (FISH) of tmRNA over the time course of the cell cycle (Russell and Keiler 2009). A proteomic identification of tmRNA substrates identified 73 proteins that are tagged by tmRNA (Hong et al. 2007).

The formation of the flagellum is also a tightly regulated process. First, the cell has to know where to assemble the flagellum, and for this, it uses the protein TipN. TipN is also called the birth scar protein and is only found at the new poles of both the swarmer and the prosthecate cells (Lam et al. 2006). TipF, a c-di-GMP phosphodiesterase, is then localized to TipN, a process essential for flagellum assembly (Huitema et al. 2006). The synthesis of the flagellum apparatus can be divided into four classes, and the expression of one class of genes requires confirmation of the successful action of proteins from the previous class. Class I genes are those that lead to expression of class II genes dependent on the cell cycle. Class I genes are regulated by CtrA (Dingwall et al. 1992). Class II genes encode the MS ring, switch complex, protein export apparatus, and regulatory proteins sigma 54, FliX, and FlbD. FliX and FlbD form the next important checkpoint in flagellum synthesis. FliX inactivates FlbD by complexation, but after completion of the MS ring, FliX repression of FlbD is relieved by an unknown mechanism (Muir et al. 2005). FlbD activates then transcription of the genes of both class III, comprising P ring, L ring, rod, and hook, and class IV which are the flagellin proteins. At this stage, translation of class IV genes is inhibited by the mRNA-binding protein FlbT (Anderson and Gober 2000), but the mechanism sensing the completion of class III proteins and transducing this information is unknown.

The attachment of *Caulobacter vibrioides* is regulated by a photosensory two-component system, LovK and LovR. LOV stands for light, oxygen, or voltage, because these proteins contain a domain that regulates blue-light-dependent processes. LovK is a histidine kinase and LovR a single-domain response regulator. Maximal transcription of *lovK* and *lovR* occurs during swarmer cell differentiation, when holdfast synthesis is active and loss of pili and flagella occur (Purcell et al. 2007).

Lipids

For decades, the cellular fatty acid composition of bacterial cells has been used as chemotaxonomic marker to compare species. Today a standardized protocol, easy handling, and a large database allow a reliable identification of isolates at genus level and often even at species level. Only fatty acids $C_{16:0}$ and $C_{18:1}\omega7c$ were found in all strains of the *Caulobacteraceae*. *Caulobacter* species contained in addition significant amounts of the unidentified fatty acid ECL 11.798 and fatty acids $C_{14:0}$, $C_{15:0}$, $C_{16:1}\omega7c$, $C_{17:0}$, $C_{17:1}\omega6c$, $C_{17:1}\omega8c$, $C_{18:1}\omega7c$ and 11-methyl-$C_{18:1}\omega5t$. *Brevundimonas* species differed from all other genera of *Caulobacteraceae* by the presence of an unidentified fatty acid at ECL 17.897. Fatty acids present in all *Brevundimonas* strains were $C_{14:0}$, $C_{15:0}$, $C_{16:0}$, $C_{16:1}\omega7c$, $C_{17:0}$, $C_{17:1}\omega6c$, $C_{17:1}\omega8c$, and $C_{18:1}\omega7c$. *Brevundimonas* strains are differentiated from *Caulobacter* strains by the absence of ECL 11.789 and by the presence of at least traces of ECL 17.897 and by a higher content

of the dominant fatty acid $C_{18:1}\omega7c$ (Abraham et al. 1999). *Phenylobacterium* differed from those of the genus *Caulobacter* by the presence of only trace amounts of $C_{14:0}$ and from the genus *Brevundimonas* by the occurrence of only trace amounts of $C_{14:0}$ and the presence of $C_{12:0}$. 11-Methyl-$C_{18:1}\omega5t$ is present in *Caulobacter* and *Phenylobacterium* species but absent in *Brevundimonas* and *Asticcacaulis* strains. A number of fatty acids, e.g., $C_{14:0}$, $C_{17:0}$, or $C_{17:1}\omega8c$, usually found in species of the other genera are found only infrequently in *Asticcacaulis* species (Vasilyeva et al. 2006).

Especially hydroxy-fatty acids have been found to be valuable biomarkers for the identification of genera. *Caulobacter* and *Asticcacaulis* species (Vasilyeva et al. 2006) contained significant amounts of the fatty acids $C_{12:1}$ 3-OH, which is probably $C_{12:1}\omega6$ 3-OH (Bellmann and Lingens 1985), while the main hydroxy-fatty acid of *Brevundimonas* strains is $C_{12:0}$ 3-OH. From this scheme *Asticcacaulis taihuensis* deviated by considerable amounts of $C_{16:0}$ 2-OH (Liu et al. 2005). Species of the genus *Phenylobacterium* differ from those of the genus *Caulobacter* by a higher amount of $C_{12:0}$ 3-OH and from the genus *Brevundimonas* by the presence of $C_{12:1}\omega6$ 3-OH. In *P. composti*, *P. lituiforme*, and *P. koreense*, $C_{18:1}$ 2-OH has also been detected, a fatty acid not found in any of the other three genera (Weon et al. 2008).

The glycolipids of *Brevundimonas diminuta* have been identified as 1-0-α-D-glucopyranosyl-D-2,3-diacylglycerol, 1-*O*-α-D-glucopyranuronosyl-D-2,3-diacylglycerol, and 1-[0-β-D-glucopyranosyl-(1 → 4)-*O*-α-D-glucopyranuronosyl]-D-2,3-diacylglycerol. One of the phospholipids was phosphatidylglycerol; the other appeared to be a new phosphoglucolipid (Wilkinson 1969). The structure of this novel phosphoglucolipid has then been elucidated, revealing 3-α-D-[6′-(1″,2″-diacyl-sn-glycero-3-phospho)] glucopyranosyl-sn-diacylglycerol (Wilkinson and Bell 1971). From *Brevundimonas bacteroides* NP-105, the same five polar lipids together with 1,2-diacyl-3-α-D-(6′-sulfo)quinovopyranosyl-sn-glycerol have been isolated (Batrakov et al. 1997). This finding of sulfoquinovosyl-diacylglycerols was surprising, because this lipid is widely known to occur in photosynthesizing microbes but is extremely rare in non-photosynthesizing bacteria. Analysis of the polar lipids of *Brevundimonas vesicularis* revealed the same lipids obtained from *B. diminuta* but also a novel lipid identified as 1,2-diacyl-3-*O*-α-D-glycero-D-glucoheptopyranosylglycerol and bearing mainly $C_{18:1}$ and $C_{16:0}$ as major fatty acids (Wilkinson and Galbraith 1979).

These studies revealed often surprisingly high concentrations of glycolipids. Some of these glycolipids are strongly acidic, and it has been speculated that these lipids could be able to function instead of the usual phospholipids. Such a concept has been substantiated by the finding that low concentrations of phosphate lead to a reduction of phospholipids in *Brevundimonas diminuta* (and in many *Hypomonadaceae*) species. This can even lead to a reduction of phospholipids as low as 0.3 % of the polar lipids (Minnikin et al. 1974).

For the described comparison of fatty acid composition, the cellular fatty acids need to be saponified from their respective lipids, proteins or saccharides. This destruction of more complex structures causes a loss of information; therefore, it was suggested that intact polar lipids could be used as biomarkers. By ionization of the polar lipids in a mass spectrometer, isolation of individual molecular ions, and analysis of their fragments, the structure of individual lipids can be elucidated. The fragmentation of the fatty acid at sn-1 of glycerol is different from the one at sn-2, allowing unambiguous assignment of their position at the glycerol moiety. For a number of isolates of the *Caulobacteraceae* and *Hyphomonadaceae*, comparison between cellular fatty acids and polar lipids profiles revealed a better chemotaxonomic resolution of the intact lipids. More than 40 different lipids belonging to the groups of phosphatidyl-, sulfoquinovosyl-, glucoronotaurine amide-, and phosphatidyl-glucopyranosyl-diacylglycerols could be identified. All *Caulobacteraceae* cells contained phosphatidylglycerol and 18:1-16:0-PG was usually the most abundant one. A huge number of different phosphatidyl-glucopyranosyl-diacylglycerols could be identified. This lipid type was present in all *Caulobacter*, *Brevundimonas*, and *Phenylobacterium* species but absent in the strains of the genus *Asticcacaulis* (Abraham et al. 2001). *Caulobacter* strains are characterized by the presence of tetraacyl-3-0-[6′-(sn-glycero-3″-phosphoryl)α-D-glucopyranosyl]-sn-glycerols of the mass 1,411 Da. *Brevundimonas* strains produce the same phosphoglycolipids, but they are characterized by the main lipid of the mass 1,413 Da and homologous compounds of 1,427, 1,439, and 1,453 Da. Both genera showed the phosphoglucolipid with the molecular mass of 1,439 Da (Abraham et al. 1997). Most *Phenylobacterium* species have the phosphoglucolipid of 1,413 Da, characteristic for *Brevundimonas* species, only *P. conjunctum* has the lighter one of 1,411 Da. *Phenylobacterium* strains also have sulfoquinovosyl-diacylglycerols which can also be found in *Brevundimonas* species but not in those of the genus *Caulobacter*. The sulfoquinovosyl-diacylglycerols from *Phenylobacterium* have, however, a fatty acid composition different to the one found in *Brevundimonas* strains (Abraham et al. 2008).

The same analysis applied to the glycolipid fractions of 70 strains of *Caulobacter*, *Brevundimonas* and *Phenylobacterium* revealed as for the phospholipids a high diversity of glycolipids. The four glucolipid types already reported from *Brevundimonas* species were confirmed, and 60 different compounds could be elucidated, 59 of them were novel. It was found that the occurrence of glucosyl-glucuronosyl-lipids was restricted to *Brevundimonas* species but 1,2-diacyl-3-*O*-α-D-glycero-D-glucoheptopyranosylglycerol was often found in *Caulobacter*, *Brevundimonas*, and *Phenylobacterium* strains but absent in *Asticcacaulis* species (Abraham et al. unpublished).

It is also interesting to have a look at the structural variations observed in the phosphoglucolipids because the individual polar lipids are not produced by chance as little variation of these lipids has been observed after *Brevundimonas diminuta* had been grown in five different media (Abraham et al. 1997). All phosphoglucolipids have C18:1ω7*c* at sn-1 of the glycerol of the phosphatidyl part, indicating that this fatty acid is important or even essential for the function of these polar lipids. Saturated

fatty acids, $C_{16:1}\omega7c$ and $C_{17:1}\omega8c$, are exclusively found at sn-2 of the glycerol. The unusual fatty acid 11-methyl-$C_{18:1}\omega5t$ (Abraham et al. 2008) is only found at the glucosidic glycerol. So the observed diversity of these phosphoglucolipids is caused by the variation of the fatty acids at sn-2, indicating that the esters at sn-2 are not as important as those at sn-1 for the still unknown function of these phosphoglucolipids (Abraham et al. 1997).

A number of species have been reported to store energy in poly-hydroxyalkonate droplets, but hydroxy-fatty acids are usually found at the lipid A core of lipopolysaccharides. Structure elucidation of lipid A from *Caulobacter vibrioides* revealed a novel structure comprising the tetrasaccharide backbone alpha-D-galactopyranuronic acid-(1 → 4)-beta-D-2,3-diamino-2,3-dideoxyglucopyranose-(1 → 6)-alpha-D-2,3-diamino-2,3-dideoxyglucopyranose-(1 → 1)-alpha-D-galactopyranuronic acid (alpha-D-GalpA-(1 → 4)-beta-D-DAG-(1 → 6)-alpha-D-DAG-(1 → 1)-alpha-D-GalpA), substituted with six fatty acids. The major lipid A component had 12:0[3-*O*-[3-OH-12:1ω6]] and 12:0[3-*O*-12:1ω6] fatty acids at either the 3′- or the 2′-positions of the distal subunit 2,3-diamino-2,3-dideoxyglucopyranose, and 3-OH-12:0 and 3,6-diOH-12:0 fatty acyl chains at 3- and 2-positions of the reducing 2,3-diamino-2,3-dideoxyglucopyranose, respectively (Smit et al. 2008). The unusual fatty acid 3-OH-12:1ω6 has also been reported from Lipid A of *Phenylobacterium immobile* (Lodowska et al. 2007).

Polyamines

The distribution of polyamines as a chemotaxonomic marker was introduced by Busse and Auling after comparing 50 species of the *Proteobacteria* (Busse and Auling 1988). This analysis has been applied to a number of *Brevundimonas* and "*Brevundimonas*-like" strains which had significant amount of homospermidine or spermidine or both. While *B. diminuta* had spermidine as the main polyamine, *B. vesicularis* had homospermidine and *Phenylobacterium haematophilum* LMG 11050^T had higher amounts of homospermidine than the *B. vesicularis* strains analyzed (Segers et al. 1994). Polyamine analyses of *Caulobacter fusiformis*, *C. vibrioides*, and five *Brevundimonas* species revealed homospermidine as the main compound. In the extracts of *Brevundimonas bullata* and *B. vesicularis*, spermidine was also found (Hamana et al. 2001). The occurrence of two different polyamines as main compounds in *Brevundimonas* is rather exceptional (Hamana et al. 2003), but the polyamine distribution does not allow any differentiation at the species level.

Polysaccharides

Caulobacteraceae are usually members of biofilm communities and contribute to their mechanical stability by the production of exopolysaccharides. From two *Caulobacter vibrioides* strains, CB2A and CB15A, the chemical composition of the exopolysaccharides has been analyzed. Analysis of the monomers revealed that both strains produce unique exopolysaccharides. While one strain CB2A contained D-glucose, D-gulose, and D-fucose in a ratio of 3:1:1, the CB15A polymer contained D-galactose, D-glucose, D-mannose, and D-fucose in a 1:1:1:1 ratio. Further analyses of the CB2A polymer showed the presence of terminal glucose and gulose groups, 3-linked fucosyl, and two 3,4-linked glucosyl units, resulting in a pentasaccharide repeating unit. Contrarily, for strain CB15A, a tetrasaccharide repeating unit consisting of terminal galactose, 4-linked fucosyl, 3-linked glucosyl, and 3,4-linked mannosyl residues was characterized (Ravenscroft et al. 1991). From *Brevundimonas vesicularis* isolated from a paper mill, the exopolysaccharide has been purified and analyzed. Size exclusion chromatography showed a mean molecular weight above 2 MDa. The exopolysaccharide consisted of rhamnose, glucose, galacturonic, and glucuronic acid. After mild hydrolysis of the polymer, a repeating unit could be identified by mass spectrometry and nuclear magnetic resonance. The structure of the repeating unit was novel and elucidated to be → 4)-α-L-glucopyranosyluronate-(1 → 4)-α-D-galactopyranosyluronate-(1 → 4)-β-L-rhamnopyranosyl-(1 → 4)-β-D-glucopyranosyl(1 → (= → 4)-α-L-Glc*p*A-(1 → 4)-α-D-Gal*p*A-(1 → 4)-β-L-Rha*p*-(1 → 4)-β-D-Glc*p*(1→). It has been speculated that the variation in sugars, conformation, and linkage type present would limit enzymatic degradation, adding another element of stability to biofilms of *Brevundimonas vesicularis* and probably also other species of *Caulobacteraceae* (Verhoef et al. 2002).

Peptidoglycan

The peptidoglycan of *Caulobacter vibrioides* CB13 has been found to contain only the amino acids alanine, diaminopimelic acid, and glutamic acid in the ratio 2:1:1 (Fujiki et al. 1976). For *Caulobacter vibrioides*, *C. fusiformis* CB27, *Brevundimonas bacteroides* CB11a, and *Asticcacaulis biprosthecum*, a ratio of alanine: glutamic acid: α,ω-diaminopimelic acid: muramic acid: glucosamine was determined to be 2:1:1:1.2:0.8. Such a peptidoglycan is richer in muramic acid than the peptidoglycan of most Gram-negative bacteria. While the ratio of these amino acids does not vary between prosthecate and swarmer cells, the composition of the sugar components does. The prosthecum of *C. vibrioides* was found to be enriched in glucosamine compared to the cell (Poindexter and Hagenzieker 1982). The lysozyme-degradation product of the murein of *Phenylobacterium immobile* was identical to the C6 muropeptide of *E. coli* (Lingens et al. 1985).

Caulobacter Henrici and Johnson 1935, emend. Abraham et al. 1999

The description of the genus *Caulobacter* follows the one given by Abraham et al. 1999. Gram-negative cells, rod-shaped, fusiform, or vibroid, 0.4–0.5 by 1.2 μm. Cells usually possess

a prostheca, but some species do not (Fig. 7.2). They tolerate only small amounts of NaCl, grow without it, but some grow optimally with 5 g NaCl l^{-1}. No growth with salt concentrations above 20 g l^{-1} was observed. All strains contain significant amounts of the fatty acids 3-OH $C_{12:1}$, $C_{14:0}$, $C_{16:0}$, sum4 (see Table 7.3), sum7 (see Table 7.3), and 11-Me $C_{18:1}\omega5$. All strains, except *C. segnis*, additionally contain ECL 11.798, $C_{15:0}$, $C_{17:0}$, $C_{17:1}\omega6c$, and $C_{17:1}\omega8c$. Polar lipids are α-D-glucopyranosyl diacylglycerol, α-D-glucopyranuronosyl diacylglycerol, 6-phosphatidyl-α-D-glucopyranosyl diacylglycerol (main mass number 1,411 Da), and phosphatidylglycerol. The GC content is 65.5–68.0 mol%. Type species is *Caulobacter vibrioides*.

The genus comprises currently the species *Caulobacter fusiformis* Poindexter 1964, *C. ginsengisoli* Liu et al. 2010, *C. henricii* Poindexter 1964, *C. mirabilis* Abraham et al. 2008, *C. segnis* (Urakami et al. 1990; Abraham et al. 1999), and *C. vibrioides* Henrici and Johnson 1935. Their distinct characteristics are compared in Table 7.2.

Asticcacaulis Poindexter 1964

The description of the genus is the emended version of the one given by Poindexter (1964) and based on our own studies (Abraham et al. 2001). Unicellular prosthecate bacteria. The prosthecum arises from a site on the cell which is not coincidental with the center of the pole of the cell (Figs. 7.3 and 7.4). The prosthecum does not possess adhesive material. Multiplication occurs by division of the prosthecate cell, giving

Fig. 7.3
Morphology of *Asticcacaulis biprosthecum* (SEM). Under certain growth conditions, the cells tend to be pleomorphic

rise to a non-prosthecate sibling which is smaller than the prosthecate sibling and is motile by means of a single flagellum which arises in an eccentric position on the pole of the cell. This cell develops a prosthecum and enters the immotile vegetative phase. Adhesive material is secreted by cells in both phases at or near the pole of the cell at a site different from that at which the prosthecum develops. The adhesive material allows cells to attach to a variety of solid substrates. The cells of known types are rod-shaped and colorless. Main hydroxy-fatty acid is 3-OH $C_{12:1}$. Species of *Asticcacaulis* differ from species of *Caulobacter* and *Brevundimonas* by the lack of 1,2-diacyl-3-*O*-[6′-phosphatidyl-*a*-D-glucopyranosyl]glycerol. They also do not contain 1,2-di-*O*-acyl-3-*O*-[D-glucopyranosyl-(1 → 4)-*a*-D-glucuronopyranosyl]-glycerol, which is found in most *Brevundimonas* species but not in strains of the genus *Caulobacter*. The GC content is 55–61 mol%. Type species of the genus is *Asticcacaulis excentricus*.

The genus comprises currently the species *Asticcacaulis benevestitus* (Vasilyeva et al. 2006), *A. biprosthecum* (Pate et al. 1973), *A. excentricus* (Poindexter 1964) and *A. taihuensis* (Liu et al. 2005). Their distinct characteristics are compared in *Table 7.3*.

Phenylobacterium Lingens et al. 1985 emend. Kanso and Patel 2004 emend. Tiago et al. 2005 emend. Zhang et al. 2007 emend. Abraham et al. 2008 emend. Oh and Roh 2012

The description follows the one emended Oh and Roh 2012: Cells stain Gram-negative, are non-spore-forming straight to slightly curved rods, coccobacilli or cocci measuring 0.7–1.0 × 1.0–2.0 μm and occur singly, in pairs, or short chains. Cells of some species have prosthecae. Cells may form rosettes.

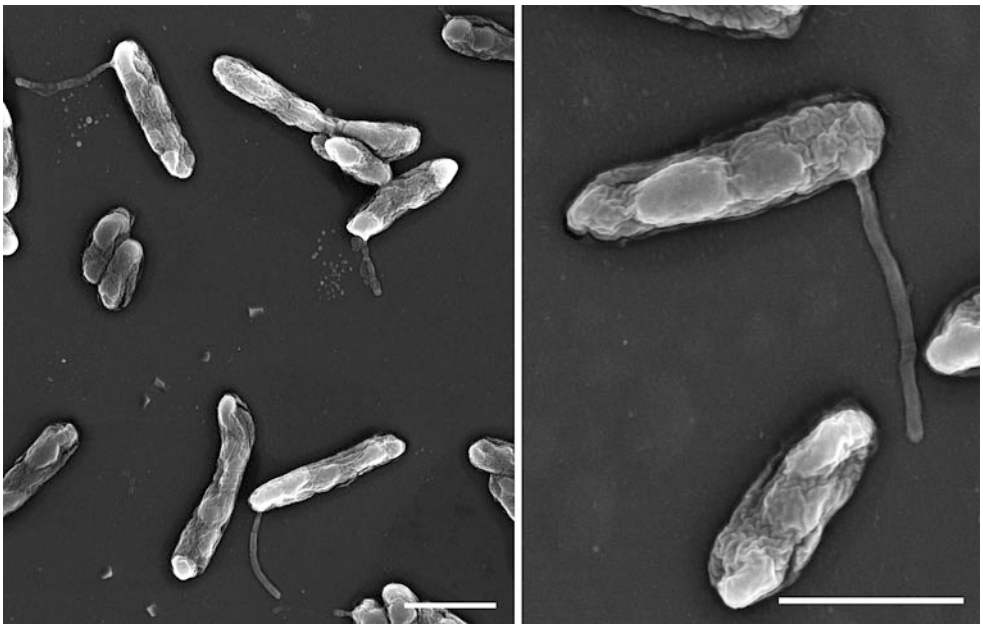

Fig. 7.4
Micrographs of *Asticcacaulis excentricus* showing the eccentric location of the prosthecum

Filamentous cells tend to form in old cultures. Species may be strict aerobes or facultative anaerobes and may be motile or nonmotile. Cells do not form sheaths and are not acid-fast. Species are negative for lipase (C14), α-galactosidase, α-mannosidase, β-glucosidase, and α-fucosidase. Utilization of antipyrine or chloridazon as sole carbon source, reduction of nitrate to nitrite, oxidase activity, and hydrolysis of casein are species dependent. All species of the genus *Phenylobacterium* have 122-G in their 16S rRNA gene sequences, while the other genera of the order *Caulobacterales* genera have 122-A. Furthermore, species of the genus *Phenylobacterium* have a 178-T which is either 178-G or 178-A in the genera *Caulobacter*, *Brevundimonas*, and *Asticcacaulis*. These three genera have a 359-G which is 359-A in all species of the genus *Phenylobacterium*. Main cellular fatty acids are $C_{16:0}$ and $C_{18:1}\omega7$. In contrast with species of the genera *Brevundimonas* and *Caulobacter*, $C_{14:0}$ is present only in traces. Hydroxy-fatty acids are 3-OH $C_{12:0}$ and 3-OH $C_{12:1}$. All species of the genus *Phenylobacterium* have the phospholipids phosphatidylglycerol and 3-O-[6′-(*sn*-glycero-3″-phosphoryl)-α-D-glucopyranosyl]-sn-glycerols. Some species also possess the sulfolipids sulfoquinovosyl-diacylglycerols. The DNA G + C ratio is between 66.5 and 72.3 mol%. Isolated from soil, water, and blood. The type species is *Phenylobacterium immobile*.

The genus comprises currently the species *Phenylobacterium composti* (Weon et al. 2008), *P. conjunctum* (Abraham et al. 2008), *P. falsum* (Tiago et al 2005), *P. haematophilum* (Abraham et al. 2008), *P. immobile* (Lingens et al. 1985), *P. koreense* (Aslam et al. 2005), *P. lituiforme* (Kanso and Patel 2004), and *P. muchangponense* (Oh and Roh 2012). Another species, "*P. zucineum*," has been invalidly described (Zhang et al. 2007), but it is discussed in this chapter because its genome has been sequenced. Characteristics of the species are shown in *Table 7.4*.

Brevundimonas Segers et al. 1994, emend. Abraham et al. 1999

Gram-negative cells, rod-shaped, fusiform, bacteroid, or vibroid, 0.4–0.5 by 1–2 μm. Cells do not usually possess a prostheca (*Fig. 7.5*), but some species do. They grow without NaCl, grow optimally with 5–20 g NaCl l^{-1}, growth is reduced at 30–80 g NaCl l^{-1} depending on the species, and they do not grow with NaCl concentrations above 80 g l^{-1}. Dominant fatty acids for all *Brevundimonas* strains are 3-OH $C_{12:0}$, $C_{14:0}$, $C_{15:0}$, $C_{16:0}$, sum4, $C_{17:0}$, $C_{17:1}\omega6c$, $C_{17:1}\omega8c$, and sum7. They are differentiated from *Caulobacter* strains by the absence of ECL 11.789 and significant amounts of 3-OH $C_{12:1}$, by the presence of at least traces of ECL 17.897 and higher amounts of 3-OH $C_{12:0}$, and by a higher content of the dominant fatty acid $C_{18:1}\omega7$. Polar lipids are α-D-glucopyranosyl diacylglycerol, α-D-glucopyranuronosyl diacylglycerol, 1,2-di-*O*-acyl-3-*O*-[D-glucopyranosyl-(1 → 4)-α-D-glucopyranuronosyl]glycerol, 6-phosphatidyl-α-D-glucopyranosyl diacylglycerol (main mass numbers 1,413 and 1,439 Da), and phosphatidylglycerol. Most strains contain sulfoquinovosyl diacylglycerol. The GC content is 61.0–68.7 mol%. Type species is *Brevundimonas diminuta*; type strain is LMG 2089^T.

The genus *Brevundimonas* is currently the largest genus of the *Caulobacteraceae* comprising the species *Brevundimonas*

alba (Poindexter 1964; Abraham et al 1999), *B. aurantiaca* (Poindexter 1964; Abraham et al. 1999), *B. aveniformis* (Ryu et al. 2007), *B. bacteroides* (Poindexter 1964; Abraham et al. 1999), *B. basaltis* (Choi et al. 2010), *B. bullata* (Gray and Thornton 1928; Kang et al. 2009), *B. diminuta* (Leifson and Hugh 1954; Segers et al. 1994), *B. faecalis* (Scotta et al. 2011), *B. halotolerans* (Abraham et al. 2010), *B. intermedia* (Poindexter 1964; Abraham et al. 1999), *B. kwangchunensis* (Yoon et al. 2006a), *B. lenta* (Yoon et al. 2007), *B. mediterranea* (Fritz et al. 2005), *B. naejangsanensis* (Kang et al. 2009), *B. nasdae* (Li et al. 2004), *B. poindexterae* (Abraham et al. 2010), *B. staleyi* (Abraham et al. 2010), *B. subvibrioides* (Poindexter 1964; Abraham et al. 1999), *B. terrae* (Yoon et al. 2006b), *B. vancanneytii* (Estrela and Abraham 2010), *B. variabilis* (Poindexter 1964; Abraham et al. 1999), *B. vesicularis* (Büsing et al. 1953; Segers et al. 1994), and *B. viscosa* (Wang et al. 2012). The distinct characteristics of these species have been listed in *Table 7.5*.

The 16S rRNA gene sequence DQ442520 submitted for *Streptomyces longisporoflavus* falls in the middle of the *Brevundimonas* phylogenetic tree. It is highly unlikely that spore-forming cells producing such a wealth of antibiotics belong to the genus *Brevundimonas*. Instead it must be assumed that a *Brevundimonas* species contaminating the *Streptomyces longisporoflavus* culture has erroneously been analyzed, and its 16S rRNA gene sequence has been deposited instead of that of the type strain of *Streptomyces longisporoflavus*. A *S. longisporoflavus* cultures properly identified by morphological and biochemical criteria should be analyzed to clarify this contradiction.

Isolation, Enrichment, and Maintenance Procedures

When isolating *Caulobacteraceae*, one has to be aware that cell densities of *Caulobacteraceae* in water and soil samples can be low because of their preferences for oligotrophic habitats, but a number of *Brevundimonas* species have also been isolated from carbon-rich sites. Many *Caulobacteraceae* stick

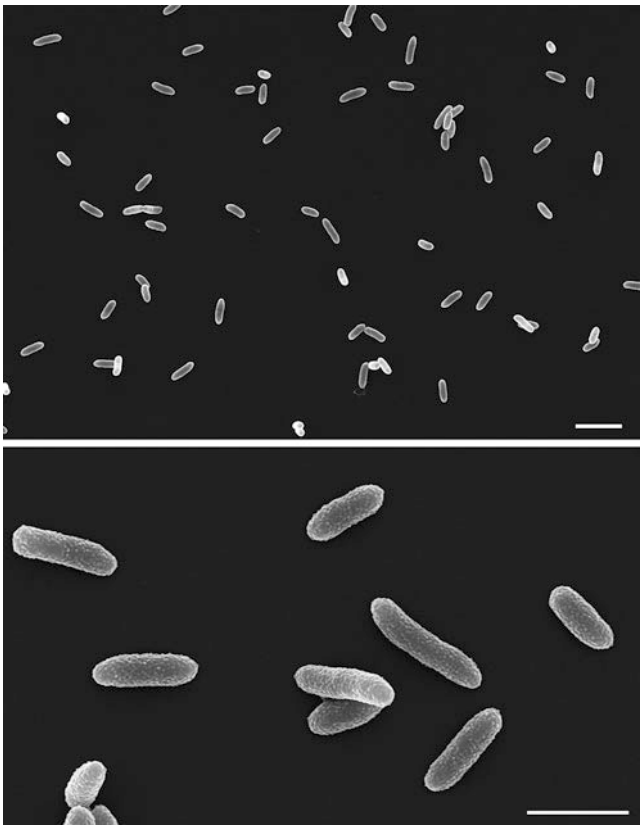

Fig. 7.5
Cells of *Brevundimonas diminuta* do not develop any prostheca. They form one example of prosthecum-less cells found in the family, other examples are *Caulobacter segnis* or *Phenylobacterium immobil*

with their holdfasts to surfaces and these surfaces can be other cells or any other substratum. Therefore, filtering the water samples before plating would lead to a loss of bacteria of many prosthecate *Caulobacteraceae*. The adaptation of the cells to starvation can be used for their isolation. Strains of *Caulobacteraceae* can be isolated from water using a standard dilution-plating method on an oligotrophic medium, e.g., R2A agar, diluted in the ratio 1:10 in tap water (1/10R2A). Media with more than 1 g l^{-1} soluble organic substrates should be avoided for bacteria from oligotrophic sites because it can cause pleomorphic cells. Cells growth is usually slow, and colonies are visible often only after one or even more weeks. Another isolation method is keeping the water sample after addition of 10–30 mg l^{-1} peptone or other carbon source at room temperature for 1–2 months and plate the formed biofilm on diluted agar. One should keep in mind that prosthecate species form clumps, and, hence, these isolates have to be checked carefully for any mixed cultures.

Most strains can be grown in

(i) PYE medium containing 200-mg peptone, 100-mg yeast extract, and 20-mg $MgSO_4 \times 7H_2O$ in 1 l autoclaved tap or deionized water (Poindexter 1964) or

(ii) PCa medium: 200-mg peptone, 20-mg $MgSO_4 \times 7H_2O$, 15-mg $CaCl_2 \times 2\ H_2O$ in 1 l autoclaved tap or deionized water (Poindexter 2006).

The great majority of isolates of the family *Caulobacteraceae* require one or more organic growth factors. For a few such strains, growth in defined media is supported by one or more B vitamins (Larson and Pate 1975; Poindexter 1964), but for most isolates, the requirements have not been determined. Significant stalk elongation of *Caulobacter vibrioides* and *Asticcacaulis excentricus* relative to cell elongation has been observed when growth is phosphate-limited (Poindexter 1981). One consequence of the lack of defined media for the majority of *Caulobacteraceae* isolates is that most studies focus on *Caulobacter vibrioides* where defined media for growth are known.

Most *Caulobacter vibrioides* isolates grow in the defined HiGg medium containing 5–10 mM glucose, 5–10 mM monosodium glutamate (filter sterilized), 0.1–1 mM KH_2PO_4, 5–10 mM NH_4Cl, and 5 mM imidazole and Hutner's mineral base (Cohen-Bazire et al. 1957; Poindexter 1978). Another minimal medium is the M2 medium: 20 mM sodium phosphate and potassium phosphate, 9.3 mM NH_4Cl, 0.5 mM $MgSO_4$, 0.5 mM $CaCl_2$, 0.01 mM $FeSO_4$, 0.008 mM ethylenediaminetetraacetic acid (Johnson and Ely 1977).

A definite medium, MS-B-AA medium, for the cultivation of *Asticcacaulis biprosthecum*, has been described: 0.1 % glucose, alanine, glutamate, serine, proline and aspartate 100 mg L-1 each, 0.075 mM $(NH_4)_2HPO_4$, 0.5 mM $NaH_2PO_4 \times H_2O$, 0.5 mM KH_2PO_4, 0.01 % $MgSO_4 \times 7H_2O$, 0.01 % sodium citrate, 4 µg l-1 D-biotin and 10-mg $CaCl_2 \times 2H_2O$, 10 mg $FeSO_4 \times 7H_2O$, 10 mg $MnSO_4 \times H_2O$, 10-mg $ZnSO_4 \times 7H_2O$, 1-mg $CuSO_4$, 1-mg $CoCl_2 \times 6H_2O$, 1-mg $K_2B_4O_7 \times 4H_2O$, and 1-mg MoO_3, per liter trace minerals (Larson and Pate 1975).

Caulobacteraceae are generally cultivated aerobically, but *Asticcacaulis biprosthecum* seems to be here an exception. Its growth was delayed and yield was reduced when vigorously aerated, but it grew when incubated under air without agitation. In fermenter cultures, it grew in the presence of 6.0–6.7 mg of 0_2 per liter, but not at levels greater than 6.7 mg l^{-1} (90 % saturation). Thus, *A. biprosthecum* appears to be an O_2-sensitive oxybiontic organism (Larson and Pate 1975; Poindexter 1981).

Caulobacteraceae are usually grown at 27 °C or 30 °C. Most species can grow well between 20 °C and 40 °C. Some species show reasonable growth at 10 °C, very few grow slowly at 4 °C (especially *Brevundimonas* isolates from cold habitats) and none at 50 °C (Abraham unpublished). The pH range for growth is around neutrality. Most strains of *Caulobacter* and *Brevundimonas* differ by their salt tolerances. While all isolates can grow with no sodium chloride, 0.5 g l^{-1} usually leads to better growth. While most *Caulobacter* species can tolerate 10 g l^{-1} of NaCl, most *Brevundimonas* species can grow well at 35 g l^{-1} and some even with 60 g l^{-1} (usually isolates from brackish or sea water). No growth with 80 g l^{-1} sodium chloride was observed (Abraham et al. 1999).

Table 7.5

Characteristics useful to discern the following *Brevundimonas* species: *1 Brevundimonas alba, 2 B. aurantiaca, 3 B. aveniformis, 4 B. bacteroides, 5 B. basaltis, 6 B. bullata, 7 B. diminuta, 8 B. faecalis, 9 B. halotolerans. 10 B. intermedia, 11 B. kwangchunensis. 12 B. lenta, 13 B. mediterranea, 14 B. naejangsanensis, 15 B. nasdae, 16 B. poindexterae, 17 B. staleyi, 18 B. subvibrioides, 19 B. terrae, 20 B. vancanneytii, 21 B. variabilis, 22 B. vesicularis, 23 B. viscosa*

For long time storage, most strains can be preserved in glycerol suspension (10 %, v/v) at −75 °C. Vegetative stocks should be maintained on 1 % 1/10 R2A agar slants at 4 °C and transferred every 2 or 3 months, incubated 2 or 3 days at room temperature then kept at 4 °C. For most strains, lyophilization is another option.

Ecology

The physiology and cell cycle of *Caulobacteraceae* demonstrate their excellent adaptation to oligotrophic habitats. This also includes motility, and it has been found that *Caulobacter vibrioides* swims about 10 times more efficiently than *E. coli* cells (Li and Tang 2006). Consequently, members of the genera *Caulobacter* and *Brevundimonas* have been reported from a wide variety of aquatic habitats (Poindexter 1981b; Ariskina et al. 2011). These habitats are mainly freshwater habitats and only few species of *Brevundimonas* have been found to thrive in brackish or even sea water (Abraham et al. 2010). Furthermore, *Brevundimonas*, *Asticcacaulis*, and *Phenylobacterium* species have also been isolated from other habitats, e.g., soil, polluted sites, ice, or even from humans. *Brevundimonas* sp. CCM 4020 comes from necrotic lesions of the epidermis of the plant *Cyprinus carpio*. Due to their excellent adaptation to oligotrophic habitats, the formation of biofilms and their ability to withstand long periods of fame *Caulobacter* species have also been found in drinking water reservoirs and even in bottled mineral drinking water (González et al. 1987). *Brevundimonas* species have been isolated from Antarctic ice cores, but it remained open whether these were indigenous bacteria or cells which have been transported by wind-blown dust into the ice (Antony et al. 2012). A *Brevundimonas* species, closely resembling *B. diminuta* but being able to grow at 5 °C, has been isolated from the water outlet of the Mont Cook Glacier, New Zealand (Abraham, unpublished). Psychrotolerance, however, is not limited to species of the genus *Brevundimonas* because a psychrotolerant *Caulobacter* strain Z-0024 has been isolated and characterized from tundra soil. It uses a wider range of organic substrates and can tolerate sodium chloride concentrations of up to 15 g l^{-1}. DNA-DNA hybridizations between strain Z-0024 and *C. vibrioides* ATCC 15252 gave only 24 % similarity; therefore, strain Z-0024 has been described as *C. tundrae*. However, the description remained invalid (Berestovskaia et al. 2006).

Brevundimonas species have also been found associated with the crude oil but not in the water at the Enermark oil field, Medicine Hat, Canada (Kryachko et al. 2012). A study on the metabolic functions of lake snow aggregates identified *Brevundimonas* species as one of the main players in the degradation of the aggregates and the release of amino acids to be consumed by other microbes (Schweitzer et al. 2001). When dry river sediments of a river in Italy was rewetted which may happen after heavy rain, *Caulobacter* and *Brevundimonas* species were among the first colonizers of the river water, demonstrating again their ability to form biofilms and to survive harsh times (Fazi et al. 2008). The ability of *Caulobacteraceae* to grow in high carbon environment and to tolerate several toxic compounds is also reflected in their occurrence in wastewater treatment systems. Here mainly *Brevundimonas* species but also some *Caulobacter* species have been isolated and characterized (MacRae and Smit 1991). In a polluted river in U.S.A., *Caulobacter* and *Asticcacaulis* species have been detected by both direct and viable counting. No significant correlation between the number of prosthecate bacteria and total coliforms in the stream could be established. During the coldest period, when the total viable counts decreased, the caulobacters increased in numbers (Staley 1971).

Prosthecate members of the *Caulobacteraceae* have mainly a sessile lifestyle sticking with their holdfasts to interfaces. Here they form monolayers where the cell densities are controlled by the availability of nutrients at the respective habitat. In flow chamber experiments, *Caulobacter vibrioides* CB15 formed also large mushroom-shaped structures. For the formation of these mushroom-like aggregates, pili are essential as pili-less mutants were not able to form these aggregates (Entcheva-Dimitrov and Spormann 2004). The ecological consequences of this finding remain to be seen, and one has to keep in mind that flow-chambers are model systems and do not always mirror conditions usually found in the environment.

Forming a biofilm, however, is not a one-way process and cells should also be able under deteriorating growth conditions to escape the biofilm community, revert to the planktonic state, and move to more favorable habitats, forming there new biofilm communities. We only just started to uncover the diverse mechanisms of bacteria for their reconversion to planktonic cells. Here *Caulobacter vibrioides* seems to have a novel and rather unique way: How to force its offsprings to alternative habitats. In many biofilms, considerable amounts of extracellular DNA (eDNA) have been detected. It seems to be produced by the autolysis of cells in the biofilm. Mechanisms by which eDNA is released are diverse and comprise, e.g., lysis of a bacterial subpopulation under the control of quorum sensing systems in *Pseudomonas aeruginosa* or autolysis by programmed cell death similar to apoptosis of eukaryotic cells in some form of an altruistic suicide in *Staphylococcus aureus* (Montanaro et al. 2011). The role of eDNA in the biofilm is not yet very clear, but it seems to contribute to its stability because biofilms can be inhibited or even dispersed by the addition of DNase I. eDNA does not seem to have such a stabilizing effect in *Caulobacter* biofilms because addition of DNase I has no effect on biofilm formation. For *Caulobacter vibrioides*, eDNA, however, has been shown to prevent the settling of swarmer cells on these biofilm communities. This is achieved by the binding of eDNA to the holdfast of swarmer cells during their transition to become sessile. The binding is very specific and only DNA from *Caulobacter* strains was able to block completely the adhesive material of the holdfast while eDNA from the closely related *Brevundimonas diminuta* was much less efficient. The mechanism for the species-specificity of the eDNA for blocking the

attachment of swarmer cells is still unknown, and several hypotheses have been discussed. While eDNA blocks holdfasts of swarmer cells, it had no effect on those of prosthecate cells, thus acting specifically on new born cells. By targeting this specific cell type, *Caulobacter* species in biofilm communities promote dispersal of their own kin, leaving the existing biofilm undisturbed and undissolved (Berne et al. 2010). This minimization of intraspecies competition is in line with the oligotrophic lifestyle of *C. vibrioides*, and it remains to be determined whether a similar mechanism is also working in other species of the *Caulobacteraceae*.

Stress Response

As most *Caulobacteraceae* thrive in oligotrophic habitats, not only their unusual cell cycle is optimized for living in such environment, they also bear a number of mechanisms allowing them to deal with the shortage of nutrient. One important goal under carbon starvation is to preserve energy, and this means reducing growth and replication. A complex network of regulons has been unraveled from *Caulobacter vibrioides*, leading to the uncoupling of the transition from the swarmer to the prosthecate cell under carbon starvation (Britos et al. 2011). Several small non-coding regulatory RNAs (sRNAs) play a key role in the posttranscriptional regulation of many genes under substrate limitation. One sRNA, specifically induced upon carbon starvation, is CrfA which strongly activates 27 genes, one-third of them are TonB-dependent receptors (Landt et al. 2010). TonB-dependent receptors are used for the uptake of compounds by active transport which are too large for uptake by simple passive diffusion. These receptors are anchored in the outer membrane and are also energy-dependent using a proton gradient. The transport process requires energy and a complex of three inner membrane proteins, TonB-ExbB-ExbD, to transduce this energy to the outer membrane. The transported substrates range in complexity from simple small molecules such as citrate to large proteins; however, the transport mechanism is still unclear (Noinaj et al. 2010). According to their oligotrophic habitats, the known genomes of *Caulobacteraceae* contain a large number of TonB-dependent receptors, e.g., *Caulobacter vibrioides* has 63 (Nierman et al. 2001).

The oligotrophic habitats of *Caulobacteraceae* may have also other limitations, e.g., that of phosphate or iron. *Caulobacter vibrioides* was shown to deal with such shortage of phosphate by the production of the outer membrane–bound lipoprotein, ElpS, which is further cleaved and released in the medium in a T2SS-dependent manner. Together with ElpS, an alkaline phosphatase is exported to enable the cells to gather inorganic phosphates (Le Blastier et al. 2010). In *Caulobacter vibrioides*, as in most other bacteria, the ferric uptake regulator, Fur, controls iron homeostasis. Genes involved in iron uptake are repressed by iron-Fur but induced under conditions of iron limitation, and genes of iron-using proteins are activated by Fur under conditions of iron availability. Contrary to a number of other bacteria, several genes are directly regulated by Fur in *C. vibrioides* and not via small RNAs. In *C. vibrioides*, Fur integrates iron metabolism and oxidative stress response (da Silva Neto et al. 2009).

When *Caulobacter vibrioides* is exposed to oxygen stress but also to cadmium, rpoE is expressed which is otherwise repressed by ChrR. The transcription of rpoE is achieved by the aid of sigma(E), a member of the ECF (extracytoplasmic function) subfamily of RNA polymerase sigma factors, which regulate gene expression in response to environmental stresses. Mutagenesis revealed that the amino acid C188 in ChrR is critical for the cadmium response, while amino acids H140 and H142 are required for oxidative stress (Lourenço and Gomes 2009). This, however, is only one aspect of the reactions of the cells to metal stress. High concentrations of uranium are simply reduced by the formation of extracellular calcium-uranium-phosphate precipitates. Analysis of whole-genome expression activities under metal stress showed that intracellular metal concentrations are reduced by several efflux pumps, shutdown of a sulfate transporter to reduce chromium uptake, and upregulation of genes involved in oxidative stress, e.g., superoxide dismutase SodA, DNA repair enzymes, etc. (Hu et al. 2005).

Predators

With the intensified study of *Caulobacteraceae*, bacteriophages were discovered infecting this group of bacteria. From sewage, the *Caulobacter vibrioides* CB13B1a bacteriophage Cd1 was isolated and found to infect both prosthecate and swarmer cells. ΦCd1 is an icosahedral DNA-phage with a short noncontractile tail (West et al. 1976). However, the DNA-containing *Caulobacter* phage phi 6 revealed different infection behaviors, attaching to pili more frequently than to flagella. As a consequence pilus-less mutants of *C. vibrioides* were resistant to its infection while flagellum-less mutants with pili were susceptible (Scholl and Jollick 1980).

Bacteriophages are not only known for *Caulobacter* species, and three phages have been isolated and characterized which were specific for *Asticcacaulis biprosthecium*. These phages with elongated cylindrical heads and noncontractile tails showed different ways of attachment to their host. Phage ΦAcM4 attached to the flagellum with the region where phage head and the tail joins which leaves the distal end of the tail free for attachment to the *Asticcacaulis* cell. Phage ΦAcM2 had a different attachment site which was at the pili and the pole of the cell by the phage tail. The third phage showed both characteristics of attachment (Pate et al. 1979). Flagellotropic phages have also been isolated from *Caulobacter* cultures (Schmidt 1966). Closer inspection of the mechanism using cryo-electron microscopy revealed that the phage attached through a filament on the phage head first with the bacterial flagellum. This results in concentration of phage particles around the pilus portals of the bacterial cell. Such a mechanism increases the likelihood of infection (Guerrero-Ferreira et al. 2011).

From nine *Brevundimonas vesicularis* isolates, seven phages were isolated and genetically characterized. All phages contained linear double-stranded DNA of a size of about 37 kb. Three phages belonged to the family *Siphoviridae* and four to the *Podoviridae* (Beilstein and Dreiseikelmann 2006). Bacteriophages of the phiCbK type, infecting *Caulobacter* species, are much larger than the ones described from *Brevundimonas*. They have 205–280 kb encoding for 318–448 proteins. Interestingly, 5 of the 6 sequenced phages possessed homologues of the *C. vibrioides* cell-cycle regulator GcrA (Gill et al. 2012). Such a homolog was also reported from another genome of a phiCbk phage (Panis et al. 2012). Such homologues may allow the phages to influence the replication status of the host cell, optimizing the condition for infection.

The paracrystalline surface (S) layer is assumed to function in the protection of the cell against predators, and it has been demonstrated that the presence of an S-layer protected *Caulobacter vibrioides* against lysis by *Bdellovibrio bacteriovorus* (Koval and Hynes 1991). However, this seems not to be the case for the predator *Bdellovibrio exovorus* (Koval et al. 2013). Pathogens however have learned to deal with such an obstacle and the bacteriophage ΦCr30 even became dependent on the presence of such an S-layer to achieve infections of *Caulobacter* cells. When *rsaA*, the gene for the S-layer protein, is deleted or mutated, *Caulobacter vibrioides* cells became resistant against this phage and susceptible again when *rsaA* was introduced via a plasmid (Edwards and Smit 1991).

Pathogenicity: Clinical Relevance

In the clinics, the ordinary microbiological analyses focus on the identification of known pathogens. Only in the last decade, it was noticed that beside these well known pathogens, a number of other bacterial species live in biofilms in the human body. Assessment both by cultivation and culture-independent methods of the phylogenetic diversity of bacteria colonizing prosthetic hip joints revealed *Brevundimonas* species both on hip joints, revealing clinical infections and asymptomatic ones (Dempsey et al. 2007). Deep-sequencing of the microbiota of the ocular surfaces of healthy volunteers revealed also highly diverse microbial communities with high intersubject variability. However, in all samples, species of *Brevundimonas* could be detected as they are members of the "core" communities in this habitat (Dong et al. 2011). Assessment of a very different habitat of the human body, aortic aneurysms, by molecular techniques detected *Brevundimonas diminuta* as members of the biofilm communities (Marques da Silva et al. 2006). The specific roles of the individual members in these biofilm communities are largely unknown, and the mere detection of *Brevundimonas* species does not implicate their role in infection processes.

Caulobacteraceae, however, play a role in infections. There was only one report of a *Caulobacter* infection in humans (Justesen et al. 2007), but a number of infections are known caused by *Brevundimonas* species. A case study of bacteremia caused by *Brevundimonas* in mostly immunocompromised patients in a hospital in Taiwan identified *Brevundimonas vesicularis* as the main pathogen (63 %), followed by *B. nasdae* and *B. diminuta*. The 30-day mortality rate was found to be 17 % and the pathogens were resistant against ciprofloxacin and colistin but susceptible to piperacillin-tazobactam and amikacin (Lee et al. 2011). *B. vesicularis* infections were also reported from neonates and could be treated with the same antibiotics (Karadag et al. 2012). These infections seem to be not limited to immunocompromised patients but were also found in immunocompetent persons (Chi et al. 2004). *Brevundimonas vesicularis* infections have also been observed in infective endocarditis (Yang et al. 2006), septic arthritis (Sofer et al. 2007), CAPD peritonitis (Choi et al. 2006), keratitis (Pelletier et al. 2010; Pandit 2012), nosocomial meningitis (Mondello et al. 2006), cutaneous infection (Panasiti et al. 2008), cystic fibrosis patient (Menuet et al. 2008), and liver abscess (Yoo et al. 2012). *Brevundimonas vancanneytii* has been isolated from blood of a patient with endocarditis and may also function as human pathogen (Estrela and Abraham 2010).

All bacteria in the human body are subject to occasional antibiotic exposure during treatment of infections. As a consequence, antibiotic resistances have also been noticed in *Brevundimonas* species. A study of clinical *B. vesicularis* isolates collected over 20 years in a hospital in Taiwan showed that 90.9 % of the isolates were susceptible to cefpirome, imipenem, and piperacillin-tazobactam; 86.4 % to gentamicin, amikacin, and ciprofloxacin; 63.6 % to ceftazidime, but only 59.1 % were susceptible to trimethoprim-sulfamethoxazole (TMP-SMX) (Zhang et al. 2012). *Brevundimonas diminuta* isolates carrying metallo-β-lactamase genes have been reported including a clinical isolate carrying the VIM-2 metallo-β-lactamase gene and protecting the isolate against carbapenem (Almuzara et al. 2012). *B. diminuta* from cancer patients were all resistant against multiple fluoroquinolones, and further examination of these isolates led to the conclusion that *B. diminuta* is intrinsically resistant to fluoroquinolones (Han and Andrade 2005). From the sewage of a hospital in Palma de Mallorca, three *Brevundimonas* strains were isolated which were resistant against the antibiotic ceftazidime. Two isolates belonged to *B. diminuta* and one to a novel species, described as *Brevundimonas faecalis*. *B. faecalis* was not shown to be a human pathogen, but it may act as a reservoir for antibiotic resistance in hospitals (Scotta et al. 2011).

Phenylobacterium species, besides species of the genera *Caulobacter* and *Brevundimonas*, were also connected to infections in humans. *Phenylobacterium haematophilum* was isolated from human blood (Abraham et al. 2008) and *P. zucineum* from a human erythroleukemia cell (Zhang et al. 2007) which may indicate their role as human commensals or pathogens. From granulomatous lesions of a patient with myelodysplastic syndrome, a *Phenylobacterium* species has been isolated as causative agent for inflammation, proving that some *Phenylobacterium* species can cause disease (Zhu et al. 2010). These reports connect three of the four *Caulobacteraceae* genera with human infections, leaving *Asticcacaulis* as the sole genus of this family with no clinical reports.

Application

Biodegradation and Biotransformation

The type species of *Phenylobacterium*, *P. immobile*, was isolated as a degrader of the herbicide chloridazon (Lingens et al. 1985). This gave species of the genus *Phenylobacterium* the character of degraders of xenobiotics. This notion has been confirmed by more reports on the involvement of *Phenylobacterium* species in degradation processes. A degrader of linear alkylbenzene sulfonate has been isolated which is mobile and can also use the xenobiotic compounds chloridazon and antipyrine as sole carbon sources. The 16S rRNA gene sequence similarity to its nearest neighbor *Phenylobacterium immobile* was 97.49 %, but the DNA-DNA relatedness was only 40 %; therefore, the species has been identified as a new member of the genus and invalidly named *Phenylobacterium mobile* GZ6T (Ke et al. 2003). Using stable isotope labeling, *Phenylobacterium* species have also been identified as one of the main degraders of the wood preservative Cu-HDO, containing the chelation product of copper and *N*-cyclohexyldiazenium dioxide (HDO) (Jakobs-Schönwandt et al. 2010).

More important for biotechnological application than *Phenylobacterium* species were *Brevundimonas* species. An isolate most closely related to *Brevundimonas mediterranea* was found to degrade fenamiphos (ethyl 4-methylthio-m-tolyl isopropylphosphoramidate), a systemic organophosphorus nematicide (Cabrera et al. 2010). Enzymes capable of cleaving organic phosphates are very interesting because of their potential application in the detoxification of organic phosphates. An isolate identified as *Brevundimonas diminuta* could saponify the phosphate ester of parathion (Serdar et al. 1982). Responsible for this metabolic capability is a plasmid which was also found in *Flavobacterium* sp. ATCC 27551 (Harper et al. 1988) and which is self-transmissible (Pandeeti et al. 2011). Fusing the phosphatase to the green fluorescent protein (gfp) revealed that the phophatase is targeted to the periplasmic face of the inner membrane in the *Brevundimonas* cell (Gorla et al. 2009). Another *Brevundimonas* strain, LY-2, was isolated from agricultural soil and proved to be a good degrader of the herbicide lactofen. Inactivation of this toxin was achieved by cleavage of the ester side chain by an esterase (Liang et al. 2010).

The urinary metabolite D-4-hydroxy-3-methoxymandelic acid is a major metabolite in humans, and the determination of this compound is used in the diagnosis of life-threatening catecholamine-secreting tumors (Kinoshita et al. 1988). A bacterial strain, tentatively identified as *Brevundimonas diminuta*, could use this substrate as sole source of carbon and energy. The degradation pathway of this strain converts the substrate to vanillylglyoxylate, which is then decarboxylated, dehydrogenated, and demethylated to protocatechuate, which is then cleaved by a dioxygenase to 2-hydroxy-4-carboxymuconic semialdehyde. The dehydrogenase converting the substrate to vanillylglyoxylate has been further characterized, and a rather narrow substrate spectrum has been revealed, making this enzyme as a potential candidate for the detection and monitoring of catecholamine-secreting tumors (Turner et al. 1996).

From a marine sediment, *Brevundimonas diminuta* MTCC 8486 has been isolated. The strains could withstand high nitrate concentrations, up to 10 g l^{-1}, and could reduce nitrate. In order to remove nitrate from ground water, the culture conditions of this strain were optimized. In a pilot treatment process, nitrate concentrations could be reduced by the application of this strain to levels below the level acceptable for drinking water (Kavitha et al. 2009). *Brevundimonas* species were also found to be good strains for the biosorption of heavy metals. From a hot spring with high background radiation, *Brevundimonas* sp. ZF12 has been isolated and shown to adsorb cadmium in high yields under acidic conditions (Masoudzadeh et al. 2011).

Brevundimonas species were also reported to be valuable strains for biotransformations. *Brevundimonas* sp. SGJ could hydroxylate under resting cell conditions L-tyrosine to give L-DOPA (3,4-dihydroxyphenyl-L-alanine), the most widely used drug for the treatment of Parkinson's disease (Surwase et al. 2012). Vitamin C, L-ascorbic acid, is widely added to food products but is not very stable in solution, especially when exposed to high temperatures and oxygen concentrations. Here, more stable derivatives of vitamin C would be of advantage, ascorbic acid-2-phosphate being one of them. From soil samples, nine isolates were obtained which were able to produce ascorbic acid-2-phosphate from L-ascorbic acid. Most isolates were identified as *Brevundimonas* species by 16S phylogenetic analysis, and *B. diminuta* KACC 10306 gave the highest yield under resting cell conditions (Shin et al. 2007).

Metabolites

Metabolites of *Brevundimonas* species were also studied, and some of them may have potential in biotechnology. Polyhydroxyalkanoates have an immense potential as biodegradable polymers, and many attempts have been made for their cheap production by microbes. When *Brevundimonas vesicularis* LMG P-23615 grows on acid-hydrolyzed sawdust as carbon source, it stores some of the carbon as poly-beta-hydroxyalkanoate granules. Such a process may offer an attractive way of converting waste into valuable products (Silva et al. 2007).

A number of *Brevundimonas* species can produce carotenoid dyes. *Brevundimonas vesicularis* DC263, isolated from surface soil, produced carotenoids, identified as hydroxylated astaxanthin. A study of the carotenoid synthesis genes identified *crtW* encoding the 4,4′-beta-ionone ring ketolase, *crtZ* encoding the 3,3′-beta-ionone ring hydroxylase, and *crtG* encoding the 2,2′-beta-ionone ring hydroxylase which can hydroxylate astaxanthin. The genes of strain DC263 had the highest sequence similarities to the corresponding genes in *Brevundimonas* sp. strain SD212, a marine isolate that also produced hydroxylated astaxanthin. The genetic organization of the carotenoid synthesis gene clusters in the two *Brevundimonas* strains was identical, suggesting a close relationship (Tao et al. 2006). When the *crtG* gene of *Brevundimonas* sp. DC263 was introduced into an *E. coli*

strain which synthesizes zeaxanthin and canthaxanthin, these carotenoids were hydroxylated to the 2-hydroxy- and 2,2-dihydroxy-products. For the rare hydroxylated canthaxanthins, a strong inhibitory effect on lipid peroxidation was demonstrated (Nishida et al. 2005).

Enzymes and Proteins

Brevundimonas species were also the source of unusual enzymes with potentials in biotechnological applications. The mononuclear molybdoenzyme isoquinoline 1-oxidoreductase from *Brevundimonas diminuta* belongs to the xanthine-dehydrogenase family of proteins. It is a molybdenum hydroxylase containing a molybdopterin cytosine dinucleotide molybdenum cofactor and two distinct iron-sulfur clusters (Israel et al. 2002). It catalyzes the conversion of isoquinoline to isoquinoline-1-one, the first step in the degradation of isoquinolines. The primary sequence and behavior, specifically its substrate specificity and lipophilicity, of the *Brevundimonas diminuta* enzyme differs from other members of the family and has been studied by crystallography (Boer et al. 2005). Another strain, *Brevundimonas diminuta* TPU 5720, produces an amidase which hydrolyzes phenylalaninamide stereoselectively to L-phenylalanine. The enzyme is Co-dependent and contains 491 amino acids with significant similarity to an aminopeptidase found in the genome of *Caulobacter vibrioides* (Komeda et al. 2006). A comparison of the N-terminal sequences of malate dehydrogenases from ten strains belonging to seven different genera of *Proteobacteria* demonstrated the enzyme sequences of *Brevundimonas* species are structurally distinct from others in the study. They clearly resembled those malate dehydrogenases with greatest similarity to lactate dehydrogenases. Further analyses of subunit molecular weights, peptide mapping, and enzyme mobilities confirmed the distinct position of the malate dehydrogenases from *Brevundimonas* species (Charnock 1997). *Asticcacaulis* strain SA7 was isolated from plants roots and could grow on agar using it as sole carbon source. It produces an extracellular agarose which may have some biotechnological applications (Hosoda and Sakai 2006).

Efficient control of mosquitoes is gaining importance for the control of several severe diseases distributed by these vectors. While chemical insecticides endanger the environment, bacterial control of mosquito larvae with *Bacillus* species producing protein toxins became attractive. However, applications using these bacteria have several drawbacks. An alternative could be genetically engineered aquatic bacteria producing the *Bacillus* toxins. *Asticcacaulis excentricus* were transformed with optimized plasmids carrying the binary toxin of *B. sphaericus*. In laboratory studies, constructs based on *A. excentricus* exhibited toxicity to *Culex* and *Anopheles* mosquito larvae, similar or even better than *B. sphaericus* strains used to control these larvae but *Caulobacter vibrioides* constructs were not viable (Liu et al. 1996).

The S-layer of *Caulobacter vibrioides* has been used for the display of proteins by genetic engineering techniques opening a broad spectrum of applications in nanobiotechnology (Ilk et al. 2011). For optimal performance, the production of the S-layer protein RsaA of *C. vibrioides* has been optimized based on an unusually stable *rsaA* mRNA with a half-life of 36 min. Using multiple copies of *rsaA*, the best constructs produced 51 % of their cell proteins as RsaA (Lau et al. 2010). Such an optimized strain has been used for the generation of anti-HIV antibodies. To achieve this goal, either domain 1 of CD4 or MIP1alpha, components needed for virus entry, were heterologous presented at the S-layer of *C. vibrioides*. The combination of both constructs was able to inhibit virus entry of many HIV-1 isolates (Nomellini et al. 2010). The same approach has been used to express the immunoglobulin G (IgG)-binding streptococcal protein G at the S-layer to be used, e.g., for immunoprecipitation or immunoadsorption-based assays (Nomellini et al. 2007), a *Pseudomonas aeruginosa* vaccine candidate protein (Umelo-Njaka et al. 2001) and a recombinant vaccine against infectious hematopoietic necrosis virus (Simon et al. 2001). Not only vaccines but also enzymes can be produced in this way as has been shown for beta-1,4-glycanase, which showed however a much reduced activity at the S-layer, probably due to misfolding (Duncan et al. 2005).

8 The Family *Cohaesibacteraceae*: The Genera *Cohaesibacter* and *Breoghania*

Cintia P. J. Rua[1] · *Fabiano Thompson*[2]
[1]Instituto de Biologia, Universidade Federal do Rio de Janeiro (UFRJ), Rio de Janeiro, RJ, Brazil
[2]Laboratory of Microbiology, Institute of Biology, Center for Health Sciences, Federal University of Rio de Janeiro (UFRJ), Ilha do Fundaõ, Rio de Janeiro, Brazil

Abstract
This chapter reviews the recently described family *Cohaesibacteraceae*, their two genera (*Cohaesibacter* and *Breoghania*) and three species (*Cohaesibacter gelatinilyticus* Hwang and Cho 2008, *Cohaesibacter marisflavi* Qu et al. 2011, and *Breoghania corrubedonensis* Gallego et al. 2010). The type species for each genus are *Cohaesibacter gelatinilyticus* and *Breoghania corrubedonensis*, respectively. *Cohaesibacteraceae* was created to accommodate strains that were not genetically similar enough to be classified into existing families of the order *Rhizobiales*. Besides the genetic dissimilarity, the sole major respiratory quinone (Q-10) and the polar lipid composition differentiate *Cohaesibacteraceae* from the other families of this order.

The members of *Cohaesibacteraceae* are Gram-negative, facultative anaerobic (*Cohaesibacter*) or aerobic (*Breoghania*) rods and are motile by polar flagella. *Cohaesibacter* comprises strains isolated from coastal waters of the east coast of Korea and China, whereas *Breoghania* has its type strain isolated from coastal waters of northwest Spain. Nothing is known about their applications or ecological importance, so this chapter only provides phenotypic and genetic characterization. Additionally, the phylogenetic relationship with other families of the order *Rhizobiales* is presented. Finally, the formal taxonomical descriptions of both genera and their respective species are given.

Introduction and General Characteristics

The family *Cohaesibacteraceae* is in the order *Rhizobiales*, which is one of the seven orders of Alphaproteobacteria. *Cohaesibacteraceae* is distinguished from the other 12 families of Rhizobiales (*Rhizobiaceae*, *Bartonellaceae*, *Brucellaceae*, *Phyllobacteriaceae*, *Methylocystaceae*, *Beijerinckiaceae*, *Bradyrhizobiaceae*, *Hyphomicrobiaceae*, *Methylobacteriaceae*, *Rhodobiaceae*, *Aurantimonadaceae*, and *Xanthobacteraceae*) by phylogenetic analysis of ribosomal DNA (16S). This recently proposed family includes two genera: *Cohaesibacter* and *Breoghania*. They are distinct lineages formed by strains from coastal marine environments that did not cluster with any other families in 16S phylogenetic analysis. In addition, the members of *Cohaesibacteraceae* have other genetic and phenotypic characteristics, which are discussed in detail in this chapter. The family and the type species of the genus *Cohaesibacter*, *Cohaesibacter gelatinilyticus*, had their emended description approved by the International Committee on Systematics of Prokaryotes and its judicial commission (Euzéby 2011).

Phylogeny

Phylogenetic analyses, including secondary structure information of 16S rRNA, from 189 species of the order *Rhizobiales* determined that strains from coastal seawaters of the east coast of Korea (CL-GR15 and CL-GR35) belong to that order but do not represent any previously described family. Thus, the family *Cohaesibacteraceae* was characterized. Later, another seawater strain (DQHS21) from the east coast of China showed greater similarity with 16S of *Cohaesibacter gelatinilyticus* Hwang and Cho 2008 than with the other Alphaproteobacteria genera. Hwang and Cho (2008) detected three signature nucleotides in the 16S gene that characterize the genus *Cohaesibacter* in a study describing the type species *Cohaesibacter gelatinilyticus*. In addition, a strain (UBF-B1) isolated from a beach in the northwest of Spain after an oil spill was phylogenetic compared with *Rhizobiales* sequences (including *Cohaesibacteraceae* strains) using the 16S fragment and other genes (atpD, pyrG, rpo and fusA). Results showed UBF-B1 clustering together with *Cohaesibacter gelatinilyticus*; however, they had only 92 % similarity. These data resulted in a new genus description: *Breoghania*.

E. Rosenberg et al. (eds.), *The Prokaryotes – Alphaproteobacteria and Betaproteobacteria*, DOI 10.1007/978-3-642-30197-1_374,

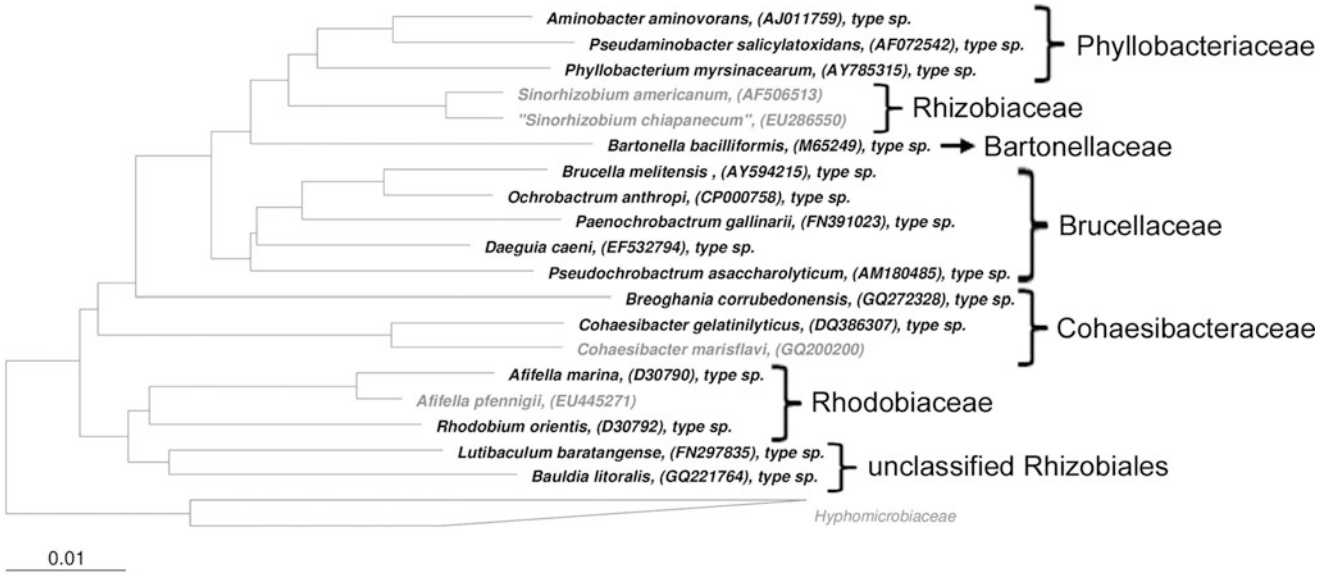

Fig. 8.1

Phylogenetic position of the family *Cohaesibacteraceae* based on 16S rRNA and created using the neighbor-joining algorithm with the Jukes-Cantor correction. The sequence dataset and alignment were used according to the All-Species Living Tree Project (LTP) database (Yarza et al. 2010; http://www.arb-silva.de/projects/living-tree). The tree topology was stabilized with a representative set of nearly 750 high-quality type-strain sequences proportionally distributed among the different bacterial and archaeal phyla. In addition, a 40 % maximum frequency filter was applied in order to remove hypervariable positions and potentially misplaced bases from the alignment. Scale bar indicates estimated sequence divergence

Taxonomy

Family *Cohaesibacteraceae*, Hwang and Cho (2008) emend. Gallego et al. (2010)

Cohaesibacteraceae (Co.hae.si.bact.er.a'ce.ae. N.L. masc. n. *Cohaesibacter*, type genus of the family; *-aceae* ending to denote a family; N.L. fem. pl. n. *Cohaesibacteraceae*, the Cohaesibacter family) (Hwang and Cho 2008).

Cohaesibacteraceae is a family phylogenetically positioned in the order *Rhizobiales* in the class *Alphaproteobacteria*. It is most closely related with the families *Brucellaceae* (genera *Ochrobactrum* and *Brucella*: 90.9–92.5 % similarity); *Rhizobiaceae* (genus *Sinorhizobium*: 90.9–91.5 %); *Bartonellaceae* (genus *Bartonella*: 90.6–91.9 %); *Rhodobiaceae* (genus *Rhodobium*: 89.3–91.2 %), and *Phyllobacteriaceae* (genus *Phyllobacterium*: 89.3–91.2 %) (◉ *Fig. 8.1*).

The members of the family have varying capabilities for nitrate reduction and the DNA composition ranges from 52 to 64 mol% G+C. The sole major respiratory quinone (Q-10) differentiates *Cohaesibacteraceae* from the families *Aurantimonadaceae*, *Phyllobacteriaceae*, *Rhodobiaceae*, *Bradyrhizobiaceae*, *Methylocystaceae* and *Hyphomicrobiaceae*. *Cohaesibacteraceae* is also differentiated from 10 families in the order *Rhizobiales* (except the families *Brucellaceae* and *Phyllobacteriaceae*) by polar lipid composition (◉ *Table 8.1*).

Genus *Cohaesibacter*, Hwang and Cho (2008) emend. Gallego et al. (2010)

Cohaesibacter [Co.hae.s'i.bac.ter. L. part. adj. *cohaesus* (from L. v. *cohaereo*) pressed together, clung together; N.L. masc. n. bacter a rod; N.L. masc. n. *Cohaesibacter* rods that appear cohesive with each other].

The members of this genus are Gram-negative, facultative anaerobic rods. They have oxidase activity and variable catalase activity. The predominant fatty acids are $C_{18:1}\omega7c$ and $C_{15:0}$ iso 2-OH and/or $C_{16:1}\omega7c$ and $C_{18:0}$. The respiratory quinone is ubiquinone 10 (Q-10). The DNA G+C content ranges from 53.0 to 55.2 mol%. The major polar lipids are phosphatidylcholine, phosphatidylglycerol, diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylmonomethylethanolamine, an unidentified aminolipid (AL1) and an unidentified glycolipid. The species of the genus have genetic signatures that are two compensatory transversion mutations (positions 678: A and 712: T) and a single transversion mutation (position 194: T). The type species is *Cohaesibacter gelatinilyticus*.

Description of *Cohaesibacter gelatinilyticus*, Hwang and Cho (2008)

Cohaesibacter gelatinilyticus (ge.la.ti.ni.ly'ti.cus. N.L. n. *gelatinum* gelatin; Gr. adj. *lutikos* able to dissolve; N.L. adj. *lyticus* dissolving; N.L. masc. adj. *gelatinilyticus* gelatin-dissolving).

Table 8.1

The cells are approximately 0.2–0.4 μm wide and 1.0–3.0 μm long. They are weakly motile by a polar flagellum. Reproduction occurs by bussing, binary fission, or asymmetric division. Rosette formation occurs. No growth occurs on trypticase soy agar (TSA), fivefold-diluted TSA, Czapek–Dox agar, MacConkey agar, blood agar, or the above media supplemented with either 3 % (w/v) NaCl or 3 % (w/v) sea salts. Circular, entire, convex and creamy white colonies appear on marine agar 2216 or R2A agar supplemented with 3 % (w/v) NaCl. At optimal growth conditions, colonies are approximately 2 mm in diameter after incubation for 1 week. Intracellular granules of poly-β-hydroxybutyrate are formed. Growth occurs on acetate, α-ketobutyric acid, citrate, D-fructose, D-glucose, mannitol, D-mannose, ribose, sorbitol, glutamic acid, glycerol, glycogen, inositol, inulin, L-arginine, L-asparagine, L-lysine, L-ornithine, *N*-acetylglucosamine, polyethylene glycol, L-pyruvate, sodium succinate, sucrose, thiamine, casamino acids, L-proline, peptone, tryptone and yeast extract. No growth occurs on acetamide, benzoate, DL-cysteine, cellobiose, D-galactose, raffinose, salicin, trehalose, L-xylose, ethanol, formic acid, glycine, 2-propanol, D-lactose, L-arabinose, ascorbate, L-rhamnose, maleic acid, oxalic acid, salicylate, tartrate or urea.

Growth occurs in temperatures between 15 °C and 31 °C (optimum, 25–30 °C), at pH 6–9 (optimum pH 8) and NaCl concentrations of 2–5 % (w/v, optimum 3 %). Decomposition of casein, cellulose, xanthine, hypoxanthine, and hydrolyses of gelatin and aesculin occur. Negative results are observed for nitrate reduction, indole production, arginine dihydrolase and urease. Alkaline phosphatase and trypsin are present. Esterase (C4), esterase lipase (C8), leucine arylamidase, acid phosphatase, naphthol-phosphohydrolase, and *N*-acetyl-β-glucosaminidase activities are weakly present. Lipase (C14), valine arylamidase, cystine arylamidase, α-chymotrypsin, α- and β-glucosidase, α- and β-galactosidase, α-mannosidase and α-fucosidase activities are absent.

Acid production from glycerol, DL-arabinose, D-ribose, DL-xylose, D-glucose, D-fructose, D-mannose, inositol, D-mannitol, D-sorbitol, *N*-acetylglucosamine, D-lyxose, L-fucose, potassium gluconate, and potassium 5-ketogluconate were observed. Acid production was not observed from erythritol, D-adonitol, methyl β-D-xylopyranoside, D-galactose, L-sorbose, L-rhamnose, dulcitol, methyl α-D-mannopyranoside, methyl α-D-glucopyranoside, amygdalin, arbutin, aesculin, salicin, D-cellobiose, maltose, D-lactose, melibiose, sucrose, trehalose, inulin,

melezitose, raffinose, starch, glycogen, xylitol, gentiobiose, turanose, D-tagatose, D-fucose, DL-arabitol, or potassium 2-ketogluconate. The cells are sensitive to (μg per disc) gentamicin (6), cephalexin (20), vancomycin (20), mitomycin C (0.6), kanamycin (20), penicillin (6), erythromycin (10), chloramphenicol (20), ciprofloxacin (3), and ampicillin (6). Cells are resistant to tetracycline (20 μg per disc), nalidixic acid (20 μg per disc) and streptomycin (6 μg per disc).

The major fatty acids are $C_{18:1}\omega7c$ (54.3–55.1 %) and $C_{15:0}$ iso 2-OH and/or $C_{16:1}\omega7c$ (summed feature 3; 19.2–20.4 %), $C_{20:1}\omega7c$ (9.6–11.1 %), $C_{18:0}$ (3.1–3.3 %), $C_{14:0}$ 3-OH and/or $C_{16:1}$ iso I (3.0 %), $C_{18:0}$ 3-OH (1.9–2.0 %), $C_{17:1}\omega8c$ (1.1–1.5 %) and $C_{16:0}$ (1.1 %). Other minor fatty acids (<1 %) are $C_{9:0}$, $C_{14:0}$, $C_{17:0}$, $C_{19:0}$, $C_{20:0}$, $C_{14:1}\omega5c$, $C_{19:0}$ cyclo ω8*c*, $C_{16:0}$ 3-OH, $C_{17:0}$ iso 3-OH and $C_{19:0}$ 10-methyl. Besides the polar lipids of the genus, *C. gelatinilyticus* has also minor amounts of an unidentified aminolipid (AL2) and unidentified lipids (L1–4). The type strain, CL-GR15^T (= KCCM 42319^T = DSM 18289^T), was isolated from coastal waters of the east coast of Korea.

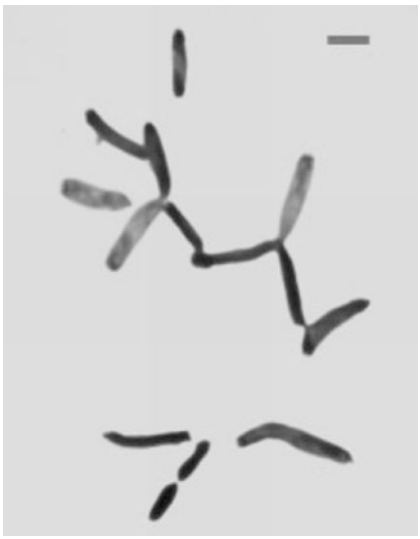

Fig. 8.2
Transmission electron micrograph of negatively stained cells of strain CL-GR15T. Bar, 1 μm (From Hwang and Cho (2008), with permission)

Description of *Cohaesibacter marisflavi*, Qu et al. (2011)

Cohaesibacter marisflavi (ma.ris.fla'vi. L. neut. n. *mare –is* the sea; L. adj. *flavus -a -um* yellow; N.L. gen. n. *marisflavi* of the Yellow Sea, referring to the isolation of the type strain).

The cells are Gram-negative, catalase-negative, oxidase-positive, facultative anaerobic rods that are 0.6–0.7 mm wide and 1.8–2.0 mm long (Fig. 8.2). Cells are motile by a single polar flagella. They reproduce by binary fission or asymmetrical division. Colonies, which grow on 2216E agar medium, are white, smooth, circular, lightly transparent, and 1.0–2.0 μm in diameter after 3–5 days of cultivation at 30 °C. Intracellular poly-b-hydroxybutyrate granules are accumulated. Positive results were obtained in API 20NE tests for indole production, utilization of D-glucose, D-mannose, malic acid, *N*-acetylglucosamine, and trisodium citrate and weakly positive for utilization of β-galactosidase, maltose and L-arabinose; results were negative for gelatin hydrolysis, D-glucose fermentation, arginine dihydrolase, and utilization of D-mannitol, potassium gluconate, capric acid, adipic acid, and phenylacetic acid. In the Biolog GN2 system, the tests were positive for utilization of dextrin, D-fructose, raffinose, glycerol, L-arabinose, *N*-acetyl-D-glucosamine and sucrose. Growth occurs in temperatures between 10 °C and 38 °C (optimum 25–30 °C) at pH 4–9 (optimum pH 7–8) and in 0.5–15 % (w/v) NaCl (optimum 3 %).

In the API ZYM test strip, the results were positive for esterase (C4), naphthol-AS-BIphosphohydrolase, and trypsin; weakly positive for acid phosphatase, alkaline phosphatase, esterase lipase (C8), and leucine aminopeptidase; and negative for cystine aminopeptidase, lipase (C14), *N*-acetyl-β-glucosaminidase, valine aminopeptidase, α-chymotrypsin, α-fucosidase, α-galactosidase, α-glucosidase, α-mannosidase, β-galactosidase, β-glucosidase, and β-glucuronidase. They also have urease and β-glucosidase (aesculin hydrolysis) activities and nitrate reduction. Cells are sensitive to (μg per disc, unless noted) ampicillin (10), carbenicillin (100), cefalexin (30), chloramphenicol (30), ciprofloxacin (5), doxycycline (30), erythromycin (15), kanamycin (30), nalidixic acid (30), neomycin (30), novobiocin (30), penicillin G (10 IU), rifampicin (5), streptomycin (10), and tetracycline (30). Cells are resistant to (μg per disc, unless noted) clindamycin (2), lincomycin (2), oxacillin (1), polymyxin B (300 IU), and vancomycin (30).

The major fatty acids are $C_{18:1}\omega7c$, $C_{18:0}$, $C_{16:0}$ and $C_{16:1}\omega7c$/iso-$C_{15:0}$ 2-OH. Ubiquinone 10 is the major quinone. The DNA G+C content is 55.2 mol%. The type strain, DQHS21^T (=CGMCC 1.9157^T = NCCB 100300^T) was isolated from sediment sampled from a seawater pond used for sea cucumber culture at Jimo, Qingdao province, China, on the west coast of the Yellow Sea.

Genus *Breoghania*, Gallego et al. (2010)

Breoghania (Bre.o.gha'ni.a. N.L. fem. n. *Breoghania*, named after *Breoghan*, according to Celtic mythology (*Leabhar Ghabhala*, XII century), the first Celtic king of *Gallaecia* (actual Galicia), founder of the city of *Brigantia* (probably A. Coruña) who built a tower on the coast from where Eire (Ireland) could be seen.

The members of this genus are Gram-negative, aerobic rods that are motile by polar flagella. Cellular division occurs by binary fission or asymmetric division. They present oxidase and catalase activity. The DNA G+C content of the type strain is 63.9 mol%. The respiratory quinone is ubiquinone 10 (Q-10). The predominant fatty acid is $C_{18:1}\omega7c$ (75.3 %); and other fatty acids found in smaller amounts are $C_{19:0}$ cycloω8c and $C_{16:0}$. The major polar

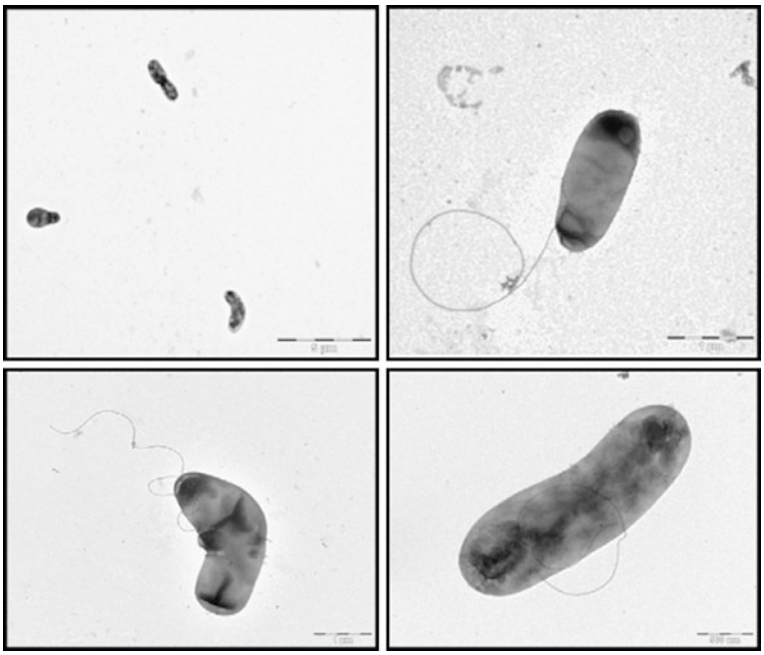

Fig. 8.3
Transmission electron micrographs of negatively stained cells of strain UBFP1T (From Gallego et al. (2010), with permission)

lipids are diphosphatidylglycerol, phosphatidylglycerol, phosphatidylethanolamine, phosphatidylmonomethylethanolamine, and phosphatidylcholine. The type species is *Breoghania corrubedonensis*.

Description of *Breoghania corrubedonensis*, Gallego et al. (2010)

Breoghania corrubedonensis (Co.ru.be.do.nen'sis N.L. fem. adj. corrubedonensis, of or belonging to Corrubedo, northwest Spain, isolated from the beach of Corrubedo, the location of the sand sample that was used to inoculate the enrichment cultures from which strain UBF-P1^T was isolated).

Cells are regular, irregular, or bulbous rods that are approximately 0.6–0.7 μm wide and 2–3.5 μm long (*Fig. 8.3*). Cells are motile by one or two subpolar flagella. Reproduction occurs by binary fission or asymmetric division. Circular, entire, convex, mucoid, and creamy white colonies appear on LB ASW, LB 3 % NaCl, or marine agar. After incubation for 5 days at optimal growth conditions, colonies are approximately 1 mm in diameter. Growth occurs on glucose, arabinose, mannitol, D-sorbitol, adipate, gluconate (w), phenyl acetate, acetate, succinate, malate, pyruvate, Casamino acids (Difco), acetone, and Tween 20. No growth occurs on D-xylose, mannose, maltose, starch, caprate, *N*-acetyl-glucosamine, citrate, lactate, oxalacetate, propionate, or methanol. Hydrolysis of gelatine or aesculin does not occur. Nitrate is reduced to nitrite, but nitrite reduction does not occur, nor does indole production or H2S formation. β-Glucosidase and β-galactosidase are not produced. Starch, DNA, and Tween 80 are not degraded. Growth occurs in temperatures between 15 °C and 40 °C (optimum 30 °C), at pH 5–8.5 (optimum 7.5) and with NaCl concentrations of 1–10 %. Aminopeptidase, arginine dihydrolase, ornithine decarboxylase, urease, catalase, oxidase, and nitrate reduction are observed. Acid production was weak produced from L-arabinose.

The major fatty acids are $C_{18:1}\omega7c$ (75.3 %), $C_{19:0}$ cyclo $\omega8c$ (6.4 %), $C_{16:0}$ (4.4 %), $C_{16:1}$ $\omega7c$ and/or $C_{15:0}$ iso 2-OH (summed feature 3, 2.5 %), $C_{18:0}$ 3-OH (2.4 %), $C_{18:0}$ (2.2 %), and $C_{20:1}$ $\omega9c$ (1.3 %). Other minor (<1 %) fatty acids are $C_{14:0}$ 3-OH or $C_{16:1}$ iso I (summed feature 2), $C_{17:1}$ $\omega8c$, $C_{17:1}$ $\omega6c$, and $C_{17:0}$. The major polar lipids are diphosphatidylglycerol (DPG), phosphatidylglycerol (PG), phosphatidylethanolamine (PE), phosphatidylmonomethylethanolamine (PME), and phosphatidylcholine (PC). The DNA G+C content is 63.9 mol%. The type strain was isolated from the beaches of Corrubedo in northwest Spain. It has been deposited in three culture collections under the numbers CECT 7622, LMG 25482, and DSM 23382.

Remarks

The whole genome sequencing of the type strain *Cohaesibacter gelatinilyticus* CL-GR15 is in progress. The South Korean project is sequencing the genome using Illumina Hiseq 2000, 454-GS-FLX (http://www.genomesonline.org/cgi-bin/GOLD/GOLDCards.cgi?goldstamp=Gi0034926).

Abstract
Erythrobacteraceae is one of the two families that belong to the order *Sphingomonadales*, and it is affiliated with the class *Alphaproteobacteria*. The family *Erythrobacteraceae* includes five genera – *Altererythrobacter*, *Croceicoccus*, *Erythrobacter*, *Erythromicrobium* and *Porphyrobacter* – for a total of 33 species, including 29 with validly published names and 4 new species. Members of the family are Gram-negative, aerobic, rod-shaped or pleomorphic coccoid bacteria; they are motile or nonmotile, chemo-organotrophic, produce pigments (yellow, orange, red or pink), and do not form spores. Some species require biotin. Most members contain bacteriochlorophyll a (*BChl a*), several types of carotenoids, and monosaccharide-type glycosphingolipid. Representatives of the clade have been isolated from diverse environments: wild rice, cold-seep sediment, desert sand, tepid water, seawater, tidal flats, marine sediment, and marine invertebrates. Whole-genome sequencing has been reported in only two genera of the *Erythrobacteraceae* family, including *Erythrobacter* (three strains) and *Porphyrobacter* (one strain). Family members offer a valuable source of information for further studies focused on aerobic anoxygenic phototrophic (AAP) metabolism, physiological nature, and high potential for biotechnological purposes by the presence of important hydrolases.

Taxonomy: Historical and Current

Erythrobacteraceae (E.ry.thro.bac.te.ra'ceae. N.L. masc. n. *Erythrobacter* type genus of the family; -aceae ending to denote a family; N.L. fem. pl. n. *Erythrobacteraceae* the *Erythrobacter* family) (Lee et al. 2005 emend. Xu et al. 2009).

Erythrobacteraceae DNA mol% G+C content varies between 54.5 and 71.5. The type genus is *Erythrobacter*. *Erythrobacteraceae* is phylogenetically closest related to the family *Sphingomonadaceae*. These two families integrate the order *Sphingomonadales*, and they are affiliated with the class *Alphaproteobacteria*.

Physiologically, the group is very similar. Members are Gram-negative, rod-shaped, or pleomorphic coccoid bacteria and aerobic chemoorganotrophs. Most species contain carotenoids and require NaCl for growth (although it is not essential in many cases), some species contain *BChl a*. Autotrophic growth has not been reported, but one genus may be facultative photoheterotrophs. Members of this taxon have been isolated

E. Rosenberg et al. (eds.), *The Prokaryotes – Alphaproteobacteria and Betaproteobacteria*, DOI 10.1007/978-3-642-30197-1_376,

mainly from aquatic environments, but there are also isolation reports from sediment, sand, and rice.

Erythrobacter, the type genus of the *Erythrobacteraceae* family, was originally described by Shiba and Simidu in 1982. Members of this genus are orange- and pink-pigmented Gram-negative bacteria. They are aerobic chemoorganotrophs that are motile by subpolar flagella. *Erythrobacter* are halophilic carotenoids that are able to use glucose, pyruvate, acetate, butyrate, and glutamate as sole organic carbon sources, but not methanol. Strains require biotin and are able to hydrolyze gelatin, tween 80, and alginate. Although these organisms do not grow phototrophically, the presence of bacteriochlorophyll *a* indicates that this taxon is most closely related to the *Rhodospirillaceae* family (*Rhodospirillales* order), so it was maintained as a new genus inside this family. Later, the nonphotosynthetic *Sphingomonas* group was included in the α-4 subclass of *Proteobacteria* (Yabuuchi et al. 1990), as well as the *Erythrobacter-Porphyrobacter-Erythromicrobium* cluster, which was defined to be most closely related to members of the genus *Sphingomonas* (Yurkov et al. 1994). A new order was proposed to accommodate this clade. The *Sphingomonadales* order was created based on 16S rRNA sequence comparisons, as well as phenotypic and morphological characteristics (Yabuuchi and Kosako 2005).

Strain representatives of the *Porphyrobacter* genus proposed by Fuerst et al. (1993) shared ultrastructural similarities with members of the *Planctomycetales*. However, 16S rRNA sequence data indicated that these bacteria shared a position within the Alfa subclass of the *Proteobacteria* with *Erythrobacter longus*, but they were distinguishable in their sequences and in other characteristics, such as their requirement of vitamins for growth; acetate, glutamate, and butyrate utilization; gelatin hydrolysis; and quantitative differences in detectable cellular fatty acids.

The photosynthetic apparatus, biochemical, morphological, and 16S rRNA sequence data for strain E5T (= DSM 8510^T) also supported the proposal that a new genus and a new species should be described. The *Erythromicrobium* genus was introduced by Yurkov et al. (1992) as a genus of freshwater, obligatory aerobic, facultative, photoheterotrophic bacteria that included five species tentatively identified on the basis of DNA–DNA hybridization and phenotypic data (Yurkov et al. 1991): *Erythromicrobium sibiricum*, *Erythromicrobium ursincola*, *Erythromicrobium ezovicum*, *Erythromicrobium hydrolyticum*, and *Erythromicrobium ramosum*. However, the genus was validly published in 1994 with *Erythromicrobium ramosum* as the type strain (Yurkov et al. 1994) and the unique valid named species in the genus. In 1997, the genus *Erythromicrobium* was taxonomically reorganized, resulting in the exclusion of *E. sibiricum* and *E. ursincola* from the genus, being transferred to new genera, *Sandaracinobacter* and *Erythromonas*, respectively (Yurkov et al. 1997). Subsequently, phylogenetic analysis of the class *Alphaproteobacteria* based on 16S rRNA sequence comparisons through phylogenetic tree led to the reclassification of the genera *Erythrobacter* (Shiba and Simidu 1982), *Porphyrobacter* (Fuerst et al. 1993), and *Erythromicrobium* (Yurkov et al. 1994) into a new family named *Erythrobacteraceae* by Lee and colleagues (2005).

Further, the *Altererythrobacter* genus was suggested by Kwon et al. (2007) to accommodate new species in the clade. *Altererythrobacter* showed high similarity to the genus *Erythrobacter* but did not share its phyletic line. Another taxonomic rearrangement was related to reclassification of *Erythrobacter luteolus* (Yoon et al. 2005a) as *Altererythrobacter luteolus* comb. nov. (Kwon et al. 2007).

The last genus introduced in *Erythrobacteraceae* family was *Croceicoccus* (Xu et al. 2009), represented by aerobic and chemoheterotrophic bacteria containing carotenoids but not *BChl a*. The emended description of the family *Erythrobacteraceae* was also included in the study of Xu et al. (2009).

At the time of writing (September 2012), the family *Erythrobacteraceae* consisted of five genera (*Table 9.1*) with 33 species (*Tables 9.2*, *9.3*, *9.4*, and *9.5*): *Erythrobacter* (type genus) (13 species, 2 of which were only effectively published), *Altererythrobacter* (12 species, 2 of which were only effectively published) *Croceicoccus* (1 species), *Erythromicrobium* (1 species), and *Porphyrobacter* (6 species).

Phylogenetic Structure of the Family and Its Genera

The phylogenetic reconstruction of the 33 type species of the family *Erythrobacteraceae* based on 16S rRNA gene sequence is represented in *Fig. 9.1*. *Erythrobacteraceae* is most closely related to *Sphingomonadaceae*. These families belong to the order *Sphingomonadales*, and it is affiliated with the class *Alphaproteobacteria*.

The five genera (*Erythrobacter*, *Altererythrobacter*, *Croceicoccus*, *Erythromicrobium* and *Porphyrobacter*) currently recognized within the *Erythrobacteraceae* family are separated in the tree based on the topology created using the randomized axelerated maximum likelihood algorithm (RAxML; Stamatakis 2006). Representative sequences from *Rhodospirillaceae* and *Rodobiaceae*, which are closely related taxa, were used as outgroups. In addition, a 10 % maximum frequency filter was applied in order to remove hypervariable positions and potentially misplaced bases from the alignment of the sequences. The scale bar in *Fig. 9.1* represents 0.02-bp substitutions per nucleotide position.

Molecular Analyses

DNA–DNA Hybridization

DNA-DNA hybridization (DDH) studies have been performed on several *Erythrobacteraceae* family members including *Altererythrobacter*, *Erythrobacter*, and *Porphyrobacter* genera, confirming the taxonomic positions of the species proposed in each taxon. *Tables 9.6*, *9.7*, and *9.8* summarize the DNA–DNA similarities among the type strains of the *Erythrobacteraceae* family.

Levels of DNA–DNA relatedness between *A. marensis* MSW-14^T and its closest relatives, *A. epoxidivorans* KCCM

Table 9.1

The genera classified within the family *Erythrobacteraceae*, as on September 2012

Genus	Number of species[a]	Type species	General properties
Erythrobacter (type genus)	13	*Erythrobacter longus*	Gram-negative aerobic chemoorganotrophs non-spore-forming containing ubiquinone-10 (Q-10) as the predominant respiratory lipoquinone, most species contain carotenoids, require NaCl for growth, utilize glucose, but do not hydrolyze starch, gelatin and do not reduce nitrate. Autotrophic growth has not been reported. Two species contain bacteriochlorophyll *a* (*BChl a*)
Altererythrobacter	12	*Altererythrobacter epoxidivorans*	The members share many phenotypic and chemotaxonomic characteristics such as the absence of motility, rod-shaped cells. C18:1 ω7*c* and ubiquinone-10 are the dominant fatty acid and respiratory quinone, respectively. Members can be characterized by the yellow to orange-red colony color on agar plates, lack of *BChl a*. DNA G+C content ranging between 54.5 and 67.2 mol%, and the temperature range for optimal growth occurs at 15–35 °C. All species can grow in the presence of NaCl, though not essential in many cases
Croceicoccus	1	*Croceicoccus marinus*	Gram-negative and non-spore-forming cocci. Divide by binary division. Capable of producing multifibrillar stalk-like fascicle structures on the cell surface. Contains carotenoids, but not *BChl a*. Aerobic and chemoheterotrophic. No growth occurs anaerobically in the light. Ubiquinone-10 is the major respiratory quinone. The polar lipid profiles comprise phosphatidylglycerol, two unidentified glycolipids, phosphatidylcholine and an unidentified phospholipid
Erythromicrobium	1	*Erythromicrobium ramosum*	Gram-negative, rod-shaped, and usually motile by means of flagella. Branching may occur. The cells are orange, contain *Bchl a* and carotenoids, and multiply by binary division. Aerobic chemoorganotrophs and facultative photoheterotrophs. No growth occurs anaerobically in the light. Ribulose diphosphate carboxylase is not detected. No fermentation and no denitrification activities occur
Porphyrobacter	6	*Porphyrobacter neustonensis*	Gram-negative, pleomorphic motile rods or cocci, non-sporulating, reproducing by polar growth or budding. Capable of producing multifibrillar stalk-like fascicle structures and crateriform structures on the cell surface. Aerobic. Chemoheterotrophic Synthesizes *BChl a* on low-nutrient media under aerobic and semiaerobic conditions. DNA base composition is 63.8–66.8 mol% G+C. Positive for calatase, presence of BChl a, and utilization of D-glucose, negative for utilization of citrate and L-Arabinose

[a]Including species whose names have been effectively but not yet validly published

42314^T and *A. luteolus* KCTC 12311^T were determined to be 26.0–27.3 % and 9.8–15.2 %, respectively (Seo and Lee 2010). The value between *A. xinjiangensis* S3-63^T and the type strain of the phylogenetically most closely related species *A. marinus* H32^T was 54.5 ± 2 % (Xue et al. 2012). DNA–DNA similarity between *A. troitsensis* KMM 6042^T and *A. dongtanensis* was 34.4 % ± 7.6 % (Nedashkovskaya et al. 2013).

DNA–DNA relatedness between *E. citreus* strains RE35F/1^T and RE10F/45 was (79 % ± 6 %). However, values between *E. citreus* strains and *E. litoralis* DSM 8509^T were 25 % ± 2 % and 34 % ± 2 %, respectively, and between *E. citreus* and *Erythromicrobium ramosum* DSM 8510^T were 20 % ± 3 % and 34 % ± 4 %, respectively (Denner et al. 2002). *E. flavus* strains SW-46^T and SW-52 exhibited DNA–DNA relatedness levels of 94.0 % and 94.7 % against each other, although *E. flavus* strains and the type strains of *E. longus* DSM 6997^T, *E. litoralis* DSM 8509^T, and *E. citreus* DSM 14432^T were 4.2 % and 3.6 %; 6.0 % and 7.4 %; and 13.1 % and 14.7 %, respectively (Yoon et al. 2003).

Levels of DNA relatedness observed between *E. aquimaris* strains SW-110^T, SW-116, and SW-140 were 88.5–102.1 %, but DNA relatedness of *E. aquimaris* strains against *E. longus*, *E. litoralis*, *E. citreus*, and *E. flavus* were between 5.3 % and 12.7 % (Yoon et al. 2004a). DNA similarity between *E. seohaensis* SW-135^T and *E. gaetbuli* SW-161^T was 12.3 %. Moreover, *E. seohaensis* SW-135^T and *E. gaetbuli* SW-161^T exhibited DNA similarity levels of 9.7–20.2 % and 8.5–18.9 % against *E. longus*, *E. litoralis*, *E. citreus*, *E. flavus*, and *E. aquimaris* (Yoon et al. 2005b).

DNA–DNA hybridization similarity among four *E. vulgaris* strains (i.e., 022-2-10^T, 022-2-9, 022-2-12 and 022-4-7) was 94–98 %. DNA relatedness between *E. vulgaris* and *E. flavus* KCCM 41642^T, *E. citreus* DSM 14432^T, *E. litoralis* DSM 8509^T, *E. aquimaris* KCCM 41818^T, and *E. longus* ATCC 33941^T were 39 %, 37 %, 33 %, 33 %, and 30 %, respectively (Ivanova et al. 2006). DNA–DNA relatedness values between *E. nanhaisediminis* T30^T and *E. aquimaris* JCM 12189^T, *E. seohaensis* JCM 21815^T, *E. citreus* JCM 21816^T, *E. vulgaris* DSM 17792^T, and *E. longus* JCM 6170^T were 56.9 %, 40.3 %, 19.7 %, 14.7 %, and 14.5 %, respectively (Xu et al. 2010). DNA–DNA relatedness between *E. pelagi* UST081027-248^T and *E. citreus* DSM14432^T,

E. seohaensis DSM 16221^T, *E. flavus* DSM16421^T, *E. vulgaris* DSM 17792^T, and *E. nanhaisediminis* DSM 16125^T were 62 %, 48 %, 24 %, 14 %, and 14 %, respectively (Wu et al. 2012).

P. sanguineus strains IAM 12620^T and ATCC 25661 showed DNA–DNA relatedness of 88 % against each other. In addition, the DNA relatedness between *P. sanguineus* IAM 12620^T and its phylogenetic neighbors *Erytromicrobium ramosum* DSM 8510^T, *P. tepidarius* DSM 10594^T, *P. neustonensis* DSM9434^T, *Erytrobacter litoralis* DSM8509^T, *Erytrobacter longus* IFO 14126^T, *Blastomonas natatoria* DSM 3183^T, and *Sphingomonas paucimobilis* IFO 13935^T were 38 %, 36 %, 31 %, 18 %, 14 %, 2 %, and <1 %, respectively (Hiraishi et al. 2002). DNA–DNA relatedness between *P. neustonensis* DSM 9434^T and *P. tepidarius* DSM 10594^T, *P. sanguineus* ATCC 25661 and IAM 12620^T, *Erytromicrobium ramosum* DSM 8510^T, *Erytrobacter litoralis* DSM8509^T, *Erytrobacter longus* IFO 14126^T, *Blastomonas natatoria* DSM 3183^T, and *Sphingomonas paucimobilis* IFO 13935^T were 38 %, 32 %, 29 %, 29 %, 14 %, 11 %, 4 %, and <1 %, respectively (Hiraishi et al. 2002).

DNA–DNA relatedness of *P. cryptus* ALC-2^T and ALC-3 strains against *P. neustonensis*, *P. tepidarius*, *Erythrobacter longus*, and *Erythromicrobium ramosum* were 25 %, 31 %, 35 %, 40 %, 19 %, 20 %, 22 %, and 21 %, respectively. DDH relatedness of *P. neustonensis* against *P. tepidarius*, *E. longus*, and *E. ramosum* were 24 %, 21 %, and 24 %, respectively. Values for *P. tepidarius* against *E. longus* and *E. ramosum* were 22 % and 24 %, respectively. DNA similarity between *E. longus* and *E. ramosum* was 25 % (Rainey et al. 2003). *P. donghaensis* strains SW-132^T and SW-158 exhibited a mean level of DNA–DNA relatedness of approximately 86 %. Values between *P. donghaensis* strains and the type strains of *Porphyrobacter* species (i.e., *P. neustonensis*, *P. tepidarius*, *P. sanguineus* and *P. cryptus*) were in the range of 9.4–20.3 % (Yoon et al. 2004b). Levels of DNA–DNA relatedness between *P. dokdonensis* DSW-74^T and the type strains *P. neustonensis*, *P. tepidarius*, *P. sanguineus*, *P. cryptus*, and *P. donghaensis* were in the range of 9–25 % (Yoon et al. 2006).

Genome Analysis

As of May 2013, no type strains genome sequence is available in the *Erythrobacteraceae* family. However, three genomes belonging to the *Erythrobacter* genus have been reported, but only one is completely closed. Moreover, a draft genome has also stated for the *Porphyrobacter* genus. The main features of these genomes are summarized in *Table 9.9*.

The *E. litoralis* genome, strain HTCC2594, was isolated from a depth of 10 m in the Sargasso Sea, Atlantic Ocean, and cultured in a low-nutrient heterotrophic medium. It contains one circular chromosome of 3,052,398 bp, 3.011 protein coding genes, one copy of 16S-23S-5S rRNA, 45 tRNA genes encoding 19 aminoacyl-tRNA sequences, and 63.07 % G+C content (Oh et al. 2009). No plasmids are present. Moreover, the HTCC2594 genome lacks reaction center genes for phototrophic metabolism, genes for CO_2 fixation such as ribulose-1,5-bisphosphate carboxylase/oxygenase, and components of the reverse trichloroacetic acid cycle.

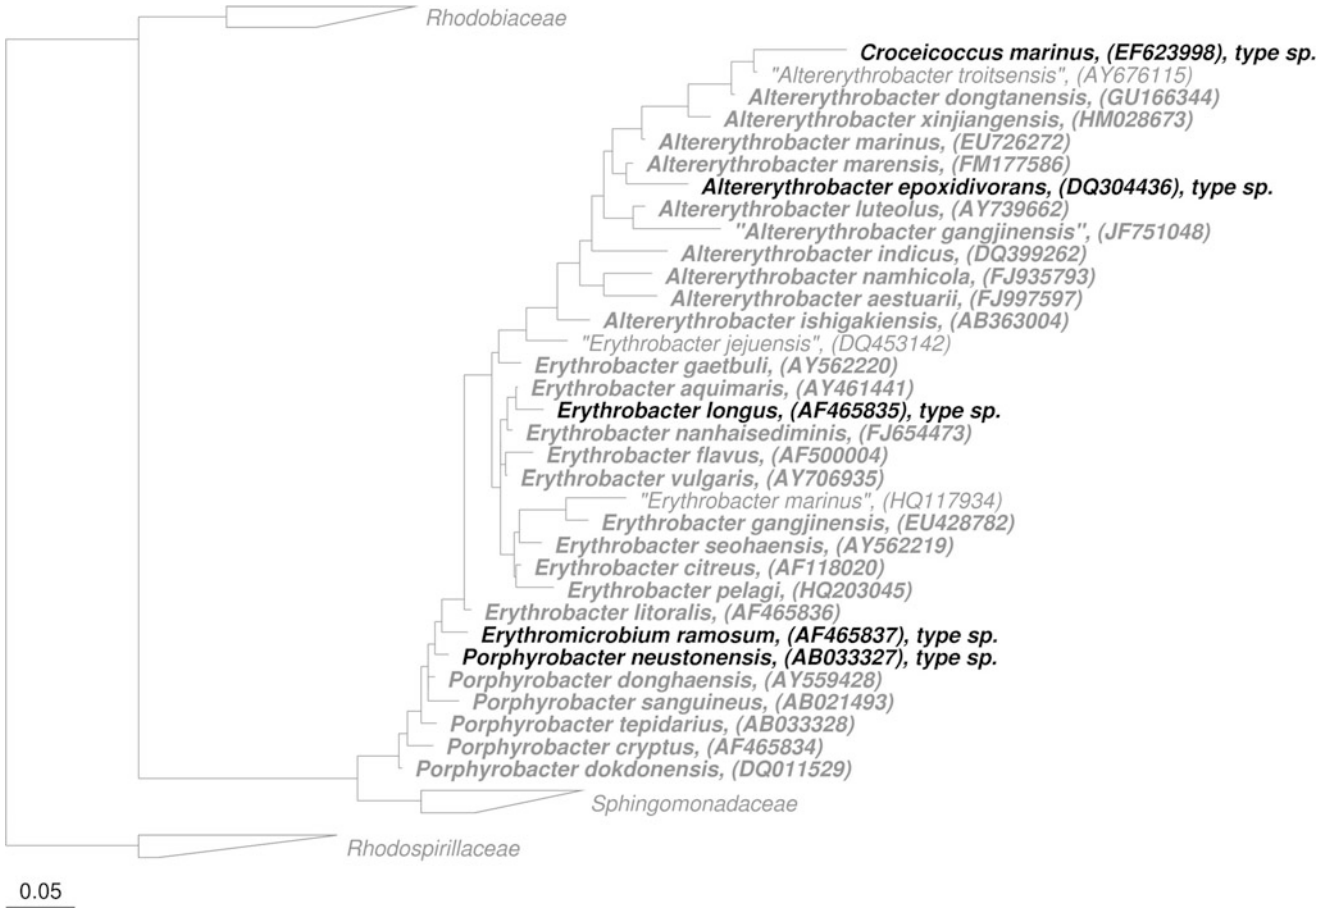

Fig. 9.1

Phylogenetic reconstruction of the family *Erythrobacteraceae* based on 16S rRNA and created using the maximum likelihood algorithm RAxML (Stamatakis 2006). The sequence datasets and alignments were used according to the All-Species Living Tree Project (LTP) database (Yarza et al. 2010; http://www.arb-silva.de/projects/living-tree). Representative sequences from closely related taxa were used as outgroups. In addition, a 10 % maximum frequency filter was applied in order to remove hypervariable positions and potentially misplaced bases from the alignment. Scale bar 2 % indicates estimated sequence divergence

The HTCC2594 strain encodes three distinct epoxide hydrolases with enantioselectivity towards styrene oxides, which may be exploited for biotechnological purposes (Woo et al. 2007; Oh et al. 2009).

So far, two other *Erythrobacter* draft genomes have been documented: *Erythrobacter* sp. strain NAP1, available as 2 scaffolds, and *Erythrobacter* sp. strain SD-21, available as 19 scaffolds. The NAP1 strain, which is an aerobic, anoxygenic, phototrophic bacterium, was isolated by plating on minimal medium from a water sample collected in the Northwest Atlantic in 2000 (Kolber et al. 2001; Koblízek et al. 2003). The genome of *Erythrobacter* sp. NAP1 consists of a single circular chromosome of 3,264,238 bp with 3.177 putative genes that cover 92 % of the genome, one copy of each of the rRNA genes, 45 genes for tRNAs, G+C content of 61 %, and a complete set of genes for bacteriochlorophyll biosynthesis and reaction center proteins (Koblízek et al. 2011). The continuous 38.9-kb-long photosynthetic gene cluster is organized as follows: *bchIDO-crtCDF-bchCXYZ-pufBALM-tspO-bch*PORF-*bchG-ppsR-ppaA-bchFNBHLM-lhaA-puhABC-acsF-puhEhemA-cycA*. Homologs of regulatory genes *ppaA* (cobalamin binding) and *ppsR* (*crtJ* homologue) are also present in the gene cluster, but most of the carotenoid biosynthesis genes are located outside the cluster (Koblízek et al. 2011). The NAP1 genome contains a full set of genes for heme biosynthesis; γ-aminolevulinic acid is synthesized through the Shemin (C4) pathway, besides a complete set of genes for the siroheme biosynthesis pathway, although final enzymes of cobalamin (vitamin B12) biosynthesis are missing.

Although the NAP1 strain lacks the genes of any autotrophic CO_2 fixation pathway (Koblízek et al. 2011), this strain may augment heterotrophic growth with light harvesting encoded by the *puf* operon and ribulose-1,5-bisphosphate carboxylase/oxygenase independent CO_2 fixation (Koblízek et al. 2003). Genes for nitrogenase or nitrate reductase are also absent in this genome, which is consistent with its inability to grow on nitrate. The NAP1 genome offers a valuable source of information for further studies focused on AAP metabolism and physiological nature (Koblízek et al. 2011).

Erythrobacter sp. strain SD-21 was isolated from surface sediment from the San Diego Bay, based on its ability to oxidize soluble Mn(II) to insoluble Mn(III, IV) oxides. The genome of SD-21 strain contains 2,970,874 bp, 2.941 protein coding genes that cover 85 % of the genome, one copy of the rRNA genes, 41 genes for tRNAs, and 62.9 % G+C content (http://www.ncbi.nlm.nih.gov/genome/browse/; https://moore.jcvi.org/moore/) (*Table 9.9*). The SD-21 strain was reported as the first bacterium within the alpha-4 Proteobacteria that is able to oxidize Mn(II) as well as the first marine Gram-negative bacterium containing Mn(II)-oxidizing proteins (Francis et al. 2001). In addition to being a robust Mn(II) oxidizer, SD-21 clusters with the aerobic anoxygenic phototrophs, which may comprise as much as 11 % of the microbial community in the upper ocean and exert a significant impact on global carbon cycling (Kolber et al. 2001). This nonphotosynthetic, manganese(II)-oxidizing bacterium (Francis et al. 2001; Oh et al. 2009) has a new type of manganese-oxidizing enzyme (Anderson et al. 2009) and may serve as a useful model for studying the mechanism of Mn(II) oxidation within the α-*Proteobacteria* and the biological function of bacterial Mn(II) oxidation.

Porphyrobacter sp. strain AAP82 was isolated from the Huguangyan Maar Lake in southern China. The genome of the AAP82 strain has a BioProject number in the Genebank

NR not reported

database (http://www.ncbi.nlm.nih.gov/genome/browse/), but no valid publication has been reported yet. This AAP bacterium represents an important microbial component in the upper layers of the water column in various freshwater lakes. The AAP82 strain genome is available in 52 scaffolds and contains 2,899,072 bp, 2789 coding sequences, one copy of each of the rRNA genes, 44 genes for tRNAs, and G+C content of 67.3 % (RAST server; Aziz et al. 2008).

The comparative analyses among these four genomes of the *Erythrobacteraceae* family has been represented by Genome Atlas (*Fig. 9.2*) based on the GeneWiz browser 0.94 server. *Sphingomonas wittichii* RW1 was used as the reference genome.

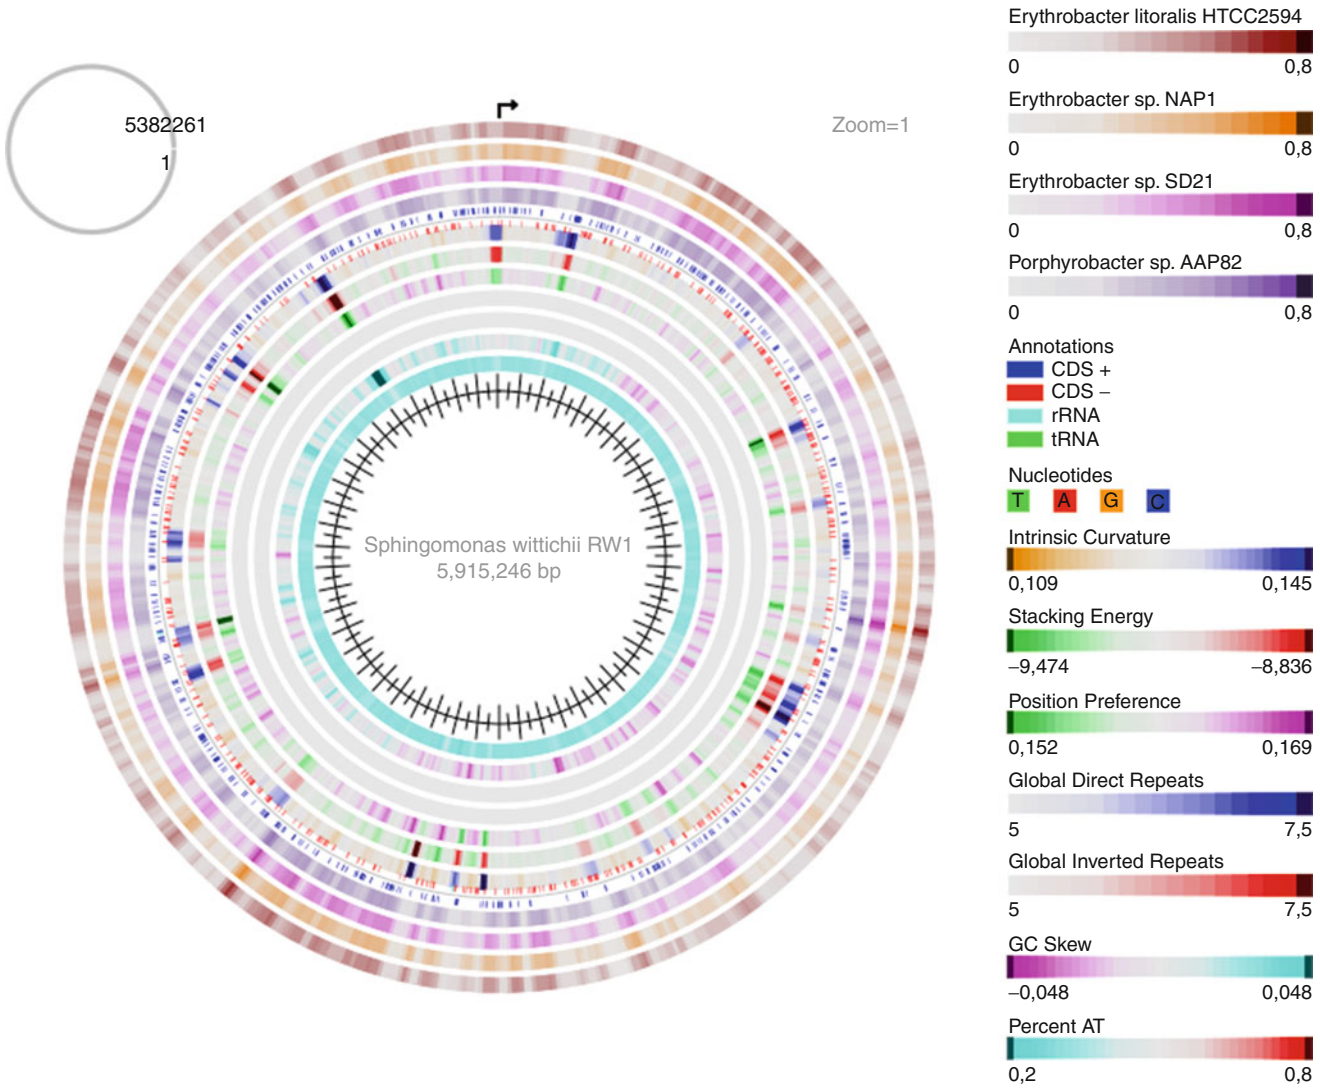

Fig. 9.2
Genome Atlas. The Atlas shows the genome comparison among *Erythrobacter litoralis* HTCC2594, *Erythrobacter* sp. strain NAP1, *Erythrobacter* sp. strain SD-21 and *Porphyrobacter* sp. strain AAP82 chromosomes. *Sphingomonas wittichii* RW1 was used as reference genome

Phages

Two prophage sequences are reported in the genome of *Erythrobacter litoralis* strain HTCC2594: a large prophage region (157,555–185,998 bp) and a medium prophage region (2,812,472–2,826,784 bp) (Oh et al. 2009). Based on the Rast Server annotation (Aziz et al. 2008), which uses the subsystem feature counts, three sequences have been allocated in the phages: a prophages category from *Erythrobacter* sp. NAP1 and two from *Erythrobacter* sp. SD-21 genomes. The main functions of the proteins in this category were phage packaging machinery and phage capsid proteins. The comparative chromosomal region for the phage genes among the three *Eryhtrobacter* strains is represented in *Fig. 9.3*. No sequence has been reported for *Porphyrobacter* sp. strain AAP82 in phages, prophages, transposable elements, or plasmids categories.

Phenotypic Analyses

Family *Erythrobacteraceae* Lee, Liu, Anzai, Kim, Aono and Oyaizu (2005). Emend Xu, Wu, Wang, Wang, Oren and Wu (2009)

Erythrobacteraceae (E.ry.thro.bac.te.ra'ceae. N.L. masc. n. *Erythrobacter* type genus of the family; -aceae ending to denote a family; N.L. fem. pl. n. *Erythrobacteraceae* the *Erythrobacter* family.

The main features of *Erythrobacteraceae* family members are summarized below and listed in *Tables 9.1*, *9.2*, *9.3*, *9.4*, and *9.5*. The family *Erythrobacteraceae* was circumscribed on the basis of the phylogenetic analysis of 16S rRNA gene sequences, hybridizations based on similarities between DNA–DNA (DDH), and phenotypic characteristics. The family is

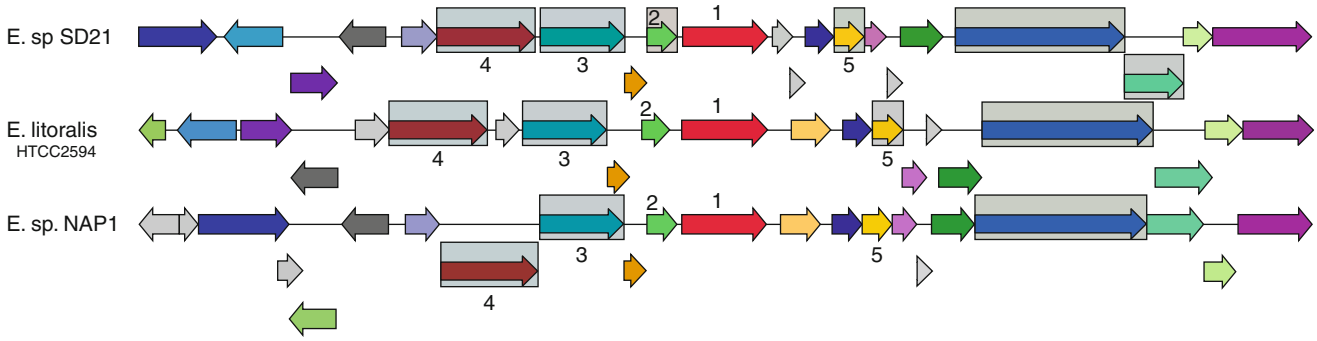

Fig. 9.3

Comparative chromosome region for phage genes among three *Erythrobacter* strains. The function predicted is represented by number: *1* Phage major capsid protein, *2* Gene transfer prohead protease, *3* Phage portal protein, *4* Gene transfer agent terminase protein, *5* Gene transfer tail protein. Sets of genes with similar sequence are grouped with the same number and color. Genes whose relative position is conserved are functionally coupled and share gray background boxes

phenotypically, metabolically, and ecologically similar. It basically includes aerobic chemoorganotrophs, but one genus may be facultative photoheterotrophs.

Genus *Erythrobacter* Shiba and Simidu (1982)

Erythrobacter (Gr. adj. *eiythrus* red; M. L. masc. n. *bacter* rod or staff; M. L. mas. n. *Erythrobacter* red rod)

Cells are yellow, orange, orange-yellow, or red-orange; ovoid to rod-shaped; and 0.3–3.0 by 0.5–5.0 um. The cells contain ubiquinone-10 (Q-10) as the predominant respiratory lipoquinone. Optimal growth occurs at temperatures between 25 °C and 37 °C and at pH values between 7.0 and 8.0. They are Gram-negative, non-spore-forming, and multiply by binary fission. Cells are motile by means of polar or subpolar flagella, or they are nonmotile. Most species contain carotenoids, require NaCl for growth, utilize glucose but do not hydrolyze starch or gelatin, and do not reduce nitrate. The Voges-Proskauer test is mostly negative. They are aerobic chemoorganotrophs; only two species present bacteriochlorophyll *a*. No growth is reported anaerobically in the light and no autotrophic growth occurs with H_2. Although small amounts of acid are produced from a wide range of carbohydrates under microaerobic conditions, metabolism is predominantly respiratory. Most species are mainly susceptible to chloramphenicol. Methanol is not utilized. Oxidase and catalase can be produced. The G+C of the DNA is 58.9–67 mol%.

Type species: *Erythrobacter longus.*

The genus currently contains 13 species, although only 2 of which were effectively published: *E. longus* (Shiba and Simidu 1982); *E. litoralis* (Yurkov et al. 1994); *E. citreus* (Denner et al. 2002); *E. flavus* (Yoon et al. 2003); *E. aquimaris* (Yoon et al. 2004a); *E. gaetbuli* and *E. seohaensis* (Yoon et al. 2005b); *E. vulgaris* (Ivanova et al. 2006); *E. gangjinensis* (Lee et al. 2010); *E. nanhaisediminis* (Xu et al. 2010); *E. pelagi* (Wu et al. 2012); "*E. jejuensis*" (Yoon et al. 2013); and "*E. marinus*" (Jung et al. 2012). *Erythrobacter luteolus* was isolated from a tidal flat of the Yellow Sea in Korea (Yoon et al. 2005a) has been transferred to *Altererythrobacter luteolus* comb. nov. (Kwon et al. 2007). *Tables 9.1* and *9.2* summarize the properties of the *Erythrobacter* genus.

Genus *Altererythrobacter* Kwon, Woo, Yang, Kang, Kang, Kim, Sato and Kato (2007). Emend Xue, Zhang, Cai, Dai, Wang, Rahman, Peng and Fang (2012)

Altererythrobacter (Al.ter.e.ryth'ro.bac'ter. L. adj. *alius*, *alterius* another, other, different; N.L. masc. n. *Erythrobacter* a genus name; N.L. masc. n. *Altererythrobacter* another or different *Erythrobacter*, because the genus shows high similarity to the genus *Erythrobacter* but does not share its phyletic line).

Cells are Gram-negative and motile or nonmotile; the color of cell suspensions and colonies can be yellow, orange-red, or ochre. Strains produce catalase and can be positive or negative for oxidase. Methanol-soluble pigments are species-dependent and are characterized by absorption maxima at 447 and 473 nm. They do not contain *BChl a* as a photosynthetic pigment. The major polar lipids are phosphatidylethanolamine, phosphatidylglycerol, diphosphatidylglycerol, and sphingoglycolipid. Anaerobic growth does not occur on marine agar (MA) or on MA supplemented with nitrate. The dominant fatty acid is C18:1 ω7*c*. They do not produce H_2S or indole, do not utilize manose, and do not hydrolyze gelatin. The dominant respiratory quinone is Q10. The optimal growth temperature occurs in mesophilic conditions. All species can grow in the presence of NaCl, although it is not essential in many cases. The DNA G+C content is 54.5–67.2 mol%.

Type species: *Altererythrobacter epoxidivorans.*

The genus currently contains 12 species, although only 2 of which were effectively published: *A. luteolus* (Yoon et al. 2005a; Kwon et al. 2007); *A. epoxidivorans* (Kwon et al. 2007);

A. indicus (Kumar et al. 2008); *A. marinus* (Lai et al. 2009); *A. marensis* (Seo and Lee 2010); *A. aestuarii* (Park et al. 2011); *A. dongtanensis* (Fan et al. 2011); *A. ishigakiensis* (Matsumoto et al. 2011); *A. namhicola* (Park et al. 2011); *A. xinjiangensis* (Xue et al. 2012); "*A. gangjinensis*" (Jeong et al. 2013); "*A. troitsensis*" (Nedashkovskaya et al. 2013).

Tables 9.1 and *9.3* summarize the properties of *Altererythrobacter*.

Genus *Croceicoccus* Xu, Wu, Wang, Wang, Oren and Wu (2009)

Croceicoccus [Cro.ce.i.coc'cus. L. adj. *croceus* yellow, golden; N.L. masc. n. *coccus* (from Gr. masc. n. *kokkos*) grain or berry; N.L. masc. n. *Croceicoccus* referring to a yellow coccoid-shaped bacterium].

Cells are Gram-negative and non-spore-forming cocci. Cells are motile and occur in pairs. Young cultures show pleomorphic coccoid cells (0.8–1.0 mm). Colonies on complex agar containing peptone, casamino acids, and yeast extract are 1–2 mm in diameter, circular, smooth, elevated, opaque, and yellow pigmented. They are oxidase negative, catalase positive, divide by binary division, and are capable of producing multifibrillar stalk-like fascicle structures on the cell surface. Cells are aerobic and chemoheterotrophic. They contain carotenoids but not *BChl a*. No growth occurs anaerobically in the light.

Ubiquinone-10 is the major respiratory quinone. The polar lipid profiles comprise phosphatidylglycerol, two unidentified glycolipids, phosphatidylcholine, and an unidentified phospholipid. The major fatty acids are anteiso-C_{15}: 0, iso-C_{14} : 0 and iso-C_{15} : 0. Cells are susceptible to ampicillin (10 mg), bacitracin (0.04 U), cefalexin (30 mg), ceftriaxone (30 mg), chloramphenicol (30 mg), erythromycin (15 mg), gentamicin (10 mg), minocycline (30 mg), neomycin (30 mg), novobiocin (30 mg), penicillin (10 mg), streptomycin (10 mg), and tetracycline (30 mg). The phylogenetic position is in the α-4 subgroup of the class *Alphaproteobacteria*. The G+C of the DNA of the type strain of the single species is 71.5 mol%.

Type species: *Croceicoccus marinus*.

Tables 9.1 and *9.4* summarizes the properties of *Croceicoccus marinus* and *Erythromicrobium ramosum*.

Genus *Erythromicrobium* Yurkov, Stackebrandt, Holmes, Fuerst, Hugenholtz, Golecki, Gad'on, Gorlenko, Kompantseva and Drews (1994)

Erythromicrobium (E.ry.thro.mi.cro'bi.um. Gr. adj. *erythrus*, red; Gr. adj. *micros*, small; Gr. n. *bios*, life; N.L. n. *Erythromicrobium*, red microbe).

The description of *Erythromicrobium* is supported by biochemical, morphological, and 16S rDNA sequence data. Cells are Gram-negative, rod-shaped cells, 0.6–1.0 by 1.3–2.5 μm, and usually motile by means of flagella. Branching may occur. The cells are orange and contain *BChl a* and carotenoids. The major carotenoids are the very polar compound erythroxanthin sulfate and bacteriorubixanthinal. Optimal growth occurs at temperatures between 25 °C and 30 °C and at pH values between 7.0 and 8.5. Multiplication occurs by binary or ternary fission. Cells are aerobic chemoorganotrophs and facultative photoheterotrophs. No growth occurs anaerobically in the light. Ribulose diphosphate carboxylase is not detected. No fermentation or denitrification activities occur. Methanol is not utilized. Cells are phylogenetically related to members of the *Proteobacteria* α-4 subclass. They are frequently found in freshwater habitats and are not halophilic. The G+C of the DNA of the type strain of the single species is 64.2 mol%.

Type species: *Erythromicrobium ramosum*.

Erythromicrobium ramosum is the only valid species published in this genus (Yurkov et al. 1994). "*Erythromicrobium sibiricum*," "*Erythromicrobium ursincola*", "*Erythromicrobium ezovicum*," and "*Erythromicrobium hydrolyticum*" were tentatively allocated in this genus by Yurkov et al. (1991). However, later "*E. sibiricum*" and "*E. ursincola*" were taxonomic transferred from this genus to new genera, *Sandaracinobacter* and *Erythromonas*, respectively, and validly published by Yurkov et al. in 1997. *Tables 9.1* and *9.4* summarize the properties of *Erythromicrobium ramosum* and *Croceicoccus marinus*.

Genus *Porphyrobacter* Fuerst, Hawkins, Holmes, Sly, Moore and Stackebrandt (1993)

Porphyrobacter (Por.phy.ro.bac.ter. Gr. adj. *porphyreos*, purple; Gr. n. *bacter*, rod; M.L. masc. n. *Porphyrobacter*, porphyrin-producing rod, referring to bacteriochlorophyll production).

Cells are members of the α-subclass of *Proteobacteria*. They are Gram-negative, ovoid-to-short rods, pleomorphic, 0.5–1.0 × 0.5–2.8 μm, and reproduce by polar growth, budding, or asymmetric cell division. Colonies on complex media containing peptone are circular, smooth, opaque, and orange or red. They are neutrophilic freshwater bacteria, mesophilic to moderately thermophilic. Growth occurs at 10–60 °C, with an optimum temperature between 30 °C and 37 °C for most species. Cells are motile by peritrichous flagella or nonmotile. They are capable of producing structures that are multifibrillar stalk-like fascicles and crateriforms on the cell surface. Cells do not form any type of internal membranes. Spores and capsules are not formed. They are aerobic and chemoheterotrophic.

Cells synthesize *BChl a* on low-nutrient media under aerobic and semiaerobic conditions. Carotenoids are present. They are positive for calatase, D-glucose utilization, and hydrolyze of aesculine, but negative for citrate, L-arabinose, and D-fructose utilization. Cells do not grow phototrophically under anoxic conditions in the light. Simple organic compounds, peptone, and yeast extract are used as electron donors and carbon sources. Straight-chain octadecenoic acid ($C_{18:1}$) is the major cellular fatty acid. 2-Hydroxy fatty acids and sphingoglycolipids are present, but 3-hydroxy fatty acids are absent. Ubiquinone-10 is the major quinine. Some strains may require vitamins for growth. The G+C of the DNA is 66.8–63.8 mol%.

Type species: *Porphyrobacter neustonensis.*

The genus currently contains six species with validly published names: *P. neustonensis* (Fuerst et al. 1993); *P. tepidarius* (Hanada et al. 1997); *P. sanguineus* (Ahrens 1968; Ahrens and Rheinheimer 1967; Hiraishi et al. 2002); *P. cryptus* (Rainey et al. 2003); *P. donghaensis* (Yoon et al. 2004b); *P. dokdonensis* (Yoon et al. 2006).

Tables 9.1 and *9.5* summarize the properties of the *Porphyrobacter* genus.

Isolation, Enrichment, and Maintenance Procedures

Members of this taxon have been isolated mainly from aquatic environments. However, there are also isolation reports from desert sand and rice in the *Altererythrobacter* genus. Growth media and culture conditions commonly used for the isolation of freshwater aerobic bacteria can be used for obtainment of *Erythrobacteraceae* members. Marine surface water, sediment, invertebrates, and freshwater environments are possible isolation sources for these organisms. MA and marine broth (MB) are the main culture media used to isolate and cultivate isolates. However, other media have been reported to be useful for isolation of *Erythrobacteraceae* members.

R_2A (Difco) plates supplemented with 1 % NaCl and solidified with 1.5 % gellan have been used to isolate *Altererythrobacter dongtanensis* (Fan et al. 2011). Tryptone soy agar was used to isolate *Altererythrobacter indicus* (Kumar et al. 2008) and *Altererythrobacter xinjiangensis* (Xue et al. 2012).

R_3A media solidified with agar (2 %, w/v) (Reasoner and Geldreich 1985; Williams and da Costa 1992) was used to isolate *Porphyrobacter cryptus* (Rainey et al. 2003). PE medium containing sodium glutamate, sodium succinate, sodium acetate, yeast extract, casamino acids, and a vitamin mixture (Hanada et al. 1995, 1997) supplemented with 1.5 % agar was used for isolation of *Porphyrobacter tepidarius.* Lake water agar (Franzmann and Skerman 1981) was used to isolate *Polphyrobacter neustonensis* (Fuerst et al. 1993). *P. sanguineum* strains were grown in MP medium, which consisted of marine broth and 0.5 % peptone water (1:1, vol/vol) (Hiraishi et al. 2002).

Erythromicrobium ramosum was isolated in a medium containing (per liter) 1.0 g of yeast extract, 1.0 g of bacto peptone, 1.0 g of sodium acetate, 0.3 g of KCl, 0.5 g of $MgS0_4.7H_20$, 0.05 g of $CaC1_2.2H_20$, 0.3 g of NH_4Cl, 0.3 g of K_2HP0_4, 20 pg of vitamin B12, and 1 ml of a trace element solution (Drews 1983; Yurkov et al. 1994). *Croceicoccus marinus* (Xu et al. 2009) was isolated by using ZoBell marine-casamino acids medium, which contained (per liter distilled water): NaCl, 19.45 g; $MgCl_2$, 8.8 g; Na_2SO_4, 3.24 g; $CaCl_2$, 1.8 g; KCl, 0.55 g; $NaHCO_3$, 0.16 g; $C_6H_5FeO_7$. $5H_2O$, 0.1 g; KBr, 0.08 g; $CsCl_2$, 34 mg; H_3BO_3, 22 mg; Na_2SiO_3, 4.0 mg; NaF, 2.4 mg; NH_4NO_3, 1.6 mg; Na_3PO_4, 8.0 mg; peptone, 0.5 g; yeast extract, 0.1 g; and casamino acids 0.1 g at a pH of 7.2 (ZoBell 1941).

Maintenance

It has been found that liquid cultures (taken from the late logarithmic growth phase) and agar surface cultures remained viable after storage at 4 °C for at least 2 months (Yurkov and Beatty 1998). Members of this family do not require special procedures for maintenance in medium and long-term storage. Strains may be preserved in screw-capped vials by freezing cell suspensions of liquid cultures or supplemented with MB (cultures mid-logarithmic growth phase) in 20 % (v/v) glycerol as a protective agent at −20 °C or at −70 °C. Long-term preservation is by lyophilization or by freezing cell suspensions in liquid nitrogen or at −80 °C in the presence of a cryoprotectant (Yurkov and Beatty 1998).

Physiological and Biochemical Features

Ecology

The habitat range of the family *Erythrobacteraceae* includes mainly aquatic environments. The original cultures were isolated from high-tidal seaweeds (Shiba and Simidu 1982), freshwater (Fuerst et al 1993; Yurkov et al 1994), cold-seep sediment (Kwon et al. 2007), and deep-sea sediment (Xu et al. 2009). This applies to most species described or reclassified recently. For instance, *Erythrobacter marinus*, *E. pelagi*, and *Porphyrobacter dokdonensis* were isolated from seawater (Yoon et al. 2006; Jung et al. 2012; Wu et al. 2012); *Altererythrobacter dongtanensis* and *A. aestuarii* were isolated from a tidal flat (Fan et al. 2011; Park et al. 2011), and *A. ishigakiensis* was isolated from marine sediment (Matsumoto et al. 2011). To date, all *Erythrobacter* species were retrieved from seawater environments, including marine invertebrates (*E. vulgaris*; Ivanova et al. 2006), as well as the monospecific *Croceicoccus* (*C. marinus*; Xu et al. 2009). The representative monospecific *Erythromicrobium* was isolated from freshwater (*E. ramosum*, Yurkov et al. 1994). *Porphyrobacter* genus includes members isolated from freshwater, brackish, and marine environments. To this genus belong isolates found in hot springs: *P. tepidarius* was isolated from a brackish hot spring (Hanada et al. 1997) and *P. cryptus* from a hot spring at Alcafache in central Portugal (Rainey et al. 2003). Both are moderately thermophilic. *Altererythrobacter* genus includes exceptions in addition to aquatic habitats: *A. indicus*, isolated from wild rice rhizosphere (Kumar et al. 2008) and *A. xinjiangensis*, isolated from desert sand (Xue et al. 2012).

The NCBI taxonomy browser *Erythrobacter* list includes isolates from a broader source than those of the type strains: marine aerosols (HQ188568); bacterioneuston (AY576736); coastal subseafloor (AB094461); soda pond (FN395246); biofilm on a copper-based antifouling paint (JN594622); *Scrippsiella* sp. laboratory culture (DQ486511); Dunhuang Mogao Grottoes 245# (JN244985); ancient salt deposits of the Yipinglang Salt Mine (EF177676); magnetite mine drainage (HQ652571); and chemocline of the hypersaline deep-sea Urania basin (AF321064).

The same search for *Porphyrobacter* resulted the following unusual sources: mine tailings ore and sand (JQ429465); an air sample collected 25 m above sea level (GQ484916); ozone-biological activated carbon filters for drinking water treatment (DQ884358); industrial site soil containing high amounts of heavy oil and heavy metals (HQ588835); Hamelin Pool stromatolites in Shark Bay, Australia (EF150743); aerobic fermentation of a mixture of bovine dung and urine, cow's milk, and yogurt (GQ246725); commercial nitrifying inoculum (AM236300); aquatic microbial mat from Antarctica (FR772128); arsenate resistant culture from estuary (AY788979); HAA degrading bacteria from drinking water (JN547328); oak (*Quercus alba*) leaf infusion (EF685171); ancient salt deposits of the Yipinglang Salt Mine (EF177679); and endophytic from a pine tree with Pine Wilt Disease (FJ784659). The NCBI taxonomy browser also includes *P. meromictius* isolated from a $Na_2SO_4^-$ dominated meromictic lake (Mahoney Lake in the Okanagan Valley of British Columbia, Canada) but the name is not valid (Rathgeber et al. 2007).

Erythromicrobium was found in mud volcano soil in Baratang Island, India (FN397674) and in arsenic-contaminated soil (AFI42455). The NCBI taxonomy browser also includes *E. ezovicum* and *E. hydrolyticum*, which are not valid names. These strains were reported to pertain to Vladimir Yurkov's personal collection and were related to tellurite resistance and reduction (Yurkov et al 1996). *Altererythrobacter* has also been recovered from Polycyclic Aromatic Hydrocarbons (PAHs) and crude oil degrading consortia enriched from marine sediments (GQ505272); mud volcano soil in Baratang Island, India (FN397680); aquatic microbial mat from Antarctica (FR772131); root interior of *Cymbidium goeringii* (GQ476825); and farming field soil (JN848799).

The genera *Erythrobacter*, *Porphyrobacter* and *Erythromicrobium* include AAP members. AAPs contain *BChl a* as a main light-harvesting pigment; however, in contrast to purple nonsulfur photosynthetic bacteria, these are obligate aerobes (Yurkov and Beatty 1998). They are facultative photoheterotrophs, metabolizing organic carbon when available, but are capable of photosynthetic light utilization when organic carbon is scarce. The first AAP bacteria discovered was *Erythrobacter longus* (Shiba et al. 1979; Shiba and Simidu 1982). *Porphyrobacter* and *Erythromicrobium* members present *BChl a* (Yoon et al. 2006; Yurkov et al. 1994; Yurkov and Gorlenko 1993), whereas the *Erythrobacter* genus includes 2 species (out of 13) that synthesize *BChl a*: the former isolated *E. longus* retrieved from high-tidal seaweeds of Tokyo Bay (Shiba and Simidu 1982) and *E. litoralis* found in marine cyanobacterial mat in a supralitoral zone (Yurkov et al. 1994). It had been suggested that cultivated *Erythrobacter* species represent the predominant AAPs in the upper ocean and should be main players in carbon cycling in the ocean, mainly in the euphotic zone (Shiba et al. 1991; Fenchel 2001; Kolber et al. 2001; Karl 2002). Later, culture-independent genomic analyses targeting photosynthetic operon genes (i.e., *puf*M) showed dissimilar results. No sequences recovered in Monterey Bay waters or in the central North Pacific Ocean (Karl and Lukas 1996) were similar to those of *Erythrobacter* species (Béjà et al. 2002).

An extensive study included samples from the Pacific, Atlantic, and Indian Oceans and West Pacific marginal seas, including the East and South China Seas – covering tropical, subtropical, and temperate zones, as well as coastal, shelf, and oceanic waters; it was able to account *Erythrobacter*- and *Roseobacter*-like sequences for approximately a quarter of the totality sequences obtained in the study (Jiao et al. 2007). For nearshore/offshore samples from a Pacific Ocean transect, only one station (out of three) presented sequences (32 %) most similar to those from cultured *Erythrobacter*, but altogether with *Rhodobacter* and *Roseobacter* genera (Ritchie and Johnson 2012). It is now clear that *Erythrobacter* species are not the oceanic-dominating AAP population and the counterparts include a wide variety of bacterial types. Therefore, the relative contribution of *Erythrobacter* spp. to oceanic carbon cycling may not be as large as previously suggested. The studies quantify *Bchl a*, and it is widespread among a phylogenetically diverse group – the AAP bacteria – in which oceanic representation of *Erythrobacter* spp. is not a consensus and may be variable (Béjà et al. 2002; Rathgeber et al. 2004; Venter et al. 2004; Jiao et al. 2007; Yutin et al. 2007; Ritchie and Johnson 2012).

Pathogenicity: Clinical Relevance

No information on pathogenicity for members of *Erythrobacteriaceae* is available heretofore (as of February 2013). The detection of naturally occurring β-lactamases in *Erythrobacter* spp. gave rise to the idea that this group, as many other marine bacteria, plays an important role as reservoir of β-lactam resistance genes, namely the oceanic resistome. A beta-lactamase II from *Erythrobacter litoralis* HTCC 2594 (ELbla2) showing *in silico* similarity with New Delhi metallo-beta-lactamase (MBL) was expressed in *E. coli* cells. These two mature proteins were purified from cultures and both presented as a monomer of 25 kDa. Antimicrobial susceptibility assay revealed that both shared similar substrate specificities, being sensitive to aztreonam and tigecycline (Zheng et al. 2011). Further, several chromosomally located MBLs have been identified from *Erythrobacter* spp. by bioinformatic analyses followed by cloning and expressing in *E. coli* cells. These MBLs showed a large diversity and belonged to subclasses B1 or B3. None of them could be considered a progenitor of the plasmid-mediated carbapenemases disseminated worldwide.

Clones expressing the MBL from *E. flavus* and *E. longus* presented decreased sensitivity to carbapenems (Girlich et al. 2012). It was hypothesized that resistance genes are transferred to the human gut microbiota by means of the consumption of nonsterilized seafood (e.g., seaweeds) (Hehemann et al. 2010; Zheng et al. 2011), given that the virus-like gene transfer system identified, likely Gene Transfer Agent (GTA) systems, are common in marine bacteria (e.g., *E. litoralis*) (Biers et al., 2008), and

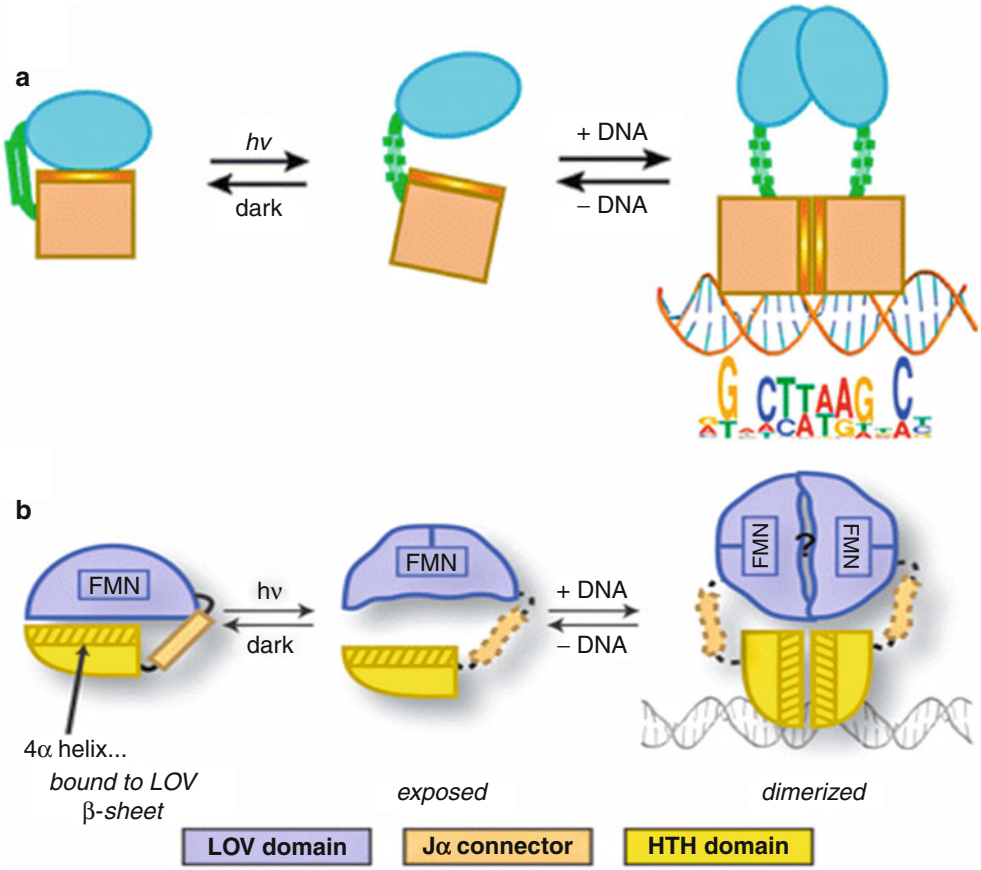

Fig. 9.4

(a) Light-oxygen-voltage (LOV) domains activation schematic model. LOV module inactive in the dark (*left*) and after blue light. activation (*center*): direct DNA binding (*right*) to regulate diverse functions (Adapted from Rivera-Cancel et al. (2012)). (b) Model for *E. litoralis* HTCC2594 LOV domain (EL222) activation. In the dark EL222 is incapable of binding DNA as the LOV domain interacts with the helix-turn-helix (HTH) module. Photo activation induces the formation of a cystein/flavin adduct in the LOV domain resulting in conformational changes that release LOV/HTH interactions. The 4α-helix is free to participate in HTH homodimerization upon binding DNA substrates (Adapted from Nash et al. (2011))

that GTAs account for an horizontal gene transfer frequency that is a million times the frequencies of transformation and transduction (McDaniel et al. 2010).

Application

A summary of the main application properties for the *Erythrobacteraceae* members is presented in *Table 9.10*.

Bioremediation

There are field and experimental evidences of the potential of *Erythrobacteraceae* members for bioremediation of heavy metals and a variety of xenobiotics, including hydrocarbons, aromatics and halogenates. For instance, *Erythrobacter* members were detected as part of the population related to alkane degradation from shoreline environments (Costa da Morte, Northwestern Spain) affected by the Prestige oil spill (Alonso-Gutiérrez et al. 2009). *Erythrobacter longus* and *E. citreus* were the closest phylogenetic neighbors related to the dominant clones identified after a bioremediated microcosm (nitrogen supplemented) experiment (Röling et al. 2002). A petroleum-aromatic-degrading active *Altererythrobacter* isolate is suggested to be a possible agent of bioremediation in and around nutrient-rich tropical marine environments (Teramoto et al. 2010). A *Porphyrobacter* strain, Oxy6 (according to 16S rRNA–based molecular phylogenetic analysis), isolated from subtropical Western Atlantic seawater, showed an ability to methyl halides degradation. This strain was even able to co-oxidize CH_3Br while growing on toluene. A variety of toluene pathway intermediates, such as benzyl alcohol, benzylaldehyde, benzoate, and catechol, could also be oxidized. Furthermore, the bacterium also oxidized *o*-xylene and the xylene monooxygenase pathway intermediate 3-methylcatechol. Considering the widespread

Table 9.10
Summary of the main application properties for the *Erythrobacteraceae* members

Bacteria name	Application	Function
Erythrobacter longus	Bioremediation	Alkane degradation[a, b]
Erythrobacter citreus		
Altererythrobacter		Petroleum-aromatic-degrading active[c]
Porphyrobacter strain – Oxy6		Methyl halides degradation[d], co-oxidize CH_3Br[d], oxidize *o*-xylene[d] and xylene monooxygenase (XMO)[d]
Erythrobacter litoralis		Resistance to tellurite and accumulation of metallic tellurium crystals[e]
Erythromicrobium ramosum		
Erythrobacter longus	Carotenoids	Twenty different carotenoids such as β-carotene and monocyclic carotenoids (e.g., rubixanthan)[f]
Erythrobacter JPCC M sp. strain 1436		Astaxanthin productivity[g]
Erythrobacter sp. strain SNB-035	Cytotoxic Compounds	Benzothiazoles Erythrazoles A-B, Erythrolic acid D (a meroterpenoid)[h]
E. litoralis strain HTCC 2594	LOV Domains	LOV-histidine kinase (LOV-HK) domain (which mediates light-activated histidine phosphorylation)[i,] EL222 DNA-binding protein (LOV domain binds and inhibits a helix-turn-helix (HTH) DNA binding domain in the dark)[j,k]

inhibitory effect of toluene on seawater samples and the substrate oxidation pattern of this *Porphyrobacter* sp., the authors suggested a possible link between aromatic hydrocarbon utilization and the biogeochemical cycle of methyl halides (Goodwin et al. 2005).

Erythrobacter and *Erythromicrobium* isolates demonstrated high-level resistance to tellurite and accumulation of metallic tellurium crystals. In *Erythrobacter litoralis* and *Erythromicrobium ramosum* isolates, crystals occupied 20–30 % of the cell volume. This reduction of tellurite to the relatively inert metallic tellurium [Te(IV) to Te(0)] with accumulation as intracellular deposits is suited to the development of microbiological methods for environmental remediation. Tellurite compounds are toxic to other bacteria and other organisms, including humans. Furthermore, bacterial cells can be harvested for pure tellurium metal in the mineral ore (Yurkov et al. 1996; Yurkov and Beatty 1998).

Carotenoids

A remarkable characteristic of many members of Erythrobacteriaceae is the pigmentation (pink/red/orange/yellow) due to the production of carotenoids (Takaichi et al. 1988, 1990, 1991; Hanada et al. 1997; Yurkov et al. 1994; Denner et al. 2002; Xu et al. 2009). *Erythrobacter longus* produces approximately 20 different carotenoids, such as β-carotene and monocyclic carotenoids (e.g., rubixanthan) (Takaichi et al. 1990). The carotenoid biosynthesis genes lycopene cyclase (*crtY*) and phytoene desaturase (*crtI*), from *E. longus* strain Och101, were cloned, sequenced, and expressed in *Escherichia coli*. The *E. coli* HB101 employed contained the other required biosynthetic genes from *Erwinia herbicola*. Zeaxanthin and lycopene were produced and accumulated in the transformed cells, but transformants containing *crtY* and *crtI* genes from *E. herbicola* gave a higher pigment yield. The weak expression of *E. longus crt* genes in *E. coli* was attributed to codon usage bias (Matsumura et al. 1997).

Erythrobacter JPCC M sp. strain 1436 was included in a patent process for its astaxanthin productivity, reported to be 35 % or more by mass of the all produced pigments. According to 16S rDNA sequence similarity, the closest neighbor was *Erythrobacter luteolus* SW-109^T (GenBank AY739662), with a low nucleotide identity of 95.7 %. Based on 16S rDNA phylogeny, the authors considered *Erythrobacter* JPCCM sp. strain 1436 (accession number NITE BP-340), a novel species belonging to the genus *Erythrobacter*, at the time of priority application (April 2007). The process was entitled "Astaxanthin-producing

bacterium, bacterium culture product, astaxanthin-containing composition, and method for production of astaxanthin"; the European Patent Register Publication Number is EP 2157169 A1 (February 2010). The invention is claimed to be useful for the production of supplement foods and feedstuffs (color-enhancing feedstuffs).

Cytotoxic Compounds

Erythrobacter sp. strain SNB-035, isolated from mangrove sediments in Trinity Bay (Galveston, TX), yielded cytotoxic compounds: the benzothiazoles erythrazoles A-B and erythrolic acid D, a meroterpenoid. Cytotoxicity was observed against non-small cell lung cancer cell lines. Erythrazole B was cytotoxic, with IC_{50} values of 1.5, 2.5, and 6.8 μM against H1325, H2122, and HCC366, respectively. Erythrolic acid D was cytotoxic, with a modest IC_{50} value of 2.5 μM against HCC44. Strain SNB-035 shares 98 % 16S rRNA identity with *E. citreus*. (Hu and MacMillan 2011; Hu et al. 2012).

Light-Oxygen-Voltage Domains

Light-oxygen-voltage (LOV) domains are photosensory-signaling modules acting as blue light–dependent regulators of numerous activities, such as enzymes and DNA binding. LOV domains are widespread and highly conserved in eukaryotes, prokaryotes (including cyanobacteria), and archaeans; thus, they are suited for model-based studies. They can be readily produced in *E. coli* in amounts sufficient for biochemical and spectroscopic analysis. LOV domains can also be engineered into a variety of exogenous targets, allowing similar regulation for new protein-based reagents (Briggs et al. 2007; Möglich and Moffat 2010; Strickland et al. 2012). *Erythrobacter litoralis* presents the LOV-histidine kinase (LOV-HK) domain, which mediates light-activated histidine phosphorylation. *E. litoralis* strain HTCC 2594 has had full-length modules expressed in *E. coli* (EL346-LOV-HK and EL368-LOV-HK). The same was performed with modules from *Brucella melitensis* (animal pathogen) and *Pseudomonas syringae* (plant pathogen), allowing descriptive and comparative analysis (Swartz et al. 2007; Briggs et al. 2007; Tseng et al. 2010). EL222, a DNA-binding protein from the same E. *litoralis* strain, is also a model system. Despite its compactness (222 amino acids), it includes both sensor and effector domains. Nash et al. (2011) demonstrated that this LOV domain binds and inhibits a helix-turn-helix (HTH) DNA binding domain in the dark, releasing these interactions upon illumination. Furthermore, the same research group identified optimal DNA binding sites for EL222 and demonstrated the light-dependent activation of transcription (*Fig. 9.4*). EL222 LOV-HTH native targets are yet to be determined; nevertheless, the portability of the system, the direct regulation of DNA binding with light, together with the fact that the DNA binding sites are identified, make it attractive for engineering in heterologous systems (Rivera-Cancel et al. 2012).

Enzymes

Three epoxide hydrolases (EHases) genes (eeh1, eeh2, and eeh3) of *Erythrobacter litoralis* HTCC2594 were cloned in *E. coli*, and the recombinant proteins (rEEH1, rEEH2, and rEEH3) were purified. The functionality of purified proteins was proved by hydrolytic activities towards styrene oxide (SO). EEH1 preferentially hydrolyzed (R)-styrene oxide, whereas EEH3 preferred to hydrolyze (S)-SO, representing enantioselective hydrolysis of styrene oxide. EEH2 could hydrolyze (R)- and (S)-SO at an equal rate. The hydrolysis rate of EEH1 towards various epoxide substrates was superior to those of EEH2 or EEH3 (Woo et al. 2007). *Erythrobacter* sp. JCS358 also presents enantioselective epoxide hydrolyzing activity. Its performance was outstanding among marine strains isolated by the capability of living on SO and further screened for retaining enantioselective EHase activities towards SO (Hwang et al. 2008). *Altererythrobacter epoxidivorans* JCS350^T was described as presenting EHase activity, but it was not reported if this activity was enantioselective (Kwon et al. 2007). Pharmaceutical industries are eager for enantioselective EHases for the production of enantiopure epoxides.

[2]Departmento de Parasitologia, Universidade Federal Rural do Rio de Janeiro (UFRRJ), Seropédica, RJ, Brazil

Abstract
The *Holosporaceae* family (Görtz H-D, Schmidt HJ (2005) Genus *Holospora*. In: Garrity et al. (eds) Bergey's manual of systematic of bacteriology, vol 2, part C, 2nd edn. Springer, New York, pp 149–151) in the *Rickettsiales* order (Gieszczykiewicz 1939) includes a group of gram-negative bacteria without motility and obligatory symbionts. Routinely, these bacteria occupy specific compartments in their host cells, which are generally rich in metabolites (Heckmann, K. Görtz H-D (1991) Procaryotic symbionts of ciliates. In: Balows A, Trüper HG, Dworkin M, Harder W, Schleifer K-H (eds) The prokaryotes, 2nd edn. Springer, Berlin/Heidelberg/New York, pp 3865–3890; Fokin and Karpov, Endocyt Cell Res 11:81–94, 1995). Individuals of this family are mostly endosymbionts of ciliated protozoa of the genus *Paramecium* (Müller 1772) that parasitize, according to the species, the macronucleus and micronucleus. The family has only one consolidated genus, *Holospora*, and others seven genera considered to be *incertae sedis* in this family, including *Caedibacter, Lyticum, Odyssella, Paracedibacter, Pseudocaedibacter, Pseudolyticum*, and *Tectibacter* (Fujishima and Fujita, J Cell Sci 76:179–187, 1985). However, *Lyticum* was recently moved to the *Midichloriaceae* family (Boscaro et al., Microb Ecol 65:255–267, 2013). Among those cited, *Holospora* and *Caedibacter* are commonly studied. Thus, *H. obtusa*, *H. caryophila*, and *H. curviuscula* are parasitize the macronucleus of *P. caudatum* and *P. biaurelia*; *H. elegans*, *H. undulate*, and *H. accuminata* can be found in micronucleus of *P. caudatum* and *P. bursaria*. The specificity for the host does not occur only by the success of cell penetration, which demonstrates that the specificity for a habitat is influenced by nuclear genes (Fujishima and Fujita, J Cell Sci 76:179–187, 1985). Its distribution is still not clearly defined, but it is believed to be associated with the distribution of its host (Fokin et al., Eur J Protistol 32:19–24, 1996).

Taxonomy, Historical and Current

Short Description of the Family and Their Genera

The taxonomy was described by Garrity et al. (2004):

Domain Bacteria (Haeckel 1894) C.R. Woese et al. 1990
Phylum Proteobacteria Garrity et al. 2005
Class *Alfaproteobacteria* Garrity et al. 2006
Order *Rickettsiales* (Gieszczykiewicz 1939) Dumler et al. 2001
Family *Holosporaceae* Görtz and Schmidt 2005.

Holosporaceae Hans-Dieter Görtz and Helmut J. Schmidt 2005, 351[VP]

Ho.lo'spo.ra.ce.ae. Gr. Fem. Adj. *holos* whole, complete; Gr. N. *sporus* seed; M.L. n. *spora* spore; M.L. fem. N. *Holospora* whole spore; *-ceae* ending to denote family; *Holosporaceae* family of *Holospora* bacteria.

Type genus: *Holospora* (ex Hafkine 1890) Gromov and Ossipov 1981, 351[VP].

Genus *Holospora (ex* Hafkine 1890) nom. rev., emend. (Ho.lo'spci.ra. Gr. adj. *holos* whole, complete; Gr. noun *sporus* seed; M.L. noun *spora* spore; M.L. fem. noun *Holospora* whole spore.). This genus is consolidated within the *Holosporaceae* family, with nine *Holospora* species described (Fokin et al. 1996; Garrity et al. 2005; Rautian and Wackerow-Kouzova 2013): *Holospora caryophila, Holospora bacillata, Holospora curvata, Holospora obtusa, Holospora undulata, Holospora elegans, Holospora recta, Holospora acuminate*, and *Holospora curviuscula*.

The *Holosporaceae* family has been undergoing constant changes based on studies being conducted. However,

E. Rosenberg et al. (eds.), *The Prokaryotes – Alphaproteobacteria and Betaproteobacteria*, DOI 10.1007/978-3-642-30197-1_264,

Table 10.1

Main characteristics of *Holosporaceae* in relation to other principal families of the *Rickettsiales* order: *Rickettsiaceae* and *Anaplasmataceae*

Character	*Holosporaceae*	*Rickettsiaceae*	*Anaplasmataceae*
Morphology[a]	Two forms:	Diplococcus-shaped, rod shaped, coccoid	Two forms: dense-core and reticulate bodies
	Reproductive form (short rod, 1.0–3.0 × 0.5 μm)		The mulberry-like appearance of the inclusions has led to the use of the term "morulae"
	Long infectious form (5.0–20.0 μm)		
Gram type	Gram negative[a]	Gram negative[a]	Gram negative[a]
Motility	Nonmotile[a]	Only *Candidatus* Trichorickettsia mobilis and *Candidatus* Gigarickettsia flagellate (these organisms possess flagella and swimming behavior inside the host cell)[b]	Nonmotile[a]
		The other specimens of this family are not motile[a]	
Acting	Obligate symbiont of protist[a]; invade host nuclei or cytoplasm[c]	Obligately intracellular (residing free in the cytoplasm or infecting the nucleus of eukaryotic host cell, depending on the species)[a]	Obligately intracellular[a] (the organism grows within cytoplasmic vacuole, infects many types of cells, as erythrocytes, granulocytes, platelets, mononuclear phagocytes, trematodes cells[d], arthropods ovaries[e])
G + C content of DNA (Mol%)	Not determined[a]	29–33[a]	30–56[a]

[d]Occur in *Neorickettsia* genus
[e]Occur in *Wolbachia* genus

independent of these suggestions and assumptions, the previous classification has been maintained. This family is included in the order *Rickettsiales*; its particular characteristics are compared with neighboring families of this order, as described in *Table 10.1*.

Regarding the context of the evolution of the whole order *Rickettsiales* (Weinert et al. 2009), a molecular clock to date the divergence of different groups showed that the common ancestor was presumably free-living. According to Weinert et al. (2009), approximately 525–775 million years ago there was a transition to living within cells, followed by a split into agent groups that originated in the *Rickettsiales* order, endosymbionts of protists (*Holospora*) and a clade that primarily infects arthropods.

Phylogenetic Structure of the Family and Its Genera

Holosporaceae is a family that belongs to *Rickettsiales* order, which has two more families, *Anaplasmataceae* and *Rickettsiaceae*, that have being known for a long time. Two new families were proposed recently: *Pelagibacteraceae* (Thrash et al. 2011) and *Midichloriaceae* (Montagna et al. 2013) (*Fig. 10.1*).

Although Garrity et al. (2004) infer that, with the exception of *Holospora*, all should be listed as "genus *incertae sedis*", many studies (Birtles et al. 2000; Baker et al. 2003; Garrity et al. 2005; Eschbach et al. 2009; Georgiades et al. 2011; Nunan et al. 2013; Boscaro et al. 2013) try to prove that other genera may be included, such as *Candidatus* Captivus, *Candidatus* Gortzia, *Candidatus* Hepatobacter, *Candidatus* Paraholospora, *Candidatus* Paracaedibacter, *Caedibacter*, *Odyssella*, and others unclassified *Holosporaceae*.

According to Lee et al. (2005), it is ambiguous to classify endosymbionts as a taxon based on 16S rRNA gene sequence analysis because of the inconsistency in defining the boundaries of a taxon with low bootstrap values, such as those found in this study (69 %). They suggest that more extensive studies for endosymbionts should be carried out to allow definite taxonomic conclusions to be made.

Ferla et al. (2013) studied phylogenies with a new rRNA gene based on the *Alphaproteobacteria* to provide perspective on major groups, mitochondrial ancestry, and phylogenetic instability. They proposed three subclasses within the *Alphaproteobacteria*: the *Caulobacteridae*, the *Rickettsidae*, and the *Magnetococcidae*. They concluded that the *Holosporaceae* did not belong more to the *Rickettsiales*, so a new order should be created, named *Holosporales* and belonging to Caulobacteridae. This would insert the *Holosporaceae* family into this classification (*Fig. 10.2*). However, this study is still very recent and additional proposals may emerge with new studies on phylogeny.

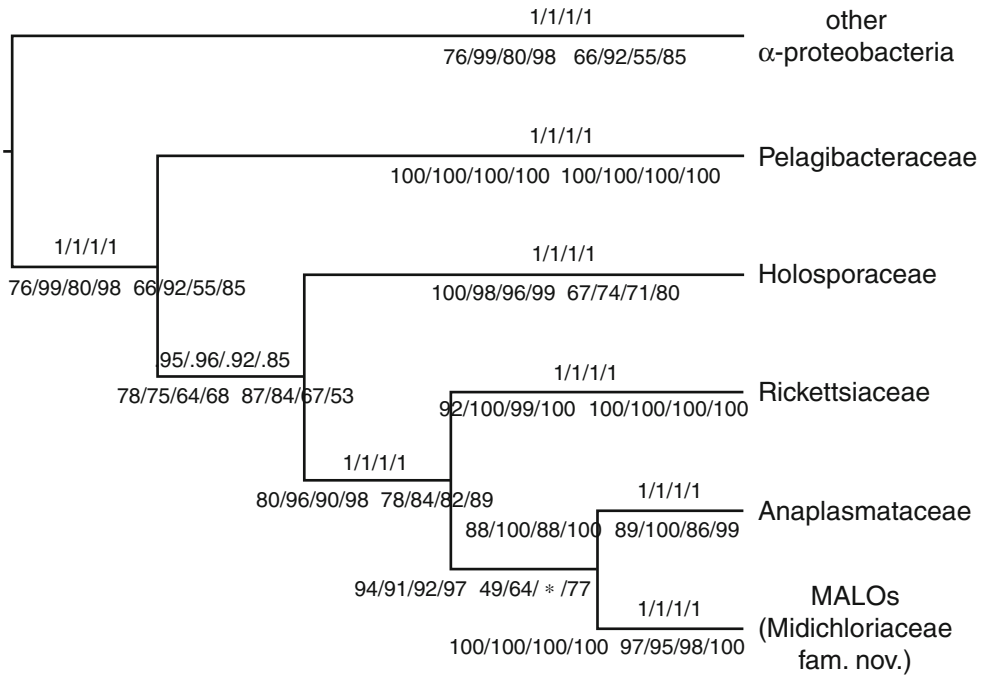

Fig. 10.1
Cladogram of the four *Rickettsiales* families, including *Holosporaceae* and *Midichloriaceae*, based on four 16S rRNA gene sequencing. The *asterisk* represents the sole branch that does not agree with the majority-rule consensus cladogram (Montagna et al. 2013)

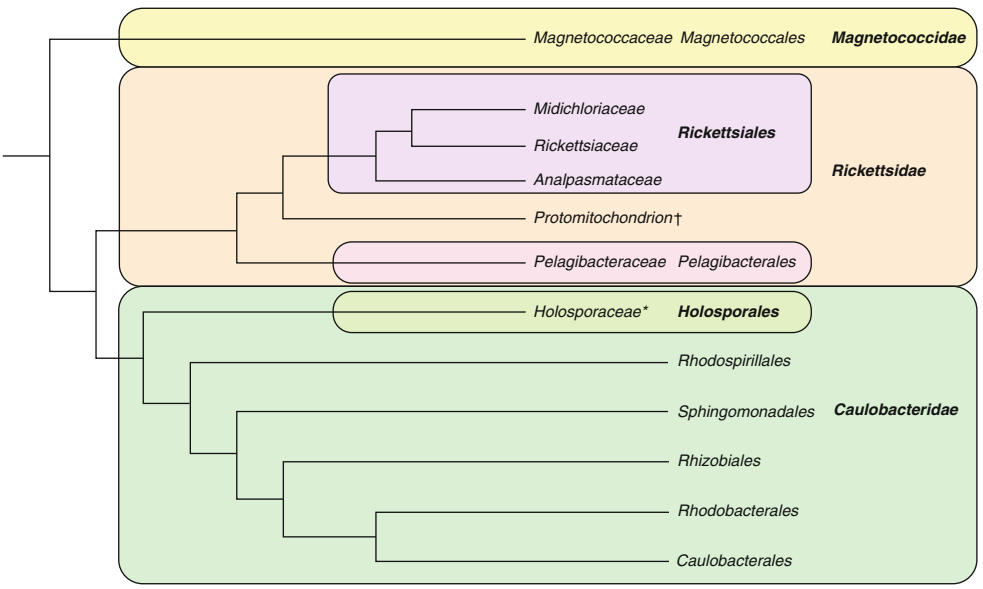

Fig. 10.2
Proposed subclasses of the *Alphaproteobacteria* (Ferla et al. 2013)

Molecular Analyses

The main studies on alphaproteocbacteria focus on the possible association with mitochondrial origin (Ferla et al. 2013) and the relationship of the symbiosis of species belonging to the *Holosporaceae* family with free-living protists. A study carried out by Lang et al. (2005), which analyzed the *H. obtusa* genome, showed that α-proteobacterial endosymbionts represent an unpredicted extensive diversity, both phylogenetically and metabolically. According to these authors, the complete genome sequence of *H. obtusa* will be the key to better understanding eukaryotic host–pathogen interactions. These results plus new investigations may also be able to provide insight into the early history of mitochondrial endosymbiosis.

Concerning *Holosporaceae*-like endosymbionts, many studies use microorganisms belonging to the *Holospora* genus to understand the mechanism of infection of Paramecia (Nunan et al. 2013) and investigate the effects on different aspects of parasite life history (Nidelet et al. 2009), for example. In a study with *Rickttsiales*-like endosymbionts, Baker et al. (2003) detected intervening sequences (IVSs) in their 16S rRNA genes. They concluded that IVSs are uncommon in rRNA genes and seem to be restricted to bacteria that live in close association with eukaryotes. In this study, the secondary structure predictions of the IVSs were made with DNA mfold analysis, a web server that is used for nucleic acid folding and hybridization prediction (Baker et al. 2003). The function of IVSs remains unknown (Pronk and Sanderson 2001), but their formation may be part of the overall process of adapting to a close working relationship with a eukaryotic host, which in bacterial endosymbionts includes genome reduction and lateral gene transfer to hosts (Andersson et al. 1998). Perhaps the IVSs specifically contribute to the likely increased communication that is required between the host and endosymbiont. In support of this hypothesis, IVSs investigated at the RNA level are all excised from the transcribed rRNA and have pronounced secondary structure suggestive of a functional RNA independent of the ribosome, but transcriptionally linked to protein production in the endosymbiont and, in some cases, the host.

Analysis of molecular variance (AMOVA) is a technique of estimating population differentiation directly from molecular information and testing suppositions about such diversity. A multiplicity of molecular data, including molecular marker data (e.g., Restriction fragment length polymorphism (RFLP) or Amplified fragment length polymorphism (AFLP)), direct sequence data, and phylogenetic trees based on such molecular information, may be analyzed using this method (Excoffier et al. 1992). A study based on the analysis of all 16S rRNA gene sequences for available *Rickettsiales* taxonomically plus 16S rRNA gene sequences available for a new family description (Montagna et al. 2013) used the method mentioned above, which was used to perform this analysis for the four *Rickttsiales* families.

Different methods are used for molecular analysis, such as AMOVA. The generalized mixed yule coalescent (GMYC) method is a likelihood method for delimiting species by fitting within- and between-species branching models to reconstructed gene trees (Fujisawa and Barraclough 2013). Principal-coordinate analysis (PCoA) (Gower 1966) is another common ordination method for data organized into distance matrices (Sneath and Sokal 1973); it is used to place the analyzed species/operational taxonomic units in a new coordinate system.

An analysis by Montagna et al. (2013) aimed to detect evolutionarily significant units within the *Rickettsiales* and the *Midichloria* and like organisms clades through the GMYC method. These authors developed for the detection of evolutionary significant units within a given data set based on a maximum-likelihood approach, which has also been applied to a 16S rRNA gene sequence data set from prokaryotes. The results obtained by different approaches (i.e., phylogeny, GMYC, PCoA, and AMOVA) indicate that current evidence places the family of ciliate-infecting bacteria *Holosporaceae* as the sister group of the lineage leading to *Rickettsiaceae*, *Anaplasmataceae*, and "*Candidatus* Midichloriaceae" Montagna et al. (2013). Although the method has been widely used, it has not previously been described in detail or evaluated fully against simulations of alternative scenarios of true patterns of population variation and divergence between species. Thus, the findings of Fujisawa and Barraclough (2013) support the robustness of GMYC as a tool for delimiting species when only single-locus information is available.

According to Reid and Carstens (2012), the GMYC model can be useful under a wide variety of circumstances, particularly in cases where divergences are deeper or taxon sampling is incomplete, as in many studies of ecological communities. However, in accordance with expectations from coalescent theory, rapid recent radiations may yield inaccurate results.

Fluorescence in situ hybridization (FISH) is a powerful technique used in the detection of chromosomal abnormalities. The high sensitivity and specificity of FISH and the speed with which the assays can be performed have made this technique a pivotal cytogenetic technique that has provided significant advances in biomedical research (Bishop 2010).

In a study by Boscaro et al. (2013) of the *Rickettsiales* order, the FISH technique was used with transmission electron microscopy, 16S rRNA gene sequencing, and phylogenetic analysis to reassess the de *Lyticum* genus. Hybridizations were performed with the specific oligonucleotide probes and Paramecium strains containing different alphaproteobacterial symbionts were employed as negative controls. This genus was framed as "*incertae sedis*" within the *Holosporacea* family (Garrity et al 2005). This research work using different techniques, including FISH, defined this genus as belonging to a new *Midichloriaceae* family (*Fig. 10.3*) (Boscaro et al. 2013).

Other molecular research was undertaken for the *Holosporaceae* family. Sequences of 1,312 and 1,293 bp were obtained for two main species, *H. obtusa* and *H. undulata*, respectively. The similarity values calculated by BLASTN with the sequence of *H. obtusa* X58198 were 99.5 % and 98.5 % (Boscaro et al. 2013). No data were found about the number of chromosomes, although *H. obtusa* and *H. undulata* were included in GenBank (NCBI 2014).

Genome

Dorah and collaborators (2013) presented the draft genome sequence of *H. undulata* strain HU1, which provides insight into the symbiotic strategy of this organism. This genome was sequenced and found to contain 1,420 protein-coding sequences, of which 650 (46 %) are hypothetical proteins without any known functions. Among the 1,420 proteins, 857 proteins (60 %) were assigned to different functional categories of National Center for Biotechnology Information (NCBI) Clusters of Orthologous Groups (COG). Eighty-six

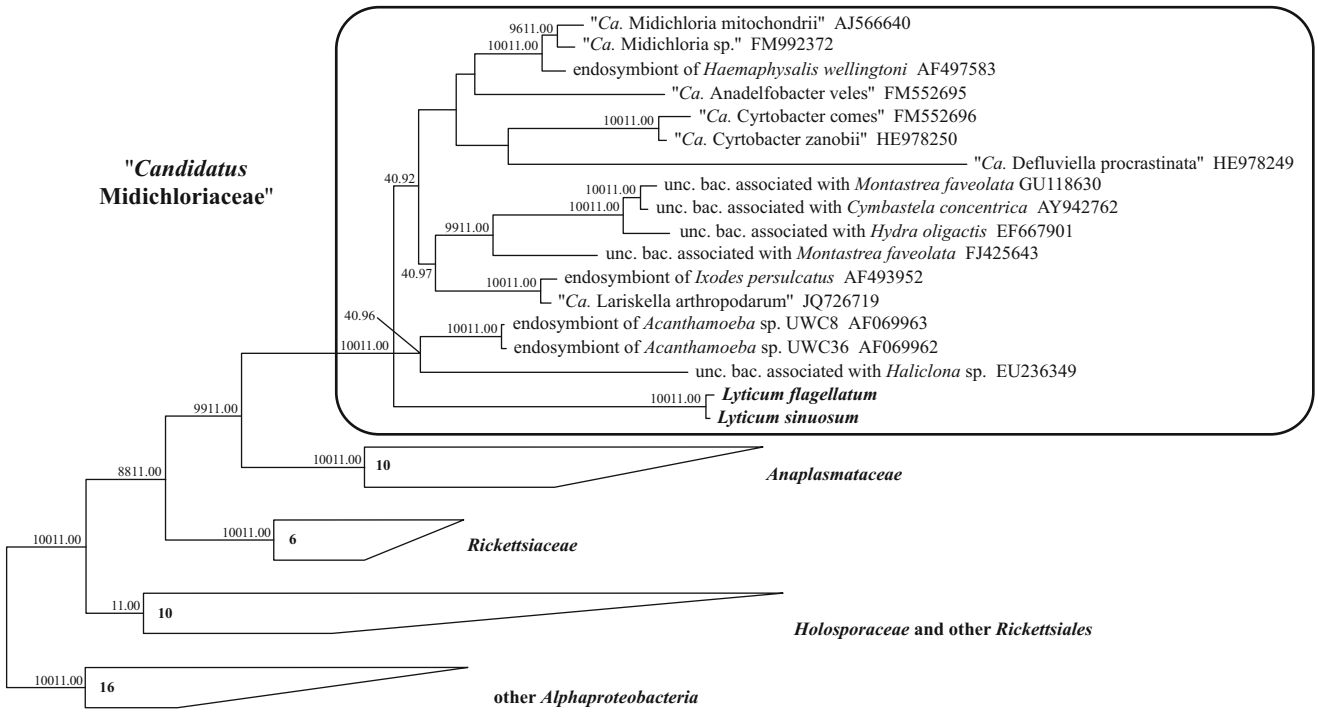

Fig. 10.3
Phylogenetic position of *Lyticum* species (Boscaro et al. 2013)

proteins were allocated to multiple COG categories. The most plentiful COG category was "Replication, recombination, and repair" (186 proteins) followed by "Translation, ribosomal structure, and biogenesis" (125 proteins), and "Cell wall/membrane/envelope biogenesis" (86 proteins). This genome represents a valuable resource for future genomic studies. The sequencing results are archived in the DNA Data Bank of Japan (DDBJ) Sequence Read Archive (DRA) database with accession number DRA001008. The *H. undulata* strain HU1 draft genome sequence has been included in GenBank with the accession number ARPM00000000 (Dorah et al. 2013).

In the NCBI database, currently the only species described with the *Holosporaceae* genome were *H. obtusa* and *H. undulate*, and both were deposited by Yamaguchi University. For the *H. obtusa* F1 strain, the total sequence length is nearly 1,334, the number of contigs is 91, and the Contig N50 has a total of 24,415. The accession number is GCA_000469665 (NCBI 2014c). The *H. undulate* HU1 strain, after actualizations, was deposited in GenBank with accession number GCA_000388175, with a total sequence length nearly of 1,402; the number of contigs represents 208, and Contig N50 had a total of 10,714 (NCBI 2014c).

Phages

It is not clear if phages exist in the *Holosporaceae* family. However, the presence of phage particles has been found in infections initiated by *Rickettsiales*-like organisms in marine bivalves (Darriba et al. 2012).

No descriptions for the *Holospora* species were found. However, endosymbiotic bacteria belong to *Caedibacter* genus, which is a "*incertae sedis*" genus of *Rickettsiales*; they were observed to inhabit the cytoplasm of the freshwater ciliate *Paramecium novaurelia*. The bacteria conferred a killer trait to their host. The production of a proteinaceous inclusion body ("R-body") in the bacterial cell makes them toxic to other paramecia after they become enclosed in food vacuoles. "R-bodies" of *Caedibacter* spp. were associated with phages, which are known in most other *Caedibacter* species to code for the R-body proteins (Kusch et al. 2000). Knowledge of the evolutionary history of *Caedibacter* will increase understanding of its species. In this unique symbiotic system, plasmids or phages induce bacterial hosts to produce "R bodies" and associated toxins, which provide their eukaryotic host cells with a selective advantage against closely related ciliates (Beier et al. 2002).

Phenotypic Analyses

A mutualistic relationship between bacteria and ciliate protozoa is very common (Görtz 1983; Fokin 2004). The bacterial symbionts have a short reproductive form (1.5–2 μm in length) and a long infectious form (5–20 μm in length) in their lifecycle. The short infectious form is observed in the nuclei of host cells,

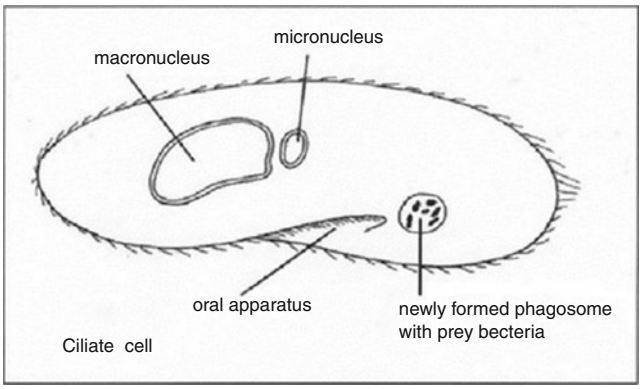

Fig. 10.4
The ciliate protozoa. Macronucleus and micronucleus are encircled by the nuclear envelope. The perinuclear space, between the nuclear envelope and the nucleus, can be colonized by bacterial symbionts. The oral apparatus (or cytostome) is where phagocytosis takes place (digestive vacuole) (Görtz 2006)

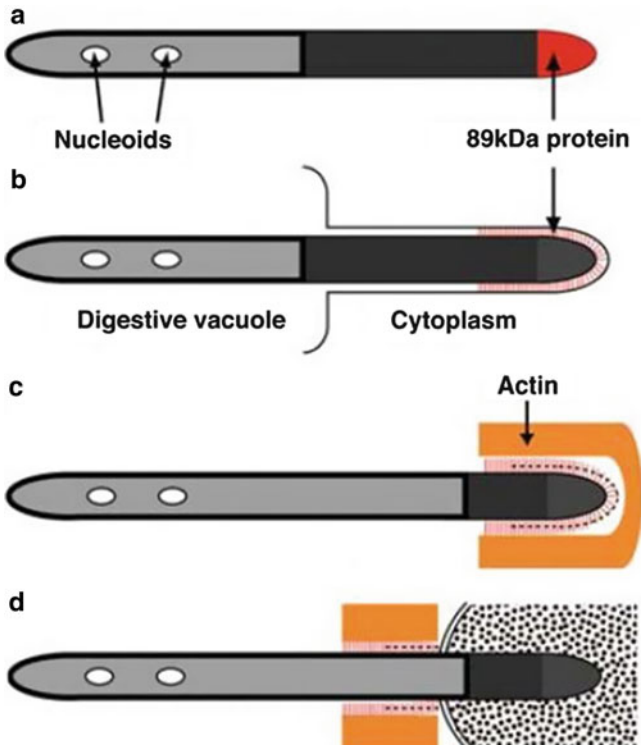

Fig. 10.5
The Infectious Form (IF) cell of *Holospora obtusa* model shows the 89-kDa-protein translocation and actin-based movement. (a) The 89-kDa-protein in the invasion tip of *H. obtusa* IF cell. (b) The vacuole membrane surrounds the bacteria starting from the invasion tip, forming the digestive vacuole in the host cell. A fibrous structure is formed between the bacteria and digestive vacuole membrane. (c) The host actin accumulates around the invasion tip in the cytoplasm. (d) In the macronucleus, the 89-kDa-protein, the actin, and the fibrous products are left behind (Masahiro 2009)

mainly in vegetative growth. The long infectious form is observed in the nuclei of starved cells; this can only infect the specific nucleus through the food vacuole, where a homogenate of bacteria-bearing cells is added to homogenized bacteria-free cells (Fujishima and Gortz 1983).

Holospora obtusa, an extensively studied obligate macronuclear endobiont of the ciliate *Paramecium caudatum*, has an infectious stage of rod-like cells (10–20 μm long) and a vegetative stage (1–3 μm long) of short cells. Morphologically, three compartments can be distinguished: the nucleoplasm, the periplasm, and the invasion tip (Görtz and Wiemann 1989).

The long infectious form of *H. obtusa* and *Holospora elegans* always enters the nuclear membrane with one of its ends. This special end of the bacterium, responsible for the nucleus entrance, can be distinguished from the other end by optical and electron microscopy as non-refractive and electron lucent. This special end is never observed in reproductive short forms (Görtz 1983). This end of *Holospora* appears to have a role in nucleus infectivity and specificity in the flagellates' protozoa. The process of entering the macronucleus or micronucleus takes about 1 h to occur (Görtz 1986), depending on the bacteria species.

Members of the spotted fever group in *Rickettsiaceae* induce polymerization of the host actin in entering hosts' cytoplasm (Heinzen et al. 1993, 1999; Gouin et al. 1999). A similar mechanism is used by *Holospora*, which forms a comet-tail-like structure around the periplasm when it is migrating through the host cytoplasm (Görtz and Wiemann 1989); the 89-kDa-protein in the special end has two actin-binding motifs. In addition of the 89-kDa-protein, this special end is called the invasion tip; it forms a fibrous structure between the bacteria and the digestive vacuole (*Fig. 10.4*). This is important for polymerization of the host's actin, the escape from the host's digestive vacuole, and the invasion of host's macronucleus (*Fig. 10.5*).

On the second day after infection of the ciliate protozoa by bacteria, almost all bacteria are still in long shapes. If these cells are transferred to a culture medium at this stage, the distribution of bacteria occurs to daughter cells without multiplication. On the third day after infection, the bacteria are in long shapes of 15 μm in length, producing about 10 reproductive short forms of 1–5 μm in length. This short form can multiply by binary fission in the host macronucleus (Fujishima and Fujita 1985).

After infection of the *Paramecium multimicronucleatum* macronucleus, bacteria multiply for 2–5 days, forming aggregates. These aggregates disappear from the host cell macronucleus around 6–12 h after the development of the first aggregate; this phenomenon occurs synchronously in all infected cells. It is still not clear if the bacteria disappear within the macronucleus or after migrating to the cytoplasm (Fujishima and Fujita 1985). Fokin et al. (2005) indicated that *P. multimicronucleatum* cells have some kind of defensive reaction against bacterial infection.

Isolation, Enrichment and Maintenance Procedures

Isolation and Enrichment

Ecology

About the biologic cycle, bacteria from this family reproduce into protozoans and possess two forms: reproductive (short cells) and infecting (long cells). In experiments with *P. multimicronucleatum*, Fok and Alen (1988) observed that the digestive vacuole (DV) of *Paramecium* can be classified into four stages, according to the penetration of infective forms of *Holospora*. When the long cells penetrate in the first form of DV (DVI), the fusion of acidisome (the organelle function of producing medium acidification) occurs. This acidification causes the bacteria to be expelled from the DVI and migrate into the macro- and micronuclei. On reaching the macronucleus or micronucleus (*H. obtusa* and *H. undulata*, respectively), the short form is multiplied by binary fission, subsequently to suffer differentiation and elongation to give rise to the long (infective) form, with the latter being able to parasite a new cell. This multiplication follows the growth of the protozoan and ceases when *Paramecium* is ingested by a host. The inhibition of protein synthesis occurs (interrupting the multiplication process) and begins the maintenance phase, distributing short forms of the nucleus of the protozoan until saturation of the medium occurs, thus promoting the death of the parasite. This allows new infectious forms to fall into the extracellular environment, which are able to infect a new cell (Dohra and Fujishima 1999; Fujishima et al. 2012). Still in the reproduction process, the infecting forms are expelled from the DVI and possibly penetrate other phases of DV, but they are not able to multiply inside the *Paramecium* and they are excreted through the cytoproct (*Fig. 10.6*).

The *Holospora* genus is composed mainly of two species, *H. undulata* and *H. obtusa*. The major differences between the species are related to the cellular type that is parasitic and to the size of its evolutive forms. *H. undulata* develops in the micronucleus of *P. caudatum*; the vegetative cells are slender and are up to 3 μm in length, whereas the infecting forms are sinuous filaments about 16 μm in length. *H. obtusa* develops in the macronucleus of *P. caudatum*; the vegetative portion is rounded and is about 3 μm in length, whereas infecting cells are lines and long, approximately 18 μm in length (Gromov and Ossipov 1981).

Caedibacter, as cited above, is am "incertae sedis" genus. It is the only one capable of producing refrateis inclusion bodies. These bodies are extended approximately 10 μm in length and are coils within the bacterial cells. As a cell is phagocytized, its bodies are unwound. These bodies are structures that possess the function of producing a major infection in the parasitized protozoan. When the *Paramecium* is parasitized by *Caedibacter*, it

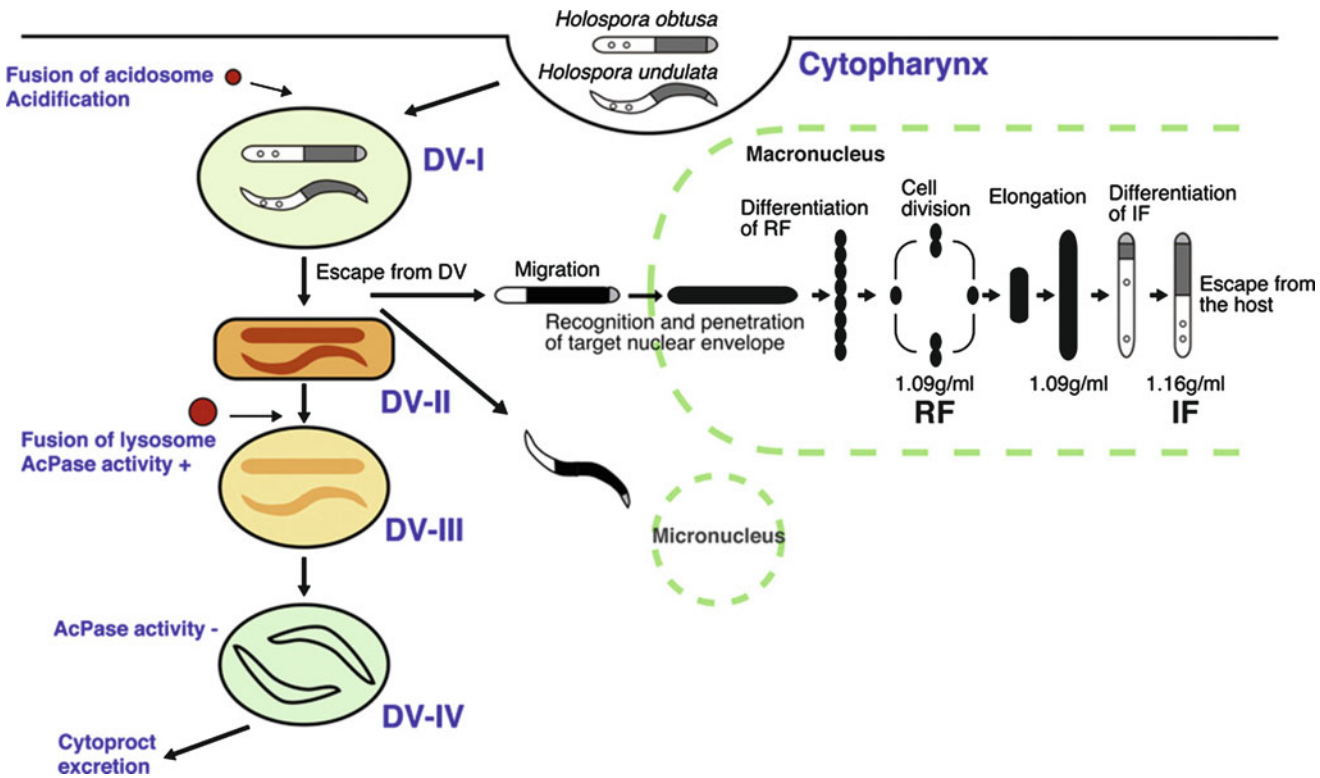

Fig. 10.6
Infection process and lifecycle of the *Holospora* species (Fujishima and Kodama 2012)

gets an ecological advantage in the niche it inhabits. These bacteria are eliminated permanently through a structure called the cytopyge. In *Paramecium* environments, when non-parasitized agents ingest bacteria, a change occurs in the pH of unfolding inclusion bodies, promoting a pathogenic action to *Paramecium* to be free of *Caedibacter*. This mechanism gives the parasitized *Paramecium* a selective advantage over competitors (Beier et al. 2002; Schrallhammer 2010). Morphologically, *Caedibacter taeniospiralis* presents rods of 0.4–0.7 × 1.0–2.5 μm, which are found at cytoplasm of *P. tetraurelia. C. caryophilus* is found in the macronucleus of *P. caudatum*, with refractory bodies measuring 1–1.5 × 0.4 μm. *C. paraconjugatus* show small rods and less than 1 % of cell have refractory bodies, having little infectivity to other *Paramecium*; they are found mainly in *P. biaurelia* (Schrallhammer 2010).

Members of this family have difficulty growing in a cultivated medium (Schmidt et al. 1987; Amann et al. 1991; Springer et al. 1993). When these bacteria are cryopreserved, good viability is observed without loss of infectivity. *H. obtusa* remained viable at −85 °C and −20 °C for up to 24 weeks (Fujishima et al. 1991). Fujishima et al. (1991) observed that the infectivity of *Holospora* is influenced by variations in its physical-chemical conditions because of verified major changes when subjected to high temperatures and large variations in pH. Thus, the bacteria lose their infective power when the temperature reaches around 30 °C and when pH undergoes major changes. However, the same study found that enzymes and other chemicals do not exert significant effects on *Holospora* infection in protozoa.

Pathogenicity and Clinical Significance

Members of this family are parasitic protozoan ciliates. Thus, they do not having pathogenicity or clinical relevance to vertebrates. However, they do act as causative agents in a poly-infection of necrotizing Hepatopancreatite of shrimp, which is a disease caused by *H. obtusa* and *C. caryophilus* that causes losses in shrimp production in Texas (Loy et al. 1996).

Application

The *Holosporaceae* family is highlighted in studies involving ecological relationships. It is a suitable model for research involving endosymbiosis because the relationship between *Paramecium* and *Holospora* is one of the most successfully studied to elucidate issues related to the origin of mitochondria. It is known that this organelle evolved from endosymbiosis between a unicellular organism and α-proteobacteria. This theory was enhanced when it was determined that the mitochondrial DNA (mtDNA) has a bacterial genome. Knowledge about α-proteobacteria, which was originally the mitochondria, is still a mystery despite persistent research (Burger and Lang 2003; Lang et al. 2005). Hori and Fujishima (2003) demonstrated that these bacteria promote the expression of heat shock protein hsp70, which is involved in stress-related physiological responses caused by variations in temperature and salinity. This increases the survival of these protozoa, which are extremely sensitive to such variations (Wichterman 1986).

11 The Family *Hyphomicrobiaceae*

Aharon Oren[1] · *Xue-Wei Xu*[2,3]
[1]Department of Plant and Environmental Sciences, The Institute of Life Sciences, The Hebrew University of Jerusalem, Jerusalem, Israel
[2]Laboratory of Marine Ecosystem and Biogeochemistry, State Oceanic Administration, Hangzhou, People's Republic of China
[3]Second Institute of Oceanography, State Oceanic Administration, Hangzhou, People's Republic of China

Abstract
The family *Hyphomicrobiaceae*, first proposed in 1950, is affiliated with the *Alphaproteobacteria*. Currently (June 2012) it

E. Rosenberg et al. (eds.), *The Prokaryotes – Alphaproteobacteria and Betaproteobacteria*, DOI 10.1007/978-3-642-30197-1_257,

encompasses 18 genera: *Hyphomicrobium* [type genus], *Ancalomicrobium*, *Angulomicrobium*, *Aquabacter*, *Blastochloris*, *Cucumibacter*, *Devosia*, *Dichotomicrobium*, *Filomicrobium*, *Maritalea*, *Methylorhabdus*, *Pedomicrobium*, *Pelagibacterium*, *Prosthecomicrobium*, *Rhodomicrobium*, *Rhodoplanes*, *Seliberia*, and *Vasilyevaea*, with a total of 54 species. Morphologically and physiologically the family is highly diverse. Many representatives are characterized by the presence of prosthecae, and many species divide by budding. Many prosthecate species are oligocarbophilic, thriving only in the presence of low concentrations of suitable carbon sources and unable to grow in rich media. Most are aerobic chemoheterotrophs. A few representatives can grow anaerobically by denitrification or mixed-acid fermentation. *Blastochloris*, *Rhodomicrobium*, and *Rhodoplanes* are genera of facultative photoheterotrophs. Facultative chemolithotrophy with hydrogen and/or reduced sulfur compounds is also encountered. Representatives of the family can be found worldwide in soils, freshwater lakes and streams, and also in the marine environment.

Taxonomy, Historical and Current

Family *Hyphomicrobiaceae* (Babudieri 1950 589[AL])

Hy.pho.mi.cro.bi.a.ce'ae. N.L. neut. n. *Hyphomicrobium*, type genus of the family; *-aceae* ending to denote a family; N.L. fem. n. *Hyphomicrobiaceae*, the *Hyphomicrobium* family.

The family *Hyphomicrobiaceae*, consisting of Gram-negative bacteria, was circumscribed on the basis of phylogenetic analysis of 16S rRNA sequences. The family is affiliated with the *Alphaproteobacteria*, order *Hyphomicrobiales*. The family is phenotypically, metabolically, and ecologically diverse. Many members reproduce by budding. The family includes organisms that are chemoheterotrophic, facultatively methylotrophic, facultatively chemolithoautotrophic, and photosynthetic (Garrity et al. 2005).

Type genus: *Hyphomicrobium*.

The mol% G+C of the DNA varies between 49 and 72.

At the time of writing (June 2012), the family contained 18 genera with 54 species whose names have standing in the nomenclature (*Tables 11.1–11.9*): *Hyphomicrobium* [type genus] (ten species, including one for which the type is no longer available), *Ancalomicrobium* (one species), *Angulomicrobium* (two species), *Aquabacter* (one species), *Blastochloris* (three species), *Cucumibacter* (one species), *Devosia* (13 species), *Dichotomicrobium* (one species), *Filomicrobium* (two species), *Maritalea* (three species), *Methylorhabdus* (one species), *Pedomicrobium* (species, including one for which the type is no longer available), *Pelagibacterium* (two species), *Prosthecomicrobium* (two species), *Rhodomicrobium* (one species), *Rhodoplanes* (four species), *Seliberia* (one species), and *Vasilyevaea* (two species).

Based on 16S rRNA sequence comparisons, a number of taxonomic rearrangements have been made in the past:

1. Reclassification of organisms formerly classified within the *Hyphomicrobiaceae* into other families:
   - The transfer of *Hyphomicrobium neptunium* (Leifson 1964) to the genus *Hyphomonas* (family *Hyphomonadaceae*, order *Caulobacterales* within the *Alphaproteobacteria*) as *Hyphomonas neptunium* (Moore et al. 1984) comb. nov.
   - The reclassification of *Hyphomicrobium indicum* (Johnson and Weisrock, 1969) as *Photobacterium indicum* (family *Vibrionaceae* in the *Gammaproteobacteria*) (Ivanova et al. 2004; Xie and Yokota 2004).
   - The transfer of *Prosthecomicrobium litoralum* (Bauld et al. 1983) and *Prosthecomicrobium consociatum* (Vasil'eva et al. 1991; Vasil'eva et al. in Validation List no. 127, 2009) to the newly established genus *Bauldia* (yet to be assigned to a family) as *Bauldia litoralis* comb. nov. and *Bauldia consociata* comb. nov. (Yee et al. 2010).
2. Placement of organisms earlier attributed to other groups as new members of the family:
   - The transfer of "*Pseudomonas riboflavina*" (Foster 1944) to become the type species of the new genus *Devosia* as *Devosia riboflavina* (Nakagawa et al. 1996).
   - The reclassification of *Rhodopseudomonas rosea* (Janssen and Harfoot 1991) to become the type species of the new genus *Rhodoplanes* as *Rhodoplanes roseus* comb. nov. (Hiraishi and Ueda 1994).
   - The reclassification of "*Rhodopseudomonas cryptolactis*" (Stadtwald-Demchick et al. 1990), a name that was effectively published but not validated, as *Rhodoplanes cryptolactis* (Okamura et al. 2007).
   - The transfer of *Rhodopseudomonas viridis* (Drews and Giesbrecht 1966) and *Rhodopseudomonas sulfoviridis* (Keppen and Gorlenko 1975) to the newly established genus *Blastochloris* as *Blastochloris viridis* and *Blastochloris sulfoviridis*, respectively (Hiraishi 1997).
3. Rearrangements within the *Hyphomicrobiaceae*, which include the following:
   - The transfer of *Prosthecomicrobium enhydrum* (Staley 1968) and *Prosthecomicrobium mishustinii* (Vasil'eva et al. 1991; Vasil'eva et al. in Validation List no. 127, 2009) to the new genus *Vasilyevaea* as *Vasilyevaea enhydra* comb. nov. and *Vasilyevaea mishustinii* comb. nov. (Yee et al. 2010).
   - The proposal to consider the genus *Maritalea* (Hwang et al. 2009) as an earlier heterotypic synonym of *Zhangella* (Xu et al. 2009), thereby renaming *Zhangella mobilis* as *Maritalea mobilis* (Fukui et al. 2012).

Some sources, including the 2nd edition of *Bergey's Manual of Systematic Bacteriology*, classify the obligately anaerobic fermentative genus *Gemmiger* within the *Hyphomicrobiaceae*. Similar to many representatives of the *Hyphomicrobiaceae*, *Gemmiger* multiplies by budding. However, phylogenetically it belongs to the order *Clostridiales*, family *Ruminococcaceae*. Therefore it is not discussed in the framework of this chapter.

Table 11.1

The genera classified within the family *Hyphomicrobiaceae*, as of June 2012

Genus	Number of species	Type species	General properties
Hyphomicrobium [type genus]	10	*Hyphomicrobium vulgare*	Cells rod-shaped with pointed ends, or oval egg, or bean-shaped, producing monopolar or bipolar hyphae or prosthecae of varying length. Hyphae may be truly branched; secondary branches are rare. Multiply by budding of a daughter cell at one hyphal tip at a time. Mature buds become motile swarmers that break off and may attach to surfaces of other cells to form clumps or rosettes. Motility is lost soon after swarmer liberation and/or attachment. Aerobic, chemoorganotrophic. Growth can occur on mineral salts media without added carbon source, possibly resulting from the presence of volatile carbon and energy sources. Good growth with C1 compounds such as methanol and methylamine, Widely distributed in soils and aquatic habitats.
Ancalomicrobium	1	*Ancalomicrobium adetum*	Non-motile bacteria with conical cells, possessing 2–8 or more prosthecae 2–5 μm in length. Prosthecae are cylindrical and taper gradually. Prosthecae may be bifurcated. Cells multiply by budding. Buds are formed directly from the mother cell, never from prosthecae. Cells contain gas vesicles. Facultatively anaerobic chemoheterotrophs that use sugars aerobically and anaerobically. Sugars are fermented by mixed acid fermentation. Some organic acids are used aerobically but not fermentatively.
Angulomicrobium	2	*Angulomicrobium tetraedrale*	Obligately aerobic, chemoorganotrohpic non-motile bacteria, having polygonal (tetrahedral or mushroom-like) cells with radial symmetry. Division is by budding. Prosthecae and gas vesicles are absent. A variety of organic acids, monosaccharides and amino acids are used. Methanol and formate can serve as energy sources only in the presence of yeast extract.
Aquabacter	1	*Aquabacter spiritensis*	Unicellular encapsulated rod-shaped cells that may become motile by flagella. Aerobic and chemoorganotrophic, using organic acids and some amino acids as carbon source. Ammonium ions can serve as sole nitrogen source. Gas vesicles may be present.
Blastochloris	3	*Blastochloris viridis*	Rod-shaped to ovoid cells, motile by means of subpolar flagella. They exhibit polar growth, budding, and asymmetric cell division and form rosette-like aggregates. Internal photosynthetic membranes are present as lamellae underlying and parallel to the cytoplasmic membrane. Photosynthetic pigments are bacteriochlorophyll *b* and carotenoids. Ubiquinones and menaquinones are present. Preferentially grow photoheterotrophically under anoxic conditions in the light. Anaerobic photoautotrophic growth may occur with thiosulfate or sulfide as electron donor. Chemotrophic growth is possible under microoxic conditions in the dark.
Cucumibacter	1	*Cucumibacter marinus*	Rod-shaped cells, motile by means of monopolar flagella. Short prosthecae are present on the cell surface. Strictly aerobic and slight halophilic. Chemoheterotrophic, using a range of sugars and some amino acids as growth substrates. The major polar lipids are phosphatidylglycerol, diphosphatidylglycerol, and a number of unidentified lipids. The predominant cellular fatty acids are $C_{18:1\ \omega7c}$, 11 methyl $C_{18:1\ \omega7c}$ and $C_{18:0}$. The predominant quinone is Q-10.
Devosia	13	*Devosia riboflavina*	Rod-shaped, sometimes oval cells, motile by one or several polar flagella; rarely nonmotile. Aerobic, chemoheterotrophic; sugars are used aerobically as carbon source. The predominant quinone is Q-10 or Q-11. The major polar lipids are phosphatidylglycerol, diphosphatidylglycerol and unknown glycolipids. The major fatty acids are $C_{18:1\ \omega7c}$, 11-methyl $C_{18:1\ \omega7c}$ and $C_{16:0}$. 3-Hydroxy fatty acids such as $C_{10:0\ 3\text{-OH}}$, $C_{18:0\ 3\text{-OH}}$, $C_{24:1\ 3\text{-OH}}$ and $C_{26:1\ 3\text{-OH}}$ are present. A relatively high content of iso-$C_{15:0}$ or $C_{18:0}$ (> 10 %) occurs in several species.
Dichotomicrobium	1	*Dichotomicrobium thermohalophilum*	Tetrahedral to spherical cells with up to four prosthecae of 0.2–0.3 μm width and varying length. Cells and hyphae may be covered with short, rigid, bent pili. Hyphae and mother cells may branch dichotomously. Cells multiply by terminal bud formation on hyphae or by intercalary budding. Propagation cells are initially spherical or pear-shaped, later tetrahedral, and never motile. Obligately aerobic, moderately thermophilic and halophilic. Inorganic nitrogen compounds and urea

Table 11.1 (continued)

Genus	Number of species	Type species	General properties
			do not serve as nitrogen sources. Carbon sources are acetate, malate, succinate, and α-ketoglutarate.
Filomicrobium	2	*Filomicrobium fusiforme*	Non-motile fusiform or bean-shaped cells with several polar prosthecae, which are approximately 0.2 μm in diameter and up to 40 μm in length. Buds are formed at the tips of the prosthecae. Aerobic and chemoheterotrophic. Acetate is used as carbon source. Glucose is not fermented. Major cellular fatty acids are $C_{18:1\ \omega7c}$ and $C_{19:0\ \omega8c\ cyclo}$. $C_{14:0\ 3\text{-}OH}$, $C_{16:0}$ and $C_{18:2\ \omega7,13}$ are present in some species. The major respiratory quinone is Q-9.
Maritalea	3	*Maritalea myrionectae*	Rod-shaped cells, motile by means of a single polar flagellum or peritrichous flagella. Strictly aerobic and slightly halophilic, found in marine environments. Chemoheterotrophic; glucose can be used as sole carbon source. Major polar lipids are phosphatidylglycerol and several unidentified lipids. The content of diphosphatidylglycerol varies between species. Minor amounts of phosphatidylethanolamine can be detected. Major cellular fatty acids are $C_{18:1\ \omega7c}$ and 11-methyl $C_{18:1\ \omega7c}$. The predominant quinone is Q-10.
Methylorhabdus	1	*Methylorhabdus multivorans*	Nonmotile, non-pigmented rods that multiply by fission, with constriction. Nitrate is reduced to nitrite. Aerobic, chemoorganotrophic and. facultatively methylotrophic. C1 compounds (dichloromethane, methanol, methylamine) are assimilated via a variant of the serine pathway. The major quinone is Q-10. Major fatty acids include $C_{18:1\ \omega7}$, $C_{19:0\ cyclo}$ and $C_{16:0}$. Major phospholipids are phosphatidylethanolamine, phosphatidylglycerol, phosphatidylcholine and cardiolipin.
Pedomicrobium	4	*Pedomicrobium ferrugineum*	Oval, spherical or rod-shaped encapsulated cells with 1–5 hyphae. At least one hypha originates laterally; others may appear at the cell poles. Buds are formed at the tips of the hyphae. Mature buds either separate from the hyphae as uniflagellated swarmers or remain attached. Oxidized iron or manganese compounds are deposited on mother cells and later on hyphae. Swarmer cells are motile by a single subpolar or polar flagellum. Other stages of the cell cycle are nonmotile. Chemoorganotrophic. Acetate is utilized as a carbon source; most strains also grow on caproate or pyruvate. Organic nitrogen sources are generally required. The major respiratory quinone is Q-9. Found in podzolic and other soils, freshwater, iron springs and seawater.
Pelagibacterium	2	*Pelagibacterium halotolerans*	Motile aerobic heterotrophic bacteria that divide by binary division. Major polar lipids are phosphatidylglycerol, diphosphatidylglycerol and two unidentified glycolipids. Major fatty acids include $C_{19:0\ cyclo}$, $C_{18:0}$, $C_{18:0\ 3\text{-}OH}$, $C_{18:1}$ and $C_{16:0}$. The main respiratory quinone is Q-10, with Q-9 as a minor component.
Prosthecobacterium	2	*Prosthecomicrobium pneumaticum*	Unicellular motile or non-motile coccobacilli or rod-shaped cells containing numerous prosthecae extending from all locations on the cell surface. Prosthecae (10 to >30 per cell) are typically <1.0 μm in length; some species also produce longer prosthecae (>2.0 μm). Cells divide by budding. Buds are produced directly from the mother cell, never from the tips of prosthecae. Motile organisms produce single polar or subpolar flagella. One species forms gas vacuoles but no flagella. Obligately aerobic, nonfermentative heterotrophs, using a variety of sugars and organic acids.
Rhodomicrobium	1	*Rhodomicrobium vannielii*	Ovoid to elongate-ovoid bacteria showing polar growth with formation of peritrichously flagellated swarmer cells and non-motile ''mother cells'', which form long prosthecae. Daughter cells originate as spherical buds at the end of the prosthecae. Internal photosynthetic membranes are of the lamellar type. Photosynthetic pigments are bacteriochlorophyll *a* and carotenoids of the spirilloxanthin series. The predominant cellular fatty acid is $C_{18:1}$. Q-10 and RQ-10 are present. Cells grow preferentially photoheterotrophically under anoxic conditions in the light. Photoautotrophic growth may be possible with hydrogen and sulfide as electron sources. Various organic substrates, molecular hydrogen, ferrous ion, and sulfide at low concentrations may be used as photosynthetic electron donors. Cells can also grow under microoxic to oxic conditions in the dark. Freshwater bacteria with a preference for acidic pH between 5.2 and 6.5.

Table 11.1 (continued)

Genus	Number of species	Type species	General properties
Rhodoplanes	5[a]	*Rhodoplanes roseus*	Motile rod-shaped cells that multiply by budding and asymmetric cell division. Internal photosynthetic membranes are present as lamellar stacks parallel to the cytoplasmic membrane. Photosynthetic pigments are bacteriochlorophyll *a* and carotenoids of the spirilloxanthin series. $C_{18:1}$ and $C_{18:0}$ are the predominant components of the cellular fatty acids. Quinones are Q-10 and RQ-10. Growth is preferentially photoheterotrophic under anoxic conditions in the light, with simple organic substrates as carbon and energy sources. Photoautotrophic growth with sulfide as the electron donor does not occur. Chemotrophic growth is possible under oxic conditions in the dark at full atmospheric oxygen tension and by denitrification under anoxic conditions in the presence of nitrate. Mesophilic freshwater bacteria with preference for neutral pH. Some representatives are thermotolerant.
Seliberia	1	*Seliberia stellata*	Chemoorganotrophic, strictly aerobic rods with a helically sculptured or furrowed topography and blunt or rounded ends. Stellate aggregates (rosettes) of sessile rods joined at one pole, and individual, shorter motile rods (swarmers) occur in the same culture. An adhesive holdfast, secreted at one pole, mediates attachment into rosettes. Growth on appropriate soil extract media may permit formation of round to ovoid "generative cells". Following unidirectional polar cell growth, a shorter motile swarmer cell and a longer sessile cell are produced by asymmetric transverse fission. A single subpolar ensheathed flagellum is characteristically present on the swarmer; several lateral flagella may also occur.
Vasilyevaea	2	*Vasilyevaea mishustinii*	Budding, prosthecate bacteria with numerous short appendages, <1 μm in length, that cover the cell surface. Aerobic and heterotrophic, using a variety of carbon sources including sugars and sugar alcohols. Cells may be pigmented.

[a]Including *Rhodoplanes cryptolactis*, a name effectively but not yet validly published

Phylogenetic Structure of the Family and Its Genera

Phylogenetically the family *Hyphomicrobiaceae* belongs to the class *Alphaproteobacteria*, order *Hyphomicrobiales* (Douglas 1957). The proposal by Kuykendall (2005) to classify the *Hyphomicrobiaceae* within the newly proposed order *Rhizobiales* cannot be accepted because of matters of priority: *Hyphomicrobium* is the type genus of the order *Hyphomicrobiales*, and therefore the name *Rhizobiales* for the order is illegitimate.

Figure 11.1 shows a neighbor-joining tree of the type strains of 52 species of the family *Hyphomicrobiaceae*. The tree clearly shows that the family *Hyphomicrobiaceae* is polyphyletic, as the genera now classified within the family are interspersed between lineages of other families: *Xanthobacteraceae*, *Beijerinckiaceae*, *Methylocystaceae*, *Methylobacteriaceae*, *Bartonellaceae*, *Cohaesibacteraceae*, and *Rhodobiaceae*.

A number of separate clusters can be observed: (1) a group that contains the prosthecate genera *Hyphomicrobium*, *Pedomicrobium*, and *Filomicrobium*, the genus *Hyphomicrobium* being split into two separate branches as shown earlier (Rainey et al. 1998; Lee et al. 2005); (2) a cluster with two other genera of prosthecate heterotrophs, *Ancalomicrobium* and *Prosthecomicrobium*, confirming the close relationship of these genera demonstrated by Schlesner et al. (1989); (3) the thermophilic and halophilic prosthecate genus *Dichotomicrobium*, phylogenetically only distantly related to the mesophilic prosthecate bacteria within the family; (4) a branch that contains two out of the three genera of phototrophs—*Rhodoplanes* and *Blastochloris*; (5) the third phototrophic genus *Rhodomicrobium* on a deep branch; (6) a large cluster that contains genera without clear prosthecae, *Devosia*, *Vasilyevaea*, *Pelagibacterium*, *Cucumibacter*, and *Maritalea*; based on the tree topology, the genus *Vasilyevaea* is not well separated from *Devosia*; (7) a branch that contains the disparate genera *Angulomicrobium* and *Methylorhabdus* (see also Fritz et al. 2004); (8) *Aquabacter*, which clusters with the *Xanthobacteraceae* as noted earlier (Rainey and Wiegel 1996); (9) *Seliberia*, forming a separate deep lineage. A maximum likelihood tree constructed based on the same dataset (not shown) differs in some details of topology, but the overall picture obtained is similar.

Based on this tree, it is clear that a thorough reevaluation of the classification of the genera of the *Hyphomicrobiaceae* and related families within the alphaprotebacterial order *Hyphomicrobiales* ("*Rhizobiales*") is long overdue.

Genome Analysis

At the time of writing (June 2012), 5 genomes of members of the *Hyphomicrobiaceae* had been sequenced and annotated, and 4 of them were published (*Table 11.10*): the type strains of

Table 11.2

Characteristics that differentiate the three subspecies of *H. facile* (subsp. *facile*, subsp. *tolerans*, subsp. *ureiphilum*):

subsp. *facile* grows on lactate and does not grow on butyrate

subsp. *facile* has a lower temperature minimum and maximum than the other subspecies

subsp. *tolerans*, named for its tolerance of high CO concentrations, is the only subspecies that grows on peptone

subsp. *ureiphilum* grows well on urea and shows α-hemolysis on sheep blood

w weakly positive, *v* variable, depending on growth conditions, *NR* not reported

Data taken from:

[a]Gliesche et al. (2005)

[b]McDonald et al. (2001)

[c]Takada (1975)

[d]Urakami et al. (1995)

[e]Izumi et al. (1982)

[f]Borodina et al. (2002). Additional data on growth substrates are given by Gliesche et al. (2005) and in the original species descriptions

[g]Gliesche et al. (2005) noted that *H. vulgare* (Stutzer and Hartleb 1899) could grow under anaerobic conditions with KNO_3, but nitrate reduction was considered to be negative

[e]Fatty acids content of phospholipids

Hyphomicrobium denitrificans (Brown et al. 2011), *Pelagibacterium halotolerans* (Huo et al. 2012), *Rhodomicrobium vannielii* (Brown et al. 2011), a second strain assigned to *H. denitrificans*, and a chloromethane-degrading *Hyphomicrobium* isolate designated strain MC1 and isolated from industrial sewage (Vuilleumier et al. 2011). The chromosomes are 3.64–4.76 Mbp in length and contain 3,600–4,952 predicted genes. *P. halotolerans* in addition contains a 4-kb plasmid.

Notable features detected in the genome of the marine *P. halotolerans* are genes for the biosynthesis and uptake of the organic osmotic solutes ectoine and glycine betaine (Huo et al. 2012). *Hyphomicrobium* MC1 possesses the genes encoding enzymes for the synthesis of the cofactor pyrroloquinoline quinone (PQQ) and for both tetrahydrofolate- and tetrahydromethanopterin-linked pathways of C_1 metabolism (Vuilleumier et al. 2011). *P. halotolerans* has proteins for the biosynthesis of PQQ, as well as PQQ-dependent alcohol and glycerol dehydrogenases. Genes for the complete serine and ethylmalonyl-CoA pathways for carbon assimilation are present, as well as nitrogen fixation genes, which are absent in the type strain of *H. denitrificans* (Vuilleumier et al. 2011).

From the "pre-genomics era" there is a report about the genome sizes of a number of members of the *Hyphomicrobiaceae*, calculated from DNA renaturation kinetics. Estimated genome sizes (in Da) for the type strains of *Hyphomicrobium vulgare*, *H. aestuarii*, *H. hollandicum*, *H. facile* subsp. *facile*, *Pedomicrobium ferrugineum*, *P. manganicum*, *Filomicrobium fusiforme* and *Dichotomicrobium thermohalophilum* were, respectively, 2.13×10^9, 2.62×10^9, 2.43×10^9, 2.35×10^9, 3.43×10^9, 2.83×10^9, 2.03×10^9, and 1.73×10^9 (Kölbel-Boelke et al. 1985). Based on a molecular mass of 607.4 Da per base pair, these values translate to 3.5, 4.3, 4.0, 5.6, 4.7, 3.3, and 2.8 Mbp. Using a the same technique, Potts et al. (1980) estimated the genome size of the type strain of *R. vannielii* at 2.1×10^9 Da = 3.45 Mbp, a value now known to be too low compared to the 4.01 Mbp of the complete genome sequence (Brown et al. 2011).

Phages

Thus far, phages have only been reported for the genus *Hyphomicrobium*. Phage Hy*Φ*30 has a molecular mass of 55.4 $\times 10^6$ Da and contains linear double-stranded DNA of 29.7 $\times 10^6$ Da (Kaplan et al. 1976). It adsorbs only to the tip of the growing stalk and the evolving daughter cell until a constriction in the stalk is formed and the daughter cell becomes flagellated. Phage maturation only occurs within the daughter cell and the stalk (Voelz et al. 1971). Specific adsorption to the developing daughter cell was found in the *Hyphomicrobium* double-stranded DNA phages Hy*Φ*22a, Hy*Φ*1a and Hy*Φ*32a. Hy*Φ*22a and Hy*Φ*1a both have a polyhedral head and a short noncontractile tail, but differ in host range and sizes of protein components. Hy*Φ*32a had a polyhedral head and a long flexible non-contractile tail with fibers attached to its distal end (Yelton et al. 1979). Preissner et al. (1988) isolated a bacteriophage from raw sewage that, out of the 21 *Hyphomicrobium* strains and 22 other bacteria tested, was only active on *Hyphomicrobium* WI-926 isolated from a German forest pond. This representative of the *Podoviridae* has an isometric head 67 nm in diameter and short 12-nm tail. Adsorption is most efficient on the daughter cells, and phage multiplication was limited to the daughter cells. Fifty-five lytic phages of different morphologies specific for *Hyphomicrobium* strains were recovered from water and soil samples. These belonged to the *Myoviridae* (5), *Styloviridae* (41) with flexible or rigid tails, and the *Podoviridae* (9). They preferentially attached to the proximal pole of the mother cell, the hyphal tip, the distal pole of the bud, and the distal pole of the swarmer cell (Gliesche et al. 1988).

Phenotypic Analyses

The Properties of the Genera and Species of *Hyphomicrobiaceae*

Phenotypically the members of the family *Hyphomicrobiaceae* are quite diverse. Most species prefer an aerobic lifestyle. Some can also grow anaerobically using nitrate as an electron acceptor. Fermentative growth is rarely encountered, with the notable exception of *Ancalomicrobium* which, in addition to aerobic respiration, can grow by fermenting sugars to acetate, ethanol, lactate, formate, succinate, H_2, and CO_2 ("mixed-acid fermentation"). The facultatively photoheterotrophic genera *Rhodomicrobium*, *Rhodoplanes*, and *Blastochloris* lead a phototrophic life under anaerobic conditions only. In the presence of oxygen, no bacteriochlorophyll is produced, and the cells live by aerobic respiration. *Blastochloris* spp. can also grow photoautotrophically. Chemolithoautotrophic growth is seldom found, but at least one *Hyphomicrobium* strain can grow autotrophically using hydrogen as an electron donor.

As expected for *Alphaproteobacteria*, the *Hyphomicrobiaceae* all possess a Gram-negative type of cell wall. The presence of prosthecae is a characteristic property of many genera of the family (Poindexter 2006), but is by no means restricted to the group. Prosthecae can be defined as "semirigid appendages extending from a prokaryotic cell with a diameter which is always smaller than that of the mature cell, and which is bounded by the cell wall" (Staley 1968). Such prosthecate species typically multiply by asymmetric division ("budding") rather than by binary fission. Endospore formation was never observed. ❯ *Figure 11.2* shows a selection of prosthecate representatives of the family with diverse types of cell morphology.

Chemotaxonomically the members of the *Hyphomicrobiaceae* resemble most other groups of *Alphaproteobacteria*. In most species, the most abundant fatty acids are $C_{18:1\omega7c}$, 11-methyl $C_{18:1\omega7c}$ and $C_{16:0}$ and $C_{18:0}$. Hydroxy fatty acids are present as well. More detailed information on the fatty acids and the types of polar lipids present can be found in ❯ *Tables 11.1*– *11.9* and in the original species descriptions.

Further information is given by Nakagawa et al. (2005)

[f]Originally, *P. pneumaticum* and *V. enhydra* were described as dividing by binary transverse fission (Staley 1968). However, a careful re-examination of slide cultures revealed that they divide by budding (Staley 1984)

All taxa are positive for oxidase and catalase activity and able to utilization of glucose. In the API ZYM system, positive for esterase (C4), esterase lipase (C8), leucine arylamidase and naphthol-AS-BI-phosphohydrolase; and negative for α-fucosidase, α-galactosidase, β-glucuronidase and α-mannosidase. The predominant ubiquinone is Q-10.

+ Positive, – negative, *NR* not reported

Data taken from:

[a]Hwang and Cho (2008)

[b]Xu et al. (2009)

[c]Hwang et al. (2009)

[d]Fukui et al. (2012)

[e]Xu et al. (2011)

[f]*PG* phosphatidylglycerol, *DPG* diphosphatidylglycerol, *PC* phosphatidylcholine, *PE* phosphatidylethanolamine, *GL* unidentified glycolipid, *PL* unidentified phospholipid, *APL* unidentified aminophospholipid, *AL* unidentified amino lipid

[g]The NaCl range for growth was determined using by sea salts (Sigma) in synthetic ZoBell broth

The most common lipiquinones are ubiquinone Q-10 or Q-9 and rarely Q-11 (Sittig and Hirsch 1992; Sittig and Schlessner, 1993). Menaquinones and rhodoquinones are found in addition in the photoheterotrophic genera.

The Prosthecate and Budding, Non-phototrophic Genera *Hyphomicrobium*, *Pedomicrobium*, *Ancalomicrobium*, *Angulomicrobium*, *Seliberia*, *Prosthecomicrobium*, *Vasilyevaea*, *Dichotomicrobium* and *Filomicrobium*

Genus *Hyphomicrobium* (Stutzer and Hartleb 1899[AL])

Hy.pho.mi.cro'bi.um. Gr. n. *huphê*, a web, thread; Gr. adj. *mikros*, small; Gr. masc. n. *bios*, life; N.L. neut. n. *Hyphomicrobium*, thread-producing microbe.

Cells are 0.3–1.2 × 1.0–3.0 μm in size; rod shaped with pointed ends or oval; they produce monopolar or bipolar filamentous hyphae or prosthecae, 0.2–0.3 μm in diameter and of varying length. Hyphae may be branched; secondary branches are rare. Cells multiply by budding of a daughter cell at one hyphal tip at a time. The mature buds break off to become motile swarmer cells. These may attach to surfaces, lose their motility, and form clumps or rosettes. Poly-β-hydroxybutyrate can be stored, usually at a distinct cell pole. Colonies on solid media are small, even after prolonged incubation. Older colonies often display concentric rings and change color to darker brown or bright yellow orange. Aerobic, chemoorganotrophic, and oligocarbophilic: growth is possible on mineral salts media without added carbon source, the cells growing on volatile carbon and energy sources. Good growth is possible with low concentrations of C_1 compounds (methanol, methylamine, and others). Ammonium is a good nitrogen source, but some amino acids are also used. Some species grow by denitrification when supplied with nitrate. Widely distributed in soils and aquatic habitats.

Table 11.8
Selected characteristics of the members of the genera *Aquabacter* and *Methylorhabdus*

Main respiratory quinone	NR	Q-10
G+C content of DNA (mol%)	67.3	66–67
Sample source and site	Spirit Lake, WA, USA	Groundwater contaminated with dichloromethane

+ Positive, – negative, *NR* not reported
Data taken from:
[a]Irgens et al. (1991)
[b]Doronina et al. (1995); Doronina and Trotsenko (2005)

The mol% G+C of the DNA is 58–66.

Type species: *Hyphomicrobium vulgare*.

The genus *Hyphomicrobium* currently contains 10 species: *H. aestuarii*, *H. chloromethanicum*, *H. coagulans*, *H. denitrificans*, *H. facile*, *H. hollandicum*, *H. methylovorum*, *H. sulfonivorans*, *H. vulgare*, and *H. zavarzinii*. Three subspecies have been described for *H. facile*: *H. facile* subsp. *facile*, *H. facile* subsp. *tolerans*, and *H. facile* subsp. *ureaphilum*. The main features of the members of the genus *Hyphomicrobium* are summarized in *Table 11.2*.

Additional comments:

- The type strain of *Hyphomicrobium coagulans* (strain Takada 10–2) does not appear to be available from culture collections. Although the species name was validly published in 1989, the organism is currently unavailable for study.
- Attachment of *Hyphomicrobium* swarmer cells to surfaces may be inhibited by light (Gliesche et al. 2005).
- Up to 12 consecutive buds can be formed on one hyphal tip, and the size of the swarmer cells produced increases with the age of the mother cell (Gliesche et al. 2005).

- Dimethylsulfone – $(CH_3)_2SO_2$ – a major product of chemical oxidation of dimethylsulfide in the atmosphere, is a growth substrate for *H. sulfonivorans* (Borodina et al. 2000).
- *Hyphomicrobium* spp. EG and VS oxidize sulfide to thiosulfate (Suylen and Kuenen 1986; Pol et al. 1994).
- *Hyphomicrobium* sp. 53–49 can grow autotrophically with $H_2/CO_2/O_2$ (Uebayasi et al. 1981).
- Small amounts of squalene and sterols (Hop-22(29)-ene) were detected in *Hyphomicrobium* strains (Urakami and Komagata 1986).

Genus *Pedomicrobium* (Aristovskaya 1961, 957[AL]) (Emend. Gebers and Beese 1988, 305)

Pe.do.mi.cro'bi.um. Gr. n. *pedon*, soil; N.L. neut. n. *microbium*, microbe; N.L. neut. n. *Pedomicrobium*, soil microbe.

Cells are oval, spherical or rod-shaped, 0.4–2.0 × 0.4–2.5 μm, with 1–5 hyphae of 0.15–0.3 μm in diameter. At least one hypha originates laterally; other hyphae may appear at the cell poles. Buds are formed at the tips of the hyphae. Mature buds either separate from the hyphae as swarmer cells or remain attached. Extracellular polymers form thick capsules around mother cells. Oxidized iron or manganese compounds are deposited around mother cells and hyphae. Swarmer cells are motile by a single subpolar or polar flagellum. Colonies are yellowish or reddish brown to dark brown, due to accumulated iron or manganese oxides. Acetate is utilized as a carbon source; most strains also grow on pyruvate or caproate. Organic nitrogen sources utilized by most strains are glutamate, aspartate, glycine, serine, threonine, and valine. Inorganic nitrogen compounds allow poor growth of some isolates; nitrate is reduced by most strains. Vitamin mixtures stimulate growth; lack of vitamins results in pleomorphic cells, which produce large granules of poly-β-hydroxybutyric acid. The major respiratory quinone is Q-10. Found in soils, freshwater, iron springs, and seawater.

The mol% G+C of the DNA is 63–67.

The type species: *Pedomicrobium ferrugineum.*

The genus currently contains four species (June 2012): *P. ferrugineum*, *P. americanum*, *P. australicum*, and *P. manganicum* (Table 11.3).

Additional comment:

- The type strain of *P. australicum* (IFAM ST-1306 = ATCC 43611) is no longer available. Phylogenetic analysis was based on DNA recovered from nonviable lyophilized cells. A second isolate of the species, strain IFAM WD-1355, studied by Gerbers and Beese (1988) was lost as well. The prospect of designating a neotype strain is remote in the absence of suitable differentiating phenotypic characteristics. Therefore Cox and Sly (1997) proposed that the species *Pedomicrobium australicum* Gebers and Beese 1988 should not be retained.

Genus *Ancalomicrobium* (Staley 1968, 1940[AL])

An.ca.lo.mi.cro'bi.um. Gr. masc. n. *ankalis*, arm; N.L. neut. n. *microbium*, microbe; N.L. neut. n. *Ancalomicrobium*, arm (−producing) microbe.

Cells are nonmotile, conical, ~1 μm in diameter, possessing 2–8 or more prosthecae. Prosthecae are cylindrical and taper gradually to a distal diameter of ~0.2 μm and a length of 2–5 μm, and may be bifurcated. Cells multiply by budding. Buds are formed from the mother cell, never from prosthecae. Gas vesicles may be present. Chemoheterotrophic, sugars can aerobically be respired or anaerobically fermented by mixed-acid fermentation. Some organic acids are used aerobically, but not fermentatively. Ammonium can be used as sole nitrogen source. Vitamins are required. Occur in freshwaters and in pulp mill oxidation lagoons.

The mol% G+C of the DNA is 70.

Type species (and currently single species): *Ancalomicrobium adetum.*

The main features of the members of the genus *Ancalomicrobium* are summarized in Table 11.4.

Additional comments:

- Buds first develop as small protuberances on a non-appendaged area of the mother cell and then enlarge and differentiate so that the daughter cell is a pseudo-mirror image of the mother cell at the time of cell separation (Jenkins et al. 2005b).
- *Ancalomicrobium* is the only member of the *Alphaproteobacteria* known to perform mixed-acid fermentation. Products of sugar fermentation are acetate, ethanol, lactate, formate, succinate, H_2, and CO_2 (Oertli et al. 2006).
- Production of gas vesicles may be especially pronounced under anaerobic conditions and at low temperature (<18 °C) (Jenkins et al. 2005b).

Genus *Angulomicrobium* (Vasil'eva, Lafitskaya, and Namsaraev 1986, 354[VP]—Validation List no. 20) (Effective Publication: Vasil'eva, Lafitskaya, and Namsaraev 1979, 1037)

An.gu.lo.mi.cro'bi.um. L. adj. *angularis*, having corners or angles, angular; N.L. neut. n. *microbium*, microbe; N.L. neut. n. *Angulomicrobium*, angular microbe.

Cells are nonmotile, polygonal (tetrahedral or mushroomlike in shape during some stages of the life cycle) with radial symmetry, 1.1–1.5 μm in diameter. Division is by budding; buds are produced on the conical point of elongation of the mother cell with a short tube connecting two cells. Prosthecae and gas vesicles are not formed. A variety of organic acids, monosaccharides, and amino acids are used. Methanol and formate can serve as energy sources only in the presence of yeast extract.

The mol% G+C of the DNA is 64–69.

Type species: *Angulomicrobium tetraedrale.*

Table 11.9

Phylogenetic reconstruction of the family *Hyphomicrobiaceae* based on the neighbor-joining algorithm with the Jukes-Cantor correction. Sequence dataset and alignments according to the All-Species Living Tree Project, release LTPs108 (Yarza et al. 2010). The tree topology was stabilized with the use of a representative set of 767 high quality type strain sequences proportionally distributed among the different bacterial and archeal phyla. In addition, a 40 % maximum frequency filter was applied to remove hypervariable positions from the alignment. Scale bar indicates estimated sequence divergence

NR not reported
[a]Brown et al. (2011)
[b]Vuilleumier et al. (2011)
[c]Huo et al. (2012)

The genus *Angulomicrobium* currently contains two species: *A. amanitiforme* and *A. tetraedrale*. The main features of the members of the genus *Angulomicrobium* are summarized in Table 11.4.

Additional comment:

– Both *Angulomicrobium* species contain phosphatidylglycerol, phosphatidyl-*N*,*N*'-dimethylethylamine, phosphatidylcholine, and unknown phospholipids. Phosphatidylglycerol was found in *A. tetraedrale* but not in *A. amanitiforme* (Fritz et al. 2004).

Genus *Seliberia* (Aristovskaya and Parinkina 1963, 56[AL])

Se.li.be'ri.a. N.L. fem. n. *Seliberia*, named for the Russian microbiologist, Professor G. L. Seliber.

Cells are rod shaped, 0.5–0.8 × 1–12 μm, with a characteristic screw-like twisting of the rod surface. The ends of the cell may be either blunt or rounded. Cultures may contain stellate aggregates (rosettes) of sessile rods joined at one pole and shorter motile rods (swarmers). Cells produce an adhesive holdfast, secreted at one pole. Capsules are not produced, but a thin glycocalyx is produced later in the growth cycle. Unidirectional polar growth followed by asymmetric transverse fission produces a shorter motile cell (a swarmer) and a longer sessile cell. Swarmer cells have a single subpolar ensheathed flagellum; several non-ensheathed lateral flagella may also be present. In liquid medium, only the sheathed type of flagellum is produced. Growth is strictly aerobic, chemoorganotrophic. Nitrate is reduced to nitrite either aerobic or anaerobic conditions. Found in soil and freshwater environments.

The mol% G+C of the DNA is 63–66.

The type species: *Seliberia stellata*.

Type species (and currently single species): *Seliberia stellata*. The main features of the members of the genus *Seliberia* are summarized in Table 11.4.

Additional comments:

– In the literature, names such as *Seliberia carboxyhydrogena* and *Seliberia hydrogenophila* can be found, referring to chemoautotrophic bacteria that grow on H_2 + CO_2 and/or on carbon monoxide (Fedorova and Volova 1988; Kryukov et al. 1990). These names have not been validly published, and the affiliation of these isolates with *S. stellata* is not clear. Therefore these isolates are not further discussed here.
– Because of problems encountered in obtaining cell lysis, it is difficult to obtain good DNA preparations of *S. stellata* (Schmidt and Kelly 2005).

Genus *Prosthecomicrobium* (Staley 1968, 1940[AL] emend. Staley 1984, 304)

Pros.the.co.mi.cro'bi.um. Gr. fem. n. *prosthêkê*, appendage; N.L. neut. n. *microbium*, microbe; N.L. neut. n. *Prosthecomicrobium*, appendage (−bearing) microbe.

Cells are coccobacilli or rod shaped, ranging in diameter from 0.8 μm to 1.2 μm, and contain numerous prosthecae

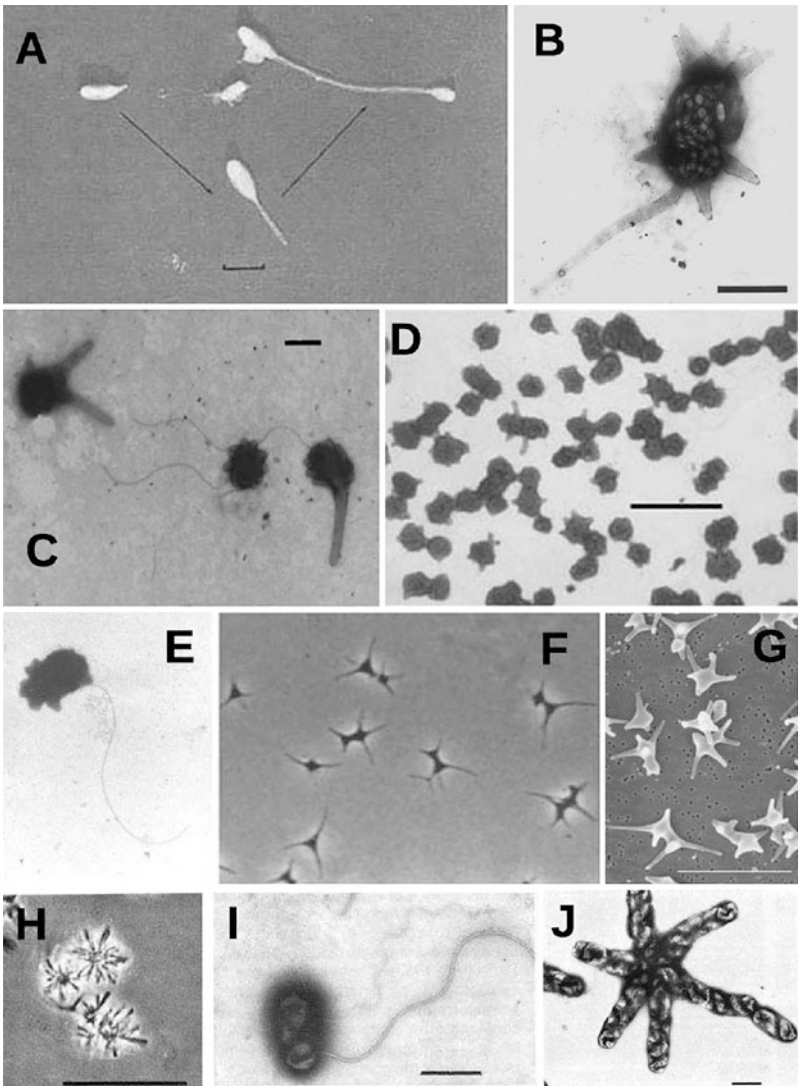

Fig. 11.2
The morphology of selected members of the *Hyphomicrobiaceae*: (a) *Hyphomicrobium* sp. Left to right in the transmission electron micrograph: swarmer, prosthecate cell, and reproducing cell. Bar = 1 μm; (b) *Prosthecomicrobium pneumaticum* ATCC 23633. Transmission electron micrograph showing gas vesicles within the cell, many short prosthecae, and a single long prostheca. Bar = 1.0 μm; (c) *Prosthecomicrobium hirschii*. Electron micrograph showing the two typical morphologies of *P. hirschii* cells. Nonmotile cells lacking flagella with long appendages, and motile cells with a single polar flagellum and shorter appendages. Bar = 1.0 μm; (d) *Prosthecomicrobium enhydrum*. Electron micrograph of a field of *P. enhydrum* cells showing the variability in prosthecae length. Bar = 5.0 μm; (e) *Prosthecomicrobium enhydrum*. Electron micrograph showing a single cell with a single subpolar flagellum. (f) *Ancalomicrobium adetum* ATCC 23632. Phase contrast image of *A. adetum* cells showing long appendages and including one with a branch; (g) *Ancalomicrobium adetum* ATCC 23632. Scanning electron micrograph. Bar = 5.0 μm; (h) *Seliberia stellata* aggregates, phase contrast microscopy. Bar = 10 μm; (i) Negative contrasted (0.5 % Na tungstate) *S. stellata* cell, having two structurally different flagella, grown on peptone-yeast extract solid medium. Bar = 1.0 μm; (j) Star-shaped rosettes of *S. stellata*, showing surface sculpturing. Bar = 1.0 μm (From Poindexter 2006 (panel a), Oertli et al. 2006 (panels b–g), and Schmidt and Swafford 2006 (panels h–i))

extending from all locations on the cell surface. Prosthecae (from 10 to more than 30/cell) are typically <1.0 μm in length; some species also produce longer prosthecae. Cells divide by budding. Buds are produced directly from the mother cell, not from the tips of prosthecae. Nonmotile or motile by means of a single polar or subpolar flagellum. One species forms gas vesicles but no flagella. A variety of sugars and organic acids are used as energy sources for growth. All strains tested require one or more B vitamins for growth. Found in freshwaters.

The mol% G+C of the DNA is 68–70.

Type species: *Prosthecomicrobium pneumaticum*.

The genus *Prosthecomicrobium* currently contains two species: *P. pneumaticum* and *P. hirschii*. The main features of the members of the genus *Prosthecomicrobium* are summarized in Table 11.5.

Additional comment:

– *P. hirschii* has a dimorphic lifestyle with a long-appendaged nonmotile stage and a short-appendaged motile stage (Semenov and Staley 1992). It is unable to use any disaccharides for growth but uses methanol and ethanol (Staley 1984).

Genus *Vasilyevaea* (Yee, Oertli, Fuerst and Staley, 2010, 2962^{VP})

Va.si.ly.e.vae'a. N.L. fem. n. *Vasilyevaea*, of Vasilyeva, named in honor of Lina Vasilyeva, a Russian microbiologist who has dedicated her career to the investigation of prosthecate bacteria and has named several new genera within this group.

Cells are less than 1 μm in length, budding, prosthecate with numerous short appendages that cover the cell surface. They use a variety of carbon sources including sugars and sugar alcohols. Thiamine, yeast extract, or B vitamins are required for growth. Cells may be pigmented.

The mol% G+C of the DNA is 63–66.

Type species: *Vasilyevaea mishustinii*.

The genus *Vasilyevaea* currently contains two species: *V. enhydra* and *V. mishustinii*. The main features of the members of the genus *Vasilyevaea* are summarized in Table 11.5.

Additional comment:

– *V. enhydra* contains two types of polar lipids only: phosphatidylglycerol and bisphosphatidylglycerol (Yee et al. 2010).

Genus *Dichotomicrobium* (Hirsch and Hoffmann 1989, 495^{VP}—Validation List no. 31) (Effective Publication: Hirsch and Hoffmann 1989, 300)

Di.cho.to.mi.cro'bi.um. Gr. adj. *dichotomos*, cutting in two, divided equally; N.L. neut. n. *microbium*, microbe; N.L. neut. n. *Dichotomicrobium*, a forked microbe.

Cells are tetrahedral to spherical, 0.8–1.8 × 0.8–2.0 μm, and have up to four prosthecae of 0.2–0.3 μm width and varying length. Cells and hyphae may be covered with short, rigid, bent pili. Hyphae and mother cells may branch dichotomously. Cells are pigmented red by carotenoids. Cells multiply by the formation of terminal buds on hyphae or by intercalary budding. Propagation cells are initially spherical or pear-shaped, later tetrahedral, and nonmotile. Poly-β-hydroxybutyrate granules may be produced, even in the hyphae. Cells are obligately aerobic, moderately halophilic, and thermophilic (maximum temperature 52–65 °C). Yeast extract is required for growth. Carbon sources are acetate, malate, succinate, and α-ketoglutarate. Inorganic nitrogen compounds and urea do not serve as nitrogen sources. The major respiratory quinone is Q-10.

The mol% G+C of the DNA is 62–64.

Type species (and currently single species): *Dichotomicrobium thermohalophilum*.

The main features of the members of the genus *Dichotomicrobium* are summarized in Table 11.5.

Genus *Filomicrobium* (Schlesner 1988, 220^{VP}—Validation List no. 25) (Effective Publication: Schlesner 1987, 65)

Fi.lo.mi.cro'bi.um. L. n. *filum*, thread; N.L. neut. n. *microbium*, microbe; N.L. neut. n. *Filomicrobium*, thread-like microbe.

Cells are fusiform or bean-shaped, 0.5–1.0 × 1.0–4.0 μm, with several polar prosthecae which are ~0.2 μm in diameter and up to 40 μm in length. Buds are formed at the tips of the prosthecae. Acetate is used as carbon source. Glucose is not fermented. Cells produce storage granules of poly-β-hydroxybutyrate. The major respiratory quinone is Q-9. Found in brackish water and oil-polluted soil.

The mol% G+C of the DNA is 59–62.

The type species: *Filomicrobium fusiforme*.

The genus currently contains two species (June 2012): *F. fusiforme* and *F. insigne* (Table 11.5).

Additional comments:

– *F. fusiforme* is pigmented red by carotenoids (canthaxanthin, echinenone) (Schlesner 1987, 2005).
– *F. fusiforme* does not use C_1 compounds, but *F. insigne* can grow on methanol and on methylamine (Wu et al. 2009).

The Non-photosynthetic Genera *Devosia*, *Cucumibacter*, *Maritalea*, *Pelagibacterium*, *Aquabacter* and *Methylorhabdus*

Genus *Devosia* (Nakagawa, Sakane and Yokota 1996, 20^{VP}) (Emend. Rivas, Willems, Subba-Rao, Mateos, Dazzo, Kroppenstedt, Martínez-Molina, Gillis and Velázquez 2003, 52, Emend. Yoo, Weon, Kim, Hong, Kwon, Cho, Go and Stackebrandt 2006, 2691, Emend. Yoon, Kang, Park and Oh 2007, 1314, Emend. Zhang, Redzic, Liu, Zhou, Schinner and Margesin 2012, 713)

De.vos'i.a.. N.L. fem. n. *Devosia*, honoring Paul De Vos, a Belgian microbiologist, for his basic contribution to the taxonomy of pseudomonads.

Cells are rod shaped, sometimes oval, 0.3–1.0 × 1.0–8.0 μm. Most species are motile by one or several polar flagella. Usually growth occurs at NaCl concentrations of 0–3 % (w/v) and

occasionally up to 5 %. Sugars are used aerobically as carbon source. Most species are negative for lipase (C14) and β-glucuronidase, and nearly all possess esterase lipase (C8) and β-galactosidase. The predominant quinone is Q-10 or Q-11. The major components in the polar lipid profile are phosphatidylglycerol, diphosphatidylglycerol, and unknown glycolipids. Found in soil and freshwater environments, including contaminated soil, glacier cryoconite, beach sediment, and plant root nodules.

The mol% G+C of the DNA is 59–67.

Type species: *Devosia riboflavina*.

The genus currently contains 13 species (June 2012): *D. albogilva*, *D. chinhatensis*, *D. crocina*, *D. geojensis*, *D. glacialis*, *D. insulae*, *D. limi*, *D. neptuniae*, *D. psychrophila*, *D. riboflavina*, *D. soli*, *D. subaequoris*, and *D. yakushimensis*.

Additional comments:

- While all other members of the genus *Devosia*, as well as most of the other genera of *Hyphomicrobiaceae*, are oxidase positive, *D. soli* was reported oxidase negative (Yoo et al. 2006). *D. psychrophila* is the only species of *Hyphomicrobiaceae* reported to be catalase negative (Zhang et al. 2012).
- All tested species have Q-10 as their major respiratory quinone, with the exception of *D. insulae* which has Q-11.
- *D. riboflavina*, a soil bacterium that oxidizes riboflavin, has unusually large amounts of the long hydroxy fatty acids 3-OH $C_{24:1}$ and 3-OH $C_{26:1}$. Hydroxy fatty acids shorter than 3-OH $C_{18:0}$ are absent (Nakagawa et al. 1996). The presence of such long-chain hydroxy fatty acids is not a general characteristic of the genus (Rivas et al. 2003).
- *D. chinhatensis*, isolated from a hexachlorocyclohexane dump site in India, contains the branched fatty acid iso-H $C_{18:1}$, a compound not present in other *Devosia* species (Kumar et al. 2008).
- *D. subaequoris*, isolated from beach sediment, was reported to grow within an unusually wide pH range between 5.1 and 12.1 (Lee 2007). However, no controlled experiments in buffered media were reported to confirm that indeed sustained growth above pH 12 is possible.
- *D. albogilva* and *D. crocina* were isolated from a hexachlorocyclohexane dump site. They tolerate high concentrations of hexachlorocyclohexane, but do not degrade the compound (Verma et al. 2009).
- *D. neptuniae* strains $J1^T$ and J2 contain two plasmids, one of which (1,600 kb) carries nitrogen-fixing (*nifH*) and nodulating (*nodD*) symbiotic genes (Rivas et al. 2003). Attempts to amplify *nifH* and *nodD* gene fragments from *D. yakushimensis* (a species isolated from root nodules of *Pueraria lobata*, a leguminous plant in Japan) or from *D. riboflavina*, *D. soli*, and *D. limi* were not successful (Bautista et al. 2010; Yoo et al. 2006).
- The marine ciliated protozoon *Euplotes magnicirratus* contains endosymbiotic bacteria in their cytoplasm. Based on 16S rRNA gene analysis and fluorescence in situ hybridization, these bacteria are affiliated with the genus *Devosia*. The organism has not yet been cultured, and the provisional name "*Candidatus* Devosia euplotis" was proposed (Vannini et al. 2004).

Genus *Cucumibacter* (Hwang and Cho 2008, 1594^{VP})

Cu.cu.mi.bac'ter L. n. *cucumis*, cucumber; N.L. masc. n. *bacter*, rod; N.L. masc. n. *Cucumibacter*, a cucumber-like rod.

Gram negative and rod shaped, 0.4–0.6 × 1.5–2.0 μm. Short prosthecae are present on the cell surface. Cells are motile by means of monopolar flagella. Slightly halophilic. Growth occurs at NaCl concentrations of 1–3 % (w/v) (optimum 2 %) or sea salts concentrations of 1–10 % (optimum 3–4 %). The major polar lipids are phosphatidylglycerol, diphosphatidylglycerol, two unidentified glycolipids, an unidentified phospholipid and an unidentified lipid. The predominant quinone is Q-10. Found in seawater.

The mol% G+C of the DNA is 62–63.

Type species (and currently single species): *Cucumibacter marinus* (Hwang and Cho 2008). The main features of the members of the genus *Cucumibacter* are summarized in Table 11.7.

Genus *Maritalea* (Hwang, Cho, Yih and Cho 2009, 613^{VP})

Ma.ri.ta'le.a. L. neut. n. *mare*, the sea; L. fem. n. *talea*, a staff, rod; N.L. fem. n. *Maritalea*, rod inhabiting marine environments.

Cells are rod-shaped cells, 0.4–0.7 × 1.0–3.3 μm, and motile by means of a single polar flagellum or peritrichous flagella. Slight halophilic: growth occurs at NaCl concentrations of 0.5–7.5 % (optimum 2 %) or sea salts concentrations of 1–10 % (w/v) (optimum 2–5 %). Glucose can be used as sole carbon source. The major polar lipids are phosphatidylglycerol, two unidentified glycolipids, an unidentified phospholipid, and another unidentified lipid. The predominant quinone is Q-10. Found in marine environments, seawater, and associated with marine organisms.

The mol% G+C of the DNA is 49–54.

The type species: *Maritalea myrionectae*.

The genus was proposed in 2009 (Hwang et al. 2009) and currently (June 2012) contains three species: *M. mobilis*, *M. myrionectae* and *M. porphyrae* (Table 11.7).

Additional comments:

- Bud formation has been observed in the species *M. myrionectae* (Hwang et al. 2009), but not in *M. porphyrae* (Fukui et al. 2012).
- *Maritalea myrionectae* was recovered from a culture of the marine ciliate *Myrionecta rubra* (Hwang et al. 2009), and *M. porphyrae* was isolated from the red alga *Porphyra yezoensis* (Fukui et al. 2012).

Genus *Pelagibacterium* (Xu, Huo, Wang, Oren, Cui, Vedler and Wu 2011, 1820^{VP})

Pe.la.gi.bac.te'ri.um. L. n. *pelagus*, the sea; N.L. n. *bacterium*, from Gr. n. *bakterion*, a small rod; N.L. neut. n. *Pelagibacterium*, a rod isolated from the sea.

Cells are motile short rod-shaped bacteria, 0.4–0.9 × 1.5–2.5 µm, which divide by binary division. The major polar lipids are phosphatidylglycerol, diphosphatidylglycerol, and two unidentified glycolipids. The main respiratory quinone is Q-10, with Q-9 as a minor component. Found in marine environments and in semi-coke samples.

The mol% G+C of the DNA is 58–60.

The type species: *Pelagibacterium halotolerans*.

The genus currently contains two species (June 2012): *P. halotolerans* and *P. luteolum* (Table 11.7).

Genus *Aquabacter* (Irgens, Kersters, Gillis and Staley 1993, 864^{VP}—Validation List no. 47) (Effective Publication: Irgens et al. 1991, 141)

A.qua.bac'ter. L. n. *aqua*, water; N.L. masc. n. *bacter*, rod; N.L. masc. n. *Aquabacter*, aquatic rod.

Cells are encapsulated rods, 0.5–1.0 × 1.5–3.0 µm. Under certain conditions cells become motile by flagella. Organic acids and some amino acids are used as carbon source. Growth occurs on minimal medium with acetate, succinate, or pyruvate as sole carbon source and ammonium ions as sole nitrogen source, along with B vitamins. Gas vesicles may be present.

The mol% G+C of the DNA is 67.

Type species (and currently single species): *Aquabacter spiritensis*.

The main features of the members of the genus *Aquabacter* are summarized in Table 11.8.

Additional comment:

– Flagella are produced when the cells are grown in semisolid media; no motility is seen when grown in typical broth media (Staley 2005).

Genus *Methylorhabdus* (Doronina, Braus-Stromeyer, Leisinger and Trotsenko 1996, 362^{VP}—Validation List no. 56) (Effective Publication: Doronina, Braus-Stromeyer, Leisinger and Trotsenko 1995, 97)

Me.thy.lo.rhab'dus. N.L. n. *methylum* (from Fr. *méthyle*, coined from Gr. n. *methu*, wine and Gr. n. *hulê*, wood), methyl radical; N.L. pref. *methylo-*, pertaining to the methyl radical; G. fem. n. *rhabdos*, rod; N.L. fem. n. *Methylorhabdus*, methyl rod.

Cells are nonmotile nonpigmented rods, 0.4–0.6 × 1.2–2.5 µm, that multiply by fission with constriction. Oxidase negative and catalase and urease positive. Some sugars and organic acids are used as carbon and energy sources. Facultatively methylotrophic. Assimilate C_1 compounds (methanol, methylamine, dichloromethane) via the isocitrate lyase-negative variant of the serine pathway. Nitrate is reduced to nitrite. Ammonium, nitrate, methylated amines, and some amino acids can be used as nitrogen sources. The major ubiquinone is Q-10. Major phospholipids are phosphatidylethanolamine, phosphatidylglycerol, phosphatidylcholine, and cardiolipins. Found in groundwater.

The mol% G+C of the DNA is 66–67.

Type species (and currently single species): *Methylorhabdus multivorans* (Doronina et al. 1995). The main features of the members of the genus *Methylorhabdus* are summarized in Table 11.8.

Additional comment:

– After division the cells remain connected by a constriction apparently formed by the outer membrane (Doronina et al. 1995).

The Facultative Anoxygenic Phototrophs: Genera *Rhodomicrobium*, *Rhodoplanes* and *Blastochloris*

Genus *Rhodomicrobium* (Duchow and Douglas 1949, 415^{AL}, Emend. Imhoff, Trüper and Pfennig 194, 341)

Rho.do.mi.cro'bi.um. Gr. n. *rhodon*, the rose; N.L. neut. n. *microbium*, microbe; N.L. neut. n. *Rhodomicrobium*, red microbe.

Cells are ovoid to elongate-ovoid, showing polar growth and performing a characteristic vegetative growth cycle, involving formation of peritrichously flagellated swarmer cells and nonmotile mother cells that form long prosthecae. Daughter cells originate as spherical buds at the end of the prosthecae. Internal photosynthetic membranes are of the lamellar type. Contains photosynthetic pigments bacteriochlorophyll *a* and carotenoids of the spirilloxanthin series. $C_{18:1}$ comprises >80 % of the membrane-bound fatty acids. Ubiquinone and rhodoquinone with ten isoprene units are present, and the lipopolysaccharides are characterized by a glucosamine-containing, phosphate-free lipid A with amide-bound $C_{16:0}$ 3OH. Cells grow preferentially photoheterotrophically under anoxic conditions in the light. Photoautotrophic growth may be possible with hydrogen and sulfide as electron sources. Various organic substrates, molecular hydrogen, ferrous ion, and sulfide at low concentrations may be used as photosynthetic electron donors. Cells are also able to grow under microoxic to oxic conditions in the dark. Mesophilic freshwater bacteria with a preference for acidic pH between 5.2 and 6.5.

The mol% G+C of the DNA is 62–64.

Type species (and currently single species): *Rhodomicrobium vannielii*.

The main features of the members of the genus *Rhodomicrobium* are summarized in Table 11.9.

Additional comments:

- A well-illustrated overview of the morphogenesis and differentiation in *R. vannielii* was given by Whittenbury and Dow (1977).
- A number of aromatic compounds by can be photocatabolized by *R. vannielii*. Benzoate was photocatabolized by all five strains tested, and benzylalcohol by 4 out of 5. Other substrates that yielded good growth were vanillate (4-hydroxy-3-methoxybenzoate) and syringate (4-hydroxy-3,5-dimethoxybenzoate). However, catabolism of vanillate and syringate led to a significant inhibition of bacteriochlorophyll synthesis, eventually causing cultures to cease growing (Wright and Madigan 1991).

Genus *Rhodoplanes* (Hiraishi and Ueda 1994, 671^{VP})

Rho.do.pla'nes. Gr. n. *rhodon*, the rose; Gr. masc. n. *planos*, a vagabond, a wanderer; N.L. masc. n. *Rhodoplanes*, a red wanderer.

Cells are rod shaped; motile by means of polar, subpolar, or lateral flagella; and multiply by budding and asymmetric cell division. Internal photosynthetic membranes are present as lamellar stacks parallel to the cytoplasmic membrane. Photosynthetic pigments are bacteriochlorophyll *a* and carotenoids of the spirilloxanthin series. Quinones are Q-10 and RQ-10. Growth is preferentially photoheterotrophic under anoxic conditions in the light, with simple organic substrates as carbon and energy sources. Photoautotrophic growth with sulfide as the electron donor does not occur. Chemotrophic growth is possible under oxic conditions in the dark at full atmospheric oxygen tension and by denitrification under anoxic conditions in the presence of nitrate. Growth factors may be required. Found in freshwater with preference for neutral pH. Some representatives may be thermotolerant.

The mol% G+C of the DNA is 66–71.

Type species: *Rhodoplanes roseus*.

The genus *Rhodoplanes* currently (June 2012) contains five species: *R. elegans*, *R. piscinae*, *R. pokkalisoli*, *R. roseus*, and *R. serenus*. The name *R. cryptolactis* was effectively but not yet validly published (Okamura et al. 2007). The main features of the members of the genus *Rhodoplanes* are summarized in Table 11.9.

Additional comments:

- *Rhodoplanes* cells are often motile in young cultures, but motile cells become extremely rare at the late-exponential phase of growth (Hiraishi and Imhoff 2005).
- *R. roseus* can also grow anaerobically or microaerophilically on pyruvate in the dark (Janssen and Harfoot 1991).
- "*Rhodoplanes cryptolactis*" (Okamura et al. 2007), originally described as "*Rhodopseudomonas cryptolactis*" (Stadtwald-Demchick et al. 1990), is a thermotolerant species, isolated from the Thermopolis Hot Springs, Wyoming.

Genus *Blastochloris* (Hiraishi 1997, 218^{VP})

Blas.to.chlo'ris. Gr. n. *blastos*, bud shoot; Gr. adj. *chlôros*, green; N.L. fem. n. *Blastochloris*, green bud shoot.

Cells are rod shaped to ovoid and motile by means of subpolar flagella. They exhibit polar growth, budding, and asymmetric cell division and form rosette-like aggregates. Internal photosynthetic membranes are present as lamellae underlying and parallel to the cytoplasmic membrane. Photosynthetic pigments are bacteriochlorophyll *b* and carotenoids. Ubiquinones and menaquinones are present, and the lipopolysaccharides are characterized by 2,3-diamino-2,3-deoxy-D-glucose-containing phosphate-free lipid A with amide-bound $C_{14:0}$ 3OH. They preferentially grow photoheterotrophically, using organic acids and other carbon sources under anoxic conditions in the light. Photoautotrophic growth may occur under anoxic conditions with thiosulfate or sulfide as electron donor. Chemotrophic growth is possible under microoxic conditions in the dark. Growth factors may be required. Found in aquatic environments of neutral pH.

The mol% G+C of the DNA is 63–72.

Type species: *Blastochloris viridis*.

The genus *Blastochloris* currently (June 2012) contains 3 species: *B. gulmargensis*, *B. sulfoviridis*, and *B. viridis*. The main features of the members of the genus *Blastochloris* are summarized in Table 11.9.

Additional comment:

- Additional comparative taxonomic and chemotaxonomic information on *Blastochloris* spp. was given by Kompantseva et al. (1998, 2007).

Isolation, Enrichment and Maintenance Procedures

Hyphomicrobium spp. can be selectively enriched and isolated using anaerobic media with methanol (0.5 %) as carbon source and nitrate (0.5 % KNO_3) as the electron acceptor (Attwood and Harder 1972; Poindexter 2006). For the other genera of the *Hyphomicrobiaceae*, no reliable enrichment and isolation procedures have been developed. One common property of many representatives of the group is their "oligocarbophilic" nature, i.e., their ability to thrive at extremely low concentrations of organic nutrients or even without any organic carbon sources added to the medium (Hirsch and Conti 1964; Gliesche et al. 2005). Growth is then based on the diffusion of volatile

carbon and energy sources from the air. Under these conditions, their growth may be slow, but they may outcompete most other groups of aerobic chemoheterotrophs. Thus, the development of *Hyphomicrobium* colonies on agar plates can be accelerated by placing a bottle of methanol in the incubator (Poindexter 2006). A compilation of suitable growth media for the enrichment and cultivation of *Hyphomicrobium* spp. was given by Gliesche et al. (2005).

No selective medium exists for the isolation of *Pedomicrobium* spp. For enrichment and isolation of aquatic strains, a dilute peptone medium (0.1 g/l peptone + mineral salts and vitamins) was recommended. Stationary cultures are incubated at 20–30 °C until a surface pellicle develops in the highest positive dilution tubes (Hirsch and Gebers 2005). Generally suitable complex media for *Pedomicrobium* spp. contain an organic acid (e.g., acetate, malate, pyruvate, succinate, gluconate) at 10 mM, a complex organic mixture (peptone, casamino acids, yeast extract), and a mixture of vitamins (Poindexter 2006). An example is medium PYVM (Gebers and Beese 1988), which contains 10 mM DL-malate, 0.25 g/l peptone, 0.25 g/l yeast extract, and vitamins and minerals solutions, pH 7.5. Gebers (1981) recommended a "*Pedomicrobium* standard medium" (PSM) with 10 mM Na-acetate, 0.5 g/l yeast extract, minerals and vitamins, pH 9.0. For the isolation of slowly growing manganese-oxidizing *Pedomicrobium* from water sources, a micromanipulation method was proposed. Colonies of Mn-oxidizers on PC medium (0.05 g/l yeast extract, 0.02 g/l $MnSO_4.4H_2O$, 2 % agar, with 50 µg/ml cycloheximide to prevent fungal growth) can be detected at an early stage of development because of the accumulation of black manganese oxide. Micromanipulation then allows selection of cells from the microcolonies before these are overgrown by faster growing bacteria (Sly and Arunpairojana 1987).

No selective enrichment protocols are known for the genera *Angulomicrobium*, *Prosthecomicrobium*, and *Ancalomicrobium*. Strains of *Angulomicrobium* have been isolated on mineral base medium supplemented with low concentrations of organic substances such as glucose (Vasilyeva 2005). Most enrichments for *Prosthecomicrobium* and *Ancalomicrobium* used low-nutrient media, e.g., 100 mg/l peptone and/or 0.5 g/l glucose, supplemented with minerals and vitamins solutions (Schlesner et al. 1989; Oertli et al. 2006). The morphological properties of *Ancalomicrobium adetum* strongly depend on the nutrient levels in the medium: when grown at >200 mg/l peptone the cells lost their prosthecae, growth became slower and finally ceased; in >0.2 g/l glucose the prosthecae became shorter and the cells lost their motility (Semenov and Staley 1992). *Prosthecomicrobium hirschii* was enriched in 0.1 g/l peptone, then isolated by streaking on MMB medium (0.15 g/l peptone, 0.15 g/l yeast extract, 1 g/l glucose, salts and vitamins) (Staley 1984).

It has been observed that cells with multiple appendages (*Prosthecomicrobium*, *Ancalomicrobium*) have less tendency to adhere to glass surfaces than non-appendaged cells. A strategy was developed on the basis of this phenomenon to enrich the appendaged forms. A culture is loaded on a column filled with 0.2 mm diameter glass beads, and the column is washed with sterile medium. Alternate drops of the effluent are added to liquid medium and spread on plates of the same medium. If growth in liquid medium after 3 weeks incubation at room temperature shows prosthecate forms, then the colonies on the plates are examined. The first drops containing cells tend to be enriched in appendaged types (Staley 1968).

To enrich (nonspecifically) for *Seliberia*-like bacteria of aquatic origin, water samples (250–800 ml) in glass beakers, either without added nutrients or with 0.01–0.05 g/l peptone, are covered with aluminum foil or plastic film and incubated at 24–26 °C for a few weeks to several months. *Seliberia* often floats at the air-water interface. Inserting glass slides or cover slips near the surface may improve the results (Schmidt and Swafford 2006).

For enrichment of *Dichotomicrobium*, clean sterile glass slides were inserted in hypersaline water from Solar Lake, Sinai. After 8–10 days the slides with attached bacteria were transferred to Solar Lake water with 0.25 g/l yeast extract. Cells can also be directly isolated by streaking water samples on plates of oligotrophic medium PYGV prepared in 2.5× concentrated artificial seawater (Hirsch and Hoffmann 1989; Hirsch 2005).

A number of *Devosia* species were first obtained as colonies on the low-nutrient R2A agar medium, commonly used for the isolation and enumeration of soil bacteria. These include *D. soli* isolated from greenhouse soil in Korea (Yoo et al. 2006), *D. geojensis* isolated from diesel-contaminated soil in Korea (Ryu et al. 2008), and *D. psychrophila*, and *D. glacialis* isolated from alpine glacier cryoconite (Zhang et al. 2012). *D. insulae* was found as a colony on a plate containing 10× diluted nutrient agar (Yoon et al. 2007).

A low-nutrient medium (0.1 g/l peptone and mineral salts) was also used for the isolation of *Aquabacter spiritensis*. The appearance of a chalky-white colony led to the discovery of this gas-vacuolate species (Irgens et al. 1991). *Maritella mobilis* was isolated by serial dilutions of a seawater sample onto a solidified seawater medium low in organic nutrients (Xu et al. 2009).

For the enrichment and cultivation of *Pedomicrobium* and *Seliberia* spp., special media were proposed based on soil extract (Aristovskaya and Parinkina 1963) or "humic gel agar." This medium contains liter 5 g (wet weight) of "humic gel" (i.e., fulvic acid iron sesquioxide complexes extracted from podzolic soils) and 18–20 g Bacto-agar, pH 5.7 (for further information, including detailed protocols for the preparation of the "humic gel" see Gebers 1981; Gebers and Beese 1988; Poindexter 2006; Schmidt and Swafford 2006). The properties of such media strongly depend on the type of soil used, and reproducibility may be poor. Hirsch and Gebers (2005) therefore dismissed routine testing of *Pedomicrobium* spp. for iron and manganese oxide accumulation from fulvic acid sesquioxide complexes as impractical because these humic substances are available solely from podzolic soils, which only occur in certain regions on earth. Instead of fuvic acid complexes embedded in agar media they recommended use of elemental iron, FeS, or $MnSO_4$ in conventional media.

Not all species of *Hyphomicrobiaceae* were isolated on special, more or less selective low-nutrient media. Quite a few were discovered during the screening of colonies on normal, high-nutrient media. *Devosia albogilva* and *D. crocina* were recovered from colonies on Luria-Bertani (LB) agar inoculated with material from a hexachlorocyclohexane dump site (Verma et al. 2009); *D. yakushimensis* was isolated by serial dilution of material from a root nodules of *Pueraria lobata* on yeast extract—mannitol agar (Bautista et al. 2010). *Cucumibacter marinus* and *Pelagibacterium halotolerans* were obtained by plating seawater directly on marine agar (Hwang and Cho 2008. Xu et al. 2011).

Some members of the family were retrieved on the basis of special substrates degraded by them: *Methylorhabdus multivorans* was isolated by plating of dichloromethane-contaminated groundwater on dichloromethane containing agar (Doronina et al. 1995). *Devosia riboflavina* was enriched in medium containing 1 g/l riboflavin and 1 g/l glucose and in addition phosphate and magnesium sulfate (Foster 1944). *Filomicrobium insigne* was enriched in a mineral medium amended with crude oil (Wu et al. 2009).

The facultatively anaerobic photoheterotrophs classified within the *Hyphomicrobiaceae* were all obtained by anaerobic enrichment in the light using different carbon sources. *Rhodomicrobium vannielii* can be enriched with succinate or ethanol in mineral media with as initial pH of 5.2–5.5 (Duchow and Douglas 1949; Imhoff 2005b). *Rhodoplanes roseus* was obtained from a Winogradsky column enrichment prepared with mud from a duck pond in a park in New Zealand (Janssen and Harfoot 1991). *Rhodoplanes pokkaliisoli* and *R. serenus* were both enriched using pyruvate as carbon source (Lakshmi et al. 2009; Okamura et al. 2009). The bacteriochlorophyll *b*-containing members of the genus *Blastochloris* were isolated on pyruvate (*B. gulmargensis*; Ramana et al. 2011), malate + yeast extract (*B. viridis*; Drews and Giesbrecht 1966) or toluene (another strain of *B. sulfoviridis*; Zengler et al. 1999). Use of appropriate light filters that allow only long wavelength radiation to penetrate increases the selectivity of the enrichment procedure (Zengler et al. 1999; Imhoff 2005a).

Maintenance

Standard techniques for maintenance of cultures can be used for the *Hyphomicrobiaceae*. For short-time maintenance (up to a number of weeks), cultures can be kept refrigerated at 4 °C. Freezing is possible as well. Gliesche et al. (2005) recommended for *Hyphomicrobium* spp. suspension in phosphate buffer and sterile glycerol, followed by immediate mixing and cooling down to −25 °C. Cells can then be kept frozen at −20 to −25 °C for several years. For *Prosthecomicrobium* and *Ancalomicrobium* spp. frozen cultures made using 15 % (w/v) glycerol and stored at −70 °C have proven to remain viable for at least 4 years. Storage of glycerol stocks at −20 °C is not recommended (Oertli et al. 2006). *Devosia* spp. can be preserved by freezing cell suspensions in nutrient both + 10 % glycerol + 7 % dimethyl sulfoxide as cryoprotective agents at −80 °C or −196 °C (Nakagawa et al. 2005).

For long-term preservation, lyophilization is recommended. Lyophilization in skim milk is the optimal method for maintenance of *Hyphomicrobium* cultures (Gliesche et al. 2005). For *Dichotomicrobium* lyophilization in growth medium gave better results than in skim milk (Hirsch 2005).

Physiological and Biochemical Features

A few special biochemical properties of a number of *Hyphomicrobiaceae* deserve to be highlighted: C_1 metabolism and metabolism of dimethyl sulfone, dichloromethane, and methamidophos by *Hyphomicrobium* spp.; C_1 metabolism in *Angulomicrobium tetraedrale*; and toluene metabolism in a strain of *Blastochloris sulfoviridis*.

Methanol is oxidized in *Hyphomicrobium* spp. by a periplasmic methanol dehydrogenase which contains PQQ (pyrroloquinoline quinone) as cofactor. Hyphomicrobia contain both tetrahydrofolate- and tetrahydromethanopterin-linked C_1 metabolites (Gliesche et al. 2005). Carbon is assimilated by the serine pathway (Izumi et al. 1982). *Methylorhabdus multivorans* uses the isocitrate lyase-negative variant of the serine pathway (Doronina et al. 1995). On the other hand, *Angulomicrobium tetraedrale* uses ribulose 1,5-bisphosphate carboxylase/oxidase (RuBisCO) when grown on C_1 substrates. It can grow on methanol and on formate, and possesses all enzymes needed for the oxidation of methanol via formaldehyde and formate to CO_2. It also can grow chemolithoautotrophically in an atmosphere of $CO_2 + H_2 + O_2$ (Doronina and Trotsenko 2006).

Dimethyl sulfone metabolism in *Hyphomicrobium sulfonivorans* strain S1 is based on constitutive separate membrane-associated dimethyl sulfone and dimethyl sulfoxide reductases. Cells growing on dimethylsulfone also oxidize DMSO and DMS. DMSO is reduced to DMS in an NADH-dependent reaction, and DMS is converted by a monooxygenase to methanethiol and formaldehyde. Methanethiol is then oxidized to formaldehyde and to sulfide, which is further oxidized to sulfate (Borodina et al. 2002).

Hyphomicrobium sp. strain DM2 uses dichloromethane as the sole carbon source for under denitrification conditions. A dichloromethane dehalogenase is induced both aerobically and anaerobically with nitrate (Kohler-Staub et al. 1995). *Hyphomicrobium chloromethanicum* strain $CM2^T$ has an inducible enzyme system for the utilization of chloromethane. The degradation is initiated by two methyltransferases: CmuA (chloromethane + a cobalamin → HCl + methyl-bound cobalamin) and CmuB (transferring the methyl group to tetrahydrofolate, McAnnula et al. 2001).

Hyphomicrobium species MAP-1 degrades the organophosphorus insecticide methamidophos and can use the compound as its sole carbon, nitrogen and phosphorus source. It is first cleaved at the P-N bond to form *O,S*-dimethyl thiophosphate and NH_3. *O,S*-dimethyl thiophosphate is hydrolyzed at the P-O

bond to release $-OCH_3$ and with the formation of *S*-methyl dihydrogen thiophosphate (Wang et al. 2010).

The type strain of *Blastochloris sulfoviridis* is unable to use toluene or benzoate as its carbon source. A new isolate was obtained that also grows on toluene under anoxic conditions in the light. Following incubation of cell extracts with toluene and fumarate benzylsuccinate was detected, showing that the anaerobic activation of the aromatic ring uses the same mechanism reported for denitrifying and sulfate reducing bacteria (Zengler et al. 1999).

Ecology

Members of the family *Hyphomicrobiaceae* can be found virtually anywhere—in freshwater, in soils, in seawater and brackish waters, and even in moderately hypersaline and hot environments. Thus, *Hyphomicrobium* spp. could be isolated from all soil samples and from nearly all water samples tested (Hirsch and Conti 1964). In freshwater habitats they are especially prevalent in the neuston layer, on submerged surfaces, and in the upper sediment layer (Gliesche et al. 2005). As discussed above, many types may have a selective advantage in oligotrophic environments. This is particularly true for the prosthecate genera, as the prosthecae increase the cells' surface area to increase uptake of nutrients (Semenov and Staley 1992). Thus, *Seliberia*-like organisms have been observed in stored samples of laboratory distilled water (Schmidt and Swafford 2006). It should be noted that prosthecae development may be aberrant, cell shape can be irregular, lysis is frequent, and cell viability in the colonies is low. Therefore the prosthecate forms are more often sighted in the environment than isolated (Poindexter 2006).

Prosthecate bacteria such as *Hyphomicrobium*, *Prosthecomicrobium*, and *Ancalomicrobium* spp. generally occur there in relatively low numbers, typically forming a small percentage of the viable colony-forming cells of heterotrophs. They have been found in freshwater (Staley 1968), brackish and marine water (Bauld et al. 1983; Schlesner et al. 1989), in groundwater, and in soil. They have been sighted in unusually large numbers in two specialized environments. A survey of 11 pulp mills waste aeration lagoons located in 6 states throughout the USA showed that 0.6–10.5 % of the prokaryotes observed ($>10^6$ per ml) could be recognized and assigned to genera of prosthecate bacteria on the basis of their morphology (Stanley et al. 1979). An unusual bloom of starlike prosthecate bacteria and filaments, with $>2 \times 10^6$ cells/ml with *Ancalomicrobium* morphology, was found in seawater used for shrimp aquaculture in Polynesia. It is possible that these prosthecate cells are not grazed by microflagellates but are available for mesoplankton larvae (Bianchi 1989).

There have been relatively few molecular ecology studies specifically targeting the *Hyphomicrobiaceae*. A specific probe for fluorescence in situ hybridization (FISH) studies of iron-depositing *Pedomicrobium* species was developed (probe "Pedo 1250", 5′-CGCUGGGUGGCUGCCCAC-3′, being complementary to the hypervariable region 8, position 1250–1268). It was successfully applied in a study of natural biofilms from the Odertal National Park, Germany (Braun et al. 2009). Another molecular study dealt with the characterization of a bacterial endosymbionts of the marine ciliate *Euplotes magnicirratus* (*Ciliophora*, *Hypotrichia*). Based on 16S rRNA sequence comparisons, this symbiont is affiliated with the genus *Devosia*, and it was provisionally named '*Candidatus* Devosia euplotis'. Oligonucleotide probe DevEup_993, 5′-AAGTCGTCCTGGTATGTC-3′, was developed for the specific visualization of the endosymbiont in FISH studies (Vannini et al. 2004).

Devosia neptuniae was isolated from the aquatic leguminous plant *Neptunia natans* indigenous to tropical and subtropical areas. It possesses genes for both nitrogen fixing and nodulation (Rivas et al. 2002, 2003). To what extent this bacterium is indeed responsible for *Neptunia*-associated nitrogen fixation remains to be ascertained. Another plant-associated *Devosia* species is *D. yakushimensis*, isolated from root nodules of *Pueraria lobata* (Bautista et al. 2010). Also here the possible nature of its interactions with the plant has not yet been reported.

Some representatives of the *Hyphomicrobiaceae* have been isolated from polluted environments: *Hyphomicrobium chloromethanicum* from soil at a petrochemical factory in Russia (McDonald et al. 2001), *Devosia albogilva* and *D. crocina* from a hexachlorocyclohexane dump site in India (Verma et al. 2009), and *Pelagibacterium luteolum* from a semi-coke sample in Estonia (Xu et al. 2011).

Pedomicrobium spp. and *Seliberia* are known to deposit iron and manganese on their cells (Aristovskaya 1961; Ghiorse and Hirsch 1979; Verkhovtseva et al. 1988; Larsen et al. 1999). Treatment with glutaraldehyde, $HgCl_2$ or heat abolished the accumulation of iron oxides by *Pedomicrobium* sp., showing that the process is biologically mediated, but did not affect manganese deposition (Ghiorse and Hirsch 1979). A later study with *Pedomicrobium* sp. ACM 3067 showed that Mn(II) adsorption to whole cells is enhanced by heat treatment but Mn(II) oxidation was abolished (Larsen et al. 1999).

The photoheterotroph *Rhodomicrobium vannielii* is commonly found in mud and water of ponds and lakes, as well as in wastewater. It prefers slightly acidic waters (Imhoff 2005b). Some *Rhodomicrobium* strains can also deposit iron hydroxides on the cell surface. Strain BS-1, enriched from a ditch in Germany, oxidizes Fe(II) in the light. This reaction appears to be a side activity of the cells, as Fe(II) oxidation does not support growth in the light over prolonged periods of time (Heising and Schink 1998).

Pathogenicity and Clinical Relevance

Recently there has been a report of an infection of a human patient in China by a bacterium claimed to be a *Rhodoplanes* sp. The bacterium first caused skin abscesses and ulcer, and later a systemic infection occurred.

+ sensitive,− resistant, +/− different reports by different authors, *NR* not reported, *w* weak, *v* variable among strains

The organism was isolated and was assigned to the genus *Rhodoplanes* solely on account of its rRNA gene sequence. No information was provided that could have confirmed the identification such as the formation of bacteriochlorophyll *a* and carotenoid pigments under anaerobic conditions in the light (Zhang et al. 2011). Beyond this single poorly documented report none of the members of the *Hyphomicrobiaceae* is known to be pathogenic to humans, animals or plants.

Table 11.11 summarizes data on the sensitivity of members of the *Hyphomicrobiaceae* to different antibiotics. Such data are not available for all members of the family, and the information present does not show any clear patterns, except for a general sensitivity to ampicillin, tetracycline, and vancomycin and for the resistance of *Devosia* spp. to kanamycin and polymyxin B.

Application

The current applications of the *Hyphomicrobiaceae* are of three main types: (1) biodegradation and bioremediation, (2) biosensors and enzymes for analytical purposes, and (3) biosynthesis of valuable chemicals. In nearly all cases members of the genus *Hyphomicrobium* are involved (Gliesche et al. 2005), but the applicative potential of *Devosia riboflavina* has also been proposed (Kizaki et al. 2008).

Diverse *Hyphomicrobium* populations are associated with sewage and water treatment plants (Holm et al. 1996). The ability of *Hyphomicrobium* spp. to remove nitrate by denitrification while using methanol as the oxidant is especially valuable, as methanol is a cheap, non-fermentable substrate that is oxidized to CO_2 (Liessens et al. 1993). Hyphomicrobia have been used for the removal of odorous volatile sulfur compounds such as H_2S, methane thiol and dimethylsulfide from air and gasses. *Hyphomicrobium* sp. strain VS, isolated from activated sludge using a medium with a low concentration of dimethyl sulfide, can use dimethylsulfide, dimethylsulfoxide, methanol, formaldehyde, formate, and methylated amines as substrates. Dimethylsulfide-grown cells respired sulfide, thiosulfate, methanethiol, dimethyldisulfide, and dimethyltrisulfide. A laboratory-scale trickling biofilter filled with this bacterium, using polyurethane and lava stone as carrier material, efficiently and rapidly removed high concentrations (1–2 μM) of dimethylsulfide from air (Pol et al. 1994). Dimethyl sulfoxide was degraded by cells of *Hyphomicrobium denitrificans* WU-K217 immobilized in calcium-alginate gel. The system may be applicable to wastewater treatment systems for removal of dimethyl sulfoxide (Murakami-Nitta et al. 2003). Specialized *Hyphomicrobium* strains can be applied to the biodegradation and bioremediation of dichloromethane in industrial wastes and in polluted groundwater (Gälli and Leisinger 1985; Diks et al. 1994; Kohler-Staub et al. 1995).

Specific strains of *Hyphomicrobiaceae* and enzymes obtained from them have been applied in biosensors for the detection of methanol, methylsulfates, methylated amines, dihalomethanes, L-serine, and glyoxylate. These applications and potential applications are based on the advantage of *Hyphomicrobium*-derived dehydrogenases such as formaldehyde dehydrogenase and methylamine dehydrogenase use the covalently bound cofactor pyrroloquinoline quinone and not the water-soluble and costly NAD or NADP that need to be supplied continuously (Jérôme et al. 2007; Hilbrig et al. 2009). Thus, a trehalose-stabilized methanol dehydrogenase from *Hyphomicrobium* X can be used for the detection of methanol (Argall and Smith 1993). A *Hyphomicrobium*-containing electrode was developed for the quantitative determination of monomethylsulfate (Schär and Ghisalba 1985). *Hyphomicrobium*-derived enzymes can be used for the assay of trimethylamine, e.g., to assess the quality of fish (Large and McDougall 1975; Wong and Gill 1987). Use of enzymes involved in the serine pathway for carbon assimilation of hyphomicrobia enabled the development of enzymatic assays for L-serine and glyoxylate (Yoshida et al. 1993).

The enzyme systems used in the above mentioned analytical applications can also be applied to large-scale stereospecific synthesis of valuable chemicals. Thus *H. methylovorum* can be used for the production of L-serine from glycine and methanol by action of methanol dehydrogenase and serine hydroxymethyltransferase. With resting cells of the wild type of *H. methylovorum* 24 mg/l of L-serine was produced from 100 mg/ml glycine and 48 mg/ml of methanol in 3 days. Use of a glycine-resistant mutant enabled improved serine production (32–34 mg/ml) (Yamada et al. 1987; Izumi et al. 1993). A novel NADH-dependent alcohol dehydrogenase of *Devosia riboflavina* can be applied in the stereoselective reduction of 3-pyrrolidinone derivatives. Optically active *N*-benzyl-3-pyrrolidinols are versatile chiral building blocks for diverse chemical syntheses (Kizaki et al. 2008).

12 The Family *Hyphomonadaceae*

Wolf-Rainer Abraham[1] · *Manfred Rohde*[2]
[1]Chemical Microbiology, Helmholtz Centre for Infection Research, Braunschweig, Germany
[2]Medical Microbiology, Helmholtz Centre for Infection Research, Braunschweig, Germany

Abstract
The family *Hyphomonadaceae* comprises strict aerobic and stalked and non-stalked species. Cells in this family can have two differing cell cycles. Species of the genera *Algimonas*, *Maricaulis*, *Oceanicaulis*, *Ponticaulis*, *Robiginitomaculum*, and *Woodsholea* divide by binary fission of the cell leading to flagellated offsprings. Species of the genera *Hellea*, *Hirschia*, *Hyphomonas*, and *Litorimonas* divide by budding, forming a flagellated cell at the tip of the prosthecum. All flagellated cells are mobile but later develop a stalk, shed the flagella, and become sessile. These two-cell different cycles are both optimal for living in oligotrophic habitats where the competition for food is fierce and should be minimized between siblings. The genus *Henriciella* is currently the only genus with species lacking any stalks. With the possible exception of *Hyphomonas polymorpha*, all species are marine isolates and require sodium chloride for optimal growth. Species of *Hyphomonadaceae* occupy various habitats in the oceans where they are usually found in oligotrophic niches from the Antarctic to deep sea vents. Only few isolates can grow on minimal media with defined carbon sources; however, most species require complex growth factors for growth. Polar lipids for most species are monoglycosyl and monoglucuronosyl diacylglycerols. Common phospholipids are phosphatidylglycerols and many species possess sulfoquinovosyl diacylglycerols and glucuronopyranosyl diacylglycerol taurine amides as well. Most species reduce nitrate and are alkaline phosphatase and leucine arylamidase positive.

Taxonomy, Historical and Current

For many decades, dimorphic, prosthecate bacteria which reproduce by the separation of two cells that are morphologically and behaviorally distinct from each other were called *Caulobacter*. One of these cells is sessile and nonmotile and prosthecate, possessing at least one elongated, cylindrical appendage, a prostheca (Staley 1968). The other cell is flagellated, bearing one polar flagellum, by which it is motile. The motile cell later develops a stalk, losses it flagellum, and becomes sessile. The mode of reproduction of the dimorphic, prosthecate bacteria is unique as a regular feature of a prokaryotic reproductive cycle. It helps to disperse the population at each generation, minimizing competition among siblings for resources. Loeffler was the first to report on the isolation of these bacteria (Loeffler 1890), but only in 1935, Henrici and Johnson described the genus *Caulobacter*, with *Caulobacter vibrioides* as the type species (Henrici and Johnson 1935). Three decades later, Poindexter (1964) described *Caulobacter maris* and *Caulobacter halobacteroides*, the first two caulobacteria from seawater. At that time, the taxonomy of the members of the genus was based almost exclusively on the characteristic morphology and mode of reproduction (Poindexter 1981). Stahl et al. (1992) sequenced the 16S rRNA of several isolates belonging to *Caulobacter*, revealing that members of *Caulobacter* actually formed three distinct lineages, one comprising the freshwater and brackish water *Caulobacter* strains and the other comprising the marine *Caulobacter* strains. Bacteria of the third lineage belong to the genus *Sphingomonas* with *S. leidyi* (Poindexter) as the only prosthecate *Sphingomonas* species so far described (Chen et al. 2012a). In 1999 Abraham et al. transferred *Caulobacter maris* to the new genus *Maricaulis* as the type

E. Rosenberg et al. (eds.), *The Prokaryotes – Alphaproteobacteria and Betaproteobacteria*, DOI 10.1007/978-3-642-30197-1_260,

species *M. maris*. For prosthecate species also proliferating by fission but being in several aspect differing from species belonging to *Maricaulis*, the novel genera *Oceanicaulis* (Strömpl et al. 2003) and *Woodsholea* (Abraham et al. 2004) were described.

In 1957, Pongratz reported the isolation of a prosthecate, but budding bacterium from the nasal mucous of a patient with sinusitis (Pongratz 1957). Because this organism grew on complex media, such as blood agar, and was unable to grow on simple mineral salt media containing only one-carbon compounds as the sole sources of carbon and energy, a new genus was proposed to accommodate this organism, and the organism was named *Hyphomonas polymorpha*. Another budding species, *Hirschia baltica*, was described in 1990, which is still the only known species of the *Hyphomonadaceae* coming from brackish water (Schlesner et al. 1990). Only with the advent of gene sequencing it became apparent that *Maricaulis*, *Oceanicaulis*, and *Woodsholea*, reproducing by fission, and *Hyphomonas* and *Hirschia*, reproducing by budding, belong to the same family which was described in 2005 as *Hyphomonadaceae* (Lee et al. 2005). This family grew considerable in size when the genera *Robiginitomaculum* (Lee et al. 2007), *Hellea* (Alain et al. 2008), *Henriciella* (Quan et al. 2009; emend. Lee et al. 2011), *Ponticaulis* (Kang and Lee 2009a), *Litorimonas* (Jung et al. 2011), and *Algimonas* (Fukui et al. 2012) were established.

Hy.pho.mo.na.da'ceae. N.L. fem. n. *Hyphomonas* type genus of the family; -aceae ending to denote a family (N.L. fem. pl. n. *Hyphomonadaceae* the *Hyphomonas* family).

The description of the family is an emended version of the description given by Lee et al. (2005): Phylogenetically together with the *Caulobacteraceae* (Henrici and Johnson 1935) and the *Rhodobacteraceae* nom. ill. (Garrity et al. 2005), a member of the order *Caulobacterales* (Henrici and Johnson 1935), phylum Proteobacteria, class *Alphaproteobacteria* (Garrity et al. 2005). Gram-negative, rod-shaped bacteria, motile. Cells do not form spores. Chemoorganotrophic. Some species require peptone or B vitamins and amino acids. Species are aerobic or facultatively anaerobic. Some species denitrify. In most species, the major isoprenoid quinone is Q-10. Most species contain the polar lipids α-D-glucopyranosyl diacylglycerol, α-D-glucuronopyranosyl diacylglycerol, and sulfoquinovosyl diacylglycerol; in some genera α-D-glucuronopyranosyl diacylglycerol taurine amide and phosphatidyl diacylglycerol are also present. Many species show a reduction of the relative amount of phospholipids, sometimes down to <1 %, in favor of glyco- and sulfolipids (Abraham et al. 1997; Batrakov et al. 1996a). Members of the family have been isolated from seawater. The family comprises the type genus *Hyphomonas* (Pongratz 1957; emend. by Moore et al. 1984) and the genera *Hirschia* (Schlesner et al. 1990), *Maricaulis* (Abraham et al. 1999), *Oceanicaulis* (Strömpl et al. 2003), *Woodsholea* (Abraham et al. 2004), *Robiginitomaculum* (Lee et al. 2007), *Hellea* (Alain et al. 2008), *Henriciella* (Quan et al. 2009; emend. Lee et al. 2011), *Ponticaulis* (Kang and Lee 2009a), *Litorimonas* (Jung et al. 2011), and *Algimonas* (Fukui et al. 2012) (*Table 12.1*).

Molecular Analyses

The four genomes of *Hyphomonadaceae* sequenced and annotated so far contain between 3.17 and 3.71 megabases. They are therefore somewhat smaller than most genomes of *Caulobacteraceae*. Usually one chromosome is present but cells of *Hirschia baltica* also harbor a plasmid of 84.492 bp. These genomes contain between 3.077 and 3.568 genes coding 3.029–3.505 proteins. Most genomes have two identical copies of ribosomal RNA operons; only *Hyphomonas neptunium* ATCC 15444^T has only one. The number of tRNA genes is also pretty uniform, and 43–45 tRNA genes were predicted from the genome sequences (*Table 12.2*).

To thrive in oligotrophic environment, highly efficient mechanisms for nutrient uptake are essential in *Hyphomonadaceae*. For the uptake of compounds which are too large for uptake by simple passive diffusion, active transports by TonB-dependent receptors are used which are both anchored in the outer membrane and energy dependent. The known genomes of *Caulobacterales* and *Hyphomonadaceae* contain a large number of TonB-dependent receptors, e.g., *Caulobacter crescentus* has 63 and *Hyphomonas neptunium* and *Hirschia baltica* 46 of these genes (Chertkov et al. 2011). However, only 24 TonB-genes were identified in the *Oceanicaulis* sp. HTCC2633 genome (Oh et al. 2011), but far too little is known to draw any conclusions from these differences.

All species of *Hyphomonadaceae* have a very characteristic cell cycle similar to most species of *Caulobacterales*. Bioinformatic analysis of genes controlling the dimorphic cell cycle revealed the conservation of 14 key proteins that function in the regulation of the cell cycle (Brilli et al. 2010). There is, however, one notable exception: DivJ, a histidine kinase, is absent in the *Hyphomonas neptunium* and *Hirschia baltica* genomes but present in the *Oceanicaulis* sp. HTCC2633 and *Maricaulis maris* MCS 10 genomes. Bacteria belonging to the *Caulobacterales* and *Hyphomonadaceae* are also known for the ability to produce a holdfast, a polar polysaccharide, required for strong adhesion to surfaces. The genes required for the synthesis (Smith et al. 2003) and anchoring (Hardy et al. 2010) of the holdfast have been identified and characterized both in *Caulobacter crescentus* and *Hirschia baltica* but were largely absent from the genome of *Hyphomonas neptunium*, which does not produce a polar holdfast. The observation that most developmental regulators and holdfast genes are conserved in the budding bacteria belonging to the *Hyphomonadaceae* as well as the non-budding bacteria belonging both to the *Caulobacterales* and the *Hyphomonadaceae* can be interpreted that this regulation of the cell cycle evolved prior to the separation of the *Hyphomonadaceae* and *Caulobacterales*.

Quite different results came from studies of the control of chromosome replication. The dimorphic growth of *Hyphomonadaceae* requires cell-type-specific controls of chromosome replication preventing replication in swarmer cells but enabling the progeny stalked cell to perform chromosome replication. This is achieved by the CtrA protein which

Table 12.2
Characteristics of annotated genomes of *Hyphomonadaceae*

Strain	Size (Mb)		rRNA operons	tRNAs	Genes	Proteins
Hirschia baltica ATCC 49814^T (Chertkov et al. 2011)	3.54	1 chromosome	2	44	3.269	3.187
	0.08	1 plasmid				
Hyphomonas neptunium ATCC 15444^T (Badger et al. 2006)	3.71	1 chromosome	1	43	3.568	3.505
Maricaulis maris MCS 10 (Copeland et al. 2011)	3.37	1 chromosome	2	45	3.133	3.063
Oceanicaulis sp. HTCC 2633 (Oh et al. 2011)	3.17	1 chromosome	2	44	3.077	3.029

binds to the chromosome origin and prevents its replication. As a consequence the CtrA protein is present in swarmer cells but absent in stalked cells (Bowers et al. 2008). A study directed to the replication origins of *Caulobacter*, *Oceanicaulis*, and *Maricaulis* strains revealed that the genera of *Caulobacteraceae* and *Hyphomonadaceae* developed differently. While all these replication origins use CtrA to repress replication, the study showed that CtrA usage evolved separately among these two families confirming the phylogeny derived from their 16S rRNA gene sequences (Shaheen et al. 2009).

Further differences between *Caulobacter* and *Hyphomonas* were found in their selenoproteins. While *Hyphomonas neptunium* encodes an L-seryl-tRNA selenium transferase, a selenocysteine-specific translation elongation factor, and a selenoprotein of unknown function, all these selenoproteins are absent in *C. crescentus*. Another argument for a clear distinction between *Caulobacteraceae* and *Hyphomonadaceae* comes from the biosyntheses of holdfasts. While *H. neptunium* and *C. crescentus* both synthesize holdfasts, none of the genes required for its synthesis have orthologs encoded in the

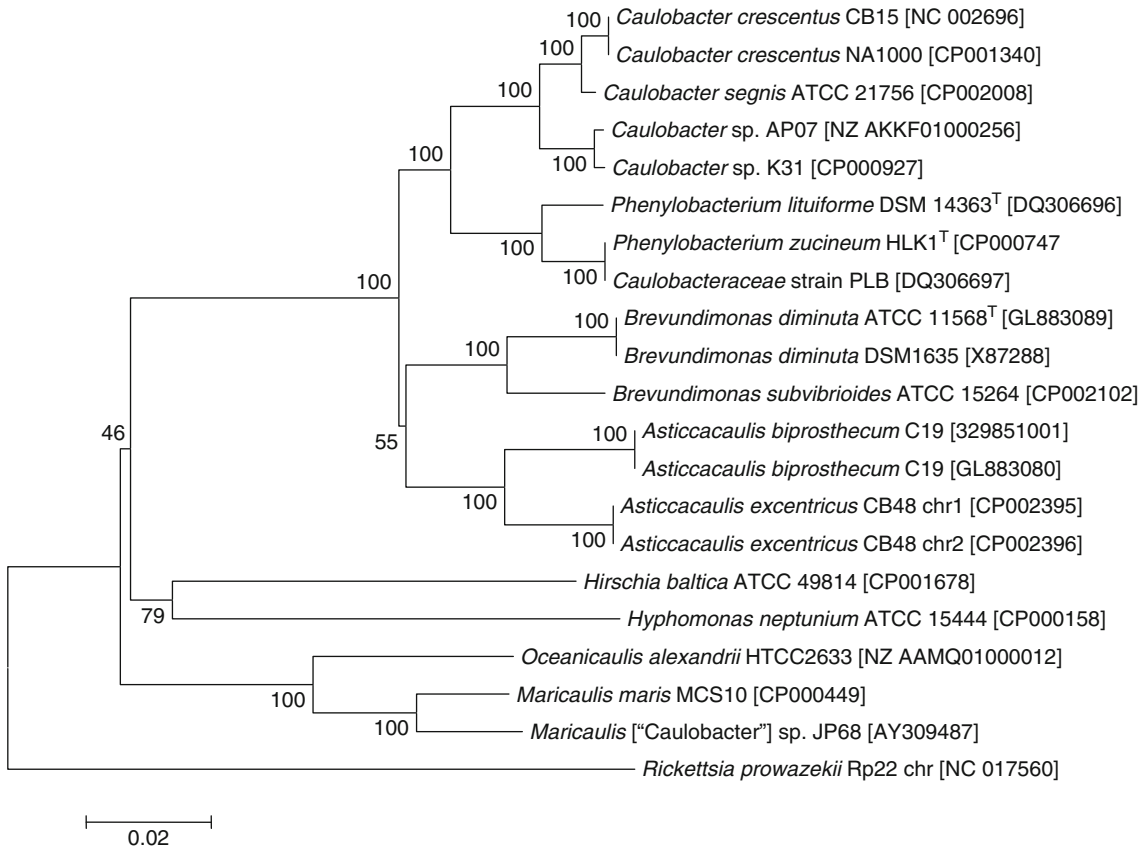

Fig. 12.1
Phylogenetic tree based on LSU rRNA gene sequences (neighbor joining, 1,000 bootstrap replication, *Rickettsia prowazekii* served as outgroup)

corresponding other genome (Badger et al. 2006). Therefore, it seems that holdfast synthesis and attachment must be achieved differently in both species. In line with these observation is also the gene organization for flagella formation in both species. While in *H. neptunium* most of the genes required for the flagellum and its synthesis are organized in one region comprising 35 contiguous open reading frames, the corresponding genes are scattered over the entire genome of *C. crescentus*. Furthermore, transcription of many flagellar genes in *C. crescentus* requires a σ^{54}-RNA polymerase holoenzyme which seems not to be involved in the corresponding transcriptions in *H. neptunium*.

Badger et al. (2005) reported that phylogenetic trees based on the 23S rRNA gene sequences differ remarkably from those calculated using the 16S rRNA gene sequences. However, using a much larger set of data, we could not find this discrepancy but a clear distinction between *Caulobacteraceae* and *Hyphomonadaceae* in phylogenetic trees based either on the 16S or the 23S rRNA gene sequences (*Figs. 12.1* and *12.2*).

DNA–DNA hybridizations between *Hyphomonas* isolates (Weiner et al. 2000), between *Maricaulis* isolates (Abraham et al. 2002), and between Henriciella isolates (Lee et al. 2011) have been reported. Applying the definition of species being distinct if DNA–DNA hybridization values are 70 % or less (Rosselló-Mora and Amann 2001) and comparing these results with the phylogenetic tree based on the 16S rRNA gene sequences, it can be concluded that only a few base pairs difference between two isolates of these genera is usually sufficient to assume two distinct species. This situation is similar to the one found in the *Caulobacteraceae* family (Abraham et al. 1999) (*Tables 12.3* and *12.4*).

This statement is corroborated by the DNA–DNA relatednesses reported between *Henriciella litoralis* SD10^T and *H. marina* Iso4^T of 12.0 % and between *H. marina* Iso4^T and *H. aquamarina* LMG 24711^T of 22.9 %.

Phenotypic Analyses

All species are oligotrophic organisms and the cells can be deformed, damaged, or even killed by higher substrate concentrations. Most strains have complex nutrient and growth factor requirements which cannot be fulfilled by simple addition of vitamins or amino acids. As a consequence cultivation on complex media is usually the only way to grow them. Most strains form biofilms and the formation of rosettes by attachment of the holdfast is a characteristic feature easily seen under the microscope.

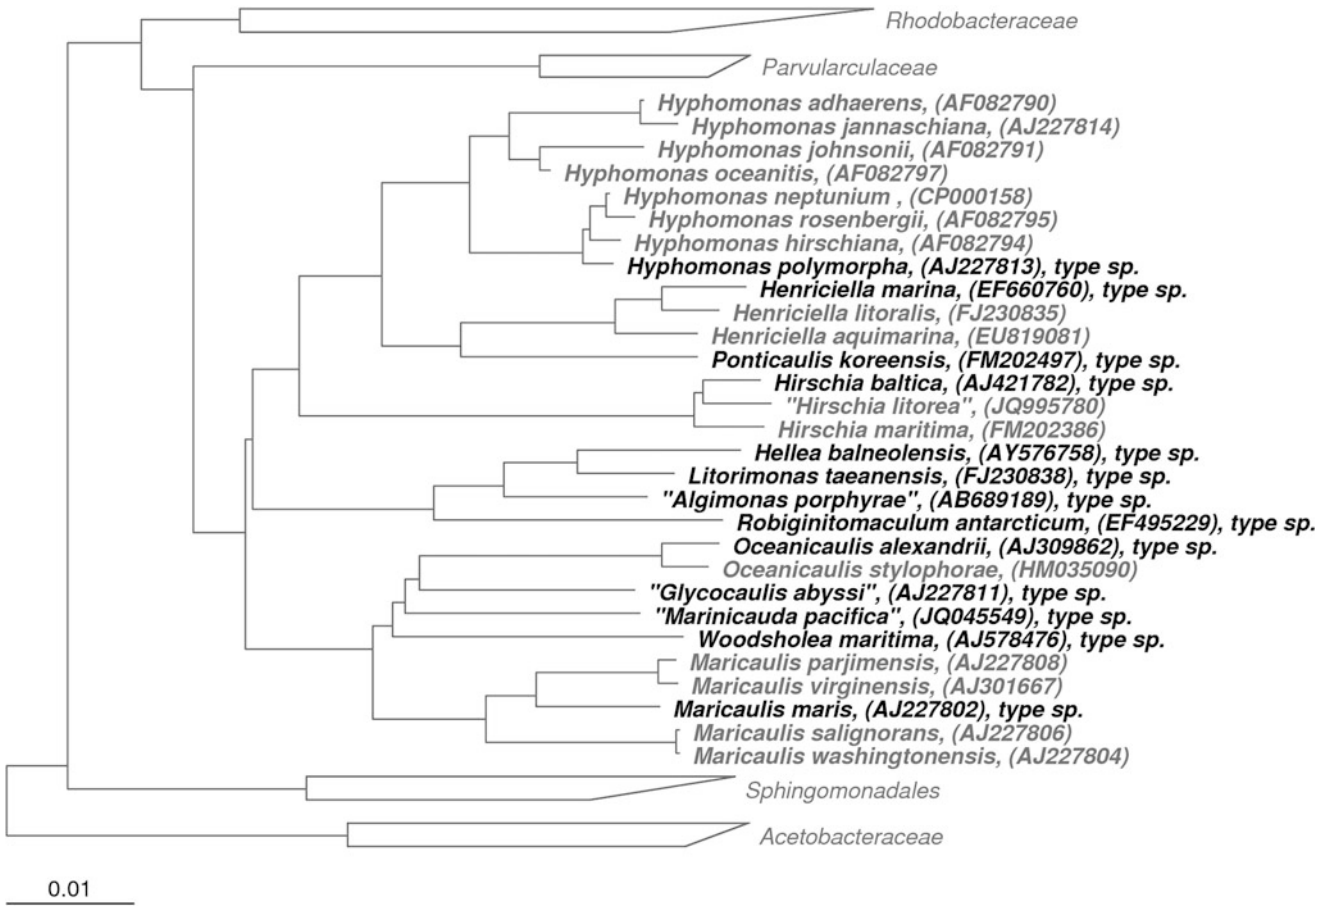

Fig. 12.2

Phylogenetic reconstruction of the family *Hyphomonadaceae* based on 16S rRNA and created using the neighbor-joining algorithm with the Jukes-Cantor correction. Scale bar indicates estimated sequence divergence

H. rosenbergii VP-6^T	5	30	11	21	19	2	4	100

Information on the antibiotic sensitivity of *Hyphomonadaceae* is scarce because only a minority of strains has been tested for their susceptibility against antibiotics. Most strains were susceptible against novobiocin, penicillin, and ampicillin, but *Hyphomonas oceanitis* SCH89^T and *Litorimonas taeanensis* G5^T were resistant against all three. *Litorimonas taeanensis* G5^T and *Robiginitomaculum antarcticum* IMCC3195^T showed also resistance against streptomycin and kanamycin. In the genome of *Oceanicaulis* sp. HTCC 2633, 15 genes for beta-lactamases and a bicyclomycin resistance protein were detected (Oh et al. 2011).

All *Hyphomonadaceae* have high activities in alkaline phosphatase. Esterase (C_4) and esterase/lipase (C_8) activities are

n.d. not determined

present in all species; however, the activity is medium in *Woodsholea*, *Henricella*, and *Ponticaulis* species. Lipase (C_{14}) activity is absent or weak in all species. Leucine arylamidase is also present in all strains and usually high, while the valine and cystine arylamidases activities are always lower and in some species weak. Trypsin activities vary considerably between strains and have not been found in some species, e.g., *Hyphomonas polymorpha* DSM 2665^T, *Algimonas* porphyrae OC-2-2^T, or *Hellea balneolensis* DSM 19091^T. Similarly α-chymotrypsin varies being strong in *Henriciella* spp., *Oceanicaulis* spp., *Maricaulis parjimensis* MCS 25^T, and *M. maris* ATCC 15268^T but weak in *M. salignorans* MCS 18^T and *M. washingtonensis* MCS 6^T and even absent in *Hirschia* spp., *Algominas porphyrae* OC-2-2^T, and *Hyphomonas polymorpha* DSM 2665^T. The activity of acid phosphatase is rather abundant but even more variable being very active in *Maricaulis parjimensis* MCS 25^T, but absent in *M. maris* ATCC 15268^T, *M. washingtonensis* MCS 6^T, *Hellea balneolensis* DSM 19091^T, and *Robiginitomaculum antarcticum* IMCC3195^T. The same behavior was found for naphthol-AS-BI-phosphohydrolase. From the group of sugar-cleaving enzymes, α-glucosidase is the most frequent enzyme. Its activity has been reported from all *Henriciella* species, *Litorimonas taeanensis* G5^T, and *Hirschia baltica* DSM 5838^T, and weak activity was also found in *Maricaulis parjimensis* MCS 25^T and *Hyphomonas polymorpha* DSM 2665^T. All other species are lacking this activity. With the exception of the *Henriciella* species, the same species all showed weak activity of β-glucosidase. Only for *Hirschia maritima GSW*-2^T and *Hellea balneolensis* DSM 19091^T activity of β-galactosidase was reported. *Hirschia maritima* GSW-2^T was the only species showing α-fucosidase activity, while *Woodsholea maritima* CM 243^T was the only species possessing weak *N*-acetyl-β-glucosaminidase activity. None of the species showed any α-mannosidase or α-galactosidase activities.

Hyphomonadaceae display some characteristic fatty acids which can be used for their identification (*Table 12.1*). *Hirschia* species are the only ones containing C14:0. *Woodsholea*, *Oceanicaulis*, *Algimonas*, and *Ponticaulis* species are lacking C15:0; *Maricaulis*, *Robiginitomaculum*, and *Hellea* species have only traces of this fatty acid which is present in higher amounts in the other *Hyphomonadaceae* genera. C16:0 is usually abundant in the cells, but *Woodsholea*, *Oceanicaulis*, *Hellea*, and *Robiginitomaculum* spp. have low amounts. Usually this fatty acid is accompanied by lower amounts of its unsaturated derivative C16:1ω7c. However, *Woodsholea*, *Henriciella*, *Oceanicaulis*, *Ponticaulis*, *Hellea*, and *Litorimonas* are lacking C16:1ω7c completely. The isoforms of C17:0, iC17:0 and iC17:1ω9c, are together with C18:1ω9c abundant only in *Maricaulis* and characteristic within the *Hyphomonadaceae* for this genus. *Oceanicaulis* and *Woodsholea* species contain significantly higher amounts of C18:0 than the species of the other genera. *Henriciella* strains are the only ones showing C20:0. The branched fatty acid, *trans*-11-methyl-12-octadecenoic acid (ECL 18.080) (Abraham et al. 2008), was found in *Maricaulis*, *Hyphomonas*, *Henriciella*, *Oceanicaulis*, *Hellea*, and *Litorimonas* species with unusually high amounts in *Oceanicaulis*. The occurrence of 10-methyl-C18:0 (TSBA) in *Hellea balneolensis* is remarkable. Hydroxy fatty acids are usually esterified with the cell wall and are often used as biomarkers for bacteria. iC11:0 3OH is only present in species of *Maricaulis* and *Hellea*. While *Hyphomonas* and *Hellea* species have more C12:1 3OH than C12:0 3OH, the contrary is the case for *Henriciella* strains. *Oceanicaulis* and *Woodsholea* species possess only C12:0 3OH. C12:0 3OH and C12:1 3OH are absent in species of *Maricaulis*, *Robiginitomaculum*, *Litorimonas*, and *Algimonas*. Only *Algimonas* and *Hellea* strains show high amounts of C18:1 2OH which was also found in much lower amounts in some *Henriciella* strains. *Woodsholea* is the only genus containing considerable amounts of the unknown fatty acid ECL 15.275.

Instead of saponifying the fatty acids for the analysis, the intact polar lipids can be used for chemotaxonomy. A detailed analysis of the polar lipids using tandem-mass spectrometry revealed that they are good biomarkers for the characterization of genera of *Hyphomonadaceae*. The glycolipid fraction of the cells can best be analyzed by chemical ionization (CI) using ammonium as ionization gas. This gives mainly the molecular ions of the individual glycolipids which can be further characterized by collision-induced decay (CID) allowing the identification of the individual fatty acids and their position at the

Table 12.5

glycerol moiety of the molecules. The pattern of the glycolipids allows a differentiation of isolates often down to the species level. In *Hyphomonadaceae* only the glycolipids α-D-glucopyranosyl diacylglycerol (MGDG) and α-D-glucuronopyranosyl diacylglycerol (GUDG) could be detected. For a similar analysis of phospho- and sulfolipids, ionization by fast atom bombardment (FAB) is more suitable. *Hyphomonadaceae* show here a rich diversity of sulfoquinovosyl diacylglycerols (SQDG), phosphatidyl diacylglycerols (PG), and α-D-glucuronopyranosyl diacylglycerol taurine amide (Tau). The distribution of SQDG, PG, and Tau is not uniform but specific for the individual taxa, and many show reduced amounts of PG which seems to be replaced by SQDG (Abraham et al. 1997). This fits to their habitats and it has been shown that limitation in phosphate leads to a shift from PG to SQDG (Batrakov et al. 1996a; van Mooy et al. 2009).

The main features of members of *Hyphomonadaceae* are listed in ❯ *Tables 12.5*, *12.6*, and *12.7*.

Hyphomonas ex Pongratz (1957), Moore et al. (1984), Weiner et al. (2000)

The description is the one given by Weiner et al. (2000) emended by our own results. *Hyphomonas* species normally generate only a single polar prosthecum and reproduce by budding (❯ *Fig. 12.3*). Members of the genus *Hyphomonas* undergo a rather complex biphasic life cycle. The life cycle consists of a swarm-cell stage that eventually metamorphoses into a benthic, reproductive cell during the biphasic developmental cycle. *Hyphomonas* cells are rod-shaped to oval, mature cells measuring 0.5–1.0 × 1.0–3.0 μm; buds are produced at the tips of polar prosthecae (❯ *Fig. 12.4*), which measure 0.2–0.3 μm in diameter and are 1.5 times the length of the cell body; and swarm cells are motile by means of a single polar to lateral flagellum located on developing buds of younger daughter cells. Gram negative, nonacid fast, aerobic, nonspore forming, and chemoorganotrophic. All strains investigated so far are catalase positive, oxidase positive, urease negative, indole negative, hydrogen sulfide negative, non-saccharolytic, and nonpathogenic for mammals. Peptone is normally required for growth. With one exception, all strains denitrify. The species catabolize amino acids for energy and growth; only *Hyphomonas johnsonii* MHS-2 T can utilize sugars. Members of *Hyphomonas*, especially the vent strains, grow along steep physicochemical gradients involving considerable temperature, pressure, and salinity variations in a broad range of environmental conditions. The optimum growth temperature range is 22–37 °C. *Hyphomonas neptunium*, *Hyphomonas polymorpha*, *Hyphomonas oceanitis*, and *Hyphomonas hirschiana* have a Q-11 ubiquinone type along with a significant amount of Q-10 (approx. 10 % of total ubiquinones) and minor amounts of Q-9 and Q-12. *Hyphomonas jannaschiana* has Q-10 as its major quinone, with trace amounts of Q-9 and Q-11. Polar lipids are 1,2-diacyl-3-α-D-glucopyranosyl-sn-glycerol, 1,2-diacyl-3-α-D-glucuronopyranosyl-*sn*-glycerol, phosphatidyl glycerol, and 1,2-diacyl-3-α-D-glucuronopyranosyl-*sn*-glycerol taurine amide (Batrakov et al. 1996a, b), while sulfoquinovosyl diacylglycerol is absent (Abraham et al. 1997). The dominant fatty acid, common to all *Hyphomonas* spp., is 18:1ω7c. The GC content of the DNA is 57–64 mol%. *Hyphomonas* species were isolated from many ocean niches, including the open ocean (the pelagic zone), mud sloughs, and different hydrothermal vent sites. They are primary colonizers of submerged marine surfaces, some species producing dense biofilms.

Maricaulis Abraham et al. (1999)

L. n. *mare -is*, the sea; L. masc. n. *caulis*, stalk; N.L. masc. n. *Maricaulis*, stalk from the sea.

The description is an emended version of the description given Abraham et al. (1999). Gram-negative cells, rod shaped, fusiform, or vibrioid, 0.4–0.5 by 1–2 μm. Cells possess a prostheca, ca. 0.15 μm in diameter and of varying length depending on the species and environmental conditions, extending from one pole as a continuation of the long axis of the cell. Adhesive material is present at the distal end of the

prostheca. Occur singly. Multiplication by binary fission. At the time of separation, one cell possesses a prostheca and the other a single polar flagellum. Each new appendage occurs at the cell pole opposite to the one formed during fission. The flagellated cell secretes adhesive material at the base of the flagellum, develops a prostheca at this site, and enters the immotile vegetative phase. Colonies circular, convex, and colorless. Chemoorganotrophic aerobes, but most of the strains tested could grow anaerobically probably using amino acid as fermentable carbon source. Nitrate is reduced to nitrite anaerobically by some strains. All strains are positive for alkaline phosphatase, esterase (C_4), esterase/lipase (C_8), leucine arylamidase, α-chymotrypsin, and naphthol-AS-BI-phosphohydrolase; trypsin activity is always present, although in some species only weakly. All species show weak activities for lipase (C_{14}) and no activities for acid phosphatase, α- and β-galactosidase, β-glucuronidase, α- and β-glucosidase, α-mannosidase, *N*-acetyl-β-glucosaminidase, and α-fucosidase (API ZYM). An exception here is *Maricaulis parjimensis* MCS 25^T which has weak α-chymotrypsin and α- and β-glucosidase activities. Most strains can store carbon as poly-β-hydroxybutyric acid. Mixtures of B vitamins, amino acids, and other organic factors are required for growth. NaCl is required for optimal growth; however, only a few strains tolerate salt concentrations above 100 g NaCl l^{-1}. All strains can grow on peptone yeast extract media with 5 g NaCl l^{-1}; optimal growth between 20 and 60 g NaCl l^{-1}. Growth is inhibited or cells become deformed in media containing 1 % or more organic material. Temperature range of most isolates is 15–40 °C, while 20–30 °C is optimal. The pH range is 6.0–8.0 and optimal pH for growth is around neutral. All strains are characterized by three major fatty acids 16:0, 17:1isoω9c, and 18:1ω7 and the following minor compounds: 17:1ω8, 17:0iso, 17:0, and 18:1ω9. 11:0iso 3-OH is the main hydroxy fatty acid. Polar lipids are α-D-glucopyranosyl diacylglycerol, α-D-glucopyranosyl diacylglycerol, sulfoquinovosyl diacylglycerol, and α-D-glucuronopyranosyl diacylglycerol taurine amide. Most strains contain also phosphatidylglycerol. All isolates were obtained only from seawater. The G+C content is 62.5–65.2 mol%.

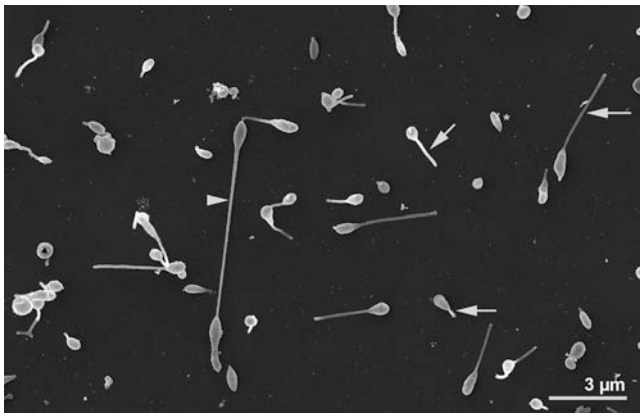

Fig. 12.3

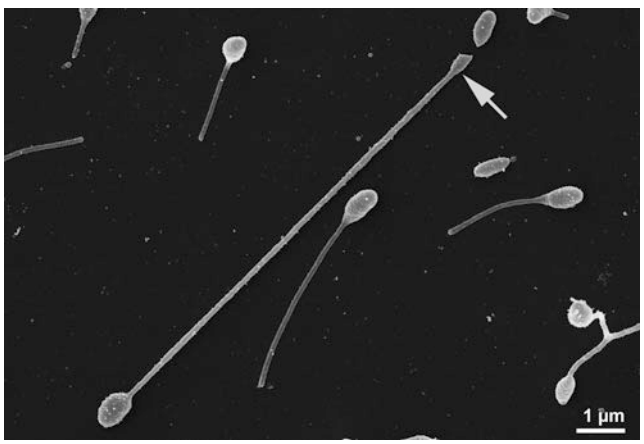

Fig. 12.4
FESEM image showing different lengths of the protheca/stalks of *Hyphomonas jannaschiana* ATCC 33883^T and starting of a budding cell from the distal end of a stalk (*arrow*)

The type species is *Maricaulis maris*. *Caulobacter halobacteroides* Poindexter 1964 was shown to be conspecific to *M. maris* by DNA–DNA hybridization.

Henriciella Quan et al. (2009); emend. Lee et al. (2011)

Henriciella (Hen.ri.ci.el'la. N. L. fem. n. *Henriciella* named after Henrici, A.T., who first described the stalked bacteria genus *Caulobacter*).

Cells are Gram-negative, aerobic, nonspore-forming, motile rods, oxidase, and catalase positive. The major respiratory quinone is Q-10. Cells are usually 0.4–0.7 µm wide and 0.7–2.8 µm long with polar flagellum. Division mode is binary fission. Some cells form mycelium, ranging from 7.8 to 8.0 µm in length. No prostheca were found in the species so far described. Good growth occurs on R2A with 1 % NaCl and MA. Colonies are translucent and shiny. Growth occurs at 10–37 °C (optimum, 20 °C), at pH 5.3–10.5 (optimum, pH 6.9–7.6), and in the presence of 10–150 NaCl g l^{-1} (optimum, 10–20 g l^{-1}). In the API ZYM system, positive for alkaline and acid phosphatase, esterase (C_4), esterase/lipase (C_8), lipase (C_{14}), leucine arylamidase, valine arylamidase, trypsin, α-chymotrypsin, α-glucosidase, and naphthol-AS-BI-phosphohydrolase activities; negative for cystine arylamidase, α-galactosidase, β-galactosidase, β-glucuronidase, β-glucosidase, α-mannosidase, and N-acetyl-β-glucosaminidase activities. *Henriciella marina* differs from this scheme by showing α-fucosidase activity but lack of cystine arylamidase activity. In the API 20NE system, negative for nitrate reduction, indole production, glucose acidification, urease, β-galactosidase, and arginine dihydrolase activities. Some species show β-glucosidase activity. Species do not hydrolyze aesculin and gelatin. The major cellular fatty acids are C18:1ω7c, C16:0, C16:1ω5c, and C17:1ω8c; hydroxyl fatty acids are C12:0 3-OH, C12:1 3-OH, and C18:1 2-OH, but from *Henriciella litoralis* SD10,^{T} no hydroxylated fatty acids were reported. The DNA G+C content of type species is 55.2–62.0 mol %. The type species is *Henriciella marina*. The only species of the genus *Maribaculum*, *Maribaculum marimum*, was transferred to this genus as *Henriciella aquamarina* (Lee et al. 2011).

Hirschia Schlesner et al. (1990); emend. Park and Yoon (2012)

Hirschia (Hirsch'i.a. M.L. fem. n. *Hirschia*, honoring Peter Hirsch, a German microbiologist who is an expert on budding and hyphal bacteria).

The description is an emended version of the description given by Schlesner et al. (1990). Gram-negative, aerobic, motile or nonmotile, oxidase- and catalase-positive, nonspore-forming, prosthecate bacteria with one or occasionally two polarly inserted prostheca (0.06–0.1 µm in diameter). Reproduction occurs by bud formation at the tips of the prostheca. The buds are polarly monotrichously flagellated. Yellow- or orange-pigmented colonies. Mature cells are spherical, oval or rod shaped and measure about 0.6–1.1 × 1.2–1.3 µm. Grow at 10–30 °C (optimum, 30 °C), at pH 6.1–10.1 (optimum, pH 8.1–9.1) with 10 g l^{-1} NaCl. Produces a non-diffusible carotenoid pigment, but bacteriochlorophyll-*a* is absent. Enzyme activities for alkaline phosphatase, trypsin, acid phosphatase, and naphthol-AS-BI-phosphohydrolase were positive, but esterase (C_4), esterase/lipase (C_8), lipase (C_{14}), valine arylamidase, cystine arylamidase, α-chymotrypsin, α-galactosidase, β-glucuronidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, and α-fucosidase were negative (API ZYM). Chemoheterotrophic, C_1 compounds are not utilized as carbon

sources. Polyhydroxybutyrate is not stored. The ubiquinone system is a Q-10 system. Main polar lipids are phosphatidylglycerol and two unidentified lipids. The major cellular fatty acids are C18:1ω7 and C16:0. Hydroxy fatty acids are 3-OH C12:0 for all known species while *Hirschia baltica* had more 3-OH C14:1. The DNA base ratio is 43.7–47 mol% G+C. The type species is *Hirschia baltica*. The genus consists currently of the species *H. baltica*, *H. maritima* Kang and Lee (2009b), and *H. litorea* Park and Yoon (2012). *H. maritima* differs from *H. baltica* by its ability to grow at 4 °C and 37 °C, its tolerance to 20 g l^{-1} NaCl, its ability to hydrolyze gelatin but not DNA, its possession of α- and β-glucosidase, and its lack of β-galactosidase and leucine arylamidase activities (Kang and Lee 2009a).

Oceanicaulis Strömpl et al. (2003)

Oceanicaulis [O.ce.an.i.cau'lis. L. masc. n. oceanus the ocean; L. masc. n. caulis stalk, referring to a prostheca; N.L. masc. n. *Oceanicaulis* stalk (ed organism) from the ocean].

The description of the genus is an emended version given by Strömpl et al. (2003). Gram negative, nonspore forming. Cells are rod shaped or vibrioid. Cultivated cells are 0.5–1 × 0.9–3 μm. In the early stage, cells are non-stalked and motile by means of a single polar flagellum. During binary fission, one cell possesses a stalk (prostheca) and the other a single polar flagellum. During binary fission, at the point of separation, one cell possesses a prostheca and the other a single polar flagellum. Adult cells are nonmotile with prostheca. Adhesive material is present at the distal end of the prostheca. Colonies on MA are round, convex, and non- or lightly pigmented. Aerobic and chemoorganotrophic. The major respiratory quinones are ubiquinone Q-10 and Q-9. Nitrate is reduced to nitrite by most strains. Strains are catalase and oxidase positive. In API ZYM tests, alkaline phosphatase, C4 esterase, C8 esterase/lipase, leucine arylamidase, valine arylamidase, cystine arylamidase, trypsin, α-chymotrypsin, acid phosphatase, and naphthol-AS-Bi-phosphohydrolase activities are present, but C14 lipase, α-galactosidase, β-galactosidase, β-glucuronidase, α-glucosidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, and α-fucosidase activities are absent. In some strains poly-β-hydroxybutyrate granule accumulation is observed. Cells grow in marine broth at full strength and at 1/10 strength. Strains tested negative for lecithinase, starch, xanthine, indole, o-nitrophenylgalactoside, and Voges–Proskauer, and most tested negative for aesculin, elastinase, gelatinase, and lipase. All strains grow with 20–90 g l^{-1} NaCl and pH 6–10. Mesophilic. Optimum growth occurs at 35–40 °C, 1–2 % NaCl, and pH 7–9. Polar lipids are phosphatidyl glycerol and sulfoquinovosyl diacylglycerol. Major fatty acids are C18:1ω7, C18:0, 7-Me-C18:1ω6, and C17:0 with 3-OH C12:0 as main hydroxy fatty acid. Many strains contain large plasmids. *Oceanicaulis stylophorae* is sensitive to gentamicin, sulfamethoxazole plus trimethoprim, rifampicin, novobiocin, chloramphenicol, nalidixic acid, and tetracycline and resistant to ampicillin, kanamycin, streptomycin, and penicillin G (Chen et al. 2012b). The G+C content of the DNA is 61–62 mol%. The type species is *Oceanicaulis alexandrii*. *Oceanicaulis* comprises two species: *O. alexandrii* and *O. stylophorae* (Chen et al. 2012b). *O. stylophorae* differs from *O. alexandrii* by its temperature range of growth of 15–45 °C (*O. alexandrii* 4–35 °C), lack of C_{14} lipase, the ability to hydrolyze casein but not CM-cellulose, and the utilization of arabinose, adipate, citrate, D-fructose, L-fucose, D-galactose, L-alanine, L-phenylalanine, and L-methionine but not maltose, α-cyclodextrin, α-D-lactose, lactulose, maltose, succinamic acid, hydroxyl-L-proline, or L-threonine.

The following genera *Algimonas*, *Hellea*, *Litorimonas*, *Ponticaulis*, *Robiginitomaculum*, and *Woodsholea* are currently monospecific. Some of their properties have been covered under "short description of genera" and in *Table 12.1*.

Algimonas Fukui et al. (2012)

Algimonas (Al.gi.mo'nas. L. n. alga, seaweed; L. fem. n. *monas*, a monad, unit; N.L. fem. n. *Algimonas*, a unit (bacterium) isolated from seaweed).

The description is the one given by Fukui et al. (2012). The type species is *Algimonas porphyrae* 0C-2-2^T isolated from the red alga *Porphyra yezoensis*. Cells are Gram-negative and straight to slightly curved rods. Many cells are non-stalked and possess a polar flagellum for motility. Some cells possess a prostheca. Multiplication occurs by binary fission. Cells produce orange carotenoid pigments but bacteriochlorophyll-*a* is not found. Aerobic condition and NaCl are required for growth. The predominant isoprenoid quinone is Q-10. Polar lipids are phosphatidylglycerol, glucuronopyranosyldiglyceride, monoglycosyldiglyceride, three unidentified phospholipids, and an unidentified glycolipid. In addition to the description of the genus, the following properties are exhibited by *Algimonas porphyrae*. The cells are 2.13 μm long and 0.37 μm in diameter in MB. Colonies on MA are circular, convex, entire, and 0.22 mm in diameter. Growth of the type strain occurs at 10–30 °C (optimum, 20 °C), pH 6.0–9.0 (optimum, pH 7.0–8.0), and 10–50 g l^{-1} NaCl (optimum, 20–30 g l^{-1}). Oxidase is negative and catalase is positive. Methyl red and Voges–Proskauer reactions are negative. H_2S and indole are not produced. Aesculin and Tween 20, 40, and 80 are hydrolyzed, but agar, alginate, DNA, gelatin, and starch are not. No acid is produced from carbohydrates. Nitrate is reduced. The type strain has alkaline phosphatase, esterase (C_4), esterase/lipase (C_8), leucine arylamidase, valine arylamidase, acid phosphatase, and naphthol-AS-BI-phosphohydrolase activities, but no lipase (C_{14}), cystine arylamidase, trypsin, α-chymotrypsin, α- and β-galactosidase, β-glucuronidase, α- and β-glucosidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, and α-fucosidase activities (API ZYM system). The type strain is susceptible to ampicillin, carbenicillin, ciprofloxacin, chloramphenicol, erythromycin, gentamicin, kanamycin, nalidixic acid, neomycin, norfloxacin, novobiocin, penicillin G, rifampicin, streptomycin, and vancomycin but resistant to polymyxin

B and tetracycline. The major cellular fatty acid is C18:1ω7*c*; the major hydroxy fatty acid is 2-OH C18:1. The G+C contents of the DNA are 58.5–60.2 mol%.

Hellea Alain et al. (2008)

Hellea (Hel.le'a. L. fem. n. Helle, a sea goddess in Greek mythology; N.L. fem. n. Hellea named after Helle in reference to the marine origin of the first strain).

The description is an emended version of the description given by Alain et al. (2008). Cells are Gram negative, nonspore forming, rod shaped to vibrioid, and dimorphic. They usually possess one polar stalk (prostheca) and are nonmotile and sessile, or they are nonstalked and motile by means of a polar flagellum. Cells divided by budding and are aerobic, heterotrophic, mesophilic, neutrophilic, and grow best at salt concentrations close to marine salinity. Colonies on MA medium are round, convex, brilliant, and pigmented a brick-red color. Optimal growth occurs at 30 °C, with growth at 15–37 °C. The pH optimum is close to neutral. Cells are catalase positive and oxidase negative and do not reduce nitrate. Hydrolysis of Tween 40 and Tween 80. Grows at NaCl concentrations of 0.2–50 g l^{-1}, with a clear optimum at 30 g l^{-1} NaCl. Growth occurs on acetate, citrate, propionate, pyruvate, succinate, aspartate, glutamate, L-alanine, L-asparagine, L-histidine, L-proline, casamino acids, peptone, tryptone, yeast extract, and D-mannitol. In addition, cis-aconitic acid, D-glucuronic acid, β-hydroxybutyric acid, γ-hydroxybutyric acid, α-ketoglutaric acid, methyl pyruvate, quinic acid, urocanic acid, L-pyroglutamic acid, hydroxy-L-proline, putrescine, *N*-acetylglucosamine, D-arabitol, myoinositol, and xylitol are used. The predominant quinone is Q-10. Polar lipids comprise glucuronopyranosyldiglyceride, monoglycosyldiglyceride, phosphatidylglycerol, an unidentified glycolipid, and two unidentified phospholipids. Main fatty acids are C18:1ω7c, C17:1ω6c, and C16:0; main hydroxy fatty acids are 2-OH C18:1 and 3-OH C10:0. The G+C content of the DNA of the type strain of the type species is 46.8 mol%. The type strain *Hellea balneolensis* 26III/A02/215^T was isolated from the surface microlayer of coastal water in the bay of Banyuls-sur-Mer, in the northwestern Mediterranean Sea on the coast of France.

Litorimonas Jung et al. (2011)

Litorimonas (Li.to.ri.mo'nas. L. n. litus -oris beach; L. fem. n. monasmonad, unit; N.L. fem. n. *Litorimonas* beach bacterium).

The description of the genus is an emended version given by Jung et al. (2011). Cells are Gram-reaction-negative, nonspore-forming, budding, straight to slightly curved rods. Usually nonstalked and motile by means of a polar flagellum; some cells possess one polar stalk (prostheca) and are nonmotile. Cells divide by budding. Oxidase and catalase positive. Neither nitrate nor nitrite is reduced. The only isoprenoid quinone detected is ubiquinone-10 (Q-10). The DNA G+C content of the type strain of the type species is 63.6 mol %. In addition to the characteristics described for the genus, the type species is characterized by the following properties. Cells are 0.4–0.6 × 1.6–2.0 μm, strictly aerobic, chemoheterotrophic, and moderately halophilic. Colonies on MA are yellow orange, convex, and round with entire margins. Growth occurs at 15–40 °C (optimum 25–30 °C), at pH 6–9 (optimum pH 7–8), and in 1–6 % (w/v) NaCl (optimum 2–3 %). Positive for assimilation of D-glucose but negative for assimilation of L-arabinose, D-mannose, maltose, D-mannitol, malic acid, potassium gluconate, *N*-acetylglucosamine, capric acid, adipic acid, trisodium citrate, and phenylacetic acid (API 20 NE). Positive for alkaline phosphatase, esterase/lipase (C_8), leucine arylamidase, valine arylamidase, cystine arylamidase, trypsin, α-chymotrypsin, acid phosphatase, and a-glucosidase activities but negative for lipase (C_{14}), α- and β-galactosidase, β-glucuronidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, and α-fucosidase activities. Weak enzymic activities are observed for esterase (C_4), β-glucosidase, and naphthol-ASB1-phosphohydrolase (API ZYM). Resistant to polymyxin B, streptomycin, gentamicin, kanamycin, novobiocin, oleandomycin, lincomycin, ampicillin, tetracycline, penicillin G, and carbenicillin but sensitive to chloramphenicol. Phosphatidylglycerol, monoglycosyldiglyceride, glucuronopyranosyldiglyceride, and two unidentified glycolipids are the polar lipids detected. The major cellular fatty acids are C18:1ω7c, C17:0, and C16:0; no hydroxy fatty acids were detected. The DNA G+C content of the type strain is 63.6 mol%; however, this value has recently been corrected drastically to 47.1 % (Fukui et al. 2012). The type strain *Litorimonas taeanensis* G5^T was isolated from beach sand in Taean, South Korea.

Ponticaulis Kang and Lee (2009a)

Ponticaulis (Pon.ti.cau'lis. L. neut. n. pontus the sea; L. masc. n. caulis a stalk, referring to a prostheca; N.L. masc. n. *Ponticaulis* stalk from the sea).

The type strain of *Ponticaulis koreensis* GSW-23^T was isolated from seawater taken from Gimnyeong Beach, Republic of Korea, and expresses the following properties (Kang and Lee 2009a). Colonies are colorless, circular, smooth, convex, and 0.3–0.5 mm in diameter after 5 days of incubation. Cells are 3.1–6.6 μm long and 0.4–0.5 μm wide. Cells are strictly aerobic, Gram-negative, nonspore-forming, non-budding, obligately halophilic rods or vibrioids that are motile by means of a polar flagellum. Multiplication occurs by binary fission. Some cells possess a long prostheca (0.2 μm in diameter) and a holdfast. The major isoprenoid quinone is Q-10. The major cellular fatty acids are summed feature 7 (C18:1ω9c, C18:1ω12t, and/or C18:1ω7c), C16:0, and C18:0. Growth occurs at 10–42 °C (optimum 30–37 °C), at pH 6.1–10.1 (optimum pH 7.1) and with up to 60 g l^{-1} NaCl. Hydrolyses DNA but not casein or starch. Degrades DL-tyrosine but not elastin, chitin, cellulose, hypoxanthine, or xanthine. Positive for gelatin hydrolysis but negative for nitrate reduction, indole production, glucose

fermentation, arginine dihydrolase, urease, aesculin degradation, and β-galactosidase (API 20NE). In API ZYM tests, positive for alkaline phosphatase, esterase (C_4) (weak), esterase/lipase (C_8) (weak), leucine arylamidase, trypsin, α-chymotrypsin, acid phosphatase, and naphthol-AS-BI-phosphohydrolase, but negative for lipase (C_{14}), valine arylamidase, cystine arylamidase, α- and β-galactosidase, β-glucuronidase, α- and β-glucosidase, *N*-acetyl-glucosaminidase, α-mannosidase, and α-fucosidase. The DNA G+C content of the type strain is 53.3 mol%.

Robiginitomaculum Lee et al. (2007)

Robiginitomaculum (Ro.bi.gi.ni.to.ma.cul'um. L. n. robigo -inis rust; L. neut. n. tomaculum, a kind of sausage; N.L. neut. n. Robiginitomaculum, a rust-colored sausage).

The type strain *Robiginitomaculum antarcticum* IMCC3195^T was isolated from surface seawater of Maxwell Bay, King George Island, West Antarctica, and possesses the following properties (Lee et al. 2007). Colonies on MA are circular, smooth, convex, viscous, rusty colored and 0.3–1.0 mm in diameter. Cells are Gram-negative; 1.3–4.5 mm long and 0.4–1.0 mm wide, with a tapered end; nonmotile; non-budding; thin prostheca-producing; and obligately aerobic rods or vibrioids. Multiplication occurs by binary fission. Flagella and holdfast are not present. Some cells possess a thin prostheca that extends along the long cell axis from one pole. Carotenoid pigments are found but bacteriochlorophyll-*a* not. Chemoheterotrophic. The predominant fatty acids are C18:1ω7c, C17:1ω8c, C17:0, and C17:1ω6c and hydroxy fatty acids are 3-OH C9:0, 3-OH C10:0, and 3-OH C11:0. The major respiratory quinone is Q-10. Growth occurs at 3–25 °C, optimally at 20 °C, but not above 30 °C. Growth occurs at pH 5–10 and 5–50 g l^{-1} NaCl, optimally at pH 7 and at 20–25 g l^{-1} NaCl. Oxidase negative and catalase positive. In API 20NE strips, positive for nitrate reduction, aesculin hydrolysis, and β-galactosidase activity. Negative for urea hydrolysis, indole production, acid production from glucose, gelatin liquefaction, and arginine dihydrolase. In the API ZYM system, alkaline phosphatase, esterase/lipase (C_8), leucine arylamidase, valine arylamidase, and cystine arylamidase activities are present. Negative for esterase (C_4), acid phosphatase, β-glucosidase, *N*-acetyl-β-glucosaminidase and α-mannosidase, lipase (C_{14}), trypsin, α-chymotrypsin, naphthol-AS-BI-phosphohydrolase, β-galactosidase, β-glucuronidase, α-galactosidase, α-glucosidase, and α-fucosidase activities. Susceptible to chloramphenicol, erythromycin, rifampicin, and tetracycline, but resistant to ampicillin, gentamicin, kanamycin, penicillin G, streptomycin, and vancomycin. The DNA G+C content is 60.3 mol%.

Woodsholea Abraham et al. (2004)

Woodsholea (Woods.hol'e.a. N.L. fem. n. *Woodsholea* named in honor of the Woods Hole Oceanographic Institution, Massachusetts, USA).

The description of the genus is the one given by Abraham et al. (2004). The type strain of *Woodsholea maritima* CM243^T was isolated from seawater taken from Woods Hole, USA, and expresses the following properties (Abraham et al. 2004): Gram-negative cells, rod shaped and vibriod. Cells possess a stalk, varying in length depending on the strain and environmental conditions, extending from one pole as a continuation of the long axis of the cell. Adhesive material is present at the distal end of the stalk. Occur singly. Multiplication by binary fission. Colonies circular, convex, colorless. Chemoorganotrophic, aerobes, cells can store carbon as poly-β-hydroxybutyric acid. Requirement for organic growth factors is complex and not satisfied by mixtures of B vitamins and amino acids. Grows on peptone/yeast extract media with 40 g NaCl l^{-1}. Growth is inhibited or cells become deformed in media containing 1 % (w/v) or more organic material. Growth temperature range is 20–40 °C and optimal pH for growth is approximately neutral. Do not reduce nitrate, oxidize tryptophan to indole, or hydrolyze arginine, urea, aesculin, gelatin, or p-nitrophenyl-3-D-galactopyranoside. Cells show no catalase activity and are positive for alkaline phosphatase, naphthol-AS-BI-phosphohydrolase, leucine arylamidase, acid phosphatase, esterase (C_4), esterase/lipase (C_8), oxidase, and trypsin but negative for α- and β-galactosidase, β-glucuronidase, α- and β-glucosidase, α-mannosidase, and α-fucosidase. Strains have no to weak α-chymotrypsin and *N*-acetyl-β-glucosaminidase activities; some isolates including the type strain have weak lipase activity. The genus is characterized by two major fatty acids, 18:0 and 18:1ω7c, and minor amounts of 12:0 3-OH, 16:0, 17:0, summed feature 3 (14:0 3-OH, 16:1 iso I, ECL 10.928, and/or 12:0 ALDE), and the unidentified fatty acid ECL 15.275. Polar lipids are α-D-glucopyranosyl diacylglycerol, α-D-glucopyranuronosyl diacylglycerol, sulfoquinovosyl diacylglycerol, and α-D-glucuronopyranosyl diacylglycerol taurine amide. Isolated from seawater. The G+C content is 65 mol%. The G+C content of the type strain is 65.2 mol%. The type species is *Woodsholea maritima*.

Isolation, Enrichment, and Maintenance Procedures

Cell densities of *Hyphomonadaceae* in sea samples are usually low because of the oligotrophic nature of the cells. At the same time the cells are adapted to starvation and this can be used for their isolation. For this reason old marine samples are usually enriched in these bacteria. Many *Hyphomonadaceae* stick with their holdfasts to surfaces, and these surfaces can be other bacteria but also eukaryotic cells. Therefore, filtering the sea samples before plating is not advisable and would lead to a loss of bacteria of interest. Strains of *Hyphomonadaceae* can be isolated from seawater using a standard dilution-plating method on an oligotrophic medium, e.g., R2A agar, diluted 1:10 in seawater (1/10R2A). Because all strains are coming from oligotrophic habitats, full media with more than 1 g l^{-1} soluble organic substrates should be avoided which will cause disfiguring of the cells (pleomorphism). Cell growth is slow

and colonies are visible often only after one or even more weeks. Another isolation method is keeping the seawater sample after addition of 10–30 mg l^{-1} peptone or other carbon source at room temperature for 1–2 months and plating the formed surface film (biofilm) on diluted agar. Instead of using the neuston of the samples, substrata can be submerged in the samples acting as target for the attachment of *Hyphomonadaceae*. The plates can then be removed and the attached bacteria scrapped off and plated. At least *Maricaulis*, *Woodsholea*, *Henriciella*, and *Oceanicaulis* species can also be grown in 0.05 % peptone, 0.05 % casamino acids, and 75–80 % seawater (CPS medium, Poindexter 1964) or marine *Caulobacter* medium SPYEM containing 30 g sea salts (Sigma), 0.5 g NH_4Cl, and 1 l deionized water. After autoclaving and cooling, 20 ml 50 × PYE (50 × PYE: 100 g peptone and 50 g yeast extract in 1 l deionized water (autoclaved)), 2 ml 50 % glucose, and 5 ml riboflavin (0.2 mg ml^{-1}) are added (Abraham et al. 1999). Further purification can be done on marine agar 2216 (MA) after culture at 20 °C for 2 weeks. One should keep in mind that most *Hyphomonadaceae* form clumps and the isolates have to be checked carefully for any mixed cultures. Almost all strains need complex media for growth. One exception is Hyphomonas neptunium which can be grown on GAMS medium: 125 mM of each glutamate, aspartate, serine, methionine, 0.26 µM calcium pantothenate, and 30 % seawater (Havenner et al. 1979). Most strains can be preserved as glycerol suspension (10 %, v/v) at −75 °C. Vegetative stocks should be maintained on 1 % 1/10 R2A agar slants at 4 °C and transferred every 8 or 9 weeks, incubated 2 or 3 days at 20–25 °C then kept at 4 °C. For many strains lyophilization is problematic and often not reliable.

Cell Morphology

All species in the family *Hyphomonadaceae* possess dimorphic cells (◉ *Fig. 12.3*) and reproduce either by binary fission or by budding. Meso-diaminopimelic acid is the diagnostic diamino acid of the cell-wall peptidoglycan. Sessile cells are connected via a stalk to their substrata. For replication in *Algimonas*, *Henriciella*, *Maricaulis*, *Oceanicaulis*, *Ponticaulis*, *Robiginitomaculum*, and *Woodsholea*, a cell is separated by binary fission from the progenitor cell. This sibling carries no stalk but a flagellum which propels it through the medium until a suitable site is found (◉ *Fig. 12.5*). Here the sibling then develops a stalk, becomes sessile, and sheds the flagellum. Long axis of cells can be distinctly curved, but may be straight in some species. Cells are long and slender, approximately 1.5–2.5 µm in length when not dividing, and less than 0.5 µm in diameter or approximately 1 µm in length when not dividing and 0.6 µm in diameter. Stalk length dependent on growth condition and species, one to four times the length of the cell body, diameter 0.11–0.18 µm (◉ *Figs. 12.6* and *12.7*). With the exception of cells of *Robiginitomaculum*, the stalk carries adhesive material at its distal end. *Hellea*, *Hirschia*, *Hyphomonas*, and *Litorimonas* replicate in a different manner. Here the stalk is a reproductive

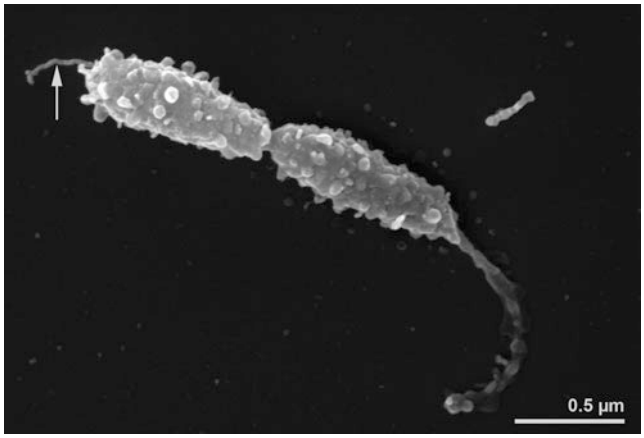

Fig. 12.5
FESEM image of a dividing *Maricaulis salignorans* MSC 18^T cell that depicts the formation of a daughter cell. A flagellum is formed from the distal end of the daughter cell

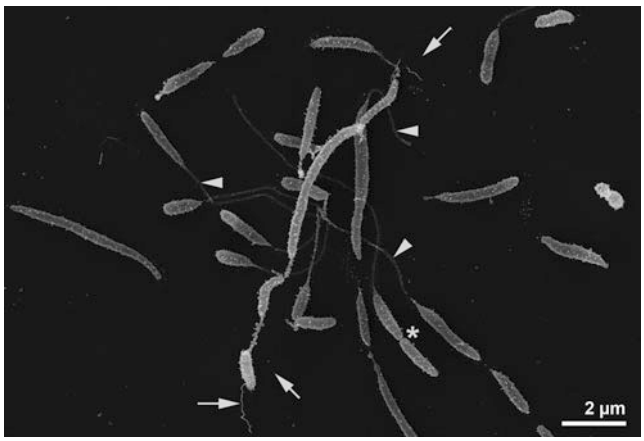

Fig. 12.6
FESEM image of logarithmically grown *Maricaulis salignorans* MSC 18^T showing the diverse distinct morphological features of formation of prostheca/stalks with different lengths (*arrowheads*) and cells with flagella (*arrows*) and a dividing cell (*star*)

structure and DNA and proteins are channeled through it to the new budding cell. Transport within the stalk is achieved in compartments, so-called pseudovesicles (Zerfas et al. 1997) (◉ *Fig. 12.8*). Cells are rod shaped to oval, 0.5–3.0 µm long, and 0.5–1.0 µm in diameter; buds are produced at the tips of polar prosthecae, which measure 0.2–0.3 µm in diameter and are one to five times the length of the cell body. Swarm cells are motile by means of a single polar to lateral flagellum located on developing buds of younger daughter cells (◉ *Fig. 12.9*).

These two groups of cells seem to differ not only in their reproduction but also in their reproductive abilities. While cells of *Maricaulis* or *Caulobacter* produce about 100 offsprings during their lifetime (Poindexter 1964; Ackermann et al. 2003), this number is limited to about 8 in budding genera (Moore 1981).

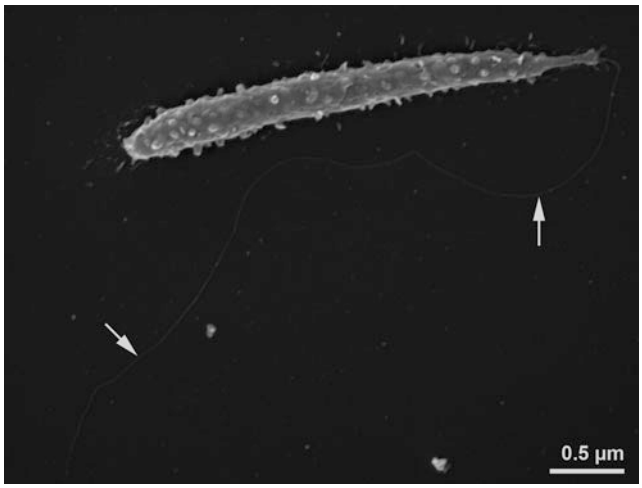

Fig. 12.7
FESEM image of a swarmer cell of *Maricaulis salignorans* MSC 18^T exhibiting a long flagellum

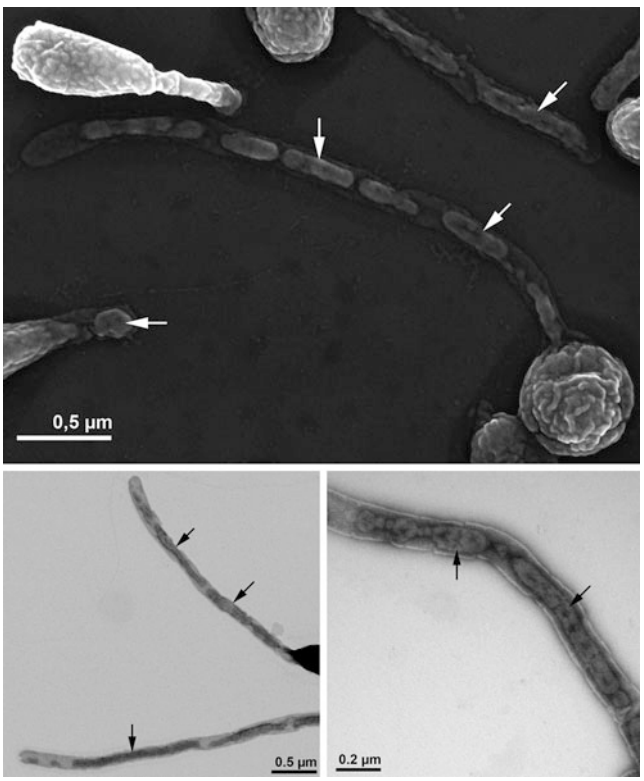

Fig. 12.8
Within the prosthecum/stalk, clearly defined pseudovesicles (*arrows*) can be distinguished by FESEM (*upper image*) or by negatively staining with 2 % uranyl acetate of logarithmically grown *Hyphomonas polymorpha* DSM 2665^T in transmission electron microscopy (*lower two images*). The pseudovesicles are covered by the outer membrane of the bacterium

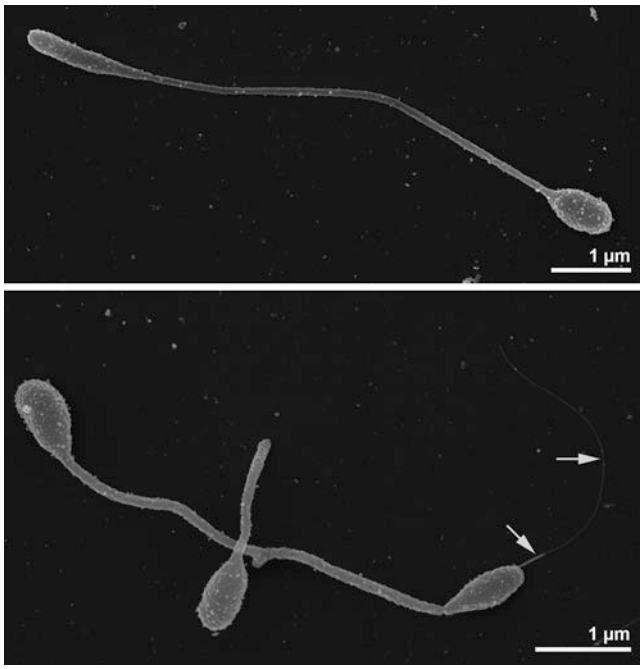

Fig. 12.9
FESEM image depicting a budding cell of *Hyphomonas jannaschiana* ATCC 33883^T from the distal end of a prosthecum/stalk (*upper image*). The formation of a flagellum (*arrows*) after dividing (*lower image*) is visible. The cell with the flagellum will be released as a swarmer cell

One way to protect cells from exoenzyme activities, antibiotics, or other noxious agents produced in biofilms is the formation of S-layers. Such an S-layer was characterized for *Hyphomonas jannaschiana* and two proteins of 29 and 116 kDa were isolated. Both proteins are glycoproteins with the heavier one being the tetramer of the smaller protein. They seemed to be linked by divalent cations because they could be solubilized by EDTA (Shen and Weiner 1998). For the stalk of *Oceanicaulis alexandrii*, it has been shown that it is also covered by an S-layer (Strömpl et al. 2003). S-layers have been found in many *Caulobacteraceae* and it can be assumed that they are also present in a number of *Hyphomonadaceae* species where they have not yet been reported.

Physiology and Metabolism

All species of *Hyphomonadaceae* are strict aerobes although many of them are able to reduce nitrate. None of the isolates have been reported to grow on any mineral medium containing a single substrate as sole source of carbon and energy. Some strains can grow on such a medium if it is supplemented by various growth factors, but most strains need complex (and often ill-defined) mixtures of growth factors or even carbon substrates. *Hyphomonas* are amino-acid-requiring isolates. *Hyphomonas johnsonii* is an outlier species in its genus because it is the only species able to use sugars.

Ecology (Main Habitats)

The main habitat of *Hyphomonadaceae* is the sea with two exceptions: *Hirschia baltica* was isolated from brackish water and *Hyphomonas polymorpha* was isolated from human nasal secretions (but the patient was a deep sea diver). The optimal growth temperature for most species is around 20–30 °C. This is also true for *Robiginitomaculum antarcticum* although it was isolated from surface seawater of Maxwell Bay, King George Island, West Antarctica. This species and species from hydrothermal vents, e.g., *Maricaulis virginensis*, however, can also grow at lower temperature which they probably experience in their special habitats. A true psychrophilic *Hyphomonas* sp. (strain SW47) was isolated from Antarctic sea ice underlining again the ability of some *Hyphomonadaceae* strains to thrive in cold habitats (Bowman et al. 1997).

Although only few reports are available, it can be expected that due to the oligotrophic nature of their habitats, cell numbers of these bacteria will be low. All *Hyphomonadaceae* have swarmer cells which are motile. The dispersal of the progenitor cells is important for species living in oligotrophic habitats because it prevents competition of the siblings for substrates. Genomic and experimental evidences indicate that at least *Hyphomonas neptunium* cells are not chemotactic. The lack of evidence for chemotaxis supports the notion that motility among *Hyphomonas* swarmer cells is a random dispersal method (Badger et al. 2006). However, for most of the *Hyphomonadaceae* species, this has not yet been investigated.

For a number of isolates, associations with eukaryotic cells were reported. *Oceanicaulis alexandrii* was isolated from the marine dinoflagellate *Alexandrium tamarense* (Lebour) Balech. *Maricaulis virginensis* VC-13 was reported to associate in cocultures with several diatoms (Poindexter 2006). The phylogenetic analysis of bacterial communities associated with leaves of the seagrass *Halophila stipulacea* revealed three clones belonging to the Hyphomonadaceae (Weidner et al. 2000). They are phylogenetically positioned between the genera *Ponticaulis* and *Henriciella*. Currently the nature of these associations is not clear, and it has been suggested that the attachment of these strains may simply be caused by the need for a surface to attach. The advantage of an attachment to eukaryotes, however, can easily exceed the mere requirement for a surface to attach. Use of exudates excreted by the eukaryotic host, consumption, and detoxification of oxygen produced by photosynthetic algae or a closed carbon cycle of oxidation of exudates to CO_2 and immediate fixation of the produced CO_2 by the photosynthetic host are only few of the many advantages such epibionts may have in the environment (Poindexter 2006). Still much more research is needed to understand the association of *Hyphomonadaceae* to their hosts.

Biological and Technological Relevance

For none of the isolates, any pathogenicity was shown. This is even the case for *Hyphomonas polymorpha* which comes from a human habitat (Pongratz 1957). Subsequent studies on the diversity of bacteria in the human nasal cavity, however, did not seem to confirm that this is a common habitat for *Hyphomonas* species (Frank et al. 2010).

Only few potential biotechnological applications for strains of the *Hyphomonadaceae* have been reported. A novel architecture has been revealed for the *N*-acetylglutamate synthase of *Maricaulis maris* MCS 10, but it is still too early to predict any biotechnological application from this finding (Shi et al. 2011). *Hyphomonadaceae* have also been shown to be major members in the degradation of municipal solid waste (Trzcinski et al. 2010), but the reported SSU RNA gene sequence is too short for identification of the genus. Strains of *Hyphomonadaceae* seem also to have abilities to degrade complex or even xenophytic organic compounds. Freshwater bacteria degrade the aromatic heterocyclic organic compound carbazole via angular dioxygenation using 1,9a-dioxygenases. A screening for marine isolates possessing this metabolic potential revealed two *Hyphomonadaceae*, strains OC-5 and OC-6 (Maeda et al. 2009). While strain OC-5 falls within the genus *Hyphomonas*, strain OC-6 seems to be a member of the genus *Henriciella*.

To form biofilms many Proteobacteria use *N*-acyl-homoserine lactones (AHLs) for communication for their quorum-sensing systems. It has been first shown for some bacteria that there are enzymes which can split these lactones quenching quorum sensing. There are enzymes cleaving AHL at the lactone site and others cleaving the acyl site chain. While cleavage at the first site is reversible, cleaving the acyl side chains destroys the bioactivity of AHL permanently. These enzymes gained more importance recently as tools to control biofilms (Abraham 2005). Kalia et al. (2011) analyzed the genomes of a number of bacteria for the presence of acyl-homoserine lactone-acylases and lactonases and found both AHL lactonase and acylase in *Hyphomonas neptunium* ATCC 15444. The positive identification of these enzymes has not only possible biotechnological applications, but it tells us also that at least this strain is possible to control biofilm formation of other bacteria by destroying their AHLs.

Concluding Remarks and Perspectives

The last decade has seen descriptions of a number of novel genera belonging to the family *Hyphomonadaceae*, and there is no reason to believe that this will come to an end. We looked at the phylogeny of clones from environmental samples which fall into the space of the *Hyphomonadaceae* to get an impression what may be in store in the future. There are a number of SSU rRNA gene sequences which do not fall into any of the described genera pointing to the existence of genera still novel to science. There are two groups of genera which will probably change if novel species will lead to a sharper definition of these genera. One of these genera is *Henriciella*. Here, only non-stalked species are known but we have isolates in

our laboratory which fall into this genus but clearly show prostheca. Although *Henriciella* is phylogenetically close to *Hyphomonas*, these isolates divide not by budding but by binary fission resembling more *Maricaulis* than *Hyphomonas* species. Another complex of genera for which the genus boundaries seem to be not well defined is formed by the genera *Maricaulis*, *Woodsholea*, and *Oceanicaulis*. Currently criteria can be extracted differentiating these genera; however, only future will tell whether we already know the whole diversity of the species of this complex. This statement is generally valid for any of the single-species genera populating the phylogenetic tree of the *Hyphomonadaceae*. From these considerations it can easily be predicted that we are still facing many exciting new discoveries in this family.

Acknowledgments

The long-standing cooperation with John Smit, Vancouver, and Edward Moore, Gothenburg, is very much acknowledged. We also thank Jennifer Knaak for technical assistance.

13 The Order *Kiloniellales*

Johannes F. Imhoff · Jutta Wiese
Marine Mikrobiologie, GEOMAR Helmholtz Centre for Ocean Research, Kiel, Germany

Abstract
The *Kiloniellaceae* family is represented currently by a single genus *Kiloniella* with the species *Kiloniella laminariae* as type species. *Kiloniella laminariae* was isolated from the marine macroalga *Saccharina latissima* (former *Laminaria saccharina*) obtained from the Baltic Sea. The bacterium is a mesophilic, typical marine bacterium. It is a chemoheterotrophic aerobic bacterium with the potential of denitrification. Growth optima are at 25 °C, pH 5.5, and 3 % NaCl. The distinguished phylogenetic position separates *Kiloniella* from other alphaproteobacterial orders. The 16S rRNA gene sequence revealed a distant relationship to species of several orders of the *Alphaproteobacteria* with less than 91 % sequence similarity. This gives rise to the recognition of *Kiloniella* as a representative of a new order of the *Alphaproteobacteria*, the *Kiloniellales*. Phylogenetic analyses revealed a distinct cluster of *Kiloniella* with an uncharacterized bacterium (isolate KOPRI 13522) from hydrothermal plumes. This cluster forms a larger group together with the distantly related *Terasakiella pusilla* (88.4 % sequence similarity of the 16S rRNA gene) and the *Thalassospira* species (88.9–90.2 % sequence similarity). These genera are supposed to form separate families within the *Kiloniellales*.

Taxonomy: Historical and Current

Among bacteria associated with the marine brown alga *Saccharina latissima* (former *Laminaria saccharina*), a new bacterium not associated to any of the known alphaproteobacterial orders was isolated. The new bacterium was described as the new species and genus *Kiloniella laminariae* and was considered as the representative of a new family and order of the *Alphaproteobacteria*, the *Kiloniellaceae* and *Kiloniellales* with the genus *Kiloniella* as the type genus of the new family (Wiese et al. 2009a). Among the *Alphaproteobacteria* the *Kiloniellales* form a distinct phylogenetic branch separate (Fig. 13.1) from *Caulobacterales*, *Sphingomonadales*, *Rhizobiales*, *Rickettsiales*, *Rhodobacterales*, *Rhodospirillales*, *Kordiimonadales*, *Sneathiellales*, and *Parvularculales* (Garrity et al. 2005; Jordan et al. 2007; Kurahashi et al. 2008; Kwon et al. 2005).

Kiloniella laminariae is phylogenetically most closely related to an undescribed isolate, KOPRI 13522, and distantly related to the genera *Terasakiella* and *Thalassospira* (Wiese et al. 2009a). Characteristic of species of these two genera as well as of *Kiloniella laminariae* is the low G+C content of 48–55 % (see Table 13.1), which differentiates these bacteria from most species of the *Rhodospirillales* which exhibit a significantly higher DNA G+C content between 62 % and 67 %, in some clusters of *Acetobacteraceae* related to *Craurococcus* species even exceeding 70 % (Shi et al. 2002). Due to the distant relationship to *Kiloniella*, *Terasakiella* and *Thalassospira* may not be considered members of the *Kiloniellaceae* family but should be included into the order *Kiloniellales* as separate families (see Fig. 13.1). According to phylogenetic calculations, all three genera are distinct from *Rhodospirillales* and other alphaproteobacterial orders (Wiese et al. 2009a).

Molecular Analyses

Sequence similarity values of the 16S rRNA gene of *Kiloniella laminariae* to the seven closest validly described type strain sequences are between 90 % and 91 % including representative of the *Rhodospirillales*, the *Rhizobiales*, the *Rhodobacterales*, and *Thalassospira xianhensis* (Table 13.2). Another 30 species similar at the level of 88.4–89.7 % include members of the *Rhizobiales* and species of *Thalassospira* and *Terasakiella*.

All phylogenetic trees confirm the close relationship of *Kiloniella laminariae* to an uncharacterized isolate (strain KOPRI 13522) from hydrothermal plumes at the East Pacific Rise (Wiese et al. 2009a). The two bacteria form a distinct group with 100 % bootstrap values separate from any known alphaproteobacterial order. They form a cluster with the distantly related *Terasakiella pusilla* IFO 13613^T and the *Thalassospira* species (*T. lucentensis* DSM 14000^T, *T. profundimaris* DSM 17430^T, *T. tepidiphila* DSM 18888^T, *T. xianhensis* JCM 14850^T, *T. xiamenensis* DSM 17429^T). Though members of the genus *Thalassospira* were provisionally assigned to the family *Rhodospirillaceae* (Lopez-Lopez et al. 2002; Kodama et al. 2008; Zhao et al. 2010), the phylogenetic analysis strongly supported the

[h]The characteristic is given for *T. tepidiphila*

[i]*T. lucentensis* shows no anoxic photosynthetic growth. *T. xiamenensis* and *T. profundimaris* were not examined

formation of a cluster including *Thalassospira* species together with *Terasakiella pusilla* and *Kiloniella laminariae* (>90 % bootstrap values) which is clearly separated from *Rhodospirillaceae* and *Acetobacteraceae* (<91 % sequence similarity) as well as other *Alphaproteobacteria* (Fig. 13.1). Although *Kiloniella laminariae* shares less than 90.3 % 16S rRNA gene sequence similarities to species of the genera *Thalassospira* and *Terasakiella* (Table 13.2), because of the clear cluster formation in phylogenetic calculations, it is suggested to include members of the genera *Thalassospira* and *Terasakiella* together with *Kiloniella* in the order *Kiloniellales*.

Those species of other alphaproteobacterial orders found similar to *Kiloniella* at an 16S rRNA sequence level of 88–91 % revealed significantly higher G + C content of their DNA: *Pelagibius litoralis* (*Rhodospirillales* – 66.3 mol%) (Choi et al. 2009), *Mesorhizobium camelthorni*, *Ensifer terangae* and *Pseudaminobacter salicylatoxidans* (*Rhizobiales* – 61.6–63.9 %) (Chen et al. 2011; Young 2003; Kämpfer et al. 1999), and *Parvularcula bermudensis* (*Parvularculales* – 60.8 mol%) (Cho and Giovannoni 2003). On the other hand, *Kordiimonas gwangyangensis* (*Kordiimonadales*) has remarkable low values of 39.3 mol% (Kwon et al. 2005).

Phenotypic Analyses

Characteristic properties of *Kiloniella* and *Kiloniellaceae* according to those of *Kiloniella laminariae* (Wiese et al. 2009a) are as follows. Colonies grown on marine broth are cream colored, smooth, soft, and have a diameter between 1 and 2 mm. Cells are motile with a monopolar flagellum. They are Gram-negative, slender, slightly curved spirilla, and their size is 0.5–0.6 × 2.5–5.0 µm. Short rodlike cells and also longer filamentous cells may occasionally be observed. Pigments are not produced under any growth condition applied.

Kiloniella species grow as chemoheterotrophic aerobic bacteria in complex media and can use nitrate as an alternative

electron acceptor. In the case of *K. laminariae*, nitrate is reduced to gaseous products (N_2O is the major product and *nosZ*, the gene for N_2O reductase, is lacking). The temperature range for growth is from 4 °C to 40 °C with an optimum of 25 °C. The pH range is pH 3.5–9.5 with an optimum at 5.5. Typical marine and moderately halotolerant bacteria. Salt is required for growth, which occurs in media containing 0.3–8.0 % NaCl (optimum 3.0 %) or 0.3–10 % artificial sea salts (optimum 4.0 %). Catalase and oxidase reactions were positive and poly-ß-hydroxybutyrate was accumulated. Luminescence was negative. Details of the physiological characteristics of *K. laminariae* including substrate utilization and enzyme activities are given in the species description (Wiese et al. 2009a).

The dominant fatty acids are *cis*-7-octadecenoic acid (C18:1ω7c), which contributed approximately 50 % of the total amount, and *cis*-7-hexadecenoic acid (C16:1ω7c) representing 31 %. The individual fatty acids and their proportions are listed in *Table 13.3*. The G + C content of the DNA of *Kiloniella laminariae* is 51.1 mol%.

Common properties of *Kiloniella laminariae* and its phylogenetic neighbors *Terasakiella pusilla* and the *Thalassospira* species are the salt requirement and tolerance up to approx. 8–10 % NaCl, the aerobic chemoorganotrophic mode of growth, the ability to reduce nitrate, the G + C content of the DNA from 48 to 55 mol%, and the spiral to vibrioid cell shape (*Table 13.1*). Differential characteristics of *Kiloniella* to these bacteria, in addition to clear differences in 16S rRNA gene sequences (88.4–90.2 mol %), are the proportions of fatty acids, in particular the production of 3-hydroxy heptadecanoic acid by *Kiloniella laminariae* and the reduction of nitrate to N_2O by this species instead of nitrite by the other bacteria (*Table 13.3*). In addition, *Terasakiella pusilla* possesses bipolar flagella compared to the single monopolar flagellum of *Kiloniella* and *Thalassospira*.

Isolation, Enrichment, and Maintenance Procedures

Homogenized and suspended tissue of *Saccharina latissima* or material from alternative sources is diluted in sterile seawater and plated on TSB medium (3 g/l Difco tryptic soy broth, 7 g/l NaCl, 15 g/l Bacto agar, pH 7.2). The plates are incubated at 22 °C, and after good growth an overlay containing TSB medium (with 8 g/l Bacto agar) inoculated with an overnight culture of *Candida glabrata* DSM 6425 is poured on top. After incubation for 24 h at 22 °C, antibiotic-active colonies are visible due to inhibition zones against *C. glabrata* and are picked and repeatedly streaked on agar plates until pure cultures are obtained. Storage at −80 °C using the Cryobank System (Mast Diagnostica GmbH) is used for maintenance (Wiese et al. 2009a).

Ecology

The worldwide distribution of *Laminaria* and related genera of marine macroalgae (Bartsch et al. 2008) and the supposed predetermination of the microbial community composition through physiological and biochemical properties of these algae (Goecke et al. 2010) suggest also wide distribution of bacteria associated with these algae in marine habitats. *Kiloniella laminariae* was one out of approximately 100 antibiotic-active bacteria isolated from the marine macroalga *Saccharina latissima* (former *Laminaria saccharina*) from the Kiel Fjord (Baltic Sea, Germany). Although by and large the ecological role of *Kiloniella* is not known, this bacterium inhibited the growth of *Bacillus subtilis* and of *Candida glabrata* (Wiese et al. 2009b), and it is assumed that it may be able to protect the host against microbial destruents and causative agents of algal diseases by producing antibiotics. Such beneficial effects also have been proposed for *S. latissima* by associated pseudomonads (Nagel et al. 2012).

Application

Kiloniella laminariae revealed antimicrobial activity against the Gram-positive *Bacillus subtilis* and the yeast *Candida glabrata* (Wiese et al. 2009b). This indicates the potential to produce compounds that can be applied against pathogens causing algal and human diseases.

[4]Department of Plant and Environmental Sciences, The Institute of Life Sciences, The Hebrew University of Jerusalem, Jerusalem, Israel

Abstract
The genus *Kordiimonas* is the only genus within the order *Kordiimonadales* (Kwon et al. Int J Syst Evol Microbiol 55:2033-2037, 2005), an order that contains a single family—the *Kordiimonadaceae*, a name we here formally propose. Currently (January 2013) the genus *Kordiimonas* contains four species: *K. gwangyangensis*, *K. lacus*, *K. aestuarii*, and *K. aquimaris*. *Kordiimonas* species form a monophyletic cluster, and can be distinguished from other groups within the *Alphaproteobacteria* by their chemotaxonomic features, especially by their cellular fatty acid composition. Branched fatty acids are seldom found in the *Alphaproteobacteria*, but high contents of iso- and anteiso-branched fatty acids were reported in *Kordiimonas* species. *Kordiimonas* is distributed globally, but has never yet been found as a dominant population. The natural habitats are mainly marine environments: seawater and marine sediments. Enrichment and isolation of *Kordiimonas* strains usually require low nutrient media and long incubation periods. No clinical reports of infections of humans or animals by *Kordiimonas* species have been published. *K. gwangyangensis* participates in polycyclic aromatic hydrocarbon degradation as well as alkane oxidation.

Taxonomy, Historical and Current

Order *Kordiimonadales* Kwon, Lee, Yang and Kim 2005, 2036[VP]

Kor.di.i.mo.na.da'les. N.L. fem. n. *Kordiimonas*, type genus of the order; suff. *–ales*, ending denoting an order; N.L. fem. pl. n. *Kordiimonadales*, the *Kordiimonas* order.

The order *Kordiimonadales*, with the genus *Kordiimonas* as the sole described genus, was proposed mainly on the basis of its phylogenetic position (Kwon et al. 2005). Thus far, no formal proposal was made to name the family in which this genus should be classified. We therefore propose here the family name *Kordiimonadaceae*.

Family *Kordiimonadaceae* (Effective publication: Xu, Wu and Oren, this publication).

Kor.di.i.mo.na.da'ce.ae. N.L. fem. n. *Kordiimonas* type genus of the family; *-aceae* ending to denote a family; N.L. fem. n. *Kordiimonadaceae* the family of *Kordiimonas*.

The descriptions of the order and the family are the same as for the genus *Kordiimonas* (see below).

The genus *Kordiimonas* (Kwon et al. 2005; emended by Xu et al. 2011; emended by Yang et al. 2013) is the only genus within the order and the family. Currently (January 2013) the genus contains four species: the type species *K. gwangyangensis* (Kwon et al. 2005), *K. lacus* (Xu et al. 2011), *K. aestuarii* (Math et al. 2012), and *K. aquimaris* (Yang et al. 2013). Several additional isolates that share >90 % 16S rRNA gene sequence similarity with *K. gwangyangensis* have been classified within the same group (Ito et al. 2011; Maeda et al. 2009, 2010). The cells are Gram-negative straight to slightly curved rods, motile by means of flagella. The G+C content of the DNA varies between 50 and 58 mol%. The predominant quinone is Q-10. The major components in the polar lipid profile are phosphatidylethanolamine and several unidentified glycolipids, aminophospholipids and amino-lipids. The major fatty acids are iso-$C_{17:1}$ $\omega 9c$, iso-$C_{15:0}$ and $C_{16:1}$ $\omega 7c$ and/or iso-$C_{15:0}$ 2-OH. $C_{16:0}$, iso-$C_{17:0}$, $C_{18:1}$ $\omega 7c$ and hydroxyl fatty acids (iso-$C_{17:0}$ 3-OH and $C_{16:0}$ 3-OH) may also occur. The 16S rRNA gene signatures common to all thus far characterized strains are 150 (C), 164 (G), 409–433 (U-A), 442–492 (G-C), and 998–1043 (A-U). *Kordiimonas* species are obligatory aerobic chemoheterotrophic bacteria, like the majority of the currently described

E. Rosenberg et al. (eds.), *The Prokaryotes – Alphaproteobacteria and Betaproteobacteria*, DOI 10.1007/978-3-642-30197-1_261,

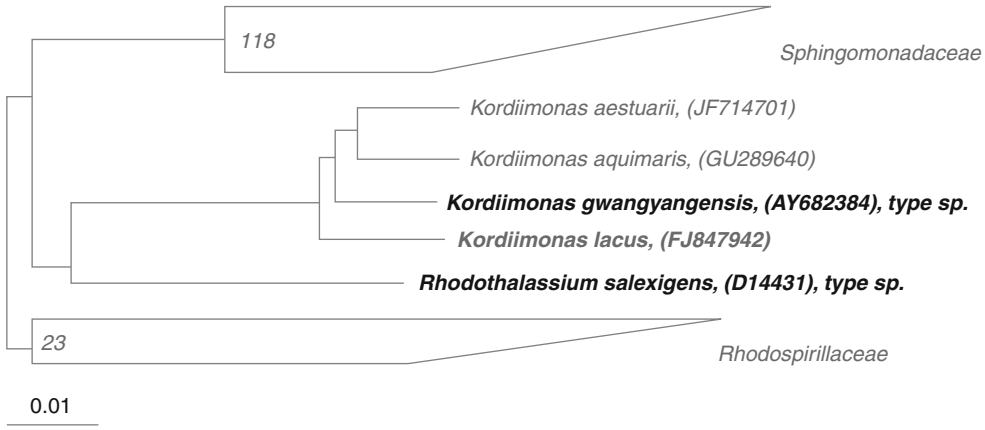

Fig. 14.1

Neighbor-joining genealogy reconstruction of the two species of the family *Kordiimonadaceae* present in the LTP_106 (Yarza et al. 2010), and two more species whose descriptions were added later. The tree was reconstructed by using a subset of sequences 767 type strains of bacteria and archaea to stabilize the tree topology. In addition, a 40 % conservational filter for the whole bacterial domain was used to remove hypervariable positions. Numbers in triangles denote number of taxa included. The bar indicates 1 % sequence divergence

strains living in marine habitats. Some participate in polycyclic aromatic hydrocarbons (PAHs) degradation as well as alkane oxidation.

Phylogenetic Structure of the Family and Its Genus

The order *Kordiimonadales* was proposed on the basis of the phylogenetic position of its representatives within the *Alphaproteobacteria* (Kwon et al. 2005). In the neighbor joining tree based on 16S rRNA sequences (Fig. 14.1), its closest relatives are *Rhodothalassium salexigens*, the family *Sphingomonadaceae*, and the family *Rhodospirillaceae*. A maximum likelihood tree shows the same topology. The four *Kordiimonas* species form a monophyletic cluster that can be distinguished from others by its chemotaxonomic features, especially the cellular fatty acid composition. Branched fatty acids are not commonly found in the *Alphaproteobacteria*, but high contents of iso- and anteiso-branched fatty acids were reported in *Kordiimonas* species. The contents of iso-branched fatty acids of type strains of *K. gwangyangensis*, *K. lacus*, *K. aestuarii* and *K. aquimaris* were 68 %, 56 %, 71 %, and 67 %, respectively (Xu et al. 2011; Math et al. 2012; Yang et al. 2013).

K. gwangyangensis GW14-5^T and *K. aestuarii* 101-1^T were isolated from marine sediments near Korea. Several other strains, isolated from seawater off the coast of Japan, were classified in the order *Kordiimonadales* on the basis of 16S rRNA gene phylogenetic analysis (Ito et al. 2011; Maeda et al. 2009). These form an independent cluster, showing a low (<93 %) 16S rRNA gene sequence similarity to the described *Kordiimonas* species, and they do not show the following 16S rRNA gene signatures of those species, 45–396 (C-G), 108 (G), 241–285 (A-U), 301 (G), 379 (G), 502–543 (U-A), 576 (C), 669–737 (G-C), 678–712 (U-A), 780 (G), 822–878 (G-C), 1122–1151 (U-A), and 1189 (U), whereas those of the unnamed isolates are 45–396 (U-A), 108 (C), 241–285 (G-C), 301 (A), 379 (C), 502–543 (C-G), 576 (A), 669–737 (U-A), 678–712 (A-U), 780 (A), 822–878 (A-U), 1122–1151 (C-G), and 1189 (C). An in-depth study of the taxonomy positions of those isolates is recommended.

Genome Analysis

No genome sequences have yet been reported for any of the species within the genus *Kordiimonas*. DNA-DNA hybridization (DDH) studies have been performed on several *Kordiimonas* type strains. *K. gwangyangensis* KACC 13321^T and *K. aestuarii* 101-1^T, sharing 97.3 % 16S rRNA gene sequence similarity, exhibit 24.8 % DDH similarity (Math et al. 2012). The DNA-DNA relatedness value between *K. lacus* JCM 16261^T and *K. aestuarii* 101-1^T (96.3 % 16S rRNA gene similarity) was 32.2 % (Math et al. 2012).

Phenotypic Analyses

The Properties of the Genus *Kordiimonas* and Its Species

Genus *Kordiimonas* Kwon, Lee, Yang and Kim 2005, 2036^{VP} (emend. Xu, Huo, Bai, Wang, Oren, Li and Wu, 2011, 424; emend. Yang, Kim, Seo, Lee, Lee, Kim and Kwon, 2013, 301).

Kor.di.i.mo'nas. N.L. fem. n. *Kordia* arbitrary name derived from the abbreviation KORDI, which stands for Korea Ocean Research and Development Institute; L. fem. n. *monas* a monad, unit; N.L. fem. n. *Kordiimonas* a microorganism described by scientists working at KORDI.

Cells are ovoid to rod-shaped, motile by means of polar or lateral flagella, and multiply by binary fission. They occur singly or in chains. Gram-negative. Strictly aerobic. No growth occurs under anaerobic conditions, although nitrate may be reduced to nitrite. The principal respiratory quinone is ubiquinone-10. Mesophilic, with optimum growth at 20–41 °C and pH 6.5–7.0. Salinity range for growth is 0–13 % NaCl. Colonies are usually smooth, translucent or opaque, raised and circular with regular borders, usually 0.5–3 mm in diameter after 3–7 days inoculation on marine 2216 agar. Colony color varies from creamy white to beige to light yellow, depending on the strain and on the age of the colonies. Oxidase and catalase positive. Chemoorganotrophic, utilizing a wide range of carbohydrates, salts of organic acids, and amino acids as sole carbon sources. Some strains hydrolyze polycyclic aromatic hydrocarbon with two to five rings. Produce an acidic reaction in mineral salts medium containing D-glucose or other carbohydrates. The polar lipid profile consists of the major components phosphatidylethanolamine and several unidentified glycolipids, amino-phospholipids, and amino-lipids. The major fatty acids are iso-$C_{17:1}$ $\omega 9c$, iso-$C_{15:0}$ and $C_{16:1}$ $\omega 7c$ and/or iso-$C_{15:0}$ 2-OH. $C_{16:0}$, iso-$C_{17:0}$, $C_{18:1}$ $\omega 7c$, and hydroxyl fatty acids (iso-$C_{17:0}$ 3-OH and $C_{16:0}$ 3-OH) may also occur. Found in marine sediment and seawater. Not encountered as clinical isolates and not known to be pathogenic for animals or plants, although some strains were isolated from algae.

The mol% G+C of DNA is 50–58.

The type species is *Kordiimonas gwangyangensis* with type strain GW14-5^T (=KCCM 42021^T = JCM 12864^T) (Kwon et al. 2005).

There are four species within the genus *Kordiimonas*: *K. gwangyangensis*, *K. lacus*, *K. aestuarii* and *K. aquimaris*. All the type strains of *Kordiimonas* species were isolated from marine environments, including marine sediment, seawater, and sediment from the ballast water tank of a crude carrier. Most common characteristics of *Kordiimonas* species are listed in the above genus description as well as in *Table 14.1*. A high content of branched fatty acids (>50 %) distinguishes the *Kordiimonas* members from their closest neighbors in the phylogenetic tree.

The phenotypic characteristics that differentiate the *Kordiimonas* species are given in *Table 14.1*. The upper NaCl concentration for growth of *K. gwangyangensis* (4 %) is much lower than that of the other three *Kordiimonas* species (9–13 %). The optimum NaCl range for growth of all *Kordiimonas* species was 2–3.5 %, coinciding with the salt concentration in their habitat. *K. gwangyangensis* GW14-5^T can degrade six different polyaromatic hydrocarbons (PAHs) with two to five rings, including fluorene, phenanthrene, anthracene, pyrene, chrysene, and benzo[a]pyrene (Kim and Kwon 2010). Several isolates with high 16S rRNA gene sequence similarity with *K. gwangyangensis* GW14-5^T also have the ability to degrade PAHs (Tian et al. 2008; Wang et al. 2010). However, there are no reports of PAHs degradation by other *Kordiimonas* species.

K. lacus reduces nitrate to nitrite and utilizes a large number of amino acids as sole carbon and energy sources, including L-alanine, L-arginine, L-asparagine, L-aspartate, L-cysteine, L-glutamate, L-glutamine, L-histidine, L-ornithine, L-serine, and L-valine. *K. lacus* produces acids from a number of sugars and sugar alcohols, including cellobiose, glucose, *myo*-inositol, maltose, and trehalose.

K. aestuarii markedly differs in cell size and colony color from *K. gwangyangensis*, but resembles *K. lacus* in these properties. The DDH similarity of type strains between *K. aestuarii* and *K. gwangyangensis* (24.8 %) was lower than that between *K. aestuarii* and *K. lacus* (32.2 %) (Math et al. 2012). The three species could be distinguished from each other by enzymatic activities and sensitivity to antimicrobial agents. For example, *K. lacus* is sensitive to chloramphenicol, nitrofurantoin, novobiocin, streptomycin and tobramycin; whereas *K. gwangyangensis* is resistant to nitrofurantoin and tobramycin, and *K. aestuarii* is resistant to chloramphenicol, novobiocin and streptomycin.

K. aquimaris has a low optimum growth temperature (20 °C) and uses a greater variety of carbon sources compared to other members. *K. aquimaris* MEBiC06554^T utilized the following Biolog GP substrates (26): erythritol, D-fructose, D-galactose, α-D-lactose, lactulose, D-mannitol, D-mannose, D-melibiose, β-methyl-D-glucoside, turanose, mono-methyl succinate, cis-aconitic acid, citric acid, D-galacturonic acid, D-gluconic acid, α-ketoglutaric acid, propionic acid, quinic acid, succinic acid, succinamic acid, L-asparagine, glycyl-L-aspartic acid, L-ornithine, γ-aminobutyric acid, glucose-1-phosphate, and glucose-6-phosphate; all these compounds are not used by *K. gwangyangensis* GW14-5^T and *K. lacus* S3-22^T (Yang et al. 2013).

Isolation, Enrichment and Maintenance Procedures

Several isolation techniques for *Kordiimonas* have been described. Usually, isolation of *Kordiimonas* strains needs low nutrient medium and a long period of enrichment. In the case of *K. gwangyangensis* GW14-5^T, approximately 1 g sediment was enriched in MM2 liquid medium [18 mM $(NH_4)_2SO_4$, 1 μm $FeSO_4 \cdot 7H_2O$, and a trace of KH_2PO_4/Na_2HPO_4 buffer solution in 1 l of aged sea water, pH 7.2] supplemented with 100 ppm each of pyrene and benzo[a]pyrene and incubated for 2 years (Kwon et al. 2005). The long-term enrichment and the presence of pyrene and its derivative inhibited the growth of most other microorganisms, enabling *K. gwangyangensis* GW14-5^T to

Table 14.1
Differential metabolic and chemotaxonomic characteristics of type strains of *Kordiimonas* species

All strains are positive for hydrolysis of starch and Tween 80, but negative for arginine dihydrolase and urease. Neither strain produces H_2S or indole. In API ZYM tests, acid and alkaline phosphatases, α-chymotrypsin, esterase (C4), esterase lipase (C8), leucine arylamidase, naphthol-AS-β-1-phosphohydrolase, valine arylamidase, and trypsin activities are detected in all
+ positive, – negative, w weakly positive, *NR* not reported
Data taken from [a]Kwon et al. 2005; [b]Xu et al. 2011; [c]Math et al. 2012; [d]Yang et al. 2013; [e]Data from Microlog GN2 (Biolog) plate readings from Yang et al. 2013

degrade the pyrene and benzo[a]pyrene as carbon and energy source. The suspension was then plated onto marine agar 2216 (BD), and the isolate was obtained by the serial dilution method. *K. gwangyangensis* S20-13 was isolated by similar methods, using crude and diesel oils as a carbon source and an enrichment time of 2–3 months (Wang et al. 2010). *K. aquimaris* MEBiC06554^T was obtained by the extinction-dilution cultivation method (Connon and Giovannoni 2002) after 9 months of enrichment. The culture broth was then spread onto twofold-diluted marine agar 2216 solid medium (BD) supplemented with seawater and incubated at 15 °C up to 4 months (Yang et al. 2013). Isolation of *Kordiimonas* strains may thus be achieved by streaking long-term enrichment cultures containing low levels of carbon and nitrogen sources on agar plates.

The members of *Kordiimonas* can be maintained for short-term storage on Marine 2216 agar slants at 4 °C for 2 months. For long-term preservation, cultures can be preserved in liquid nitrogen, by lyophilization or frozen at −80 °C.

Ecology

Habitat

The natural habitats of *Kordiimonas* are mainly marine environments. They are found in seawater collected offshore (Thompson et al. 2011; Yang et al. 2013) and from the ocean (Pham et al. 2008; Wang et al. 2010), in estuarine (Tian et al. 2008) and deep-sea sediment (Li et al. 2009, 2011), as well as in

ballast water tanks of commercial ships (Xu et al. 2011), hydrothermal vent chimneys (Peng et al. 2010), and marine sponges (Anderson et al. 2010). They have been reported as important components of biofilms in a reverse osmosis seawater desalination system (Bae et al. 2011). McKew et al. (2011) reported a low abundance (0.2 %) of *Kordiimonas*-related 16S rRNA gene sequences in the sediments from a creek near a salt marsh in the UK (36 ‰ salinity). *Kordiimonas* strains are distributed globally. They were found in Asia (Tian et al. 2008), Europe (McKew et al. 2011), South America (Thompson et al. 2011), the Pacific Ocean (Liao et al. 2011), the Atlantic Ocean (Wang et al. 2010), the Indian Ocean (Peng et al. 2010), and the Arctic Ocean (Li et al. 2009). However, they were never found to dominate the bacterial community. Relative abundances of *Kordiimonas* in their natural habitats are usually less than 2 %. Generally, the natural habitats of *Kordiimonas* seem to be oligotrophic environments containing salt and low concentrations of organic matter and temperatures of 1–30 °C. The ability of *K. gwangyangensis* strains to hydrolyze PAHs may be an advantage for growth and survival in oligotrophic and polluted environments.

The type strains of the four species were isolated from marine sediments collected from the Gwangyang Bay in Korea (*K. gwangyangensis*) (Kwon et al. 2005), from a ballast water tank of a ship, which can be considered to form a man-made incubator for growth of microorganisms, releasing invasive aquatic species to coastal regions (*K. lacus*) (Xu et al. 2011), from sediment from a sea-tidal flat in Korea (*K. aestuarii*) (Math et al. 2012), and from seawater near the Anmok Port in Korea (*K. aquimaris*) (Yang et al. 2013).

Pathogenicity, Clinical Relevance

No clinical reports of infections of humans or animals by *Kordiimonas* species have been published. Antibiotic sensitivity of three type strains tested, *K. gwangyangensis*, *K. lacus* and *K. aestuarii*, showed susceptibility to penicillin G, but resistance to ampicillin, carbenicillin, kanamycin, and tetracycline (Math et al. 2012; Xu et al. 2011). Susceptibility to chloramphenicol, nitrofurantoin, novobiocin, streptomycin, and tobramycin differs among the three species (*Table 14.1*). The antibiotic sensitivity of *Kordiimonas* species might be used to specifically isolate different *Kordiimonas* strains.

Application

Bioremediation

Because of their ability to degrade a wide variety of PAHs, *K. gwangyangensis* strains are of potential interest in bioremediation. PAHs with two to five rings (fluorene, phenanthrene, anthracene, pyrene, and benzo[a]pyrene) were degraded to a large extent by *K. gwangyangensis* GW14-5^T, but chrysene was not degraded within one week of incubation (Kim and Kwon 2010; Kwon et al. 2005). Among the isolates from a PAH-polluted site in a mangrove ecosystem, *K. gwangyangensis* strains capable of degrading pyrene and fluorene formed an important component (Liu et al. 2010; Tian et al. 2008). Molecular studies revealed that *K. gwangyangensis* strains possess alkane hydroxylases. The integral membrane nonheme di-iron alkane hydroxylases (e.g., AlkB and AlkM) are one of the most important enzyme systems in the terminal oxidization of medium-length alkanes in prokaryotes (Wang et al. 2010). *K. gwangyangensis* S20-13 isolated from pelagic surface water has two alkane hydroxylase genes (A*lkB*) and is able to grow on diesel oil (Wang et al. 2010). However, the industrial application of *K. gwangyangensis* has been hampered by its relatively slow growth and its ability to use of a large number of carbohydrates, which are potentially competitive substrates during degradation of PAHs or alkanes.

[3]Department of Biochemistry, Henriette Raphael House, King's College London, London, UK

Abstract
The *Methylobacteriaceae* comprise a large family of *Alphaproteobacteria* within the Order *Rhizobiales* and currently contains three genera, *Methylobacterium*, *Microvirga*, and *Meganema*. The largest genus currently contains 44 validated species of *Methylobacterium*, most of which are facultative methylotrophs able to grow on methanol and other one-carbon compounds as sources of energy and carbon. Most are pink-pigmented, exhibit common fatty acid profiles, and contain ubiquinone Q-10. The eight species of *Microvirga* and the single species of *Meganema* are not methylotrophic. The phylogenetic and phenotypic properties of *Meganema* indicate that it is wrongly placed in this family. *Methylobacterium* species are ubiquitous in the natural environment, both as free-living organisms in soil and water, but also on the phylloplane of plants, and in the leaf, stem, and root tissues of plants: Some induce plant leaf and root nodule formation, and can promote plant growth by production of auxins. Some species are opportunistic human pathogens; others have been found in insect tissues. Some are important for their role in the degradation of pollutants, and they may also cause commercial problems such as the fouling of aircraft fuels. *Microvirga* species occur in diverse habitats as free-living species, and others are colonists in plant root nodules. The filamentous *Meganema* has only been recovered as an organism involved in the fouling and blocking of water filtration systems. The genomes of several *Methylobacterium* species have been sequenced, and they show considerable interstrain homology. Significant genome plasticity is indicated by the large number of insertion elements in some genomes, and some methylotrophic functions seem to have been acquired by horizontal gene transfer.

Methylobacteriaceae Garrity, Bell, and Lilburn 2005, 567

Meth.yl.o.bac.te.ri.a'ce.ae. M.L. neut. N. *Methylobacterium* type genus of the family; *-aceae* ending to denote family; M.L. fem. Pl. n. *Methylobacteriaceae* the *Methylobacteriaceae* family.

The *Rhizobiales* (Kuykendall 2005) comprise Order VI of the Class *Alphaproteobacteria*, and contains ten families, of which Family IX is the *Methylobacteriaceae* (Garrity et al. 2005). The family was defined on the basis of phylogenetic analysis of the 16S rRNA gene sequences, and currently comprises three genera, *Methylobacterium*, *Methylovirga*, and *Meganema*. All are chemoorganotrophic, most *Methylobacterium* species are facultative methylotrophs, and most species of *Methylobacterium* and *Microvirga* form pink or red colonies.

Type genus: *Methylobacterium* Patt, Cole, and Hanson 1976, 28 emend. Green and Bousfield 1983, 876. The second edition of *Bergey's Manual of Systematic Bacteriology* (Brenner et al. 2005) described only one genus in this family, *Methylobacterium* (Green 2005), with 12 species. Currently, 44 species are given on the *List of Prokaryotic names with Standing in Nomenclature*, curated by J. P. Euzéby (LPSN; http://www.bacterio.cict.fr/m/

E. Rosenberg et al. (eds.), *The Prokaryotes – Alphaproteobacteria and Betaproteobacteria*, DOI 10.1007/978-3-642-30197-1_256,

methylobacterium.html). The two further genera subsequently assigned to the family are *Microvirga* with eight validly published species (http://www.bacterio.cict.fr/m/microvirga.html), and *Meganema* (http://www.bacterio.cict.fr/m/meganema.html) with a single validated species. The links to the LPSN provide the deposition history and the culture collections which hold each species; they also provide direct links to most of the original publications describing each species, and to the 16S rRNA gene sequence accession numbers for the type strain of each species.

Genus *Methylobacterium*

Meth.yl.o.bac.te'ri.um. M.L. n. *methyl* the methyl radical; Gr. n. *bacterion* a small rod; M.L. neut. n. *Methylobacterium* methyl bacterium.

History and Taxonomy

The advent of taxonomic alignments based on 16S rRNA gene sequence homologies was extremely beneficial in establishing the relationships among the diverse pink-pigmented facultative methylotrophs (PPFMs), most of which are now classified as *Methylobacterium* species. Prior to this rationalization, PPFMs had been assigned to diverse genera, based on morphological and nutritional differences, including variation among species in the ability to grow on methylamine, glucose, fructose, fucose, xylose, arabinose, and some organic and amino acids (Green 2006). The genus was established by Patt et al. (1976 and emended by Green and Bousfield 1983), with *Mtb organophilum* established as the type species of the genus. This assignment was somewhat anomalous as (a) the original description of *Mtb organophilum* was based on the properties of a single strain (strain XX), while later recommendations were that new species descriptions should be based on more than one, and even on five, strains (Stackebrandt et al. 2002), although this criterion is commonly not observed (Drancourt and Raoult 2005); and (b) strain XX was claimed to oxidize methane, a property that was used to exclude non-methane-oxidizing PPFM strains from the genus. Strain XX subsequently "lost" (or had never had) the ability to use methane, and the genus description was changed to delete methane use as a characteristic property of *Methylobacterium* species (Green and Bousfield 1983; Green 2006). As the original basis of the genus description was flawed, it is arguably regrettable that *Mtb extorquens* was not chosen to be the type species (see below), as it was initially isolated as the first example of the genus in 1913 (but not transferred to *Methylobacterium* until 1985), whereas *Mtb organophilum* was isolated in 1974. *Mtb extorquens* is a "classic" example of the genus, strains of which have been the subject of more physiological, biochemical, and molecular studies than of any other *Methylobacterium* species, but of course *Mtb organophilum* has strict taxonomic precedence.

Only 12 species of *Methylobacterium* were recognized by Green (2005, 2006), but at the time of writing (2012) there were 44 validated species names (◉ *Table 15.1*; ◉ *Fig. 15.1*). While validly named, three of the *Methylobacterium* species have been proposed to be later synonyms of existing validly published species, with which they share essentially 100 % 16S rRNA gene sequence identity: *Mtb chloromethanicum* CM4 (McDonald et al. 2001) and *Mtb dichloromethanicum* DM4 (Doronina et al. 2000) are regarded as strains of *Mtb extorquens*; and *Mtb lusitanum* as a strain of *Mtb rhodesianum* (◉ *Table 15.1*; Kato et al. 2005). Marx et al. (2012) proposed that *Mtb populi* should also be regarded as a synonym for *Mtb extorquens*, based on whole genome comparisons of the two species. This proposal is not currently acceptable, as current phylogenetic relationships are based on 16S rRNA gene sequence comparisons, and *Mtb populi* has closer phylogenetic relatives (*Mtb thiocyanatum* and *Mtb rhodesianum*; ◉ *Fig. 15.1*) than *Mtb extorquens*. Both *Mtb populi* and *Mtb extorquens* are members of a distinct 10-species phylogenetic cluster of the genus (from *Mtb aminovorans* to *Mtb podarium* in ◉ *Fig. 15.1*), and reassignment of *Mtb populi* alone could not be justified until complete genome comparison among all ten species is possible. Reclassification based on complete genomes could result in amalgamation (or "lumping") of numerous species into single overarching species, possibly even the lumping of all the species in each of the clusters of species (up to seven in ◉ *Fig. 15.1*, and other published trees) into one species for each cluster. This would, however, be undesirable, as it would obscure the physiological and phenotypic differences among those species.

Possibly the earliest strain of a PPFM to be described was the oxalate-degrading organism isolated from earthworm excreta ("worm casts"), in the Botany Department garden of Basel University, in 1909 by Bassalik (1913). This organism was variously named *Bacillus extorquens*, *Vibrio extorquens*, *Pseudomonas extorquens*, *Pseudomonas methylica*, *Mycoplana rubra*, *Flavobacterium extorquens*, *Protaminobacter ruber*, *Protomonas extorquens*, and finally its current definition as *Methylobacterium extorquens* (Bassalik 1913; Bassalik et al. 1960; Bhat and Barker 1948; Bousfield and Green 1985; Breed et al. 1957; Den Dooren de Jong 1927, 1957; De Vries and Derx 1953; Green 1992, 2006; Green and Bousfield 1983; Janota 1950, 1956; Janota-Bassalik and Pedyk 1961; Krasil'nikov 1949; Stocks and McCleskey 1964; Urakami and Komagata 1984). Unfortunately Bassalik's original isolate perished in 1939 (as an early casualty of World War II), but a very similar strain was recovered in 1948 from soil in the Botany Department garden of Warsaw University by Ludmila Janota (Janota 1950, 1956). This neotype strain, initially named *Pseudomonas extorquens*, was deposited in the NCIMB in 1960 by Ludmila Janota-Bassilik to become the type strain of *Mtb extorquens* (NCIB 9399^T; ATCC 23326^T, DSM 1337^T, TK 0001^T).

The 12 species recognized in the second edition of *Bergey's Manual of Systematic Bacteriology* (Green 2005) were initially assigned to the genus on the basis that they were PPFMs with similar morphology, physiology, and growth properties (optimum pH, optimum temperature, ranges of organic substrates used for chemoorganotrophic growth; Green 2005, 2006). All showed similar percentages of GC in their genomic DNA (68–73 mol%) and were subsequently shown to share reasonably

Table 15.1

Type strains of the species of *Methylobacterium*, 16S rRNA gene accession numbers, and some distinguishing properties. All 44 validated names are shown (LPSN; http://www.bacterio.cict.fr/)

Species	Culture collection accession number[a]	GenBank accession number	G+C content of type strain DNA (mol %)	Isolation source of the type strain	Growth on glucose/motility
Mtb adhaesivum	CCM 7305	AM040156	63.6	Drinking water	−/+
Mtb aerolatum	KACC 11766	EF174498	73.2	Air (Korea)	(+)/+
Mtb aminovorans	JCM 8240	AB175629	68.0	Soil	−/+
Mtb aquaticum	DSM 16371	AJ6353033	67.5	Drinking water	+/+
Mtb brachiatum	NCIMB 14379	AB175649	69.5	Freshwater	−/+

[a]Culture collection into which the type strain was originally deposited
[b]A contemporary synonym for this species is *Mtb funariae* (Schauer and Kutschera 2011); 16S rRNA: FJ157975
[c]Kato et al. (2005) reclassified both these strains as heterotypic synonyms of *Mtb extorquens*
[d]GC value from the complete genome of *Mtb dichloromethanicum* DM4 (Marx et al. 2012)
[e]GC value from the complete genome of *Mtb extorquens* AM1 (Marx et al. 2012)
[f]These strains are non-pigmented
[g]Kato et al. (2005) showed this to be a heterotypic synonym of *Mtb rhodesianum*
n.a., Data not available; +, growth; −, no growth; (+) weak growth

similar 16S rRNA gene sequences: with 11 species showing 96–97 % sequence identity to the type species, *Mtb organophilum*. The type species and the other ten species showed 95–100 % identity to *Mtb extorquens* (authors' data). As the number of species described rose to more than 40, principally on the basis of being phylogenetically similar PPFMs, and distinguishable by DNA-DNA hybridization, the inhomogeneity of the group has become progressively apparent: Phylogenetic trees demonstrate that the species cluster in a number of distinct clades (*Fig. 15.1*; also see the 16S rRNA trees in Dourado et al. 2012a, b; Idris et al. 2006; Knief et al. 2010a; Tani et al. 2012a, b; Wellner et al. 2012). Up to seven distinct clades have been shown in this way (Dourado et al. 2012b; Idris et al. 2006; Knief et al. 2010a, b; Tani et al. 2012a, b). The genus consequently begins to resemble an organized chaos reminiscent of a Jackson Pollock masterwork.

The authors do not believe, however, that this diversity justifies splitting the genus into multiple genera, as the major physiological and biochemical properties (especially facultative methylotrophy, and in most cases the carotenoid pigment) are common to most members of the genus. The criterion of ability to use or not use specific organic compounds as growth substrates (e.g., glucose and other sugars, citrate and methylamines; Green 2006) remains a useful property, especially when distinguishing phylogenetically very similar species. Such differences can, however, be due to relatively small biochemical variations, such as absence of a gene involved in encoding a transport protein or a primary process such as sugar phosphorylation. It is interesting to note that the type strain of *Mtb extorquens* is usually reported as unable to grow on glucose (Green 2005), but in her original work after isolating the type strain, Janota (1956) used Warburg manometry to show glucose oxidation by bacteria previously grown on a meat extract/peptone/glucose medium. Using vacuum-dried bacteria she found glucose oxidation to proceed rapidly with a CO_2 produced/O_2 consumed ratio around 0.70, which is less than the ratio of 1.0 required for complete oxidation:

$$C_6H_{12}O_6 + 6\ O_2 \rightarrow 6\ CO_2 + 6\ H_2O$$

In the presence of 5 mM sodium azide, however, this ratio increased to 0.93–1.07. The lower ratio would be consistent with some glucose-carbon being assimilated, but this was inhibited by azide. Moreover, the use of vacuum-dried cells by Janota would have abolished any uptake barrier preventing rapid glucose transport into the bacteria. A possibility is that the ability of the type species to use glucose was subsequently lost in culture.

The description of the genus in *Bergey's Manual* (Green 2005) is adequate, although it was based on the properties of only 12 species, but needs to be updated to note that two of the currently described 44 species are not pigmented, and that some species are capable of inducing nodulation of the leaves and roots of some plants.

Molecular Analyses

Complete genome sequencing of some *Methylobacterium* species. To date, the genomes of 13 strains of *Methylobacterium* have been sequenced, and they are available in completed or permanent draft form on the Joint Genome Institute website (http://img.jgi.doe.gov/cgi-bin/geba/main.cgi?section=FindGenomes?page=findGenomes) and the NCBI Genome database

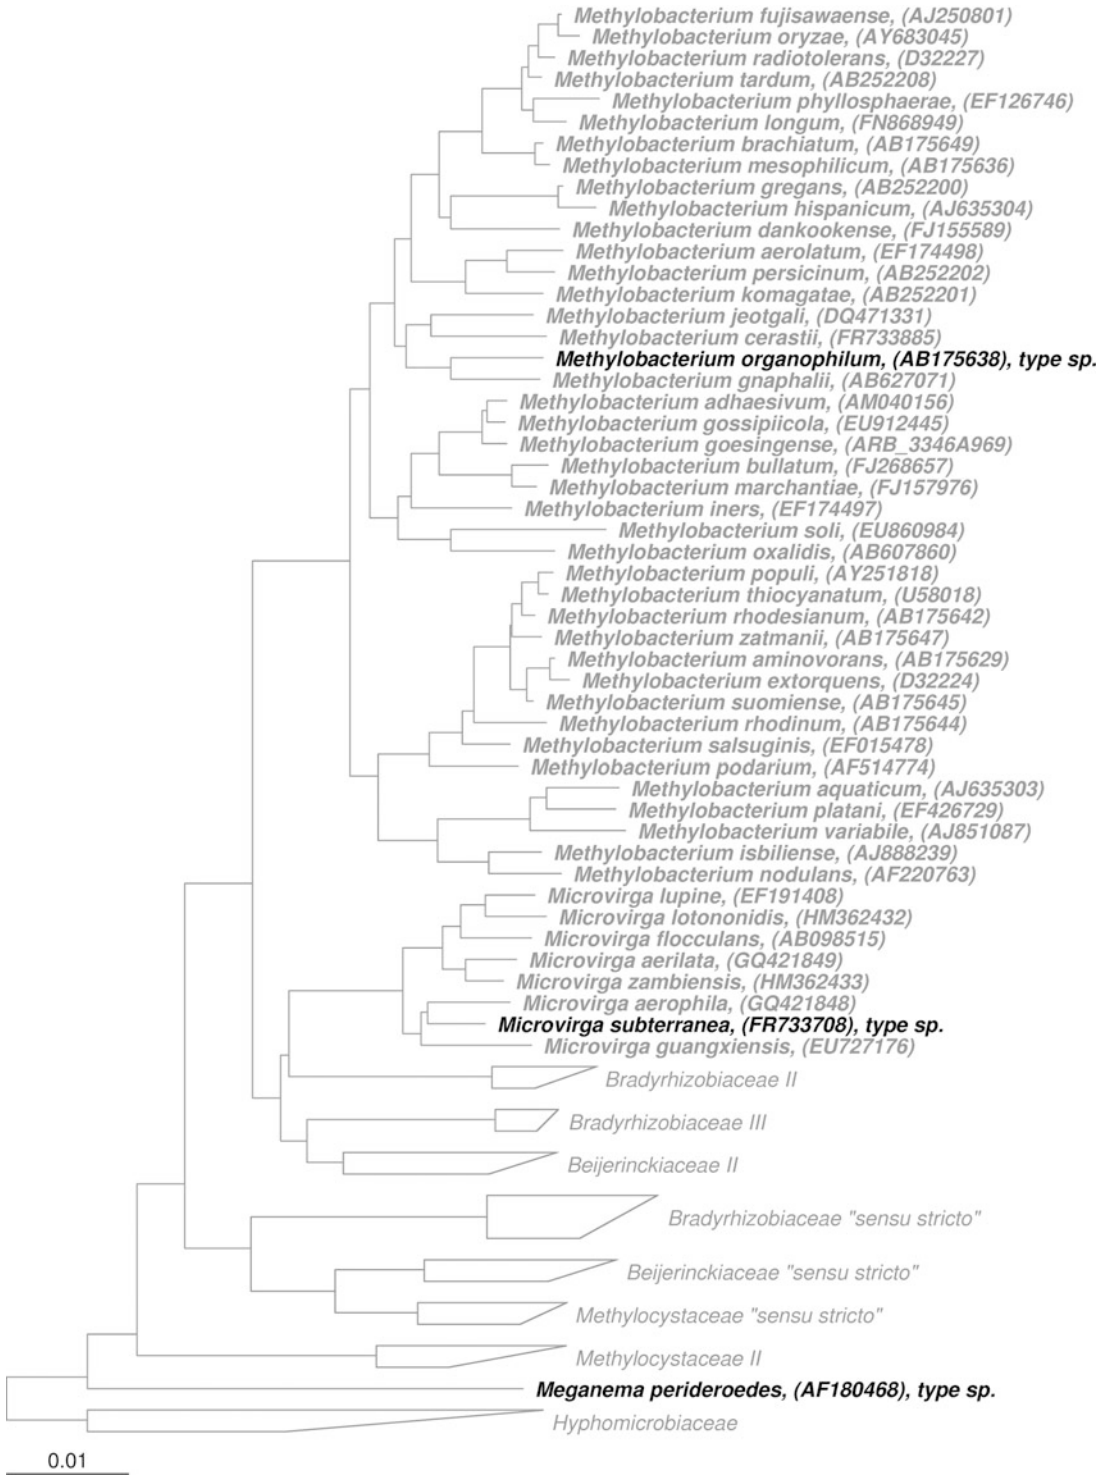

Fig. 15.1

Phylogenetic reconstruction of the family *Methylobacteriaceae* based on 16S rRNA and created using the neighbor-joining algorithm with the Jukes-Cantor correction. The sequence datasets and alignments were used according to the All-Species Living Tree Project (LTP) database (Yarza et al. 2010; http://www.arb-silva.de/projects/living-tree). The tree topology was stabilized with the use of a representative set of nearly 750 high-quality type strain sequences proportionally distributed among the different bacterial and archaeal phyla. In addition, a 40 % maximum frequency filter was applied in order to remove hypervariable positions and potentially misplaced bases from the alignment. All validated names for *Methylobacterium*, *Microvirga*, and *Meganema* are shown, except for *Mtb chloromethanicum* and *Mtb dichloromethanicum* (which are synonyms of *Mtb extorquens*) and *Mtb lusitanum* (a synonym of *Mtb rhodesianum*). Scale bar indicates estimated sequence divergence

(http://www.ncbi.nlm.nih.gov/genome?term=methylobacterium). The available genomes are for *Mtb extorquens* strains AM1 (NCIMB 9133), CM4, DM4, PA1, and strain F (DSM 13060), *Mtb nodulans* (ORS 2060^T), *Mtb populi* (BJ001^T), *Mtb radiotolerans* (JCM 2831^T), *Methylobacterium* sp. strain 4–46 (Marx et al. 2012), *Methylobacterium* sp. strain GXF4 (Gan et al. 2012), and strains WSM2598, 77, and 88A. Neither the genome of the type species, *Mtb organophilum*, nor that of the type strain of *Mtb extorquens* (NCIMB 9399^T) has yet been sequenced. The genomes of *Mtb mesophilicum*, *Mtb oryzae*, and *Methylobacterium* strain MB200 are included in current sequencing projects (2012). Comparative analysis of the genomes should reveal further insights into the nature of methylotrophy in this genus.

The sequenced genomes show considerable ranges of sizes (5.47–8.84 Mb), plasmid number (0–8), and plasmid size (0.01–1.26 Mb), as illustrated in Table 15.2. All the genomes possess several conserved gene clusters known to be involved in methylotrophy in *Methylobacterium* (Chistoserdova 2011). Interestingly, five strains have been shown to possess gene clusters associated with photosynthesis (Marx et al. 2012). The genomes of *Mtb extorquens* strains AM1 and DM4 (formerly *Mtb chloromethanicum*; Doronina et al. 2000) have been studied in the most detail, and exhibit considerable genome-wide homology and gene synteny (Vuilleumier et al. 2009), consistent with their being very closely related strains of the same species (Kato et al. 2005). This homology includes nearly identical genes associated with methylotrophy. Major exceptions were (1) a dichloromethane utilization (*dcm*) gene cluster (126 kb; essential for growth on dichloromethane as sole carbon and energy source) is present in strain DM4, but is absent from strain AM1; and (2) the methylamine utilization (*mau*) gene cluster is found only in strain AM1, indicating strain DM4 to use an alternative, unidentified pathway for growth on methylamine (Vuilleumier et al. 2009). The origins of these *dcm* and *mau* gene clusters are intriguing, as both are located on genomic islands in the respective chromosomes. The *dcm* cluster is located in a 1,054 kb genomic island in the DM4 chromosome (17.7 % of the chromosomal DNA), and the *mau* cluster is part of a 652 kb island in the AM1 chromosome (11.5 % of the chromosome). The presence of the *dcm* and *mau* gene clusters in genomic islands supports the redefinition of strain DM4 (formerly *Mtb dichloromethanicum*) as a strain of *Mtb extorquens* (Kato et al. 2005), as these clusters would have entered either strain DM4 or AM1 by horizontal gene transfer (HGT) and become incorporated into the respective genomes (Juhas et al. 2009; Vuilleumier et al. 2009), making the physiological differences between DM4 and AM1 the result simply of chance HGT events, rather than reflecting any deeper taxonomic difference. The GC content (60.5 %) of the 126 kb *dcm* gene cluster in strain DM4 differs markedly from the average GC content of the genome (68 %), indicative of its acquisition by horizontal transfer (Vuilleumier et al. 2009). A similar acquisition of the *cmu* gene cluster, enabling use of chloromethane by *Mtb extorquens* strain CM4 (formerly *Mtb chloromethanicum*; McDonald et al. 2001), might thus also have occurred by HGT. Apart from *dcm* and *mau* examples, few of the genomic islands appear to encode central metabolic functions or methylotrophy. Strain AM1 has a 47.5 kb genomic island that encodes a hypothetical protein polypeptide of 15,831 residues, which, if it were actually expressed, would be one of the largest-known biological proteins (Vuilleumier et al. 2009). The large sets of insertion elements identified in strains AM1 and DM4 indicate the potential for significant genome plasticity in the species.

In addition to their chromosomes, several strains contain very large plasmids (Table 15.2), the largest being that of *Mtb extorquens* AM1 at 1.26 Mb, or 18 % of the total chromosomal and plasmid DNA. The megaplasmid of strain AM1 has a 130 kb block of genes (with no known functions) which occurs on the chromosome of strain DM4, which has no megaplasmid. This synteny is consistent with the recent evolutionary divergence of the two strains. The genomes analyzed to date also contain variable numbers of pseudogenes, ranging from only four in *Methylobacterium* strain GXF4, through 47–114 in strains AM1, PA1, *Mtb populi*, and *Mtb radiotolerans*, to 206–336 in strains DM4, CM4, and 4–46, and to a remarkable 602 in *Mtb nodulans*, of which 275 (47 %) are on the two very large plasmids (Table 15.2).

The *mxaF* gene as a taxonomic tool. An *mxaF* gene is found in diverse methylotrophs in the *Alpha-*, *Beta-*, and *Gammaproteobacteria*: It encodes the large (α-) subunit of the methanol dehydrogenase protein (MxaF). While the active site of this enzyme is highly conserved (McDonald and Murrell 1997), there is considerable diversity among the amino acid sequences of the encoded MxaF protein; for example, identities (% by BLASTP or TBLASTX) for the MxaF of *Mtb organophilum* compared to *Mtb extorquens*, *Hyphomicrobium methylovorum*, *Paracoccus denitrificans*, *Methylobacillus flagellatus*, *Granulibacter bethesdensis*, and *Xanthomonas campestris* were 95.3 %, 79.2 %, 75.1 %, 61.4 %, 49.3 %, and 41.9 %, respectively (authors' data). In contrast, amino acid sequence identities for MxaF between *Methylobacterium* species were mostly in the range 90–100 % (authors' data). Phylogenetic trees of *mxaF* gene sequences from numerous *Methylobacterium* species were superficially similar to the trees for 16S rRNA gene sequences (e.g., Fig. 2 of Wellner et al. 2012), showing the *mxaF* genes to fall into seven distinct clades (Dourado et al. 2012a; Wellner et al. 2012). Comparison of the 16S rRNA and *mxaF* trees showed, however, that there was not universal congruence between the trees. Both trees were congruent for *Mtb oryzae*, *Mtb phyllosphaerae*, *Mtb fujisawaense*, and *Mtb radiotolerans*, with all four falling in the same or closely linked clades. This was also the case for the pairs *Mtb goesingense/Mtb adhaesivum*, *Mtb gregans/Mtb hispanicum*, and *Mtb suomiense/Mtb aminovorans*. Other species (including *Mtb organophilum/Mtb thiocyanatum*, *Mtb aquaticum/Mtb platani*, *Mtb rhodinum*, *Mtb aerolatum*, and *Mtb iners*) fell into very divergent clades on both trees. For example, using BLASTN, *Mtb oryzae*, *Mtb fujisawaense*, and *Mtb phyllosphaerae* showed 99.0–99.8 % 16S rRNA sequence identity and 100 % identity of their *mxaF* genes, while *Mtb aquaticum* and *Mtb platani* showed 98 % 16S rRNA sequence identity but only 89 % *mxaF* identity, and *Mtb podarium* and

Table 15.2

Properties of the sequenced genomes of several strains of *Methylobacterium*. Data were retrieved from the NCBI and JGI genome databases

[a]No gene or pseudogene present

[b]No pseudogenes recorded separately on the JGI database

[c]Value taken from Gan et al. (2012)

Mtb aerolatum showed 100 % *mxaF* identity but only 94 % 16S rRNA identity (authors' data).

Comparing *mxaF* genes and gene products can be an alternative taxonomic tool, especially when comparing identities and properties of *Methylobacterium* strains isolated from diverse habitats (e.g., different plant species), but is not an exclusive alternative to comparison of phylogeny based on 16S rRNA genes. The congruence of 16S rRNA and *mxaF* genes in some species is indicative of a shared common history, while the divergence seen with other species is most likely due to later acquisition of the *mxaF* genes by horizontal gene transfer. The most extreme diversity is seen with the *mxaF* genes of *Mtb variabile* (EU194913) and *Mtb isbiliense* (EU194912), which show very low similarity with that of *Mtb extorquens* (69.9 % and 68.6 %, respectively), and very low or no similarity to some other *Methylobacterium* species. The *mxaF* of *Mtb variabile* shows only 69.5–71.9 % identity to those of several *Methylobacterium* species (*Mtb cerastii*, *Mtb salsuginis*, *Mtb mesophilicum*, *Mtb radiotolerans*, *Mtb organophilum*, *Mtb suomiense*, and *Mtb populi*), and 78.2 % to that of *Mtb isbiliense* (EU194912), showing the genes from *Mtb variabile* and *Mtb isbiliense* were not significantly related. The *mxaF* sequence of *Mtb variabile* does show 98.4 % identity to those of methylotrophic strains of *Mucilaginibacter* (EU912494), *Methylobacillus* (EU194909), and *Pedobacter* (EU194901), and 96.8 % to that of *Burkholderia vietnamensis* (EU194908), but 81 % identity to those of *Flavisolibacter* (EU912489) and *Pantoea* (EU439310). The *Mtb isbiliense mxaF* shows relatively low identity to any other database sequences, for example, 89.6 % to *Methylophilus* (EU19404), and only 82.8–83.5 % to *Flavisolibacter*, *Pantoea*, and *Pseudomonas* strain CBMB18 (EU439305). This extreme diversity suggests either a very different, and independent, acquisition history of the *mxaF* genes of *Mtb variabile* and *Mtb isbiliense* compared to the other *Methylobacterium* species, or raises questions about the taxonomic status of these two species.

Maldi-TOF/MS spectra were reported for some *Methylobacterium* species and provided a means of distinguishing *Mtb oxalidis* from *Mtb iners* (Tani et al. 2012a). This technique is the most recent and very promising method for distinguishing species and lineages of *Methylobacterium* strains: Tani et al. (2012d) applied whole-cell matrix-assisted laser desorption/ionization time-of-flight mass spectrometry analysis (WC-MS) to assess the diversity of about 200 *Methylobacterium* type species and newly isolated strains. WC-MS spectral peaks for *Mtb extorquens* AM1 cells were due mainly to ribosomal proteins, and showed many identical proteins in *Mtb oryzae*, *Mtb phyllosphaerae*, *Mtb extorquens*, *Mtb chloromethanicum*, and *Mtb dichloromethanicum*, comprising the "*Mtb extorquens* group." Some of these proteins were shared with those of *Mtb populi* and *Mtb radiotolerans*. Strains of 37 named species were compared in this way, but no single ribosomal protein was found that was common to all the species analyzed, although the method provided a threshold similarity value for species-level discrimination, including some type strains that could not easily be discriminated solely by their 16S rRNA gene sequence similarity. Notably, *Mtb nodulans* and *Methylobacterium* sp. strain 4–46 shared some proteins, but did not share any with the *Mtb extorquens* group. Evaluating WC-MS data from 191 isolates from various plants showed that 16S rRNA gene sequencing mainly matched the identification by WC-MS, with the possibility that some isolates with unique spectra may be novel species. Strains of *Mtb extorquens*, *Mtb adhaesivum*, *Mtb marchantiae*, *Mtb komagatae*, *Mtb brachiatum*, and *Mtb radiotolerans* (and "novel lineages" related to *Mtb adhaesivum*) were the most frequent phyllosphere colonists. The WC-MS technique could thus assist identification of novel species without the requirement for 16S rRNA gene sequencing (Tani et al. 2012d). It should be recognized, however, that although the spectral differences reflect the diversity of *Methylobacterium* species, they do not necessarily indicate their evolutionary relationships, so MALDI-TOF MS cannot be used definitively for phylogenetic analyses. A joint international project is in progress to carry out MALDI-TOF analyses of a range of *Methylobacterium* species, with an emphasis on the rhizobial strains (J. K. Ardley, personal communication, 2012).

Phenotypic Analyses

Common properties of *Methylobacterium* species. The species are typically Gram-negative short rods, 0.8–1.5 × 1.0–8.0 μm, occurring singly, in pairs or aggregates, and occasionally rosettes. Rosette formation ("Sternbildung") was probably first observed for a *Methylobacterium* in the species now known as *Mtb rhodinum* (Heumann 1962).

Many species are motile (*Table 15.1*) by means of a single polar, subpolar, or lateral flagellum. Colonies of nearly all species, on methanol-agar or richer media, range from pale pink to bright orange-red or red in color, growing to 1–4 mm in diameter in 3–7 days. Methanol is reported in their original descriptions to be used for growth by all validly named species, although some species have subsequently proved capable only of poor (or no) growth on methanol, or to require a vitamin supplement for growth. These include *Mtb isbiliense*, *Mtb variabile*, *Mtb platani*, and *Mtb aquaticum* (J. K. Ardley and P. N. Green, personal communications, 2012). Many species grow on other C_1-compounds (those with no carbon-carbon bonds), including mono-, di-, and trimethylamines; formaldehyde (at 1 mM or lower); formate; chloro- and dichloromethane; and methylated sulfur compounds such as dimethylsulfide, dimethylsulfone, and methanesulfonate. Most species grow optimally around neutral pH, and rapidly between pH 6 and 9, but growth of some has been observed at the extremes of pH 4.0 and pH 10. The temperature range for most species is 15–37 °C, with an optimum between 25 °C and 30 °C, but *Mtb cerastii* has an optimum of 20 °C (Wellner et al. 2012) and some have an optimum of 37 °C, with slow growth at 4 °C and 43 °C, but not at 55 °C. Numerous organic substrates can serve for heterotrophic growth, but many species do not use glucose or some other sugars and some amino acids.

No requirement for NaCl has been shown, but most species tolerate NaCl at concentrations approaching 1 % (w/v); few will tolerate concentrations higher than 1.5 % (w/v). An exception is *Mtb podarium* (Anesti et al. 2004) which tolerates 2.5 % (w/v) NaCl. Interestingly, *Mtb salsuginis* was isolated as apparently the only example of a *Methylobacterium* from seawater (Wang et al. 2007), but it could not grow at NaCl concentrations of 1.5 % (w/v) or above. This suggests that it was not a true marine organism as seawater contains 2.8 % (w/v) NaCl (=480 mM), while *Mtb salsuginis* tolerated less than 260 mM NaCl.

Pink pigmentation. This is a characteristic of most *Methylobacterium* species and is due to water-insoluble pink to red-colored carotenoid pigments. A study of three (non-type) strains of *Mtb extorquens*, *Mtb fujisawaense*, and *Mtb mesophilicum* showed them to contain 0.23–0.45 mg carotenoids (mg dry wt)$^{-1}$ (Konovalova et al. 2006, 2007). Thin-layer and liquid chromatography and spectral analysis showed the principal carotenoids (tetraterpenoids) to be xanthophylls, particularly hydroxycarotenoids, and to include oscillixanthin and 3,4-didehydrolicopene: These accounted for about 80 % of the total cellular carotenoids (Konovalova et al. 2007). In all the species for which pigment identity has been determined, the spectral properties are similar, indicating common pigment chemistry. These include *Mtb extorquens*, *Mtb cerastii*, *Mtb gnaphalii*, *Mtb organophilum*, *Mtb oxalidis*, *Mtb fujisawaense*, *Mtb rhodinum*, *Mtb thiocyanatum*, *Mtb suomiense*, *Mtb lusitanum*, *Mtb aminovorans*, *Mtb phyllosphaerae*, *Mtb oryzae*, *Mtb populi*, and *Mtb marchantiae*, which show absorbance peaks in the ranges 461–473, 490–505, and 520–534 nm. Some also show peaks at 233 and 358–360 nm (*Mtb oryzae*, *Mtb phyllosphaerae*, *Mtb cerastii*) or 390–394 nm (*Mtb populi*, *Mtb oxalidis*). Some variations in these maxima might be due to extraction methods and the solvents used by different workers (80 % and 100 % methanol; chloroform:methanol at 1:1; acetone:methanol at 3:1 and 7:2; hexane; benzene; and carbon disulfide). Some species have apparently not been analyzed in this way, including *Mtb persicinum*, *Mtb komagatae*, *Mtb brachiatum*, *Mtb tardum*, *Mtb gregans*, *Mtb dankookense*, *Mtb iners*, *Mtb aerolatum*, and *Mtb salsuginis*, so the possible taxonomic usefulness of any pigment variation cannot be comprehensively assessed at present (Şahin 2011). Two species (*Mtb nodulans* and *Mtb jeotgali*) are non-pigmented, but this does not necessarily pose a taxonomic problem, as the loss of carotenoid pigment by *Mtb extorquens* can be induced by a single mutation in the gene encoding phytoene dehydrogenase (Van Dien et al. 2003).

Some methylobacteria have also been shown to produce chlorophyll-like pigments, including the demonstration of bacteriochlorophyll/chlorophyll *a*, and chlorophyllide synthase genes in *Mtb extorquens*, *Mtb radiotolerans*, and *Mtb populi* (http://www.ncbi.nlm.nih.gov/gene/6313745#reference-sequences), and a light-harvesting pigment encoded in the genome of *Mtb extorquens*: http://www.ebi.ac.uk/ena/data/view/ACS42880, described as a "Major Facilitator Family (MFS) transporter (Bch2-like)."

Fatty acids and quinones. Cellular fatty acid profiles (fatty acid methyl ester—FAMES—analyses) have been determined for a large number of *Methylobacterium* species to assess the taxonomic usefulness of comparative profiles. Comparing fatty acid data for 17 species showed the major fatty acid in all cases to be C18:1ω7, with lesser amounts of C18:0 and C16:0, with variable amounts of 2-OH and 3-OH hydroxyacids. The range of amounts reported for each of the three acids (as % of total fatty acids) was quite wide: 74.8–93.1 %, 1.2–8.8 %, and 1.5–4.1 %, respectively. Some determinations reported by different authors for the *same* species were, however, also quite diverse; for example, C18:1ω7 has been reported as 83.7–93.1 % for *Mtb organophilum*, 75.1–87.2 % for *Mtb phyllosphaerae*; for C16:0, 0–4.8 % in *Mtb fujisawaense* and 1.5–4.1 % in *Mtb oryzae*. Consequently differences among some minor fatty acids may have taxonomic usefulness, but variation in major acids is of limited value, and clearly requires absolute standardization of analyses. Mean values for the species analyzed to date are C18:1ω7, 89.6 %, C16:0, 4.0 %, and C18:0, 3.2 %, with quite high standard deviations around the means.

All the species analyzed contain ubiquinone Q-10, typically at 95–100 % of total quinones, including *Mtb extorquens*, *Mtb fujisawaense*, *Mtb radiotolerans*, *Mtb mesophilicum*, *Mtb komagatae*, *Mtb brachiatum*, *Mtb tardum*, *Mtb hispanicum*, and *Mtb soli*. The presence of ubiquinone Q-9 in *Mtb gnaphalii* was a feature differentiating it from its closest phylogenetic relatives (Tani et al. 2012b).

Pyrroloquinoline quinone (PQQ, an essential cofactor in the methanol dehydrogenase of *Methylobacterium*) is secreted into the culture medium in variable amounts by some species, for example, 2.3 and 24.6 μg ml^{-1} by *Mtb oxalidis* and *Mtb gnaphalii*, with a mean for 191 type and other strains of 4.6 μg ml^{-1} (Tani et al. 2012a, b, c).

Ecology, Isolation, Properties, Culture Media, and Growth Conditions for *Methylobacterium*

Methylobacterium species are seemingly ubiquitous and have been isolated from soils, dust, the air, fresh- and seawater, the Antarctic, domestic and clinical water supplies, polluted waters, sewage treatment stations, activated sludge, industrial fermentations (e.g., those degrading formaldehyde), high-temperature geological petroleum reservoirs (Orphan et al. 2000), coal fields, aviation fuels (fuel/water interfaces), fermented seafood, earthworms, from the human body (foot, mouth and eye), and as opportunistic pathogens, and from a vast range of plants (Corpe and Rheen 1989; Madhaiyan et al. 2012; Romanovskaya et al. 2009a; Trotsenko et al. 2001). There is no unique pattern determining the habitat from which any particular species may be found, as many occur in multiple locations. Consequently ecological descriptions are based on specific habitats in some of the following sections and concentrate on physiological properties relevant to their ecology, as well as the conditions required for culture of the organisms.

Media for isolation and cultivation. Numerous medium formulations have been used for the isolation, culture, and maintenance of methylotrophs. Some in common use are given below; others may be found in Atlas (2010) and Hanson (1998). Nitrogen can be supplied as either ammonium or

nitrate salts, or as thiocyanate. The pH of media can be varied by using different ratios of acid and basic phosphates (i.e., KH_2PO_4/Na_2HPO_4). The media can be used with methanol, methylamines, or multicarbon substrates. Enrichment from environmental samples can be by inoculation of samples of soil, water, air-filters, or from leaf impressions on agar, or dissected leaf tissues into media with methanol or methylamine. To prevent overgrowth of fungi, especially in the agar used for leaf-impression cultures, addition of cycloheximide (100 mg l^{-1}) has been recommended (Hanson 1998).

DSMZ Medium No. 632: Nitrate Mineral Salts Medium

(http://www.dsmz.de/microorganisms/medium/pdf/DSMZ_Medium632.pdf)

KNO_3	1.0 g
KH_2PO_4	0.272 g
$Na_2HPO_4{\cdot}12H_2O$	0.717 g
$MgSO_4{\cdot}7\ H_2O$	1.0 g
$CaCl_2{\cdot}6H_2O$	0.2 g
Fe(III)NH_4-EDTA	0.004 g
Trace element solution (see below)	0.5 ml
Distilled water	1,000 ml

Adjust to pH 6.8. Autoclave at 121 °C for 15 min. Methanol (1 or 2 ml) is added from a sterile stock after autoclaving, immediately before use. For solidified medium, add agar (12.5 g) before autoclaving.

Trace element solution:

Na_2-EDTA	0.5 g
$FeSO_4{\cdot}7H_2O$	0.2 g
$ZnSO_4{\cdot}7H_2O$	0.01 g
H_3BO_3	0.03 g
$CoCl_2{\cdot}6H_2O$	0.02 g
$MnCl_2{\cdot}4H_2O$	0.003 g
$Na_2MoO_4{\cdot}2H_2O$	0.003 g
$NiCl_26H_2O$	0.002 g
$CaCl_2{\cdot}2H_2O$	0.001 g
Distilled water	1,000 ml

Methylobacterium Medium with Ammonium as Nitrogen Source

NH_4Cl	0.50 g
K_2HPO_4	0.70 g
KH_2PO_4	0.54 g
$MgSO_4{\cdot}7H_2O$	1.0 g
$CaCl_2{\cdot}2H_2O$	0.2 g
$FeSO_4{\cdot}7H_2O$	0.004 g
H_3BO_3	300 μg
$CoCl_2{\cdot}6H_2O$	200 μg
$ZnSO_4{\cdot}7H_2O$	100 μg
$MnCl_2{\cdot}4H_2O$	30 μg
$CuCl_2{\cdot}2H_2O$	10 μg
$NiCl_2{\cdot}6H_2O$	20 μg
$Na_2MoO_4{\cdot}2H_2O$	60 μg
Distilled water	1,000 ml

Adjust to pH 6.8. Add sterile methanol to a concentration of 0.5 % to the sterilized medium. The medium may be solidified with 15 g agar l^{-1}.

Kelly and Wood (1998) Medium

This high phosphate medium was used for the culture of several methylotrophs and the isolation of *Mtb thiocyanatum* and *Mtb podarium* (Kelly and Wood 1998). It contains (g l^{-1}): $Na_2HPO_4{\cdot}2H_2O$ (7.9), KH_2PO_4 (1.5), NH_4Cl (0.8), $MgSO_4{\cdot}7H_2O$ (0.1), trace metal solution (10 ml l^{-1}; Kelly and Wood 1998), with separate autoclaving of the phosphates. This is supplemented with one of (mM): methanol (50), methylamine (20), dimethylamine (10), trimethylamine (10), sodium formate (25), sodium methanesulfonate (15), formaldehyde (0.5), dimethylsulfide (10, but added in 1–1.5 mM aliquots during growth because of its possible toxicity), dimethylsulfone (10), dimethylsulfoxide (10). For heterotrophic growth, the following can tested (note: some species do not use sugars): sucrose (5), glucose (10), sodium succinate (10), or sodium acetate (20). Methanol, DMS, DMSO, and formaldehyde need to be injected into flasks or tubes containing sterile medium, sealed with gas-impermeable vaccine stoppers (to prevent loss of these volatile substrates). For solid media, Oxoid Bacteriological Agar No. 1 at 1.5 % (w/v) is added. For agar-medium cultures, methanol, formaldehyde, DMS, and DMSO need to be supplied on sterile filter paper in the lids of inverted Petri plates (Anesti et al. 2005) or added to the airspace above a slant before sealing the lid. Agar plates with methanol, DMS, DMSO, or formaldehyde should be incubated in gastight containers to prevent loss of the volatile substrates.

Glucose Medium with Thiocyanate as Sole Nitrogen Source

KSCN	0.25 g
$MgSO_4{\cdot}7H_2O$	0.10 g
K_2HPO_4	1.5 g
$Na_2HPO_4{\cdot}2H_2O$	7.9 g

Glucose	4.5 g
2 % $FeSO_4 \cdot 7H_2O$	1 ml
Distilled water	1,000 ml

Glucose can be replaced with 0.2 %, 0.5 %, or 1 % (v/v) methanol.

Heterotrophic Media

The following have been widely used for culture and maintenance. Commercial nutrient agar is not successful with all species.

R2A Medium

This has been used at full strength or in various dilutions (10 % and 50 %) and contains (g) (Reasoner and Geldreich 1985):

Yeast extract	0.5
Difco Proteose Peptone No. 3	0.5
Difco Casamino acids	0.5
Glucose	0.5
Soluble starch	0.5
K_2HPO_4	0.3
Sodium pyruvate	0.3
$MgSO_4 \cdot 7H_2O$	0.05
Agar	15
Distilled water	1,000 ml

Adjust to pH 7.2 by adding K_2HPO_4 or KH_2PO_4, and add agar before autoclaving.

Glycerol Peptone (GP) Agar

This can be used for maintaining stocks of pure cultures and contains (g):

Agar	15
Glycerol	10
Difco Peptone	10
Distilled water	1,000 ml

Adjust to pH 7.0 before autoclaving.

Methylobacterium and Plants

Several species associate with plants (monocotyledons, dicotyledons, ferns, mosses, and liverworts), both as epiphytes on the phylloplane and rhizoplane, and as endophytes in internal tissues. These can have symbiotic or growth-promoting roles, and in some cases induce root nodulation and enable nitrogen fixation. Earlier work on the relationship of methylobacteria and plants focused on temperate and tropical crop plants, where the bacteria promoted seed germination and increased crop yield, resistance to pathogens, and tolerance of drought stress (Irvine et al. 2012; Raja et al. 2008). Recent studies have identified methylobacteria in "wild" higher plants, liverworts, mosses, and ferns. Among the species found as commensals with plants are *Mtb extorquens*, *Mtb mesophilicum*, *Mtb rhodinum*, *Mtb radiotolerans*, *Mtb bullatum*, *Mtb thiocyanatum*, *Mtb populi*, *Mtb suomiense*, *Mtb aminovorans*, *Mtb fujisawaense*, *Mtb gossipiicola*, *Mtb hispanicum*, *Mtb nodulans*, *Mtb oxalidis*, *Mtb marchantiae*, *Mtb zatmanii*, *Mtb oryzae*, *Mtb gnaphalii*, *Mtb cerastii*, and *Mtb longum*. Interestingly, in a study of the epiphytic methylobacterial community of the surfaces of sunflower plants, *Mtb extorquens* comprised 36 % of the community, *Mtb mesophilicum*, 18–32 %, *Mtb radiotolerans*, 3–10 %, but with 22–43 % being unidentified *Methylobacterium* species (Schauer and Kutschera 2008). Similarly, a phylogenetic study of the bacterial community on the rehydrating phylloplane of the Resurrection Fern (*Polypodium polypodioides*) showed numerous isolates of *Methylobacteriaceae*, including some related to *Mtb aquaticum*, *Mtb hispanicum*, and *Mtb radiotolerans*, as well as at least 12 novel isolates (Jackson et al. 2006).

Phyllosphere colonists. *Methylobacterium* species are among the principal members of the bacterial flora of plant surfaces (Delmotte et al. 2009; Knief et al. 2010a, b; Poonguzhali et al 2008; Tani et al. 2012a, b; Vorholt 2012), in some cases accounting for up to 80 % of the bacterial colonists on leaves (Corpe and Rheen 1989). Several studies have reported the predominant species as *Mtb extorquens* (on more than 50 plant species; Corpe 1985; Trotsenko et al. 2001), *Mtb bullatum* strain F3.2, *Mtb mesophilicum*, and *Mtb rhodinum* (Irvine et al. 2012). A study of plants in the Ukraine showed phyllosphere methylobacteria in more than 200 species of agricultural, decorative, medicinal, and wild plants (Romanovskaya et al. 1996; Trotsenko et al. 2001). Phyllosphere methylobacteria exhibit properties valuable for survival in the potentially extreme conditions that leaves can be subjected to, showing resistance to dehydration, UV and ionizing radiation, and high temperature (Romanovskaya et al. 1998; Trotsenko et al. 2001). For example, *Mtb extorquens* and *Mtb mesophilicum* (typically the most abundant epiphytes) tolerated UV radiation in excess of 250 J m^{-2}; their LD_{90} and $LD_{99.9}$ doses for γ-radiation were 2.0–3.4 and 4.4–6.0 kilogray (J g^{-1}), respectively (Romanovskaya et al. 2002, 2009b). Leaf temperatures in summer can exceed 30 °C even in temperate climates, and can exceed 40 °C in tropical and arid regions, but methylobacteria can survive these conditions. An extreme example of their temperature resilience is seen in the method employed to prepare a soil sample for isolation of *Mtb soli* (Cao et al. 2011): The soil sample was dried at room temperature for 7 days, then heated for 1 h at 80 °C, after which the dry soil was suspended in sterile distilled water, and aliquots spread on agar medium, resulting in the successful isolation of *Mtb soli*.

Studies by Knief et al. (2008, 2010a, b, 2012) on *Arabidopsis thaliana*, and 25 other plant genera, have shown that

colonization efficiency by different *Methylobacterium* species was linked to their phylogeny, rather than to the geographical origin or the plant genus being colonized, with *Mtb extorquens* and *Mtb tardum* being the most aggressive phyllosphere colonists. Dourado et al. (2012a) reported a large study of 120 DNA sequences of partial 16S rRNA and *mxaF* gene sequences from 60 endophytic *Methylobacterium* strains (including 23 strains identified as *Mtb extorquens*, *Mtb fujisawaense*, *Mtb hispanicum*, *Mtb mesophilicum*, *Mtb populi*, and *Mtb radiotolerans*) isolated from six plant species: *Borreria* (12 strains), *Capsicum* (7 strains), *Citrus* (18 strains), *Coffea* (8 strains), a *Eucalyptus* hybrid (7 strains), and *Saccharum* (8 strains). Some *Methylobacterium* strains were "generalists" able to colonize more than one host plant (e.g., for named strains: *Mtb fujisawaense* from *Saccharum*, *Citrus*, and *Capsicum*). Other strains were exclusive to only one plant species. Comparing 16S rRNA and *mxaF* genes from these revealed seven phylogenetic groups for each of 16S rRNA genes and *mxaF* genes, and showed that congruence between host and colonist phylogeny was higher in the *mxaF* gene groups than for the 16S rRNA gene sequences. Some *mxaF* groups showed significant specificity for particular plant species: Thus *mxaF* groups IV and V were only with *Citrus*, and group VI mainly with *Borreria*, while *mxaF* group VII contained isolates from five of the six plant species. Dourado et al. (2012a) concluded that such "niche specialization" results from a function-based selection whereby the plant species interact with potential *Methylobacterium* colonists to select strains most suited to endophytic colonization. Discrimination among different endophytic species has relied mainly on identification by standard phylogenetic analyses, but Lacava et al. (2006) described a quantitative PCR-based method specific for detection and monitoring of the development in *Citrus* plants of endophytic *Mtb mesophilicum*. Primers for the intergenic region of the ribosomal operon of *Mtb mesophilicum* produced a 390 bp amplicon (sensitive to around 130 bacterial cells per assay) with *Mtb mesophilicum*, but did not react with *Mtb extorquens*, *Mtb radiotolerans*, *Mtb zatmanii*, or *Mtb fujisawaense*. Such an assay for other species would need to be equally specific.

Symbiosis and growth-promoting secretions from *Methylobacterium*. Green (2006) commented that while extra- and/or intracellular symbiotic or mutualistic associations apparently existed between plants and some strains of *Methylobacterium*, there was no further evidence at that time to support the theory of a symbiotic association. Corpe and Basile (1982) had suggested that the PPFM bacteria present on mosses and liverworts might produce growth-stimulatory substances for those plants. Since the completion of Green's review, the nature of some of the symbioses has become better understood. Examples of stimulated germination, growth, and yield by methylobacteria are common (Holland 1997; Madhaiyan et al. 2007; Mattilä 2001; Pirttilä et al. 2000; Trotsenko et al. 2001), as are examples of the deleterious effect of the *absence* of methylobacteria from seed or plant surfaces. For example, heating soya bean seeds reduced the population of symbiotic bacteria by up to 97 % and lowered subsequent plant biomass production by 75 %. This effect was not due to damage to the seeds, as the effects were prevented by inoculation, after heating, with methylobacteria, which increased germination rates and biomass production over those of control seeds (Trotsenko et al. 2001). Spraying corn, spinach, beet, and soya bean plants with methanol solutions augmented yield, an effect attributed to the doubling of methylobacteria numbers following spraying (Trotsenko et al. 2001). This artificial stimulation by exogenous methanol parallels the demonstration by Sy et al. (2006) that a competitive advantage in phyllosphere colonization of *Medicago trunculata* by *Mtb extorquens* was provided by the methanol excreted by the plant, as wild-type bacteria were more effective colonizers than mutants defective in methanol oxidation. Seedlings of *Ginkgo biloba* (the maiden hair tree; *Ginkgophyta*) grew more rapidly in the presence of methylobacteria compared to an aseptic control, suggesting the epiphytic *Methylobacterium* might provide stimulatory phytohormones (Hellmuth and Kutschera 2008; Kutschera and Niklas 2009). In a study of methylobacteria on strawberry leaves (*Fragaria* × *ananassa* cv. Elsanta), Abanda-Nkpwatt et al. (2006) isolated strains of *Mtb extorquens* and *Methylobacterium* sp. strain ME4, all of which promoted the growth of various plants: Seedling weight and shoot length of *Nicotiana tabacum*, *Lycopersicon esculentum*, *Sinapis alba*, and *Fragaria vesca* were all increased by the methylotrophs. Bacterial culture supernates also stimulated germination, suggesting the production of a growth-promoting agent. Bacterial growth was correlated with methanol production by the plants and consequent growth promotion: The output of methanol from *Nicotiana tabacum* seedlings, without methylobacteria, was up to 0.7 ppbv, but was decreased to 0.005–0.01 ppbv when the seedlings were cocultivated with *Mtb extorquens* ME4, showing consumption of the methanol by the bacteria. This indicated a truly symbiotic "cross-feeding" between plant and bacteria.

Direct evidence for the production and secretion of specific hormones by *Methylobacterium* species includes the secretion of zeatin (cytokinin) by *Mtb mesophilicum* (Ivanova et al. 2000; Koenig et al. 2002; Lee et al. 2006), and in the cells of methylotrophs isolated from *Arabidopsis*, maize, barley, and soya beans (Trotsenko et al. 2001). *Trans*-zeatin secretion and enhancement of wheat seed germination by the culture filtrates from two new *Methylobacterium* isolates was observed by Meena et al. (2012), who showed that four new isolates and *Mtb extorquens* all secreted *trans*-zeatin, which they suggested resulted from tRNA turnover, rather than from de novo synthesis.

Other work has shown that the auxin, indole-3-acetic acid (IAA), which has roles in promoting cell division, expansion, differentiation, root formation, leaf fall, and fruit ripening in plants is produced by methylobacteria, including *Mtb mesophilicum* (Doronina and Trotsenko 2002; Hornschuh et al. 2006; Ivanova et al. 2001; Omer et al. 2004). Also, the presence of the *IpdC* gene encoding indolepyruvate decarboxylase in *Methylobacterium extorquens* AM1 (Fedorov et al. 2010) indicated the presence of an IAA-biosynthetic pathway. Knockout of

the *IpdC* gene decreased IAA secretion by more than 50 %, while complementing the mutation increased IAA secretion into the culture medium 6.3-fold compared to the mutant. Radha (2007) studied numerous plant-associated methylobacteria, which secreted soya-bean-growth-promoting compounds into the medium: IAA up to 28 μg (ml culture filtrate)$^{-1}$, cytokinin (zeatin) up to 8 μg ml^{-1}, and gibberellic acid up to 70 μg ml^{-1}. Tani et al. (2012c) in a survey of 191 type and non-type *Methylobacterium* strains found their average auxin production to be 1.28 μg ml^{-1}.

The availability of the complete genome sequences of several *Methylobacterium* species has provided molecular evidence for auxin secretion by the bacteria: For example, the proteosomes of *Methylobacterium* sp. strain 4–46 (http://www.ncbi.nlm.nih.gov/nuccore/NC_010511.1), *Mtb populi* strain BJ001 (NCIMB 13946), *Mtb extorquens* strains PA1, AM1, DSM 13060, and CM4, *Mtb radiotolerans*, and *Mtb nodulans* ORS 2060 (LMG 21967) all contain sequences predicted to encode membrane-integrated auxin-efflux-carrier proteins of 309–322 amino acids. The predicted proteins for the four *Mtb extorquens* strains and *Mtb populi* show 96–100 % amino acid sequence identity to each other, but only 27–33 % identity to those of *Mtb nodulans*, *Mtb radiotolerans*, and *Methylobacterium* strain 4–46 (determined by the authors, using the BLASTP algorithm from the NCBI database). The predicted protein sequence for *Mtb radiotolerans* shows 44 % identity to that for strain 4–46, but only around 30 % to the other species. There is obviously species-related diversity among the efflux proteins, possibly indicative of acquisition of the encoding genes from diverse sources by horizontal gene transfer. It is interesting to note that some plants (including *Arabidopsis*) secrete chloromethane (Anderson et al. 2010; Nadalig et al. 2011), which can be a substrate for *Mtb extorquens* strain CM4, a property not shared with *Mtb extorquens* strain AM1 or with the dichloromethane-using strain DM4 of *Mtb extorquens*.

Stimulation of liverworts and mosses by methylobacteria is a well-established phenomenon (Hornschuh et al. 2002, 2006; Kutschera and Koopmann 2005; Schauer and Kutschera 2011). Thallus growth of liverworts (*Marchantiophyta*, bryophytes) and moss development show symbiotic stimulation by the phytohormones (cytokinins, auxins) secreted by the methylobacteria (Hornschuh et al. 2002; Kutschera 2007). Growth of the moss *Racomitrium* is stimulated by a methanol-mediated symbiosis with several strains of *Methylobacterium*, phylogenetically most similar to *Mtb extorquens*, *Mtb aquaticum*, *Mtb oryzae*, *Mtb tardum*, and *Mtb zatmanii* (Tani et al. 2011, 2012a, b, c). This mutualism has been exploited practically in the use of *Racomitrium* to create roof-coverings of the moss to reduce roof and building temperatures, save energy (e.g., air-conditioning) in hot latitudes, and in urban storm-water management (Anderson et al. 2010; Tani et al. 2012c). *Racomitrium* is a primary plant colonizer in hostile environments, resistant to extreme desiccation and very sunny conditions, commonly known as the "woolly moss" and "woolly fringe-moss" found abundantly in the natural environment (Tani et al. 2012c; Woolly moss Iceland: http://icelandairhotels.com/sites/default/files/imagefield_thumbs/IH_natturu_31x42_230511_LQ.pdf; Woolly fringe-moss on a dry stone wall, Scotland: http://icelandairhotels.com/sites/default/files/imagefield_thumbs/IH_natturu_31x42_230511_LQ.pdf).

While novel species, some as yet unnamed, of *Methylobacterium* are present on/in the phylloplane, rhizosphere, and tissues of numerous plants, a novel species has been well characterized from a "lower plant," the moss *Funaria*. *Methylobacterium* sp. strain F3.2 was isolated and described as an epiphytic growth-promoter of protonemal filaments of the moss *Funaria hygrometrica* (Hornschuh et al. 2002; Schauer and Kutschera 2011). Strain F3.2 was separately given new species names by two separate groups, as *Mtb funariae* (Schauer and Kutschera 2011) and as *Mtb bullatum* (Hoppe et al. 2011). *Mtb bullatum* was, however, the name validated for strain F3.2 (http://www.bacterio.cict.fr/m/methylobacterium.html), with *Mtb funariae* as a synonym. Identical 16S rRNA gene sequences are thus available in GenBank as FJ268657 (*Mtb bullatum*; 1,448 bp; Hoppe et al. 2011) and FJ157975 (*Mtb funariae*; 1,421 bp; Schauer and Kutschera 2011). Phylogenetically, *Mtb bullatum* is closely related to *Mtb marchantiae* (Schauer and Kutschera 2011), as their 16S rRNA gene sequences are 99.3 % identical; its next nearest phylogenetic neighbor is *Mtb adhaesivum* (at only 97.9 % sequence identity). Interestingly, *Mtb marchantiae* was isolated as a growth-promoter of another "living fossil" plant, the liverwort *Marchantia polymorpha* (Kutschera and Koopmann 2005; Schauer et al. 2011).

Strains highly similar to *Mtb bullatum* strain F3.2 have notably also been found on the phyllosphere and root zones of higher plants (Irvine et al. 2012; Schauer and Kutschera 2008), including *Methylobacterium* strain 5a.1.5 from sunflower, which showed only one nucleotide difference in its 16S rRNA gene sequence (FJ157965) from that of the type strain of *Mtb bullatum*.

The phytosymbiotic association between methylobacteria and mosses and liverworts is likely to be an extremely ancient one (300–400 Ma BCE), of considerable evolutionary significance (Hornschuh et al. 2002, 2006; Kutschera, 2006; Kutschera and Koopmann 2005; Schauer and Kutschera 2011), and probably significant in the establishment of commensal associations of methylobacteria with higher plants. Tani et al. (2012d) have shown that 18 out of 57 new isolates from bryophytes appeared, from WC-MS analysis, to be new lineages within the *Methylobacterium* genus, consistent with a very long-standing relationship between this bacterial group and the bryophytes.

Endophytic colonization and nodulation of plant roots and leaves. The earliest isolation of a nodule-inducing methylotroph from a plant was of *Mycoplana rubra* (now *Mtb extorquens* strain RP4, NCIMB 10409) from surface-sterilized leaf nodules of the Zimbabwean evergreen tree, *Psychotria mucronata* (*Rubiaceae*; now *P. kirkii*), by M. E. Rhodes-Roberts (cited by Green 2006; Miller et al. 1983). Several reports have demonstrated that *Methylobacterium* species could be isolated from root nodules of some leguminous plants (Jaftha et al. 2002; Sy et al. 2001a, b), and a study of a homogeneous group of 72

isolates of non-pigmented *Methylobacterium* from three species of *Crotalaria* resulted in the description of the novel species, *Mtb nodulans* from *C. podocarpa* (Dakar, Senegal; Jourand et al. 2004; Sy et al. 2001b). This species contains the nodulation gene *nodA*, the *nifH* gene, encoding nitrogen fixation, and *mxaF* for a methanol dehydrogenase subunit. It is able to grow on methanol, formaldehyde, and formate, and promotes nodulation and nitrogen fixation in *Crotalaria* (Jourand et al. 2004, 2005; Renier et al. 2011). In comparison, *Mtb extorquens*, *Mtb organophilum*, *Mtb radiotolerans*, *Mtb rhodinum*, *Mtb mesophilicum*, *Mtb rhodesianum*, and *Mtb zatmanii* were unable to induce root nodule formation in legumes (Sy et al. 2001b). In addition, eight nodulating bacteria were isolated from *Lotononis* species and were called *Rhizobium* or *Methylobacterium* strains xct7-xct17 (Jaftha et al. 2002). Ardley et al. (2009) assessed 11 pink-pigmented *Methylobacterium* strains from the Western Australian Soil Microbiology (WSM) collection (Murdoch University, Western Australia; Yates et al. 2007), as well as several reference strains. Ten of these were from *Lotononis* root nodules, including two (WSM 2598 and 3035) from *L. bainesii*, six from *L. listii*, and two from *L. solitudinis*. In addition, *Methylobacterium* sp. strain 4–46 was apparently effective in fixing nitrogen in association with nodules of *L. bainesii* (J. K. Ardley, personal communication, 2012). None of the WSM strains could grow on glucose (Ardley et al. 2009).

The availability of the fully sequenced genomes of *Mtb nodulans*, *Methylobacterium* strain 4–46, and *Methylobacterium* WSM 2598 enabled comparison of their *nodA* nodulation genes and the encoded NodA proteins. Comparative sequence analysis (by the authors) of the predicted NodA amino acid sequences (using pairwise BLASTP) of *Mtb nodulans* (http://www.ebi.ac.uk/ena/data/view/CAN84682), *Methylobacterium* 4–46 (http://www.ebi.ac.uk/ena/data/view/ACA18208), and *Methylobacterium* WSM 2598 (http://www.ebi.ac.uk/ena/data/view/AEQ76835) showed them all to be 214–220 amino acids in length. The highest sequence identity (99 %) was between strains 4–46 and WSM 2598, but the strain 4–46 and WSM sequences showed only 80–81 % identity to that of *Mtb nodulans*. This illustrates that there are host-plant determinants in the nodulation mechanisms that are specific for each bacterial strain in the case of *Lotononis*, and indicates that the WSM strains are apparently distinct from *Mtb nodulans* and remote from most other *Methylobacterium* species by 16S rRNA phylogeny. A further striking similarity between strains 4–46 and WSM2598 is their almost identical genome size, compared to most other *Methylobacterium* species (◗ *Table 15.2*). Their chromosomes are both 7.66 Mb, compared to an average of 5.8 Mb for most of the species in ◗ *Table 15.2*, and to 7.77 Mb for *Mtb nodulans*. Their total genome sizes (including plasmids) are 7.74 and 7.66 Mb, compared to 8.84 for *Mtb nodulans*, and an average of 6.34 Mb for the other species (◗ *Table 15.2*). While *Mtb nodulans* clearly differs from all the other species, it seems a characteristic of these three legume-nodulating strains to have considerably larger genomes than the other species.

Phylogenetic relationship of the nodulating strains and *Methylobacterium*. As discussed above, numerous strains can induce root nodule formation: *Mtb nodulans* (isolated from *Crotalaria*), *Methylobacterium* sp. strain 4–46, 17 strains from *Lotononis* species, including nine *Rhizobium* strains: xct7, 8, 9, 10, 12, 13, 14, 16, and CB376 and eight WSM strains: WSM 2598, 2693, 2799, 3032, 3950, 3960, 3962, and 3966. Strain CB376 was isolated from *Listia bainesii* root nodules in Kenya in 1954 by J. P. Botha (Ardley et al. 2009; Yates et al. 2007). It is the current Australian commercial inoculant for *L. bainesii* and is synonymous with strain xct9, also isolated from *L. bainesii* in South Africa (Jaftha et al. 2002; personal communication from Ian Law, ARC Plant Protection Research Institute, Pretoria, to J. K. Ardley). Most of the listed strains are pink-pigmented, except *Mtb nodulans* which is pigmentless. Strain CB376 has a GC content of 68.9 % (Godfrey 1972), in the range for other *Methylobacterium* species. Its carotenoid pigments have been thoroughly studied (Godfrey 1972; Kleinig and Broughton 1982) and shown to be identical to those of the strain of *Pseudomonas rhodos* which is now the type strain of *Mtb rhodinum* (Kleinig and Broughton 1982). Of particular interest is that its carotenoid biosynthesis was suppressed when inoculated into *L. bainesii* (Godfrey 1972), compared to *Mtb nodulans* which always appears pigmentless. The original source of *Methylobacterium* sp. strain 4–46 is uncertain. It was believed to be one of four PPFM strains originally isolated from soil in Bayreuth, Germany, by Heinz Stolp (Heumann et al. 1984), and variously coded Stolp 37 and PPFM 37 (Wolfrum et al. 1986), before being redesignated by Wolfram Heumann as strain 4–46 (D. Nayak, personal communication, 2012). Strain 4–46 was later reported as being synonymous with the South African strains CB376 and xct9 (Fleischman and Kramer 1998). It seems possible that all three strains might have been independent isolations of the same organism, or that strain 4–46 was actually strain CB376 and not Stolp's PPFM 37 (J. K. Ardley, personal communication, 2012). The latter view is supported by the observation that the original strain PPFM 37 grows on methanol, but strain 4–46 does not (P. N. Green, personal communication, 2012); strain 4–46 induced nodulation in *Listia bainesii* and could be re-isolated from those nodules (J. K. Ardley, personal communication, 2012). Strain 4–46 is described on its NCBI genome web page as a "methanol-utilizing bacterium" (http://www.ncbi.nlm.nih.gov/genome/13594?project_id=58843), but this is not confirmed by the available published literature. The medium used for its original isolation and culture contained methanol with 0.05 % (w/w) yeast extract, but it was subsequently found unable to grow on methanol or methylamine alone (C. Marx and S. Vuilleumier, personal communications, 2012). The xct strains of Jaftha et al. (2002) were described as able to grow on 1 % (v/v) methanol, but this could not be confirmed for strain xct9, or for the ten WSM strains, which were all unable to oxidize or grow on methanol, and lacked the typical *mxaF* gene for the small subunit of methanol dehydrogenase (Ardley et al. 2009). BLASTN and TBLASTP of the strain 4–46 genome detected an *mxaF*-like gene encoding a "methanol-ethanol family PQQ-dependent dehydrogenase." This showed only 74 % nucleotide and 53 % amino acid sequence identity to the *mxaF* and MxaF of

Mtb extorquens strain AM1 (our data), but showed 94 % nucleotide identity to the *xoxF* gene of strain AM1. The strain 4–46 genome also contains two further *xoxF* homologues. This is intriguing as the *xoxF1* and *xoxF2* homologues are jointly essential for the expression of methanol dehydrogenase activity (Skovran et al. 2011), whereas the complete genomes of strains 4–46 and WSM 2598 lack an *mxa* operon. This operon is carried in the genome of most *Methylobacterium* species: An exception is *Mtb nodulans* in which the *mxa* operon is carried on its PMNOD02 plasmid, rather than the chromosome (Marx et al. 2012; J. K. Ardley, personal communication, 2012).

The closest named phylogenetic relatives of *Methylobacterium* strain 4–46 are *Mtb isbiliense* and *Mtb nodulans* (at 97.9 and 97.6 % 16S rRNA gene sequence identities), but it shows only 96.4 % and 95.8 % identity to *Mtb variabile*, and *Mtb rhodinum* (our BLAST determinations). Strain 4–46, xct strains 7–10, 13, 14, and 16, and WSM strains 2598, 2693, 2799, 3032, 3950, 3960, 3962, and 3966 share 97–100 % 16S rRNA gene sequence identity with each other, but only 95–97.6 % to *Mtb nodulans* and *Mtb isbiliense*, and only 92–96 % identity to all other current *Methylobacterium* species (authors' data; Ardley et al. 2009; Jaftha et al. 2002; Yates et al. 2007). The phylogenetic homogeneity of these strains suggests they could be strains of a single (novel) species, or might be closely related species of a novel genus. This possibility would need further clarification of the failure of the xct and WSM strains, and strain 4–46, to grow on methanol or methylamine. Proof of failure of these strains (and some type species) to grow on methanol (or other methylated C_1-compounds) inevitably suggests that these strains should perhaps not be classified as *Methylobacterium*, as a tenet of the genus definition is "methylotrophy." It is conjectural to propose that this clade, albeit closely related to *Methylobacterium*, arose by loss of the ability for methylotrophy: By analogy with *Mtb nodulans*, if the *mxa* operon of their ancestral form was plasmid-borne, loss of the plasmid could produce the phenotype exhibited by these strains. This also possibly makes *Mtb nodulans* a descendent of the precursor to these strains, retaining the plasmid-borne *mxa* operon, but having lost the characteristic pink pigmentation of most *Methylobacterium* species. A number of anomalies are clearly in need of resolution.

Methylobacterium and Animals

Methylobacterium species appear to be normal, stable rather than transient, commensals with humans as part of the foot and mouth microbiota (Anesti et al. 2004, 2005; Hung et al. 2011, 2012). Their occurrence in the earthworm gut and as human opportunistic pathogens appear to be transient or opportunistic events, the former probably from earthworm consumption of plant débris. There are several examples of apparent symbioses between *Methylobacterium* strains and insects. One is of an endosymbiotic strain of *Methylobacterium* from the small parasitic wasp *Tamarixia rediata* (which is a parasitoid of the plant pathogen *Diaphorina citri*; Meyer and Hoy 2008). This strain showed 100 % 16S rRNA gene sequence identity to *Mtb lusitanum* (NCIMB 13379) and 99.6 % identity to *Mtb rhodesianum* (NCIMB 12249). A second example is from *Tetraponera binghami*, ants which live only in nest cavities in the hollow internodes of bamboo. These cavities contain numerous *Kermicus wroughtoni* pseudococcids, which provide the ants with amino acid-deficient honeydew. The ants are believed to obtain amino acids produced by bacteria in the dense aggregations of bacterial symbionts located in a pouch-shaped organ located at the junction of the midgut and intestine of the ants (Van Borm et al. 2002). Among these bacteria is a strain provisionally identified as a *Methylobacterium* by Van Borm et al. (2002). The 16S rRNA gene sequence of this organism (AF459799) shows about 96 % identity to each of *Mtb oryzae*, *Mtb radiotolerans*, and *Mtb fujisawaense* (authors' data). An area needing further study is clearly to determine how widespread insect/invertebrate/*Methylobacterium* symbioses may be.

***Methylobacterium* species as human pathogens.** *Methylobacterium* strains have been increasingly reported as infectious agents in humans (Borsali et al. 2011; Holton et al. 1990; Lambert et al. 1983; Sanders et al. 2000; Truant et al. 1998), with 30 clinical cases reviewed by Sanders et al. (2000). Clinically recovered *Methylobacterium* strains are typically regarded as opportunistic pathogens in immunocompromised patients, such as those on chemotherapy (Engler and Norton 2001; Sanders et al. 2000), and with immunosuppression due to alcoholism, renal failure, diabetes, tuberculosis, or (uncommonly) from patients with no previous underlying clinical condition (Gilardi and Faur 1984; Lai et al. 2011; Lambert et al. 1983; Liu et al. 1997; Strazzi et al. 1992; Truant et al. 1998). Symptoms due to *Methylobacterium* infections range from bacteremia, fever, sepsis, empyema, pneumonia, peritonitis, to eye or urinary tract infection (Borsali et al. 2011; Brown et al. 1996; Fernandez et al. 1997; Furuhata et al. 2006; Hiraishi et al. 1995; Lee et al. 2004; Sanders et al. 2000).

Methylobacterium species have been isolated from blood, lymph nodes, bone marrow, corneal scrapings, peritoneal, pleural effusion, ascitic and cerebrospinal fluids, synovia, skin ulcers, and bronchial washings (Flournoy et al. 1992; Sanders et al. 2000). A frequent isolate from infected patients has been *Mtb mesophilicum* (Engler and Norton 2001; Holton et al. 1990; Kaye et al. 1992; Sanders et al. 2000), which has also been shown as the cause of a postoperative septicemia case (Barriere et al. 2008). Other species (including *Mtb radiotolerans*, *Mtb aminovorans*, *Mtb thiocyanatum*, *Mtb extorquens*, *Mtb zatmanii*, *Mtb fujisawaense*, *Mtb lusitanum*, and *Mtb podarium*) have also been reported (Borsali et al. 2011; Fanci et al. 2010; Furuhata et al. 2006; Hornei et al. 1999; Lai et al. 2011; Truant et al. 1998), with *Mtb extorquens* earning the clinical nickname "the red phantom" (Holton et al. 1990). It has been suggested that infection rates may be underestimated because of the difficulty of identifying *Methylobacterium* strains which grow only slowly on commonly used clinical media (Hornei et al. 1999), and underreporting of infection by *Methylobacterium* species due to difficulties in identification using standard clinical practices (Blomqvist et al. 1997; Lee et al. 2004). It is also likely that

infections involving *Methylobacterium* species, prior to recognition of the genus, and progressive identification of its species, have been diagnosed only as "caused by Gram-negative rods" (Blomqvist et al. 1997; Korvick et al. 1989), possibly "uncharacterized *Pseudomonas*," or as organisms which were subsequently reclassified as *Methylobacterium*. Examples are the fortuitous recovery of *Mtb fujisawaense* after long incubation of mycobacterial blood cultures (Fanci et al. 2010), infections attributed to *Pseudomonas mesophilica* (Gilardi and Faur 1984; Rutherford et al. 1988), *Protomonas extorquens* (Hayashi et al. 1990; Holton et al. 1990), and *Vibrio extorquens* (Lambert et al. 1983).

The ubiquitous distribution of *Methylobacterium* poses problems in determining sources and how infection can occur, and in eliminating external contamination (of patients, patient samples, or equipment) as a source during handling of clinical samples or preparation and cleaning of equipment such as catheters, bronchoscopes, endoscopes, and so on. It has been exhaustively demonstrated that *Methylobacterium* is present in domestic water systems (Gallego et al. 2005a, b, c, 2006; Rice et al. 2000), shower curtains and bath rails (Kelley et al. 2004; Rutherford et al. 1988), clinical and dental unit water supplies (Barbeau et al. 1996; Flournoy et al. 1992; Thomas et al. 2006), and in the biofilms formed on bronchoscopes, endoscopes, and in small-bore waterline tubing (Barbeau et al. 1996; Flournoy et al. 1992; Imbert et al. 2005; Kovaleva et al. 2012, 2013). A common route for entry of the infection is via a catheter, with the contaminant potentially coming from hospital tap water, which has been reported to contain *Mtb fujisawaense*, *Mtb aquaticum*, *Mtb mesophilicum*, *Mtb radiotolerans*, *Mtb zatmanii*, and other species (Furuhata et al. 2006; Hornei et al. 1999). Flournoy et al. (1992) described a "pseudo-outbreak of *Methylobacterium mesophilica*" in which the organism *Mtb mesophilicum* was transmitted to seven patients (or samples from them) as a contaminant in the hospital tap water during bronchoscopy. A further consideration is that several *Methylobacterium* strains are found in or on the human body, being found in the mouth, and on the foot, and skin (Anesti et al. 2004, 2005; Greub et al. 2004; Hung et al. 2011, 2012; Strazzi et al. 1992).

In many of the cases of *Methylobacterium* infection, antibiotic treatment eradicated the organism and cured the symptoms, providing strong but circumstantial evidence that the two are linked: the organism being the cause of the infection. This link was probed by Borsali et al. (2011) in considering the diagnostic difficulty of relating the presence of *Mtb podarium* to the eye infection reported by them. It is not simple to consider the *Methylobacterium* case in terms of Koch's postulates: The first postulate ("The microorganism must be found in abundance in all organisms suffering from the disease, but should not be found in healthy organisms") was abandoned as a universal rule by Koch on discovering asymptomatic carriers of cholera and typhoid fever, and asymptomatic carriers are now known to be a common feature of many infectious diseases, and could be the case for the commensal strains of *Methylobacterium*. The second postulate has been fulfilled frequently ("The microorganism must be isolated from a diseased organism and grown in pure culture"). The third and fourth postulates have not been tested in humans or to our knowledge in any animal model ("The cultured microorganism should cause disease when introduced into a healthy organism" and "the microorganism must be re-isolated from the inoculated, diseased experimental host and identified as being identical to the original specific causative agent"), although observed resurgence of the infection (and organism) in patients partly supports those criteria. Probably a convincing early example of *Mtb extorquens* as a primary pathogen was the chronic progressive skin nodulation and ulceration seen in a previously healthy individual, 15 years after hysterectomy and radiation therapy, in which the patient developed a high agglutination titer to the organism (Lambert et al. 1983). This infection was completely resolved after 18 months treatment with a regime of ethambutol, isoniazid, rifampin, and kanamycin, and did not recur.

It is notable that clinical and laboratory studies have shown marked antibiotic resistance among *Methylobacterium* strains, with some infections proving difficult to eradicate. In one example, intervention with five antibiotics was needed to cure the infection (Hornei et al. 1999). Aminoglycoside antibiotics (imipenem, ticarcillin-clavulanic acid, sulfamethoxazole, and trimethoprim), tetracycline, rifamycin, and gentamycin have been reported to be effective against *Methylobacterium*, but a number of studies have shown resistance of some strains to antibiotics, including cephalosporins, ampicillin, piperacillin, carbenicillin, spectinomycin, puromycin, cefuroxime, erythromycin, vancomycin, chloramphenicol, fosfomycin, piperacillin, cefazolin, cefotetan, cerfuroxime, ceftazidime, ceftriaxone, ciprofloxacin, meropenem, nalidixic acid, teicoplanin, gentamycin, amikacin, nitrofurantoin, and *p*-fluorophenylalanine (Borsali et al. 2011; Brown et al. 1992; Furuhata et al. 2006; Goodwin et al. 1988; Korvick et al. 1989; Lee et al. 2004; Zaharatos et al. 2001). Brown et al. (1992) showed the majority of 15 clinical isolates of *Methylobacterium* were resistant to β-lactam drugs, with the exceptions of ceftriaxone and ceftizoxime, and that six of these were β-lactamase-negative with a minimum inhibitory concentration for ampicillin of 4 μg ml^{-1}, whereas nine β-lactamase-positive isolates were resistant to 8–32 μg ml^{-1} (or more). Significantly, they found that even β-lactam drugs usually resistant to β-lactamase inactivation had very little activity against the *Methylobacterium* isolates, suggesting that mechanisms other than drug inactivation by lactamases might be involved in the resistance. Genes encoding β-lactamase have been predicted in the completely sequenced genomes of *Mtb radiotolerans* JCM 2831 (http://www.uniprot.org/uniprot/B1LXB8), *Methylobacterium* sp. strain 4–46 (http://www.uniprot.org/uniprot/B0UJG8), and *Mtb extorquens* strain CM4 (http://www.uniprot.org/uniprot/B7KSG2).

A potentially useful variability thus exists in the effectiveness of different antibiotics against various strains of *Methylobacterium*. This was further illustrated by Lai et al. (2011) using clinical isolates of five different species: Two *Mtb thiocyanatum* isolates were resistant to aztreonam and

ciprofloxacin; two *Mtb lusitanum* isolates were resistant to aztreonam, ceftazidime, and ciprofloxacin; and *Mtb radiotolerans* was resistant to aztreonam, ceftazidime, cefepime, and piperacillin/tazobactam (a combination in which tazobactam is a β-lactamase inhibitor). The sixth isolate, *Mtb aminovorans*, was resistant to all the antimicrobial agents tested. It might be possible for clinical microbiology laboratories to be able to infer the species identity of a *Methylobacterium* isolate from antibiotic sensitivity and thereby recommend an optimal regime of antibiotic treatment. Differential sensitivity has also been suggested as a means of phenotypic identification at the genus level of clinical isolates as *Methylobacterium* (Zaharatos et al. 2001). This conjecture was based on differential sensitivity of four clinical isolates and ATCC cultures of *Mtb extorquens*, *Mtb organophilum*, and *Mtb mesophilicum* to imipenem (extreme susceptibility) and meropenem (high resistance).

The definitive method for identification of clinical isolates of *Methylobacterium* must, however, be comparative sequencing of the 16S rRNA genes of the isolates (Borsali et al. 2011; Fanci et al. 2010; Hornei et al. 1999; Lai et al. 2011; Zaharatos et al. 2001).

Methylobacterium in Biotechnology and Biodeterioration

The importance of *Methylobacterium* strains in damaging or assisting man-made systems, and in their potential for biotechnological exploitation has been recognized increasingly in recent years. *Methylobacterium* strains have been applied commercially to fermentation processes in the manufacture of coenzyme Q-10, lysine, tyrosine, phenylalanine, vitamin B12, enzymes, bioactive peptides, bio-insecticides, biopolymers such as poly-β-hydroxybutyrate (PHB), and copolymeric polyalkanoates (Bormann et al. 1997; Bourque et al. 1995; Desmarteaux et al. 2012; Green 2006; Höfer et al. 2011; Kim et al. 1999; Yezza et al. 2006). *Methylobacterium* strains were never regarded as likely candidates for the commercial production of single-cell-protein as a foodstock, or for biosynthesis of deuterated and $^{13}C/^{15}N$-labeled ribonucleotides, as their growth yields (protein produced/mol methanol consumed) were inferior to those of methylotrophs such as *Methylophilus methylotrophus*, which used the Quayle cycle for C_1-assimilation, rather than the serine pathway found in *Methylobacterium* (Batey et al. 1996; Schrader et al. 2009; Westlake 1986).

A strain of *Methylobacterium* related to *Mtb extorquens*, isolated from contaminated groundwater, was shown to have commercial potential as a producer of polyhydroxyalkanoates of high yield and quality (Yezza et al. 2006). This strain yielded PHB from 0.5 % (v/v) methanol at 40 % (w/w) of the dry biomass produced. It could be induced also to synthesize the co-polyester poly-3-hydroxybutyrate-poly-3-hydroxyvalerate (PHB/PHV) when grown with methanol + valeric acid (7:1 w/w/ratio): This resulted in PHB/PHV accumulation reaching 30 % of the dry biomass, with PHV at twice the PHB content (Yezza et al. 2006). Potassium-limitation of *Mtb organophilum* had also been shown previously to enhance co-polyalkanoate formation (Kim et al. 1999). Using both feeding with different n-alkenoic acids and genetic modification of a proprietary *Methylobacterium* strain could enable production of the "functionalized" polyhydroxyalkanoates required as advanced materials for tissue engineering, biocomposites, biodegradable polymers, and several medical uses (Höfer et al. 2010, 2011).

Methylobacterium strains have also been implicated as beneficial to bioremediation of diverse contaminated environments. Very high tolerance to toxic metals (e.g., cadmium and lead, arsenate and chromate) and to naphthalene, xylene, styrene, phenol, and other organic pollutants led De Marco et al. (2004) to describe two strains of *Mtb extorquens* and one of *Mtb fujisawaense* as "super-bugs." Synergism in increasing biodegradation of methyl t-butyl ether (MTBE) and trichloroethylene was seen when mixtures of degrader strains and these metal-resistant strains were present together (Fernandes et al. 2009). Multiple-metal resistance has been found in 109 isolates of strains of *Methylobacterium* (related to *Mtb fujisawaense*, *Mtb radiotolerans*, *Mtb oryzae*, *Mtb populi*, *Mtb aminovorans*, *Mtb thiocyanatum*, *Mtb extorquens*, and several uncharacterized *Methylobacterium* species) present as endophytes of three mangrove species involved in the remediation of oil-polluted mangrove ecosystems (Dourado et al. 2012b). MTBE is a potentially serious pollutant of wastewater and groundwater as it is added (at 5–15 % w/v) to vehicle fuels (petrol/gasoline). MTBE is resistant to degradation in soil and activated sludge (Fujiwara et al. 1984; Jensen and Arvin 1990; Mo et al. 1997), but was efficiently degraded by a strain of *Methylobacterium* isolated from *Ginkgo biloba*.

A potential pollutant, from some natural and industrial sources, is dimethyl isophthalate (used as a polyacrylate resin comonomer and as a perfume fixative), which can be degraded by consortial activity of *Mtb mesophilicum* and *Klebsiella oxytoca* (Li and Gu 2007). Waste treatment bioreactors are used to remove the highly toxic formaldehyde from waste liquors, and one study has shown a *Methylobacterium* strain to have been the organism responsible (Chongcharoen et al. 2005). That strain (BIP) showed 98 % 16S rRNA gene sequence similarity to that of *Mtb thiocyanatum* and could be acclimatized to an input concentration of 100 mM formaldehyde in a substrate-limited continuous flow chemostat (Chongcharoen et al. 2005). Formaldehyde is normally tolerated as a growth substrate by *Methylobacterium* species in batch culture only up to about 1 mM.

"Phytoremediation" of toxic pollutant nitro-substituted explosives (TNT, RDX, and HMX) involving *Methylobacterium* strains has also been reported (Fournier et al. 2005; Van Aken et al. 2004, 2011). Degradation of these explosives is catalyzed by hybrid poplar trees (*Populus deltoides x nigra* DN34), and this property was attributed to the phytosymbiotic role of endophytic *Mtb populi* strain BJ001^T (Van Aken et al. 2011). Pure cultures of strain BJ001 completely degraded these explosives, with over 50 % of RDX- and HMX-carbon converted to carbon dioxide. During aerobic RDX degradation, a ring-cleavage metabolite can accumulate as a "dead-end" product

(Fournier et al. 2002): This is 4-nitro-2,4-diazobutanal (NDAB), which can also arise from hydrolysis of HMX. NDAB was degraded as a nitrogen source for growth by *Methylobacterium* strain JS178 isolated from sludge out of an aerobic treatment plant at a US air force base (Fournier et al. 2005). This strain was also identified as *Mtb populi* and indicates that both endophytic and "free-living" strains are effective in the degradation of these complex molecules. The further application of *Methylobacterium* species for targeted bioremediation (in soils, activated sludge, fluidized beds, etc.) merits more study: For example, Green (2006) suggested that cyanate and thiocyanate wastes might be degraded by some *Methylobacterium* strains, such as *Mtb thiocyanatum* (Wood et al. 1998), and that strains showing radiation-tolerance comparable to that of *Deinococcus radiodurans*, might be suitable as indicator organisms for quality-control monitoring in the food and packaging industries.

In addition to the beneficial effects ascribed to methylobacteria, they have been implicated in corrosion and fouling. A particular problem is the fouling of fuels and fuel delivery systems by bacteria capable of growth on hydrocarbons, particularly those of chain lengths less than C_{18} (Green 2006; Passman and McFarland 1997). Aviation fuel (a middle-distillate fuel) is subject to fouling, where storage tanks, aircraft wing tanks, fuel filters, and fuel injectors are all affected (Brown et al. 2010). Analysis of 16S rRNA clone libraries showed *Methylobacterium* strains to be the dominant organisms in samples of one fuel type (Jet A) and highly significant in another (JP-8), accounting for 55 % and 18 %, respectively, of the total genera identified (Brown et al. 2010). Besides fouling, fuel tanks are also subject to microbial corrosion as a consequence of biofilm formation, likely to involve methylobacteria (Brown et al. 2010; McNamara et al. 2005; Rauch et al. 2006).

Physiology

All species are facultative heterotrophs, capable of growth on a wide range of multicarbon substrates, with sugars being poorly or not used by several species. The most-studied species, *Mtb extorquens*, can express enzymes for the serine cycle (for one-carbon-unit assimilation for biosynthesis), a complete Krebs tricarboxylic cycle, a glyoxylate-regeneration cycle, the ethylmalonyl CoA pathway, the tetrahydomethanopterin (H_4MPT)-dependent formaldehyde oxidation pathway, and enzymes for glycolysis, amino acid, fatty acid, and alcohol metabolism (Chistoserdova 2011; Chistoserdova et al. 2003, 2009; Lidstrom 2006; Vuilleumier et al. 2009).

Metabolism of one-carbon compounds. Most of the validly published species of *Methylobacterium* oxidize methanol, and can grow on it as the source of energy and carbon. Many, but not all, can also grow on methylamine, and on a wide range of other C_1-compounds, including dimethylamine, trimethylamine, methanethiol, dimethylsulfide, dimethylsulfoxide, dimethylsulfone, methanesulfonate, chloromethane, dichloromethane, formaldehyde, and formate. Most of these compounds are ubiquitous in the natural environment, with methanol, dimethylsulfide, methanesulfonate, and trimethylamine being important atmospheric or biogenic products from plants, animals, and bacteria (Fall and Benson 1996; Gout et al. 2000; Jourdain and LeGrand 2001; MacDonald and Fall 1993; Murrell and Kelly 1996; Nemecek-Marshall et al. 1995; Schink and Zeikus 1980; Yang and Xianfeng 2006). Methanol comprises 40–60 % of the total atmospheric volatile organic carbon (Trotsenko et al. 2001), and its input to the atmosphere from living plants and plant decay, principally from pectin degradation, is about 151 Tg $year^{-1}$ (Jacob et al. 2005). Methanol emission by 11 different plant species (including *Populus deltoides*, Russian olive, and several bean genera) was analyzed in detail by Nemecek-Marshall et al. (1995), who showed emission rates of up to about 100 μg h^{-1} (g dry weight)$^{-1}$ and showed internal leaf pools of up to about 60 μg methanol (g fresh weight)$^{-1}$. Forests are likely to be a major source of atmospheric methanol. An unquantifiable amount of the methanol produced by living plants, especially from young growing leaves, is intercepted by the epiphytic and endophytic populations of methylobacteria.

The biochemistry and genetics of C_1-compound oxidation and assimilation have been exhaustively studied for over 40 years (Anthony 1982; Chistoserdov et al. 1994; Chistoserdova 2011; Chistoserdova and Lidstrom 1994, 1997; Chistoserdova et al. 2003; 2009; Kirikova 1970; Machlin et al. 1988; McDonald and Murrell 1997). The pathway of methanol oxidation is common to many methylotrophic genera and is initiated by the periplasmic quinoprotein, methanol dehydrogenase, which has pyrroloquinoline quinone (PQQ) as its prosthetic group, requires Ca^{2+} for activity, and has cytochrome c_L as the electron acceptor. The active enzyme protein is a $\alpha_2\beta_2$ tetramer, with a large α-subunit (66 kDa polypeptide encoded by the *mxaF* gene) and a small β-subunit polypeptide (8.5 kDa polypeptide encoded by the *mxaI* gene). The 17 or more gene-encoding proteins for methanol oxidation by *Mtb extorquens* are located in three different places on the chromosome, with a single operon of 14 genes encoding the complex of methanol dehydrogenase polypeptides (*mxaFJGIRSACKLDEHB*). Chistoserdova et al. (2003) have shown that methylotrophs express over 100 genes to enable oxidation of C_1-compounds and biosynthesis from them, and that these belong to specialized "metabolic modules" with some genes in the modules located in "methylotrophy islands," and others are located as "singular entities" in the chromosome (Chistoserdova et al. 2003; Lidstrom 2006). Several enzymes catalyzing the primary oxidation of methylamines by methylotrophs are known (Anthony 1982; Chistoserdova et al. 2003; Lidstrom 2006): These include methylamine, dimethylamine, and trimethylamine dehydrogenases, dimethylamine and trimethylamine monooxygenases, and methylamine oxidase. The methylamine dehydrogenase of *Mtb extorquens* is a periplasmic tryptophan-tryptophylquinone (TTQ)-dependent tetrameric quinoprotein ($\alpha_2\beta_2$), encoded by *mauA* (small subunit), *mauB* (large subunit), and *mauC* (the amicyanin acceptor), which are part of an 11-gene operon (*mauFBEDACJGLMN*). The primary product of methanol and methylamine oxidation (and of methanesulfonate, oxidized by

a methanesulfonate monooxygenase) is formaldehyde. This is the metabolic branch point for oxidation and biosynthesis from the serine cycle. Other C_1-compounds must also undergo formaldehyde-producing metabolism for these purposes. Formaldehyde can be oxidized by several enzyme systems, producing formate, which is further oxidized to carbon dioxide, or is channeled into the serine cycle (Chistoserdova et al. 2003; Kelly and Murrell 1999; Lidstrom 2006).

Metabolism of oxalate. Oxalate is found in all plants, primarily in leaves, but also found in some plant stems and roots, although in an extreme range of concentrations. It is produced from glucose and Krebs' cycle intermediates via glycolate and glyoxylate, and is essentially an obligatory end product of metabolism, as an excretion of carbon dioxide in its mildly reduced form, HOOC-COOH. It is thus a ubiquitous natural product, both in the plant and released into the soil. The most productive accumulators are *Oxalis* species (ca. 900 spp., including sorrels and shamrocks), with *O. pes-caprae* accumulating up to 16 % of its dry weight as oxalic acid (Millerd et al. 1963). Rhubarb leaves are also well known as oxalate accumulators, with up to 5.3 g per kg fresh weight. Concentrations (g per kg) in common vegetables range from 0.4 to 1.0 for parsnip, pea, okra, onion, potato, and tomato and up to 6.1–17.0 for beet leaves, spinach, cassava, chives, purslane, and parsley (USDA 1984).

Numerous bacteria have been reported as oxalotrophs, degrading oxalate as a source of energy and carbon. The earliest report of an oxalate-degrader was the *Bacillus extorquens* (*Vibrio extorquens*, now *Mtb extorquens*) described by Bassalik (1913). This organism should not be confused with the unrelated *Vibrio oxalaticus* (Bhat and Barker 1948), which, like *B. extorquens*, was isolated from the excreta of earthworms: It is a member of the *Betaproteobacteria* and was successively reclassified as *Pseudomonas oxalaticus*, *Ralstonia oxalatica*, and finally as *Cupriavidus oxalaticus* (Vandamme and Coenye 2004). The re-isolation of *Mtb extorquens* (as *Pseudomonas extorquens*) by Janota (1956), using a mineral medium with 1.2 g ammonium oxalate per liter, enabled further study of oxalate metabolism by *Methylobacterium*. She demonstrated by Warburg manometry that oxalate oxidation initially proceeded with a (carbon dioxide output/oxygen uptake) ratio of about 2, which fell to a long-term (4 h) steady-state ratio of 0.94 ± 0.3. The complete oxidation of oxalate would require a balance of:

$$2(COOH)_2 + O_2 \rightarrow 4\ CO_2 + 2\ H_2O\ [CO_2/O_2 = 4.0]$$

The observation of maximum ratio of 2.0 and a steady-state ratio of only about 1.0 indicates incomplete oxidation and the likelihood of formation of partially oxidized intermediates and fixation of some oxalate-carbon into biomass.

Subsequently the pathways of oxidation and assimilation of oxalate were established by Blackmore and Quayle (1970), using (as they thought) four different species of pink-pigmented methylotrophs: *Pseudomonas AM1*, *Pseudomonas* AM2, *Protaminobacter ruber*, and *Protomonas extorquens* (all of which are *Mtb extorquens*). During growth on oxalate, all the organisms were shown to contain oxalyl-CoA decarboxylase, formate dehydrogenase, and oxalyl-CoA reductase. This was consistent with oxidation of oxalate involving oxalyl-CoA, formyl-CoA and formate as intermediates, and the reduction of oxalyl-CoA to glyoxylate. The oxalate-grown organisms also contained L-serine-glyoxylate aminotransferase and hydroxypyruvate reductase, indicating that synthesis of C_3-compounds from oxalate occurred by a variant of the serine pathway "used by *Pseudomonas* AM1 during growth on C_1-compounds" (Blackmore and Quayle 1970). This metabolism was subsequently confirmed for other *Methylobacterium* species and for *Mtb extorquens* strain AM1 (Schneider et al. 2012), and the mechanism of oxalate oxidation and assimilation is available on the MetaCyc database for *Mtb extorquens* (http://metacyc.org/META/NEW-IMAGE?type=NIL&object=PWY-6696) and *Mtb chloromethanicum* (http://biocyc.org/MCHL440085/NEW-IMAGE?object=Oxalate-Degradation).

Şahin et al. (2008) tested 12 oxalotrophic strains, isolated from soil or plant tissues, which fell into four groups of strains, which were closest to the type strains of *Mtb thiocyanatum*, *Mtb aminovorans*, *Mtb extorquens*, and *Mtb organophilum*. They also tested 20 type cultures of *Methylobacterium* for their use of oxalate: *Mtb radiotolerans*, *Mtb aminovorans*, *Mtb fujisawaense*, *Mtb thiocyanatum*, *Mtb rhodesianum*, *Mtb rhodinum*, *Mtb zatmanii*, *Mtb mesophilicum*, *Mtb dichloromethanicum*, *Mtb chloromethanicum*, *Mtb suomiense*, *Mtb lusitanum*, *Mtb organophilum*, *Mtb hispanicum*, *Mtb nodulans*, *Mtb adhaesivum*, *Mtb isbiliense*, and *Mtb podarium* were all oxalate-users, but *Mtb variabile* and *Mtb aquaticum* were not. Oxalotrophy is thus a common feature of the majority of species tested to date.

Oxidation of thiosulfate. Some *Methylobacterium* strains have been shown to gain energy from the oxidation of thiosulfate to sulfate, which increased growth yields in mixotrophic culture with methanol or succinate as the carbon source (Anandham et al. 2007, 2009). This was demonstrated for *Mtb fujisawaense*, *Mtb goesingense*, *Mtb oryzae*, and *Mtb thiocyanatum*, but not for *Mtb suomiense* or *Mtb rhodinum*. *Mtb phyllosphaerae*, previously grown on a yeast extract + thiosulfate medium oxidized tetrathionate, trithionate, sulfite, and elemental sulfur as well as thiosulfate (Anandham et al. 2008).

Genus *Microvirga*

Mi.cro.vir'ga Gr. adj. *mikros* small; L. fem. n. *virga* rod; N.L. fem. n. *Microvirga* a small rod. Type species *Mv subterranea*: sub.ter. ra'ne.a L. fem. adj. underground, subterranean.

Taxonomy

Microvirga was assigned to the *Methylobacteriaceae* in the second edition of *Bergey's Manual of Systematic Bacteriology*, but no description was given (Garrity et al. 2005). The eight validly published species form a self-contained cluster on the basis of their 16S rRNA gene sequences, which is distinct from *Methylobacterium*, but is clearly related to it as a separate

Table 15.3

Type strains of the species of *Microvirga*, 16S rRNA gene accession numbers, and some distinguishing properties. All validated names are shown (LPSN; http://www.bacterio.cict.fr/)

Species	Culture collection accession number	GenBank accession number	GC content of type strain DNA (mol %)	Isolation source of the type strain	Growth on glucose/nitrate reduction	Motility/ colony color
Mv aerilata	KACC 12744	GQ421849	61.5	Atmosphere (Korea)	−/−	−/Pink
Mv aerophila	KACC 12743	GQ421848	62.2	Atmosphere (Korea)	−/−	−/Pink
Mv flocculans	ATCC BAA-817	AB098515	64.0	A hot spring (Japan)	−/−	−/White
Mv guangxiensis	JCM 15710	EU727176	64.3	Soil (rice field, China)	+/+	+/Pink
Mv lotononidis	LMG 26455	HM362432	62.9	N_2-fixing nodules of *Listia angolensis* (Zambia)	+/+	+/Pink
Mv lupini	LMG 26460	EF191408	61.9	N_2-fixing nodules of *Lupinus texensis* (Texas)	+/−	−/Orange
Mv subterranea^T	ATCC BAA-295	FR733708	63.5	Geothermal bore hole	−/+	+/Pink
Mv zambiensis	LMG 26454	HM362433	62.6	N_2-fixing nodules of *Listia angolensis* (Zambia)	+/+	+/Cream

genus of the *Methylobacteriaceae* (Fig. 15.1; Ardley et al. 2012; Weon et al. 2010). Like most *Methylobacterium* species, some of its species produce pink colonies, have similar rod-shaped morphology, similar major fatty acid profiles, and contain ubiquinone Q-10. Unlike *Methylobacterium*, *Microvirga* species do not use methanol or other C_1-compounds for energy or carbon.

The original genus description (Kanso and Patel 2003) has been subject to two emendations to date, as new species were characterized (Weon et al. 2010; Zhang et al. 2009) and can now be updated as below.

Strictly aerobic, small, Gram-negative rod-shaped cells; different species produce light-pink, pale orange, white, or cream colonies. The optimum temperature for growth is 37–45 °C, with a species-dependent temperature range for growth between 10 °C and 45 °C. Four of the eight species cannot grow on glucose. They all reduce nitrate to nitrite. Cells are susceptible to antibiotics that inhibit members of domain *Bacteria*. Bacteriochlorophyll is absent but carotenoids are present; PHB is produced. Thiosulfate does not stimulate growth. Positive for catalase, but negative for hydrolysis of casein, chitin, carboxymethylcellulose, and for xanthine, indole production, glucose fermentation, and arginine dihydrolase. The predominant isoprenoid quinone is Q-10. The major fatty acid is C18:1ω7c (63.3–73.8 % of total fatty acids). The polar lipids consist of phosphatidylcholine and phosphatidyl-ethanolamine as major components, and phosphatidyl-monomethyl-ethanolamine, phosphatidyl-dimethyl-ethanolamine, diphosphatidyl-glycerol and phosphatidyl-glycerol in moderate amounts. The GC content of the DNA is 61.5–64.3 mol%. 16S rRNA gene sequence analysis indicates that it is a member of the *Alphaproteobacteria*, placed almost equidistantly between *Chelatococcus asaccharovorans* and *Bosea thiooxidans*, respectively, members of the families *Beijerinckiaceae* and *Bradyrhizobiaceae*, as the nearest phylogenetic relatives. The type species is *Microvirga subterranea*.

Molecular Analyses

The genomes of *Mv lupini* strain Lut6 and *Mv lotononidis* strain WSM 3557 have been sequenced http://www.ncbi.nlm.nih.gov/genome/13788?project_id=66529 and http://www.ncbi.nlm.nih.gov/genome/13788?project_id=167863. Lut6 contains 9,633,614 bp; with 61.58 mol% GC; and only one gene each for 5S, 16S and 23S rRNA. WSM 3557 contains 7,082,538 bp; 63.08 mol% GC; three genes encoding 5S rRNA, one for 16S rRNA, and two for 23S rRNA.

Phenotypic Analyses

Some distinguishing features of the eight species are summarized in Table 15.3. Four of the species have cell sizes (μm) of 0.4−0.8 × 1.0−2.2, but the other four are larger: *Mv subterranea*, *Mv flocculans*, *Mv aerophila*, and *Mv aerilata* being 1.0 × 1.5−4.0; 0.5−0.7 × 1.5−3.5; 0.8−1.1 × 1.6−4.2; and 1.2−1.5 × 1.6−3.3, respectively. Only three species (*Mv lotononidis*, *Mv zambiensis*, and *Mv flocculans*) are motile by means of polar flagella. Their optimum temperatures and pH for growth are in the range 35–45 °C and pH 7.0–8.5. None will tolerate more than 2 % (w/v) NaCl. Some will grow in minimal media while some require yeast extract as an absolute requirement, and all grow with complex media. Growth with ranges of multicarbon substrates is detailed in the original species descriptions, as is antibiotic sensitivity for some species. The three root nodule species (Ardley 2011; Ardley et al. 2010, 2012) grow on glucose, fructose, L-arabinose, and mannitol, and are oxidase negative, but the other species are mainly negative for these substrates (or have not been tested), and four of the five other species are oxidase positive. Only the root nodule

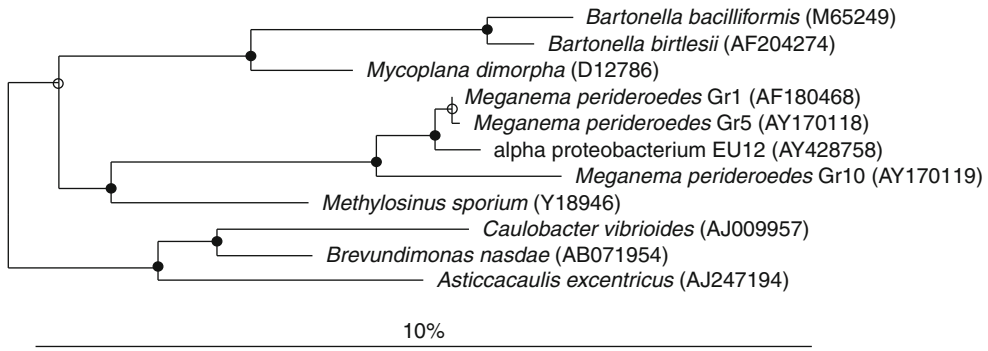

Fig. 15.2

Phylogenetic analysis of 16S rRNA gene sequences from *Meganema perideroedes* (ATCC BAA-740^T; DSM 15528^T), other *Meganema* strains, and the closest phylogenetic relatives of the type strain. Sequences were aligned using the ARB-SILVA database (Ludwig et al. 2004), and phylogenetic trees were constructed from 1,190 bp of aligned sequence using neighbor-joining (NJ) in the ARB software environment. The scale bar represents 10 % sequence divergence, and bootstrap values, from 100 replicates, are represented at the tree nodes: ● >90 % and ○ 70–90 % similarity

species (*Mv lotononis*, *Mv lupini*, and *Mv zambiensis*) have been shown to fix nitrogen: The other five species have not been tested.

Ecology, Isolation, Properties, Culture Media, and Growth Conditions for *Microvirga*

Microvirga species have been isolated from water (a thermal spring and a thermal aquifer), air, and soil and as endosymbionts of the legumes *Listia* (formerly *Lotononis*) and *Lupinus* (Ardley et al. 2012; Kanso and Patel 2003; Takeda et al. 2004; Weon et al. 2010; Zhang et al. 2009). The type species, *Mv subterraneae*, came from free-flowing geothermal water from a borehole (source depth, 295 m; Kanso and Patel 2003).

The medium used by Kanso and Patel (2003) for the type species is suitable for all the current *Microvirga* species, and contains (g):

Yeast extract	1
Peptone	5
$MgSO_4 \cdot 7H_2O$	0.20
$CaCl_2$	0.05
Ferric ammonium citrate	0.15
$MnSO_4 \cdot 4H_2O$	0.05
$FeCl_3 \cdot 4H_2O$	0.01
Vitamin solution	10 ml
Trace element solution	1 ml
Distilled water	1,000 ml

For solid medium, 17 g agar was added; adjusted to pH 7.1 with NaOH. Vitamin solution was that used by Wolin et al. (1963), and the trace element solution was that of Zeikus et al. (1979). Other media used have been half-strength lupin agar (½ LA; Yates et al. 2007), and R2A agar (described above). Glucose, yeast extract-malt extract media, and Luria Broth also support growth (Zhang et al. 2009).

Genus *Meganema*

Me.ga.ne'ma. Gr. nom. neut. adj. *mega* big; Gr. nom. neut. n. *nema* thread; N.L. neut. n. *Meganema* large thread-like microorganism. *Meganema perideroedes*: pe.ri.de.ro'ed.es N.L. neut. adj. necklace-like.

Ecology, Isolation, Culture Media, Growth Conditions, Taxonomy, Molecular and Physiological Properties of *Meganema*

The type strain of *Mn perideroedes* was isolated by micromanipulation from mixtures of filamentous bacteria in the activated sludge biomass causing bulking in a wastewater treatment plant (Thomsen et al. 2006). To date, the only other named isolates were from the same source, comprising five strains that form a monophyletic cluster, and show 97.7–99.6 % sequence identity for their 16S rRNA genes, but the most dissimilar strains (Gr1^T and Gr10) still showed 71.5 % DNA/DNA hybridization. All five were thus strains of a single species (*Figs. 15.1* and *15.2*). The GC content of its genomic DNA, determined by the DSMZ, was reported as 42.9 % (Thomsen et al. 2006), but sequencing of its genome has shown this figure to be incorrect, and the true GC content is 67.2 %.

Mn perideroedes was described after completion of the second edition of *Bergey's Manual of Systematic Bacteriology* and was assigned to the *Methylobacteriaceae* (http://www.bacterio.cict.fr/m/meganema.html) without further discussion. The family was circumscribed for *Bergey's Manual* "on the basis of phylogenetic analysis of 16S rRNA sequences" (Garrity et al. 2005).

Table 15.4

Comparative sequence identities of the 16S rRNA gene sequence of *Meganema perideroedes* and species of other genera of *Rhizobiales* and *Caulobacteraceae*, and comparison with the genomes and GC content (mol%) of the other genera

Genus/species	Genome size (Mb)	GC content (%) of genomic DNA	GenBank accession number (16S rRNA)	% sequence identity to *Meganema perideroedes*
Rhizobiales				
Meganema perideroedes	3.41	67.2	AF180468	100

Brevundimonas subvibrioides	3.45	68.4	NR_037107	88.3
Brevundimonas diminuta	3.24	67.1	NR_040805	88.7

na, Genome sequence not yet available

Its cells are 1.5–2.0 µm in length in filaments about 1.5 µm in width, Gram-negative, with PHB and Neisser-positive granules; the major respiratory quinone is Q-10, and the predominant fatty acid is C18:1ω7c (86.4 % for the type species). Its cells are nonmotile and grow between 15 °C and 35 °C, with an optimum between 25 °C and 30 °C; it will not grow in defined mineral media, and requires a relatively rich medium (R2A, described above) for growth; cannot grow anaerobically with nitrate; tolerates 2 % but not 3 % (w/v) NaCl.

The genome of *Mn perideroedes* has been sequenced as part of the Genomic Encyclopedia of Type Strains (http://www.ncbi.nlm.nih.gov/genome?term=meganema; http://img.jgi.doe.gov/cgi-bin/w/main.cgi?section=TaxonDetail&page=taxonDetail&taxon_oid=2515154196). The genome contains 3,409,949 bp, of which 89.68 % are coding bases, and contains 3,092 genes, of which 98.09 % are protein coding. The genome size (*Table 15.4*) is thus much larger than those of *Bartonella* species, and half or less of those of *Methylobacterium* and *Microvirga* species, but similar to those of some genera within the *Rhizobiales* (e.g., 3.2–3.6 Mb for *Brucella*, *Mycoplana*, and *Hyphomicrobium*) and the *Caulobacteraceae* (3.2–4.3 Mb for *Brevundimonas*, *Asticcacaulis*, and *Caulobacter*).

In our view, *Meganema* has been erroneously placed in the *Methylobacteriaceae*. Unlike most members of the other genera in the family, *Methylobacterium* and *Microvirga*, its cells form filaments as its normal morphology, and its colonies are white, with no pink pigmentation (Thomsen et al. 2006). The phylogenetic tree presented in the primary description of *Meganema* included no species of *Methylobacterium* or *Microvirga* as phylogenetic relatives (Thomsen et al. 2006). Its nearest neighbors (*Fig. 15.2*) were apparently *Brevundimonas*, *Asticcacaulis*, and *Caulobacter* (in Order V, *Caulobacterales*, Family *Caulobacteraceae*), and *Mycoplana* (Order VI, *Rhizobiales*, Family *Brucellaceae*). Its closest phylogenetic relative was reportedly *Brevundimonas*, but at only 89.8 % 16S rRNA gene sequence similarity. BLASTN comparison of the 16S rRNA gene sequence of *Meganema* with *Methylobacterium organophilum*, *Mtb extorquens*, *Microvirga subterranea*, and *Mv aerilata* showed only 86.9–87.8 % sequence identity, compared to 92.7–93.4 % identity between the sequences of the *Methylobacterium* and *Microvirga* species. The supposed affiliation of *Meganema* with *Methylobacterium/Xanthobacter* (Thomsen et al. 2006) was based on the major fatty acid being C18:1ω7c, but this (and other C18:1 fatty acids) is also significant in the other genera including *Brevundimonas*, so this property is not a distinguishing criterion. Our phylogenetic tree (*Fig. 15.1*) shows rather distant relationships of *Meganema* to *Hyphomicrobiaceae* and *Methylocystaceae*, but BLAST2 comparisons of its 16S rRNA gene sequences showed only 88–90 % identity to *Hyphomicrobium vulgare*, *Methylocystis parvus*, and

Methylosinus species (Fig. 15.2; Table 15.4). Comparing the 16S rRNA gene sequences to a range of possibly related *Alphaproteobacteria* indicated *Meganema* to have no close phylogenetic relatives, as all the sequence identities were in the range 86.8–90 % (Table 15.4). The principal ubiquinone in most of the compared genera was Q-10, but some genera are distinguished from *Meganema* by containing Q-8 (*Methylocystis* and *Methylosinus*) or Q-9 (*Hyphomicrobium*). Several online taxonomic assignment databases can be interrogated for the position of *Meganema*. Also, the principal fatty acid in *Meganema* is C18:1ω7c, but C18:1ω8c in *Methylosinus*. Using the SILVA database project (http://www.arb-silva.de/) the assignments predicted by SILVA, RDP, and EMBL are all to the *Methylobacteriaceae*, but the *Greengenes Taxonomy* analysis unequivocally places *Meganema* in the *Caulobacterales* (http://greengenes.lbl.gov/cgi-bin/nph-browse.cgi#focus), specifically the *Caulobacteraceae* (http://www.arb-silva.de/browser/ssu/AF180468). While three genera of the *Caulobacteraceae* are prosthecate, the 4th, *Phenylobacterium*, is not. The DNA of strains of *Phenylobacterium* contains 65–68.5 % GC, its 16S rRNA gene (Y18216) shows 87 % identity to that of *Meganema*, and its cells (0.7–1.0 × 1.0–2.0 µm) become pleomorphic in old cultures, forming filament-linked long chains. The two genera thus share several structural properties, which suggest that both could be genera of the *Caulobacteraceae*.

Numerous other strains showing 97.9–99.8 % 16S rRNA gene sequence identity to the type strain of *Meganema* have been reported, as well as many uncultured clones (NCBI database, as revealed by BLASTN of the NCBI database with the *Meganema* sequence). This indicates that strains of this filamentous genus occur widely, especially in activated sludge and water treatment plants (Levantesi et al. 2004; Thomsen et al. 2006; Jiang et al. 2009).

The genus *Meganema* should thus either be reassigned to the *Caulobacterales* as a novel genus within the *Caulobacteraceae*, or if retained in the *Rhizobiales*, needs to be established as a new Family, the *Meganemaceae*, initially with the one genus and species, represented by *Meganema perideroedes*.

16 The Family *Methylocystaceae*

Hayden K. Webb · Hooi Jun Ng · Elena P. Ivanova
Faculty of Life and Social Sciences, Swinburne University of Technology, Hawthorn, VIC, Australia

Abstract
Methylocystaceae, a family belonging to the order *Rhizobiales*, within the class *Alphaproteobacteria*, consist of genera *Albibacter*, *Hansschlegelia*, *Methylocystis*, *Methylopila*, *Methylosinus*, *Pleomorphomonas*, and *Terasakiella*. Most members of the family *Methylocystaceae*, with the exception of the genera *Pleomorphomonas* and *Terasakiella*, are type II methanotrophs, which assimilate C_1 carbon compounds (most commonly methane and methanol) via the serine pathway. All known species of these genera are gram-negative with the G+C content ranging from 50.7 to 70.4 mol%. The phylogenetic clustering within the group is somewhat weak, and as further strains are identified and classified to the family, some reorganization may occur.

Taxonomy: Historical and Current

Short Description of the Family

Methylocystaceae, Bowman (2005)

Me.thy.lo.cys.ta'ce.ae. N.L. masc. (sic) n. *Methylocystis*, type genus of the family; suff. *-aceae*, ending to denote family; N.L. fem. pl. n. *Methylocystaceae*, the *Methylocystis* family (Bowman 2006).

Methylocystaceae belongs to the order *Rhizobiales*, within the class *Alphaproteobacteria*. The family is classified as type II methanotrophs, in which the species belonging to the family are able to utilize methane and its derivatives as the carbon sources through the serine pathway. Many of these methanotrophic bacteria perform important environmental functions as they are a link in the global carbon cycle, act as nitrogen fixers, and have the ability to degrade a variety of organic contaminants (Gulledge et al. 2001). Currently, the family *Methylocystaceae* contains seven established genera, namely, *Albibacter*, *Hansschlegelia*, *Methylocystis*, *Methylopila*, *Methylosinus*, *Pleomorphomonas*, and *Terasakiella*.

Phylogenetic Position

Based on the 16S rRNA phylogenetic tree, the nearest families that are related to *Methylocystaceae* are *Beijerinckiaceae*, *Bradyrhizobiaceae*, *Methylobacteriaceae*, *Xanthobacteriaceae*, and *Hyphomicrobiaceae*. The 16S rRNA phylogenetic trees were constructed based on maximum likelihood (*Fig. 16.1*) and neighbor-joining (not shown) algorithms, and both agreed that the genera *Terasakiella* and *Pleomorphomonas* may be more distantly related to the other members of *Methylocystaceae*. Also, the family *Methylocystaceae* appeared not to be

E. Rosenberg et al. (eds.), *The Prokaryotes – Alphaproteobacteria and Betaproteobacteria*, DOI 10.1007/978-3-642-30197-1_254,

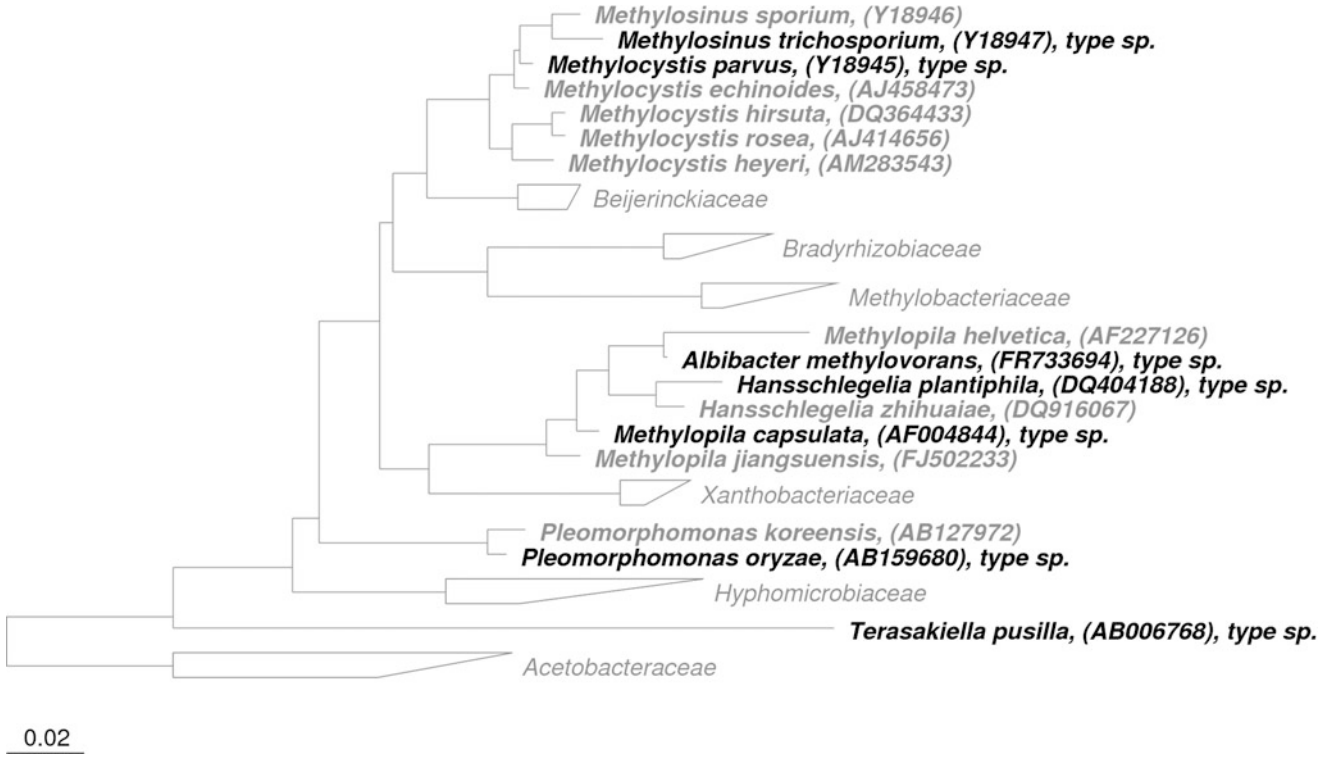

Fig. 16.1

Phylogenetic reconstruction of the family *Methylocystaceae* based on 16S rRNA gene sequences and created using the maximum likelihood algorithm RAxML (Stamatakis 2006). The sequence dataset and alignment were used according to the All-Species Living Tree Project (LTP) database (Yarza et al. 2010); http://www.arb-silva.de/projects/living-tree. Representative sequences from closely related taxa were used as out-groups. In addition, a 40 % maximum frequency filter was applied in order to remove hypervariable positions and potentially misplaced bases from the alignment. Scale bar indicates estimated sequence divergence

monophyletic and has two branches, one associated with *Methylocystis* and the other with *Methylopila*. The position of *Methylopila helvetica* suggests that it may be more closely related to the genus *Albibacter*.

The following is a list of *Methylocystaceae* type strains used for dendrogram construction: *Albibacter methylovorans* DSM 22840^T, *Hansschlegelia plantiphila* S1^T, *Hansschlegelia zhihuaiae* S113^T, *Methylocystis echinoides* IMET 10491^T, *Methylocystis heyeri* H2^T, *Methylocystis hirsuta* CSC1^T, *Methylocystis parvus* NCIMB 11129^T, *Methylocystis rosea* SV97^T, *Methylopila capsulata* IM1^T, *Methylopila helvetica* DM9^T, *Methylopila jiangsuensis* JZL-4^T, *Methylosinus sporium* NCIMB 11126^T, *Methylosinus trichosporium* NCIMB 11131^T, *Pleomorphomonas koreensis* Y9^T, *Pleomorphomonas oryzae* F-7^T, and *Terasakiella pusilla* IFO 13613^T.

Molecular Analyses

Only a few studies have reported on DNA-DNA hybridization (DDH) results for members of the family *Methylocystaceae*. Only two pairs of species have been demonstrated to possess considerable similarity (>40 %) between their genomes; *Hansschlegelia plantiphila* and *H. zhihuaiae* were shown to share 44.9 % of their genomes, and *Methylocystis hirsuta* and *M. rosea* share 41.1 %.

Phenotypic Analyses

Methylocystis, Whittenbury, Phillips, and Wilkinson (1970) and Emend. Bowman, Sly, Nichols, and Hayward (1993)

N.Gr. n. *methyl* (from Gr. n. *methu* wine and Gr. n. *hulê*wood) methyl group; N.L. fem. n. *cystis* (from Gr. fem. N. *kustis*) the bladder and, in biology, a cyst; N.L. fem. n. *Methylocystis* methyl cyst (Whittenbury et al. 1970; Bowman et al. 1993).

Cells belonging to the genus *Methylocystis* are gram-negative reniforms, coccobacilli, or rods and are 0.3–1.2 μm wide by 0.5–4.0 μm long in size. Most of the species belonging to the genus were grown on nitrate mineral salts (NMS) medium, with the exception of *M. heyeri* which was grown on medium M2. Colonies vary from white, highly raised, and slimy to opaque, smooth, low convex, circular with entire edges, butyrous consistency, and pale pink to tan/white color. *M. parvus* also produces a brown diffusible pigment.

Methylosinus, Whittenbury, Phillips, and Wilkinson (1970) and Emend. Bowman, Sly, Nichols, and Hayward (1993)

N.L. n. *methylum* (from French *méthyle*, back-formation from French *méthylène*, coined from Gr. n. *methu*, wine and Gr. n. *hulê*, wood), the methyl radical; N.L. pref. *methylo-*, pertaining to the methyl radical; L. masc. n. *sinus*, a bent surface, curve; N.L. masc. n. *Methylosinus*, methyl bender (Whittenbury et al. 1970; Bowman et al. 1993).

The cells of *Methylosinus* are gram-negative, pyriform or vibrioid, which range in size from 0.5 to 1.0 μm wide by 1.5 to 3.0 μm long. Colonies grown on NMS agar are opaque with smooth surfaces, low convex, and circular with entire edges; have a butyrous consistency; and are white to buff or buff to tan. *M. sporium* may also produce diffusible brown pigment or a bright red prodigiosine-like pigment.

Methylopila, Doronina, Trotsenko, Krausova, Boulygina, and Tourova (1998)

N.L. n. *methylum* (from French *méthyle*, back-formation from French *méthylène*, coined from Gr. n. *methu*, wine and Gr. n. *hulê*, wood), the methyl group; N.L. pref. *methylo-*, pertaining to the methyl radical; L. fem. n. *pila*, ball or sphere; N.L. fem. n. *Methylopila*, methyl-using sphere (Doronina et al. 1998).

Methylopila cells are gram-negative rods, 0.5–1.2 μm wide by 0.8–2.0 μm long in size. Colonies grown on methanol-salt agar are white, semitransparent, convex, and circular with entire edges. *M. capsulata* and *M. jiangsuensis* were also grown well in complex media, e.g., nutrient agar, Luria-Bertani agar, or trypticase soy medium. Granules of poly-β-hydroxybutyric acid (PHB) are observed in cells within this genus.

Albibacter, Doronina, Trotsenko, Tourova, Kuznetsov, and Leisinger (2001)

L. adj. *albus*, white; N.L. masc. n. *bacter*, rod; N.L. masc. n. *Albibacter*, white rod (Doronina et al. 2001).

Albibacter cells are gram-negative rods, 0.9–1.0 μm wide by 1.2–1.8 μm long in size. Colonies on methanol or peptone yeast glucose (PYG) agar are circular, white, convex, translucent to opaque, and mucoid and are 1–2 mm in diameter. To date, only one species has yet been described within this genus.

Terasakiella, Satomi, Kimura, Hamada, Harayama, and Fujii (2002)

N.L. fem. dim. n. *Terasakiella*, named to honor Y. Terasaki, the Japanese microbiologist who has made many contributions to our understanding of the classification and identification of spiral-shaped bacteria (Satomi et al. 2002).

Cells belonging to *Terasakiella* are gram-negative spirilla, ranging in size between 0.3 and 0.5 μm wide by 1.2–4.0 μm long. Colonies grown on medium 325 semisolid agar at 48 h are punctiform, entire, granular, convex or pulvinate, and glistening; yellowish-white butyrous consistency was observed after 7 days of incubation. *T. pusilla* is the only species belonging to this genus to date.

Pleomorphomonas, Xie and Yokota (2005)

N.L. masc. adj. *pleomorphus* (from Gr. adj. *pleos*, full, and Gr. n. *morphê*, form, shape), pleomorphic; Gr. fem. n. *monas*, monad, unit; N.L. fem. n. *Pleomorphomonas*, pleomorphic monad (Xie and Yokota 2005).

Pleomorphomonas cells are gram-negative pleomorphs or rods, with the size ranging from 0.3 to 1.0 μm wide by 1.0–5.0 μm long. The colonies of *P. oryzae* grown on the nitrogen-free agar are colorless, while the colonies of *P. koreensis* grown on the R2A agar are smooth, low convex, circular, translucent, non-shiny, and white in color.

Hansschlegelia, Ivanova, Doronina, and Trotsenko (2007) and Emend. Euzéby (2010)

N.L. fem. n. *Hansschlegelia*, named after Prof. Hans Schlegel, the famous German microbiologist known for his classic studies on autotrophic bacteria (Ivanova et al. 2007; Euzéby 2010).

Cells belonging to the genus *Hansschlegelia* are rods/cocci, 0.6–0.9 μm wide by 1.0–1.5 μm long in size. *H. plantiphila* forms round, low-convex, colorless, entire-edge, semitransparent, and granulous colonies when grown on agar medium supplemented with CH_3OH, while *H. zhihuaiae* forms circular and white colonies when grown on yeast-tryptone-$CaCl_2$ (YTC) agar (*Tables 16.1* and *16.2*).

Isolation, Enrichment, and Maintenance Procedures

Methylocystis

The species of *Methylocystis* were isolated from different sources as well as from different geographical regions as in *Table 16.3*. All species were cultivated on nitrate mineral salt (NMS) medium, except *M. heyeri* which was obtained using liquid medium M2 at pH 5.5 (Dedysh et al. 1998), and pure culture isolated from gellan gum (Gel-Gro, ICN Biomedicals) agar.

Methylosinus

The source of *Methylosinus* species was from NCIMB. They were grown under a methane-air-CO_2 (5:4:1) atmosphere, at 28 °C, on NMS agar.

Methylopila

The type species of the genus *M. capsulata* was isolated from Uzbekistan. The culture was incubated with medium K and maintained on medium K solidified with Difco Bacto agar or PYG agar. The strains of *M. helvetica* were isolated from soil and water samples in the Netherlands, Germany, and Switzerland. They were grown on medium K at 29 °C and stored in the freeze-dried form with skim milk at −80 °C for long-term storage. *M. jiangsuensis* was isolated from an activated sludge of a synthetic pyrethroid-manufacturing wastewater treatment facility on medium K. Colonies were maintained on the medium K supplemented with 0.5 % methanol at 30 °C.

Albibacter

Albibacter methylovorans was first isolated in Switzerland from groundwater samples contaminated with DCM. Colonies were isolated on DCM agar, and pure cultures were maintained on minimal medium K (2 g KH_2PO_4, 2 g $(NH_4)_2SO_4$, 0.025 g $MgSO_4.7H_2O$, and 0.5 g NaCl, pH7.2).

Terasakiella

T. pusilla strains are typically maintained by stab culture in medium 325 (IFO 1996) semisolid agar. The medium contains 1.0 % (w/v) polypeptone (Difco), 0.2% yeast extract (Difco), 0.05 % $MgSO_4.7H_2O$, 75 % (w/v) seawater, 25 % (w/v) distilled water, and 0.2 % agar. The pH should be adjusted to 7.2 by the addition of 1 MNaOH. Cultures require approximately 3 days of incubation at 20 °C.

Pleomorphomonas

The type species of the genus *P. oryzae* was isolated from *Oryza sativa* in Japan in 1982. Strains were grown in nitrogen-free medium (10 g glucose, 0.1 g $CaCl_2.2H_2O$, 0.1 g $MgSO_4.7H_2O$,

0.9 g K_2HPO_4, 0.1 g KH_2PO_4, 5 g $CaCO_3$, 10 mg $FeSO_4.7H_2O$, and 5.0 mg $Na_2MoO_4.2H_2O$, pH 7.3) at 25 °C. *P. koreensis* was isolated from a contaminated culture of the phototrophic bacterium R. palustris by direct plating on R2A agar. Colonies were maintained on R2A agar/broth at 30 °C and stored as glycerol suspension (20 %, w/v) at −70 °C for long-term storage.

Hansschlegelia

The type species of the genus *H. plantiphila* was first isolated from the linden *Tilia cordata* L. and lilac *Syringia glauca* L. buds, as well as the needles of the blue spruce *Picea pungens var. glauca* L., in February 2003, from Pushchino City, Moscow, at −17 °C. Plant samples were first incubated with medium K (2 g $(NH_4)_2SO_4$, 2 g KH_2PO_4, 0.5 g NaCl, 0.125 g $MgSO_4.7H_2O$, 0.02 g $FeSO_4.7H_2O$, 0.2 mL yeast autolysate, and 10 mL methanol, pH 7.2) at 29 °C for 5 days. Pure cultures were obtained after subculturing twice and exhaust plating on K medium agar. On the other hand, the second species of the genus *H. zhihuaiae* was isolated from sulfonylurea herbicide-contaminated farmland soil in Jiangsu, China. Soil samples were incubated with mineral salt medium (MSM) (1 g NaCl, 1.5 g K_2HPO_4, 0.5 g KH_2PO_4, 0.1 g $MgSO_4.7H_2O$, 0.025 g $FeSO_4$, and 10 mL trace element solution, pH 7.0) supplemented with glucose and 50 mg metsulfuron-methyl as the sole carbon source at 30 °C for 7 days. Cultures were obtained after the fifth subculturing, followed by serial dilutions in MSM for the enrichment of strains that were capable of degrading metsulfuron-methyl. Pure cultures were

obtained by selecting the cultures that still exhibit metsulfuron-methyl degradation capability from the highest dilution and preserved in 25 % (v/v) glycerol solution in distilled water at −80 °C (Huang et al. 2007).

Pathogenicity and Clinical Relevance

There is only little information regarding the pathogenicity or clinical relevance on species belonging to family *Methylocystaceae*. However, a small amount of data is available on the antibiotic sensitivity for selected species (◉ *Table 16.4*).

Applications

The members of the family *Methylocystaceae* are known for their methanol-utilizing abilities as well as the use of the serine pathway for formaldehyde assimilation. *Albibacter methylovorans* and *Methylopila helvetica* have been reported to be able to utilize dichloromethane (DCM) or methylene chloride (CH_2Cl_2), industrial waste compounds which are toxic, mutagenic, and potentially carcinogenic (Doronina et al. 2000, 2001). *Hansschlegelia zhihuaiae* has been isolated for its degradation capability on a variety of sulfonylurea herbicides, and a novel sulfonylurea herbicide de-esterification esterase gene (*SulE*) was successfully identified from this strain (Hang et al. 2012). All *Methylocystis* species, with the exception of *M. parvus* OBB^T and *M. rosea* $SV97^T$, are able to express a soluble form of methane monooxygenase (sMMO) at low copper concentrations (Lindner et al. 2007). Recently, unidentified nitrogen-fixing *Pleomorphomonas* strains have been reported to be able to methylate mercury and produce hydrogen sulfide (Achá et al. 2012); however, the isolated strains are yet to be validly described.

17 The Family *Parvularculaceae*

Giselle Cavalcanti[1] · *Fabiano Thompson*[2]
[1]Institute of Biology, Federal University of Rio de Janeiro (UFRJ), Rio de Janeiro, RJ, Brazil
[2]Laboratory of Microbiology, Institute of Biology, Center for Health Sciences, Federal University of Rio de Janeiro (UFRJ), Ilha do Fundaõ, Rio de Janeiro, Brazil

Abstract
Parvularculaceae, a family within the order *Parvularculales* in the *Alphaproteobacteria*, embraces the genus *Parvularcula*. It forms a deep branch in the *Alphaproteobacteria*, on the basis of 16S rRNA analysis, distinct from other orders. The genus *Parvularcula* currently comprises three species: *Parvularcula bermudensis,* a marine bacterium isolated from the western Sargasso Sea using dilution-to-extinction culturing; *Parvularcula lutaonensis,* a moderately thermotolerant marine bacterium recovered from a coastal hot spring; and *Parvularcula dongshanensis,* recently isolated from soft coral. *Parvularcula* isolates are Gram-negative, strictly aerobic, chemoheterotrophic, slightly motile short rods with a single flagellum. Colonies on marine agar are very small (0.3–0.8 mm in diameter), yellowish-brown, and very hard. They are oxidase positive and catalase negative. Phylogenetically, the genus forms a novel seventh order of the *Alphaproteobacteria*. The type species of the genus is *Parvularcula bermudensis*.

Taxonomy, Historical and Current

Short Description of the Family

Par.vu.lar.cu.la.' ce.ae. M. L. fem.n. *Parvularcula* type genus of the family; −aceae ending to denote a family; M. L. fern. pl.n. *Parvularculaceae* the *Parvularcula* family.

Phylogenetically the sole member of the order *Parvularculales*, the seventh order in the class *Alphaproteobacteria*, the family *Parvularculaceae* was circumscribed on the basis of phylogenetic analysis of 16S rRNA sequences (Cho and Giovannoni 2003). Distantly related to the orders *Rhodobacterales* and *Rhizobiales* in the neighbor-joining phylogenetic tree, the 16S rRNA sequence similarities of *Parvularculaceae* strains to the other members of these orders were less than 89.4 % (*Fig. 17.1*). The family comprises a single genus *Parvularcula* proposed by Cho and Giovannoni (2003).

According to the phylogenetic branching of 72 completely or nearly completely sequenced *Alphaproteobacteria* in a species tree produced from a concatenation of alignments for 104 well-behaved protein families, *Parvularculaceae* is related to *Caulobacterales* and *Hyphomonadaceae* (Williams et al. 2007). A characteristic linking the *Hyphomonadaceae* and Caulobacterales, a proliferation of TonB-dependent receptors (Badger et al. 2006), is shared by *Parvularcula*; however, this characteristic may not be highly distinctive (Blanvillain et al. 2007). The robust specie tree for *Alphaproteobacteria* suggest a unification of *Caulobacterales* and *Hyphomonadaceae* within the order *Caulobacterales*, additionally including the Parvularculaceae, with the abandonment of the order *Parvularculales* (Williams et al. 2007). Comprehensive comparative genome analysis of the single *Parvularcula* genome will be a significant next step in considerate the family phylogenetic affiliation.

Uncultured *Parvularculaceae* bacteria clones identified by 16S ribosomal RNA have been recently documented in several environmental samples, exemplified by marine sediment, *Siderastrea stellate* coral bleached colonies (Lins-de-Barros et al. 2012), conventional activated sludge processes from petroleum refineries (Silva et al. 2010), shoreline environments affected by the prestige oil spill (Alonso-Gutierrez et al. 2009), and biofilms (D'Auria et al. 2010).

Molecular Analyses

Genome Structure

Presently only the complete genome sequence of *Parvularcula bermudensis,* the type strain branching within the 16S rRNA gene tree of *Parvularculaceae*, has been released (Oh et al. 2011). The 2,902,643 bp long single replicon genome is part of the Moore Foundation Microbial Genome Sequencing Project.

E. Rosenberg et al. (eds.), *The Prokaryotes – Alphaproteobacteria and Betaproteobacteria*, DOI 10.1007/978-3-642-30197-1_375,

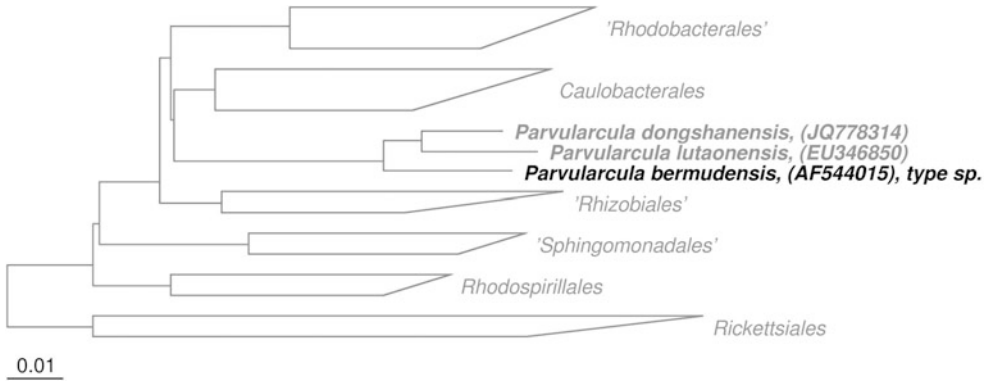

Fig 17.1
Neighbor-joining tree showing the phylogenetic positions of *Parvularcula* representatives *Parvularcula dongshanensis* (JQ778314), *Parvularcula lutaonensis* (EU346850), *Parvularcula bermudensis* (AF544015), type sp., and representatives of the α-Proteobacteria, inferred from 16S rRNA gene sequence analyses

The complete genome sequence of *P. bermudensis* HTCC2503^T is 2,902,643 bp long, contains 2,687 open reading frames, including one 16S-23S-5S rRNA operon with 43 tRNA genes, and the mol% G+C of DNA is 60.0 %. *Strain HTCC2503T* is predicted to hold complete metabolic pathways, including glycolysis, the pentose phosphate pathway, tricarboxylic acid cycle, and amino acid synthesis. The genome also codes for genes for DMSP demethylase, type IV secretion/conjugal transfer systems, and Ton and Tol transport systems as well as a plethora of genes for cobalt-zinc-cadmium resistance. In accord with the previous specie description (Cho and Giovannoni 2003), the *P. bermudensis* genome is predicted to code for genes for carotenoid biosynthesis, lactamase, flagella synthesis, and various catalytic enzymes for utilizing carbon compounds. *Parvularcula bermudensis* replicon is represented in ❯ *Fig. 17.2*, where the distribution of two-component system (TCS) genes is summarized. The TCS is the dominant prokaryotic-signaling pathway, typically comprised of a pair of signal-transduction proteins - a histidine kinase (HK) and partner response regulator (RR) – both of which are multi-domain proteins, which regulate a wide range of physiological processes. P2CS, a database of prokaryotic two-component systems (Barakat et al. 2011), predicted 39 HK and 33 RR proteins in the *P. bermudensis* genome (❯ *Fig. 17.2*).

Phenotypic Analyses

The family *Parvularculaceae* currently comprises a single genus, *Parvularcula.*

Parvularcula (Par.vu.lar'cu.la. L. adj. parvulus very small; L. fem. n. arcula a jewel-casket; N.L. fem. n. Parvularcula a very small jewel-casket) forms a deep branch in *Alphaproteobacteria.* The cells are Gram-negative, strictly aerobic short rods that occur singly, are sometimes coccoid, multiply by binary fission, and are slightly motile with a single flagellum (❯ *Fig. 17.3*). Endospores and poly-β-hydroxybutyrate granules are not formed. Colonies on marine agar are very small (0.3–0.8 mm in diameter), yellowish-brown, circular, dry, and very hard. They produce carotenoid pigments but not bacteriochorophyll a, and they are catalase-negative and oxidase-positive. Nitrate is reduced to nitrite. Urea and gelatin are hydrolysed, but aesculin is not. Chemoheterotrophic and moderately halophilic, they require NaCl for growth. Cellular fatty acids are even-numbered monounsaturated or saturated fatty acids. The major fatty acid is cis-7-octadecenoic acid (73.3 %) (Cho and Giovannoni 2003).

The genus comprises three species based on 16S rRNA gene sequences phylogenetic analysis (❯ *Fig. 17.1*). The genus type species is *Parvularcula bermudensis,* named for the Bermuda Islands, the geographical origin of the type strain of the species (Cho and Giovannoni 2003). *Parvularcula* also encompass the species *Parvularcula lutaonensis*, named for Lutao, a small volcanic island off the eastern coast of Taiwan (Arun et al. 2009), and *Parvularcula dongshanensis,* named for Dongshan, a city in Fujian, China, where the type strain was first isolated (Yu et al. 2012).

The main phenotypic characteristics as well as the differences among *Parvularcula* members—*Parvularcula bermudensis*, *Parvularcula lutaonensis,* and *Parvularcula dongshanensis*—are given in ❯ *Table 17.1*.

Isolation, Enrichment, and Maintenance Procedures

All *Parvularculaceae* members were isolated from marine environments. The first described member of the family, *Parvularcula bermudensis,* was isolated using high-throughput culture methods that rely on dilution to extinction in very-low-nutrient media (Connon and Giovannoni 2002). Oligotrophic seawater was diluted to 10 cells ml^{-1} in low-nutrient heterotrophic medium (0.2 mm-filtered and autoclaved sea water, modified with 1.0 mMNH_4Cl and 0.1 mMKH_2PO_4), supplemented with 0.001 % (w/v) D-glucose, D-ribose, succinic acid, pyruvic acid, glycerol and N-acetyl-D-glucosamine, 0.002 % (v/v) ethanol and Va vitamin solution at 10^{-4} dilution

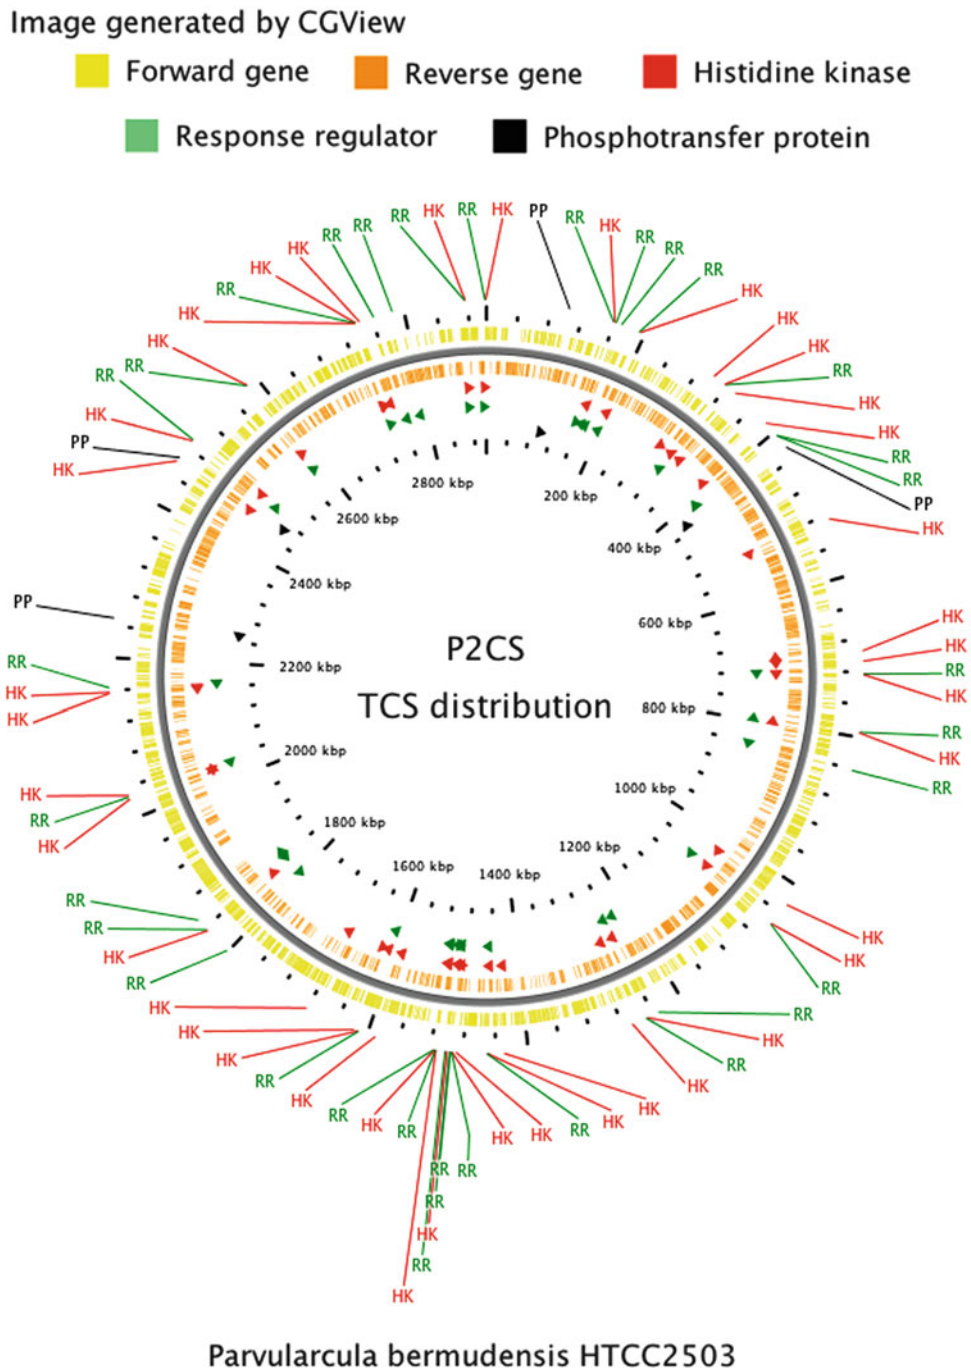

Fig. 17.2
Distribution of two-component system (TCS) genes, the dominant prokaryotic-signaling pathway, around *Parvularcula bermudensis* replicon. CGView representation generated using P2CS (database of prokaryotic two-component systems) (Barakat et al. 2011)

(Davis and Guillard 1958). Microtiter dish wells were scored for growth by microscopic examination, using a procedure for creating cell microarrays (Connon and Giovannoni 2002). Positive cultures were spread onto marine agar (MA), incubated at 25 °C for 14 days, purified by subsequent streaking onto MA, and stored as 10 % (v/v) glycerol suspensions in liquid nitrogen (Cho and Giovannoni 2003).

The moderately thermotolerant marine bacterium *Parvularcula lutaonensis* was isolated from a bacterioplankton community of a coastal hot spring (temperature 55 °C; pH 7.3; salinity 32 %). Isolation and maintenance was performed on marine agar after 37 °C for 48 h incubation (Arun et al. 2009). The last member currently described within *Parvularculaceae* family, *Parvularcula dongshanensis,* was isolated from soft

coral. Small pieces of coral tissue extensively washed with sterilized seawater were macerated with 0.85 % sterilized NaCl solution, spread onto MA plates, and incubated aerobically for 7 days at 25 °C without light (Yu et al. 2012).

Ecology

Habitat

The main habitat of the Parvularcula group is the marine environment. However, each species currently described was recovered from a distinct characteristic site. The type species of the genus, *Parvularcula bermudensis*, was isolated from an oligotrophic region in the western Sargasso Sea, Atlantic Ocean. Two strains of *Parvularcula bermudensis* (HTCC2503^T and HTCC2517) were isolated from 10-m depth seawater at the Bermuda Atlantic Time Series (BATS) station using dilution-to-extinction culturing (Cho and Giovannoni 2003). *Parvularcula lutaonensis* (strain CC-MMS-1T), a thermotolerant bacterium, was recovered from water samples collected from a rare coastal hot spring located in a small volcanic island off the east coast of Taiwan (Arun et al. 2009). A single symbiotic species belonging to *Parvularcula* genus was identified at present. *Parvularcula dongshanensis* (strain SH25^T) was isolated from soft coral collected from Dongshan Island, Fujian Province, China (Yu et al. 2012).

The sampling of diverse environments, such as soil and marine sediment, has recovered several uncultivable members of *Parvularculaceae* family. The apparent rarity of this order may be due to most species being uncultured, rather than an actual scarcity in the environment. Frequently, numerous environmental nongrowers require growth factors from other bacteria. In a siderophore-based approach, D'Onofrio and colleagues (2010) have enabled the culturing of previously uncultured isolates from marine sediment biofilm grow on a Petri dish in the presence of cultured organisms from the same environment. A single *Parvularculaceae* isolate KLE1250 was recovered in this study, showing 93.7 % identity by 16S rRNA gene sequence to *Parvularcula bermudensis* KCTC 1208T, was suggested to represent a new genus within this putative order (D'Onofrio et al. 2010).

Culture Independent-Studies

Nonculture molecular techniques have been increasingly applied in order to characterize the microbial communities (bacteria and fungi) associated with diverse eukaryotic hosts. Comparative metagenomics of the community structure and functional profile of bacteria on healthy and diseased thalli of the red seaweed *Delisea pulchra* have shown that the phylogenetic differences between healthy and bleached communities mainly reflected relative changes in few taxa, including Parvularcula (Fernandes et al. 2012). Taxonomically, healthy algae tissue was characterized by the abundance of bacteria belonging to the genera *Parvularcula* and *Haliscomenobacter* and the family *Rhodobacteraceae*. While the ecological roles of these bacterial associates that dominate the community of healthy *D. pulchra* is not clear, it was proposed they might be involved in the biogeochemical cycling of sulfur because the genus *Parvularcula* also harbors genes for the degradation of the abundant algal osmolyte dimethylsulfoniopropionate (DMSP) (Oh et al. 2011) and are known to oxidize inorganic sulfur metabolites (Sorokin 2005), such as the byproducts of DMSP degradation (Wagner-Döbler and Biebl 2006). Additionally, pyrosequencing of bacterial symbionts within *Axinella corrugata* sponges have highlighted taxa not typically previous found in sponge symbiont surveys, including *Parvularcula sp.* (White et al. 2012).

Still, the characterization of the bacterial and fungal communities associated with different lesion sizes of dark spot syndrome occurring in the coral *Stephanocoenia intersepta* has pointed to a possible pathogenic role for *Parvularcula* symbionts (Sweet et al. 2013). In this study, only four bacteria were absent from healthy tissues, increased in apparently healthy tissues, and were dominant in all the diseased tissues; these included ribotypes related to a *Corynebacterium sp.* (KC190237), an *Acinetobacter sp.* (KC190251), a *Parvularculaceae sp.* (KC190270), and an *Oscillatoria sp.* (KC190271).

Pathogenicity, Clinical Relevance

Currently, all described *Parvularculaceae* strains were recovered from environmental studies. No information on human pathogens is reported. However, a recent metagenomic study has highlighted an uncultured *Parvularculaceae sp.* as a potential coral pathogen (Sweet et al. 2013).

P. bermudensis is sensitive by the agar diffusion method to ciprofloxacin, gentamincin, kanamycin, ofloxacin, tetracycline, vibramycin, lincomycin, penicillin G, clindamycin, and Polymyxin B.

P. lutaonensis cells are susceptive to ciprofloxacin, gentamincin, kanamycin, ofloxacin, tetracycline, vibramycin, but resistant to lincomycin, penicillin G, clindamycin, and Polymyxin B.

P. dongshanensis cells are susceptive to lincomycin, penicillin G, and clindamycin. Cells are resistant to ciprofloxacin, gentamincin, kanamycin, ofloxacin, tetracycline, vibramycin, and Polymyxin B.

Applications

Evidence that the *Parvularculaceae* family may be involved in biotechnological applications originates from a study by Silva et al. (2010), where the bacterial diversity of petroleum refineries wastewater treatment systems were investigated through 16S rRNA gene libraries. Sequencing and phylogenetic analysis showed that the bacterial community composition of

conventional activated sludge (CAS) clones were mostly related to class *Alphaproteobacteria*, represented by uncultured bacteria related to the order *Parvularculales* (Silva et al. 2010). *Parvularcula* sp. clone identification at higher taxonomic ranks was not possible by comparison of 16SrRNA gene sequences with databases and subsequent phylogenetic analyses, suggesting that the corresponding organisms may represent new taxa.

18 The Family *Phyllobacteriaceae*

Anne Willems
Laboratory of Microbiology, Department of Biochemistry and Microbiology, Faculty of Science, Ghent University, Ghent, Belgium

Abstract
The family *Phyllobacteriaceae* belongs to the order *Rhizobiales* in the *Alphaproteobacteria* and currently comprises the 72 species in 13 genera: *Ahrensia*, *Aliihoeflea*, *Aminobacter* (including *Chelatobacter*), *Aquamicrobium* (including *Defluvibacter*), *Chelativorans*, *Hoeflea*, *Lentilitoribacter*, *Mesorhizobium*, *Nitratireductor*, *Phyllobacterium*, *Pseudahrensia*, *Pseudaminobacter*, and *Thermovum*. They form a single cluster within the 16S rRNA gene phylogeny. The family consists of environmental (soil, water) and plant-associated bacteria that have a heterotrophic respiratory metabolism with oxygen as terminal electron acceptor. One *Aquamicrobium* species can use nitrate as an alternative terminal electron acceptor. One *Mesorhizobium* species is facultatively chemolithotrophic using thiosulfate or elemental sulfur as sole energy source. *Candidatus Liberibacter*, a group of uncultivated phloem-inhabiting bacteria that are associated with various plant diseases in citrus and *Solanaceae* or are endophytic in pear plants, is also associated with the family. However, comprehensive phylogenetic analyses indicate the position of this group as a member of the *Phyllobacteriaceae* is uncertain.

Taxonomy, Historical and Current

Short Description of the Family

Phyl.lo.bac.te.ri.a'ce.ae. N.L. neut. n. *Phyllobacterium*, type genus of the family; suff. *-aceae*, suffix to denote a family; N.L. fem. pl. n. *Phyllobacteriaceae*, the *Phyllobacterium* family.

The family *Phyllobacteriaceae* belongs to the *Rhizobiales* order in the *Alphaproteobacteria* class of the phylum Proteobacteria. It was proposed by Mergaert and Swings (2005a) in *Bergey's Manual of Systematic Bacteriology* and was validated in 2006. At the time the family comprised six genera and one *Candidatus* genus: *Phyllobacterium, Aminobacter*, *Aquamicrobium*, *Defluvibacter*, *Candidatus Liberibacter*, *Mesorhizobium*, and *Pseudaminobacter*. *Defluvibacter* has since been transferred to *Aquamicrobium* (Kämpfer et al. 2009). *Aminobacter* includes *Chelatobacter heintzii* which is regarded as a later subjective synonym of *Aminobacter aminovorans* (Kämpfer et al. 2002). The basis for the proposal of this family was that these genera form a cluster in the 16S rRNA gene phylogeny. The description of the family (Mergaert and Swings 2005a) is rather brief: "Rod-shaped, ovoid, or reniform cells when cultured in vitro. Nonsporeforming. Gram negative. Aerobic. Cells cultured in vitro are motile by means of polar, subpolar, or lateral flagella. Strains grow well on complex solid media at 28 °C. Occur in leaf nodules and the rhizosphere of higher plants. The mol % G+C of the DNA is 60–62". With the inclusion of the additional genera *Ahrensia*, *Chelativorans*, *Hoeflea*, *Lentilitoribacter*, *Nitratireductor*, *Pseudahrensia*, and *Thermovum* to the *Phyllobacteriaceae* cluster, most of this definition still applies except that cells can also be nonmotile and members of the family can also occur in seawater, marine sediments, activated sludge, and soil and

E. Rosenberg et al. (eds.), *The Prokaryotes – Alphaproteobacteria and Betaproteobacteria*, DOI 10.1007/978-3-642-30197-1_298,

thermophilic members are found in compost. The range of the G+C content of DNA is 48–65 %. Comprehensive phylogenetic analysis reveals that the position of *Candidatus Liberibacter* as a member of the *Phyllobacteriaceae* cluster is uncertain (see below).

Phylogenetic Structure of the Family and Its Genera

In the 16S rRNA gene phylogeny, the *Phyllobacteriaceae* family forms a single cluster in the phylum Alphaproteobacteria, and inside this large cluster, the different species generally group together per genus, in support of the current taxonomy (Fig. 18.1).

An important exception is the genus *Mesorhizobium*: these species make up several groups and separate lineages grouping in between the other genus clusters (Fig. 18.1). The type species *Mesorhizobium loti* forms tight subcluster with *Mesorhizobium ciceri*, *Mesorhizobium australicum*, *Mesorhizobium shangrilense*, *Mesorhizobium sangaii*, and *Mesorhizobium qingshengii*. *Mesorhizobium chacoense* forms a separate but related lineage, and the *Aminobacter* cluster is their nearest neighbor. Nineteen species form the largest subcluster: *Mesorhizobium metallidurans*, *Mesorhizobium temperatum*, *Mesorhizobium mediterraneum*, *Mesorhizobium gobiense*, *Mesorhizobium tarimense*, *Mesorhizobium caraganae*, *Mesorhizobium robiniae*, *Mesorhizobium muleiense*, *Mesorhizobium tianshanense*, *Mesorhizobium tamadayense*, *Mesorhizobium amorphae*, *Mesorhizobium septentrionale*, *Mesorhizobium huakuii*, *Mesorhizobium plurifarium*, *Mesorhizobium silamurunense*, *Mesorhizobium opportunistum*, *Mesorhizobium abyssinicae*, *Mesorhizobium hawassense*, and *Mesorhizobium shonense*. *Mesorhizobium albiziae* groups at the periphery of this subcluster as does *Mesorhizobium thiogangeticum*. The position of the two latter species, however, varied depending on the filter applied. In most trees, it constitutes a separate lineage at some distance from other *Mesorhizobium* subclusters or other genera of the family. *Mesorhizobium thiogangeticum* was not recovered from legume nodules but was isolated from soil by enrichment using reduced sulfur compounds as sole electron sources; it is the only *Mesorhizobium* species reported to be facultatively chemolithoautotrophic. Two other species, *Mesorhizobium camelthorni* and *Mesorhizobium alhagi*, make up a further subcluster that groups most closely to the *Chelativorans* cluster. The 16S rRNA gene phylogeny of *Mesorhizobium* is thus polyphyletic, and the genus may in the future require taxonomic rearrangements if further evidence would support these observations.

Ahrensia and *Lentilitoribacter* group together with *Hoeflea* species, but, according to branch length, are clearly distinct.

Nitratireductor species form a single cluster, except for *Nitratireductor basaltis* which is located separately.

Candidatus Liberibacter, consisting of psyllid-transmitted, as yet uncultured, phloem-limited bacteria associated with greening disease or huanglongbing disease of citrus and yellows disease of various *Solanaceae* plants or endophytic in pear plants, was initially placed inside the *Phyllobacteriaceae* based on a limited phylogenetic indications (Mergaert and Swings 2005a; Garnier 2005). A more comprehensive analysis performed for this chapter revealed that the position of *Candidatus Liberibacter* as a member of the *Phyllobacteriaceae* cluster is uncertain. Although it does group on a long branch inside the *Phyllobacteriaceae* cluster in Fig. 18.1, in most other trees calculated using other filters and including other neighboring taxa, *Candidatus Liberibacter* grouped outside the family and occupied a separate position in the *Alphaproteobacteria*. Its membership of the family therefore seems not strongly supported by 16S rRNA phylogeny.

Comments on the Membership of the Family

Although the genus *Ahrensia* is was classified in the *Rhodobacteraceae* in *Bergey's Manual of Systematic Bacteriology* (Garrity et al. 2005) based on the phylogenetic analysis of 16S rRNA genes, since then more taxa have been described in the *Rhizobiales*, and current 16S rRNA gene phylogeny places *Ahrensia* in the *Phyllobacteriaceae* (Living Tree Project, release 111). It is therefore included in this chapter.

"*Aliihoeflea aestuarii*" gen. nov., sp. nov. was described for a bacterium isolated from tidal flat sediments (Roh et al. 2008). Its 16S rRNA gene sequence was reported to cluster with members of the *Phyllobacteriaceae*. Fatty acid data, quinone, and DNA G+C content data are also in agreement with the family characteristics; therefore, although *Aliihoeflea aestuarii* has as yet not been included in a validation list, it is included here in the chapter on *Phyllobacteriaceae*.

Molecular Analyses

DNA-DNA Hybridization Studies

In all multispecies genera of the family, DNA-DNA hybridizations with existing species have been performed to justify proposals of new species.

Other Sequence Analyses

Genes other than the 16S rRNA gene have been reported in *Mesorhizobium* where recA sequences are available for all species and a number of other genes including *atpD*, *gyrB*, *dnaK*, and *rpoB* have also been reported for several of the *Mesorhizobium* species. However, for other *Phyllobacteriaceae* genera, only in a few cases have other genes been reported and used for phylogenetic purposes: for three of six *Aminovorans* species sequences are available for *atpD*, *dnaK*, and *recA* (Maynaud et al. 2012); for four of eight *Phyllobacterium* species, an *atpD* sequence has been reported, as well as a *recA* sequence for one species

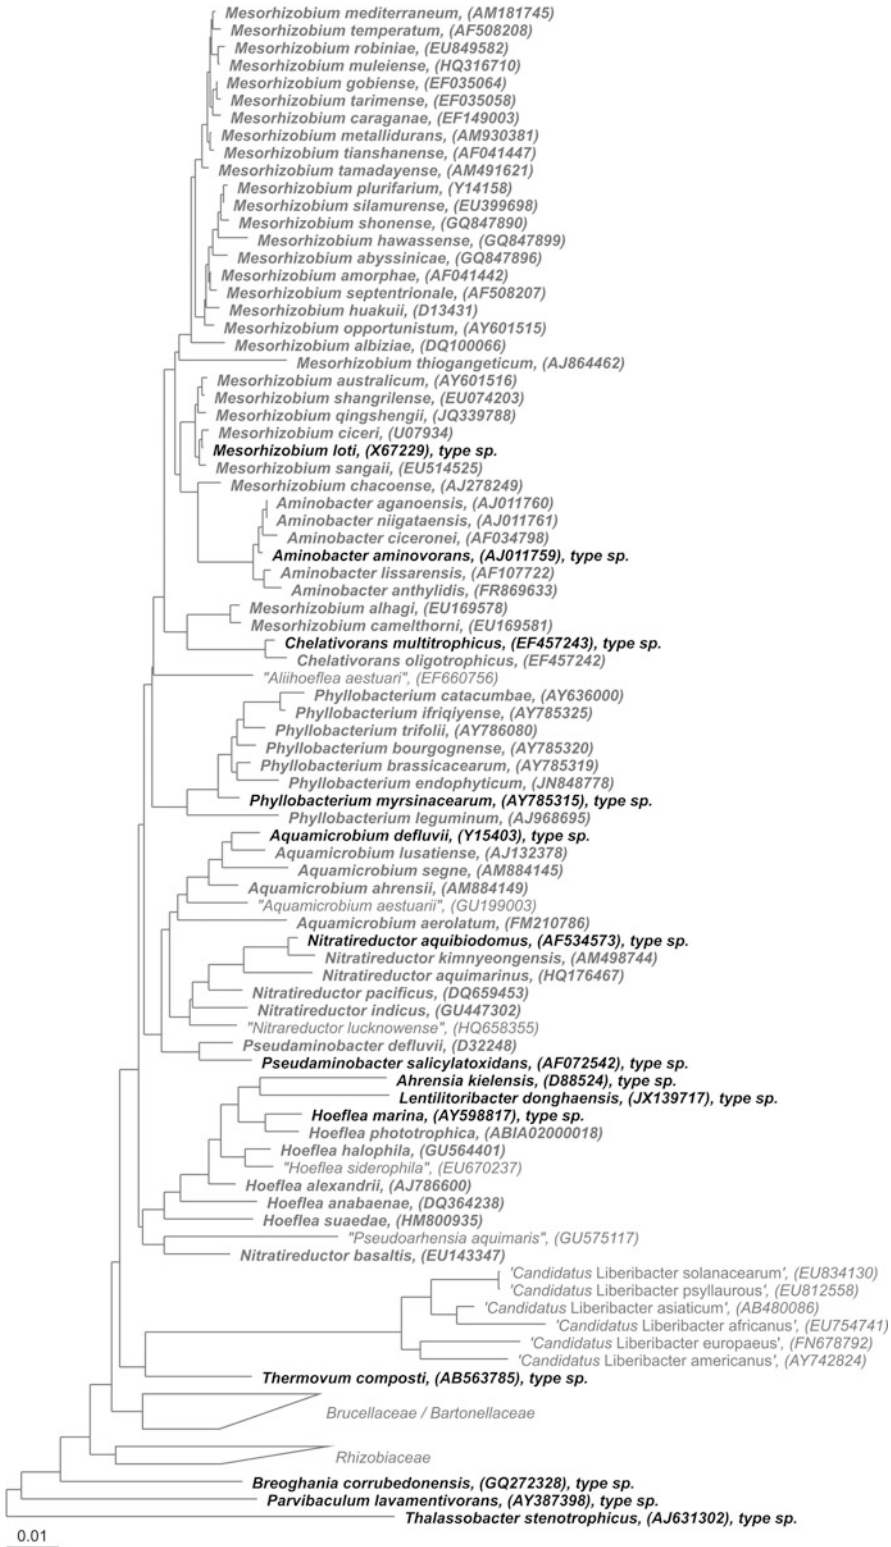

Fig. 18.1

Phylogenetic reconstruction of the family *Phyllobacteriaceae* based on 16S rRNA and created using the neighbor-joining algorithm with the Jukes-Cantor correction. The sequence datasets and alignments were used according to the All-Species Living Tree Project (*LTP*) database (Yarza et al. 2010; http://www.arb-silva.de/projects/living-tree). The tree topology was stabilized with the use of a representative set of nearly 750 high-quality type strain sequences proportionally distributed among the different bacterial and archaeal phyla. In addition, a 40 % maximum frequency filter was applied in order to remove hypervariable positions and potentially misplaced bases from the alignment. Scale bar indicates estimated sequence divergence

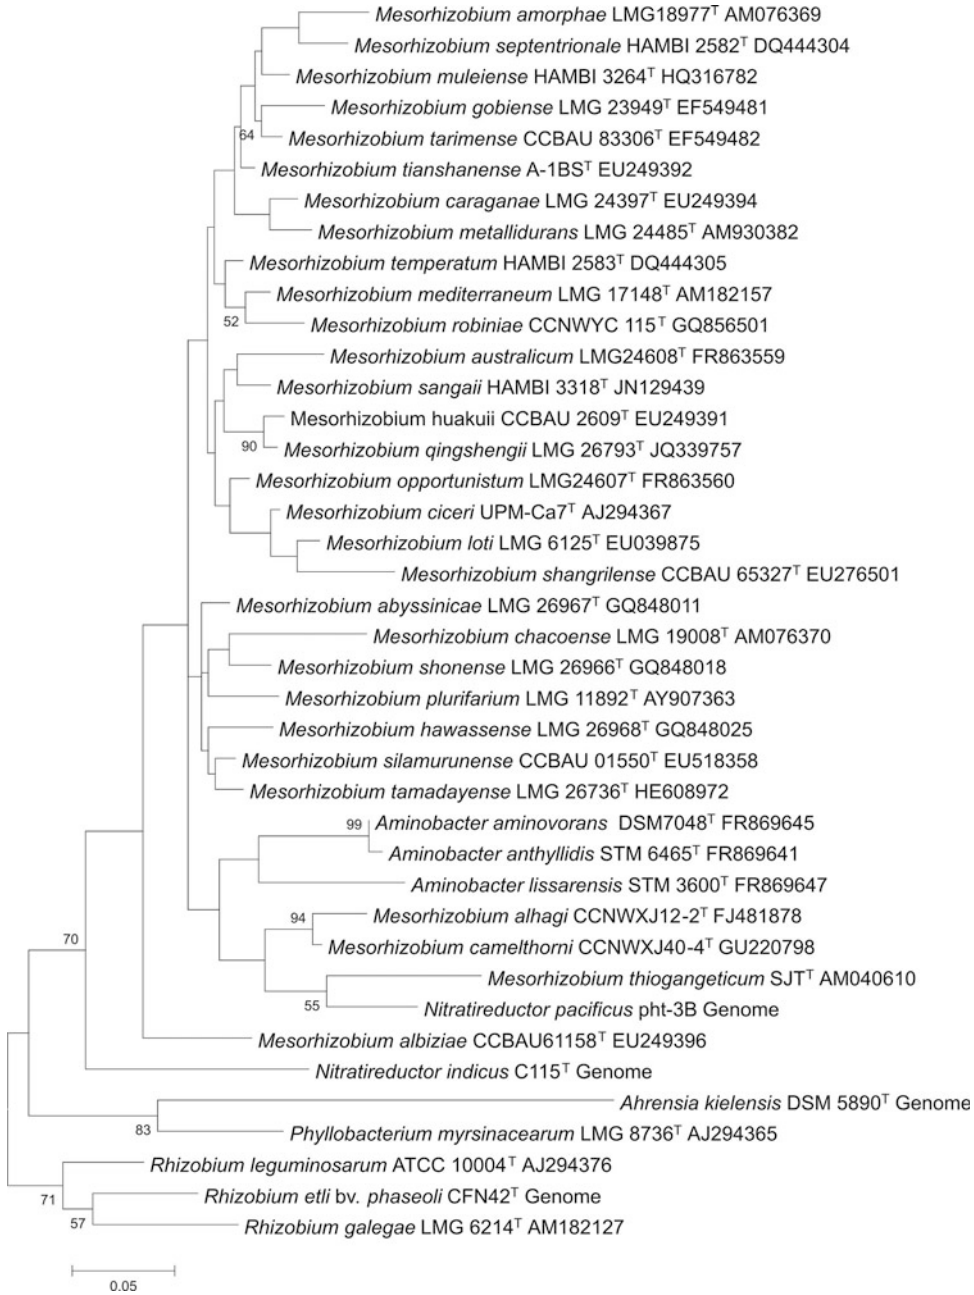

Fig. 18.2

Phylogenetic reconstruction of the family *Phyllobacteriaceae* based *recA* sequences. The tree was constructed using the maximum likelihood method and general time-reversible model in MEGA (Tamura et al. 2011). A bootstrap analysis with 500 replicates was performed to assess the support of the clusters; values above 50 % are shown at the nodes

(Mantelin et al. 2006b), and for two of six *Nitratireductor* species, an *rpoD* sequence is available (unpublished data available through NCBI dataportal). Given this lack of data for all genera, it is currently not possible to comprehensively assess the phylogeny of the family using a housekeeping gene other than the 16S rRNA gene. At present most data are available for *recA* where 6 of the 13 genera are represented (three of these are extracted from total genome information). Given that *Mesorhizobium* is represented with 30 species versus only 8 species from other genera, this tree (*Fig. 18.2*) does not permit a comprehensive comparison with the 16S rRNA gene phylogeny (*Fig. 18.1*). It thus remains to be established whether the subclusters of *Mesorhizobium* in the latter phylogeny are confirmed by *recA* or other gene phylogenies.

Data obtained from the NCBI genome pages (http://www.ncbi.nlm.nih.gov/genome)

Genome Comparisons

Only in recent years have some complete genome sequences been reported or drafts made available. An overview of the type strains and a few other strains is given in *Table 18.1*. Unpublished draft genomes are available in public database online for *Ahrensia kielensis*, *Chelativorans* sp., *Hoeflea phototrophica*, *Mesorhizobium australicum*, *Mesorhizobium ciceri* bv. *biserrulae*, and *Mesorhizobium opportunistum* (*Table 18.1*).

The genome of *Mesorhizobium loti* MAFF303099 was reported more than 10 years ago (Kaneko et al. 2000); however, later this strain was shown to be a representative of another *Lotus* symbiont, *Mesorhizobium huakuii* bv. *loti* (Turner et al. 2002). Its genome consists of one chromosome (7 Mb) and two megaplasmids (352 kb and 208 kb); a transmissible symbiotic island containing 580 protein-encoding genes including genes for nodulation and nitrogen fixation was identified on the chromosome, inserted into the phe-tRNA gene as in other *Mesorhizobium loti* strains (Kaneko et al. 2000). The genomes of several other *Mesorhizobium* strains have been sequenced and had a similar size between 6.2 and 7.6 Mb with one circular chromosome and either no, one or two megaplasmids (*Table 18.1*). *Mesorhizobium amorphae* CCNWGS0123 is a copper-resistant rhizobium that contributes to survival of the

host plant in copper-, zinc-, and chromium-containing environments. Its genome was found to harbor numerous genes involved in copper resistance including a copper efflux system and multicopper oxidases, as well as various genes for plant growth promotion that most rhizobia share. In addition genes involved in the biosynthesis of a number of antibiotics and in chloramphenicol resistance were present (Hao et al. 2012). *Mesorhizobium alhagi* CCNWXJ12-2^T is very resistant to salt (0.8 M) and alkali (pH 12). Its genome was found to encode various systems contributing to salt resistance and osmoregulation including multiple membrane transport system (Zhou et al. 2012).

The genomes have been reported for three *Nitratireductor* strains. For the type species, *Nitratireductor aquibiodomus* strain RA22 from a marine water sample in India has been sequenced; its 16S rRNA gene was reported as 100 % identical to that of the type strain. Annotation revealed genes for iron acquisition, ammonia and sulfur assimilation, biosynthesis of ectoine and betaine, and uptake of choline and betaine, indicative of its marine habitat requiring osmotic stress tolerance. Genes for catabolism of aromatic compounds, including genes for the chloroaromatic degradation pathway, correspond with the observation that many *Nitratireductor* strains were obtained from sources contaminated with pyrene, crude oil, or pesticide (Singh et al. 2012). *Nitratireductor pacificus* pht-3B^T, although isolated from a pyrene-degrading consortium from deep-sea sediments, is unable to utilize pyrene, and this was confirmed by the absence of polycyclic aromatic hydrocarbon (PAH)-degrading dioxygenase in its genome (Lai et al. 2012a). *Nitratireductor indicus* C115^T originates from a crude oil-degrading consortium from deep seawater; however, it cannot degrade *n*-alkanes or PAHs as sole carbon source. Also here, the genome sequence confirmed the absence of any alkane-degrading monooxygenase or PAH-degrading dioxygenase (Lai et al. 2012b).

Two complete genomes have been reported representing *Candidatus Liberibacter*, a group of uncultured bacteria associated with *citrus* and *Solanaceae* plant diseases; genomes were obtained from DNA isolated from the phloem-feeding psyllid vectors that transmit the pathogen (Duan et al. 2009; Lin et al. 2011). As can be expected for obligate intracellular endophytes, the genomes are small and have a low GC content: 0.99 Mb and 36.5 mol % and 1.26 Mb and 35.2 mol % for *Candidatus Liberibacter asiaticus* psy62 and *Candidatus Liberibacter solanacearum* CLso-ZC1, respectively. *Candidatus Liberibacter asiaticus* psy62 harbored few genes for the biosynthesis of compounds that can be obtained from the host and more genes for motility such as type IV pili and flagellar genes; it had no transposons or insertion elements but did have some phage-related genes (Duan et al. 2009). Its genome also revealed the absence of several key components required for oxidative phosphorylation and several terminal oxidases, pointing to a limited potential for aerobic respiration; genome analysis suggests that the organism cannot reduce sulfur compound, but instead anaerobic respiration is coupled to nitrogen metabolism. The presence of an active TCA cycle suggests that a range of amino acids (present in phloem fluid) may serve as energy sources (Duan et al. 2009). *Candidatus Liberibacter solanacearum* shares 884 protein-encoding genes with *Candidatus Liberibacter asiaticus*. Comparison of both genomes revealed many rearrangements and gene losses/gains (Lin et al. 2011). *Candidatus Liberibacter solanacearum* also contained several small and two large phage-derived segments, one of which was similar to a segment in *Candidatus Liberibacter asiaticus*. The analysis of its gene repertoire suggests it can take up glucose but not sucrose or fructose and has limited capacity for aerobic respiration and for the biosynthesis of amino acids and lacks a complete restriction-modification system. It has several transport systems for amino acids and a system (NttA) for the uptake of ATP and ADP from the host. The comparison further revealed that *Candidatus Liberibacter solanacearum* has reduced capacity for nucleic acid modification, increased potential for amino acid and vitamin biosynthesis, and a high-affinity iron transport system (Lin et al. 2011). Lin et al. (2011) point out that the approach of extracting bacterial genome information from the vector does not exclude that other genetic components such as plasmids or linear chromosomes could be present.

Based on the complete genome (Duan et al. 2009; Tyler et al. 2009), a computational analysis of the *Candidatus Liberibacter asiaticus* proteome has been performed, and the results predicting 3D structure, function, cellular localization, and potential virulence factors are publically available (http://prodata.swmed.edu/liberibacter_asiaticus/curated/) as a tool for further study of this pathogen (Cong et al. 2012).

Phenotypic Analyses

A comparison of some general features of the members of the *Phyllobacteriaceae* is given in *Table 18.2*.

Ahrensia Uchino et al. 1999, 1^{VL}

Ah.ren'si.a. N.L. fem. n. *Ahrensia*, named in honor of R. Ahrens, a German microbiologist, for his contribution to the taxonomy of marine species of *Agrobacterium*.

The genus *Ahrensia* comprises rod-shaped cells that do not form spores. They are motile with polar flagella. Aerobic and oxidase and catalase positive. The major quinone is ubiquinone Q10; the major fatty acid is C18:1; the main hydroxy fatty acid is C12:0 3-OH. No 2-hydroxy fatty acids are present. The G+C content of the DNA is 48 mol %. The type species is *Ahrensia kielensis*.

The following description of *Ahrensia kielensis* is based on those from Uchino et al. (1998) and from Rüger and Höfle (1992). The species is able to grow at 5 °C, but not at 37 °C. Na^+ is required. Cells are motile rods, 0.6–1.0 × 2.0–4.0 μm. Hardly any carbon sources are used: the type strain tested negative for 12 carbohydrates, 11 carboxylic acids, 3 alcohols, 7 amino acids, and putrescine (Rüger and Höfle 1992). H_2S is produced from cysteine; hydrolysis of gelatin and starch is negative. Nitrate is not reduced to nitrite or gas. Acids are

Table 18.2

Morphological and chemotaxonomic characteristics of the genera of *Phyllobacteriaceae*

Genus	Source	# species	Morphology	Motility	Metabolism	Temperature preference	Major fatty acids	Major hydroxy fatty acids	G+C content
Ahrensia	Seawater	1	Rods	Polar flagella	Aerobic respiration	Mesophilic	C18:1 ω7c	C12:0 3-OH	48
Aliihoeflea	Tidal flat sediment	1	Rods	Not reported	Aerobic respiration	Mesophilic	C18:1 ω7c, C19:cyclo ω8c	–	53.4
Aminobacter	Soil, root nodules	6	Rods	Subpolar flagella	Aerobic respiration	Mesophilic	SF7 (C18 :1 ω7c/C18:1 ω9t/C18:1 ω12t)	C12:0 3-OH	62.5–63.8
Aquamicrobium	Air from a duck shed, biofilter for the treatment of animal rendering waste gas, activated sludge	6	Rods	+	Aerobic respiration; one species also uses nitrate as respiratory electron acceptor	Mesophilic	C18:1 ω7c	–	58.7–61.7
Chelativorans	Soil, activated sludge, sewage sludge	2	Rods	+/–	Aerobic respiration	Mesophilic	SF7 (C18:1 ω7c/C18:1 ω9t/C18:1 ω12t), C19:0 cyclo ω8c	–	60.8–63.1
Hoeflea	Seawater, in cultures of marine dinoflagellates or cyanobacteria, root surface of a halophyte	7	Rods	One polar flagellum or nonmotile	Aerobic or microaerophilic respiration	Mesophilic	C18:1 ω7c	None or C12:0 3-OH	53.1–59.7
Lentilitoribacter	Seawater	1	Rods, short rods	–	Aerobic respiration	Mesophilic	C18 :1 ω7c, 11-methyl-C18:1 ω7c, SF3 (iso-C15:0 2-OH and/or C16:1 ω7c)	C10:0 3-OH	49.3
Mesorhizobium	Nodules of legume plants or soil	30	Rods	+	Aerobic respiration; one species is fac. chemolithotrophic using thiosulfate or elemental sulfur	Mesophilic	C18:1 ω7c		57.9–65.1
Nitratireductor	Marine sediment, seawater, beach sand, dried seaweed sample	7	Rods or coccoid cells	+/–	Aerobic respiration	Mesophilic	C18:1 ω7c/ω6c	–	56.7–63
Phyllobacterium	Root or leaf nodules, tuff volcanic rock	8	Rods	+	Aerobic respiration	Mesophilic	C16:0, C18:1 ω7c, C18:1 ω7c 11-Me, C19:0 cyclo ω8c	C16:0 3-OH, C18:1 2-OH	52–58.5
Pseudahrensia	Seawater	1	Ovoid to rod shaped	–	Aerobic respiration	Mesophilic	C18:1 ω7c	C18:0 3-OH, iso-C13:0 3-OH	60.1
Pseudaminobacter	River water, activated sludge	2	Coccoid to rod shaped	+	Aerobic respiration	Mesophilic	C18:1 (ω7c/ω9t/ω12t), C19:0 cyclo ω8c	C15:0 iso 3-OH	62.9–63.9
Thermovum	Compost	1	Ovoid	–	Aerobic respiration	Thermophilic	C18:1 ω7c, C19:0 ω8c and C18:0	–	63.4

Data taken from the original descriptions and references as given in the main text

produced from fructose, maltose, xylose, and glycerol after 4–6 weeks of incubation. Negative in the following tests: indole production, methyl red, Voges-Proskauer, lysine and ornithine decarboxylase, and hydrolysis of casein, chitin, and alginate.

The major fatty acid is C18:1 ω7c; C12:0 3-OH and iso-C13:0 3-OH are present, but 2-hydroxy fatty acids are absent (Uchino et al. 1998; Park et al. 2013). The G+C content of the DNA is 48 mol %.

The type strain IAM 12618^T was isolated from seawater of the Baltic Sea.

Aliihoeflea Roh et al. 2008

A.li.i.ho.e.fle'a, L. adj. and pronoun *alius*, other, another, different; N.L. fem. n. *Hoeflea*, a bacterial genus name; N.L. fem. n. *Aliihoeflea*, the other *Hoeflea*.

Aliihoeflea comprises rod-shaped cells that are catalase and oxidase positive. The major quinone is ubiquinone Q10; the major fatty acids are C18:1 ω7c and C19:0 cyclo ω8c. G+C content is approximately 53 mol %. The type species is *Aliihoeflea aestuarii*.

The following description of the phenotype is based on the description of the strain N8^T, thus far the only strain of *Aliihoeflea aestuarii* (Roh et al. 2008). Cells are rod shaped (0.50–0.75 μm × 1.25–1.50 μm). Colonies on MA are circular with entire margin, convex, shiny, and cream colored. Growth is also possible on Trypticase soy agar, SA, LA, and yeast mannitol agar, but not on R2A. Temperature range for growth is 17–37 °C; the optimal growth temperature is 30 °C. Optimal NaCl concentration is 1 % (w/v), although NaCl is not required and up to 8 % is tolerated during growth. Nitrates are not reduced to nitrites or nitrogen. Indole is not produced. Glucose is not fermented, and hydrolysis of starch, esculin, gelatin, and PNPG (*p*-nitrophenyl-β-D-galactopyranoside) is negative. Urease positive and arginine dihydrolase negative. Glycogen, Tween 80, L-arabinose, D-fructose, pyruvic acid methyl ester, succinic acid monomethyl ester, acetic acid, α-hydroxybutyric acid, β-hydroxybutyric acid, γ-hydroxybutyric acid, α-ketobutyric acid, α-ketoglutaric acid, α-ketovaleric acid, D,L-lactic acid, succinic acid, succinamic acid, L-alaninamide, D-alanine, L-alanine, L-glutamic acid, glycyl-L-glutamic acid, L-leucine, L-serine, inosine, uridine, and thymidine can be used as sole carbon sources. Positive for alkaline phosphatase, esterase (C4), esterase lipase (C8), leucine arylamidase, valine arylamidase, cystine arylamidase, trypsin, α-chymotrypsin, naphthol-AS-BI-phosphohydrolase. Negative for lipase (C14), acid phosphatase, α-galactosidase, β-galactosidase, β-glucuronidase, α-glucosidase, β-glucosidase, N-acetyl-β-glucosaminidase, α-mannosidase, and α-fucosidase. The genomic DNA G+C content is 53.4 mol %. The type strain KCTC 22052^T was isolated from tidal flat sediment in Yeosu (34°47′26″ N 127°34′01″ E), Republic of Korea.

Aminobacter Urakami et al. 1992, 90^{VP}

Am.i.no.bac'ter, N.L. n. *aminum*, amine; N.L. masc. n. *bacter*, rod; N.L. masc.n. *Aminobacter*, amine rod.

The genus *Aminobacter* comprises non-spore-forming rod-shaped cells that can utilize methylamine. Cells are motile by means of subpolar flagella. They multiply by budding. Poly-β-hydroxybutyrate granules are accumulated in the cells. Good growth in nutrient broth and PYG broth. No water-soluble fluorescent pigment is produced. No growth factors are required. Oxidase and catalase positive and urease negative. Aerobic respiratory metabolism, not fermentative (Urakami et al. 1992).

The following tests are negative: methyl red, Voges-Proskauer, indole production, hydrogen sulfide production, hydrolysis of gelatin and starch, denitrification, litmus milk, and fermentation of sugars.

Ammonia is produced. Acids are produced from sugars oxidatively. Monomethylamine, trimethylamine, trimethylamine-N-oxide, and sugars are utilized. Methanol, methane, and hydrogen are not utilized. Ammonia, nitrate, urea, peptone, and methylamine are utilized as nitrogen sources.

Good growth occurs at pH 6.0–8.0 and at 30–37 °C. No growth above pH 9.0 and below pH 5.0 at 42 °C and in the presence of 3 % NaCl (Urakami et al. 1992).

The type strains of all species can utilize L-arabinose and L-alanine; none can use adonitol (McDonald et al. 2005; Maynaud et al. 2012). McDonald et al. (2005) performed a biochemical characterization of all *Aminobacter* species except *Aminobacter anthyllidis* and found that all type strains could utilize *N*-acetyl-D-glucosamine, D-cellobiose, D-fructose, D-galactose, D-glucose, D-mannose, D-maltose, D-ribose, D-xylose, i-inositol, D-mannitol, D-sorbitol, acetate, 4-aminobutyrate, DL-3-hydroxybutyrate, DL-lactate, oxoglutarate, L-histidine, L-leucine, L-ornithine, and L-proline and hydrolyze bis-*para*-nitrophenyl (pNP)-phosphate, pNP-phenyl-phosphonate, L-alanine-*para*-nitroanilide (pNA), and L-proline-pNA. None of the strains could utilize *p*-arbutin, α-D-melibiose, salicin, maltitol, putrescine, cis-aconitate, trans-aconitate, adipate, azelate, citrate, fumarate, itaconate, mesaconate, suberate, L-phenylalanine, 3-hydroxybenzoate, and phenylacetate. All type strains used sucrose. None of the strains could hydrolyze esculin, pNP-β-D-galactopyranoside, pNP-β-D-glucuronide, 2-deoxythymidine-5′-pNP-phosphate, and L-glutamate-γ-3-carboxy-pNA and none produced acid from lactose, adonitol, rhamnose, methyl D-glucoside, erythritol, and melibiose. Additional features and differentiating characteristics of the species are shown in *Table 18.3*.

Only strains of *Aminobacter ciceronei* and *Aminobacter lissarensis* utilize several methyl halides as sole carbon sources (*Table 18.3*). Of all *Aminobacter* strains tested, two strains of *Aminobacter ciceronei* (ER2 and C147; not the type strain) were the sole *Aminobacter* strains that could degrade atrazine and carbofuran (McDonald et al. 2005). *Aminobacter anthyllidis*, which is capable of nodulation and was isolated from a Zn-Pb

Data taken from the descriptions in the references that are listed in the table. Fatty acid data from McDonald et al. (2005)

[a]Positive according to Maynaud et al. (2012)

[b]Negative according to Maynaud et al. (2012)

[c]Requires the presence of cyanocobalamin (1 $mg.l^{-1}$)

mining site through trapping with *Anthyllis vulneraria*, can tolerate 1–2 mM of Zn and 0.3–1 mM of Cd in YEM broth after 1 week (Maynaud et al. 2012).

The DNA base composition ranges from 62 to 64 mol % G + C. The main cellular fatty acids include C18:1, and the main hydroxy fatty acids include C12:0 3-OH. The ubiquinone system is ubiquinone Q10.

The type species is *Aminobacter aminovorans*, originally described as *Pseudomonas aminovorans* (Urakami et al. 1992).

Aquamicrobium Bambauer et al. 1998, 631[VL] emend. Lipski and Kämpfer 2012

A.qua.mi.cro'bi.um, L. n. *aqua*, water; N.L. neut. n. *microbium*, a microbe; N.L. neut. n. *Aquamicrobium*, a bacterium living in water/wastewater.

This description is based on the emended description of Lipski and Kämpfer (2012). *Aquamicrobium* consists of pleomorphic or regularly shaped short rods that are mesophilic and grow best at pH 6–9. They can tolerate up to 7 % NaCl (w/v) and utilize sugars, carbonic acids, amino acids, and alcohols for growth. Major quinone is Q10, major fatty acid is C18:1 *cis*-11, major polyamine is spermidine, and main polar lipids are phosphatidylglycerol, phosphatidylcholine, and phosphatidylethanolamine. G+C content of the DNA is 57–65 mol %. The type species is *Aquamicrobium defluvii*.

A number of phenotypic and other characteristics of the *Aquamicrobium* type strains are listed in Table 18.4. All species are oxidase and catalase positive. *Aquamicrobium defluvii* is able to utilize thiophene-2-carboxylate as sole carbon source in the presence of molybdate (Bambauer et al. 1998). In addition, acetate, propionate, butyrate, crotonate, glucose, fructose, mannose, xylose, mannitol, and sorbitol are used for growth with oxygen or nitrate as electron acceptors. Nitrate is reduced to nitrite. No growth was observed with thiophene-2-acetate, thiophene-3-carboxylate, thiophene-3-acetate, thiophene-2-carbaldehyde, thiophene-2-methanol, thiophene-2-mandelate, thiophene-2-acrylate, thiophene, benzothiophene, dibenzothiophene, pyrrole-2-carboxylate, furan-2-carboxylate, pyridine, nicotinate, benzoate, phenylacetate, phthalate, galactose, ribose, sorbose, maltose, saccharose, cellobiose, and lactose. Hydrolysis of gelatin, arginine dihydrolase, lysine decarboxylase, and urease is negative (Bambauer et al. 1998). *Aquamicrobium lusatiense* is able to degrade 4-chlorophenol, 2,4-dichlorophenol, and phenol, and this capacity was not lost over repeated transfers and attempts at curing. Indeed, genes for chlorocatechol 1,2-dioxygenase and 2,4-dichlorophenol hydroxylase were shown to be located on the chromosome rather than on a megaplasmid (Fritsche et al. 1999). Hydrolysis of urea, starch, gelatin, casein, DNA, Tween 80, and esculin is negative (Fritsche et al. 1999). *Aquamicrobium aerolatum* is positive for phosphatase and L-alanine aminopeptidase (Kämpfer et al. 2009).

Small amounts of 12:0 3-OH were reported for *Aquamicrobium defluvii* and *Aquamicrobium lusatiense* and iso-15:0 3-OH for *Aquamicrobium aerolatum* by Kämpfer et al. (2009), but a later study comprising all species did not find hydroxy fatty acids (Lipski and Kämpfer 2012).

Chelativorans Doronina et al. 2010, 1047[VP]

Che.la'ti.vo.rans. N.L. n. *chelatum*, a chelate; L. part. adj. *vorans*, devouring; N.L. masc. n. *Chelativorans*, a bacterium digesting metal chelates.

Chelativorans strains are non-spore-forming rods. The genus was described as nonmotile (Doronina et al. 2010), although flagella were later reported for *Chelativorans multitrophicus* DSM 9103^T and several *Chelativorans* sp. strains (Kaparullina et al. 2011). They often occur as pairs and multiply by binary fission. They form small white colonies on EDTA/mineral salt agar (diameter 0.1–0.3 mm after 7 days at 30 °C). Optimal NaCl concentration for growth is 1.5 %. No PHB inclusions; electron dense inclusions are thought to consist of calcium and magnesium phosphates and are absent in cells grown on fumarate. Oxidase and catalase positive; indole is produced; no nitrate reduction to nitrite; no nitrogen fixation. Optimal temperature and pH for growth are 25–35 °C and 6.5–7.5. Aerobic respiratory metabolism; able to use EDTA as carbon, nitrogen and energy source, either facultatively (*Chelativorans multivorans*) or obligately (*Chelativorans oligotrophicus*). No autotrophic or methylotrophic growth; unable to use methanol or methylated amines as carbon, nitrogen, or energy source (Doronina et al. 2010). Unable to use alcohols, amines, malate, pyruvate, L-alanine, and L-serine as carbon and energy sources (Kaparullina et al. 2011). *Chelativorans oligotrophicus* has several defective or missing enzymes in the central carbon metabolism. The tricarboxylic acid cycle lacks α-ketoglutarate dehydrogenase activity, and 6-phosphofructokinase (ATP/PPi) is also absent (Doronina et al. 2010). The major cellular fatty acids are summed feature 7 (C18:1 ω7c, C18:1 ω9t and/or C18:1 ω12t) and C19:0 cyclo ω8c. Hydroxy fatty acids C12:0 3-OH, C13:0 3-OH, and C15:0 iso 3-OH are absent. The major ubiquinone is Q10. Predominant polar lipids are phosphatidylcholine, phosphatidylglycerol, phosphatidylethanolamine, phosphatidyldimethylethanolamine, phosphatidylmonomethylethanolamine, and diphosphatidylglycerol. *Mesorhizobium*-specific ornithine lipid is absent. sym-Homospermidine is the main polyamine with small amounts of spermidine and putrescine present. The DNA G+C content is 60–64 mol %. The type species is *Chelativorans multitrophicus* (Doronina et al. 2010).

Additional characters and differentiating features of both species are shown in Table 18.5.

Hoeflea Peix et al. 2005, 1165[VP]

Hoef.le.a'. N.L. fem. n. *Hoeflea* honoring Manfred Höfle, German microbiologist, in recognition of his contribution to the taxonomy of marine bacteria.

Data from Doronina et al. (2010) and Kaparullina et al. (2011)

Cells are non-spore-forming, motile short rods. They are aerobic chemoorganotrophs and are oxidase and catalase positive except for *Hoeflea alexandrii* which was described as oxidase negative. Cells do not require NaCl; however, they can grow in the presence of up to 5 % NaCl. Growth is possible at a temperature of 18–33°C although some species can grow at higher and lower temperatures (*Table 18.6*). pH range for growth is 6–8 or 9, and *Hoeflea suaedae* has a more wide pH range of 5–10. No nitrate reduction to nitrite or nitrogen except for *Hoeflea suaedae* which was reported to reduce nitrate to nitrite.

The main fatty acid is C18:1 ω7c, and other important fatty acids (>3 %) are C16:0, 11-Me C18:1 ω7c, and C19:0 cyclo ω8c. Only small amounts of hydroxy fatty acid are present. Ubiquinone Q10 is the major quinone; the main polar lipids are phosphatidylglycerol, phosphatidylethanolamine, phosphatidylmonomethylethanolamine, and sulfoquinovosyldiacylglyceride, although the latter polar lipid was not reported from *Hoeflea anabaenae*. The G+C content of the DNA ranges from 53 to 60 mol %. The type species is *Hoeflea marina*.

Additional characters and differentiating features of the five *Hoeflea* species are shown in *Table 18.6*.

Hoeflea anabaenae cells attach to *Anabaena* heterocysts; of the other *Hoeflea* species, only *Hoeflea phototrophica* has been observed to do this, although at a much lower frequency (Stevenson et al. 2011). *Hoeflea siderophila* is the only species reported to be iron oxidizing, using FeS, $FeSO_4$, or $FeCO_3$ for lithotrophic growth while depositing iron oxides on the cell surface. It also has a facultative anaerobic metabolism. In anaerobic, iron-oxidizing conditions, it uses nitrate or N_2O as terminal electron acceptor. Nitrate is converted to nitrite which inhibits growth as it accumulates. In those conditions, nitrite can chemically oxidize up to 20 % of Fe(II). When N_2O is given as an electron acceptor, there is virtually no chemical Fe(II) oxidation, and N_2 is formed. The organism is also able to grow mixotrophically or

organotrophically in microaerobic or anaerobic condition, using nitrate or N_2O as electron acceptors. Nitrite, ClO_4^-, S^0, thiosulfate, and $Fe(OH)_3$ are not used as electron acceptors, and H_2 oxidation is not possible (Sorokina et al. 2012).

Lentilitoribacter Park et al. 2013, 2365[VL]

Len.ti.li.to.ri.bac'ter. L. masc. adj. *lentus*, slow, delayed; L. n. *litus-oris*, the seashore, coast; N.L. masc. n. *bacter*, rod; N.L. masc. n. *Lentilitoribacter*, slowly growing rod from the coast).

Lentilitoribacter cells are non-spore-forming, nonmotile, and rods to short rods. They are catalase and oxidase positive and do not reduce nitrate to nitrite. Aerobic. The predominant ubiquinone is Q10. The major fatty acids are C18:1 ω7c, 11-methyl-C18:1 ω7c, and summed feature 3 (iso-C15:0 2-OH and/or C16:1 ω7c). The major polar lipids are phosphatidylglycerol and phosphatidylmonomethylethanolamine. The DNA G+C content is 49.3 mol %. The type species is *Lentilitoribacter donghaensis*.

Lentilitoribacter donghaensis cells are rods, 0.3–0.6 × 0.6–4.0 μm. Colonies on marine agar are circular, slightly convex, smooth, whitish yellow and less than 0.5 mm in diameter after 10 days at 25 °C. Optimal growth temperature is 25 °C; growth occurs at 4 and 30 °C, but not at 35 °C. Optimal pH is between 7.0 and 7.5; growth occurs at pH 5.5, but not at pH 5.0. Grows in the presence of 1.0–5.0 % NaCl (bstl growth with 2.0 % NaCl). Requires Mg^{2+} ions for growth. Hydrolyzes Tween 20, 40, 60, and 80, but not esculin, casein, gelatin, hypoxanthine, L-tyrosine, starch, and xanthine. Acid is produced from D-xylose, but not from L-arabinose, D-cellobiose, D-fructose, D-galactose, D-glucose, myo-inositol, lactose, maltose, D-mannitol, D-mannose, D-melezitose, melibiose, D-raffinose, L-rhamnose, D-ribose, D-sorbitol, sucrose, and D-trehalose. In the API ZYM tests, alkaline phosphatase, esterase lipase (C8), and leucine arylamidase are positive, while esterase (C4), trypsin, and acid phosphatase activities are weakly present, and lipase (C14), valine arylamidase, cysteine arylamidase, α-chymotrypsin, naphthol-AS-BI-phosphohydrolase, α-galactosidase, β-galactosidase, β-glucuronidase, α-glucosidase, β-glucosidase, N-acetyl-β-glucosaminidase, α-mannosidase, or α-fucosidase activities are negative. The major fatty acids (>10 %) are C18:1 ω7c, 11-methyl-C18:1 ω7c, and summed feature 3 (iso-C15:0 2-OH and/or C16:1 ω7c). C10:0 3-OH is the only hydroxy fatty acid detected.

The type strain CCUG 62792^T was isolated from seawater from the coast around Baekdo harbor in the East Sea, South Korea. Its DNA G+C content is 49.3 mol %.

Mesorhizobium Jarvis et al. 1997, 897[VP]

Me.so.rhi.zo'bi.um. Gr. adj. *mesos*, middle; N.L. neut. n. *Rhizobium*, bacterial genus name; N.L. neut.n. *Mesorhizobium*, rhizobia, phylogenetically intermediate between the genera *Bradyrhizobium* and *Rhizobium*. This etymology is given in the original description (Jarvis et al. 1997); alternatively in the List of Prokaryotic names with Standing in Nomenclature (www.bacterio.cict.fr), the name *Mesorhizobium* is said to refer to the growth rate of the bacteria which is intermediate between that of the genera *Rhizobium* and *Bradyrhizobium*.

The genus *Mesorhizobium* comprises 30 species, most occurring as nitrogen-fixing endosymbionts in root nodules of various legume plants. The species *Mesorhizobium thiogangeticum* was isolated from the soil adjacent to the roots of the legume *Clitoria ternatea*, by enrichment using reduced sulfur compounds as sole carbon and energy source (Ghosh and Roy 2006).

All species comprise rod-shaped cells that form creamy, white, or colorless colonies on agar media. They are aerobic organotrophs; only *Mesorhizobium thiogangeticum* is capable of facultative chemolithotrophic growth using thiosulfate or elemental sulfur as energy source (Ghosh and Roy 2006). Optimal temperature for growth is around 28 °C, and optimal pH is about 7. Three species have been reported to grow at 4°C: *Mesorhizobium ciceri*, *Mesorhizobium sangaii*, and *Mesorhizobium shonense* (Zhou et al. 2013); *Mesorhizobium ciceri* is the only species reported to grow at 40 °C (Jarvis et al. 1997; Zhou et al. 2013). Several species can grow in the presence of 1 or 2 % NaCl (*Table 18.7*); for *Mesorhizobium shangrilense*, even growth with 3 % NaCl was reported (Lu et al. 2009).

The fatty acid C18:1 ω7c is present in all species in large amounts (at least 10 % detected in itself or as part of a summed feature), while C16:0, 11-Me C18:1 ω7c, and C19:0 cyclo ω8c are also important (at least 5 %) in more than two thirds to half of the species. Hydroxy fatty acids have been reported at more than 1 % in 7 of the 30 species and comprise mostly C12:0 3-OH and/or iso-C13:0 3-OH; only in *Mesorhizobium albiziae* and *Mesorhizobium temperatum* has iso-C15:0 3-OH been reported at more than 1 % (Wang et al. 2007). Polar lipids have been reported for six of the species (*Table 18.7*): all comprised phosphatidylethanolamine, phosphatidylglycerol, and phosphatidylcholine, while five also contained diphosphatidylglycerol and several unidentified phospholipids (Zhang et al. 2012; Zheng et al. 2013). The DNA G+C content ranges from 57.9 % to 65.1 %.

The type species is *Mesorhizobium loti*. Additional characters and differentiating features of *Mesorhizobium* species are shown in *Table 18.7*.

Nitratireductor Labbé et al. 2004, 54[VP]

Ni.tra.ti.re.duc'tor. N.L. masc. n. *nitras*, nitrate; L. v. *reducere*, to bring back, to reduce; N.L. masc. n. *nitratireductor*, nitrate-reducing bacterium.

The genus *Nitratireductor* comprises six species that occur in various marine habitats. All species are aerobic chemoorganotrophs; nitrate reduction varies between strains. Cells are rods, short rods, or coccoid. Motility is variable. Optimum temperature for growth is 25–35 °C. No growth below 10 °C. pH range is 5–12. All species are oxidase and catalase positive. Major quinone is ubiquinone Q10. The main fatty acid is C18:1 ω7c/ω6c. DNA G+C content is 56.7–63 mol %. The type species is *Nitratireductor aquibiodomus*.

For substrate utilization and resistance, only characters with data for at least 10 species are listed; data were compiled from the original descriptions; *v* different report differ in this character, *w* weak positive. Empty cells indicate no data available

[a]*PEA* Phosphatidylethanolamine, *PG* phosphatidylglycerol, *DPG* diphosphatidylglycerol, *PC* phosphatidylcholine, *UPL* unidentified phospholipids

All species are positive for leucine arylamidase (API ZYM tests) and for the use of D-glucose and N-acetyl-glucosamine (API 20NE); all are negative for indole production (API 20NE). Further characteristics and differentiating features of the species are given in *Table 18.8*.

Phyllobacterium (*ex* Knösel 1962) Knösel 1984, 356[VP]

Phyl.lo.bac.te'ri.um. Gr. neut. n. *phyllon*, leaf; L. neut. n. *bacterium*, rod; N.L. neut. n. *phyllobacterium*, leaf bacterium (occurring in leaf nodules of higher plants).

Cells are rods and motile by means of polar, subpolar, or lateral flagella. The optimal growth temperature is 28 °C, and there is no growth at 40 °C. Growth occurs in 1 % NaCl. Glucose metabolism is oxidative. Oxidase positive; urease is positive except for *Phyllobacterium endophyticum*. Indole production, β-galactosidase, and gelatinase are negative for all species. Some other enzyme activities that were originally included in the genus description, however, have not been reported for all species. These include DNase (negative, but no data for *P. endophyticum* and *P. trifolii*), hydrolysis of Tween 80 (negative, but not tested for *P. catacumbae*, *P. endophyticum*, and *P. trifolii*), starch (negative for *P. myrsinacearum* and *P. catacumbae*), pectin and cellulose (both only reported as negative for *P. myrsinacearum*), nitrate reduction (positive for *P. myrsinacearum*, negative for *P. catacumbae*, *P. endophyticum* and *P. trifolii*). Esculin is hydrolyzed (weak reaction for *P. trifolii*). 3-Ketolactose test is negative (no data for *P. endophyticum* and *P. trifolii*). Assimilation of D-glucose, D-mannose, L-arabinose, D-mannitol, and N-acetylglucosamine is positive for all species. Maltose is used by all species except *P. endophyticum*. Quinones have only been reported for *Phyllobacterium endophyticum* and comprised Q10 (88 %) and Q9 (12 %) (Flores-Felix et al. 2013). Additional characteristics of the *Phyllobacterium* species are given in *Table 18.9*.

The G+C content of the DNA ranges from 51 to 61 mol % (Tm). The type species is *Phyllobacterium myrsinacearum*.

Pseudahrensia Jung et al. 2012, 2059[VP]

Pseu.dah.ren'si.a. Gr. adj. *pseudes*, false; N.L. fem. n. *Ahrensia*, a bacterial genus name; N.L. fem. n. *Pseudahrensia*, the false *Ahrensia*.

Pseudahrensia cells are aerobic, non-spore-forming, nonmotile, and ovoid to rod shaped. Catalase, oxidase, and nitrate reduction are positive. The predominant ubiquinone is Q10. The major fatty acid is C18:1 ω7c. The major polar lipids are phosphatidylcholine, phosphatidylglycerol, diphosphatidylglycerol, and phosphatidylethanolamine. The DNA G+C content of the type strain of the type species is 60.1 mol %. The type species is *Pseudahrensia aquimaris*.

Pseudahrensia aquimaris cells are nonmotile, ovoid to rod shaped, and 0.5–1.0 × 1.0–7.0 µm. Colonies on MA are circular, convex, smooth, glistening, cream colored and 1.0–1.5 mm in diameter after 5 days at 30 °C. Temperature range for growth is 4–32 °C; optimal growth at 30 °C, pH 7–8, and 2–3 % NaCl. Grows at pH 5.5, but not pH 5. Can grow in 10 % NaCl, but not in 11 % or without NaCl. Na^+ and Mg^{2+} ions are required for growth. No anaerobic growth on marine agar. Nitrate is reduced to nitrite. Gelatin is hydrolyzed. H_2S is not produced. Esculin; casein; hypoxanthine; starch; Tween 20, 40, 60, and 80; L-tyrosine; urea; and xanthine are not hydrolyzed. Acid is positive from D-fructose, D-galactose, D-glucose, lactose, maltose, D-mannose, D-ribose, and sucrose; no acid production from L-arabinose, cellobiose, myo-inositol, D-mannitol, melezitose, melibiose, raffinose, L-rhamnose, D-sorbitol, trehalose, or D-xylose. Susceptible to ampicillin, cephalothin, chloramphenicol, gentamicin, kanamycin, neomycin, novobiocin, penicillin G, polymyxin B, and streptomycin; resistant to carbenicillin, lincomycin, oleandomycin, and tetracycline. The following enzymes are present (API ZYM): alkaline phosphatase, esterase (C4), leucine arylamidase, acid phosphatase, esterase lipase (C8) (weak), and trypsin (weak); the following enzymes are absent: lipase (C14), valine arylamidase, cystine arylamidase, α-chymotrypsin, naphthol-AS-BI-phosphohydrolase, α- and β-galactosidase, β-glucuronidase, α- and β-glucosidase, N-acetyl-β-glucosaminidase, α-mannosidase, and α-fucosidase (Jung et al. 2012).

Major fatty acid (>10 %) is C18:1 ω7c; no other fatty acids are present at more than 5 %; the only hydroxy fatty acid detected is C18:0 3-OH, apart from the possible presence of C14:0 3-OH as part of summed feature 2 (Jung et al. 2012). However, Park et al. (2013) report the presence of iso-C13:0 3-OH and the absence of C18:0 3-OH.

The type strain (CCUG 60023^T) was isolated from seawater, Yellow Sea of the island of Hwang-do, Korea.

Pseudaminobacter Kämpfer et al. 1999, 894[VP]

Pseud.ami.no.bac'ter. Gr. adj. *pseudos*, false; N.L. masc.n. *Aminobacter*, bacterial genus name; N.L. masc. n. *Pseudaminobacter*, false *Aminobacter*.

Pseudaminobacter cells are rod shaped and motile. Obligate aerobic heterotrophs. They have an oxidative metabolism and can use D-glucose, D-ribose, D-xylose, acetate, propionate, pyruvate, β-alanine, N-acetyl-D-glucosamine, 4-aminobutyrate, DL-3-hydroxybutyrat, DL-lactate, oxoglutarate, L-alanine, L-histidine, L-leucine, and L-proline as sole carbon source. Growth occurs on nutrient agar (Oxoid), Caso agar, R2A agar (Oxoid), and TSB agar (BBL). Colonies are circular, entire, slightly convex and smooth, glistening, and pale beige on nutrient agar at 25 °C. Oxidase and catalase positive. Main ubiquinone is Q10. The major polyamines are spermidine, sym-homospermidine, and putrescine. Polar lipids include phosphatidylcholine, phosphatidylglycerol, phosphatidyldimethylethanolamine, phosphatidylmonomethylethanolamine, phosphatidylethanolamine, and diphosphatidylglycerol in nearly the same amounts. Main fatty acids are C18:1 and C19:0 cyclo ω8c. The only hydroxy fatty acid is C15:O iso 3-OH. The G+C content of the

Table 18.10
Characteristics of the two *Pseudaminobacter* species. Data taken from Kämpfer et al. (1999)

Characteristic	*Pseudaminobacter defluvii* NBRC 14570^T	*Pseudaminobacter salicylatoxidans* DSM 6986^T
Source	Activated sludge	6-Aminonaphthalene-2-sulfonate-degrading consortium from river water
Cell shape	Coccoid to rod shaped	Rods
Cell size	0.8–0.8 × 0.8–1.2 μm	0.5–0.8 × 1–1.5 μm
Temperature range	10–40	20–40
Major fatty acids (>10 %)	C18:1 (ω7c/ω9t/ω12t), C19:0 cyclo ω8c	C18:1 (ω7c/ω9t/ω12t), C19:0 cyclo ω8c
Important fatty acid (5–10 %)		C17:0
Hydroxy fatty acids	C15:0 iso 3-OH	C15:0 iso 3-OH
DNA G+C content (mol %)	62.9	63.9
Acid produced from D-mannitol, dulcitol, and melibiose	–	w
Assimilation of D-maltose, D-trehalose, adonitol, D-mannitol, D-sorbitol, *cis*-aconitate, glutarate, L-malate, L-aspartate, and 4-hydroxybenzoate	–	+
Assimilation of L-ornithine and L-serine	+	–

DNA is 62.9–63.9 mol %. The type species is *Pseudaminobacter salicylatoxidans*.

One additional species was described, *Pseudaminobacter defluvii*. Both species produce acid weakly from glucose, but not from lactose, sucrose, salicin, inositol, sorbitol, L-arabinose, raffinose, maltose, D-xylose, trehalose, cellobiose, D-arabitol, mannose, adonitol, rhamnose, methyl D-glucoside and erythritol. Both species hydrolyze bis-para-nitrophenyl (pNP)-phosphate, pNP-phenyl-phosphonate, L-alanine-para-nitroanilide (pNA), and L-proline-pNA, but not pNP-α-D-glucopyranoside, pNP-β-D-glucopyranoside, pNP-phosphorylcholine, esculin, pNP-β-D-galactopyranoside, pNP-β-D-glucuronide, 2-deoxythymidine-5′-pNP-phosphate, and L-glutamate-γ-3-carboxy-pNA. They do not assimilate p-arbutin, D-melibiose, salicin, maltitol, putrescine, trans-aconitate, adipate, azelate, fumarate, itaconate, mesaconate, suberate, L-tryptophan, 3-hydroxybenzoate, and phenylacetate. Additional characteristics of the *Psedaminobacter* species are given in Table 18.10.

Thermovum Yabe et al. 2012, 2994^{VP}

Ther.mo'vum. Gr. n. *thermê*, heat; L. neut. n. *ovum*, egg, oval; N.L. neut. n. *Thermovum*, a heat(-loving) oval-shaped organism.

Thermovum comprises Gram-positive ovoid cells that do not form spores. Thermophilic. Major fatty acids (>10 %) are C18:1 ω7c, C19:0 ω8c, and C18:0. Polar lipids comprise phosphatidylcholine, phosphatidylglycerol, phosphatidylethanolamine, hydroxyphosphatidylethanolamine, phosphatidylinositol, phosphatidylmonomethylethanolamine, an unknown glycolipid, and a ninhydrin-positive phospholipid. The main quinone is ubiquinone Q10. The type species is *Thermovum composti*.

Thermovum composti cells are nonmotile, ovoid shaped, and 0.9 μm × 1.4 μm (after 2 days at 50 °C). Catalase and oxidase positive. Growth occurs at 23–57 °C, with optimal growth at 50 °C, at pH 5.9–8.8 (optimum, pH 7.0) and in the presence of 0–4 % (w/v) NaCl. In addition to the major fatty acids listed above in the genus description, C16:0 is a further important fatty acid (5–10 %) in *Thermovum composti*, while no hydroxy fatty acids were reported. Negative for gelatinase, urease, and indole production. Positive for nitrate reduction and for the utilization of D-arabinose, L-arabinose, D-ribose, D-xylose, D-galactose, D-glucose, cellobiose, lactose, melibiose, gentiobiose, D-fucose, and potassium 5-ketogluconate; negative for the utilization of glycerol, erythritol, L-xylose, D-adonitol, methyl β-D-xylopyranoside, D-fructose, D-mannose, L-sorbose, L-rhamnose, dulcitol, inositol, D-mannitol, D-sorbitol, methyl α-D-mannopyranoside, methyl α-D-glucopyranoside, N-acetylglucosamine, amygdalin, arbutin, esculin ferric citrate, salicin, maltose, sucrose, trehalose, inulin, melezitose, raffinose, starch, glycogen, xylitol, turanose, D-lyxose, D-tagatose, L-fucose, DL-arabitol, potassium gluconate, and potassium 2-ketogluconate. The following enzyme activities were present (API ZYM): esterase C4, esterase C8, leucine arylamidase, α-chymotrypsin, naphthol-AS-BI-phosphohydrolase, trypsin, and valine arylamidase; the following were absent: alkaline phosphatase, lipase C14, cystine arylamidase, acid phosphatase, α-galactosidase, β-galactosidase, α-glucosidase, β-glucosidase, β-glucuronidase, N-acetyl-β-glucosaminidase, mannosidase, and α-fucosidase. The type strain JCM 17863^T was isolated from compost. The G+C content of its DNA is 63.4 mol %.

If appropriate, the description of metabolic pathways and/or physiology may deserve an individual heading.

Isolation, Enrichment, and Maintenance Procedures

The genera and species of the family have an aerobic respiratory metabolism and originate from a wide range of habitats. No single isolation or enrichment procedure is available to selectively obtain all or most members of the family, and therefore the genera are discussed separately below.

The only species of the genus *Ahrensia*, *Ahrensia kielensis*, was isolated from the Baltic Sea during studies of star-shaped-aggregate-forming bacteria and was originally named *Agrobacterium kielense* (Ahrens 1968). Because Dr. Renata Ahrens later withdrew the proposal, these species were not documented elsewhere in the following years, and no details on specific isolation conditions are available in recent literature (Rüger and Höfle 1992). With the recent sequencing of the genome of this organism, it may become possible in future to propose suitable isolation or enrichment strategies. The organism can be cultivated on regular marine media (e.g., Difco Marine Broth) at 26 °C and can be freeze-dried for long-term preservation.

Aliihoeflea was isolated from tidal flat sediment samples by plating on marine agar 2216 (Difco). Circular colonies—convex with entire margin, shiny, and cream colored—were 0.5–1.0 mm in diameter after 2 days incubation at 30 °C. Growth also occurs on trypticase soy agar (TSA, Difco), Luria agar (Difco), and yeast extract mannitol agar (YMA, per liter, 10 g D-mannitol, 0.5 g KH_2PO_4, 0.2 g $MgSO_4 \cdot 7H_2O$, 0.1 g NaCl, 4 g $CaCO_3$, 0.4 g yeast extract, 15 g agar; pH 6.8–7.0) (Roh et al. 2008).

All *Aminobacter* species were isolated from the soil using various enrichment or trapping methods. *Aminobacter anthyllidis* was isolated from the nodules of *Anthyllis vulneraria* that was used as a trapping plant and was grown in soil from a zinc and lead mining site (Maynaud et al. 2012). The surface-sterilized nodules were crushed in sterile water, and the bacteria were isolated by streaking the suspension on YMA (Vincent 1970; recipe as listed above) and incubating at 28 °C.

Aminobacter aganoensis, *Aminobacter aminovorans*, and *Aminobacter niigatensis* were isolated from soil by enrichment using methylamine compounds (mono-, di-, tri-, or tetramethylamine, trimethylamine-*N*-oxide, or tetramethylammonium hydroxide) or methylformamide compounds (*N*-methylformamide or *N*,*N*-dimethylformamide) (Urakami 2005). For routine growth of PYG medium, pH 7.0 can be used at 30 °C (Urakami et al. 1992).

Aminobacter ciceronei and *Aminobacter lissarensis* are methylotrophic species. *Aminobacter ciceronei* was isolated from CH_3Br-fumigated soil in the USA by enrichment on a mineral salt medium under a modified atmosphere of air plus CH_3Br (Miller et al. 1997). *Aminobacter lissarensis* strain CC495 was isolated from the top 5 cm of soil in a beech wood in County Down, Northern Ireland, by enrichment with CH_3Cl as the sole carbon and energy source. One gram of soil was added to 100 ml of minimal medium in 500-ml flasks containing 0.125 g of CH_3Cl. The minimal medium had the following composition (in grams per liter): KH_2PO_4 (4.5), K_2HPO_4 (10.5), $MgSO_4 \cdot 7H_2O$ (0.15), and NH_4NO_3 (1.5), pH adjusted to 7.2 with 6 M NaOH; a trace element solution was added (10 ml. l^{-1}) containing (in $mg.l^{-1}$) H_3BO_3(500), $CuSO_4 \cdot 5H_2O$ (40), KI (100), $FeSO_4 \cdot 7H_2O$ (200), $MnSO_4 \cdot 7H_2O$ (400), $(NH_4)6Mo_7O_{24} \cdot 4H_2O$ (200), and $ZnSO_4$ (400). In the pure cultures, the medium was additionally supplemented with a vitamin solution (5 $ml.l^{-1}$) containing (in milligrams per liter) folic acid (4), p-aminobenzoic acid (200), and cyanocobalamin (200). CH_3Cl (0.15 g) was added as an aqueous solution to give a concentration in the culture medium, after equilibration of the gaseous and aqueous phases, of 11.8 mM (30 mM if partitioning is neglected and the total CH_3Cl present is expressed as a concentration in the aqueous phase) (Coulter et al. 1999).

All *Aminobacter* species can be stored in broth medium plus 20 % glycerol at −80 °C or can be lyophilized and stored at 4 °C.

Two *Aquamicrobium* species were isolated from activated sludge, *Aquamicrobium defluvii* and *Aquamicrobium lusatiense* (Bambauer et al. 1998; Fritsche et al. 1999; Kämpfer et al. 2009). The former species originated from a municipal wastewater plant and was obtained on a mineral medium with thiophene-2-carboxylate as the sole source of carbon and nitrate as the electron acceptor. The mineral salt medium (Bambauer et al. 1998), also used for cultivation, contained per l 3.56 g $Na_2HPO_4 \cdot 2H_2O$, 0.4 g NH_4Cl, and 0.07 g K_2SO_4. After autoclaving, 1 l of medium was supplemented with 2 ml of a sterile solution containing per l 100 g MgCl2, 25 g CaCl2, 10 ml vitamin solution (Balch et al. 1979), and 1 ml trace element solution (Widdel et al. 1983). Thiophene-2-carboxylate (2–30 mM final concentration) was added from a sterile, tenfold concentrated stock solution. For anaerobic growth, the medium was supplemented with 5–20 mM KNO_3 (Bambauer et al. 1998).

Three other species were isolated from air or waste gas in a duck shed and an animal rendering plant: *Aquamicrobium aerolatum*, *Aquamicrobium ahrensii*, and *Aquamicrobium segne* (Kämpfer et al. 2009; Lipski and Kämpfer 2012). The latter two species were isolated on Antibiotic Sulfonamide Sensitivity-test agar (Merck 1.05392) (Ahrens et al. 1997). *Aquamicrobium aerolatum* was isolated collecting bioaerosol samples by filtration over gelatin filters and isolation on trypticase soy agar incubated at 26 °C. The organism can also be grown on nutrient agar (Kämpfer et al. 2009). *Aquamicrobium aestuarii* was isolated from crude oil-contaminated sediments of a tidal flat (Jin et al. 2013) by incubating approximately 10 g of sediment with 100 ml of 0.2 µm filtered seawater containing 3 ml crude oil in 500-ml Erlenmeyer flask at 25 °C. The enrichment was aerated (180 rpm) and was transferred (1:20) four times every 2 weeks. For isolation, the enrichment was plated on marine agar 2216 (BD) plates and incubated under aerobic conditions at 25 °C for 5 days. In addition, the species grows well on R2A agar (BD), Luria-Bertani agar, trypticase soy agar, and marine agar (Jin et al. 2013).

Chelativorans strains were obtained from sludge samples. *Chelativorans multitrophicus* was isolated from a mixed microbial culture enriched in a column packed with activated carbon that was continuously fed with a mineral medium containing EDTA as sole source of carbon, nitrogen, and energy. The original inoculum of the column was activated sludge from various industrial wastewater treatment plants and soil extracts. For the isolation, further aerobic enrichment in continuous culture on a column packed with glass beads and fed with mineral medium (per liter, 1.0 g MgSO4 · $7H_2O$, 0.2 g $CaCl_2$ · $2H_2O$, 0.13 g KH_2PO_4, and 0.615 g Na_2HPO_4, 2 ml of Widdel trace element solution (Pfennig et al. 1981) and 1 ml of a vitamin solution (Egli et al. 1988)) containing 200–300 $mg.l^{-1}$ EDTA as well as batch cultures to establish optimal growth conditions were used (Weilenmann et al. 2004). The best conditions for growth were 30 °C, initial EDTA concentration in the range of 1–1.5 $g.l^{-1}$, $CaCl_2$ · $2H_2O$ concentration in the mineral medium of 0.4 $g.l^{-1}$ and an initial pH of 7.0. Pure cultures were obtained by successive plating on Plate Count Agar and liquid culture in the mineral medium (Weilenmann et al. 2004). *Chelativorans multitrophicus* was obtained by enrichment from municipal sludge samples: 10 g of sample was suspended in 100 ml of medium (per liter, 1.0 g EDTA, 1.0 g MgSO4 · $7H_2O$, 0.4 g $CaCl_2$ · $2H_2O$, 0.26 g KH_2PO_4, and 0.83 g Na_2HPO_4 · $12H_2O$ and trace elements and vitamins (Egli et al. 1988), pH 7.0). The medium was incubated in a 750-ml flask on a shaker (150–200 rpm) at 28 °C for 2 weeks. Five milliliters of this enrichment then inoculated into a 750-ml flask with 100 ml of fresh medium and cultivated for 2 weeks. After five such transfers, pure colonies were picked from plates of the same medium plus agar (Chistyakova et al. 2005).

Hoeflea species have been isolated from different aquatic environments. *Hoeflea marina* comprises one strain, LMG 128^T, that was originally classified as *Agrobacterium ferrugineum* (other strains of this species have been renamed as *Pseudorhodobacter ferrugineus*, a member of the *Rhodobacteraceae*). *Hoeflea marina* was isolated from water from the Baltic Sea, off the coast of Germany, during a study of star-forming bacteria (Ahrens 1968; Peix et al. 2005). *Hoeflea phototrophica* was isolated from cultures of the marine dinoflagellates *Alexandrium lusitanicum* and *Prorocentrum lima*. Wine red colonies were obtained by plating washed single dinoflagellate cells onto 1/10-strength Difco marine agar. Pigmentation was found to depend on the salt concentration with cultures with 3, 6, or 9 $g.l^{-1}$ sea salts being very pink, while at 35 $g.l^{-1}$ cultures were colorless (Biebl et al. 2006). *Hoeflea alexandrii* was purified from cultures of another marine dinoflagellate, *Alexandrium minutum*. In this case, the washed dinoflagellate cells were sonicated prior to plating on full- and half-strength Difco marine agar and incubation during 7 days at 15 °C. Brown-pigmented colonies were obtained. Marine agar or broth was used for routine cultivation at 30 °C (Palacios et al. 2006). *Hoeflea anabaenae* was isolated from a culture of the cyanobacterium *Anabaena* under heterotrophic conditions in the brackish marine purity liquid medium (per liter, 20 g NaCl, 17 g AC broth (Difco), 8 g $MgSO_4 \cdot 7H_20$, 1.5 g $CaCl_2 \cdot 2H_20$ (Stevenson and Waterbury 2006)) from a culture in which it was attached almost exclusively to *Anabaena* heterocysts. It is also able to grow aerobically at 30 °C in full- and half-strength marine broth (Difco) and marine agar and liquid or solid PY medium (20 g sea salts, 3 g peptone, and 0.5 g yeast extract per liter (Biebl et al. 2005)). *Hoeflea suaedae* was isolated from the root surface of the halophyte *Suaeda maritima*. Surface-sterilized and dried root pieces (1 g) were ground in 9 ml of autoclaved filtered seawater (AFS) with a sterile mortar and pestle. Dilution series were plated in triplicate on one-tenth-strength R2A (1/10 R2A) medium in filtered seawater and supplemented with 50 μg/ml cycloheximide. Plates were incubated at 28 °C for 2–3 weeks. Routine maintenance is on 1/10 R2A medium in filtered seawater, and the organism can be stored with 15 % glycerol at −70 °C (Bibi et al. 2012).

Hoeflea siderophila was isolated from fresh ochreous sediments collected near the outlet of an iron-rich brackish spring using dilution plating on the following medium (g per liter): NaCl, 20; NH_4Cl, 0.3; $CaCl_2 \cdot 6H_2O$, 0.3; $MgCl_2 \cdot 7H_2O$, 3; $NaHCO_3$, 0.5; 10 % phosphate buffer (pH 7.0), 0.1; Hepes buffer (pH 7.2), 3.0; KNO_3, 0.3; CH_3COONa, 0.15; vitamins and trace elements (Pfennig and Lippert 1966); Difco agar, 5.0; and pH 7.0. Before inoculation, the medium was supplemented with fresh sterile FeS suspension (Hanert 1981) (0.2 mL per 10 mL of medium). Inoculated media were incubated for 2–3 weeks at 28 °C. Growth consisted of dense spherical colonies, orange-colored due to the formation of iron oxides. In liquid medium, iron oxidation results in an ochreous precipitate (Sorokina et al. 2012).

Hoeflea hydrophila was isolated from marine sediments by serial dilution in filter-sterilized natural seawater containing 0.1 % yeast extract. After aerobic incubation at 25 °C for 2 weeks, a sample from the lowest dilution showing growth was plated on the same medium, and after incubation at 25 °C for 2 weeks, single colonies that were beige, circular, and convex with regular edges were purified on marine agar 2216 (Difco). This species can be routinely grown on marine broth or marine agar. Marine broth cultures plus 20 % glycerol can be stored at −80 °C (Jung et al. 2013).

Lentilitoribacter was isolated from coastal seawater by dilution plating on marine agar 2216 (Becton–Dickinson) at 25 °C. These conditions were also used for routine cultivation. For short-term preservation, marine agar cultures can be stored at 4 °C, while for long-term preservation, glycerol suspensions (20 %) can be stored at −80 °C (Park et al. 2013).

Mesorhizobium comprises soil bacteria that can live endosymbiotically in root nodules on various legume plants where they can fix atmospheric nitrogen contributing to plant nutrition. A widely used approach to isolate rhizobia is through the use of legume plants to trap the bacteria from a particular soil. Surface-sterilized seeds are allowed to germinate in the soil, and after the plants develop, nodules are harvested for isolation of the bacteria (Vincent 1970). A similar approach is also used to verify the nodulation capacity of a strain with a particular host species. Isolation from surface-sterilized and crushed nodules is performed using yeast mannitol agar (YMA, per liter, 10 g

D-mannitol, 0.5 g KH_2PO_4, 0.2 g $MgSO_4 \cdot 7H_2O$, 0.1 g NaCl, 4 g $CaCO_3$, 0.4 g yeast extract, 15 g agar, pH 6.8–7.0). Incubation at 28 °C will result in the formation of creamy, entire, and convex mucoid colonies after 3–4 days. This procedure can result in growth of not only *Mesorhizobium* strains but also other rhizobia. Phenotypic distinctions are not straightforward: *Mesorhizobium* members can in some cases be distinguished in that they have a moderately fast growth rate (generation time 4–15 h) compared to *Rhizobium* (<6 h) and *Bradyrhizobium* (>6 h). Also they produce acid on YMA (as do *Rhizobium* strains), while *Bradyrhizobium* strains produce alkali (Chen et al. 2005). More certain genus assignment, however, requires verification of the partial 16S rRNA gene sequence.

All *Mesorhizobium* species have been isolated using the trap legume method except for one species, *Mesorhizobium thiogangeticum*, which was obtained from soil adjacent to the root of the legume *Clitoria ternatea* through enrichment using reduced sulfur compounds as sole carbon and energy source. Soil was supplemented with $Na_2S_2O_3 \cdot 5H_2O$ (5 %), Na_2S (1 %), and elemental sulfur powder (5 %) and incubated at 30°C for 2 weeks with intermittent sprinkling of sterile water. After this enrichment, soil samples (1 %, w/v) were incubated on a rotary shaker at 30 °C in mineral salt thiosulfate yeast extract liquid medium (20 mM $Na_2S_2O_3 \cdot 5H_2O$ supplemented with 5 g yeast extract per liter, pH 7.0–7.5) in mineral salt solution that contained (per liter of distilled water) 1 g NH_4Cl, 4 g K_2HPO_4, 1.5 g KH_2PO_4, 0.5 g $MgSO_4 \cdot 7H_2O$, and 5.0 ml trace metal solution (Vishniac and Santer 1957). When the color of the phenol red indicator had changed to yellow, serial dilutions were plated on the same agar medium for the isolation of pure cultures (Ghosh and Roy 2006).

Nitratireductor strains have been isolated from diverse marine sources, often by standard dilution plating techniques. *Nitratireductor aquibiodomus* was isolated from a marine aquarium denitrification system fitted with cellulose carriers. For the isolation, cellulose carriers were homogenized, and a dilution series was plated onto trypticase soy agar and R2A and incubated at room temperature for 3 weeks. *Nitratireductor aquibiodomus* was one of the several organisms that were picked up (Labbé et al. 2003); its colonies were white, smooth, circular, and convex (Labbé et al. 2004). *Nitratireductor basaltis* was isolated from black sand from Soesoggak beach, Jeju Island, Korea, by dilution plating onto marine agar 2216 (Difco) and incubating at 30–37 °C. It is not reported whether other organisms were able to grow in these conditions; the colonies of *Nitratireductor basaltis* were creamy, circular, convex, and smooth (Kim et al. 2009). *Nitratireductor kimnyeongensis* was isolated from a dried seaweed sample from Kimnyeong beach in Jeju, Republic of Korea (Kang et al. 2009), by transferring a piece of dried seaweed directly transferred onto isolation medium (WAT-SW agar) consisted of 0.05 % $MgSO_4.7H_2O$, 0.05 % $CaCl_2.2H_2O$, and 1.5 % agar in 60 % natural seawater and 40 % distilled water (pH 7.3) (Lee 2006). The organism can also be conveniently grown on trypticase soy agar where, after 5 days of incubation, colonies are small (0.5–1 mm in diameter), light yellow, circular, convex, smooth, and entire (Kang et al. 2009). *Nitratireductor aquimarinus* was isolated from exponential cultures of the marine diatom *Skeletonema costatum* by plating a 10-µl sample on marine agar 2216 (Difco) and incubating aerobically for 1 week. Colonies are creamy, smooth, circular, and convex. Growth is also good on trypticase soy agar at 35 °C. Strains can be preserved in trypticase soy broth supplemented with 30 % glycerol and −80 °C (Jang et al. 2011). *Nitratireductor indicus* was isolated from a deep-sea water sample taken at a depth of 2,488 m taken with Niskin bottles attached to a CTD (conductivity, temperature, and depth) sampler at 25.3217°S 70.0405°E in the southwestern part of the Indian Ridge. The seawater was enriched with 1 % sterilized crude oil, and after two months, bacteria were isolated by using the plating on 216L medium (per liter seawater: 1.0 g CH_3COONa, 10.0 g tryptone, 2.0 g yeast extract, 0.5 g sodium citrate, and 0.2 g NH_4NO_3; pH 7.5) (Lai et al. 2009; Lai et al. 2011b). On marine agar, colonies are unpigmented, smooth gray, and slightly raised in the center and have a regular margin (Lai et al. 2011a). *Nitratireductor pacificus* was also isolated from deep-sea water samples, this time from a pyrene-degrading enrichment (described in Wang et al. 2008) by using phthalate as sole carbon source in mineral medium (MM, comprising per liter: 3.5 g $MgSO_4 \cdot 7H_2O$, 0.05 g $CaCl_2$, 24 g NaCl, 0.35 g KCl, 1.0 g NH_4NO_3, 1.0 KH_2PO_4, 1.0 g K_2HPO_4, 0.01 g $FeCl_3$, 0.0001 g $ZnSO_4 \cdot 7H_2O$, 24 mg $SrCl_2 \cdot 6H_2O$, and 0.08 g KBr, adjusted to pH 7.4) (Wang et al. 2008; Lai et al. 2011a). On marine agar, colonies are smooth gray, nonpigmented with a regular margin, and slightly raised in the center (Lai et al. 2011a).

Most recently, a new species, *Nitratireductor lucknowense*, was published, though not yet validated. It was isolated from pesticide-contaminated soil from a γHCH (lindane) manufacturing site in India. Five-gram soil samples collected from three different locations were mixed together in 50 ml of sterile mineral medium (Senoo and Wada 1989). After the slurry had settled, the liquid phase was used to enrich for bacteria on 0.34 M lindane. On trypticase soy agar, the new species produces colonies that are straw yellow, smooth, circular, glistening, opaque, and convex with an entire margin (Manickam et al. 2012). NaCl is tolerated up to 2 % (Manickam et al. 2012), considerably less than most other *Nitratireductor* species which can tolerate up to 7 or 8 % (❯ *Table 18.8*).

Most *Phyllobacterium* species are plant associated, and while the first species were isolated from tropical ornamental plants, these bacteria have since also been isolated from other plants elsewhere and from non-plant sources such as volcanic rock used for construction. Different isolation procedures have been used and are summarized in the following overview. The selectivity in most cases is not documented.

Phyllobacterium myrsinacearum and its junior subjective synonym *Phyllobacterium rubiacearum* (Mergaert et al. 2002) have been isolated from leaf nodules of members of the plant families *Rubiaceae* (*Pavetta zimmermanniana*) and *Myrsinaceae* (*Ardisia crispa*, *Ardisia crenata*). Washed leaf pieces carrying nodules were macerated by rubbing and placed in saline. After shaking, dilutions were plated onto carrot juice agar containing yeast extract (fresh carrot juice, 500 ml; water, 500 ml;

$FeSO_4 \cdot 7H_2O$, 0.1 g; $MnSO_4 \cdot H_2O$, 0.1 g; agar, 15 g; pH 7.2; the medium is sterilized by fractional sterilization). After incubation at 28 °C, typical nonpigmented to beige, slimy, and circular colonies that are translucent to opaque in the center are transferred into liquid carrot juice medium. After 24- to 48-h phase, contrast microscopy can be used to verify the formation of star-shaped clusters. Stock cultures can be kept on trypticase soy agar at 5 °C for 1–2 months, and cultures can be lyophilized for long-term preservation (Knösel 1984). Isolates of this species have also been obtained from the root surface of sugar beet by using trypticase soy broth agar as a nonselective medium (Lambert et al. 1990; Mergaert et al. 2002).

Phyllobacterium trifolii was isolated from the nodules of *Trifolium pratense* as described above for *Mesorhizobium* species. Colonies on YMA are white, mucoid, translucent, and convex. The growth rate of this *Phyllobacterium* species (generation time 2 h) is faster than most mesorhizobia. Growth is also possible on nutrient agar (Valverde et al. 2005).

A further five species were also obtained using the same procedure, this time from roots of *Brassica napus* cv. Eurol (*Phyllobacterium bourgognense*, *Phyllobacterium brassicaearum*), root nodules of *Lathyrus numidicus* and *Astragalus algerianus* (*Phyllobacterium ifriqiyense*), root nodules of *Astragalus algerianus* and *Argyrolobium uniflorum* (*Phyllobacterium leguminum*) (Mantelin et al. 2006b), and root nodules of *Phaseolus vulgaris* (Flores-Felix et al. 2013). Colonies are circular, white or cream colored with regular margins, and in most strains highly mucoid (Mantelin et al. 2006b).

Phyllobacterium catacumbae does not originate from a plant-associated source. It was isolated from tuff, volcanic rock used in the walls of the Roman catacombs of Saint Callixtus, Rome, Italy. The B-4 medium used for isolation contained (per liter) 2.5 g calcium acetate, 4 g yeast extract and 15 g agar, pH 8, and incubation was at 28 °C. Colonies are circular, smooth, and beige. Growth is also good on trypticase soy agar (Jurado et al. 2005).

Phyllobacterium species can be stored at −80 °C in broth medium plus 20 % glycerol or at 4 °C lyophilized.

Pseudahrensia was isolated from seawater from the Yellow Sea, Korea, by the standard dilution plating on marine agar 2216 (Difco) and incubating at 25 °C. Colonies are circular, convex, smooth, glistening, and cream colored. This organism can be routinely cultivated on marine agar at 30 °C (Jung et al. 2012).

Although no precise isolation media have been published, *Pseudaminobacter* strains have been isolated by exploiting specific degradation capacities. The *Pseudaminobacter salicylatoxidans* type strain was isolated as a degrader 6-aminonaphthalene-2-sulfonate from a microbial consortium degrading this substrate and originating from the river Elbe, Germany (Nortemann et al. 1986; Kämpfer et al. 1999). The type strain of *Pseudaminobacter defluvii* was isolated from activated sludge which was enriched with thiocyanate (Katayama-Fujimura et al. 1983; Kämpfer et al. 1999). Growth is possible on several media including nutrient agar, trypticase soy agar, trypticase soy broth plus 1.5 % agar, and R2A (Oxoid) (Kämpfer 2005).

Thermovum composti was isolated from mature compost produced by a field-scale composter used for the treatment of livestock excreta. Dilution series of 1 g of compost in saline solution were plated onto isolation medium composed of (per liter distilled water) 1 g yeast extract, 2 g tryptone, 1 g NaCl, 1 g $MgSO_4 \cdot 7H_2O$, 20 g agar, 20 mg trimethoprim, 10 mg nalidixic acid, and 20 mg kanamycin, pH 7.0. After incubation at 50 °C for 7 days, colonies were picked and repeatedly transferred for purification. Colonies on nutrient agar are cream colored. Stock cultures in trypticase soy broth, grown for 2 days at 50 °C, can be supplemented with 20 % glycerol and stored at −80 °C (Yabe et al. 2012).

Ecology

Members of the *Phyllobacteriaceae* are versatile environmental bacteria that occur in diverse habitats that often are polluted or nutritionally rather rich. These habitats can be marine (*Aliihoeflea*, *Ahrensia*, *Aquamicrobium*, *Hoeflea*, *Lentilitoribacter*, *Nitratireductor*, *Pseudahrensia*) or polluted freshwater (*Pseudaminobacter*, *Aquamicrobium*, *Chelativorans*) systems, soil (*Aminobacter*, *Chelativorans*, *Mesorhizobium*, *Nitratireductor*, *Phyllobacterium*, *Thermovum*), or air (*Aquamicrobium*). Several genera are plant associated or associated with dinoflagellates or cyanobacteria (*Hoeflea*, *Mesorhizobium*, *Phyllobacterium*).

Aquamicrobium species have been isolated from diverse polluted environments (activated sludge, oil-polluted sediments, air/waste gas from poultry/animal rearing) and have degradative capabilities that may significantly contribute to the breakdown of pollutants: *Aquamicrobium defluvii* is able to degrade thiopene-2-carboxylate (Bambauer et al. 1998), *Aquamicrobium lusatiense* can utilize phenol and chlorophenols such as 4-chloro-2-methylphenol, 2,4-dichlorophenol, and 4-chlorophenol (Fritsche et al. 1999), and *Aquamicrobium aestuarii* was enriched from marine sediments using crude oil (Jin et al. 2013).

Chelativorans species have been found in municipal and industrial sludge samples and are able to degrade EDTA, a chelating agent with many applications that is generally recalcitrant to biodegradation. *Chelativorans multitrophicus and Chelativorans oligotrophicus* are able to use EDTA as sole carbon, nitrogen, and energy source, facultatively and obligately, respectively. They may have a significant role in the clearing of EDTA pollution in surface waters (Doronina et al. 2010).

Hoeflea phototrophica contains bacteriochlorophyll at reduced salt concentrations, but not at the concentration seawater (3.5 %); it also contains a carotenoid pigment thought to be spheroidenone and was found to contain *pufL* and *pufM* genes coding for proteins of the photosynthetic reaction center. However, *Hoeflea phototrophica* does not grow anaerobically in light or dark conditions, and conditions under which it may

live phototrophically have not been described in detail (Biebl et al. 2006).

Hoeflea siderophila is able to grow mixotrophically and organoheterotrophically. It is the only species of the genus that is capable of fac. chemolithotrophic growth through iron oxidation at neutral pH, in anaerobic conditions with nitrate or N_2O as terminal electron acceptor, and microaerobically with oxygen. It is one of the rare species that is capable of neutrophilic lithotrophic iron oxidation (Sorokina et al. 2012).

Mesorhizobium strains are soil bacteria that can, in the vicinity of a compatible legume host species, enter into a molecular dialogue with the plant, resulting in the formation of root nodules on the plant that can be occupied by the bacteria. The bacteria receive a safe habitat and food, while they in turn can fix atmospheric nitrogen and thus contribute to plant nutrition. Most *Mesorhizobium* species (29 of 30) have been described as symbiotic with various legume species (*Table 18.11*). The only species that was not obtained from nodules, *Mesorhizobium thiogangeticum* obtained through enrichment from the soil adjacent to the legume *Clitoria ternatea*, was not able to nodulate this host nor *Pisum sativum* or *Cicer arietinum* (Ghosh and Roy 2006). *Mesorhizobium* has occasionally also been reported from marine systems (Sfanos et al. 2005; Krick et al. 2007) and from aquatic microbial mats in Antarctica (Peeters et al. 2012).

Several *Phyllobacterium* species have been isolated from leaf or root nodules of plants and contribute to plant growth promotion (*Table 18.12*). For *Phyllobacterium myrsinacearum*, there is no direct evidence that it actively induces nodule formation in leaves. Nodulation has been confirmed for *Phyllobacterium trifolii* (Valverde et al. 2005),

Unspecified *Phyllobacterium* strains have also been reported from the rhizosphere of *Lotus* spp. (Oger et al. 2004), associated with roots in *Brassica napus* (Bertrand et al. 2001), as endophytes in *Ipomea batatas* (Khan and Doty 2009), and in root nodules of many legumes including *Dalbergia louvelii* (Rasolomampianina et al. 2005), *Lathyrus gmelinii* (Baymiev et al. 2011), *Acacia* sp. (Hoque et al. 2011), *Sophora alopecuroides* (Zhao et al. 2010), *Vicia* sp. (Lei et al. 2008), and *Ononis tridentata* (Rincon et al. 2008). They have also been found as free-living bacteria in water (Mergaert et al. 2001) and associated with unicellular organisms (Gonzalez-Bashan et al. 2000).

The possible symbiotic function of phyllobacteria is reported to be the production of plant growth hormones, protective antibacterial and antifungal activity (Lambert et al. 1990), phosphate solubilization (Chen et al. 2006), root hair elongation (Galland et al. 2012), and nitrogen fixation (Valverde et al. 2005).

Both *Pseudaminobacter* species have been isolated from polluted aquatic environments (Kämpfer et al. 1999). *Pseudaminobacter salicylatoxidans* can degrade substituted naphthalenesulfonates and substituted salicylates. One strain has also shown to be a facultative sulfur chemolithotroph that can oxidize $S_2O_3^{2-}$, $S_4O_6^{2-}$, SO_3^{2-}, S_2^{2-}, and S^0 directly to SO_4^{2-} without any intermediate formation (Ghosh and Dam 2009). In polluted oligotrophic aquatic systems, these bacteria may play an important role in biodegradation.

Thermovum is the only genus of the family that is thermophilic (maximum growth temperature 60 °C). It was isolated from mature compost; its role in the compost ecosystem is not documented (Yabe et al. 2012).

Pathogenicity, Clinical Relevance

Mesorhizobium amorphae has been reported as an amoeba-associated bacterium that may be involved in nosocomial pneumonia through contaminated water supplies (La Scola et al. 2003; Berger et al. 2006). As no recent reports confirming these observations were found, the significance of *Mesorhizobium amorphae* as a nosocomial pathogen is not clear. No other animal or human pathogens are among the current members of the *Phyllobacteriaceae*.

Many species, particularly of *Mesorhizobium* and *Phyllobacterium*, are plant endophytes, rhizoplane or rhizosphere bacteria that have plant beneficial effects (see next section below).

No plant pathogenic effects have been reported for most members of the family *Phyllobacteriaceae*. *Candidatus Liberibacter* is, however, a serious plant pathogen. It is included here, although the membership of this group is currently uncertain (see above under Sect. 1.2, "Phylogenetic Structure of the Family and Its Genera"). The trivial name "liberobacter" (*sic*) (from the Latin liber [bark] and bacter [bacteria]) was proposed in 1994 for a phloem-limited bacterium-like organism associated with citrus greening disease, also known as huanglongbing disease or yellow dragon disease, a severe and widespread citrus disease that is transmitted by the Asian citrus psyllid (*Diaphorina citri*) and the African citrus psyllid (*Trioza erytreae*) (Jagoueix et al. 1994). The disease causes yellowing and blotchy mottling of the leaves, production of bitter, small and misshapen fruits, and ultimately death of the tree (http://www.aphis.usda.gov/plant_health/plant_pest_info/). Two species, *Candidatus Liberibacter asiaticus* (originally Liberobacter asiaticum) and *Candidatus Liberibacter africanus* (originally Liberobacter africanum), were proposed for the Indian and South African liberibacters, respectively, which can be distinguished based on temperature sensitivity (in Africa symptoms occur only in cooler regions), serology, and genomic properties (Jagoueix et al. 1994). Garnier et al. (2000) corrected the spelling of the genus name and proposed a separate subspecies, *Candidatus Liberibacter africanus* subsp. capensis, for a South African liberibacter in the ornamental rutaceous tree, *Calodendrum capense*. The citrus disease was later also reported from Brazil, and the pathogen recognized as a new species, *Candidatus Liberibacter americanus*, spread by the vector *Diaphorina citri* (Texeira et al. 2005). Although the species epithet originally referred to the geographic occurrence of the group, *Candidatus Liberibacter asiaticus* has also been found in the Americas (Raddadi et al. 2011). In the USA, the Asian citrus psyllid,

Phyllobacterium myrsinacearum	Leaf nodules of *Pavetta zimmermannia*, *Ardisia crispa*, and *Ardisia crenata;* root surface of sugar beet	No nodulation data	Knösel 1984; Lambert et al. 1990; Mergaert et al. 2002
Phyllobacterium trifolii	*Trifolium pratense, Trifolium repens, Lupinus albus*	Nodulates *Trifolium pratense, Trifolium repens*, and *Lupinus albus*; nodD gene present	Valverde et al. 2005

Diaphorina citri, has been present in Florida since 1998, and *Candidatus Liberibacter asiaticus* was found in Florida in early September 2005. In 2010, the USDA imposed a plant quarantine in several states and territories in the USA to stop the spread of citrus greening (http://www.aphis.usda.gov/plant_health/plant_pest_info/). The disease was reported in South California in 2012 (www.californiacitrusthreat.com). The European and Mediterranean Plant Protection Organization (EPPO) has placed *Liberibacter africanus*, *Liberibacter asiaticus*, and *Liberibacter americanus* and the vector *Diaphorina citri* on its A1 list of pests recommended for regulation as quarantine pests. This list comprises pests regarded as absent from the EPPO region. The vector *Trioza erytreae* was included on the A2 List of pests recommended for regulation as quarantine pests that are locally present in the EPPO region.

Citrus huanglongbing disease is regarded as a pest of urgent phytosanitary concern for southern parts of the EPPO region where citrus is grown. Several PCR and real-time PCR tests have been developed for the detection of these *Candidatus Liberibacter* sp. in plants and in the psyllid vectors (Morgan et al. 2012 and references therein). To eliminate or suppress *Candidatus Liberibacter asiaticus*, a combination of penicillin and streptomycin administered by trunk injection or root soaking was shown to be effective in citrus plants (Zhang et al. 2011).

Several additional species have more recently been reported to affect *Solanaceae* plants. *Candidatus Liberibacter psyllaurous* is associated with psyllid yellows disease of potato (*Solanum tuberosum* L.) and tomato (*Solanum lycopersicum* L.) in North America and is transmitted by *Bactericera cockerelli* (Hansen et al. 2008). *Candidatus Liberibacter solanacearum* was reported from tomato, capsicum (*Capsicum annuum*), potato, tamarillo (*Solanum betaceum*), cape gooseberry (*Physalis peruviana*), and chilli (*Capsicum* sp.) from New Zealand; it is transmitted by the psyllid *Bactericera cockerelli*. It has also been detected in the USA in potatoes affected by zebra chip disease (Liefting et al. 2009). *Candidatus Liberibacter solanacearum* and its vector *Bactericera cockerelli* have been placed on the EPPO A1 and A2 lists, respectively, and are considered of particular concern for southern and central parts of the EPPO region and for areas with mild winters in the northern part (http://www.eppo.int/QUARANTINE/quarantine.htm).

Candidatus Liberibacter europaeus, the most recently described species, is the only one presently considered to be an endophyte rather than a plant pathogen. It was reported from Italy and is found in the midgut lumen, salivary glands, and Malpighian tubules of the pear psyllid pest *Cacopsylla pyri* and has been detected in pear plant tissue, both in laboratory-inoculated plants and in field-collected samples. However, the plants remained free of disease symptoms (Raddadi et al. 2011).

As the family *Phyllobacteriaceae* comprises many soil bacteria and other free-living bacteria, it is not surprising that many species show diverse resistance patterns to a number of antibiotics which they can be expected to encounter in their natural habitat. These characters can often be used for phenotypic differentiation and have therefore been included above in the Sect 3, "Phenotypic Analyses".

Application

Most strains of the genus *Mesorhizobium* are capable of nitrogen-fixing symbiosis in root nodules of legume plants, allowing the host plant to grow in soils with lower nitrogen content than other plants. Several agricultural crops, including chickpea

(*Cicer arietinum*), alfalfa or lucerne (*Medicago sativa*), and several *Lotus* species (Table 18.11), are nodulated by mesorhizobia, and these bacteria thus make an important contribution to the success of these crops. Interest to introduce new *Lotus* forage species in Australia has stimulated research into compatible *Mesorhizobium* strains (Howieson et al. 2011). *Mesorhizobium* strains are also important as symbionts of legume trees such as *Acacia* and *Prosopis* spp. used in tropical agroforestry systems (de Lajudie et al. 1998; Bala et al. 2003; Degefu et al. 2013).

In addition to symbiotic nitrogen fixation, several strains of *Mesorhizobium* and *Phyllobacterium* are recognized for other plant growth-promoting effects. Mesorhizobia can exert these effects by producing the plant hormone indole acetic acid or ammonia (Ahmad et al. 2008). *Mesorhizobium mediterraneum* PECA21 was shown to solubilize phosphorus from tricalcium phosphate and improve growth and phosphorus content in chickpea (Peix et al. 2001). *Mesorhizobium loti* MP6 was shown to increase yield and resistance to white rot (*Sclerotinia sclerotiorum*) in *Brassica campestris* in India (Chandra et al. 2007). Other strains are resistant to heavy metals (Maynaud et al. 2013). *Phyllobacterium brassicacearum* STM 196 was shown to promote the growth of oilseed rape and *Arabidopsis* and to stimulate root hair elongation possibly through activation of the ethylene signalling pathway (Mantelin et al. 2006a; Galland et al. 2012).

A strategy for the regeneration of disused mining site is through revegetation to allow sustainable plant cover to stabilize the site and limit wider environmental impact. In France, *Anthyllis vulneraria* is one of the legume species tolerant of these contaminated sites (Mahieu et al. 2011). It is nodulated by two members of the *Phyllobacteriaceae*: *Aminobacter anthyllidis* and *Mesorhizobium metallidurans.* Both species are tolerant to high concentrations of heavy metals and contribute through this symbiosis to the success of the legume species in the process of revegetation of contaminated sites (Vidal et al. 2009; Maynaud et al. 2012). The combined inoculation of legumes with plant growth-promoting rhizobacteria and *Mesorhizobium loti* strains that have the enzyme 1-aminocyclopropane-1-carboxylate (ACC) deaminase which hydrolyzes the precursor to the plant hormone ethylene was shown to have a synergistic positive effect on plant growth, nutrition, and adaptation to metal-polluted soils. The ACC-hydrolyzing bacteria eliminate the plant growth inhibition caused by increased ethylene production and can thus be valuable participants in the phytostabilization of contaminated mining sites (Safronova et al. 2012). In an application of the same mechanism, a strain of *Mesorhizobium ciceri* transformed to express exogenous ACC deaminase was shown to improve yields of chickpea and reduce susceptibility to root rot disease (Nascimento et al. 2012). One highly chromium-tolerant *Mesorhizobium* strain was shown to improve the yield and decrease chromium uptake in chickpea (Wani et al. 2008).

Aminobacter strains were reported to be responsible for the degradation of 2,6-dichlorobenzamide, a frequent groundwater pollutant that is a degradation product of the herbicide 2,6-dichlorobenzonitrile (dichlobenil). A specific PCR test targeting the 16S rRNA genes was designed to monitor the distribution of *Aminobacter* strains (Sjoholm et al. 2010). *Aminobacter aminovorans* strains previously classified as *Chelatobacter heintzii* are able to degrade nitrilotriacetate and EDTA (Auling et al. 1993; Nortemann 1999). *Chelativorans* species are also able to degrade EDTA and particularly *Chelativorans oligotrophicus* has been applied in biofilters to remove EDTA and EDTA-metal complexes (Kuvichkina et al. 2012; Kaparullina et al. 2012).

Pseudaminobacter strains have been investigated for use in bioremediation of soil contaminated with atrazine and one strain was reported to use as sole carbon and nitrogen source (Topp 2001). They have also been implicated in the degradation of methyl parathion (Zhang et al. 2005).

The salicylate 1,2-dioxygenase from *Pseudaminobacter salicylatoxidans* BN12T has been characterized extensively (Hintner et al. 2004; Matera et al. 2008; Ferraroni et al. 2012). A soil isolate very similar to *Pseudaminobacter salicylatoxidans* was shown to be a sulfur chemolithotroph (Bagchi et al. 2005; Mandal et al. 2007).

Abstract
Rhizobiaceae is a family of *Rhizobiales* order into *Alphaproteobacteria* class that presents genera associated with soil and planta hosts. *Rhizobium* is the type genus and encompasses the largest number of species into the family. Taxonomy is mostly supported by phylogenetic analyses based on 16S rRNA sequences and nomenclature in *Rhizobiaceae* is one issue that has caused much discussion. Bacteria are phenotypically heterogeneous, predominately aerobic, and Gram-negative rod-shaped. Many species present large plasmids which harbor a large proportion of genome generally including genes involved in interaction with specific hosts. Some members of the *Rhizobiaceae* family are characterized by their ability to establish symbiotic associations with host plants and develop the process of biological nitrogen fixation. In contrast, others are able to establish pathogenicity against plants. Both skills can be exploited for applied purposes. The selection of efficient strains from *Rhizobium* and *Ensifer* designed to plant inoculants is one of important research viewing the production of microbial inoculants to help plant development. Considering *Agrobacterium tumefaciens*, the management of its natural ability to transform plants is directed to obtaining disarmed strains and clone vectors widely applied to recombinant DNA technology and plant biotechnology. Finally, some genera in *Rhizobiaceae* family have intriguing metabolisms which allow degradation of potentially toxic molecules and thus could be applied as biomarkers or in bioremediation.

Taxonomy: Historical and Current

The family *Rhizobiaceae* Conn 1938 (order *Rhizobiales*, class *Alphaproteobacteria*) is composed of at least nine genera: *Rhizobium* (type genus), *Agrobacterium*, *Carbophilus*, *Chelatobacter*, *Ensifer*, *Sinorhizobium*, *Allorhizobium*, *Kaistia*, and *Shinella* (Conn 1938; Kuykendall 2005; Euzéby 1997; Parte 2014). Currently, the *Rhizobiaceae* taxonomy is based on 16S rRNA gene sequence analysis, and it is a phenotypically heterogeneous family of aerobic and Gram-negative, rod-shaped bacteria. The family included only four genera (*Rhizobium*, *Bradyrhizobium*, *Agrobacterium*, and *Phyllobacterium*) in the 1984 edition of *Bergey's Manual of Systematic Bacteriology*, and the separation of these genera was predominantly based on the ability to stimulate the production of root or leaf nodules in host plant species (Jordan 1984).

More recently, it became evident that the symbiotic trend and range of host plants are not closely and easily correlated with kinship based on phylogenetic comparisons of the ribosomal marker. It was particularly noted that *Rhizobium* and *Shinorhizobium* are more closely related to *Agrobacterium* and more distantly related to *Bradyrhizobium* (family *Bradyrhizobiaceae*—Garrity et al. 2005) and *Phyllobacterium* (family *Phyllobacteriaceae*—Mergaert and Swings 2006).

Studies on the microbiology and taxonomy of *Rhizobiaceae* began with the classical works of Hellriegel and Wilfarth (1988), who determined that microbes allowed some leguminous to obtain nitrogen from the atmosphere in their root nodules. Subsequently, Beijerinck (1888) isolated and cultured those bacteria, thereby confirming their role in the nitrogen fixation process. These bacteria were dubbed *Bacillus radicicola*. Finally, Frank (1889) changed the name of this bacterium species to *Rhizobium leguminosarum*, which became the type species for the genus *Rhizobium* (Willems 2006).

The original genus *Rhizobium* (from *rhiza*—*bios*: which lives in a root) underwent several subsequent changes in recent years, giving rise to many other taxa. Nodulation tests on host plants to determine cross-inoculation groups (Fred et al. 1932) were extensively used in the early twentieth century to identify and characterize bacteria belonging to this genus. Subsequently,

An erratum to this chapter can be found at
http://dx.doi.org/10.1007/978-3-642-30197-1_501

E. Rosenberg et al. (eds.), *The Prokaryotes – Alphaproteobacteria and Betaproteobacteria*, DOI 10.1007/978-3-642-30197-1_297,

starting in the second half of the century, traditional phenotypic methods were also applied to identify and characterize these bacteria, including analysis of colony morphology in culture medium; intrinsic antibiotic resistance; biochemical, metabolic and nutritional characteristics; bacteriophage susceptibility; and serological reactions (Graham 1963; Graham 1964; Moffet and Colwell 1968; Vincent and Humphrey 1970). Finally, simple characteristics based on DNA molecular analysis were added to the numerical taxonomic studies (De Ley and Rassel 1965; Somasegaran and Hoben 1994; Zakhia and de Lajudie 2001).

The systems of classification have acquired a phylogenetic nature because of the advancement of novel molecular biology techniques applied to taxonomic studies, particularly the development of the Polymerase Chain Reaction (PCR), DNA-DNA and DNA-RNA hybridization, G+C content determination, and the sequencing of genetic markers (Somasegaran and Hoben 1994; Albuquerque et al. 2009). Unlike the phenetic classification that groups organisms based on their phenotypic properties without considering their evolutionary course, phylogenetic taxonomy organizes taxa based on their ancestral evolutionary lineages. Even microorganisms that have evolved differently and are evolutionary distantly related may develop similar characteristics (Atlas 1997). As a result, there was a steady increase in the number of genera and species recognized as rhizobia and other soil bacteria (Graham et al. 1991; Bécquer 2004; Willems 2006; Zakhia and de Lajudie 2006).

The sequencing and analysis of the 16S rRNA gene has been one of the most important resources contributing to the phylogenetic diversity of *Rhizobiaceae*, as well as of any other bacterial group (Peter et al. 1996); however, in some cases, the data contrast those obtained using phenetic analysis. Phylogenetic studies led to a revision and dismemberment of the genus *Rhizobium* and its relatives of the class *Alpha-proteobacteria*. *Rhizobium*, *Agrobacterium*, and *Allorhizobium* (*Rhizobiaceae*) form more a closely related group (i.e., with a higher degree of kinship), whereas *Sinorhizobium* (*Rhizobiaceae*), *Bradyrhizobium* (*Bradyrhizobiaceae*), *Mesorhizobium* (*Phyllobacteriaceae*), and *Azorhizobium* (*Hyphomicrobiaceae*) form separate groups (Willems 2006).

A recent discussion of a proposal to incorporate the closely related (although phenotypically distinct) genera *Agrobacterium* and *Allorhizobium* exclusively into the genus *Rhizobium*, and *Sinorhizobium* into *Ensifer*, has caused a division in the scientific community (Young et al. 2001, 2003; Farrand et al. 2003; Willems et al. 2003; Tindall 2008; Young 2010). There also have been disagreements regarding whether the genera *Ensifer* and *Sinorhizobium* (*Fig. 19.1*) should belong to a single taxon. The subcommittee on the taxonomy of *Agrobacterium* and *Rhizobium* prioritizes the genus *Ensifer* (Lindström and Martinez-Romero 2002); however, this position also found no general support and required consideration by a Judicial Commission. Formally, the genera recognized in *Rhizobiaceae* are *Rhizobium, Ensifer, Carbophilus, Kaistia*, and *Shinella*. From the four genera and 10 species reported in 1984 (Jordan 1984), the more recent taxonomic studies in *Rhizobiaceae* led to a total of five genera and over 100 species being recognized (Euzéby 1997; Kuykendall 2005; Young 2010; Parte 2014).

The application of polyphasic taxonomy has had greatest impact of the various techniques for resolving the taxonomic uncertainties and defining the taxonomy of *Rhizobiaceae* and other families (Cardoso et al. 2012). The polyphasic classification is based on the combination of phenotypic data obtained by the various available methods, consistent with the phylogenetic classification using sequence data from 16S rRNA or 23S rRNA. The accepted consensus classification must have a minimum of contradictions (Vandamme et al. 1996). However, the conclusive certification of a new species relies on comparative genomics, which is currently easier to apply due to the expansion of whole genome sequencing projects.

Young (2013) conducted a survey of the nomenclature used in several publications from 1982 to 2012 for species related to the genus *Ensifer*. Due to the controversies that genus transfer have caused in the scientific community regarding the taxonomy and nomenclature of some bacterial species, terms designating synonymous, equivalent names, common names, and scientific names for bacteria remain (LPSN; Taxonomy Browser/NCBI; UniProtKB taxonomy). In this chapter, we chose to maintain the common name for some species.

Molecular Analyses

The *Rhizobiaceae* family contains a fast growing number of species that may be saprophytic or able to establish beneficial or deleterious plant interactions (Ferreira et al. 2011). Due the absence of phenotypic information to differentiate the rhizobial species, the identification of members of these families is mainly based on gene sequencing (Ferreira et al. 2011). Decades ago, gene sequencing was a very expensive and time-consuming method, and this fact was considered to be one of the major hurdles for the study of the *Rhizobiaceae* family at molecular level. Different approaches were used during the 1980s and 1990s, and along with biochemical assays, molecular techniques such as Multilocus Enzyme Electrophoresis (MLEE), DNA fingerprinting, and DNA-DNA hybridization were well employed for the identification and analysis of *Rhizobiaceae* members (Van Berkun et al. 1998). Even today, MLEE is still considered to be a marker with perfectly known Mendelian inheritance, which is applicable for multilocus analysis of most living organisms and can be applied at a reasonable cost (Tibayrenc 2009). Recently, these out-of-fashion techniques have been replaced by more sophisticated approaches, such as matrix-assisted laser desorption/ionization-time of flight (MALDI-TOF) mass spectrometry, and phylogeny based on gene sequencing. Indeed, molecular approaches, especially those that rely on PCR amplification and sequencing, provide outstanding advantages (Tibayrenc 2009). For instance, both multiplex PCR and recA-based PCR were used to assess the diversity of the *Rhizobium*/*Agrobacterium* species (Puławska et al. 2006; Shams et al. 2013).

Currently, with the development of next-generation sequencing instrumentation, phylogenetic analysis based on gene and genome sequencing is considered to be one of the most trustworthy methods to study the *Rhizobiaceae* family at

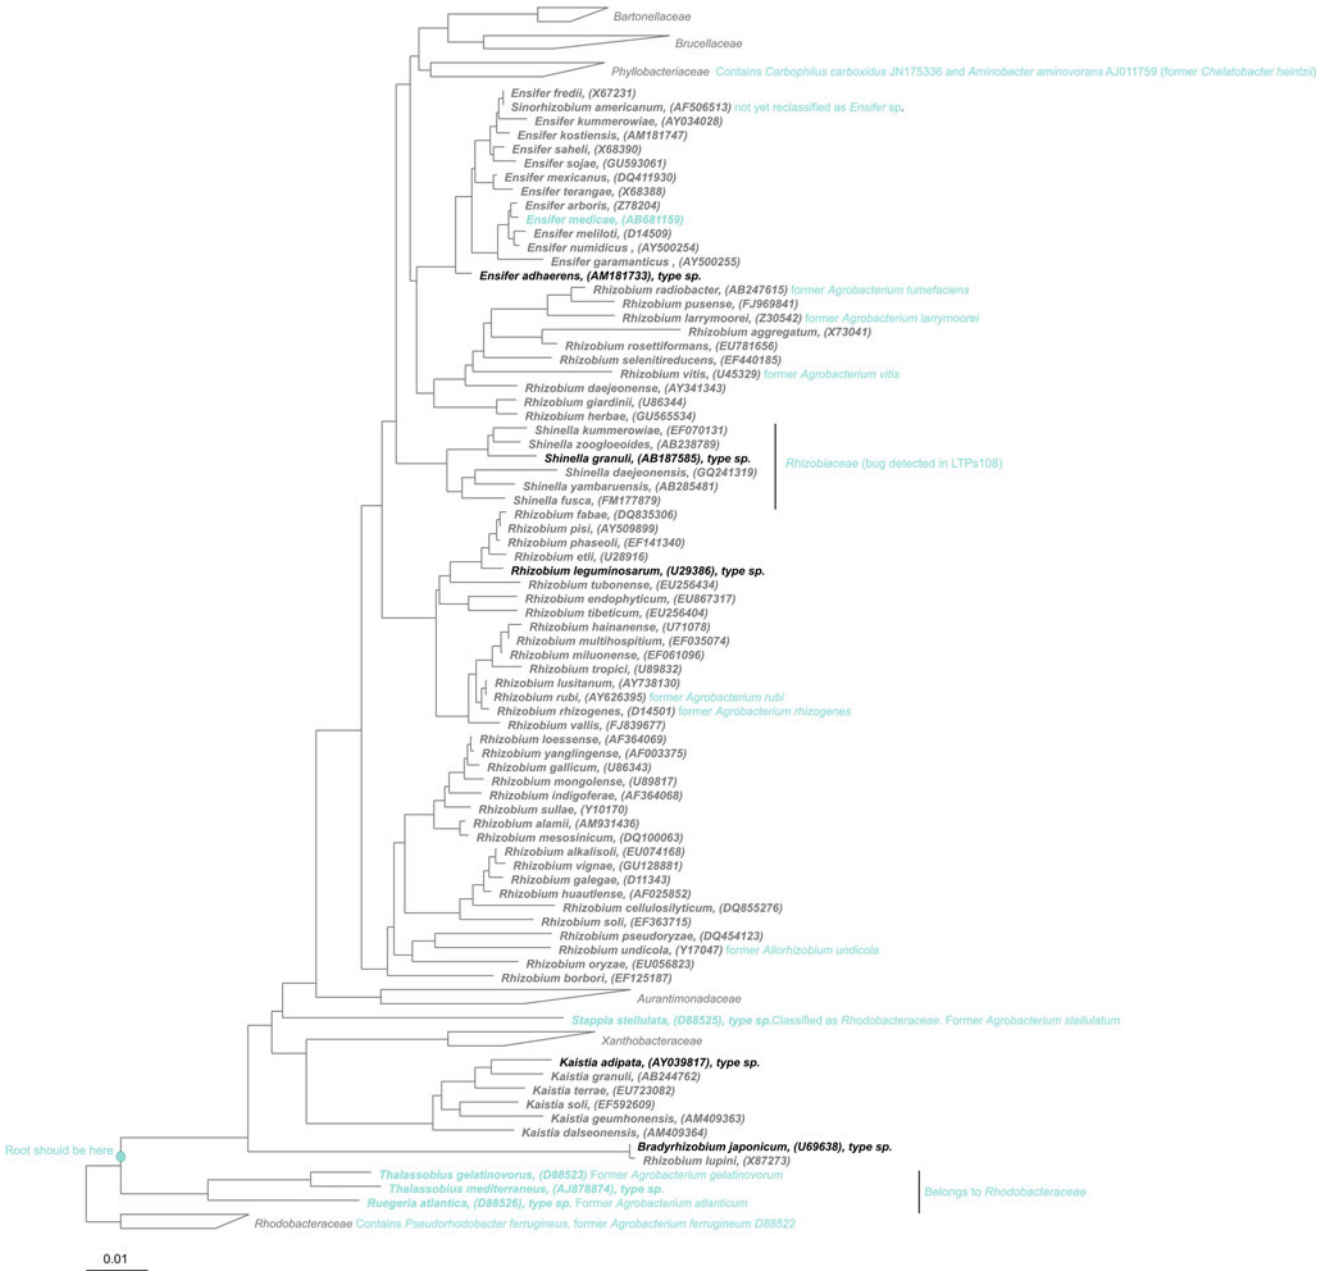

Fig. 19.1

Phylogenetic reconstruction of the family Rhizobiaceae based on 16S rRNA and created using the neighbor-joining algorithm with the Jukes–Cantor correction. The sequence datasets and alignments were used according to the All-Species Living Tree Project (LTP) database (Yarza et al. 2010, http://www.arb-silva.de/projects/living-tree). The tree topology was stabilized with the use of a representative set of nearly 750 high-quality type strain sequences proportionally distributed among the different bacterial and archaeal phyla. In addition, a 40 % maximum frequency filter was applied in order to remove hypervariable positions and potentially misplaced bases from the alignment. Scale bar indicates estimated sequence divergence

the molecular level. However, for wide population identification and classification, MALDI-TOF mass spectrometry is also considered to be a reliable and alternative method that yields similar results as those obtained using gene sequencing and phylogenetic analysis (Ferreira et al. 2011).

The employment of these different molecular techniques allowed for the identification of different *Rhizobiaceae* genera over the past several years. Indeed, the *Rhizobiaceae* diversity is vast, and the deluge of genomic data generated by different genome and environmental sequencing projects over the last 10 years has created new challenges for *Rhizobiaceae* researchers to analyze and classify both genus and species levels. Therefore, the identification, classification, and differentiation of the members of this family are still in progress. Different research groups interested in *Rhizobiaceae* biology are working to classify new members, and this often results in new arrangements in

the family classification. For instance, the family can be described in the literature as containing seven genera: *Rhizobium* and *Agrobacterium, Ensifer* and *Sinorhizobium, Carbophilus, Kaistia,* and *Shinella.* However, during the last decade, species have been arranged into five genera, *Rhizobium, Ensifer, Carbophilus, Kaistia*, and *Shinella* (Lin et al. 2008; An et al. 2006). The genera *Agrobacterium* and *Allorhizobium* are now included in the *Rhizobium* genus (Young et al. 2001), and *Sinorhizobium* is currently named *Ensifer* (Judicial Commission 2008; Young 2010).

In addition, for identification and classification purposes, genome sequencing has delivered many new insights about the biology of the family, particularly for the genome evolution and structure. For instance, genomic comparisons among sequenced strains using bioinformatics approaches indicated that the members of the *Rhizobiaceae* family have a diverse genomic structure and architecture. The number of replicons is varied, including single chromosomes, extrachromosomal replicons (ERs), and plasmids of various size (Slater et al. 2009).

Interestingly, a large proportion of the *Rhizobiaceae* genomes are located in the ERs (Althabegoiti et al. 2014). The ERs are represented in the genomic databases as a "second chromosome" or "megaplasmid." These carry a sufficient number of distinct and consistent properties that allow researchers to distinguish them from chromosomes and plasmids (Harrison et al. 2010). For instance, they carry essential genes for growth under most conditions, together with plasmid-type replication and partitioning systems. Moreover, these extrachromosomal replicons do not use a chromosome-type replication system, and the majority of their genes are genus-specific genes that confer accessory functions, such as pathogenesis, symbiosis, metabolism, and antibiotic resistance. Therefore, these secondary replicons are not chromosomes and should not be referred to as such (Harrison et al. 2010). Recently, it was suggested that the term "chromid" or "ER" be used to distinguish them from the chromosomes and plasmids (Harrison et al. 2010; López-Guerrero et al. 2012).

The chromids/ERs are often found in the *Rhizobium/Agrobacterium* and *Ensifer/Sinorhizobium* genomes, and they represent at least half of these genomes (López-Guerrero et al. 2012; Althabegoiti et al. 2014). Interestingly, some of the nodulation and nitrogen fixation genes may reside in these chromids (Harrison et al. 2010; Althabegoiti et al. 2014). Another remarkable feature is that the chromid-carrying bacteria from the genus *Rhizobium/Agrobacterium* and *Ensifer/Sinorhizobium* are able to grow faster in culture than those that do not carry chromids (Harrison et al. 2010).

In contrast to the diversity provided by the chromids/ERs, important genetic mechanisms are also observed and considered to be key agents for the diversity of the *Rhizobiaceae* genomes. Their large capacity to adapt to different plant hosts may be an indicator of the acquisition of fitness genes via lateral gene transfer (Martínez-Romero 2009). In particular, it is proposed that the *Rhizobiaceae* nodulation ability originated recently during the coevolution with the plant hosts and other rhizobia populations (Martínez-Romero 2009; Provorov and Vorobyov 2008). This fact suggests that lateral gene transfer has a key role in this process. Indeed, some of the symbiotic islands that are common in the chromosome, chromids/ERs, and plasmids have a different evolutionary history than the chromosomal "core" genome, which is a clear indication that these genes were acquired by lateral transfer events (Martínez-Romero 2009).

Aside from the diverse genomic structure and architecture caused by lateral gene transfer and by the presence of chromids/ERs observed in the *Rhizobiaceae* family, genome sequencing and its associated bioinformatics tools have also yielded important insights regarding the biology of the group. Indeed, whole genome sequencing is an important tool that is used to explore the biology of many life forms on Earth. For instance, the atrazine-degrading genes (atzABC and trzD) of *Chelatobacter* are located on three plasmids with sizes varying from 44 to 178 kb. Moreover, the atzABC and trzD genes are located in the vicinity of Insertion Sequences (ISs). These ISs are transposons that facilitate the spread of the atrazine catabolic genes via the lateral gene transfer and enhance the degradation of atrazine between members of the soil microbial community (Rousseaux et al. 2002).

In addition, several different species of the genus *Rhizobium/Agrobacterium* and *Ensifer/Sinorhizobium* were already partially and fully sequenced according both the GenBank and Genomes Online databases (Pagani et al. 2012). Genomic information is accumulating on the public databases, and our knowledge regarding the biology of the family is increasing each year. For instance, the *Rhizobium leguminosarum* is subdivided into biovars that nodulate peas and common beans (biovar viciae), clovers (biovar trifolii), or kidney beans (biovar phaseoli) (Young et al. 2006). These biovars are closely related based on DNA-DNA reassociation experiments that determined that the level of DNA relatedness among these strains varies between 58 % and 67 % (Berkum et al. 1996). Currently, the GenBank database accounts for up to 39 draft genomes, whereas 14 are represented by biovar trifoli and viciae and only one is from biovar phaseoli. Moreover, three *R. leguminosarum* genomes were already fully sequenced, whereas two and one are from the *trifolii* and *viciae* biovars, respectively (Young et al. 2006; Reeve et al. 2010). The *trifolii* biovars were isolated from Mediterranean and South America clovers, whereas the viciae were isolated from peas from the United Kingdom (Young et al. 2006; Reeve et al. 2010). Interestingly, all fully sequenced strains bear more than three copies of distinct plasmids, corroborating previous observations that indicated that at least three different plasmids are necessary to carry the genes necessary for symbiosis (Hynes and McGregor 1990).

A survey on the genome structure and architecture of the *R. leguminosarum* bv. viciae strain 3841 (Rlv3841) has determined a genome of 7.75 Mb that is composed of six large plasmids in addition to a large chromosome, with 61 % of G+C overall (Young et al. 2006). The whole genome encodes for a total of 7,263 genes, and the essential protein-encoding genes, such as the housekeeping genes, all three rRNA operons, and 52 tRNA genes, are mainly located on the large chromosome

(Young et al. 2006). Moreover, the Rlv3841 genome has two main components: a "core," which is higher in G+C content, is mostly chromosomal, and shares at least 2,056 genes with closely related organisms such as *A. tumefaciens*, and an "accessory" component composed of 90 % of the 7,263 genes and is not universally shared even among closely related species, is lower in G+C content, and has a sporadic distribution along the plasmids and chromosomal islands (Young et al. 2006). Several of these genomic islands are flanked by tRNA genes, suggesting that they may be mobile elements that target tRNA genes (Young et al. 2006). That observation has also been described for other symbiosis islands located in the genome of the closely related *M. loti* from the *Phyllobacteriaceae* family (Kaneko et al. 2000) and in many genomic and pathogenicity islands identified in other bacteria genera (Young et al. 2006). In summary, the "accessory" genes include mobile genetic elements, such as phages and transposons and the most well-known symbiosis-related genes. Young and collaborators (2006) proposed that these "accessory" genomes hold the key to unraveling bacterial adaptation and specialization. Indeed, lateral gene transfer is a key agent for *Rhizobium*/*Agrobacterium* and *Ensifer*/*Sinorhizobium* genome evolution.

In a second survey, the soil-borne and biotroph pathogen *A. tumefaciens* (currently named as *R. radiobacter*) was found to alter the physiology and morphology of infected host plants, causing crown gall disease (Wood et al. 2001). Over the last decade, plant scientists have disclosed an impressive portfolio of agrobacterial infection strategies, and the plant defense mechanisms counteracting these strategies are equally diverse and impressive (Pitzschke 2013). The genomic research employed to study the biology of *A. tumefaciens* led scientists to develop "disarmed" *Agrobacterium* strains with the aim of creating efficient delivery systems for the genetic manipulation of plants (Pitzschke 2013). This manipulation has been vastly explored in the development of modern plant genetics and agricultural biotechnology as a means of inserting foreign genes into plants (see section "Application").

Genomes from all three *Agrobacterium* biovars are now available (Slater et al. 2009): the genomes of the biovar I strain *A. tumefaciens* C58; *Agrobacterium radiobacter* K84, an avirulent biovar II strain; and *A. vitis* S4 (S4), a virulent biovar III strain (Slater et al. 2009). According the genomic databases, the genome size varies from 5.67 Mb (C58) to 7.27 Mb (K84), encoding from 5,385 to 6,752 genes and containing an overall 59 % G + C content (Slater et al. 2009). Moreover, the genome replicon compositions also vary between the biovars. The C58 genome consists of a circular chromosome I, a linear chromosome II, and two plasmids, whereas both the K84 and S4 genomes consist of two circular chromosomes (I and II) in addition to four and five plasmids, respectively (Slater et al. 2009).

Recent studies have shown that chromosome II of C58 and S4 and the 2.65-Mbp megaplasmid of K84 originated from intragenomic transfers from primary chromosomes to ancestral plasmids, whereas large blocks of DNA, including rRNA operons and other essential genes, have transferred from the chromosome I (Slater et al. 2009). Although they share a common origin and common properties, these three replicons are indeed chromids/ERs by the definition criteria (Slater et al. 2009; Harrison et al. 2010). The only differences between these chromids/ERs are that the K84 chromid does not have any ribosomal RNA genes (Harrison et al. 2010). In contrast, the virulence and inter-kingdom gene transfer capability is encoded in the transfer DNA (T-DNA) region, which is carried by the tumor-inducing (Ti) plasmid (Pitzschke 2013). The virulence proteins carried by the T-DNA regions include VirD2, VirE2, VirE3, VirD5, and VirF, and they are inserted in the host cell using a type IV secretion system (Pitzschke 2013; Cascales and Christie 2003). Another remarkable genomic feature found in the genomes of *Agrobacterium* biovars are the genomic islands, which are spread throughout the genome replicons (Slater et al. 2009). These islands are common associates of transposases and phage-related genes (Varani et al. 2013). Along with these islands, at least six and nine regions resemble events of prophage infection in C58 and S4, respectively (Varani et al. 2013). In addition, the chromids/ERs have a nucleotide composition close to that of chromosome I (Harrison et al. 2010), whereas the genomic islands and prophages have a variable nucleotide composition similar to that of the chromosome (Varani et al. 2013). Interestingly, the sequenced genomes from the *Ensifer*/*Sinorhizobium* group follow the trends observed in the *Rhizobium*/*Agrobacterium* group. They are composed of a diverse number of replicons, including the chromosome, chromids/ERs, and plasmids (Harrison et al. 2010).

In summary, this section/topic described the molecular aspects employed to identify and classify the *Rhizobiaceae* family over the last several decades; in particular, the advancements made by new techniques related to gene and genome sequencing were noted, and the main discoveries in the biology of the *Rhizobiaceae* family that were found using genome sequencing were explored. Both gene and genome sequencing have shown that plant—rhizobium interactions are directly related to and dependent on the genome constitution, structure, and architecture. The bacterial chromid/ER gene constitution and the impact and effects of lateral gene transfer in the chromosome, chromids/ERs, and plasmids are the main features of *Rhizobiaceae* genomes, and these topics are currently being explored by the scientific community.

Phenotypic Analyses

The family *Rhizobiaceae* has been described in the literature as consisting of nine genera: *Rhizobium, Agrobacterium, Allorhizobium, Ensifer, Sinorhizobium, Carbophilus, Kaistia, Shinella*, and *Chelatobacter*. However, during the last decade, species were arranged into seven genera: *Rhizobium, Ensifer, Carbophilus, Kaistia, Shinella, Allorhizobium, and Chelatobacter* (Lin et al. 2008; An et al. 2006). The genus *Agrobacterium* is now included in genus *Rhizobium* (Young et al. 2001), and *Sinorhizobium* is currently named *Ensifer* (Judicial Commission 2008; Young 2010). The genera *Allorhizobium* and *Chelatobacter*

have been proposed to be in *Rhizobium* and *Aminobacter*, respectively (Young et al. 2001; Kampfer et al. 2002). However, the International Committee on Systematics of Prokaryotes did not recognize this reclassification. Thus, we will present the biochemical, morphological, and microbiological characteristics of the seven genera formerly belonging to *Rhizobiaceae*, considering that two of them are currently formed by the fusion of two genera (Table 19.1). This topic will be covered due to several controversies regarding this new classification and to properly encourage the reader to compare the genera through these traditional approaches.

The identification of members of the family *Rhizobiaceae* is necessarily based on gene sequencing because there is no phenotypic information that allows the differentiation and identification of rhizobial species. This family is currently composed of fast-growing species of bacteria that may be saprophytic or able to establish beneficial or deleterious plant interactions. The vast majority of species were isolated from soil or plant tissues and are Gram-negative, aerobic bacteria, exhibiting the morphological, biochemical, and microbiological characteristics briefly described in Table 19.2, which were mostly obtained from Kuykendall (2005).

The bacteria within the *Rhizobium/Agrobacterium* cluster, despite different opinions (Farrand et al. 2003), are officially classified in the genus *Rhizobium*, regardless of their symbiotic characteristics or rhizogenic or tumorigenic ability. These species are rod-shaped, and their sizes range from 0.5 to 1.0 μm in width and from 1.5 to 3.0 μm in length.

Rhizobium species exhibit a Y shape when they are present in the root nodules of leguminous, but they form colonies in medium containing Congo Red assuming the traditional normal rod-shaped. All species from the genus are motile by polar or peritrichous flagella and produce copious water-soluble exopolysaccharide gum. This component has an important role during the development process of nodules in the roots of leguminous plants (Masson-Boivin et al. 2009). The colony is similar between the species, as is the cultivation temperature and optimal pH for development; in this respect, the symbiotic species demonstrate resistance to a broader pH range (pH 4–10). Species previously classified as *Rhizobium* contain poly-β-hydroxybutyrate granules, and the pathogenic *Agrobacterium* form cellulose fibrils during their attachment to plants in vitro. The DNA C+G content of the species of the two groups classified as belonging to the genus *Rhizobium* is similar, ranging from 57 % to 66 %.

Species of the *Rhizobium/Agrobacterium* cluster use a large variety of carbohydrates and salts from organic acids as their carbon source and use ammonium salts, nitrate, and several amino acids as their nitrogen source (Kuykendall 2005). These bacteria are not able to perform carbon assimilation; however, the *Rhizobium* fix nitrogen in symbiosis with leguminous plants. In culture, there is a single difference between strains of *Rhizobium* and *Agrobacterium*: the former does not grow in medium with 2 % NaCl, while the latter tolerate this salt concentration. In addition, *Agrobacterium* species are capable of growing under anaerobic conditions in the presence of nitrate or under reduced oxygen stress in plants.

A revision accepting the inferred phylogeny of the taxon that takes account the supporting phenotypic data, which show *Allorhizobium undicola* to be indistinguishable from *Rhizobium*, would have this species included in the genus *Rhizobium*. Although both perform symbiotic nitrogen fixation, these two genera have both similar and distinct characteristics (Table 19.2). De Lajudie et al. (1998) considered the *Neptunia* isolate (*A. undicula*) to be a separate genus because it had some phenotypic and genotypic characteristics that were distinct from *R. leguminosarum*. However, there are no single or multiple phenotypic characteristics reported in the generic circumscriptions of *Rhizobium*, *Agrobacterium*, *Allorhizobium*, or *Sinorhizobium* (other nitrogen fixation bacterium in this family) by which these taxa, as genera, can be differentiated. The taxonomy of rhizobia, which are bacteria capable of nodulating leguminous plants, has changed considerably over the last 25 years and needs to be defined.

Another group with controversial classification is the genus *Ensifer*. This genus is composed of two old genera, the *Ensifer* and the *Sinorhizobium* (Table 19.1). The morphological, biochemical, and microbiological characteristics of these bacteria are separated in Table 19.2 to help the reader observe why there are disagreements with the classification of this bacterium genus. When the characteristics of these two groups of bacteria are compared, we can conclude that none of them are similar between previously classified *Ensifer* and *Sinorhizobium* microorganisms.

Ensifer have important features (Table 19.2), including cell division by budding at one pole, asymmetric polar growth, and binary fission; the mother and daughter cells are the same size or the latter are slightly smaller. The cells have a length of approximately 1–2 μm and form a large and grayish-white colony (10–15 mm), and a film and/or sediment can be observed in broth medium. A bar of darkly stained material is visible using electron microscopy; its chemical composition has not been determined, and it extends between the bacteria and its host (Casida 1982 to see images). The *Ensifer* attaches end-wise to various Gram-negative and Gram-positive host bacteria and causes lysis; however, it is not an obligate predator.

On the other hand, the *Sinorhizobium* group is composed of rods that are up to 3 μm in length, and they form colonies that are 2–4 mm diameter and grow quickly (high turbidity) in aerobic or agitated broth. These bacteria have strains that can tolerate temperatures from 10 °C to 44 °C and a pH of 10.5 and can grow in YM medium with 1–4.5 % NaCl. The organisms are able to form nodules in the roots of temperate-zone and tropical-zone leguminous plants and fix nitrogen as a microsymbiont cell, with pleomorphic forms and named bacteroides. Using phenotypic characteristics, the *Sinorhizobium* bacteria have not been distinguished from the genus *Rhizobium*. Instead, researchers use the quantitative fatty acid composition differences of and 16S rDNA sequences (Tighe et al. 2000). Recently, the sequenced genome of the *E. medicae* strain WSM419 demonstrated higher similarity between 16S rRNA gene sequences between strains from *E. meliloti* and *E. fredii* than with other related species of *Bradyrhizobium*, *Mesorhizobium*, and *Rhizobium* (Reeve et al. 2010).

Table 19.1

Type Species of *Rhizobiaceae* family and local of isolation

Genera	[a]*Rhizobium/Agrobacterium* group		*Allorhizobium*	[b]*Ensifer/Sinorhizobium* group		*Carbophilus*	*Kaistia*	*Shinella*	*Chelatobacter*
	Rhizobium	*Agrobacterium*		*Ensifer*	*Sinorhizobium*				
Reference	Frank 1889	Smith and Townsend 1907; Young et al. 1978	De Lajudie et al. 1998 and Young et al. 2001	Casida 1982	Scholla and Elkan 1984 and Chen et al. 1988	Meyer et al. 1993	Im et al. 2004	An et al. 2006	Auling et al. 1993 and Kampfer et al. 2002
Type species	*R. leguminosarum*	*A. tumefaciens*	*A. undicola*	*E. adhaerens*	*S. fredii*	*C. carboxidus*	*K. adipata*	*S. granuli*	*C. heintzii*
Number of species[c]	70	11	1	14	11	1	8	6	1
Origin	Soil or nodule from root nodules of leguminous plants	Soil and crown gall tissues	Isolates from *Neptunia natans*, an indigenous stem nodulated tropical legume found in waterlogged areas	Isolated from soil where had a predatory activity in indigenous gram-negative bacterium	Soil and root nodules of leguminous plants	Garden soil at the city of Moscow	Soil sample collected in an industrial stream	Isolated from an upflow anaerobic sludge blanket reactor	Soil

[a]The type species of *Agrobacterium* was transferred to *Rhizobium* by Young et al. (2001). Consequently, the genus *Agrobacterium* would be included in the genus *Rhizobium*. However, this transfer is highly controversial (Farrand et al. 2003; Young et al. 2003)

[b]"In response to a Request for an Opinion, the Judicial Commission (Opinion 84) confirmed the earlier synonym, *Ensifer*, as the correct name for the genus better known as *Sinorhizobium*. The Judicial Commission considered that this decision would not cause sufficient confusion to justify the conservation of the latter name. The Subcommittee on the Taxonomy of *Agrobacterium* and *Rhizobium* of the International Committee on Systematics of Prokaryotes (ICSP) publicly disagreed with this conclusion" (Young 2010)

[c]Number of species cited in the List of Prokaryotic names with Standing in Nomenclature (http://www.bacterio.net/index.html)

Table 19.2

Morphological, microbiological, biochemistry and molecular characteristics of type species from genera of *Rhizobiaceae*

Genera	*Rhizobium/Agrobacterium cluster*		*Allorhizobium*	*Ensifer/Sinorhizobium cluster*		*Carbophilus*	*Kaistia*	*Shinella*	*Chelatobacter*
	Rhizobium	*Agrobacterium*		*Ensifer*	*Sinorhizobium*				
Morphology	Rods (0.5–1.0 × 1.2–3.0 μm). Withe colonies on YMA agar plate with 0.025 % Congo Red	Rods, single or pair (0.6–1.0 × 1.5–3.0 μm)	Rods (0.5–0.7 pm × 2.0–4.0 μm)	Rods, single or pair (0.7–1.1 × 1.0–1.9 μm). Cell division is by budding at one pole, asymmetric polar growth and binary fission	Rods pleomorphics under adverse growth conditions (0.5–1.0 × 1.2–3.0 μm)	Rod-shaped (0.7–0.9 × 0.9–1.7 μm)	Short rod to coccus-shaped bacterium. 0.7–0.9 mm long	Rod-shaped (0.2–0.5 × 4.0–6.0 μm)	Rod with rounded ends (0.7–0.9 × 1.0–2.0 μm). Pleomorphic, L-, Y- or X-shapedCells occur singly
Special internal structures, storage and important compounds	Poly-β-hydroxybutyrate and water-soluble extracellular polysaccharide	Copious extracellular polysaccharide slime. Cellulose-containing fibrils are formed by pathogenic strains during their attachment to plant cell, in vitro	Produce extracellular polysaccharide	A bar of darkly stained material is visible by electron microscopy, between this bacteria and its hosts	Poly-β-hydroxybutyrate granules in older cells. Produce copious extracellular polysaccharide slime in carbohydrate medium	None	None	None	All isolates exhibit an outer membrane closely associated with the underlying murein layer
Motility	Motile (1 or 2 polar flagella or 1–6 peritrichous flagella)	Motile (1 or 4 peritrichous flagella)	Motile (subpolar or peritrichous flagella)	Motile (tuft of 3–5 subpolar flagella)	Motile (1 polar or sub-polar flagellum or 1–6 peritrichous flagella)	Motility variable, whem present is by mean of 5 peritrichous flagella (maximal in late exponential growth phase)	Non-motile	Motility by multiple polar flagella	Motile (2 or 3 subpolar flagella)
DNA G+C %	57.0–66.0	57.0–63.0	60	63	57–66	63.8	67.4	64–66	62–63
Colony size, appearance and color	2–4 mm diameter (3–5 days incubation). Colony is circular, and convex, opaque or semi-translucent, white or beige	Colony is convex, circular, smooth, nonpigmented to light beige	0.5–3 mm diameter (1–2 days on YMA). Colonies are round, creamy, convex to drop-like, beige coloured; margin and surface have a smooth aspect	10–15 mm diam (6 days incubation on heart infusion agar diluted 10 times), Colony is grayish white, circular with undulated margins, convex, slimy, moist and opaque. Pelicule and sediment can be observed in broth medium	2–4 mm diameter (3–5days incubation) and pronounced turbidity after 2–3 days on aerated or agitated broth. Colonies are white, circular, convex, usually opaque (some translucent), raised, and mucilaginous	White to cream colored colony	Ivory-pigmented and round, raised with greasy surface	Amorphous or finger-like flocculent growth occurs in liquid media	2–3 mm (4–5 days incubation on PCA medium). Round and smooth, beige-brown colony. The colony morphology can change in different medium
Optimal temperature	25–30 °C (maximum growth temperature 38 °C)	25–28 °C (not grow above 30 °C)	28 °C	27 °C (range 20–37 °C)	25–30 °C optimal, same species can tolerate 10 °C, 35 °C, 42–44 °C	30 °C	10–37° (optimal 37 °C) not grow at 42 °C	4–40 °C	30 °C and 37 °C, but does not occur at 42 °C
Optimal pH	6–7 (range 4–10)	7.1 (range 5–9)	Not determined	6.0–7.0	6.0–8.0 optimal, same strains can grow at pH 5.0 and others tolerate pH10.5	Not determined	6.0–7.0	pH 6–10	pH 6.0–8.0

Metabolic and cultural characteristics	Aerobic	Aerobic some strains are capable of anaerobic in presence of nitrate and most strains are able to growth under reduced oxygen tension in plant	Aerobic, Chemoorganotrophic	Aerobic with oxidative metabolism of glucose and galactose	Aerobic, with the oxygen as a terminal electron acceptor	Aerobic, with the oxygen as a terminal electron acceptor	Aerobic. Chemoorganotrophic. This strain was resistant to 1 mM phenol and 4-chlorophenol concentrations for 1 week culturing	Aerobic and Grows in 1–4 % NaCl	Aerobic. Metabolism is strictly respiratory and not fermentative
	Chemoorganotrophic	Grows in medium with 2 % NaCl	Pronounces turbidity after 1–2 days in agitated yeast mannitol mineral salts broth	Chemoorganotrophic. Tthe growth is inhibited in 4 % but not in 2.5 % of NaCl. Definite but slow grow on soil extract agar	Chemoorganotrophic, Tolerate 1 % NaCl and some strains grow on YM medium with 4.5 % NaCl	Facultatively Chemolithoautotrophic			Grow in presence of 1 % NaCl and no grow occurred with 10 %
	Not grows in medium with 2 % NaCl								
Main carbon source	Use wide range of carbohydrate and salts of organic acids as a carbon source	Use wide range of carbohydrate and salts of organic acids as a carbon source	Use some carbohydrates, organic acids and amino acids that can be discriminatory to the specie	Utilizes a variety of organic carbon sources	Several carbohydrates and salts of organic acids as a carbon source	Use several salts of organic acids (except citrate), amino acids, sugars and sugars alcohol	Utilized a broad spectrum of carbon sources	Several carbohydrates, organic acids and some amino acids as a carbon source	Grow abundantly in nutrient broth and peptone, yeast extract, glucose broth. Can use nitriloacetate as a unic source of carbon, energy and nitrogen
Main nitrogen source	Ammonium salts, nitrate and amino acids	Ammonium salts, nitrate and amino acids	Not determined	Nitrite and nitrate are reduced	Ammonium salts, nitrate, nitrite and most of amino acids	Ammonia, Hydroxyamine, nitrate and urea	Not determined	Not determined	Ammonia, nitrate, urea and peptone
N_2 fixation	In root nodules the bacteria occurs as a entophytic, bacteroides, which reduced or fix atmospheric nitrogen that can be used by the plant	No	In root nodules the bacteria occurs as a entophytic, bacteroides, which reduced or fix atmospheric nitrogen, is host specific	No	Yes in symbiosis with temperate-zone and tropical-zone leguminous plant	No	No	No	No
C assimilation	No	No	No	No	No	Yes, CO as a energy source and CO_2 as a carbon source with H_2. (Cypionka et al. 1980)	No, reduces nitrate to nitrite	No	No
Biological characteristics	All species induced hypertrophisms in plant root nodules with or without symbiotic nitrogen fixation	Strains of some species invade the crown, roots and stems of a great variety of plants causing transformation of the plant and autonomously proliferating tumor cells	Induce nitrogen-fixing nodules on their original host *N. natans* and can also nodulate *M. sativa* and other tropical-zone leguminous plants	Attaches end-wise to various gram-negative and gram-positive host bacteria and causes lysis	Form nodules in root of leguminous plant and fix nitrogen as a microsymbiont cell	The type specie is isolated from the soil, it's only bacteria that can oxidizing CO that has the inability to growth on H_2 and CO_2 chemolhitoautotrophic conditions	Bacteria resistant to phenolic compounds	Isolated from an upflow anaerobic sludge blanket reactor	A nitrilotriacetate-utilizing organism

The genus *Carbophilus* is represented by a unique species, *C. carboxidus*. This bacterium was isolated from the soil near a stream in Moscow, Russia. This species was originally named *Achromobacter carboxydus* and later *Alcaligenes carboxydus*, as described by Meyer (2005). *C. carboxidus* is able to grow with CO as the energy source and CO_2 as the carbon source under aerobic chemolithotrophic conditions. This species is separated from the other aerobic carboxidotrophic bacteria (*Oligotropha*, *Bradyrhizobium*, and *Zavarzia*) because it cannot grow chemolithotrophically on H_2 and CO_2. This bacterium species is rod-shaped and has variable motility. It displays white- to cream-colored colonies and uses several organic molecules as a carbon source (except citrate). Ammonia, hydroxylamine, and nitrate can be used as a nitrogen source, and it cannot fix dinitrogen. The optimal pH and the tolerance to pH have not been determined.

The other two genera from the *Rhizobiaceae* family are *Kastia* and *Shinella*, described by Im et al. (2004) and An et al. (2006), respectively. *Kastia* is a genus that includes strains such as *K. adipata*, a bacterium isolated from soil samples collected in an industrial stream near an industrial complex in Korea. This bacterium could not degrade phenolic compounds but instead was resistant to such compounds. The cells are rod- and cocci-shaped with sizes varying from 0.7 to 0.9 mm long. Colonies formed on a nutrient agar plate are ivory-pigmented, round, and raised with a greasy surface. The cells are non-motile and can grow at 10–37 °C but not at 42 °C. The optimum temperature for growth is 37 °C at a pH of 6–7. They grow aerobically and utilize a broad spectrum of carbon sources such as mannitol, D-glucose, salicin, D-melibiose, L-fucose, D-sorbitol, L-arabinose, 2-ketogluconate, L-proline, rhamnose, *N*-acetyl-glucosamine, D-ribose, inositol, D-sucrose, maltose, lactate, L-alanine, 5-ketogluconate, glycogen, and mannose. This species also reduces nitrate to nitrite.

Shinella is a genus of motile rods characterized by an amorphous or finger-like flocculent growth in liquid media. The type species is *Shinella granuli* (An et al. 2006). These cells are 0.2–0.5 μm in width and 4–6 μm in length. Colonies on R2A agar media are glistening, convex with an entire margin, viscous, and pale yellow. Growth occurs at 4–40 °C, with 1–4 % NaCl and at pH 6–10. The bacteria use several carbohydrates, organic acids, and some amino acids as a carbon source and can perform nitrate reduction. The genus *Shinella* comprises six recognized species: *S. granuli* and *S. zoogloeoides* (An et al. 2006), *S. kummerowiae* (Lin et al. 2008), *S. yambaruensis* (Matsui et al. 2009) and *S. fusca* (Vaz-Moreira et al. 2010), and *S. daejeonensis* (Lee et al. 2011). These species have been isolated from a variety of locations including an upflow anaerobic sludge blanket reactor, sewage treatment systems, root nodules of herbal legumes, soil with sulfur, kitchen refuse compost, and the sludge from a leachate treatment plant. Furthermore, they have several characteristics that permit their use in biotechnological applications.

The genus *Chelatobacter* is another controversial genus in the *Rhizobiaceae* family. At first, this genus was composed of a single species, *Chelatobacter heintzii*. This species was classified as a new genus in the *Rhizobiaceae* family (Auling et al. 1993) based on its cell and colony morphology; cultural, nutritional, and physiological characteristics; and some biochemical components (ubiquinone Q-10 and polyamines patterns). *Chelatobacter heintzii*, which was described as a nitrilotriacetate-utilizing organism, was re-investigated, and on the basis of 16S rDNA sequence comparisons, this species clusters phylogenetically with species of the genus *Aminobacter*. The fatty acid patterns, polar lipid profiles, polyamine patterns, quinone system, and DNA–DNA similarity studies supported this placement (Kampfer et al. 2002). The name *Chelatobacter heintzii* is considered to be synonymous with Aminobacter aminovorans (Notification List IJSEM 2002).

The most important feature of *Chelatobacter* is its ability to grow with the metal-chelating aminopolycarboxylic acid nitrilotriacetic acid (NTA) as the sole source of carbon, energy, and nitrogen. Another interesting characteristic of this genus is the colony morphology and growth in different media. On PCA media, *Chelatobacter* exhibited round and smooth, beige-brown colonies of 2–3 mm after 4–5 days of growth. When 0.2 × PCA medium was used, the colonies were round, light-beige, translucent, and smaller than the colonies grown in PCA media. The colonies were round and volcano or fried-egg-like and can have rings around the outside. Alternatively, the bacteria grown on NTA-containing medium were white, tough, and pin-point in size at early growth time points. Later, a brown center appeared, and after 4–5 days, the colony turned black and was polygonal in shape. The growth on diluted PCA broth is faster than with the original conditions. The growth in batch culture with NTA increased the pH and inhibited growth. Notably, growth in NTA and other carbon sources such as glucose is faster than with NTA alone.

Isolation, Enrichment, and Maintenance Procedures

Bacteria from *Rhizobium* and *Agrobacterium* (*Rhizobium* Genus), *Sinorhizobium* (*Ensifer* Genus), and *Allorhizobium* can be isolated from soil, root nodules, or gall tissue. *Rhizobium* and *Sinorhizobium*, both symbiotic species, are best isolated from freshly excised legume root nodules. Their isolation directly from soil is difficult, and generally, this process needs trap hosts (Abd-Alla et al. 2012). On the other hand, *Agrobacterium* is isolated from gall tissue or soil or from still water samples (Kumar et al. 2013).

Root material must be washed in running tap water to remove any adherent soil. Individual nodules are dissected from the roots using a flame-sterilized scalpel and tweezers. If the nodules are very small, a small amount of root tissue can be left attached to either side of the nodule. Nodules need to be washed thoroughly in sterile water and non-ionic surfactant such as Tween-80 (100 ml/l) to remove all traces of soil. The nodules are then transferred to sterile Petri dishes and surface sterilized by immersion in 5 % sodium hypochlorite for 10–30 min, depending on the nodule size. This is followed by incubation in 70 % ethanol for 1 min and subsequently rinsing

three times with sterile water. Individual nodules may be crushed using a glass rod and then suspended in a liquid medium. Large nodules can be sliced using a sterile scalpel blade, and portions of the interior can be removed with a needle. The exudates obtained are aseptically streaked onto surface-dried yeast extract mannitol agar (YEMA) plates (Vincent 1970). Agar plates are incubated at 30 °C for 3–4 days, and individual colonies appearing over this period are re-streaked onto YEMA plates.

Isolating of *Agrobacterium* from gall tissue is a similar process to that used for the nodule. The difference is that the gall tissues must be finely chopped. These pieces are placed into a culture tube containing sterile distilled water or buffer, vortexed, and allowed to stand for at least 30 min. Using an inoculating loop, the suspension is streaked on medium and incubated at 25–27 °C. Several types of medium have been used to isolate *Agrobacterium*. The most common are Medium of Schroth et al. (1965), Medium 1A and 2E (Brisbane and Kerr 1983), or, more recently, YEMA medium (Kumar et al. 2013).

To isolate these bacteria (i.e., *Rhizobium*, *Agrobacterium*, *Sinorhizobium*, and *Allorhizobium*) directly from soil samples, it is necessary to prepare a dilution series of the sample in water or buffer and culture the sample on medium at 27 °C. The isolates can be maintained on agar slants in a screw-capped vials at 4 °C for 2 months or in 80 % Glycerol in water at −20 °C or −80 °C. Lyophilized cultures stored at 4 °C remain viable for at least 25 years.

The *Ensifer* adhaerens (*Ensifer* genus) are frequently obtained from soil. These isolates have predatory activity in indigenous Gram-negative bacterium. The enrichment and isolation procedures can use a host organism, and frequently, the host is *Agromyces ramosis*, *Micrococcus luteus*, *Staphylococcus aureus*, or some *Myxococcus* or *Streptomyces* soil isolates. To isolate these bacteria using a host, there are two procedures. In the first, the host organism must be added to natural soil, followed by the addition of water to adjust the soil water content to 50 % or 60 %, and the sample is incubated for 4–6 days at 25–27 °C. After incubation, soil dilutions are plated on desoxycholate agar or MacConkey agar. The soil dilution may also be spread on surface plates using pre-grown lawns of the host organism. The plates are then incubated to isolate a characteristic colony (grayish white, circular with undulated margins, convex, slimy, moist, and opaque). In the second isolation procedure, the host organism is smeared on a sterile glass slide, the cells are dried at room temperature, and the slide is placed in contact with the soil sample. Water is added to the soil sample. After incubating at 27 °C for 3–4 days, the lawn of host organisms is streaked by a loop, and the material is placed onto the surface of plates containing desoxycholate or MacConkey agar (Balkwill 2005).

The *Ensifer* genus consists of bacteria that are not obligate predators, and they grow well on most media. Currently, there are several studies that isolated *E. adhaerens* directly from biological samples, such as from the gut of *Holotrichia parallela* larvae (Huang et al. 2012b), from water biofilm (Huang et al. 2012c), or directly from soil samples (Guang-can Zhou et al. 2013).

The *Carbophylus* genus is represented by the species *Carbophylus carboxidus*. This species grows with CO as the energy source and CO_2 as the carbon source under aerobic, chemolithoautotrophic conditions (Meyer 2005). The metabolic characteristics of this bacterium are similar to other aerobic carbon monoxide-oxidizing microorganisms, such as *Oligotropha* from the *Bradyrhizobiaceae* Family. The most important factor in the process to enrich and isolate these bacteria is to use the appropriate gas atmosphere composition. Normally, culturing is performed in mineral medium incubated in an atmosphere composed of 5 % CO_2, 45 % CO, and 50 % air or alternatively 5 % CO_2, 10 % O_2, and 85 % CO. The enrichment is performed in batch cultures, with or without shaking, at 30 °C in the dark. Isolation and maintenance can be performed in mineral agar medium supplied with nutrient broth in the same atmosphere composition. These bacteria are slow-growing microorganisms; fast-growing colonies are generally CO-tolerant contaminants.

The two newest genera from the *Rhyzobiaceae* family, *Kastia* and *Shinella*, are composed of aerobic chemorganotrophic species. Therefore, these bacteria are isolated using a non-selective complex medium such as R2A agar plates, plate count agar, nutrient agar, or AG medium (Matsui et al. 2001). Cultures are incubated at 27 °C to 30 °C in the same isolation medium and cryopreserved at −80 °C in broth supplemented with 15 % (v/v) glycerol (Lee et al. 2007; Vas-Moreira et al. 2010).

Strains from the *Chelatobacter* genus can be isolated from soil, wastewater, or surface waters. These bacteria can be isolated in media with NTA as the only carbon and nitrogen source. Maintenance must be in freeze-dried conditions or alternatively in culture grown with NTA, glycerol (15 %, v/v), or DMSO (50 %, v/v). The cultures should be revived directly onto NTA agar plates, and the cultures must be transferred to new plates every week because growth leads to increased pH, which leads to growth inhibition.

Ecology

Some members of the family *Rhizobiaceae* are characterized by their ability to establish symbiotic associations with host plants to develop the process of biological nitrogen fixation (BNF). This ability is not limited to members of this family; it extends to a diverse group of bacteria collectively called rhizobia. Rhizobia can be differentiated by morphophysiological characteristics, growth time, and pH reaction in medium containing yeast extract, mannitol, mineral salts, and agar (YMA—Vincent 1970). Their members are distributed across six genera: *Rhizobium*, *Sinorhizobium/Ensifer*, and *Allorhizobium/Rhizobium* (*Rhizobiaceae*), which contains predominantly fast-growing and acidifying strains; *Mesorhizobium* (*Phyllobacteriaceae*), which contains intermediate- to fast-growing and acidifying strains; *Bradyrhizobium* (*Bradyrhizobiaceae*), which is represented by slow-growing and alkalinizing strains; and *Azorhizobium* (*Xanthobacteraceae*), which consists of fast-growing and alkalinizing strains (Moreira and Siqueira 2006).

Although they might grow in any region, fast-acidifying strains predominate in temperate regions, whereas the slow-alkalinizing strains predominate in tropical climates (Norris 1965).

Nitrogen-fixing organisms provide a source of nitrogen that can be assimilated by other organisms such as plants and animals, and the nitrogen can be incorporated into amino acids and other essential organic compounds. This ability is restricted to organisms that exhibit nitrogenase, an enzyme complex capable of catalyzing the molecular transformation of atmospheric nitrogen (N_2) into ammonia (NH_3) (Rees and Howard 2000). Despite the diversity of nitrogen-fixing bacteria, there is high homology between the fixing systems based on the nitrogenase complex (Burris 1991). BNF through symbiosis with members of the family *Rhizobiaceae* is almost exclusively restricted to leguminous plants (Fabaceae), with the exception of *Parasponia* (Ulmaceae) (van Rhijn and Vanderleyden 1995; Crawford et al. 2000).

Bacterial strains of any genus exhibit different specificities to host plants depending on the type of nodulation (Nod) factors produced, and *Rhizobium* is one of the genera that displays the greatest promiscuity (Pueppke and Broughton 1999). The plant signals associated with the expression of these Nod factors are plant-specific flavonoids. For example, the flavone luteolin and the chalcone 4,4′-dihydroxy-2′-methoxychalcone, which are capable of stimulating *Sinorhizobium meliloti*, are found in plants of the genus *Medicago*, whereas *S. fredii* is stimulated by the isoflavone daidzein produced by *Glycine max*. Naringenin is a flavanone found in plants of the genus *Vicia*, and it is capable of stimulating *R. leguminosarum* bv. *viciae* (Crawford et al. 2000). The structural organization of the genes for nodulation and nitrogen fixation is usually a grouped one that forms symbiotic islands. These islands are located in megaplasmids denoted as "pSym" in bacteria of the genera *Rhizobium* and *Sinorhizobium* (Batut et al. 1985; Renalier et al. 1987; Galibert et al. 2001).

Plants and bacteria create a species-specific root nodule environment through endophytic colonization, which becomes able to support symbiosis, ATP synthesis, and the BNF process in a microaerophilic environment. The bacterium turns into a pleomorphic form called a "bacteroid," which is the morphophysiologically active type located inside the root nodules exhibiting nitrogenase activity (Jones et al. 2007; Oldroyd and Downie 2008). The plant's metabolism produces organic acids that serve as food for the bacteroid and provides carbonate skeletons for the organic nitrogen compounds produced in return (generally in the form of amides (glutamine and asparagine) or ureides (allantoin and allantoic acid)). In turn, these compounds are produced from the metabolic interrelation of the macro-and microsymbiont after the reduction of N_2 into NH_3 and its subsequent acidification into ammonium (NH_4^+) in the interior of the bacteroids (Lodwig and Poole 2003; Lodwig et al. 2003).

C. carboxidus, the only species of the genus *Carbophilus*, was defined as a carboxydotrophic bacterium capable of using carbon monoxide (CO) as the sole source of carbon and energy both in aerobic and denitrifying conditions (Meyer et al. 1993). Bacteria with this ability are considered to be primary colonizers on recent volcanic deposits and are metabolically versatile; therefore, they are potential residents in inhospitable conditions with primordial chemolithotrophic features. The presence of the carbon monoxide dehydrogenase gene enables CO oxidization and allowed this bacterium to be present in the early and subsequent stages of ecological succession (Weber and King 2010).

The genus *Chelatobacter* comprises one single species, *C. heintzii*, which has the ability to degrade nitriloacetate (NTA) under aerobic conditions. This activity allows this bacterium to take part in the mineralization of NTA (i.e., removing this chelating agent from the environment) (Kampfer et al. 2002; Yuan and Van Briesen 2006). NTA, as well as EDTA, are agents employed in the removal of metal residues from contaminated environments; however, their indiscriminate use allows their accumulation and transformation into a potential pollutant. *Chelatobacter henintzii* assimilates NTA and generates three intermediates: iminodiacetate (IDA), glyoxylate, and glycine. These latter two are innocuous, contributing to bacterial growth and complete mineralization of NTA. IDA is the only intermediate product that retains complex metal characteristics, and the effects of initial chelation may persist in the environment (Yuan and Van Briesen 2006).

The genus *Kaistia* contains species isolated from environmental samples such as soil and sediments, including those originating from turf and anaerobic sludge blanket reactors. The latest isolate of this genus was obtained from the skin of *Hirudo verbana*, a leech with medical applications (Glaeser et al. 2013). The ability to reduce nitrate was detected for some species of this genus (Kim et al. 2010).

The genus *Shinella* also has species with ability to reduce nitrate and nitrite. Some of these bacteria were found when searching for microorganisms with industrial potential and were originally isolated from sludge reactors or waste treatment stations (An et al. 2006; Vaz-Moreira et al. 2010; Lee et al. 2011). The concentration of organic matter is relatively high in these environments, thereby contributing to an increase in the nitrogen content. Thus, the transformations performed by bacteria of this genus contribute to ammonia production and maintenance of the degradation process of these residues in addition to the maintenance of the microbial community in anaerobic environments (Franke-Whittle and Insam 2013; Murto et al. 2004; De Vrieze et al. 2013). One species of this genus, *S. kummerowiae*, is able to establish symbiosis with the leguminous *Kummerowia stipulacea*, having been isolated from the root nodules of this plant in a province of China. This strain contains the *nodC*, *nod*, and *nifH* genes, which share high levels of similarity with those of *R. tropici*, demonstrating possible potential for nitrogen fixation (Lin et al. 2008).

Pathogenicity: Clinical Relevance

Agrobacterium is the most important genus of *Rhizobiaceae* regarding pathogenicity, with representatives that are even characterized by this criterion. Three disease-causing agents in plants

are noteworthy: the species *A. tumefaciens* (causative agent of crown gall tumors), *A. rhizogenes* (causative agent of hairy root disease), and *A. vitis* (causative agent of tumors and necrotic disease on grapevines) (Matthysse 2006). The range of dicotyledonous host plants varies according to species; however, the plant *Helianthus annuss* is susceptible to the largest range of tumorigenic strains. Conversely, *A. vitis* and *A. rubi* have limited host ranges (Young et al. 2005).

The chromosomal genes involved in pectin breakdown are the main virulence factors in *A. vitis*. The presence of the bacterium is generally limited to the phloem or to tissues directly beneath the bark of grapevines. The tumors caused by *Agrobacterium* are self-proliferative and can be transmitted by grafting. The induction and maintenance of tumors is due a tumor-inducing plasmid (Ti-plasmid) present in *A. tumefaciens* and *A. vitis*, whereas hairy root induction is due to a root-inducing plasmid (Ri-plasmid) present in *A. rhizogenes* (Young et al. 2005; Matthysse 2006).

The infection of plant tissues by parasites occurs through different injuries suffered by the plant. Through these injuries, the plant exudes phenolic compounds, sugars, and amino acids that perform positive chemotactism, and the bacterium invades the injured surface usually in the interface between the soil and the shoots. The bacterium is required for tumor induction, and the chromosomal genes *chvA*, *chvB*, and *pscA* are needed for the initial attachment of *Agrobacterium* onto the plant cell (Sheng and Citovsky 1996; Tzfira and Citovsky 2000). However, the tumor is maintained as a result of a genetic transformation in the plant cells through the transfer of some genes contained in the Ti plasmid in a region named T-DNA (transferable portion of the Ti genome to the nucleus of the plant). The release and transfer of T-DNA into the plant genome occurs through a diverse class of virulence genes (*vir*). Plant phenolic compounds such as p-hydroxybenzoic acid and vanillin induce the expression of the *vir* genes (Maury et al. 2010; Wise et al. 2010).

The T-DNA encodes enzymes involved in the biosynthesis of cytokinins and auxins and is expressed at its integration site, thereby promoting hormonal imbalance in the plant. The chaotic proliferation of transformed plant cells originates a tumor known as "crown gall" (Yamaguchi et al. 2012; Gohlke et al. 2013). For *A. rhizogenes*, the expressed oncogenes induce the proliferation of hairy roots at the injury site (Georgiev et al. 2012). Additionally, T-DNA encodes for enzymes responsible for the synthesis of opines, such as nopaline, octopine, or agropine, which vary depending on the group of *Agrobacterium* that carry them. The opines produced by the transformed plant cells are derivatives of amino acids and sugars and are the chemical intermediates of parasitism; they are used as a nutritional source by the bacteria (Tzfira and Citovsky 2000). Some species of *Agrobacterium* are susceptible to agricins, which are antibiotic-like compounds produced by certain *A. radiobacter* strains. However, this does not seem to be an efficient method for biological control of plant parasitic strains, specifically for *A. vitis* (Matthysse 2006).

With less important pathogenicity, the genus *Ensifer* comprises the species *E. adhaerens*. This species lives in the soil and was originally described as a non-obligatory predator of *Micrococcus luteus* (Casida 1982). The range of bacteria susceptible to attack by *Ensifer* is usually limited to certain bacteria that were added to the soil, including *Agromyces ramosus*, *Staphylococcus aureus*, and strains C2 and 34 of *Streptomyces*. Both Gram-positive and Gram-negative cells may be lysed by *Ensifer*, which becomes an obligatory predator in conditions of nutrient limitation (Germida and Casida 1983; Zeph 1986; Zeph and Casida 1986).

Application

In quantitative terms, the symbiosis between nitrogen-fixing bacteria and their leguminous host plants can be considered to be one of the most productive systems when the BNF is taken into account. Many important agro-economic plants worldwide are leguminous species, such as alfalfa, clover, beans, and soybeans. A major portion of the global process of BNF lies on these cultivated leguminous, and this is a crucial step in the nitrogen cycle that annually adds 50–70 million tons (Tg) of nitrogen to the soils (Herridge et al. 2008; Lindström et al. 2010).

Although microbial inoculants based on bradyrhizobia for soybean are the most widespread due to the great importance of soybean worldwide, the inoculation of other leguminous grain crops, green manure, foragers, and trees have drawn particular attention to the group of rhizobia, which belongs to the family *Rhizobiaceae* (Moreira et al. 1993; Lindström et al. 2010). Among these host species, *Phaseolus vulgaris* (common bean) is considered to form one of the most important symbiotic associations with rhizobia of the genera *Rhizobium* and *Sinorhizobium* (Ribeiro et al. 2009; Mnasri et al. 2012).

The industry and market for inoculants for bean crops is considerably smaller than those for soybean; however, the importance and benefit of inoculation for bean productivity is not ignored (Hungria et al. 2000; Lindström et al. 2010). Maximization of the BFN process in leguminous crops can be compromised by several limiting properties to the establishment of symbiosis and nitrogen fixation efficiency. These include biotic factors such as competition with native soil bacteria, as well as abiotic factors such as temperature, humidity, and pH (Valentine et al. 2010). The selection of efficient strains capable of performing BNF with agriculturally important plants has been the subject of extensive research, and in it rests the success of inoculant application in these crops (Thies et al. 2001; Pinto et al. 2007; Ribeiro et al. 2009; Olivares et al. 2013).

BNF is not exclusively an applied process that can be exploited by members of *Rhizobiaceae*. In addition to nitrogen fixation, interaction with rhizobia also enables the rhizosphere of leguminous plants to benefit from other molecules able to stimulate plant growth, form other symbiotic associations, and control phytopathogens (Dakora 2003). Some bacteria of the genus *Rhizobium* colonize the rhizosphere and the rhizoplane of cultivated plants and promote plant growth by mechanisms that include the production of phytohormones of the gibberellins, auxins, and cytokinins classes. Therefore, these bacteria act as

Plant Growth-Promoting Rhizobacteria (PGPR) (Lugtenberg and Kamilova 2009) and can be exploited as inoculants directed to other agroecological properties.

Certain polymers produced by bacteria belonging to the family *Rhizobiaceae* may also have industrial applications, particularly the extracellular polysaccharides denominated exopolysaccharides (EPS). These are strain-specific homo- or hetero-polysaccharides with biological functions such as recognition and adhesion to host plant cells (Sutherland 2001; Skorupska et al. 2006; Castellane and Lemos 2007). The bacterial EPS has been shown provide bacteria protection from various environmental insults such as desiccation, predation, and the effects of antibiotics (Donot et al. 2012). The EPS originated in rhizobia has several functions in nature including participation as receptor molecules in cell-cell interactions and triggering of the nodulation process (Kirichenko et al. 2004); induction of the formation of nodules and micro-colonies (Becker and Pühler 1998); participation in the development of the nodule (Kosenko et al. 2001); and acting as ion exchange resins to concentrate minerals and nutrients around the cell (Whitfield 1988).

The interest in EPSs has increased considerably in recent years because these compounds are candidates for many commercial applications, including as food products, pharmaceuticals, bioemulsifiers (Xie et al. 2013), bioflocculants (Sathiyanarayanan et al. 2013), chemical products (Wang et al. 2008; Shah et al. 2008), and antibiofilm agents (Rendueles et al. 2013) and in the biosorption of heavy metals (Mohamad et al. 2012). These EPSs can be applied as thickeners, stabilizers, emulsifiers, coagulants, biofilms, lubricants, gelling agents, dispersants, and suspending agents (Sutherland 1998).

A number of microorganisms have been demonstrated to produce polysaccharides and other biopolymers that exhibit metal-binding properties (Gutnick and Bach 2000), such as the water-soluble and amphipathic exopolysaccharides (EPS). Rhizobial exopolysaccharides have been studied extensively for their role in plant host specificity (Dudman 1984); however, only recently has their metal sorption capacity been investigated (Wu et al. 2010). Several works illustrate metal-binding properties from the bacteria of the *Rhizobium* genus. Douka and Xenoulis (1988) reported a significant reduction in radioactive metal concentration by nodulated pasture legumes after the Chernobyl radioactive fallout. A study by Abd-Alla et al. (2012) reported that the *R. leguminosarum bv. viciae* isolate can be useful as an inexpensive and efficient bioremediation technology to remove and can recover heavy metal (Co^{2+} and Cd^{2+}) ions from an aqueous solution. *Mesorhizobium amorphae* isolated from the root of *Robinia pseudoacacia* in tailings from plumber and zinc mines in Gansu (China) was used to help host plants to survive in environments contaminated with copper, zinc, and chromium, indicating a potential application in the remediation of heavy metals (Mohamad et al. 2012). Cells of this bacterium exhibited a good ability to bind Cr ions, with a desorption efficiency of 70 % for Cr (III) and 76 % for Cr (VI), suggesting a potential application in the bioremediation field (Mohamad et al. 2012; Xie et al. 2013). However, there are few studies available on the ability of rhizobia and EPS being used as biosorbents of ions in an aqueous environment, particularly containing chromium and copper.

Studies have demonstrated the action of EPSs produced by a variety of Gram-negative bacteria as a potential bioemulsifier in the degradation of hydrocarbons. Huang et al. (2012a) tested the optimization of EPS production from three strains isolated from roots, namely *Rhizobium miluonense* (CC-B-L1), *Burkholderia seminalis* (CC-IDD2w), and *Ensifer adhaerens* (CC-GSB4), by adjusting culture medium components, as well as by testing the effect of EPS production on the performance of diesel oil emulsification. The study demonstrated that EPS production by the three strains was approximately 200 mg L^{-1}, and the emulsification index (E24) was on average 60 %. Changes in culture conditions resulted in increased EPS production and greater efficiency of the emulsification process.

Castellane and Lemos (2007) cultured *Rhizobium tropici* SEMIA 4077 and SEMIA 4080 in different carbon sources for exopolysaccharide production and observed that exopolysaccharides consisted of glucose and galactose residues with traces of mannose, rhamnose, and uronic acids. However, the proportions of sugar in these biopolymers displayed variations in each exopolysaccharide produced. Rheological properties and the effects of salt addition on the viscosity of exopolysaccharides produced by these bacteria showed that the EPS molecules can be applied in food sectors (Aranda-Selverio et al. 2010).

There is evidence that the EPS synthesis is inversely proportional to the synthesis of poly-3-hydroxybutyrate (PHB), another important polymer. PHB is the most well-known among the bacterial biodegradable polymers denominated by polyhydroxyalkanoates. This polymer aroused much interest in the petrochemical industry because the structural similarity of PHB with polypropylene attracted attention from various industries seeking to find a substitute for plastics with a petrochemical origin, as well as in the medical field in which biodegradability and biocompatibility are both important factors. The production of both polymers (EPS and PHB) by the same cells requires a biochemical regulation of bacteria because both metabolic pathways are large drains on carbon skeletons. *Rhizobium* is not yet used for PHB industrial production; however, Paganelli et al. (2011) demonstrated that some strains have potential for this purpose. These strains demonstrated the ability to accumulate PHB in relatively high amounts with sucrose.

Bacteria of the genus *Ensifer*, in addition to having the ability to produce EPS, can participate in important environmental and biotechnological processes. Thiamethoxam (THIA), a second-generation neonicotinoid insecticide in the thianicotinyl subclass, is used worldwide. Environmental studies revealed that microbial degradation is the major mode of removal of this pesticide from the soil. The nitrogen-fixing and plant-growth-promoting rhizobacterium *E. adhaerens* TMX-23, which is able to degrade THIA, has the potential for bioaugmentation as well as for promoting the growth of field crops in THIA-contaminated soil (Guang-can Zhou et al. 2013). A strain of *E. adhaerens* with the ability to produce alliinase was isolated from a soil sample. The enzyme was purified to characterize its general properties and to evaluate its application in

on-site production of allicin-dependent fungicidal activity. Allicin is best-known as the active compound in freshly crushed garlic extract, and it is known to possess a vast variety of biological effects, including antimicrobial, anti-inflammatory, antithrombotic, anticancer, and antiatherosclerotic activities (Yutani et al. 2011).

The natural ability of *Agrobacterium* to transfer and stably integrate DNA into plant genomes has led to an extensive exploration of this model for use as vectors for genetic transformation of plant cells using recombinant DNA technology (Tzfira and Citovsky 2006). Certain strains are used to obtain disarmed strains, aiming to integrate *Agrobacterium* in genetic engineering and biotechnology methodologies. In these lineages, the original Ti plasmid retains only the *vir* region, whereas the border sequences and the T-DNA are deleted along with the oncogenes. The chromosomal genes required for virulence also remain in the disarmed strains (Zambryski et al. 1983; Kiyokawa et al. 2009).

To obtain the cloning vectors, usually by double recombination, the original T-DNA has its oncogenes removed and replaced by selection markers, multiple cloning sites, and promoters for heterologous expression in plants. Thus, these modified plasmids retain the ends of the T-DNA required for their transfer, and genes of interest can be cloned in between. Vectors carrying the border sequence and the genes of interest can be transferred via triparental mating by *Escherichia coli* into the disarmed *A. tumefaciens* or *A. rhizogenes*, which will be used for infection and transformation of the plants of interest (Zambryski et al. 1983; Matthysse 2006; Kiyokawa et al. 2009). Plant explants used for transformation are selected using the appropriate antibiotic, and the transformed plant is regenerated using tissue culture, whereas the *Agrobacterium* is eliminated with the application of cefotaxime (Valvekens et al. 1988; Dhekney et al. 2008; Marcondes and Hansen 2008).

Finally, the most relevant application proposed for *Carbophilus*, *Chelatobacter*, *Kaistia*, and *Shinella* according to their environmental origins consists of exploiting their metabolism for use in bioremediation and biodegradation. In addition to the degradation of organic matter, the chemolithotrophic metabolisms capable of degrading carbon monoxide, nitrate, nitrite, and metal chelating agents can be exploited both under aerobic or anaerobic conditions in some cases. Thus, bacteria of the family *Rhizobiaceae* can aggregate the microbial consortia applied for the detoxification of industrial effluents and for the treatment of organic waste (Ilyin et al. 2004; Murto et al. 2004; De Vrieze et al. 2013; Franke-Whittle and Insam 2013).

Abstract

The family *Rhodobacteraceae* can be considered a paradigm of modern taxonomy of prokaryotes. Taking into account the number of species and genera that conforms the family, together with the knowledge about their abundance and vast global distribution, it surprises that most of them have been described relatively recent to our days. Two notable exceptions are *Rhodonostoc capsulatum* (Molisch, Die purpurbakterien nach neuen untersuchungen, vols i–vii. G. Fischer, Jena, pp 1–95, 1907) and *Micrococcus denitrificans* Beijerinck and Minkman (Zentbl Bakteriol, Parasitenkd, Infektionskr Hyg. Abt II 25:30–63, 1910), early basonyms of *Rhodobacter capsulatus* and *Paracoccus denitrificans*, respectively. The fact that so many descriptions within this family are recent means that some studies have been concomitant and pose a challenge not only for pure taxonomic studies but also for interpreting other studies in which a rapidly evolving nomenclature had to be used anyway. The metabolic and ecological diversity of the group adds further complexity. In spite of all these difficulties, the picture is far from being a chaos and it can be considered an exciting and important bacterial group to study.

Rhodobacteraceae are, fundamentally, aquatic bacteria that frequently thrive in marine environments. They comprise mainly aerobic photo- and chemoheterotrophs but also purple non-sulfur bacteria which perform photosynthesis in anaerobic environments. They are deeply involved in sulfur and carbon biogeochemical cycling and symbiosis with aquatic micro- and macroorganisms.

One hundred genera are currently recognized as members of the family although the *Stappia* group, *Ahrensia*, *Agaricicola*, and *Rhodothalassium* do not belong, phylogenetically, to the family. The 90 other genera are distributed in 5 phylogenetic groups (the *Rhodobacter*, the *Paracoccus*, the *Rhodovulum*, the *Amaricoccus*, and the *Roseobacter* clades) that might be considered a family on its own.

Taxonomy, Historical and Current

Rho.do.bac.ter.a'ce.ae. M.L. masc. n. *Rhodobacter*, type genus of the family; -aceae ending to denote family; M.L. fem. pl. n. *Rhodobacteraceae*, the *Rhodobacter* family.

The family *Rhodobacteraceae* was first established by Garrity et al. (2005) as the sole member of the order *Rhodobacterales* (class *Alphaproteobacteria*, phylum Proteobacteria) in the 2nd edition of *Bergey's Manual of Systematic Bacteriology*. Both names were validated in Validation List 107 (Euzéby 2006). The circumscription of the taxon was based on the phylogenetic analysis of 16S rRNA gene sequences of their members, which, at that time, comprised 31 genera (*Rhodobacter*, the type genus, plus *Ahrensia*, *Albidovulum*, *Amaricoccus*, *Antarctobacter*, *Gemmobacter*, *Hirshia*, *Hyphomonas*, *Jannaschia*, *Ketogulonicigenium*, *Leisingera*, *Maricaulis*, *Methylarcula*, *Octadecabacter*, *Pannonibacter*, *Paracoccus*, *Pseudorhodobacter*, *Rhodobaca*, *Rhodothalassium*, *Rhodovulum*, *Roseibium*, *Roseinatronobacter*, *Roseivivax*, *Roseobacter*, *Roseovarius*, *Rubrimonas*, *Ruegeria*, *Sagittula*, *Staleya*, *Stappia*, and *Sulfitobacter*). In the same year, Lee et al. described the family *Hyphomonadaceae*, removing the prosthecate genera *Hirshia*, *Hyphomonas*, and *Maricaulis* from *Rhodobacteraceae* (Lee et al. 2005) among other proposals for the subdivision of *Alphaproteobacteria* that were also based on 16S rRNA gene analysis. These authors did not recognize *Rhodobacterales* as an order, but included both the families *Rhodobacteraceae* and *Hyphomonadaceae* in the order *Caulobacterales*, along with *Caulobacteraceae*. Whatever the hierarchy considered, *Hyphomonadaceae* is a neighboring family to *Rhodobacteraceae* (*sensu stricto*) (see *Fig. 20.1*, General tree of the family *sensu lato*). The family *Hyphomonadaceae* contains a dozen of genera of prosthecate marine bacteria. The next closer neighbor is represented by the family *Kordiimonadaceae* that includes only the genus *Kordiimonas*, with two marine and one terrestrial species. However, phylogenetic analysis using different data sets and methods, as the concatenated alignments for 104 well-behaved protein families (Williams et al. 2007), splits *Hyphomonadaceae* apart from the order *Rhodobacterales*, forming an expanded group with *Caulobacterales* that also includes *Parvularcula*.

According to Rule 51b (1) of the *Bacteriological Code*, the family name *Rhodobacteraceae* (Garrity et al. 2005) is illegitimate because the family contains the genus *Hyphomonas* (ex Pongratz 1957, Moore et al. 1984) which is the type of the family *Hyphomonadaceae* (Lee et al. 2005; Euzéby 2006).

Since the publication of these studies, and following an increase of taxonomic attention to the marine microbiota, dozens of new genera have been described into the family *Rhodobacteraceae*. To date it comprises 99 genera and 288 species, being one of the most "populated" families of the Domain Bacteria (*Table 20.1*).

As already stated at the time of its establishment, the family is phenotypically, metabolically, and ecologically diverse, including photoheterotrophs able to grow photoautotrophically or chemotrophically, aerobic and facultative anaerobic chemoorganoheterotrophs, and facultative methylotrophs. Several members are aerobic anoxygenic phototrophs (AAP) while others, as the type genus of the family, are classical purple non-sulfur photosynthetic bacteria, whose phototrophic ability is restricted to anaerobic conditions. The vast majority of the species contained in the family are aquatic, and many of them require sodium ion or combined salts for growth. Their cells are Gram negative and multiply by binary fission or by budding, following monopolar growth. When motile, they exhibit flagella, usually

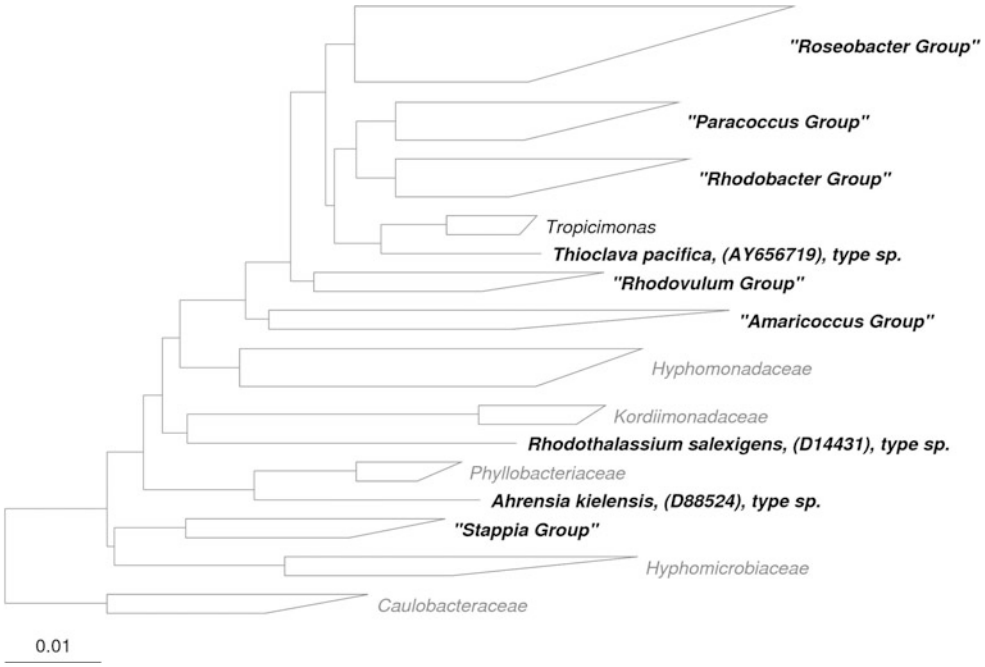

Fig. 20.1

Phylogenetic reconstruction of the family *Rhodobacteraceae* based on 16S rRNA and created using the neighbor-joining algorithm with the Jukes-Cantor correction. The sequence data sets and alignments were used according to the All-Species Living Tree Project (LTP) database (Yarza et al. 2010; http://www.arb-silva.de/projects/living-tree). The tree topology was stabilized with the use of a representative set of nearly 750 high-quality type strain sequences proportionally distributed among the different bacterial and archaeal phyla. In addition, a 40 % maximum frequency filter was applied in order to remove hypervariable positions and potentially misplaced bases from the alignment. Scale bar indicates estimated sequence divergence

polar. Most species are positive for oxidase. Pigmentation does occur, not only in photosynthetic members (that present Bchl *a* and carotenoids of spheroidene class) but also in non-phototrophic members. Carbon reserve material is formed by some members as polyhydroxyalkanoates (PHA), commonly polyhydroxybutyrate (PHB). The major or only respiratory quinone is ubiquinone 10 (as occurs almost universally in the Class *Alphaproteobacteria*), and their cellular fatty acids are usually dominated by C18:1 ω7c, which very often constitutes more than 50 % of the total. Polar lipids may include phosphatidyl glycerol, diphosphatidyl glycerol, phosphatidyl ethanolamine, phosphatidyl choline, and several amino-, phospho-, and glycolipids in different combinations. The mol% G+C content of their DNA is above 50 %, with only one exception known (*Pelagicola*, 47 mol%), and being the most common range 55–70 mol% and the total range 47–76 mol%. A summary of the chemotaxonomic features of the genera is included as *Table 20.2*.

After introducing the common traits of the family, it should be stressed that its internal heterogeneity is not just a matter of metabolic or physiological diversity and/or versatility but also a matter of lack of phylogenetic homogeneity: as can be observed in *Fig. 20.1*, a bunch of genera formally included in the family lay far away from the large clade that comprises the true rhodobacters (family *Rhodobacteraceae sensu stricto*). These outsider genera fall in three groups: a well-defined clade comprising seven genera and sixteen species, labeled as "*Stappia* group," the genus *Ahrensia* (related to *Phyllobacteriaceae*), the genus *Agaricicola* (not shown), and the purple non-sulfur genus *Rhodothalassium*, which forms a distinct lineage in this part of the alphaproteobacterial tree. The separate position of this genus was already underlined in a Bergey's Editorial Note and by placing it as incertae sedis in the manual (Imhoff 2005). In fact, it was stated that *Rhodothalassium* could constitute a family on its own, but the scarcity of sequence data available prevented the proposal at that time.

Thus, the family *Rhodobacteraceae* formally contains, up to date, these ten genera (http://www.bacterio.cict.fr/classifgenerafamilies.html#Rhodobacteraceae) although they could certainly constitute two additional families, "*Stappiaceae*" (with *Labrenzia*, *Nesiotobacter*, *Pannonibacter*, *Polymorphum*, *Pseudovibrio*, *Roseibium*, and *Stappia*) and *Rhodothalassiaceae* (monogeneric) [Note: During the writing of the chapter, the proposal of *Rhodothalassiaceae* fam. nov. and *Rhodothalassiales* ord. nov. was published by Venkata Ramana et al. (2013), with an emended description of the genus *Rhodothalassium*]. On the other hand, *Ahrensia* could be transferred to the family *Phyllobacteriaceae*, where it is placed with *Hoeflea* species in more detailed trees (see the last release of the Living Tree Project 16S rRNA gene tree, LTP111, Yarza et al. 2010), and *Agaricicola*,

Table 20.1

List of genera in the family *Rhodobacteraceae sensu lato* (=order *Rhodobacterales*: 99 genera, 288 species), distributed by groups (tentative new families) by phylogenetic assignment

***Rhodobacter* group = *Rhodobacteraceae* (*sensu stricto*): 11 genera, 35 species**

Pseudovibrio	*Roseibium*	***Stappia***	
Unaffiliated: 3 genera, 3 species			
Agaricicola	*Ahrensia*	*Rhodothalassium*	

[a]Empty genera, all their species have been reclassified into other genera

which is related to *Prosthecomicrobium pneumaticum* (LTP111), should be also excluded from the family *Rhodobacteraceae*.

The remaining 89 genera (268 species) form a monophyletic clade that may be considered the true *Rhodobacteraceae* family, from a strictly phylogenetic point of view. Phylogenetic analysis, based on 16S rRNA gene sequences, allows the recognition of five well-defined groups among these 89 genera. Lee et al. (2005) already recognized these five main groups, although their work included less than 20 % (46 out of 268) of the currently established species. In *Figs. 20.1*, *20.2*, *20.3*, *20.4*, *20.5*, and *20.6* and *Table 20.1*, each of these groups is named after the senior genus contained. *Table 20.1* also reflects a suggestion for the nomenclature to be used if these groups are finally recognized as new families, a proposal that, in our opinion, merits consideration but is outside of the aim of this chapter. As it can be observed, the distribution of genera

Table 20.2

Chemotaxonomic traits of the genera in the family *Rhodobacteraceae sensu lato*, distributed by groups (tentative new families). Empty cells indicate that no information could be retrieved for that particular genus and trait. +, positive; −, negative; *v*, variable

Genus	Quinone	Polar lipids	Pigments	PHB/PHA	GC mol%	Other
Sagittula			Bchl *a* −	yes	65	
Salinihabitans	Q10		Bchl *a* −		63.5	
Salipiger	Q10		Bchl *a* −	yes	64.5	
Sediminimonas	Q10	DPG, PG, PC, 4PL	Bchl *a* −	no	63–64	
Seohaeicola	Q10	PC, PG, PE, L			63.4	
Shimia	Q10		Bchl *a* −	no	55–57	
Sulfitobacter	Q10	PC, PG, PE, DPG[ab], AL[ac], PL[ad]	Bchl *a* −	v	55–62	
Tateyamaria	Q10	PG, PE, PC, L	Bchl *a* v		56–62	
Thalassobacter		PG, DPG, PC, 2PL, AL, PE[ae]	Bchl *a* +	yes	59	
Thalassobius	Q10	PC, PG, PE, L	*pufLM* −[af]	yes	57–61	
Thalassococcus	Q10	PG, PC, Ls, AL[ag], PE[ah]		v	57.8–58	
Tranquillimonas	Q10		Bchl *a* −	yes	69	
Tropicibacter	Q10	PE, PG, PC, AL, 4PL	Bchl *a* −	yes	58–65	
Tropicimonas	Q10 and Q9	PC, PG, DPG, AL, Ls, PL[ai]	Bchl *a* −	yes	66.5–69.6	
Vadicella	Q10	PC, PG, PA, AL, L, PE	Bchl *a* −		56–60	
Wenxinia	Q10	PG, PC, GL, PE, PL	Bchl *a* −	yes	69.4	
Yangia	Q10		Bchl *a* −	yes	63	
***Stappia* group**						
Stappia	Q10	DPG, PC, PG, PE, PMME[aj], AL[ak], PL[al]	Bchl *a* v		59–65.9	Major polyamines: spermidine and spermine
Labrenzia	Q10	DPG, PC, PG, PE, PMME, ALs, SQDG	Bchl *a* v		56–60	
Nesiotobacter			Bchl *a* −		61	
Pannonibacter	Q10	DPG, PG, PE, PC[am], PMME[am], 2AL[am], PS[an], PL[an]	Bchl *a* −		63–64.6	*m*-DAP
Polymorphum	Q10	DPG, PMME, PG, PC, AL, PLs, SQDG	Bchl *a* −		65.6	
Pseudovibrio			Bchl *a* −		50–52	
Roseibium	Q10	PG, DPG, PE, PC, SQDG, PMME, AL	Bchl *a* +		57.6–63.4	
Unaffiliated						
Ahrensia	Q10		Bchl *a* −	no	48	
Agaricicola	Q10	DPG, PC, PG, PE	Bchl *a* −	yes	62.7	
Rhodothalassium	Q10, MK10	DPG, PG, OL, PL, AL, L	Bchl *a* +, carotenoids: spirilloxanthine series		60–62.8	Contains aminopropylhomospermidine

Quinone systems: MK10, menaquinone 10; Q9, ubiquinone 9; Q10, ubiquinone 10

Polar lipids: *AL* aminolipid, *APL* aminophospholipid, *DPG* diphosphatidylglycerol, *GL* glycolipid, *L* lipid, *LPE* lysophosphatidylethanolamine, *OL* ornithine lipid, *PA* phosphatidic acid, *PC* phosphatidylcholine, *PE* phosphatidylethanolamine, *PG* phosphatidylglycerol, *PL* phospholipid, *PMME* phosphatidylmonomethylethanolamine, *PS* phosphatidylserine, *SL* sulfonolipid, *SQD* sulphoquinovosyldiglyceride, *SQDG* sulphoquinovosyldiacylglycerol

Other: *m*-DAP, meso-diamino pimelic acid in peptidoglycan

[a]spheroidene and spheroidenone/neurosporene in *R. viridis*; [b]DPG only in *G. caeni* and *G. nanjingensis*; [c]in *G. aquatilis*; [d]2SL *in R. bhavnagarense*; [e]SQD, DPG (cardiolipin) and APL in *R. euryhalinum* and *R. tesquicola*; [f]PC only in *A. xiamenensis*; [g]chemotaxonomic information, except for G+C mol%, only investigated in *A. kaplicensis*; [h]PL only in *R. shengliensis*; [i]ubiquinone 8 in *P. yeei*; [j]only in *C. neptunius*; [k]except in *J. seosinensis* and *J. donghaensis*; [l]except for *J. seohaensis*; [m]DPG in *L. janthinus*; [n]in *L. atrilutea*, *L. maricola*, and *L. tamlensis*; [o]DPG only in some species of *Loktanella*; [p]Bchl *a* + in *L. maricola*; [q]*pufLM* + in *L. vestfoldensis*; [r]PL in *P. gallaeciensis*, *P. inhibens*, *P. daeponensis*; [s]PHA/PHB in *P. caeruleus*; [t]DPG and PL in *P. aquimaris*; [u]PC, AL, and L in *P. lutimaris*; [v]DPG absent in *R. litoreus*; [w]PE in *R. aerolatum*; [x]AL absent in *R. marina*; [y]DPG in *R. conchae*, *R. faecimaris*, *R. halocynthiae*, and *R. atlantica*; [z]PL in *R. conchae* and *R. marina*; [aa]PE in *R. marina*; [ab]DPG absent in *S. guttiformis*; [ac]AL in *S. brevis* and *S. guttiformis*; [ad]PL in *S. brevis* and *S. donghicola*; [ae]PE in *T. arenae*; [af]*pufLM* in *T. aestuarii*; [ag]AL in *T. lentus*; [ah]PE in *T. halodurans*; [ai]PL absent in *T. sediminicola*; [aj]PMME in *S. indica* and *S. stellulata*; [ak]AL in *S. indica*; [al]PL in *S. taiwanensis*; [am]PC, PMME, and 2AL in *P. indica*; [an]PS and PL in *P. phragmitetus*

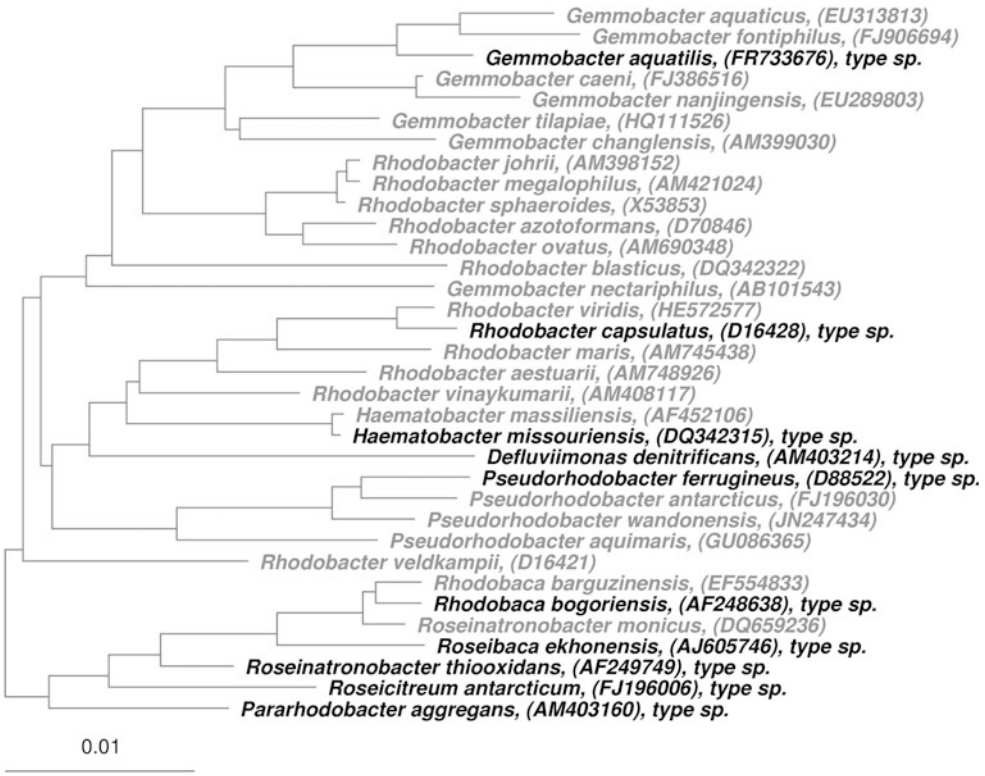

Fig. 20.2

Phylogenetic reconstruction of the *Rhodobacter* group based on 16S rRNA and created using the neighbor-joining algorithm with the Jukes-Cantor correction. The sequence data sets and alignments were used according to the All-Species Living Tree Project (LTP) database (Yarza et al. 2010; http://www.arb-silva.de/projects/living-tree). The tree topology was stabilized with the use of a representative set of nearly 750 high-quality type strain sequences proportionally distributed among the different bacterial and archaeal phyla. In addition, a 40 % maximum frequency filter was applied in order to remove hypervariable positions and potentially misplaced bases from the alignment. Scale bar indicates estimated sequence divergence

among these groups is not even, but heavily biased to the *Roseobacter* group, that contains nearly 70 genera and more than 160 species. Metabolic, physiological, and ecological traits may differ between groups, giving a base for their suggested recognition as new families. For example, the *Rhodobacter* group contains mainly species from freshwater and terrestrial habitats, with few showing salt requirements, while *Rhodovulum* group is dominated by halophilic, marine species. On the other hand, the *Roseobacter* group contains mostly aerobic chemoorganoheterotrophs, occasionally AAP, isolated from marine habitats, but no purple non-sulfur photosynthetic genera, which are dominant in *Rhodobacter* and *Rhodovulum* groups. The *Paracoccus* group is composed almost exclusively by species of this genus, which thrives commonly in aquatic environments, including sewage and sewage treatment plants and is widely known for the denitrification activity displayed by some of its members.

Strains of the *Rhodobacteraceae* are successfully preserved in 20 % (w/v) glycerol suspension at −80 °C. Long-term preservation by freeze-drying gives good results. In our experience at CECT, the best protecting agent for lyophilization is 5 % (w/v) inositol. Some strains need the addition of salts for maintaining the ionic stability in the suspension. This could be achieved by adding the recommended culture broth to the cryoprotectant solution in a proportion of 1 to 1. Some strains could not be lyophilized successfully. Preservation and storage of these strains in liquid nitrogen is possible with 5 % (v/v) DMSO as cryoprotectant.

The *Rhodobacter* Group

This group comprises the following genera: *Defluviimonas*, *Gemmobacter*, *Haematobacter*, *Pararhodobacter*, *Pseudorhodobacter*, *Rhodobaca*, *Rhodobacter*, *Roseibaca*, *Roseicitreum*, *Roseinatronobacter*, and *Thioclava*.

The group contains a diverse collection of metabolic lifestyles, as purple non-sulfur photosynthetic bacteria (*Rhodobacter*, the type genus of the family, plus *Rhodobaca*), aerobic anoxygenic photoheterotrophs (*Roseibaca*, *Roseicitreum*, and *Roseinatronobacter*), chemoorganoheterotrophs (most *Gemmobacter* species, *Defluviimonas*, *Haematobacter*, *Pararhodobacter*, and *Pseudorhodobacter*), and facultative sulfur chemolithotrophs (*Thioclava*).

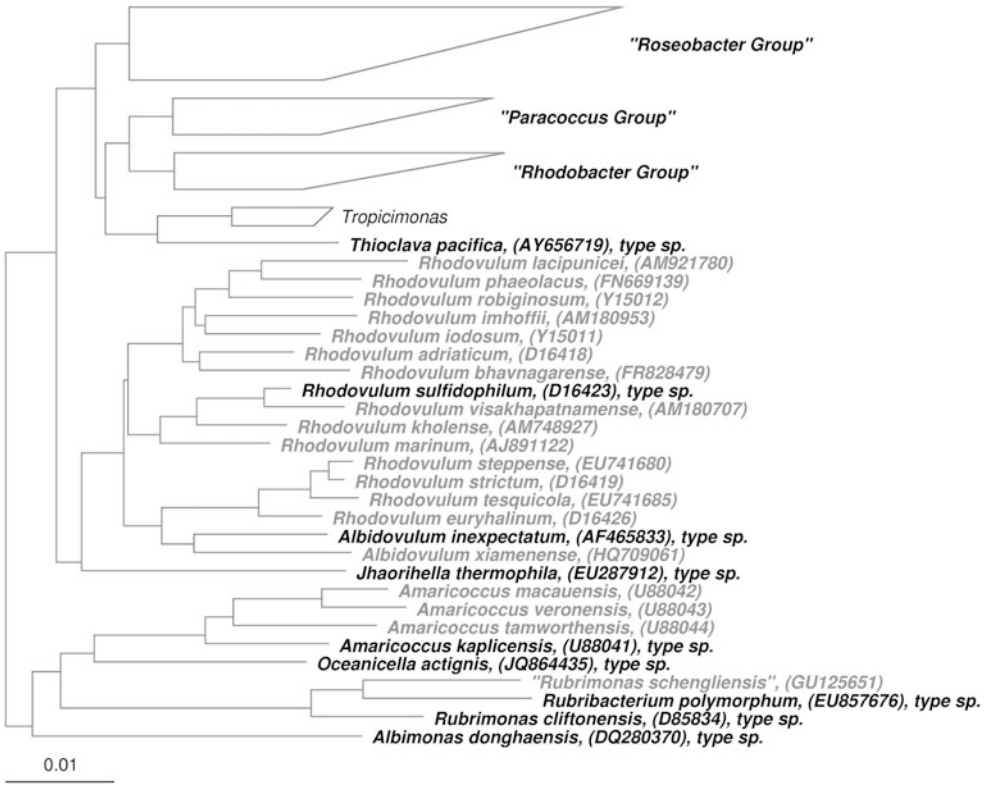

Fig. 20.3

Phylogenetic reconstruction of the *Rhodovulum* and *Amaricoccus* groups based on 16S rRNA and created using the neighbor-joining algorithm with the Jukes-Cantor correction. The sequence data sets and alignments were used according to the All-Species Living Tree Project (LTP) database (Yarza et al. 2010; http://www.arb-silva.de/projects/living-tree). The tree topology was stabilized with the use of a representative set of nearly 750 high-quality type strain sequences proportionally distributed among the different bacterial and archaeal phyla. In addition, a 40 % maximum frequency filter was applied in order to remove hypervariable positions and potentially misplaced bases from the alignment.
