All of them, except for *Thioclava*, are grouped in a well-defined clade, whose nearest neighbor is the *Paracoccus* group (*Fig. 20.2*). *Thioclava* does not merge with the clade in the NJ analysis, but is clearly included when ML is used (not shown), having *Defluviimonas* as closest relative. The internal phylogenetic structure of the group does not reflect a separation of lifestyles or habitats, as a close relationship is found, for example, between the clinical chemoorganotrophic *Haematobacter* species and a subset of *Rhodobacter* species that include the three isolated from marine samples. An exception is the grouping of all AAPs together with the two *Rhodobaca* species, as most of them share hypersaline soda lake water as a common habitat (*Table 20.3*).

Rhodobacter

The type genus of the family, *Rhodobacter*, has been thoroughly treated by Imhoff (2005, 2006). The reader is addressed to those chapters for more detailed information on this genus (as well as *Rhodobaca* and *Rhodovulum*). A summary of its general characteristics is given here together with information on those species described after the reference work of Imhoff cited above.

Rhodobacter is defined, among all the phototrophic alphaproteobacteria, by a set of characters that include cellular morphology and division mode, intracytoplasmic membrane type, pigment composition, optimal phototrophic conditions, polar lipid content, saline preferences, and major products of sulfide oxidation. *Rhodobacter* cells are ovoid or short rods, with polar flagella (when motile) that divide by binary fission (sometimes forming chains) and exhibit vesicular intracytoplasmic membrane systems when grown phototrophically (an exception is *R. blasticus*, formerly *Rhodopseudomonas blastica*, which forms peripheral lamellae and divide by budding).

They present Q-10 as predominant quinone and have C18:1 ω7c as dominant cellular fatty acid, accompanied by C18:0 and C16:0 (Girija et al. 2010). Polar lipids may include PE and sulfolipids in addition to PC and PG. The DNA G+C content is 62–73 mol%.

Their preferred metabolism is photoorganoheterotrophy, with light and organic carbon and electron sources in anaerobic

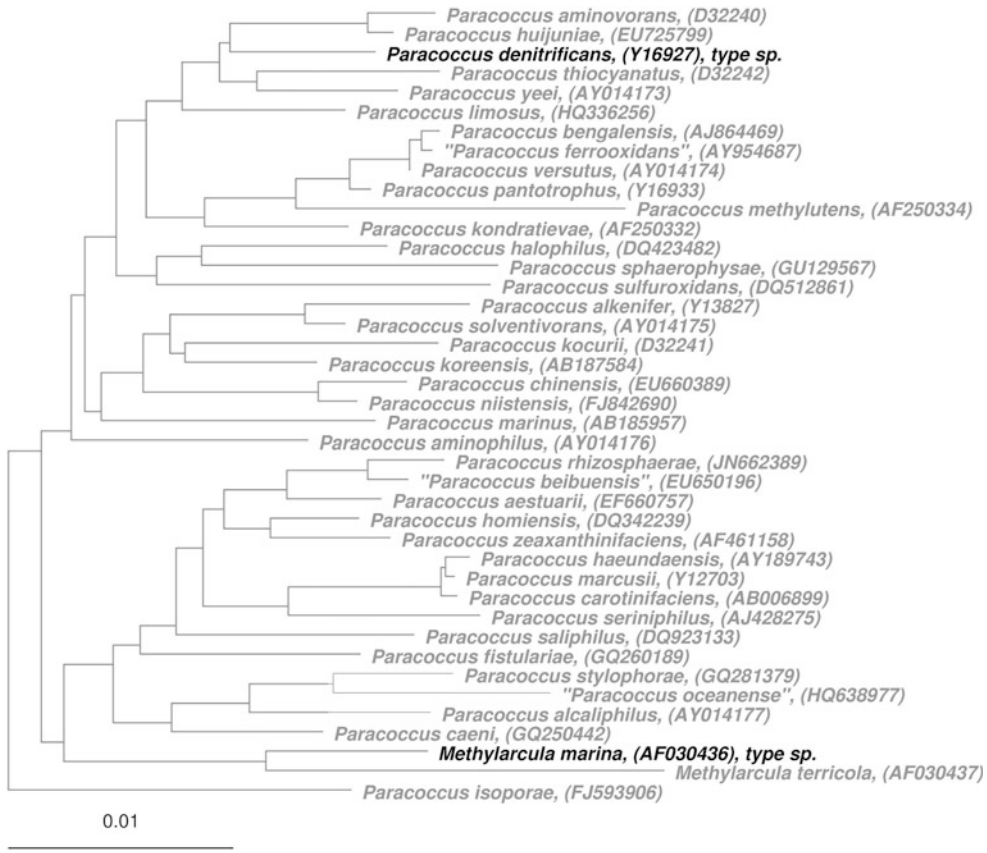

Fig. 20.4

Phylogenetic reconstruction of the *Paracoccus* group based on 16S rRNA and created using the neighbor-joining algorithm with the Jukes-Cantor correction. The sequence data sets and alignments were used according to the All-Species Living Tree Project (LTP) database (Yarza et al. 2010; http://www.arb-silva.de/projects/living-tree). The tree topology was stabilized with the use of a representative set of nearly 750 high-quality type strain sequences proportionally distributed among the different bacterial and archaeal phyla. In addition, a 40 % maximum frequency filter was applied in order to remove hypervariable positions and potentially misplaced bases from the alignment. Scale bar indicates estimated sequence divergence

conditions. Phototrophically grown cultures are yellow brown to yellow green, but turn pink or red when exposed to oxygen. Main photosynthetic pigments are Bhcl *a* and carotenoids of the spheroidene series, with spheroidene and spheroidenone as the major components, except for *R. viridis* (Shalem Raj et al. 2013) which presents neurosporene as major carotenoid. In addition to the photoheterotrophic growth, some rhodobacters are able to thrive as photolithoautotrophs, using reduced sulfur compounds (sulfide, thiosulfate) or hydrogen as electron donors and bicarbonate/CO_2 as carbon source (fixed through Calvin cycle). Elemental sulfur is the common end product of sulfide oxidation, although some species can oxidize it to sulfate (*R. veldkampii*). Chemoheterotrophic growth in the dark by aerobic respiration is also common, being pyruvate, succinate, lactate, and other organic acids and sugars usually used. In anaerobic conditions, denitrification, other anaerobic respiration processes (with TMAO or DMSO), or fermentation (on pyruvate or sugars) could support chemoheterotrophic growth of some species. Chemolithoautotrophic growth is also possible with hydrogen being used by some species. Metabolic versatility, is, thus, considered a prominent character of this genus. Nevertheless, ability for photolithoautotrophic growth is restricted to only two out of the seven species described since 2007 and chemolithoautotrophy is even rarer. Thus, the current balance is that most *Rhodobacter* species are unable to growth autotrophically.

All *Rhodobacter* species have vitamin requirements (vitamin B12, biotin, niacin, thiamin, and/or *p*-aminobenzoic acid). Ammonium salts are the best nitrogen source, but they are also able to fix molecular nitrogen, both in phototrophic and in chemotrophic regimes (in this later case, with microoxic conditions). Sulfate is used as sulfur source by most species but some require reduced sulfur compounds.

Species of *Rhodobacter* are inhabitants of freshwater environments and are mesophilic and non-halophilic, being this later trait one that distinguish *Rhodobacter* from the members of *Rhodovulum*. While this assertion is true for the older members of the genus, however, three of the newest species come from marine samples and one of them displays saline requirements, as it needs NaCl for growth (*R. vinaykumarii*, Srinivas et al. 2007a).

Phylogenetic reconstruction of the *Stappia* group based on 16S rRNA and created using the neighbor-joining algorithm with the Jukes-Cantor correction. The sequence data sets and alignments were used according to the All-Species Living Tree Project (LTP) database (Yarza et al. 2010; http://www.arb-silva.de/projects/living-tree). The tree topology was stabilized with the use of a representative set of nearly 750 high-quality type strain sequences proportionally distributed among the different bacterial and archaeal phyla. In addition, a 40 % maximum frequency filter was applied in order to remove hypervariable positions and potentially misplaced bases from the alignment. Scale bar indicates estimated sequence divergence

Other rhodobacters of marine origin are *R. maris* and *R. aestuarii* (Venkata Ramana et al. 2008, 2009), although they do not require NaCl for growth. The remaining recently recognized species have been isolated from soil (*R. megalophilus*, Arunasri et al. 2008; *R. jhorii*, Girija et al. 2010) or freshwater environments (*R. ovatus*, Srinivas et al. 2008; *R. viridis*, Shalem Raj et al. 2013).

A remarkable finding in one of the newly described species, *R. johrii*, is the ability to form endospores (Girija et al. 2010). This species was isolated from pasteurized rhizosphere soil and, after careful assessment of purity both by cultural and molecular methods, the presence and characteristic features of endospores were confirmed: dipicolinic acid content, staining behavior, induction upon stress, thermoresistance, thermal activation, ultrastructural appearance (not typical). To the best of our knowledge, genes encoding this complex ability have not been investigated; thus the ability is pending confirmation as in the case of other alleged endospore-formers outside *Firmicutes* (e.g., *Mycobacterium marinum*, Ghosh et al. 2009; Traag et al. 2010).

The complete genome sequence of *R. capsulatus* SB 1003 has been reported (Strnad et al. 2010). It consists of a 3.7 Mb chromosome and a 133 kb plasmid. The genome encodes genes for photosynthesis, nitrogen fixation, utilization of xenobiotic organic substrates, and synthesis of polyhydroxyalkanoates. In the case of *R. sphaeroides*, four strains have been fully sequenced (strains 2.4.1^T, ATCC 17019, ATCC 17025, and KD131) having two chromosomes, except strain ATCC 17019 with only one, one to five plasmids, and 4.5–4.7 Mb total size (Choudhary et al. 2007; Lim et al. 2009). In a recent comprehensive analysis of genomic islands in 70 selected marine bacterial genomes, Fernández-Gómez et al. found that *R. sphaeroides* ATCC 17025 had the highest ratio (0.12, genomic islands size/genomic size) of all.

Species of *Rhodobacter* separate in two clades (◉ *Fig. 20.2*), both in NJ and ML trees (ML not shown) suggesting a polyphyletic nature for the genus. In one hand, *R. capsulatus* joins *R. aestuarii*, *R. maris*, *R. vinaykumarii*, and *R. viridis* in a group that is more closely related to *Haematobacter* spp. than to the rest of *Rhodobacter* spp. On the other hand, the species *R. azotoformans*, *R. johrii*, *R. megalophilus*, *R. ovatus*, and *R. sphaeroides* form another clade that is closer to *Gemmobacter* species. *R. blasticus* is marginally related to this group and *R. veldkampii* occupies an isolated position among the main lineages.

Defluviimonas

Defluviimonas is a recently described monospecific genus, whose only species; *D. denitrificans* was isolated from a fluidized bed reactor from a recirculating marine aquaculture system (Foesel et al. 2011). *Defluviimonas* presents as Gram-negative rods that may be motile by polar flagella and divide by binary fission. They are chemoorganotrophic and facultatively anaerobic, with a strictly respiratory metabolism. Oxidase and catalase are positive. It is nonpigmented and non-phototrophic. *D. denitrificans* is able to grow anaerobically by denitrification, with N_2 as end product of the process. NaCl is not needed for growth, but it is tolerated up to 5 %. Q10 is the predominant quinone and C18:1 ω7c the major cellular fatty acid. DNA G+C content is 65 mol%.

Gemmobacter

The genus *Gemmobacter*, as currently defined, contains *G. aquatilis*, the type species (Rothe et al. 1987), *G. fontiphilus*

Table 20.3
Species in the *Rhodobacter* group

Species (synonym)	Isolation/habitat	Metabolism[a]	Na^+ requirement, others	References
Rhodobacter capsulatus (*Rhodopseudomonas*)	Stagnant freshwater exposed to the light with reduced oxygen, USA and Cuba	PNS	No	Imhoff et al. 1984
R. aestuarii	Microbial mat at mangrove forest, India	PNS	No	Venkata Ramana et al. 2009
R. azotoformans	Photosynthetic sludge from wastewater treatment, Japan	PNS	No	Hiraishi et al. 1997
R. blasticus (*Rhodopseudomonas*)	Stagnant freshwater exposed to the light with reduced oxygen, UK	PNS	No	Kawasaki et al. 1993
R. johrii	Pasteurized rhizosphere soil, India	PNS	No	Girija et al. 2010
R. maris	Coastal marine sediment, India	PNS	No	Venkata Ramana et al. 2008
R. megalophilus	Soil, Himalayas, India	PNS	No	Arunasri et al. 2008
R. ovatus	Sediment of industrially polluted pond, India	PNS	No	Srinivas et al. 2008
R. sphaeroides	Stagnant freshwater exposed to the light with reduced oxygen, the Netherlands and USA	PNS	No	Imhoff et al. 1984
R. veldkampii	Stagnant freshwater exposed to the light with reduced oxygen, Netherlands	PNS	No	Hansen and Imhoff 1985
R. vinaykumarii	Tidal seawater, India	PNS	Yes	Srinivas et al. 2007a
R. viridis	Stream water and mud, India	PNS	No	Shalem Raj et al. 2013
Defluviimonas denitrificans	Biofilter, marine aquaculture recirculating system, Israel	COH	No	Foesel et al. 2011
Gemmobacter aquatilis	Forest pond, USA	COH fac an	No	Rothe et al. 1987
G. aquaticus (*Catellibacterium*)	Water reservoir, China	COH	No	Chen et al. 2013a; Liu et al. 2010
G. caeni (*Catellibacterium*)	Activated sludge, China	COH	No	Chen et al. 2013a; Zheng et al. 2011a
G. changlensis (*Rhodobacter*)	Snow, Himalayas, India	PH	No	Chen et al. 2013a; Anil Kumar et al. 2007
G. fontiphilus	Freshwater spring, Taiwan	COH	No	Chen et al. 2013a
G. nanjingensis (*Catellibacterium*)	Activated sludge, China	COH	No	Chen et al. 2013a; Zhang et al. 2012a
G. nectariphilus (*Catellibacterium*)	Activated sludge, Japan	COH	No	Chen et al. 2013a; Tanaka et al. 2004
G. tilapiae	Freshwater fish culture pond, Taiwan	COH	No	Sheu et al. 2013a
Haematobacter missouriensis	Clinical samples (blood, wounds), USA	COH a	No	Helsel et al. 2007
H. massiliensis (*Rhodobacter*)	Amoebal coculture from nasal swab, France	COH a	No	Helsel et al. 2007; Greub and Raoult 2003
Pararhodobacter aggregans	Biofilter, marine aquaculture recirculating system, Israel	COH a	No	Foesel et al. 2011
Pseudorhodobacter ferrugineus (*Agrobacterium*)	Seawater, Baltic Sea, Germany	COH a	No	Lee et al. 2013a; Chen et al. 2013b; Jung et al. 2012a; Uchino et al. 2002
P. antarcticus	Intertidal sandy sediment, Antarctica	COH a	No	Chen et al. 2013b
P. aquimaris	Seawater, S. Korea	COH a	Yes (+ Mg^{2+})	Jung et al. 2012a
P. wandonensis	Wood falls at South sea, S. Korea	COH a	No	Lee et al. 2013a
Rhodobaca bogoriensis	Water and sediment of alkaline soda lakes, Rift Valley, Kenya	PNS	No, alkaliphilic	Milford et al. 2000

[a]*AAP* aerobic anoxygenic photoheterotroph, *COH* chemoorganoheterotroph, *COH a* chemoorganoheterotroph aerobic, *COH fac an* chemoorganoheterotroph facultative anaerobic, *fac CLA* facultatively chemolithoautotroph, *PH* photoheterotroph, *PNS* purple non-sulfur anoxygenic photoheterotroph

(Chen et al. 2013a), and *G. tilapiae* (Sheu et al. 2013a), and five species transferred from the genus *Catellibacterium* as new combinations (Chen et al. 2013a): *G. aquaticus*, *G. caeni*, *G. changlensis*, *G. nectariphilus*, and *G. nanjingensis*. As it can be observed in *Fig. 20.2*, the phylogenetic relationship within this group supports the combination of all species in one genus, with only some concern about the doubtful position of *G. nectariphilus*. *Gemmobacter* stands as a close relative of the "sphaeroides" clade of *Rhodobacter*.

After several emended descriptions of both *Catellibacterium* and *Gemmobacter* genera, the recent reclassification of Chen et al. (2013a) leaves the following general properties as characteristic of the newly defined *Gemmobacter*: Gram-negative rod-shaped cells that sometimes reproduce by budding and do not form endospores. Most species are nonmotile (except for *G. aquaticus*, with one polar flagellum). Chemoheterotrophs (*G. changlensis* is photoheterotroph able to live as chemoheterotroph in aerobic, dark conditions) use mainly carbohydrates aerobically (*G. aquatilis*, *G. nanjingense*, and *G. fontiphilus*, also anaerobically) as carbon and energy sources. Oxidase and catalase are positive. Main cellular fatty acid is C18:1 ω7c. Common polar lipids are PG, PE, PC, and one unidentified aminolipid. Q10 is the dominant ubiquinone. G+C content of DNA is 61–69.5 mol%. All species of *Gemmobacter* have been isolated from freshwater environments, including activated sludge and aquaculture facilities. They are non-halophilic and some have a low tolerance to NaCl (e.g., the maximum salinity tolerated by *G. fontiphilus* is 0.5 %, while *G. aquaticus* and *G. tilapiae* only tolerate 1 %). They are mesophilic and neutrophilic. One species isolated from snow at the Himalayas, *G. changlensis*, is able to grow at low temperatures (5 °C), but optimum is 25–30 °C.

DNA-DNA hybridization (DDH) experiments have been used to define the position of several close species of the group: type strains of *G. nanjingensis* and *G. caeni* show low levels of DDH (14–19 %, Zhang et al. 2012a); *G. tilapiae* and *G. aquatilis* are related by values of 45–48 % (Sheu et al. 2013a), *G. fontiphilus* and *G. aquatilis* show 46–52 %, *G. fontiphilus* and *G. aquaticus* 52–57 %, and *G. fontiphilus* and *G. caeni* 40–53 % DDH (Chen et al. 2013a).

The draft genome of *G. nectariphilus* DSM 15620^T has 4.52 Mb.

Haematobacter

Haematobacter was described in 2007 from a context atypical for members of *Rhodobacteraceae*, the clinical environment. In fact, it is the only genus being involved to some extension in pathogenicity, as it has been related to opportunistic infections. The genus name is taken from the most common source of isolates, human blood samples, although one species has been obtained from a nasal swab. The genus is defined as Gram negative, nonmotile, nonspore-forming, non-fermentative, and pleomorphic. Cultural properties have been determined as usual for clinical isolates, assuming chemoorganotrophy as the sole metabolic lifestyle; thus no information about other potential metabolisms is available. They are aerobic, oxidase and catalase positive, and not pigmented. DNA G+C content is around 65 mol% and main cellular fatty acids are C18:1 ω7c (50–90 %), C10:0 3OH, C16:1 ω7c, C16:0, C18:0, C18:1 ω9c, and C19:0 cyclo ω8c. There are two named species, *H. missouriensis* and *H. massiliensis*, related by interspecies DDH values of 40–55 % and one unnamed genospecies that shows 63–64 % DDH with *H. massiliensis* and *H. missouriensis* strains (Helsel et al. 2007). Buscher et al. (2010) have isolated a *Haematobacter*-like monoculture from blood of a patient with endocarditis which is only 96.7 % similar in its 16S rRNA gene sequence to the closer *Haematobacter* species. *H. massiliensis* was formerly described as a *Rhodobacter* species

(Greub and Raoult 2003) and was isolated through amoebal coculture; it was lately confirmed as able to resist amoeba grazing.

Aminoglycosides, fluoroquinolones, carbapenems, tetracycline, and chloramphenicol have good activity against *Haematobacter* isolates, while aztreonam and piperacillin have higher MIC values (Helsel et al. 2007).

Pararhodobacter

Pararhodobacter was described for accommodating one isolate obtained from the same environment that rendered *Defluviimonas denitrificans* (Foesel et al. 2011; see above). It was defined by its proximity to *Rhodobacter*, although its position in the complete *Rhodobacteraceae* tree seems closer to the *Rhodobaca* clade (Fig. 20.2). *Pararhodobacter* comprises Gram-negative, nonmotile, nonspore-forming rods that divide by binary fission and are chemoorganotrophic and strictly aerobic. Non-phototrophic. Catalase is positive but oxidase is negative. Similarly to *Defluviimonas denitrificans*, *Pararhodobacter aggregans*, the only species described so far, does not need NaCl for growth but tolerates up to 5 %. It grows with several organic acids and a few amino acids and sugars. It does not reduce nitrates or nitrites. DNA G+C content is 68 mol%. Q10 is the predominant quinone and C18:1 ω7c the main fatty acid.

Pseudorhodobacter

Pseudorhodobacter currently contains four species of chemoorganotrophs, unable to synthetize Bchl *a* and with a strictly respiratory type of metabolism. The type species *P. ferrugineus*, formerly one of the so-called marine *Agrobacterium* species (Rüger and Höfle 1992; Uchino et al. 1997), was reclassified to this new genus after an extensive study of the features common and differential from *Rhodobacter*, its closer neighbor (Uchino et al. 2002). The later descriptions of a second (*P. aquimaris*, Jung et al. 2012a) and a third species (*P. antarcticus*, Chen et al. 2013b) both including emended genus descriptions had modified slightly the original profile of the genus, which currently encompasses Gram-negative rods that may be motile or nonmotile, oxidase and catalase positive, with optimal growth at temperatures from 15 °C to 30 °C and with 1–3 % of NaCl. They contain Q10 as major quinone, C18:1 ω7c as predominant fatty acid, and C10:0 3OH as major hydroxylated fatty acid. Polar lipids include PG, PC, two unidentified aminophospholipids, and one unidentified aminolipid. G+C content is 57–62 mol%. *P. aquimaris* requires NaCl and Mg ions for growth, while the other species of the genus grow optimally in the presence of 1–3 % NaCl and do not have an absolute requirement of marine cations. The draft genome of *P. ferrugineus* DSM 5888^T contains 3.43 Mb. DNA-DNA relationship among *Pseudorhodobacter* species has been determined for *P. ferrugineus* to *P. antarcticus* (56 %; Chen et al. 2013b) and to *P. wandonensis* (12 %; Lee et al. 2013a). The four species form a well-defined clade in the vicinity of *Rhodobacter*, to which they associate, but not as closely as *Gemmobacter* or *Haematobacter* (Fig. 20.2).

Rhodobaca

The genus *Rhodobaca* comprises two species of alkaliphilic purple non-sulfur bacteria that have been isolated from distant soda lakes. The type species *R. bogoriensis* was described upon the study of several strains isolated from water and sediment samples from two African soda lakes located in the Rift Valley, Kenya (Milford et al. 2000), while *R. barguzinensis* corresponds to isolates obtained from a shallow, small soda lake in Siberia, Russia (Boldareva et al. 2008). Both species share a common metabolic profile that includes the ability for photoorganotrophic growth in anaerobic, light conditions, using several organic acids and some sugars, and also as chemoorganotrophs, in aerobiosis with almost the same carbon sources. None of them are able, apparently, of autotrophic growth, as they lack RubisCo gene nor are they able to fix N_2. They do not use nitrate as N source, but ammonium salts, urea, serine, or glutamate. Sulfide is oxidized to sulfur under photoheterotrophic growth conditions. Interestingly, both species are able to reduce tellurite and selenite to Te and Se, respectively, which are accumulated outside the cells. They synthetize Bchl *a* and carotenoids of the spheroidene series, being the major carotenoid demethylspheroidenone in the case of *R. bogoriensis* and demethyl spheroidene for *R. barguzinensis*. Cells of *Rhodobaca* species are motile, coccoid to short rods, and accumulate PHB-resembling granules. Under phototrophic conditions, they present vesicular intracytoplasmic membranes that are scarce and located in the peripheral zone of the cell. *R. barguzinensis* produces abundant slime and, unlike *R. bogoriensis*, divides by unequal fission. Biomass produced in anaerobic, light conditions is yellow brown (*R. bogoriensis*) or beige (*R. barguzinensis*), turning pink in both cases after exposure to oxygen or when cultured in aerobiosis.

Rhodobaca species behave as alkaliphiles: they do not grow at pH 7.0; their range starts at 7.5 and extends up to 10. The optimal pH of the type species is 9.0 while for *R. barguzinensis* is 8.2. They are mesophilic but *R. bogoriensis* has optimal and minimal temperatures for growth notoriously higher than the Siberian species (minimum 30, optimum 39 °C). Both are stimulated by NaCl but only *R. barguzinensis* has an absolute need of Na ion for growth.

Their major cellular fatty acids are C18:1 ω7c accompanied by C16:0, 11-methyl C18:1 ω7c, C16:1 ω7c, and C14:1 ω7c. The DNA G+C content is 58.8–59.8 mol%.

Rhodobaca-like isolates have been identified among the dominant bacteria obtained during the late-flooded phase of ephemeral hypereutrophic playa lakes in the Mojave Desert (Navarro et al. 2009).

Rhodobaca species form a coherent clade that also includes the following three genera, all of them aerobic, bacteriochlorophyll-containing heterotrophs isolated from soda lakes or

hypersaline lakes around the world (Table 20.3). The *Rhodobaca* clade lays at the edge of the *Rhodobacter* group (Fig. 20.2).

Roseibaca

Roseibaca contains a single species, *R. ekhonensis*, isolated from Ehko Lake, a hypersaline, meromictic, heliothermal lake in Antarctica (Labrenz et al. 2009). This species is similar to *Roseinatronobacter*, but alkalitolerant instead of alkaliphilic. It has been characterized more deeply in its chemotaxonomic features: it contains Q10 as predominant quinone, presents DPG, PE, PG, and PC as main polar lipids, meso-diaminopimelic acid in its peptidoglycan, and has a G+C content of 61 mol% in its DNA. The main fatty acids are C18:1 ω7c, C14:1 3OH, C16:1 ω9c, and C18:1 ω9c. *R. ekhonensis* is a strict aerobe and heterotroph, which synthetizes Bchl *a* and carotenoids, producing red to pink colonies. Cells are rod shaped, with a narrower end that suggests budding division, produce fimbria, and sometimes stemlike structures. The cells are often associated forming rosettes. They are nonmotile and accumulate PHB. It has an optimum temperature of 16 °C but grows from 10 °C to 30 °C and has a wide range of pH for growth (from as low as 5.5, in contrast with *Roseinatronobacter* and *Rhodobaca* species) with optimum between 7.0 and 9.0. It has an absolute requirement for Na ion and grows optimally at 2.5 % NaCl. It is positive for oxidase and gives a weak catalase reaction. Growth of *R. ekhonensis* requires thiamine and vitamin B12. Carbon sources used for growth include several organic acids and a large list of carbohydrates.

Roseicitreum

Roseicitreum is another AAP genus, currently containing a sole species, *R. antarcticum*, which was isolated from intertidal, sandy sediments in the coastal area of East Antarctica (Yu et al. 2011). Among its chemotaxonomic features, it contains the common quinone system of the family (Q10); its polar lipid composition includes PG, PE, PC, and one unidentified aminolipid; and its major fatty acids are C18:1 ω7c, C10:0 3OH, C16:0, C17:0 cyclo, and C19:0 cyclo ω8c. The DNA G+C content is 63 mol%. *R. antarcticum* cells are nonmotile, lemon shaped (hence the generic name), and accumulate PHB. They produce a small quantity of peripheral vesicles, similar to *Rhodobaca* cells. Colonies are pink to red. Bchl *a* is produced but *Roseicitreum* is unable to growth as photoautotroph or as anaerobic photoheterotroph. It is positive for oxidase and catalase tests. It uses carbohydrates and some organic acids as carbon and energy sources for growth. Preferred temperatures are in the mesophilic range (25–27 °C), but it is able to grow from 0 °C to 33 °C. Although Na ions are not required, growth is optimum at 7–8 % and occurs up to 15 % NaCl. The pH range is 5–9.5, with an optimum at 7.0. Thus, it is psychrotolerant and non-alkaliphilic.

Roseinatronobacter

Roseinatronobacter is the eldest of these *Rhodobaca*-associated soda lake AAPs. It was described by Sorokin et al. (2000) after the study of one pink pigmented, alkaliphilic strain isolated from a microbial mat sample obtained in a steppe soda lake in Siberia. The strain was able not only to synthetize Bchl *a* but also to oxidize thiosulfate to sulfate, using it as additional electron donor during heterotrophic growth. The species *R. thiooxidans* is also able to oxidize other sulfur compounds (sulfide, elemental sulfur, sulfite) producing sulfate. A second species was described in 2007, *R. monicus*, based on two strains isolated from Mono Lake, California (Boldareva et al. 2007). The cells of *R. thiooxidans* are elongated while *R. monicus* has oval cells, but both are nonmotile, divide by binary fission, and accumulate PHB. They are strictly aerobic and heterotrophic and able to oxidize thiosulfate, sulfide, polysulfide, and elemental sulfur. They synthetize Bchl *a* and carotenoids of the spheroidene series. Light inhibits synthesis of bacteriochlorophyll, and in the case of *R. thiooxidans*, full oxygen tension also inhibits bacteriochlorophyll and pigmentation. The highest pigment content is obtained in media rich in organic nitrogen compounds, micro-oxic, and in the dark. Both species are mesophilic, slightly halophilic (but do not have a strict Na ion requirement), and obligately alkaliphilic, with a pH range of 8.5 to 10.4 and optima at 9.0–10.0. They contain C18:1 ω7c as major cellular fatty acid, accompanied by C18:2 ω6,9c, 11-methyl C18:1 ω7c, C16:0, C14:1 ω7c, and C16:1 ω7c. G+C content is 59–61.5 mol% (Boldareva et al. 2007). The two species described so far are related by levels of DDH of 22–25 %. It is noteworthy that, based on 16S rRNA gene comparison, *R. monicus* is closer to *Rhodobaca* species than to *R. thiooxidans* (Fig. 20.2).

Roseinatronobacter-like isolates and phylotypes have been detected in soda lakes of other Russian regions (Gorlenko et al. 2010) and European countries (Borsodi et al. 2013).

Thioclava

The genus *Thioclava* does not show a definite affiliation to the *Rhodobacter* group when 16S rRNA gene sequences are analyzed through NJ method (Figs. 20.1 and 20.2) but relates to *Tropicimonas* species. However, its link to the *Rhodobacter* group is clear in ML analysis (not shown). Former phylogenetic analysis showed *Thioclava* grouped with two *Rhodobacter* species, *R. maris* and *R. aestuarii* (LTP111). Thus, *Thioclava* has been included in the *Rhodobacter* group. The genus is monospecific (A second species of the genus *Thioclava*, *T. dalianensis*, has been recently proposed for an isolate unable to grow chemolithoautotrophically on inorganic sulfur compounds. Its description is accompanied by an emended description of the genus *Thioclava* (Zhang et al. 2013)) since its description (Sorokin et al. 2005a) and contains *T. pacifica*, a species of facultative autotrophic, sulfur-oxidizing marine bacteria that was isolated from a coastal sulfidic hydrothermal area in Papua New Guinea. *T. pacifica* forms cells with widely different

[a]*COH* chemoorganoheterotroph, *PNS* purple non-sulfur anoxygenic photoheterotroph

morphologies depending of the media and growth conditions, from long filaments with swollen ends to short rods. This later morphology may exhibit motility by a polar flagellum. Oxidase and catalase are positive. *Thioclava* is mesophilic, neutrophilic, and requires NaCl for growth (1–8 %, optimum 3–4 %). It does not synthetize Bchl or carotenoids and is a strictly aerobic chemotroph, able to grow chemoautotrophically by thiosulfate (or sulfide) oxidation (CO_2 is then fixed through Calvin cycle) or chemoheterotrophically, using organic acids, carbohydrates, or amino acids as carbon and energy sources. It requires thiamine and biotin. It is also able to oxidize thiosulfate in mixotrophic conditions (acetate + thiosulfate), producing sulfate as terminal by-product. It does not ferment glucose and does not denitrify. The RubisCo produced by *Thioclava* is the green form of type I and its gene sequence (cbbL gene) relates specifically (but not very closely) to the corresponding genes of *Rhodobacter* spp., *Rhodovulum* spp., and *Hydrogenophilus thermoluteus* (a betaproteobacterium).

T. pacifica presents Q10 as sole quinone. The G+C content of its DNA is 63 mol%.

The *Rhodovulum* Group

Members of this group include the marine purple non-sulfur photosynthetic genus *Rhodovulum* that currently contains 15 species, along with the chemoorganotrophic, unpigmented, and slightly thermophilic species of *Albidovulum* and *Jhaorihella* (*Table 20.4*). *Albidovulum* is closely related to one of the subclades of *Rhodovulum* (*R. euryhalinum*, *R. steppense*, *R. strictum*, *R. tesquicola*), while *Jhaorihella* is marginal to the whole group (*Fig. 20.3*). Altogether, they form a clade that relates with the combined *Roseobacter* plus *Paracoccus* plus *Rhodobacter* groups, as can be seen in *Figs. 20.1* and *20.3*.

Rhodovulum

Rhodovulum is the largest genus in this group and the only one behaving as purple non-sulfur photosynthetic bacteria. The genus was created to accommodate three former *Rhodobacter* species of marine origin, with salt requirements for optimal

growth. Not only salt requirement but also sulfide tolerance, final product from sulfide oxidation, and polar lipid composition allow the differentiation of the species *R. sulfidophilum*, *R. adriaticum*, and *R. euryhalinum* from the freshwater, true *Rhodobacter* species (Hiraishi and Ueda 1994). Only 1 year later, the same authors described a fourth species, *R. strictum* (Hiraishi and Ueda 1995), which was followed by the recognition of *R. iodosum* and *R. robiginosum*, two ferrous iron-oxidizing new species (Straub et al. 1999). These six species were included in the excellent chapter on phototrophic Alphaproteobacteria (Imhoff 2006), where a full account for taxonomy, phylogeny, habitats, methods of isolation, culture and preservation, physiology, and metabolism of the whole group is given. The reader is addressed to this chapter for wider treatment of genus *Rhodovulum*, in all these aspects. Its general properties are summarized here, after including the nine *Rhodovulum* species described later, with special emphasis in those features that differed from the commonly accepted for the genus.

Rhodovulum includes purple non-sulfur anoxygenic photoheterotrophs that inhabit marine or saline shallow water masses or their sediments and form oval- to rod-shaped cells that are mainly nonmotile (when motile, they exhibit polar flagella). Cellular size is 0.5–0.9 × 0.9–3.8 μm. They are typical Gram-negative cells and display intracytoplasmic membrane invaginations of the vesicular type when grown in phototrophic regime. Division takes place by binary fission. They synthetize Bchl *a* and carotenoids of the spheroidene series (spheroidene, spheroidenone, demethylspheroidene, hydroxyspheroidene, neurosporene) in different proportions. They are mesophilic, with optimum temperatures between 25 °C and 35 °C, and slightly halophilic, growing best at salinities 1–7.5 %. Most of them require NaCl for growth. Two species *R. steppense* and *R. tesquicola*, isolated from shallow soda lakes, are alkaliphilic, with optimum growth at pH 8.5–9.0, and unable to grow at pH 7.0. They are closely related to *R. strictum*, also slightly alkaliphilic, to which they show moderate DDH values (40–53 %) (Kompantseva et al. 2010, 2012).

Preferred metabolism is photoorgano- or photolitho-heterotrophic, in anaerobiosis with light, (sulfide/thiosulfate) and organic carbon sources, but most can also thrive as chemoorganoheterotrophs, with oxygen and organic carbon in the dark (*R. euryhalinum*, *R. adriaticum*, *R. phaeolacus*, and *R. bhavnagarense* are exceptions, as they require sulfide or thiosulfate in addition to the organic compound). Some can also develop as photo- or chemo-lithoautotrophs, using reduced sulfur compounds (sulfide, thiosulfate, and sulfur), hydrogen, or ferrous iron as electron donors and bicarbonate as carbon source. Sulfur compounds are oxidized to sulfate (with a transitory deposition of extracellular elemental sulfur during sulfide oxidation in *R. steppense* and *R. tesquicola*, Kompantseva et al. 2010, 2012). Several species are unable to grow autotrophically: *R. marinum*, *R. lacipunicei*, *R. phaeolacus*, *and R. bhavnagarense*. None of the species described so far is able to grow fermentatively.

The preferred organic carbon sources for growth are organic acids such as pyruvate, lactate, Krebs cycle intermediates, and short-chain fatty acids. Some amino acids and sugars, as well as formate, may be used by some species. Vitamin requirement is a general rule for all species, which are variable for the given combination they need.

Species of *Rhodovulum* have C18:1 ω7c as major cellular fatty acids, with minor amount of C18:0, C16:0, 11-methyl C18:1 ω7c, and C10:0 3OH. The polar lipid composition includes PE, PG, several sulfolipids (including sulfoquinovosil diglyceride, SQD), and other lipids, but excludes PC. Although not regularly investigated, the two species that have been analyzed for this trait, *R. bhavnagarense* (Srinivas et al. 2012) and *R. tesquicola* (Kompantseva et al. 2012), confirm this general behavior. The major ubiquinone is Q10. The DNA G+C content, reported to be 62–69 mol% in the genus description (Hiraishi and Ueda 1994), has to be lowered, as *R. imhoffii* shows 58 mol% (Srinivas et al. 2007a) and *R. visakhapatnamensis* has 61.2 mol% (Srinivas et al. 2007b).

Recently, Khatri et al. (2012) have reported the 4.8 Mb draft genome of *Rhodovulum* sp. strain PH10 isolated from a mangrove soil sample. It contains 3 copies of the rRNA genes, 47 aminoacyl tRNA synthetase genes, and a DNA G+C content of 69.7 mol%.

Rhodovulum species (*R. sulfidophilum* in particular) have been investigated for the interest of some of its activities: hydrogen production (Cai and Wang 2013), PHB production (Cai et al. 2012), or anti-viral RNA aptamer secretion for aquaculture improvement (Hwang et al. 2012; Suzuki et al. 2010).

Albidovulum

The genus *Albidovulum* was described by Albuquerque et al. (2002) as a non-photosynthetic, thermophilic relative of *Rhodovulum*, with a single species, *A. inexpectatum*. Recently, a second species *A. xiamenense* (Yin et al. 2012) has been described and corresponds also to an inhabitant of a coastal hot spring. Similarity in 16S rRNA gene sequence between both species is around 96 %. Main characteristics of the genus include the absence of Bchl *a* and carotenoid production, the chemoorganotrophic, strict aerobic nature of its metabolism, and the slightly thermophilic character, with temperature optimum for growth at 50–58 °C (ranges: 28–65 °C for *A. xiamenense*, 35–60 °C for *A. inexpectatum*). Their cells are rod shaped and only *A. xiamenense* shows polar flagella and motility, while *A. inexpectatum* is nonmotile. They are positive for oxidase and catalase tests, reduce nitrates to nitrites (but are unable to grow with nitrate in anaerobiosis), do not ferment carbohydrates, and use a variety of organic compounds as carbon sources (sugars, polyols, amino acids, and organic acids) but are unable to fix CO_2. *A. inexpectatum* is facultatively chemolithoorganotrophic on reduced sulfur compounds, as it is able to oxidize thiosulfate to sulfate, deriving energy for increased growth, in the presence of organic carbon sources. Thiosulfate oxidation was not tested on *A. xiamenense*.

Table 20.5
Species in the *Amaricoccus* group

Species (synonym)	Isolation/habitat	Metabolism[a]	Na^+ requirement, others	References

[a]*AAP* aerobic anoxygenic photoheterotroph, *COH* chemoorganoheterotroph, *COH a* chemoorganoheterotroph aerobic, *PNS* purple non-sulfur anoxygenic photoheterotroph

Jhaoriella

Jhaoriella thermophila is the only recognized species of the genus *Jhaoriella* (Rekha et al. 2011). In spite of the specific name and isolation source, it is not a true thermophile, as it grows optimally at 37–45 °C and is able to grow from 25 °C up to 55 °C. The genus was defined on the basis of its deep lineage within the *Rhodobacteraceae*. It was found distantly related to some members of the *Roseobacter* clade and was compared to them in the description. It is a rod-shaped, unpigmented, nonmotile bacterium which shows Q10 as major respiratory quinone; PC, PG, and PE as major identified polar lipids; and cellular fatty acids dominated, as usual, by C18:1 ω7c. It requires seawater or combined sea salts for growth (2–6 %, with optimum at 3–4 %) and is obligately aerobic, unable to grow with nitrate in anaerobic conditions. It is positive for oxidase and catalase tests and PHB accumulation. The only known strain was isolated from a coastal hot spring and has a DNA G+C content of 65 mol%.

The *Amaricoccus* Group

In this group, five genera are recovered as part of a clade that always represents the deepest rooted and more distantly related clade to the rest of the family (*sensu stricto*) (*Fig. 20.3*). It includes *Amaricoccus* (with four species), *Albimonas* (one species), *Oceanicella* (one species), *Rubribacterium* (one species), and *Rubrimonas* (two species). Again, the group contains a purple non-sulfur photosynthetic member (*Rubribacterium*) and also aerobic anoxygenic phototrophs (*Rubrimonas* sp.), along with chemoorganotrophic, non-phototrophic members (*Table 20.5*).

Amaricoccus

The four species that constitute the genus *Amaricoccus* (Maszenan et al. 1997) were isolated after micromanipulation from activate sludge biomass obtained in geographically distant wastewater treatment plants. The aim of the study by Maszenan and coworkers was the isolation and characterization of the so-called G-bacteria, a morphotype common to the sludge and particularly difficult to cultivate. This morphotype corresponded to Gram-negative cocci arranged in tetrads and sheets. After trying a wide range of media, the isolates could be grown only in medium GS (Williams and Unz 1985) that contains (per liter) 0.15 g glucose, 0.50 g $(NH_4)_2SO_4$, 0.10 g $CaCO_3$, 0.10 g $Ca(NO_3)_2$, 0.05 g KCl, 0.05 g K_2HPO_4, 0.05 g $MgSO_4{\cdot}7H_2O$, 0.187 g $Na_2S{\cdot}9H_2O$, 15 g bacteriological agar (Difco), and 1.0 ml of a 10x vitamin stock solution. The new genus was described as large, Gram-negative, nonspore-forming cocci (mean cell diameter, 1.3–1.8 μm), usually arranged in tetrads. The cells were not motile and did not accumulate polyphosphate granules, either when growing in the sludge or in axenic lab cultures. They are aerobic chemoheterotrophs that use a large variety of carbohydrates and organic acids as substrates. They are oxidase positive, mesophilic (20–37 °C), and grow at pH between 5.5 and 9.0. The DNA G+C content is 51–63 mol%. According to Falvo et al. (2001), *A. kaplicensis* is able to store acetate as PHB at high rates. In a recent study, Albuquerque et al. (2012) report that this species is able to grow without NaCl addition and contains PE, PC, PG, and two unidentified aminolipids and one phospholipid as major polar lipids. These authors also report ubiquinone 10 as dominant quinone system, although its detection was difficult.

The four species can be distinguished by the differential use of several carbon sources, ability to reduce nitrate to nitrite,

some enzymatic activities (as determined in API ZYM strips), and the G+C content. *Amaricoccus kaplicensis* type species was isolated in Czech Republic, while *A. tamworthensis*, *A. veronensis*, and *A. macauensis* were isolated from Australian, Italian, and Macau wastewater samples, respectively. Up to date, activated sludge seems to be the only habitat of species of this genus that have been studied in different wastewater treatment systems by using in situ detection with FISH (Maszenan et al. 2000). They occur in large numbers not only in enhanced biological phosphate removal (EPBR) treatment plants (in which their abundance was suspicious of a detrimental role by competing phosphate removing bacteria) but also in conventional plants. They were particularly abundant in aerobic-anaerobic systems, although no evidence of that detrimental role has been found (Seviour et al. 2000). The effect of periodic acetate feeding in sequencing batch reactor on substrate uptake and storage rates by a pure culture of *A. kaplicensis* was investigated by Aulenta et al. (2003), who found that different cycle lengths resulted in different lengths of famine periods and different specific PHB contents at the end of each cycle. Moreover, as cycle length increased, flocculation and settleability of the culture significantly worsened, whereas the observed yield increased, showing that substrate removal was mainly due to oxidation and storage, whereas the growth played a minor role. Thus, a longer famine period caused a higher capacity of cells to answer quickly to sudden change of substrate availability.

Albimonas

Albimonas is a genus marginally related to the *Amaricoccus* group, from which it separates in some of the phylogenetic analysis performed. It is the deepest branch in the NJ analysis (◉ *Fig. 20.3*) but relates closely with the *Rubribacterium-Rubrimonas* subclade when ML is used for tree reconstruction. *Albimonas* contains one species, *A. donghaensis* (Lim et al. 2008), isolated in Marine Agar from seawater of the East Sea. It is an aerobic chemoorganotroph that does not synthetizes Bchl *a* and is not pigmented. Cells are short, nonmotile rods. It is positive for oxidase and catalase and negative for nitrate reduction to nitrite. Q10 is the major isoprenoid quinone, C18:1 ω7c and its 11-methyl derivative are the major cellular fatty acids, and PG, DPG, PE, and PC the major polar lipids. The DNA G+C molar content of the type strain is 72.0.

A. donghaensis grows as a mesophile, between 10 °C and 38 °C, with an optimum at 28–30 °C and pH 6.0–9.5 (optimum 7–8). It does not require sodium ions for growth, which is possible at salinities of 0–14 % (optimum 2–5 %).

Oceanicella

The genus *Oceanicella* (Albuquerque et al. 2012) has been recently described as the closer relative to *Amaricoccus*, with which it shares little resemblance in metabolic or ecological features. The pairwise similarities between *Amaricoccus* and *Oceanicella* 16S rRNA gene sequences are 93–95 %, and the relationship is supported by a bootstrap value of 96 % in the original phylogenetic analysis reported in *Oceanicella* description. *Oceanicella actignis*, the only species of the genus, is a slightly thermophilic and halophilic bacterium that forms pleomorphic, nonmotile cells. It was isolated from a shallow marine hot spring on a beach of Azores Islands. The genus is defined as organotrophic, strict aerobic, and oxidase and catalase positive. The major cellular fatty acids are C18:1 ω7c and 11-methyl C18:1 ω7c, while the major polar lipids are PC, PG, and one aminolipid. Q10 is the major respiratory quinone and the DNA G+C content of the type species is 71.2 mol%.

The temperature range for growth of *O. actignis* is 25–57.5 °C, with an optimum at 50 °C. Optimum pH is 7.5–8.0 and optimal salinity is 2–5 % (range, 1–9 %). The species does not grow without added NaCl. It reduces nitrate to nitrite, degrades gelatin and DNA, but not casein or starch. A few carbohydrates (glycerol, mannitol), several organic acids (2-oxoglutarate, lactate, acetate, pyruvate, succinate, malate, and fumarate), and several amino acids (aspartate, glutamate, alanine, asparagine, serine, leucine, proline, glutamine, phenylalanine, and isoleucine) are assimilated. *O. actignis* grows as unpigmented colonies in Degryse medium 162 (Degryse et al. 1978), containing 0.25 % yeast extract, 0.25 % tryptone, and 2 % NaCl.

Rubribacterium

In contrast to the previous genera, *Rubribacterium* and *Rubrimonas*, the remaining members of *Amaricoccus* group are phototrophic. Namely, *Rubribacterium* was described as purple non-sulfur anoxygenic photosynthetic bacterium, while *Rubrimonas* is an aerobic anoxygenic photoheterotroph (AAP) that contains two species of pink pigmented bacteria. The genus *Rubribacterium* (Boldareva et al. 2009) was established to account for a new alkaliphilic, phototrophic isolate from a soda lake in Siberia, described as a purple non-sulfur bacterium that lacks RuBisCo and grows better in aerobic than anaerobic conditions under illumination. The key difference between *Rubribacterium* and *Rubrimonas* is the ability of the former to grow photo-heterotrophically and form vesicular type of photosynthetic membranes in anaerobic conditions. *Rubribacterium polymorphum* cells are oval in young cultures, but become polymorphic with age and the accumulation of large storage granules interpreted as PHB. They may be motile by polar flagella. Carotenoids of both spheroidene and spirilloxanthin groups are formed. C18:1 ω7c is the major cellular fatty acid, accompanied by its 11-methyl derivative, C18:0, and C16:0. DNA G+C base content is 70 mol%, in the same range that of *Rubrimonas*.

Rubribacterium is a facultative anaerobe, able to grow (poorly) in anaerobiosis as photoheterotroph, with glucose, fructose, sucrose, pyruvate, malate, casein hydrolysate, yeast extract, and soyotone. These substrates also support good chemoheterotrophic growth in aerobic conditions in the dark. Nitrate is reduced to nitrite, but this activity does not support

growth. Ammonium salts are used as nitrogen source. *Nif* genes and RuBisCo activity are absent.

Rubribacterium polymorphum is a moderate alkaliphile, unable to grow at neutral pH, and shows optimal growth at 8.5–9.5. NaCl is required (0.5–4.0 %, optimum 1.0 %). Good growth occurs between temperatures of 20 °C and 35 °C.

Rubrimonas

Rubrimonas cliftonensis, the type species of the genus *Rubrimonas*, was isolated from a saline lake in Australia (Suzuki et al. 1999a). The genus was defined as aerobic and chemoheterotrophic, with the ability to synthesize Bchl *a* under aerobic conditions. Carotenoid pigments are also produced. Chemotaxonomic features include the presence of Q10 as ubiquinone system, C18:1 ω7c as dominant cellular fatty acid, and a 74–75 mol% G+C content of DNA. This later value has to be extended to a lower limit of 68 mol% with the recent recognition of a second species *R. shengliensis* (Cai et al. 2011), isolated from oil-contaminated saline soil. These authors reported data on the polar lipid composition of both species, which include PG, PC, and unidentified lipids and aminolipids. They are mesophilic (optimum 27–30 °C, but *R. shengliensis* has a wide temperature range for growth, 4–50 °C), neutrophilic (optimum pH 7–8), and slightly halophilic, with *R. cliftonensis* requiring NaCl for growth (range 0.5–7.5 %) and *R. shengliensis* being able to grow without NaCl, but growing optimally at 1 % (range 0–10 %). The cells of *R. cliftonensis* are polarly flagellated rods while *R. shengliensis* presents oval, nonmotile cells. Both form pink colonies, are positive for catalase, but differ in oxidase, nitrate reduction (see Cai et al., ❯ *Table 20.1*), gelatinase and amylase production, and ability to produce acid from several carbohydrates. Species of *Rubrimonas* show 95.7 % similarity on their 16S rRNA gene sequences, but also display a moderate similarity to *Rubribacterium polymorphum* sequence, the third member of the subgroup.

The *Paracoccus* Group

The clade that contains the forty species of the genus *Paracoccus* also groups the facultative methylotroph genus *Methylarcula*, with two species (❯ *Table 20.6*). They have the *Rhodobacter* group as closest relative (❯ *Fig. 20.4*). The close phylogenetic relationship between *Rhodobacter* and *Paracoccus* groups is also revealed by phylogenomic analysis of signature proteins, as reported by Gupta and Mok (2007) who suggest that both *Rhodobacter* and *Paracoccus* form a distinct clade that appears as the outgroup of other *Rhodobacterales* species.

In contrast with the previous groups in this chapter, *Paracoccus* encompasses strictly chemotrophic species, with no example of phototrophic activity, either aerobic or anaerobic.

Paracoccus

The genus *Paracoccus* was the subject of a thorough chapter by Kelly and colleagues (Kelly et al. 2006a) in the 3rd edition of The Prokaryotes, and the interested reader is addressed to this chapter for information on all the general aspects of this genus and the summary of the fourteen species included at that time. By then, a publication note came out (Kelly et al. 2006b) to clarify the taxonomic status of the culture collection strains of two key species of *Paracoccus*, the type species *P. denitrificans* and *P. pantotrophus*, which had been used for many years in fundamental biochemical studies and as reference species in the identification of new isolates of *Paracoccus*. Here, the complementary information on the 26 species described thereafter is developed, along with the emendation of the genus (Liu et al. 2008), underlying those aspects that complement, extend, or modify the previous information.

Paracocci have Gram-negative cells described as coccoid, coccobacilli, or short rods, usually nonmotile. When motile, they may present polar flagella (*P. homiensis*, *P. oceanense*, and *P. versutus*) or peritrichous (*P. carotinifaciens*). *P. chinensis* and *P. rhizosphaerae* are described as motile without reference to the flagellar arrangement. The remaining 34 species are nonmotile. They divide by binary fission and occur as single cells, pairs, short chains, or irregular clusters. They commonly contain PHB as carbon reserve material. Several species display pigmented colonies, most commonly orange to red, due to the production of carotenoids.

They are catalase and oxidase positive and contain ubiquinone 10 (Q10) as sole or dominant quinone, sometimes accompanied by small amounts (<5 %) of Q9 and Q11. Only one species differs from this pattern, *P. yeei*, as it has been reported to contain Q8 as major quinone (Daneshvar et al. 2003).

Major cellular fatty acids (FAs) are C18:1 ω7c, C18:0, 19:0 cyclo ω7c, and 16:0, and among the hydroxylated, C10:0 3OH is commonly present. C18:1 ω7c represents usually more than 70 % of the total FAs detected. Exceptions to this behavior are *P. caeni* (54 %, Lee et al. 2011a), *P. halophilus* (60 %, Liu et al. 2008), and *P. oceanense* with no C18:1 ω7c detectable (instead, it contains 39 % of C18:1 ω6c, Fu et al. 2011). C10:0 3OH is undetectable in *P. fistulariae* and *P. sulfuroxidans*, both containing other hydroxylated FAs (Kim et al. 2010a; Liu et al. 2006), and in *P. oceanense*, with no hydroxylated FAs reported (Fu et al. 2011).

Information on polar lipid (PL) composition is scarcer than other chemotaxonomic features. Kelly et al. (2006a) do not report PL composition of the fourteen *Paracoccus* species available, and the pattern is included only in part of the more recent descriptions. The information briefed here comes from the analysis of less than a half of the currently recognized species. Major PL recorded in all species reported are phosphatidyl glycerol (PG) and phosphatidyl choline (PC), while diphosphatidyl glycerol (DPG) is detected in most, but not all, the species tested. Phosphatidyl ethanolamine (PE) is present in *P. huijuniae*, *P. kondratievae*, and *P. rhizosphaerae*, out of the 15 species compositions known. One sphingoglycolipid is detected

Table 20.6
Species in the *Paracoccus* group

Species (synonym)	Isolation/habitat	Metabolism[a]	Na^+ requirement, others	References
Paracoccus denitrificans	Soil, sewage, manure, mud	fac CLA	No	Rainey et al. 1999; Ludwig et al. 1993; Nokhal and Schlegel 1983
P. aestuarii	Tidal flat sediment, S. Korea	COH	No	Roh et al. 2009
P. alcaliphilus	Soil	COH	No	Urakami et al. 1989
P. alkenifer	Biofilters treating waste gas from animal rendering plant	COH	No	Lipski et al. 1998
P. aminophilus	Soil, Japan	COH	No	Urakami et al. 1990
P. aminovorans	Soil, Japan	COH	No	Urakami et al. 1990
P. beibuensis	Seawater, S. Korea	COH	No	Zheng et al. 2011b
P. bengalensis	Rhizosphere of leguminose (*Clitoria*), India	fac CLA	No	Ghosh et al. 2006
P. caeni	Sludge from disposal plant, S. Korea	COH	No	Lee et al. 2011a
P. carotinifaciens	Soil, Japan	COH	No	Tsubokura et al. 1999
P. chinensis	Sediment from eutrophic water reservoir, China	COH	No	Li et al. 2009
P. ferrooxidans	Denitrifying fluidized bed bioreactor, the Netherlands	fac CLA	No	Kumaraswamy et al. 2006
P. fistulariae	Intestine of marine fish (*Fistularia*), S. Korea	COH	Yes (or Mg^{2+} at 0 % NaCl)	Kim et al. 2010a
P. haeundaensis	Seawater, S. Korea	COH	No	Lee et al. 2004
P. halophilus	Marine sediment, South China Sea, China	COH	Yes	Liu et al. 2008
P. homiensis	Sea sand, S. Korea	COH	No	Kim et al. 2006a
P. huijuniae	Activated sludge of a wastewater biotreatment facility, China	COH	No	Sun et al. 2013
P. isoporae	Reef-building coral (*Isopora*), Taiwan	COH	No	Chen et al. 2011a
P. kocurii	Activated sludge system for wastewater of semiconductor manufacturing process, Japan	COH	No	Ohara et al. 1990
P. kondratievae	Maize rhizosphere, Russia	COH	No	Doronina et al. 2002; Doronina and Trotsenko 2000
P. koreensis	Anaerobic sludge blanket reactor, S. Korea	COH	No	La et al. 2005
P. limosus	Activated sludge, sewage treatment plant, S. Korea	COH	No	Lee and Lee 2013
P. marcusii	Contaminant of agar plate	COH	No	Harker et al. 1998
P. marinus	Coastal seawater, Japan	COH	Yes	Khan et al. 2008
P. methylutens	Ground water contaminated with dichloromethane, Switzerland	COH	No	Doronina et al. 1998
P. niistensis	Forest soil, India	COH	No	Dastager et al. 2011
P. oceanense	Seawater, West Pacific Ocean	COH	Yes	Fu et al. 2011
P. pantotrophus (*Thiosphaera*)	Denitrifying, desulfurizer effluent treatment system, the Netherlands; soil (GB)	fac CLA	No	Rainey et al. 1999; Robertson and Kuenen 1983
P. rhizosphaerae	Rhizosphere of plant (*Crossostephium*), Taiwan	COH	Yes	Kämpfer et al. 2012
P. saliphilus	Saline soil near Ebinur Lake, China	COH	Yes (optimum 8 % NaCl)	Wang et al. 2009a
P. seriniphilus	Bryozoan (*Bugula*), North Sea, Germany	COH	Yes	Pukall et al. 2003
P. solventivorans	Soil at natural gas company site, Germany	COH	No	Lipski et al. 1998; Siller et al. 1996
P. sphaerophysae	Root nodules of leguminose (*Sphaerophysa*), China	COH	No	Deng et al. 2011

Table 20.6 (continued)

Species (synonym)	Isolation/habitat	Metabolism[a]	Na^+ requirement, others	References
P. stylophorae	Reef-building coral (*Stylophora*), Taiwan	COH	No	Sheu et al. 2011
P. sulfuroxidans	Activated sludge of a wastewater treatment bioreactor, China	fac CLA	No	Liu et al. 2006
P. thiocyanatus	Activated sludge with thiocyanate, Japan	fac CLA	No	Katayama et al. 1995
P. tibetensis	Permafrost, Tibet plateau, China	COH	No, alkaliphilic	Zhu et al. 2013
P. versutus	Soil, USA	fac CLA	No	Katayama et al. 1995; Harrison 1983
P. yeei	Clinical samples (wounds, bile, blood, eye), USA, Canada	COH	No	Daneshvar et al. 2003
P. zeaxanthinifaciens	Seaweed, Red Sea	COH	No	Berry et al. 2003
Methylarcula marina	Estuary seawater, Azov Sea, Russia	fac M	Yes	Doronina et al. 2000
M. terricola	Coastal salty soil, Black Sea, Russia	fac M	Yes	Doronina et al. 2000

[a]*COH* chemoorganoheterotroph, *fac CLA* facultatively chemolithoautotroph, *fac M* facultatively methylotroph

in *P. oceanense* (Fu et al. 2011) and several unidentified amino-phospho- and glycolipids are present in some species.

The molar % C+G content is 63–71 in Kelly et al. (2006) and Spanning et al. (2005), but several species with lower values have been described afterwards: *P. caeni*, 58.7 (Lee et al. 2011a); *P. oceanense*, 59.5 (Fu et al. 2011); *P. saliphilus*, 60.3 (Wang et al. 2009a); *P. sulfuroxidans*, 61.3 (Liu et al. 2006); *P. yeei*, 62 (Daneshvar et al. 2003); and *P. aestuarii*, 62.0 (Roh et al. 2009). Thus, the range of molar % G+C extends now from 58 to 71.

Other chemotaxonomic features, such as diamino acid on peptidoglycan or polyamine pattern, have been determined only for few species. *P. rhizosphaerae* (Kämpfer et al. 2012) contains *m*-diaminopimelic acid as diagnostic diamino acid and spermidine (SPE) and putrescine (PUT) as major polyamines, with cadaverine (CAD) and diaminopropane (Dap) as minor components. Hamana and Matsuzaki (1992) had previously determined the presence of PUT and SPE as the dominant polyamines in five species analyzed (*P. denitrificans*, *P. alcaliphilus*, *P. aminophilus*, *P. aminovorans*, and *P. kocurii*).

Species in the genus *Paracoccus* are chemoorganoheterotrophic, with a respiratory metabolism which uses oxygen as terminal electron acceptor. Some species can use, alternatively, nitrate which is reduced to nitrite or to molecular nitrogen. Nitrous oxide is also used by some species. Denitrification is not limited, when present, to chemoorganotrophic growth, but is also performed under chemolithoautotrophic conditions by some species (Kumaraswamy et al. 2006). None of the species is able to grow anaerobically by fermenting carbohydrates, although acid is produced aerobically from some of them. None of the species has been found to contain bacteriochlorophyll a, but carotenoids are common (astaxanthin, zeaxanthin, β-carotene). The range of organic substrates oxidized and used as carbon sources by paracocci is wide, including carbohydrates, organic acids, amino acids, and alcohols. In addition to this general mode of metabolism, several species in the genus, including the type species *P. denitrificans*, are able to grow as facultative chemolithoautotrophs, using reduced sulfur compounds as substrates (thiosulfate, tetrathionate, sulfur, or sulfide), and some are also able to oxidize hydrogen or ferrous iron. Finally, some species are able to live as facultative methylotrophs, using methylamines or methanol as substrate. During autotrophic growth, the Calvin-Benson cycle is used to fix CO_2. The chemoautotrophic ability is not always investigated when describing new species, so there is incomplete information about this trait in several of the 26 species not included in Kelly et al. (2006). In any case, at least two (*P. bengalensis* and *P. sulfuroxidans*) are able to thrive by oxidizing reduced sulfur compounds (Ghosh et al. 2006; Liu et al. 2006; Ghosh and Roy 2007) and one oxidizes Fe^{2+} (*P. ferrooxidans*, Kumaraswamy et al. 2006).

Some species have a requirement for growth factors when grown in minimal media (thiamine, biotin, B12, or unknown factors that may be covered with yeast extract).

Paracoccus species are mesophilic, growing optimally at 25–37 °C. The upper limit was established in 42 °C, but among the species recently described, *P. saliphilus* is able to grow up to 55 °C and *P. sphaerophysae* up to 60 °C. The optimal pH for most species is between 6.5 and 8.5, but there are moderate alkaliphilic species, as *P. alcalophilus*, that grows up to 9.5 (with optimum at 8–9) and a truly obligate alkaliphile, *P. tibetense*, which grows in the range 8.5–13.0 (optimum 9.5).

Paracocci are ubiquitous and ecologically diverse. While the earlier 14 species of *Paracoccus* were isolated from terrestrial or continental aquatic habitats (see *Table 20.6*), and none of

them displayed saline requirements for growth (Kelly et al. (2006)), most of the newly described species come from marine environments (seawater, tidal flat sediment, sand, and different marine organisms), and some are strictly halophilic (*P. halophilus*, *P. marinus*, *P. oceanense*, *P. rhizosphaerae*, *P. saliphilus*, and *P. seriniphilus* do not growth without NaCl). Others, although able to grow without added NaCl, have optimal growth at salinities ≥2 %. This motivated the emended description of the genus (Liu et al. 2008), aimed to account for the existence of halophilic and halotolerant species.

Three main environments have been the source of almost all the new descriptions of *Paracoccus* spp.: first, the already mentioned marine habitats; second, activated sludge from bioreactors in wastewater treatment plants; and finally, the rhizosphere and other plant-related sources. Interestingly, one species has been isolated from clinical sources (*P. yeei*), and since its description, it has been found in relation to opportunistic infections in the USA and Canada (Daneshvar et al. 2003; Funke et al. 2004; Schweiger et al. 2011).

The new species have been delineated with the aid of 16S rRNA gene sequence analysis and DNA-DNA hybridization (DDH) experiments. Thus, DDH values around 36 % relate *P. aminovorans* and *P. huijiniae* DNAs, *P. bengalensis* and *P. versutus* show values around 45 %, *P. chinensis* and *P. niistensis* have 44 % relatedness, *P. haeundaensis* and *P. marcusii* present 47 %, and *P. ferrooxidans* relates to *P. versutus*, *P. denitrificans*, and *P. pantotrophus* by 32–43 %. The former pairs are the closest in the tree, as can be seen in Fig. 20.4. However, some critical values are still missing, as the ones relating *P. carotinifaciens* with *P. marcusii* and *P. haeundaensis*. But being the type and only strain of *P. carotinifaciens* (IFO 16121^T) a patented strain, deposited only in one culture collection, it has not been possible to assess their DDH values. This fact also puts in question the status of the species *P. carotinifaciens*, according with rule 30 of the International Code of Nomenclature of Bacteria (http://www.bacterio.cict.fr/code.html). Other pairs of close species for which there are no DDH figures are *P. oceanense-P. stylophorae* (97.1 % similarity in 16S rRNA gene sequences) and *P. beibuensis-P. aestuarii* (97.2 %).

The genus *Paracoccus* is one of the most diverse carriers of insertion sequences within the *Alphaproteobacteria*. Dziewit et al. (2012) used trap plasmids (enabling positive selection of transposition events) to identify transposable elements residing in 25 strains representing 20 species of the genus *Paracoccus*. As a result, 41 elements were captured representing (i) insertion sequences, (ii) an IS-driven composite transposon, and (iii) non-composite transposons of the Tn3 family. By analyzing the functional transposable part of the mobilome, not only the dynamics of the process of transposition is better understood, but also its role in the dissemination of diverse genetic information (possibly of adaptative value) by HGT.

The genome of strain PD1222, a genetically modified version of strain *P. denitrificans* DSM 413^T, consists of two chromosomes and one plasmid totaling 5.24 Mb. The partial genome (contig assembly level) of *P. denitrificans* SD1 sourced from coal mine tailings in India and capable of *N*,*N*-dimethylformamide degradation has also been reported (Siddavattam et al. 2011). Yet, another draft genome sequence has been reported from a strain interesting for xenobiotic biodegradation and metabolism, *Paracoccus* sp. strain TRP isolated from activated sludge, that could completely biodegrade chlorpyrifos and 3,5,6-trichloro-2-pyridinol (Li et al. 2011a).

Paracoccus aminophilus JCM 7686^T has one chromosome and eight plasmids (total size 4.87 Mb) whereas the genome sequence of *P. zeaxanthinifaciens* ATCC 21588^T is only available as draft (3.05 Mb).

Methylarcula

The genus *Methylarcula*, the second component of the *Paracoccus* group, includes two species of facultative methylotrophs isolated from coastal saline environments (Doronina et al. 2000). Its separation by 16S rRNA sequence analysis from the genus *Paracoccus* is not as evident now as it was at the time of its description, although it occupies a marginal position in the clade, with only *P. isoporae* being more external to the main group (Fig. 20.4). The main characteristics of the genus are Gram-negative, nonmotile rods (0.5–0.8 × 1.0–2.0 μm in size), asporogenous, not pigmented; they divide by binary fission and accumulate PHB (up to 10–40 % of their total dry cell weight). Common cellular fatty acids are C18:1 ω7c (73–74 %), C18:0 (14–15 %), C19:0 cyclo (5–6 %), and C17:0 (2–3 %). Major PLs are PE and PC, with minor amounts of PG and DPG. The quinone system is Q10. Major compatible solute is ectoine. Molar % G+C is 57–61.

Both species require NaCl for growth, which is optimal at 3–8 % NaCl. Salinities over 12 % (*M. marina*) and 14 % (*M. terricola*) inhibit growth. Temperature range for growth is 10–42 °C with optimum at 30–35 °C and pH 7.5–8.5. They are oxidase positive, aerobic chemoorganotrophs, and facultatively methylotrophic, using methylamine, fructose, glucose, maltose, lactose, mannose, ribose, trehalose, galactose, xylose, sucrose, succinate, pyruvate, and acetate as carbon and energy sources. No growth is observed with $CO_2/H_2/O_2$ or CH_4/O_2. Growth factors are not required. Gelatin and starch are not hydrolyzed. Nitrate is not used as nitrogen source (ammonia and methylamine are) nor is it reduced to nitrite or further. Doronina et al. (2000) confirmed the presence of the (isocitrate lyase-negative) serine pathway for formaldehyde assimilation in methylamine-grown cells. The DDH values relating both species of this genus are 25–32 %.

The *Roseobacter* Group

It is the largest group in the family and the one that keeps enlarging at a fastest rate. At the moment of writing this chapter, 69 genera (comprising one hundred sixty species) have been described that join the phylogenetic group around the genus *Roseobacter*, the first described aerobic anoxygenic phototroph on this family (Fig. 20.5).

The clade is dominated by species of marine origin, chemoorganoheterotrophic, non-fermentative, most of them requiring Na ion (or sometimes combined marine salts) for growth. Thirteen of the genera contain at least one species that synthetize Bchl *a* (*Dinoroseobacter*, *Jannaschia*, *Loktanella*, *Marivita*, *Roseibacterium*, *Roseicyclus*, *Roseisalinus*, *Roseivivax*, *Roseobacter*, *Roseovarius*, *Sulfitobacter*, *Tateyamaria*, and *Thalassobacter*), and one more has been described as possessing *pufLM* genes, although Bchl *a* is not detected in the isolates grown at the lab (*Planktotalea*). No classical purple non-sulfur photosynthetic bacteria (anaerobic photoheterotrophs such as *Rhodovulum*) are included in this group, which also lacks any known autotrophic member. Some of them are able to oxidize sulfur compounds (sulfite, thiosulfate) with energy gain; thus, they may be defined as chemolithoheterotrophs. Carbon monoxide oxidation is a common ability of members of this group as well as the ability to degrade dimethylsulfoniopropionate (DMSP), either by the cleavage pathway or by the demethylation/dethionation pathway (Wagner-Döbler and Biebl 2006). González et al. (2000) reported that estimated abundance of *Roseobacter*-related bacteria was positively correlated with the concentration of DMSP in samples from a DMSP-producing algal bloom in the North Atlantic.

As already noted, the habitat of most of its members is the marine environment, including seawater, sea ice, estuarine, coastal and deep marine sediments, phytoplankton, algal surfaces, and marine invertebrates (sponges, ascidians, corals, mollusks, echinoderms), sometimes as biofilms attached to inert or living surfaces. A smaller group has been isolated from hypersaline environments (solar saltern water and sediments, salt lakes, salt mine sediment), and a minority comes from terrestrial (natural or man-made) environments: *Ketogulonicigenium* from soil samples and *Rubellimicrobium* from air, soil, and paper industry samples (❯ *Table 20.7*).

The so-called *Roseobacter* group/clade/lineage is usually one of the outstanding groups of marine bacteria detected in culture-independent studies, accounting for as much as 20 % of the total bacterial signal (Buchan et al. 2005; Wagner-Döbler and Biebl 2006; Brinkhoff et al. 2008; Giebel et al. 2011; Lenk et al. 2012). Its role on carbon and sulfur cycles in the marine environment as well as their contribution to other key activities (AAP, symbiotic relationships and pathogenesis, production of secondary metabolites) in the marine environment have been summarized and revised by Wagner-Döbler and Biebl (2006), and an excellent condensed overview on diversity, ecology, and genomics of the group was published by Brinkhoff et al. (2008). Recently, a comparative genomic approach (Chen 2012) revealed that many marine *Roseobacter* clade bacteria have the genetic potential to utilize methylated amines as alternative nitrogen sources since about half of the genomes available contained the key genes involved in this metabolism. Representative species bearing such potential were tested to confirm their abilities to use methylated amines. Moreover, trimethylamine monooxygenase (*tmm*) and gammaglutamylmethylamide synthetase (*gmaS*), two of the key enzymes, were chosen and successfully used as functional markers for detecting methylated amines-utilizing marine *Roseobacter* clade bacteria in the environment. These results suggest that methylated amines may serve as important nitrogen sources for *Roseobacter* clade bacteria in the marine environment and help to explain their numerical prevalence in the oceans.

The relative abundance of *Roseobacter* clade sequences among the alphaproteobacteria was quite different between two similarly hypersaline coastal lagoons as revealed through a metagenomic approach. At Mar Menor (Spain), they represented 30 % of all alphaproteobacterial reads, whereas at Punta Cormoran in Galapagos Islands (Ecuador), they were the most abundant representatives (Ghai et al. 2011, 2012). The study of coastal bacterioplankton community dynamics over an 8-month period, which encompassed a large storm event, revealed that during the natural perturbance, common bacterioplankton community members such as marine *Synechococcus* sp. and members of the SAR11 clade of *Alphaproteobacteria* decreased in relative abundance in the affected coastal zone, whereas several lineages of *Gammaproteobacteria*, *Betaproteobacteria*, and members of the *Roseobacter* clade increased (Yeo et al. 2013).

The nearly 70 genera that currently constitute the *Roseobacter* group have been defined (mainly) on a phylogenetic basis using 16S rRNA gene sequence analysis, and genomic relatedness based on DDH is commonly applied for species delimitation at high 16S rRNA sequence similarity (>97.0 %). A few descriptions also include an additional gene (*gyrB*) for inferring phylogeny but Multilocus Sequence Analysis (MLSA) as taxonomic tool is uncommon. Determination of alternative genomic parameters, as ANI values, is seen in the most recent species descriptions (Lucena et al. 2013). The accelerated pace of the new genera and species descriptions in the last few years is causing misclassifications, particularly affecting members of polyphyletic genera, as *Roseovarius* or *Oceanicola*.

Phylogenomics using protein signatures or other inference tools has been applied on data from complete genomes (Gupta and Mok 2007; Tang et al. 2010; Newton et al. 2010), with interesting results about the internal structure of the clade, but the limited number of representative taxa leave wide areas of shadow. These studies revealed five to six subclades within the group and are helpful to elucidate ecological strategies and evolutionary events.

Genome sequences and features of members of the *Roseobacter* group are reported and updated at the site Roseobase-Genomic Resource for Marine Roseobacters (http://www.roseobase.org/index.html).

Roseobacter

Roseobacter contains two species, *R. litoralis* and *R. denitrificans*. In spite of being the oldest named genus of the group, no other species has been added since the genus description (Shiba 1991). This description was based on the study of one strain, formerly identified as *Erythrobacter* sp., plus seven additional isolates from surface of seaweeds. In contrast with the orange pigmented

Table 20.7
Species in the *Roseobacter* group

Species (synonym)	Isolation/habitat	Metabolism[a]	Na^+ requirement, others	References
Roseobacter litoralis	Surface of marine algae, Japan	AAP	Yes	Shiba 1991
R. denitrificans	Surface of marine alga (*Enteromorpha*), Japan	AAP	Yes	Shiba 1991
Actibacterium mucosum	Seawater, Western Mediterranean Sea, Spain	COH	Yes	Lucena et al. 2012a
Antarctobacter heliothermus	Water, hypersaline Ekho Lake, Antarctica	COH	Yes	Labrenz et al. 1998
Celeribacter neptunius	Seawater, Australia	COH	Yes	Lee et al. 2012a; Ivanova et al. 2010
C. baekdonensis	Seawater, East Sea, S. Korea	COH	Yes	Lee et al. 2012a
Citreicella thiooxidans	O_2/H_2S interface Black Sea, Russia	COH/CLH ($S_2O_3^{2-}$ ox.)	Yes	Sorokin et al. 2005b

[a]*AAP* aerobic anoxygenic photoheterotroph, *CLH* chemolithoheterotroph, *COH* chemoorganoheterotroph, *COH a* chemoorganoheterotroph aerobic, *COH fac an* chemoorganoheterotroph facultative anaerobic, *fac M* facultatively methylotroph

Erythrobacter, these strains were pink pigmented, contained a particular bacteriochlorophyll-protein complex and carotenoids not found in *Erythrobacter*, and showed unappreciable levels of DDH to the type strain of *E. longus* (3–5 %). The pink strains formed two genospecies, according to DDH values, one including seven isolates with 74–98 % intragroup relatedness and a second with only one strain, which showed 41–59 % DDH to the various strains in the former group. Thus, the new genus was described as containing two species, with the following general properties (Shiba 1991; Shiba and Imhoff 2005): cells are Gram negative, ovoid to rod shaped, motile by subpolar flagella, and divide by binary fission. They synthetize Bchl *a* (only in aerobic conditions) and spheroidenone as major carotenoid pigments. The major quinone is Q10 (menaquinones are absent), polar lipids include PG and DPG, and the dominant cellular fatty acid is C18:1 ω7c. DNA G+C content is 56–60 mol%. *Roseobacter* species are aerobic chemoheterotrophs that require biotin, thiamine, and nicotinic acid, as well as sodium ions, for growth. Preferred carbon sources are organic acids (acetate, pyruvate, succinate, malate, and citrate), some sugars (glucose) and amino acids (glutamate), but not methanol. They are proteolytic on gelatin, hydrolyze Tween 80, and are positive for both oxidase and catalase. Light inhibits respiration, decreasing O_2 consumption but not growth. The stronger suppression of respiration by light is observed when organic substrates are scarce (Shiba and Imhoff 2005). Bacteriochlorophyll synthesis is suppressed by anaerobiosis and by continuous light.

They are mesophilic (optimum 20–30 °C), neutrophilic (optimum pH 7–8), and slightly halophilic (optimum 2.5 %). The two named species differ, basically, in the denitrification activity, which gives name to *R. denitrificans* and confers to it the ability to thrive anaerobically, a lifestyle that is not possible for the type species *R. litoralis*. In addition to denitrification, *R. denitrificans* can also develop in anaerobiosis by using TMAO as electron acceptor.

A lytic siphovirus, designated RDJLΦ1, infecting *R. denitrificans* OCh 114^T has been characterized (Zhang and Jiao 2009), its genome fully sequenced (Huang et al. 2011), and the response to the infection of the host has been analyzed through real-time atomic force microscopy and proteomics (Zhang et al. 2012b).

The type strains of *R. litoralis* and *R. denitrificans* have their genomes fully sequenced (Swingley et al. 2007; Kalhoefer et al. 2011). A comparison indicates that major differences between them are due to lateral gene transfers and genome rearrangements. *R. litoralis* Och 149^T contains one chromosome (4.5 Mbp) and three plasmids (63.5–93.5 Kbp) with 4,537 protein-coding genes predicted. *R. denitrificans* OCh 114^T

genome is composed of one chromosome of 4.1 Mbp and four plasmids ranging from 5.8 to 106.5 Kbp, with a total of 4,129 predicted protein-coding genes. Genes shared by both type strains account for 3,415, a 75 % of *R. litoralis*' total genes. Photosynthetic genes are plasmid encoded in *R. litoralis*, but chromosomic in *R. denitrificans* (Kalhoefer et al. 2011; Pradella et al. 2004). The plasmid location of *pufML* genes also occurs in *Sulfitobacter* (*Staleya*) *guttiformis* (Pradella et al. 2004). Scaffolds or contigs of five additional *Roseobacter* sp. strains (AzwK-3b, CCS2, GAI101, MED193, and SK209-2-6) are also available at public repertories.

Roseobacter species form a compact grouping with members of the genus *Sulfitobacter* and *Oceanibulbus* in all assayed phylogenetic trees, and these three genera represent one of the few stable clades within this branch of the *Rhodobacteraceae*.

Actibacterium

Actibacterium is a recently described genus containing one species, *A. mucosum* (Lucena et al. 2012a), isolated from coastal seawater. *Actibacterium* is a strictly aerobic chemoorganotroph with complex ionic requirements. Cells do not accumulate PHB and contain PG, an unidentified aminolipid and a lipid as major polar lipids. Q10 is the predominant quinone and C18:1 ω7c the major fatty acid. It is oxidase and catalase positive and its DNA G+C content is around 61 mol%. *A. mucosum* is not pigmented and its cells are ovoid to rod shaped and nonmotile. It is mesophilic (15–37 °C) and halophilic (1.7–5 % total salinity) and requires a mixture of marine salts that include Na, K, Ca, Mg, and sulfate ions for optimal growth or the addition of seawater to the medium. It does not reduce nitrates and does not have growth factor requirements, as it is able to grow on defined medium with several carbohydrates, organic acids, and amino acids as sole carbon and energy sources. Its cellular fatty acids include, in addition to the dominant C18:1 ω7c, C16:0, C10:0 3-OH, and C12:0 3OH. *Actibacterium* was found to constitute an independent lineage, with no close relatives, in 16S rRNA gene-based trees and also in *gyrB* gene trees (Lucena et al. 2012a). In the complete tree of ❯ *Fig. 20.5*, *Actibacterium mucosum* relates distantly (but stably) to the newly described *Hasllibacter halocynthiae*, both lying near the edge of the *Roseobacter* group.

Antarctobacter

Antarctobacter and its sole species *A. heliothermum* described in the 1990s were one of the first members of the *Roseobacter* clade (Labrenz et al. 1998) from water samples of the hypersaline Antarctic Ehko Lake. It is a Gram-negative, budding bacterium that forms rosettes and accumulates PHB. Cells may be motile (one to three polar flagella). Colonies are brownish yellow or brownish red, depending upon the medium, and have a wide range of growth temperatures (from less than 3 °C to 43 °C) and pHs (5.3 to 9). NaCl is required for growth (optimum 2–6 %). Not phototrophic, Bchl *a* is not synthetized. Oxidase and catalase are positive. Peptidoglycan contains *m*-diaminopimelic acid and is direct cross-linked (A1γ). It contains Q10 as respiratory quinone; its main polar lipids are PG, PC, and unknown phospho- and aminolipids. C18:1 ω7c is the dominant fatty acid and C12:1 3OH is a diagnostic one. The DNA G+C content is 63 mol%. The species, *A. heliothermus*, has the following additional characteristics: requires thiamin and nicotinic acid; reduces nitrate, at least to nitrite; hydrolyzes gelatin and DNA; and grows with small organic acids (acetate, pyruvate, butyrate, malate, and succinate) and with glucose or glutamate.

Celeribacter

Celeribacter was described by Ivanova et al. (2010) as a new genus containing the species *C. neptunius*. Lee et al. (2012a) described a second species *C. baekdonensis* and emended the genus description. Currently, *Celeribacter* contains ovoid- to rod-shaped Gram-negative cells that may be motile by a single polar or subpolar flagellum or nonmotile. Q10 is the predominant quinone; C18:1 ω7c is the major fatty acid, accompanied by 11-methyl C18:1 ω7c, C18:0, C16:0, and C10:0 3OH. The polar lipid profile was somewhat under dispute, but Lee et al. (2012a) determined for both species that common polar lipids were PG, one unidentified aminolipid and one lipid. The G+C content was 59–61 mol%. *Celeribacter* species are chemoorganotrophic, do not produce Bchl *a* nor other pigments, do not accumulate PHB, and are able to grow anaerobically on Marine Agar. Although *C. neptunius* was described as oxidase negative, Lee et al. (2012a) found a positive response for this test in both species that differ in Na ion requirement and in the ability for nitrate reduction, proteolytic activity, and production of acid from a large number of carbohydrates. They show low levels of DDH (17 %). Both species are mesophilic (5–35 °C, optimum 25–30 °C), neutrophilic (with optimum at pH 7–8), and slightly halophilic, with *C. baekdonensis* having a range from 0 % to 13 % NaCl (optimum: 2 %) and requiring Mg ion and *C. neptunius* growing between 1 % and 8 % and requiring Na ion. *Celeribacter* species are phylogenetically close to *Huaishuia halophila*, *Vadicella arenosi*, and both species of *Pseudoruegeria* in the *Roseobacter* detailed tree (❯ *Fig. 20.5*). The draft genome of *C. baekdonensis* B30 has 4.33 Mb.

Four strains (YSCB1, YSCB2, YSCB3, and YSCB4) were found to produce unique intracellular chromium-rich aggregates. This remarkable capacity makes them model bacteria for studies of chromium metabolism and its biological function and suitable candidates for chromium decontamination and environmental remediation (Gao et al. 2006). These strains exhibit yet another interesting feature, since they produce spinae that are built from proteolysis-resistant filaments winding into a tubular architecture by a mechanism different from those of other bacterial appendages. An excellent study, including many striking micrographs, was published recently (Bernadac et al. 2012). Although reported as *Roseobacter* sp., they can be now

identified as members of the genus *Celeribacter*, probably *C. baekdonensis*, according to 16S rRNA data.

One of the few known roseophages is a *Celeribacter* phage, P12053L. Its complete genome has been sequenced recently (Kang et al. 2012).

Citreicella

The study of strains isolated from the oxygen-sulfide interface of the Black Sea served Sorokin and colleagues to describe a new genus of lithoheterotrophic sulfur-oxidizing bacteria *Citreicella* that presently contains three species: *C. thiooxidans* (Sorokin et al. 2005b), *C. marina* (Lai et al. 2011a), and *C. aestuarii* (Park et al. 2011). The genus is defined as Gram-negative, nonmotile (or sometimes motile by lateral flagella, as in *C. aestuarii*) cells with lemon-shaped morphology, obligately heterotrophic, and aerobic. Carbon sources used for chemoheterotrophic growth are short-chain organic acids, hexoses, and amino acids. Catalase and oxidase are positive. Citreicellas do not synthetize Bchl *a* or other pigments; they form PHB granules and oxidize, at least, thiosulfate to sulfate (*C. thiooxidans* also oxidizes sulfide and sulfur), gaining energy from this activity during its heterotrophic growth. Its predominant quinone is Q10, C18:1 ω7c is the major fatty acid (with C16:0 and C19:0 cyclo ω8c also abundant), and the DNA G+C content is between 67 and 69 mol%. They prefer neutrophilic and mesophilic conditions (25–30 °C is the optimal range) but could grow from 4 °C (*C. marina*) to 40 °C (*C. thiooxidans*). They require sodium ion (at least 0.5–1 % NaCl) and grow optimally with 2–7 % NaCl, with a maximum of up to 12 % in *C. marina*, the more halotolerant and 6 % in *C. thiooxidans*, the less halotolerant. *C. marina* and *C. thiooxidans*, the closest species, are related by DDH values of 48 % (Lai et al. 2011a). Recently, a draft genome sequence of a strain (not the type strain) of *C. aestuarii* isolated from a petroleum contaminated beach has been reported (Suarez-Suarez et al. 2012): it contains, among the genes for major metabolic pathways, sox genes (sulfite oxidation) and cox genes (carbon monoxide oxidation), and some 120 protein-coding genes were found that may be involved in the metabolism of aromatic compounds.

All three species of *Citreicella* form a well-defined clade whose nearest neighbors are *Yangia pacifica* and *Citreimonas salinaria*.

Citreimonas

Citreimonas and its sole currently recognized species *C. salinaria* were isolated and described from samples of solar saltern water (Choi and Cho 2006a). Although it is next to *Citreicella* spp. in the 16S rRNA-based tree, they do not show the thiosulfate-oxidizing ability that characterizes *Citreicella* species. *Citreimonas salinaria* is, as *Citreicella*, obligately heterotrophic, aerobic, positive for catalase (but it is negative for oxidase), and unable to synthetize Bchl *a* or carotenoids. Cells are ovoid to rod shaped and nonmotile. They do not accumulate PHB. The two major fatty acids are C18:1 ω7c and C19:0 cyclo ω8c and the DNA G+C content is in the same range than *Citreicella* (67.3 % mol%). The ranges for temperature and salinity are also similar (15–40 °C and 1–10 % total salts, with optima at 30–35 °C and 5–6 %, respectively). It grows with a large variety of sugars and some organic acids and amino acids as carbon and energy sources in a basal medium supplemented with low levels of yeast extract. It reduces nitrate and is proteolytic on gelatin.

Dinoroseobacter

The genus *Dinoroseobacter* (Biebl et al. 2005a) contains a single species, *D. shibae*, isolated from the marine dinoflagellate *Prorocentrum lima*. Members of the genus are Gram-negative cocci or ovoid rods, motile by a single polar to subpolar flagellum. Pigmentation of cultures is pink to wine red, provided that the incubation is performed in the dark or with intermittent illumination. They are strict aerobes, non-fermentative heterotrophs, which synthetize Bchl *a* and carotenoids (spheroidene). They require at least 1 % sea salts for growth and have Q10 as predominant quinone. The species *D. shibae* requires biotin, nicotinic acid, and 4-aminobenzoic acid for growth and uses acetate, succinate, fumarate, malate, lactate, citrate, pyruvate, and some simple carbohydrates (glucose, fructose, glycerol) and glutamate as carbon and energy sources (but no butyrate, ethanol, or methanol). Nitrate is reduced to N_2 and gelatin and Tween 80 are degraded. Cells of *D. shibae* contain PG, DPG, one unidentified aminolipid, and other lipids as principal polar lipids. As usual in the family, C18:1 ω7c is the dominant fatty acid, with minor amounts of C18:0, C12:1 ω5c, C10:0 3OH, C14:1 3OH, and C19:0 cyclo ω8c. DNA G+C content is 65 mol%. *Dinoroseobacter* is consistently located next to *Roseibacterium* species in the *Roseobacter* phylogenetic tree, either using NJ (*Fig. 20.5*) or ML (LTP108) methods.

D. shibae is an algal symbiont that lives attached to the surface of different algal partners (*Prorocentrum*, *Alexandrium*, *Isochrysis*), some of them toxic and responsible of diarrheic shellfish poisoning (Wagner-Döbler et al. 2010). A symbiotic relationship in which the bacterium provides the algae with growth-limiting vitamins (B12) and the bacterium thrives on the organic matter synthetized by the alga has been suggested, based in physiological and field data and also in the information provided by the study of the complete genome of *D. shibae* type strain (Wagner-Döbler et al. 2010). Moreover, research in metabolic pathways of *D. shibae* has served as a model for the understanding of the whole *Roseobacter* group in terms of the general pattern of carbon fluxes (Fürch et al. 2009). *D. shibae* DFL12^T has a genome composed of one chromosome and five plasmids (total 4.4 Mbp), containing around 4,200 protein-encoding genes. In common with known *Roseobacter* spp. genomes, it harbors information for important biogeochemical metabolic abilities, such as anoxygenic photosynthesis

(*pufLM* genes), oxidation of CO (*cox* genes), degradation of aromatic compounds (*pcaGH* and *boxC* genes), sulfur oxidation (*soxB*), dimethylsulfoniopropionate use (*dmdA*), denitrification (*nirS*/*K*), and also several families of transposases/integrases and site-specific recombinases/resolvases, which indicates a large potential for DNA exchange. Through functional analysis, Fürch et al. (2009) demonstrated that *D. shibae* metabolizes glucose exclusively through the Entner-Doudoroff pathway, has an active cyclic respiratory TCA cycle, and incorporates CO_2 through a mechanism that does not involve PEP synthesis from pyruvate, as previously thought. Tomasch et al. (2011) suggest that *D. shibae* might use the 3-hydroxypropionate cycle for CO_2 fixation, in addition to showing the changes in photoheterotrophic behavior in response to light regime and organic carbon availability.

Donghicola

Donghicola is an inconspicuous genus of chemoheterotrophic, aerobic, nonpigmented, nonmotile bacteria which was described on an isolate from seawater (Yoon et al. 2007a). Cells are coccoid to rod shaped and do not synthetize Bchl *a* or carotenoids. Basic chemotaxonomic features (quinone system, major fatty acids) are the common in the group and the DNA G+C content is 59–62 mol%. Two species have been recognized, *D. eburneus* (Yoon et al. 2007a), the type species, and *D. xiamenensis* (Tan et al. 2009), that differ mainly in the pattern of carbon source utilization. Both species are catalase and oxidase positive, slightly halophilic, requiring NaCl for growth (optimum 1–3 %, tolerance up to 11 %), mesophilic, and neutrophilic. Their closest phylogenetic relatives are a group of four *Roseovarius* species that do not include the type species of *Roseovarius*, but the relationship is not maintained in other methodological conditions. The draft genomes of *D. xiamenensis* DSM 18339^T and *Donghicola* sp. S598 have 4.73 and 3.22 Mb, respectively.

Epibacterium

Epibacterium ulvae, the type and sole species of *Epibacterium* (Penesyan et al. 2013), is rod shaped and motile by a polar flagellum. Generic features include, in addition to cell morphology, presence of catalase and oxidase activities and requirement of aerobic conditions and sodium for growth. Polar lipids are PG and PC plus two unidentified aminolipids and four unidentified phospholipids. Cellular fatty acids include C18:1 ω7c, C16:0, C18:2, C10:0 3OH, C12:0, C20:1 2OH, C16:0 2OH, C12:0 3OH (amide linked), and C18:0. Q10 is the sole respiratory quinone. The type strain of *E. ulvae* has a DNA G+C content of 52.6 mol %. Strains of this species, isolated from the surface of the marine alga *Ulva australis*, are brown-black pigmented but do not produce Bchl *a* or possess *pufLM* genes. Its optimal growth conditions are 25 °C, neutral pH, and 2–3 % NaCl. Growth is produced on a variety of carbon sources that include hexoses, disaccharides, and organic acids. *E. ulvae* strains are able to inhibit the growth of other marine bacteria through production of antibacterial compounds of unknown chemical nature. The species is related to the *Thalasobium-Thalassococcus* subclade within the *Roseobacter* group.

Hasllibacter

Hasllibacter is another recently described genus, interesting because of its ability to produce cholic acid derivatives (Kim et al. 2012a, e), including nutriacholic acid. Strains of the only described species *H. halocynthiae* are Gram negative, ovoid, or rod shaped, with a single polar flagellum, that may reproduce by budding. They have Q10 as predominant quinone and C18:1 ω7c as major fatty acid (plus C18:0, C10:0 3OH, C19:0 cyclo ω8c, and C20:1 ω7c). They are strict aerobes and have an absolute requirement for Na and Mg ions (optimal growth: 1–5 % NaCl). Their colonies are light-red pigmented (but no data on Bchl *a* or carotenoid synthesis is given in the description). The G+C content is 71.6 mol%. On 16S rRNA trees, it forms a deep lineage distantly related to *Actibacterium mucosum*.

Huaishuia

Huaishuia contains a single species, *H. halophila*, isolated from seawater during a massive green algal bloom (dominated by *Enteromorpha prolifera*) (Wang et al. 2012). It is Gram negative, nonmotile, strictly aerobic, and slightly halophilic. PHB accumulation is not observed. Catalase and oxidase are positive. Nitrate is not reduced. Major fatty acids are C18:1 ω7c, C18:1 ω6c, and 11-methyl C18:1 ω7c. It presents PG, one unidentified aminolipid, and two unidentified phospholipids as major polar lipids and a DNA G+C content of 60 mol%. Requires sodium ion and grows between 0.5 % and 11 % NaCl and between 4 °C and 45 °C. *H. halophila* appears among the members of the *Celeribacter* subclade (which groups the two *Celeribacter* species, plus *Vadicella arenosi* and *Huaishuia halophila*, and is close to *Pseudoruegeria* spp.).

Hwanghaeicola

Kim et al. (2010b) described *Hwanghaeicola aestuarii* as a new genus and species from an isolate obtained from a tidal flat. It is entirely typical in its chemotaxonomic and biochemical features: contains Q10 (major quinone), C18:1 ω7c, plus C16:0 and C10:0 3OH (major fatty acid), is a strict aerobe with oxidase and catalase activities, not able to reduce nitrate and with a DNA G+C content of 61 mol%. The strain requires Na and Mg ions for growth, which is optimal at 2–3 % NaCl (range: 1.5–6 %) and 25–30 °C (range: 15–35 °C) and neutral pH (6.0–8.0). Colonies of *H. aestuarii* are pale pink, but no information on Bchl *a* synthesis is given in the description. It shows a distant relationship with *Maribius* species.

Jannaschia

Jannaschia is a well-defined, coherent genus that currently contains seven species isolated from seawater of distant geographic areas, seashore sand, tidal flat sediment, and solar saltern water. The type species *J. helgolandensis* (Wagner-Döbler et al. 2003) and the remaining six species *J. rubra*, *J. seosinensis*, *J. donghaensis*, *J. pohangensis*, *J. seohaensis*, and *J. aquimarina* constitute a stable clade in all analyses performed on 16S rRNA gene sequences so far, an unusual case among the multispecies genera of the *Roseobacter* group. The genus, as originally defined (Wagner-Döbler et al. 2003), contains Gram-negative, irregular rods, with a tendency to form chains, that grow optimally at 30 °C, at pH of 7.0–8.0, and have an absolute requirement of sea salts, not fulfilled by the sole addition of NaCl to the medium (salinity range: 1–7 % sea salts). They are heterotrophic, strict aerobes, non-fermentative, not able to reduce nitrates, and give a weak response to the oxidase test. Main fatty acids are C18:1 ω7c, C18:0, C19:0 cyclo, C17:0, C10:0 3OH, C14:0, C14:0 3OH/C14:1 3OH, and C12:1. They contain Q10 as predominant respiratory quinone and PG, DPG, PC, PE and one aminolipid as major polar lipids. DNA G+C content of the type species is 63 mol%. The remaining six species generally fulfill this description with only a few exceptions: nitrate reduction to nitrite is performed by some species; the salinity range may be slightly wider, 11-methyl C18:1 ω7c is a major part of the fatty acid profile of most species. The polar lipid profile does not include DPG or AL in some species (*J. donghaensis*, *J. seosinensis*). In addition, the G+C of the genus expands up to 68 mol%. Most species are pigmented in various shades of orange, yellow, or red but only one of them has been confirmed as synthetizing Bchl *a* (*J. seohaensis*). Reports on oxidase activity are sometimes contradictory: *J. seosinensis* is described as negative (Choi et al. 2006) but reported as positive in a later study (Yoon et al. 2010a). Motility is variable among species, but when present it is due to flagella (usually several) located polarly. Levels of DDH between different species are low: *J. pohagensis* shows 21 % against *J. helgolandensis*, a 38 % against *J. rubra*, and 24 % against *J. seosinensis* (Kim et al. 2008a), *J. rubra* is related to *J. helgolandensis* by a value of 42 % DDH (Macián et al. 2005a), and *J. seosinensis* and *J. seohaensis* show only 17 % relatedness (Yoon et al. 2010a). The genus is phylogenetically close to *Thalassobacter stenotrophicus*, which currently contains the former *Jannaschia cystaugens* (Adachi et al. 2004). *J. cystaugens* was found to be a heterotypic synonym of *T. stenotrophicus* (Pujalte et al. 2005b).

Despite the fact that only one of the seven species of *Jannaschia* is able to produce Bchl *a*, *Jannaschia*-related clones are a substantial part of the AAP bacteria in some extensively studied environments, as the Central Baltic Sea (Salka et al. 2008), where they account for 25–30 % of the total AAP clones obtained and occur in all locations investigated. *Jannaschia* sp. and *Sulfitobacter brevis* are two of the prominent members of experimental microcosms that show an increase after exposition to crude oil contamination (Jung et al. 2010b).

The first complete *Jannaschia* genome obtained corresponds to strain CCS1, a *Jannaschia* sp. isolated from Pacific coastal seawater and Bchl *a* producer: it consist of one chromosome (4.3 Mbp) and one plasmid (86 Kbp). Among others, it contains information for phototrophy, CO oxidation, aromatic compound degradation, nitrate assimilation, and DMSP demethylation. *Jannaschia* sp. CCS1 possesses six distinct ring-cleaving pathways, all of them chromosomally encoded (Moran et al. 2007). An enzyme produced by this strain, a D-hydantoinase is of interest, due to the application of these enzymes to the industrial production of pure amino acids (Cai et al. 2009).

Ketogulonicigenium

The genus *Ketogulonicigenium* is atypical within the *Roseobacter* group because its natural habitat is not the marine environment but continental and soil related. The two species included in the genus were obtained after a search for strains able to efficiently convert L-sorbose to 2 keto L-gulonic acid (2-KLG) from soils of different locations in the USA. This conversion is of great interest for the industrial production of L-ascorbic acid (vitamin C), and in fact strains of the type species *K. vulgare* are used for this purpose in coculture with *Bacillus megaterium* (Zhang et al. 2011a).

The genus is defined as containing Gram-negative, facultatively anaerobic cells, ovoid to rod shaped, that may form flagella and fimbriae. They produce a tan pigmentation that is diffusible in agar cultures of 48 h or more. Catalase and oxidase are positive. Best growth is observed at 27–31 °C, pH 7.2–8.5, and 117–459 mM Na^+, although this ion is not required for growth. They are chemoheterotrophs which use a wide range of carbohydrates for growth (inositol, mannitol, glycerol, sorbitol, lactose, and arabinose are preferred). All strains produce 2-KLG from L-sorbose. Major cellular fatty acids are C18:1 ω7c and C16:0. DNA G+C content is 52–54 mol%, according to the genus description, but complete genome sequencing of various strains gives somewhat higher figures (≈61–62 mol%). Both species, *K. vulgare* and *K. robustum*, could be distinguished by motility, intensity of pigmentation, and DDH values of 37–40 % (reciprocal values are much lower, 11–18 %). The type strains *K. vulgare* DSM 4025^T and *K. robustum* X6L^T are patented strains (Urbance et al. 2001); thus, according to Rules 27(3) and 30 of the Bacteriological Code, these names are not validly published (see notes for the genus at Euzéby's site, now http://www.bacterio.net/).

Complete genome sequences of two industrial *K. vulgare* strains (Y25 and WSH-001) reveal that they are composed of a circular chromosome and two plasmids (sizes: ≈2.77 Mbp, 267–268 Kbp, and 242–243 Kbp for the plasmids). Genes encoding sorbose dehydrogenase are chromosomic and are in multiple (four) copies, hence the highly efficient conversion of sorbose exhibited by these strains (Xiong et al. 2011; Liu et al. 2011).

Leisingera

Leisingera is a genus described in 2002 by Schaefer and col., which currently contains three species: *L. methylohalidivorans*, *L. aquimarina* (Vandecandelaere et al. 2008a), and *L. nanhaiensis* (Sun et al. 2010). The most outstanding activity of *Leisingera* species is their ability to oxidize methyl halides (methyl chloride, methyl bromide) with the concomitant liberation of halide atoms into the atmosphere (where they contribute to ozone destruction). At the time of the description of *L. methylohalidivorans*, the type species of the genus, the knowledge of marine methyl halide-oxidizing strains was scarce. Strain MB2^T was obtained from enrichment cultures inoculated with tide pool seawater after more than 3 years of maintenance with MeBr as sole carbon and energy source. The strain grows as regular straight rods with methyl halides, methionine, or DMS on mineral medium but forms elongated rods and filaments when grown on yeast extract or glycine betaine. It is Gram negative, motile, and not pigmented. Additional genus features are as follows: obligate aerobic, moderately halophilic, and growing by oxidation of methyl halides or selected methylated substrates, such as methionine. The DNA G+C content of the type strain is 60 mol%. The emendation to the genus description by Martens et al. (2006) added the following information: Q10 is the predominant quinone; PG, PE, one phospholipid, one aminolipid, and two other lipids are produced; but PC is absent in the polar lipid profile; major fatty acids are C18:1 ω7c, C16:0 2OH, C16:0, 11-methyl C18:1 ω7c, C18:1 ω9c, C14:1, C10:0 3OH, and C12:0 3OH (amide linked). In addition, the type species is defined as having temperature and pH optima of 27 °C and 7.7, respectively, and requiring Na^+ for growth that occurs only with more than 1 % NaCl. It is catalase and oxidase positive, not able to respire with nitrate as alternative electron acceptor, and shows a narrow number of carbon sources, which include methyl halides, DMS, methionine, and glycine betaine as methylotrophic substrates, and excludes carbohydrates, amino acids (other than methionine), and small organic acids. Growth is possible on yeast extract and Casamino acids-based media and in Marine Broth.

L. aquimarina is closely related to the type species, to which it shows a 56 % value of DDH. In contrast to *L. methylohalidivorans*, it is unable to grow on methionine and it is pigmented (dark beige pink).

A third species was described recently, *L. nanhaiensis* (Sun et al. 2010), which uses both methionine and betaine and shows a profile of polar lipids, fatty acids, and DNA G+C content compatible with the genus description. However, it is not unambiguously linked to the other two species and shows a closer relationship with *Litorimicrobium taeanense*, another recently described member of the *Phaeobacter* subclade.

Leisingera-like isolates have been obtained as a part of the culturable microbiota of Chinese sea anemones (Du et al. 2010).

Lentibacter

The genus *Lentibacter* was recently described (Li et al. 2012) as containing the species *L. algarum*. The strains were isolated from a seawater sample obtained during a massive algal bloom dominated by *Enteromorpha prolifera* in China. The genus is defined as Gram negative, aerobic, not flagellated, and lacking Bchl *a*. Additional features included in the genus description are a narrow range of growth temperatures (22–28 °C) and slow growth; a salinity range of 3–9 %; oxidase, catalase, and PHB production; and ability to reduce nitrate to nitrite. Major fatty acids are C18:1 ω7c, C18:0, and C16:0. Major polar lipids are PG, PE, PC, one amino lipid, and one lipid. Q10 is the predominant respiratory quinone. The DNA G+C content is between 54 and 57 mol%. The species is notable for its wide pH range (from 2.0 to 9.0) enabling growth—the lowest pH registered in the whole *Roseobacter* group.

In addition to its original isolation, *Lentibacter* sp. has been simultaneously isolated and detected as a dominant band in DGGE from seawater samples obtained during algal blooms in the North Sea (Hahnke et al. 2013b).

Lentibacter algae forms a moderately deep lineage in the *Roseobacter* group, with *Nereida ignava* as relative.

Litoreibacter

Litoreibacter (Kim et al. 2012b; Romanenko et al. 2011a) contains four species: *L. albidus*, *L. janthinus*, *L. meonggei*, and *L. arenae* (formerly, *Thalassobacter arenae*). They have been isolated from marine invertebrates and sediments and they are defined by the following traits: Gram negative, strictly aerobic, oxidase and catalase positive, and rod-shaped bacteria which divide by budding. Chemoorganoheterotrophic. Sodium ion is essential for growth. The predominant isoprenoid quinone is Q10. Common polar lipids are PC, PG, PE, an unidentified lipid, and an aminolipid. The predominant fatty acid is C18:1 ω7c. The G+C content is 56–60.4 mol%. In addition to these characters, species of the genus lack Bchl *a*, do not reduce nitrate to nitrite, and are psychrotolerant (temperature minimum is 4–5 °C, optimum being 25–30 °C). Some species produce PHB granules (*L. meonggei* and *L. arenae*) and most are pigmented (*L. janthinus*, grayish violet; *L. arenae*, brown; and *L. meonggei*, yellow) and nonmotile (exception is *L. arenae*, which forms polar flagella).

DDH levels between *Litoreibacter* species are low: Romanenko et al. (2011a) reported levels of 15 % between type strains of *L. albidus* and *L. janthinus*. Kim et al. (2012b) found values of 12 %, 14 %, and 9 % when testing *L. meonggei* type strain against *L. albidus*, *L. janthinus*, and *L. arenae* type strains, respectively. The four species form a well-defined clade, with *Pacificibacter marinus* and *Roseovarius marinus* (that might be considered a misclassified species) as nearest neighbors. The draft genome of *L. arenae* DSM 19593^T has 3.69 Mb.

Litorimicrobium

The genus *Litorimicrobium* (Jin et al. 2011) currently contains the single species *L. taeanense*. It contains Gram-negative, nonmotile, ovoid rods, which are oxidase and catalase positive and reduce nitrates to nitrites. They present Q10 as predominant quinone and C18:1 ω7c as major fatty acid, followed by its 11-methyl derivative, C12:1 3OH, C16:0 2OH, and C16:0. Its most abundant polar lipids are PG, DPG, PC, an unidentified aminolipid, a phospholipid, and a lipid. DNA G+C content is 62.4 mol%.

The closest relative to *L. taeanense* in the 16S rRNA gene trees is *Leisingera nanhaiensis*, followed by several *Phaeobacter* species and *Seohaeicola saemankumensis*.

Loktanella

Loktanella is the most populated genus in the *Roseobacter* group, with a total of 13 species described so far (*Roseovarius* equals this figure but the taxonomic status of some of its species deserves a reevaluation). The genus was proposed by Van Trappen et al. (2004) after studying isolates from microbial mats of Antarctic lakes (Fryxell Lake, Ace Lake, Organic Lake, Pendant Lake) and has been further enlarged to encompass species isolated from diverse marine samples (seawater, sediments, and beach sand) around the world. Emended descriptions of the genus accompanied the descriptions of *L. pyoseonensis* (Moon et al. 2010), *L. tamlensis* (Lee 2012), and *L. cinnabarina* (Tsubouchi et al. 2013). The following are currently considered the basic properties of the genus: cells are Gram negative, rod shaped, nonspore-forming, strictly aerobic, chemoorganotrophic, and moderately halotolerant. Oxidase and catalase are positive. Motility is variable among species. Colony color is also variable (white, pink, beige, light orange). Optimal temperature is around 25 °C. The most abundant fatty acid is C18:1 ω7c, Q10 is the predominant quinone, and major polar lipids are DPG, PC, and PG. DNA G+C content is 55–69 mol%.

The genomes of two strains of *L. vestfoldensis* (DSM 16212^T and SKA53) have been sequenced: the draft genomes are 3.7 and 3.1 Mbp in size and have 61.8 and 60.0 mol% G+C content, respectively. *L. cinnabarina* LL-001^T and *L. hongkongensis* DSM 17492^T have similar genome sizes (3.9 Mb and 3.2 Mb, respectively) but higher G+C content (66.7 and 68.4 mol%, respectively).

Data from DDH experiments give the following figures for the species that have been submitted to this determination: *L. vestfoldensis*, *L. fryxellensis*, and *L. salsilacus* type strains are interrelated by values from 10 % to 18 % (Van Trappen et al. 2004); *L. vestfoldensis* and *L. agnita* show a 35 % relatedness (Ivanova et al. 2005); Hosoya and Yokota (2007a) reported a 28–36 % relatedness between *L. atrilutea* and *L. salsilacus* and an 11–31 between *L. atrilutea* and *L. fryxellensis*; *L. tamlensis* (Lee 2012) is related to *L. rosea* by 11–15 % values and by just 8 % to *L. maricola* (Yoon et al. 2007c); finally, *L. cinnabarina* and *L. hongkongensis* show 41–44 % DDH values (Tsubouchi et al. 2013).

The thirteen *Loktanella* species recognized so far differ in several traits, in addition to motility (three species are motile, *L. atrilutea*, *L. pyoseonensis*, and *L. tamlensis*) and pigmentation: one of them is the requirement of Na^+ for growth, which occurs in all but four species (*L. salsilacus*, *L. fryxellensis*, *L. vestfoldensis*, and *L. atrilutea*), nitrate reduction (positive only for *L. agnita*, *L. koreensis*, and *L. pyoseonensis*), psychrotolerant character (all but *L. litorea* and *L. cinnabarina* are able to grow at 4–8 °C), use of carbohydrates (present only in *L. hongkongensis*, *L. maricola*, *L. atrilutea*, *L. pyoseonensis*, and *L. litorea*), and Bchl *a* synthesis, found in *L. maricola* (although *L. vestfoldensis* also contains photosynthetic genes).

All *Loktanella* species are included in a single clade (*Fig. 20.5*) except for three: *L. hongkongensis*, *L. pyoseonensis*, and *L. cinnabarina* (all with DNA G+C content in the upper limit of the genus) that merge with the genus *Ketogulonicigenium*.

In addition to the isolation sites of the type strains, Loktanellas have been isolated and/or detected among the microbiota of hypersaline, cold environments (Jiang et al. 2010; Niederberger et al. 2010) and have been found associated to some members of marine fauna: tentacles of cnidarians (Doepke et al. 2012) and sea anemones (Du et al. 2010). *Loktanella* AAP clones have also been found in high proportions as a part of the AAP bacteria in localized basis of Central Baltic Sea (Salka et al. 2008). They are also a major part of clone libraries obtained at the surface of tropical South Pacific Ocean, along with SAR86 and unclassified Flavobacteria (Stevens and Ulloa 2008), components of biofilms formed in marine coastal water, after the first 24–36 h colonization (Lee et al. 2008), and members of summer community of ephemeral desert playa lakes (Costa et al. 2008).

L. rosea has raised interest for its highly unusual LPS composition, which includes an atypical lipid A composed of a trisaccharide backbone lacking the phosphate groups (two β-glucosamines plus an α-galacturonic acid) and a core region with unusual composition (Ieranò et al. 2010) not seen in other Gram-negative marine bacteria studied so far (Nazarenko et al. 2011).

Lutimaribacter

Lutimaribacter saemankumensis is the type and only species of the genus *Lutimaribacter* (Yoon et al. 2009a). They are Gram-negative, non-flagellated rods, positive for oxidase and catalase, and facultatively anaerobic. Q10 is the predominant quinone and C18:1 ω7c plus its 11-methyl derivative are the major cellular fatty acids. The species shows the following traits: it is pigmented (pale yellow), grows in Marine Agar in anaerobic conditions, does not reduce nitrates, requires Na^+ for growth, tolerates up to 10 % NaCl, and does not synthetize Bchl *a*. Its major polar lipids are PC, PG, PE, an unidentified aminolipid, and two phospholipids. The DNA G+C content is 63.5 mol%. The closest neighbor of *L. saemankumensis* is *Oceanicola pacificus*, one of the *Oceanicola* species that appears to be misclassified.

Mameliella

Mameliella (Zheng et al. 2010a) contains a single species, *M. alba*, isolated from seawater. The genus is described as follows: Gram-negative, nonmotile rods that multiply by binary fission and accumulate PHB granules. The predominant respiratory quinone is Q10. It is oxidase and catalase positive but negative for urease, hydrolysis of starch and gelatin, and indole production. Forms white colonies in RO (Rich Organic) medium containing (in grams per liter) yeast extract, 1.0; Bacto Peptone, 1.0; sodium acetate, 1.0; KCl, 0.3; $MgSO_4 \cdot 7H_2O$, 0.5; $CaCl_2 \cdot 2H_2O$, 0.05; NH_4Cl, 0.3; K_2HPO_4, 0.3; and NaCl, 20.0; plus 20 μg of vitamin B12, 200 μg of nicotinic acid, 80 μg of biotin, 400 μg of thiamine, and 1.0 ml of a trace element solution. The species is described as mesophilic and neutrophilic and is able to grow with 1–10 % NaCl in the medium and able to reduce nitrates and to use several carbohydrates and some organic acids. Contains C18:1 ω7c, C18:0, C12:1 3OH, C16:0, and 11-methyl C18:1 ω7c as major fatty acids. Its DNA G+C content is 63.7 mol%. In spite of its general lack of phenotypic distinctiveness, *M. alba* forms a distinct lineage in the 16S rRNA tree, forming a long branch connected to the pair *Antarctobacter heliothermus-Sagittula stellata*.

Maribius

The genus *Maribius* (Choi et al. 2007) contains two species *M. salinus* and *M. pelagius* isolated from distant saline waters (a Chinese solar saltern and Sargasso Sea seawater). They form a tight group, related to *Hwanghaeicola aestuarii* and to the newly described *Profundibacterium mesophilum*. The main characteristics of the genus are: rod-shaped, nonmotile, Gram-negative cells. They are obligate aerobic heterotrophs, positive for oxidase and catalase, and require Na^+ and Mg^{2+} for growth. They accumulate PHB and have Q10 as predominant quinone and C18:1 ω7c plus C19:0 cyclo ω8c as major fatty acids. Colonies on Marine Agar are opaque and beige in color and do not contain Bchl *a*. The DNA G+C content is 66–70 mol%. None of the species reduces nitrate to nitrite or hydrolyzes gelatin, but both are amylolytic. Surprisingly, the species isolated from seawater tolerates higher salinities (up to 15 %) than the one isolated from solar saltern water, *M. salinus* (up to 10 %).

Marinovum

A long path took the former *Roseobacter algicola* (Lafay et al. 1995) and then *Ruegeria algicola* (Uchino et al. 1998) to be finally recognized in a separate genus *Marinovum* (Martens et al. 2006) as *M. algicola*. The strains that served to describe the species were isolated from cultured, toxin-producing dinoflagellate *Prorocentrum lima*. The phylogenetic position of *Marinovum algicola* as an independent branch, separated from true *Roseobacter* and *Ruegeria* species, is clear in all analyses.

The genus contains Gram-negative, ovoid cells, motile through flagella that are subpolarly inserted. Colonies develop a pinkish-beige pigmentation after a few days incubation. They do not accumulate PHB but Lafay et al. (1995) show electron micrographs in which refringent spherical bodies can be seen inside the cells. They are strict aerobes, non-fermentative, unable to denitrify, and oxidase, catalase, and gelatinase positive. Do not synthetize Bchl *a*. They are mesophilic (optimum temperature 25–30 °C) and require Na^+, thiamine, and biotin for growth. They use several carbohydrates (hexoses, disaccharides) and some organic acids (pyruvate, malate, and citrate) as carbon sources. The major quinone is Q10; dominant fatty acids are C18:1 ω7c, 11-methyl C18:1 ω7c, C18:0, C12:0 3OH, and C10:0 3OH (amide linked); and major polar lipids are PG, PE, PC, an unidentified phospholipid, one lipid, and one aminolipid. The G+C content is not included in any of the three papers that concern the taxonomy of the genus. Pradella et al. (2010) determined the structure of the genome in several strains of *M. algicola*, including the type strain: it is composed of one circular chromosome (3.60–3.74 Mbp) and 9–12 plasmids (7–477 Kbp), giving a total genome size of 5.0–5.35 Mbp.

Maritimibacter

Maritimibacter alkaliphilus, the single species of the genus *Maritimibacter*, was isolated by applying dilution-to-extinction, high-throughput culturing methods to Sargasso Sea seawater (Lee et al. 2007a). The strain that served to describe the new genus and species is a Gram-negative, nonmotile, rod-shaped bacterium that does not accumulate PHB and does not synthetize Bchl *a* or carotenoids. It is chemoheterotrophic, strict aerobe and requires sodium ion for growth. Its dominant fatty acids are C16:0 2OH, C16:0, C18:1 ω7c (in lower proportion than is usual in the family), 11-methyl C18:1 ω7c, and C18:1 2OH. Q10 is the predominant quinone. Major polar lipids are PC, PE, and PG. In addition to these generic characteristics, the species presents the following traits: mesophilic (16–37 °C, optimum 30 °C), slightly halophilic (0.5–7.5 % NaCl, optimum 2.5–3.0 %), and alkaliphilic (4–12, optimum pH 10). Catalase, oxidase, and urease are positive. Although no nitrate reduction is detected in the API strips, the draft genome of the strain has been obtained, and it contains a complete nitrate reduction pathway to N_2. Other specific genes include two putative Na^+/H^+ antiporters, considered essential for alkaliphilic behavior. Genome size of *M. alkaliphilus* HTCC2654^T is 4.53 Mbp and its G+C content is 64 mol%. It contains 49 tRNA genes and one each of 5S rRNA, 16S rRNA, and 23S rRNA genes (Thrash et al. 2010a).

The position of *M. alkaliphilus* in the *Roseobacter* group is isolated, with no close relative and by the edge of the clade.

Marivita

The genus *Marivita* was proposed to accommodate two species, *M. cryptomonadis* and *M. litorea*, isolated from a culture of *Cryptomonas* sp. and a coastal seawater sample, respectively

(Hwang et al. 2009), and nowadays it contains six. Among the species added later, *M. byunsanensis* corresponds to a reclassification of the former *Gaetbulicola byunsanensis* (Yoon et al. 2010b) (so the genus *Gaetbulicola* is now "empty") and the remaining three have been isolated from seawater (*M. hallyeonensis*, *M. geojedonensis*) or estuarine water (*M. roseacus*). The genus has been emended twice (Budinoff et al. 2011; Yoon et al. 2012).

Marivita species form one of the few well-defined, tightly delimited, generic clades in the *Roseobacter* group, with all the six species closely located at the end of a rather long branch that joins to a clade of misplaced *Oceanicola* spp. (see below). Pairs of *Marivita* species for which DDH has been determined show low levels of relatedness: *M. cryptomonadis* and *M. litorea* show 13 % DDH value (Hwang et al. 2009); *M. hallyeonensis* shows 15, 17, and 11 % to *M. cryptomonadis*, *M. litorea*, and *M. byunsanensis*, respectively (Yoon et al. 2012); *M. roseacus* shows 30–33 % against *M. litorea* and 19–20 to *M. cryptomonadis* (Budinoff et al. 2011). Finally, *M. geojedonensis* presents values between 17 % and 22 % to *M. cryptomonadis*, *M. litorea*, *M. byunsanensis*, and *M. hallyeonensis* (Yoon et al. 2013b).

The genus, as presently recognized, contains Gram-negative, strictly aerobic, heterotrophic bacteria that contain genes for Bchl *a* synthesis (although some of them do not produce the pigment). Oxidase and catalase are positive. Cell morphology varies from short rods to long rods associated in chains or pleomorphic cells. May be motile by polar flagella or nonmotile. Major fatty acid is C18:1 ω7c. Q10 is the predominant quinone, while major polar lipids are PC, PG, PE, and an unidentified aminolipid. The DNA G+C content is 58–65 mol%.

Species of *Marivita* differ in motility (although there are contradictory data in different studies, see Budinoff et al. (2011) on motility and nitrate reduction activity of *M. cryptomonadis* and *M. litorea*), PHB production, nitrate reduction, pigmentation (from cream to pink or light yellow), and the use of different carbon sources (if any). All species require Na^+ for growth, some also Mg^{2+}, yet others combined sea salts. They are mesophilic, neutrophilic, and able to grow with 0.5–1.0 to a maximum of 6–10 % salinity, depending of the species. *M. cryptomonadis*, *M. litorea*, and *M. roseacus* have *puf* genes encoding phototrophic ability, but only *M. roseacus* synthetizes Bchl *a* in standard growth conditions. The rest of the species have not been tested for *puf* genes.

Nautella

The genus *Nautella* (Vandecandelaere et al. 2009a) contains one species, *N. italica*, isolated from a marine electroactive biofilm grown on a stainless steel cathode exposed to natural seawater. *Nautella* is defined as Gram-negative, motile, rod-shaped, strictly aerobic and moderately halophilic, with a positive response to catalase and oxidase tests and able to grow in the range of 4–45 °C.

The species is characterized by the following properties: cells are motile by a polar flagellum and accumulate PHB. Colonies are beige. They require Na^+ and grow from 1 % to 7 % NaCl (optimum 2–3 %). Temperature optimum is 20–28 °C and optimum pH is between 6.0 and 8.0. They are non-fermentative and do not reduce nitrate to nitrite or hydrolyze gelatin, casein, starch, chitin, or DNA. They contain C18:1 ω7c, C16:0 2OH, 11-methyl C18:1 ω7c, C10:0 3OH, C18:0 2OH, C12:0 3OH, C16:0, and C18:0 as major fatty acids. Their DNA G+C content is 61 mol% (Vandecandelaere et al. 2009a).

At the moment of its description, the closer relatives to *Nautella* were *Phaeobacter* species. Thus, in addition to the intraspecific level of DDH between the five isolates included in the species description, the relatedness with some *Phaeobacter* species (*P. daeponensis*, *P. inhibens*, and *P. gallaeciensis*) was also determined and found to be low (7–17 %).

Nautella-like isolate R11 (formerly *Ruegeria* sp. R11) has been characterized as an algal pathogen, causing bleaching disease in the marine red alga *Delisea pulchra* (Case et al. 2011). Sequencing and analysis of its genome has revealed clues for understanding the pathogenicity of the strain: adhesion mechanisms, transport of algal metabolites, oxidative stress protection, cytolysins, and other pathogen-related activities were found coded in the genome of *Nautella* sp. R11 (Fernandes et al. 2011). The genome of this strain is composed of a circular chromosome of 3.62 Mbp and a plasmid of 197 Kbp. Other closely related strains show detrimental activities in different marine organisms, as *Raphidophyceae* algae, sea urchins, and corals.

Nereida

Nereida was described as a genus containing Gram-negative, strictly aerobic, chemoorganotrophic, slightly halophilic bacteria (Pujalte et al. 2005a). They are positive for oxidase and catalase, mesophilic, require combined sea salts for growth and do not ferment carbohydrates or reduce nitrates. They do not form gas vesicles or PHB granules in the cells, which are nonmotile, coccoid, elongated, or tear-shaped rods that divide by budding. They contain C18:1 ω7c, C18:0, and C16:0 as main fatty acids and have a G+C content of 56 mol%.

The only species so far recognized in the genus is *N. ignava*, related to the sequences of uncultured symbiotic bacteria from the galls of the alga *Prionitis lanceolata* and neighbor to the recently described *Lentibacter algarum*. The species shows undetermined nutritional requirements and uses a narrow range of carbon sources, provided that the basal medium is supplemented with low amounts of yeast extract.

Oceanibulbus

Oceanibulbus indolifex is the sole species of the genus *Oceanibulbus* (Wagner-Döbler et al. 2004). This species is a member of the subclade containing *Roseobacter* and *Sulfitobacter* species. In fact, it is so closely related to the species *Sulfitobacter delicatus* and *S. dubius* (99.5 % 16S rRNA sequence

similarity, according to Ivanova et al. 2004) that they might well be members of a single genus, if only phylogenetic information were used to define the rank. *Oceanibulbus* is Gram-negative and nonmotile and the cells are irregular rods with swollen ends and inclusion bodies (PHB). They do not synthetize Bchl *a*. They are strictly aerobic, non-fermentative heterotrophs that require sea salts (NaCl alone does not support growth) and are able to develop in media with 1–7 % sea salts content. Optimum temperature and pH are 25–30 °C and 7.0–8.0, respectively. Oxidase reaction is weak. Do not reduce nitrates to nitrites. They contain Q10 as predominant quinone. PG, DPG, PC, PE, and an aminolipid are the main polar lipids and C18:1 ω7c, C18:0, C16:1 ω7c, C16:0, C10:0 3OH, and C12:1 3OH as major fatty acids. *O. indolifex* has a 60 mol% G+C content. It shows 21 % relatedness on DDH experiments to *Sulfitobacter mediterraneus* (Wagner-Döbler et al. 2004). To the best of our knowledge, the DDH levels between *O. indolifex* and *S. delicatus* and *S. dubius* have not been tested.

O. indolifex produces some interesting secondary metabolites, as indole and several indole derivatives, some cyclic dipeptides and tryptanthrin (Wagner-Döbler et al. 2004). It also produces sulfur volatiles during metabolism of S-containing compounds, as sulfides and thioesters, some of them were new natural compounds as 5-methyl phenylethanethioate and butyl methanesulfonate (Thiel et al. 2010). It was one of the species included in the development of genetic tools for investigation of regulatory and metabolic networks in the *Roseobacter* group (Piekarski et al. 2009). The genome of the type strain has an estimated size of 4.11 Mbp and contains 4,153 ORFs, with a G+C content of 59 mol%.

Oceanicola

The genus *Oceanicola* currently contains seven species: *O. granulosus*, the type species, and *O. batsensis*, both isolated by high-throughput culturing methods from seawater (Cho and Giovannoni 2004); *O. nanhaiensis*, obtained from deep (1,100 m) marine sediments (Gu et al. 2007); *O. marinus*, from seawater (Lin et al. 2007); *O. pacificus*, also from deep marine sediments (Yuan et al. 2009); *O. nitratireducens*, from seawater (Zheng et al. 2010b); and *O. litoreus* (Park et al. 2013a) from seashore sediment. The phylogenetic relationships among the members of the genus are, however, dubious, as the type species separates from the larger *Oceanicola* clade (*O. batsensis*, *O. nanhaiensis*, *O. nitratireducens*, *O. marinus*) and associates with *Roseisalinus antarcticus*, while *O. pacificus* groups very close to *Lutimaribacter saemankumensis* (both with NJ and ML). Given that the genus seems polyphyletic (as it was also recognized and reported by Thrash et al. (2010b) and Newton et al. (2010)), the generic assignment of all (but type) species is pending of a reevaluation taking into account all the neighboring new taxa recognized since the genus was first described. This situation is not uncommon; similar problems affect the genus *Roseovarius* and *Phaeobacter*. Despite the large separation in the 16S rRNA tree, the type strains of *O. granulosus* and *O. batsensis* displayed 48 % relatedness in DDH determinations (Wagner-Döbler et al. 2004). DDH values relate *O. marinus* to *O. granulosus* by 7 % and to *O. batsensis* by 26 % (Lin et al. 2007). *Oceanicola* comprises Gram-negative, nonmotile short rods that multiply by binary fission and accumulate PHB granules. They do not synthetize Bchl *a*. Their metabolism is chemoorganotrophic and aerobic to microaerotolerant (*O. marinus* and *O. litoreus* are described as facultative anaerobes due to their ability to grow on Marine Agar in anaerobic conditions, but they do not ferment glucose nor do they respire with nitrate). Oxidase test is positive but they are negative for denitrification, glucose acidification, arginine dihydrolase, indole production, and gelatinase. Main fatty acids are C18:1 ω7c, C16:0, and C 19:0 cyclo (except for *O. nitratireducens* and *O. nanhaiensis*). DNA G+C content is 64–73 mol%. Predominant quinone is reported to be Q10 for *O. nanhaiensis*, *O. nitratireducens*, and *O. litoreus*. Polar lipid composition is reported only for *O. litoreus* and *O. granulosus* (Park et al. 2013a) and consists of PC, PG, PE, an unidentified aminolipid, and a lipid for *O. litoreus*, while the type species lacks PE. Species of *Oceanicola* are neutrophilic and mesophilic but display a wide range of growth temperatures, with four of the species growing from 4 °C to 40 °C (*O. granulosus*, *O. batsensis*, *O. marinus*, and *O. litoreus*). All, except *O. nanhaiensis*, need Na^+ for growth (*O. litoreus*, also requires Mg^{2+}) and grow from 0.5 to 7–10 % salinity. They could be differentiated by the carbon sources used, presence of urease, minimum growth temperature, gelatin and esculin hydrolysis, and the percentage of the fatty acid C10:0 cyclo. As many other roseobacters, *Oceanicola* sp. participate in the transformation of DMSP in DMS, as documented by Curson et al. (2008) and Mou et al. (2005).

The genomes of *O. granulosus* and *O. batsensis* type strains have been sequenced (Thrash et al. 2010b). The genome of the type species comprises 4.04 Mbp, 3,855 ORFs and has a G+C content of 70.4 mol%. It contains genes for the Calvin cycle including the large (but not the small) RuBisCo subunit. The genome of *O. batsensis* comprises 4.44 Mbp, 4,261 ORFs and has a G+C content of 66 mol%. It does not contain *che* gene homologs, in contrast *to O. granulosus* genome. Both have putative genes for PHB synthesis. The draft genome of a third *Oceanicola* sp. strain able to degrade xylan has been reported (Kwon et al. 2012).

Oceaniovalibus

Oceaniovalibus and its single species *O. guishaninsula* (Liu et al. 2012) occupy a detached position, next to *Pontibaca methylaminivorans*, in the *Roseobacter* clade. It contains Gram-negative, ovoid to coccoid cells and is nonmotile and unable to produce PHB or synthetize Bchl *a*. Pigmentation of the colonies grown in Rich Organic medium or Marine Agar is pink. Catalase, oxidase, and nitrate reduction to nitrite are positive. They contain C18:1 ω7c, C19:0 cyclo, and C16:0 as major fatty acids and Q10 as predominant quinone.

O. guishaninsula was isolated from surface seawater. Its DNA G+C content is 62 mol%. It is neutrophilic (pH 4–10, optimum 6–9), mesophilic (16–40 °C, optimum 20–30 °C), and slightly halophilic (0.5–12 % NaCl, optimum 4–5 %). It is amylolytic but not gelatinolytic, uses as carbon sources some carbohydrates (L-arabinose, D-cellobiose, D-mannitol, and D-glucose), organic acids, and amino acids. Major polar lipids are PG and DPG. A draft genome (2.9 Mb) of the type strain JLT2003^T has been reported (Tang et al. 2012).

Octadecabacter

Octadecabacter is one of the oldest members of the *Roseobacter* group, described by Gosink et al. (1997) from sea ice samples obtained at the two polar regions. It contains heterotrophic, psychrophilic, gas vacuolated, nonpigmented bacteria distributed in two species: *O. arcticus* from Arctic ice samples and *O. antarcticus* from Antarctic sea ice. The two species maintain a moderate relatedness, a 42 % level of DDH (Gosink et al. 1997). Their distribution at the poles was the basis for discussion about biogeography of sea ice bacteria (Staley and Gosink 1999; Brinkmeyer et al. 2003).

Octadecabacter comprises Gram-negative, nonmotile rods with gas vesicles. They are aerobic to microaerophilic and do not reduce nitrates. Bacteriochlorophyll *a* is not synthetized. Catalase test is positive, but oxidase is negative (an uncommon trait in the *Roseobacter* group). True psychrophilic, they grow down to 4 °C (with maxima at 10–15 °C). No growth is observed without Na^+; the salinity growth range is 1.7 –7 %. They have nutritional requirements that may be covered by yeast extract, but even with the addition of this supplement, turbidity of the cultures is always low. Carbon sources used include L-glutamate, glycerol, and Casamino acids. The dominant fatty acid is C18:1 ω7c and the DNA G+C content is 56–57 mol%. *O. arcticus* requires thiamine, nicotinic acid, and pantothenic acid and grows up to 15 °C, while *O. antarcticus* grows only up to 10 °C. Both species contain, in addition to C18:1 ω7c, C16:1 ω7c, C16:0, and C10:0 3OH as major fatty acids.

The two species form a tight, isolated clade in the 16S rRNA tree.

Genomes of the types of both species have been finished and manually annotated (Vollmers et al. 2013). The genome size of *O. arcticus* 238^T is 5.20 Mbp (with 4,683 protein-coding genes) and 4.88 Mbp for *O. antarcticus* 307^T (4,492 protein-coding genes), both having the same DNA G+C content, 55 mol%, and exhibiting a high genome plasticity caused by an unusually high density and diversity of transposable elements. Interestingly, genes representing a new subgroup of xanthorhodopsins as an adaptation to icy environments were found in both *Octadecabacter* strains that differed from the previously characterized xanthorhodopsins of *Salinibacter ruber* and *Gloeobacter violaceus* in phylogeny, biogeography, and the potential to bind 4-keto-carotenoids. Biochemical characterization of the *Octadecabacter* xanthorhodopsins revealed that they function as light-driven proton pumps (Vollmers et al. 2013).

Pacificibacter

Pacificibacter (Romanenko et al. 2011b) accounts for marine bacteria which display the following properties: they are Gram-negative budding rods, strictly aerobic, chemoorganotrophic, and oxidase and catalase positive. They require sodium ions for growth. Q10 is the predominant quinone and their polar lipids contain PC, PG, DPG, and unidentified lipids as major components. The most abundant fatty acids are C18:1 ω7c, C16:0, C10:0 3OH, and C12:1 3OH. The only species of *Pacificibacter* currently recognized is *P. maritimus* (although the close position of *Roseovarius marinus* in the 16S rRNA tree suggests that it might be reclassified as a second species of *Pacificibacter*), which is nonmotile, unpigmented, does not synthetize Bchl *a*, and grows at 0.5–6 % salinity, at 2–36 °C (optimum 25–30 °C), and at pHs of 5.5–9.5 (6.5–8.5 optimum). It uses a few sugars (glucose, maltose, cellobiose, melibiose) and organic acids (acetate, lactate, and citrate) as carbon sources. *P. maritimus* is unable neither to reduce nitrates nor to hydrolyze gelatin, casein, or DNA. The DNA G+C content is 52.6 mol%.

Palleronia

Palleronia is one of the few genera in the *Roseobacter* clade that have been isolated from a non-marine habitat: its type species *P. marisminoris* was obtained from a saline soil sample in the surroundings of a solar saltern in Murcia, Spain (Martínez-Checa et al. 2005). *Palleronia* is defined as Gram negative, rod shaped, nonmotile, chemoheterotrophic, and aerobic. It does not synthetize Bchl *a* and it is unable to grow anaerobically either by fermentation, nitrate or fumarate reduction, or photoheterotrophy. Oxidase test is negative. They produce pink-pigmented colonies, are strictly halophilic, and require sodium, magnesium, and potassium ions for growth. They have a low nutritional versatility. Chemotaxonomic markers include Q10 as dominant quinone and C18:1 ω7c plus C19:0 cyclo ω8c as major fatty acids.

P. marisminoris is an exopolysaccharide-producing species that forms capsulated cells and mucoid colonies. Salinity growth range is 0.5–15 %, with an optimum at 5 %. Mesophilic, it grows from 20 °C to 37 °C and at pH from 5 to 10. It is negative for nitrate reduction to nitrite and for hydrolytic activities on gelatin, casein, lecithin, starch, Tween 80, or DNA. No growth was obtained in any of 35 carbon sources tested (Martínez-Checa et al. 2005). The cells accumulate polyhydroxyalkanoate granules. The DNA G+C content is 64 mol%.

The species is located next to *Tranquillimonas alkanivorans* and *Salipiger mucosus* (another taxon isolated from hypersaline soil).

Pelagibaca

Pelagibaca bermudensis is the only named species of the genus *Pelagibaca* (Cho and Giovannoni 2006). Isolated from Sargasso

Sea water by high-throughput culturing involving dilution to extinction, it is another new taxon recovered along with *Maritimibacter alkaliphilus*, *Oceanicola granulosus*, and *O. batsensis*. The genus is chemoheterotrophic and facultatively anaerobic. Cells are ovoid, nonmotile, divide by binary fission, and do not produce PHB or exopolysaccharides. Bchl *a* and carotenoids are absent. Able to reduce nitrate and nitrite. They require sodium ion for growth and are slightly halophilic. Glucose is acidified. They use a wide variety of sole carbon sources for growth. Their predominant fatty acid is C18:1 ω7c and its 11-methyl derivative. The only respiratory quinone is Q10 and the G+C content of DNA is 65.4 mol%.

P. bermudensis displays the following specific traits: grows between 10 °C and 40 °C (optimum 30–33 °C), at pH 5.5–10.5 (optimum 8.5) and from 0.25 % to 15 % salinity (optimum 3.0 %). It is oxidase and catalase positive; hydrolyzes gelatin, urea, and esculin; uses a large number of carbohydrates, organic acids, and amino acids as sole carbon and energy sources, including methanol. In addition to the fatty acids cited above, it contains more than 1 % of C16:0 and C12:0 3OH.

It is marginally related to the loose clade that contains *Saligipiger mucosus*, *Palleronia marisminoris*, and *Tranquillimonas alkanivorans*. At the time of its description, *Salipiger mucosus* was the nearest taxon, so the levels of DDH with its type strain were determined, resulting in a value of 26 % (Cho and Giovannoni 2006).

Pelagibaca sp. has been isolated, among other genera of the *Roseobacter* clade, as phthalate-degrading bacteria from seawater off the coast of Japan (Iwaki et al. 2012b).

A draft genome sequence of *P. bermudensis* HTCC2601^T has been obtained (Thrash et al. 2010a): it comprises 5.43 Mbp, 5,522 ORFs and has a G+C content of 66.4 mol%. It contains fifty-six tRNA genes, five 5S rRNA genes, four 16S rRNA genes, and five 23S rRNA genes. In addition to the general information for central metabolic pathways (complete glycolysis, Entner-Doudoroff pathway, TCA cycle), pathways for oxidation of C1 compounds are present, as well as a complete RubisCo complex, unique to the currently sequenced roseobacters. Other information includes biosynthesis of most essential amino acids and some vitamins, assimilatory nitrate reduction pathway, several type VI secretion genes, complete *sec* pathways, and a large number (362) of ABC transporters. These later gene groups are similarly present in other *Roseobacter* clade representatives sequenced so far.

Pelagicola

The genus *Pelagicola* and is type species *P. litoralis* (Kim et al. 2008b) are similar in most traits to other members of the group, except for a low G+C content, 47 mol%, which is the lowest recorded in the whole group and the only one below 50 mol%. Other traits are typical of roseobacters: they are Gram negative, nonmotile, strict aerobic and the cells are club shaped. Do not accumulate PHB. Catalase and oxidase are positive. Bchl *a* is absent. Q10 is the predominant quinone and C18:1 ω7c the major fatty acid. It contains PC, PG, PE, an unidentified aminolipid, and three lipids as major polar lipids. *Pelagicola litoralis*, which is close to the main *Roseovarius* clade, is not pigmented, grows with 2–6 % sea salt concentration (optimum 3–4 %), at 20–30 °C, and pH 6–8. Hydrolyzes starch and Tween 80 but not gelatin and does not reduce nitrate to nitrite. Sole carbon sources include acetate, betaine, glucose, L-lysine, L-proline, and L-serine. The type strain was isolated from costal seawater.

Pelagimonas

Pelagimonas is a recently described genus (Hahnke et al. 2013a) related to the *Sulfitobacter* subclade (in the paper) or to *Tropicibacter* genus (NJ tree, ❯ *Fig. 20.5*). The type strain of the type and only species *P. varians* was isolated from a seawater sample taken during an algal bloom at the North Sea. It is Gram negative, aerobic, chemoorganotrophic, catalase positive but oxidase negative. The cells are irregular rods. It does not synthetize Bchl *a* or other pigments, and *puf* genes for bacterial photosynthesis are absent. They require vitamins and sodium ion for growth. Major quinone is Q10. Dominant fatty acids are C18:1 ω7c and C18:2, accompanied by C10:0 3OH, C12:1, C14:1 3OH, C16:0, C18:0, and 11-methyl C18:1 ω7c. Major polar lipids are PC, PG, PE, DPG, PME, an unidentified aminolipid, one PL, and one lipid. The species is characterized by the presence of at least one flagellum, the ability to grow from 4 °C to 37 °C (optimum 28–32 °C), at pH 6.0–9.5 (optimum 7.0–8.5) and with salinities from 1.25 % to 8 % (optimum 1.25–5 %). It requires nicotinic acid amide. Does not reduce nitrate to nitrite. It grows with several amino acids, sugars, and organic acids as carbon sources. The G+C content of the DNA is 55 %.

Phaeobacter

The genus *Phaeobacter* currently contains five species: *P. gallaeciensis* (formerly *Roseobacter gallaeciensis*), the type species (Martens et al. 2006; Ruiz-Ponte et al. 1998), *P. inhibens* (Martens et al. 2006), *P. daeponensis* (Yoon et al. 2007d), *P. arcticus* (Zhang et al. 2008), and *P. caeruleus* (Vandecandelaere et al. 2009b). Phaeobacters are often regarded as efficient surface colonizes and as producers of inhibitory compounds that enable them to antagonize invertebrate settlement and algal or microbial growth.

General properties of the genus, as described by Martens et al. (2006) and emended by Yoon et al. (2007b) are as follows: cells are Gram negative, ovoid, and multiply by binary fission. They are motile by polar flagella and have a tendency to aggregate in liquid medium forming rosettes. Colonies are generally pigmented, brown/ochre, yellow, or blue. May produce a diffusible brownish pigment. Bchl *a* is absent. They do not grow photoheterotrophically or with methyl halides or DMS. Metabolism is chemoheterotrophic and obligately

aerobic. Oxidase and catalase are positive, but amylase, gelatinase, and tweenase are negative. The major respiratory lipoquinone is Q10. Polar lipids comprise PG, PE, PC, one aminolipid, and two phospholipids. Fatty acids comprise C18:1 ω7c, 11-methyl C18:1 ω7c, C16:0, C16:0 2OH, C18:0, C10:0 3OH, C14:1, C12:0 3OH (amide linked), and C14:1 3OH (amide linked).

The currently recognized species of *Phaeobacter* display a DNA G+C content of 55–65 mol%.

DDH experiments between different type strains of these species have been published in some of the original descriptions, for example, *P. gallaeciensis* and *P. inhibens* are related by figures of 16–20 % (while *P. gallaeciensis* showed less than 5 % against *Leisingera methylohalidivorans*, *Roseobacter* spp., and *Ruegeria*—now *Marinovum—algicola*). *P. daeponensis* was related to *P. gallaeciensis* and *P. inhibens* by values of 15 % and 18 %, respectively. *P. arcticus* showed 33 % relatedness to *P. inhibens*, the only species with more than 97 % 16S rRNA gene similarity at that time. Finally, *P. caeruleus* exhibits DDH levels of 25 % to *P. inhibens*, 28 % to *P. daeponensis*, and 40 % to *P. gallaeciensis*, well in the range for congeneric species. However, the values shown by this species towards type strains of closely related genera are, sometimes, even higher, and specially with two species of the genus *Leisingera*, the type species *L. methylohalidivorans* (55 %) and *L. aquimarina* (35 %). Also noticeable are the levels displayed with *Ruegeria atlantica* (23 %), *Silicibacter lacuscaerulensis* (29 %), and *Silicibacter pomeroyi* (18 %). These values are understandable in the light of the phylogenetic relationships revealed by comparative 16S rRNA analysis: as it can be observed in ❯ *Fig. 20.5*, the five *Phaeobacter* species are distributed in two subclades, one of them, that includes *P. gallaeciensis*, *P. inhibens*, and *P. arcticus*, relates with some recently described genera as *Seohaeicola* and *Litorimicrobium*, as well as to one misplaced *Leisingera* species, *L. nanhaiensis*, while the other two *Phaeobacter* spp., *P. daeponensis* and *P. caeruleus*, both merge with *Leisingera methylohalidivorans* and *L. aquimarina*, to which *P. caeruleus* showed the high DDH levels commented above. Clearly, a revision of the generic assignment of several species of the *Roseobacter* clade is pending, and among them *Phaeobacter* spp.

The draft genomes of three *P. gallaeciensis* and one *Phaeobacter* sp. strains are available: strain ANG1 (Collins and Nyholm 2011), strain DSM 17395^T, strain 2.10 (Thole et al. 2012) and strain Y4I (Roseobase). The estimated genome sizes are 4.16–4.59 Mbp, with 3,723–4,358 ORFs. G+C content is 59–62.6 mol% in *P. gallaeciensis* strains and 64 mol% in *Phaeobacter* sp. Y4I (an indigoidine producer).

An outstanding feature of some members of *Phaeobacter* is the ability to synthetize the antibiotic tropodithietic acid (TDA), which occurs also in members of the genera *Silicibacter* and *Ruegeria* (Brinkhoff et al. 2004). The antibiotic seems to have a key role in the interactions with algae and bacteria. TDA, a biologically active sulfur-containing tropolone compound, is synthetized in response to quorum sensing signals: *N*-acyl homoserine lactones (Berger et al. 2011) and TDA itself (Geng and Belas 2010) can act as autoinducers. Synthesis of the brown pigment is also controlled through the same regulatory mechanism and, consequently, they are enhanced in biofilms (and other aggregative growth forms, as rosettes or colonies).

Other bioactive compounds that have been studied among the secondary metabolites produced by phaeobacters are the roseobacticides (Seyedsayamdost et al. 2011a, b), compounds pertaining to the troponoid family, as TDA, which are produced and act as algaecides in response to algal senescence factors, changing the mutualistic behavior that maintain algal surface-colonizing phaeobacters to an opportunistic parasitic lifestyle. Another antimicrobial secondary metabolite indigoidine is produced by *Phaeobacter* sp. Y4I and has been demonstrated that contributes to competitive surface colonization and inhibition of *Vibrio* spp. (Cude et al. 2012). Indigoidine is synthetized via a nonribosomal peptide synthase (NRPS)-based biosynthetic pathway, one of the several identified in members of the *Roseobacter* clade (Martens et al. 2007).

As a consequence of its ability to efficiently adhere and grow on surfaces (Thole et al. 2012) and to secrete inhibitors active on other potentially harmful colonizers (pathogenic bacteria, fouling organisms), *Phaeobacter* spp. are candidates to be used as probiotics in marine aquaculture, where they have been studied as fish probiotics (Porsby et al. 2008; Prol et al. 2009; Pintado et al. 2010; D'Alvise et al. 2013) and bivalve probiotics (Prado et al. 2009; Kesarcodi-Watson et al. 2012).

In addition to the close link with algae and phytoplankton members, to which *Phaeobacter* cells associate (*Emiliania huxleyi*, e.g., Seyedsayamdost et al. 2011b), an intimate association has been documented between *P. gallaeciensis* and the accessory nidamental gland of the bobtail squid *Euprymna scolopes*, where its cells represent the dominant fraction of bacterial consortia (Collins and Nyholm 2011).

Planktotalea

Planktotalea (Hahnke et al. 2012) contains a single species, *P. frisia*, isolated from filtered seawater during a phytoplankton bloom in the North Sea. Although *Pelagicola litoralis* is cited as the nearest phylogenetic neighbor of *P. frisia* in its description, the analysis shown in ❯ *Fig. 20.5* presents *Planktotalea* as a distinct lineage in the subclade defined by *Litoreibacter* spp. and *Pacifibacter maritimus*.

Members of *Planktotalea* are Gram negative, irregular small rods. They are aerobic, oxidase and catalase positive, require vitamins and sodium ion for growth, and grow poorly on media with single (carbon) substrates. They possess *pufLM* genes. Major respiratory lipoquinone is Q10; polar lipids are PC, PG, an aminolipid, and a phospholipid, and the major fatty acids comprise C18:1 ω7c, C18:2, C16:0, C18:0, C12:1, C10:0 3OH, C12:1 3OH, and 11methyl C18:1 ω7c.

P. frisia forms small, unpigmented colonies on Saltwater Medium. Flagella are not observed and swimming motility was not clearly determined, although the cells exhibit wobbling. It grows in the ranges 4–32 °C (optimum 20–25 °C), pH 6.0–9.5 (optimum 7.5–9.0), and 1.25–8.0 % salinity (optimum 3.75 %).

It requires pantothenic acid and nicotinic acid amide. It is negative for denitrification, gelatin, and starch hydrolysis but positive for Tween-80 hydrolysis. It utilizes several amino acids, sugars, and organic acids as carbon and energy sources. Despite the presence of *pufLM* genes, Bchl *a* is not produced in laboratory cultures. The DNA G+C content is 53.8 mol%.

Pontibaca

Pontibaca methylaminovorans, the type species of the genus *Pontibaca* (Kim et al. 2010c), was isolated after an enrichment culture of a shallow marine sediment sample with trimethylamine in anaerobic conditions: as a result, two facultatively anaerobic strains were isolated which served to describe the new genus and species. Phylogenetically, *P. methylaminovorans* is loosely related to *Oceaniovalibus* and the subclade containing *Maribius* spp. (NJ) or to *Donghicola* (ML, not shown), but no close relative is evident in the trees.

Pontibaca is described as containing Gram-negative, nonmotile ovoid rods, which are slightly halophilic and facultatively anaerobic. They reduce nitrates and nitrites and do not synthetize Bchl *a*. Catalase and oxidase tests are positive. The major polar lipids are PC and PG. The dominant fatty acids include C18:1 ω7c, C16:0, and C19:0 cyclo ω8c. Q10 is the predominant respiratory quinone. The species is defined as unpigmented, mesophilic (15–37 °C, optimum 30 °C), neutrophilic (pH 6–10, optimum 7–8), and slightly halophilic (0.5–10 % NaCl, optimum 2–3 %). It presents urease activity and produces acid from several carbohydrates but does not hydrolyze gelatin, casein, or starch. Trimethylamine, dimethylamine, methyl amine, and tetramethylammonium are used as sole carbon sources both in aerobic and anaerobic conditions. It also uses acetate, 3-hydroxybutyrate, and L-serine. The DNA G+C content is 65 mol%.

Ponticoccus

Ponticoccus (Hwang and Cho 2008) contains a single species, *P. litoralis*, isolated from coastal seawater. The species joins to the base of the clade formed by *Antarctobacter heliothermus*, *Sagittula stellate*, and *Mameliella alba* but shows not close relatedness with them or the rest of the *Roseobacter* clade. The genus does not have a clear set of distinctive features and shows the same general profile of other roseobacters: Q10 as predominant quinone, C18:1 ω7c as major fatty acid (plus 11methyl C18:1 ω7c, C16:0, C18:0, and C12:1 3OH), and polar lipids that include PC, PG, PE one glycolipid, two aminolipids, and a lipid. The G+C content is 68 mol%. Cells are coccoid to rod shaped and nonmotile, strictly aerobic, and oxidase and catalase positive. No Bchl *a* is detected in the cultures. In addition, the species *P. litoralis* is characterized by the following traits: it is positive for PHB accumulation, mesophilic (10–37 °C, optimum 20 °C), neutrophilic (pH 6–8, optimum 7), and slightly halophilic (1–15 %, optimum 3–5 %), with ionic requirements that are not fulfilled only by sodium ion. It is positive for gelatin and starch hydrolysis but negative for Tween-80 hydrolysis. It reduces nitrate to nitrite and uses several carbohydrates, organic acids, and amino acids as sole carbon and energy sources.

Poseidonocella

Poseidonocella, containing the species *P. pacifica* and *P. sedimentorum*, was isolated from sediment samples taken at the Sea of Japan (Romanenko et al. 2012). The pair has *Roseivivax* spp. clade as the closest neighbor (*Fig. 20.5*) but relates to *Loktanella* spp. in other analyses. Generic features include Gram-negative cells with enlarged poles that divide by budding. They are strict aerobes, oxidase and catalase positive, chemoorganoheterotrophic, and Na^+ requiring. They do not produce Bchl *a*. PC, PG, DPG, phosphatidic acid, one aminolipid, and other lipids are present. C18:1 ω7c and its 11-methyl derivative are the major fatty acids. Q10 is the predominant quinone. The two recognized species have ovoid, nonmotile cells and produce beige or yellowish beige colonies. Their temperature range is 5–42 °C (*P. pacifica*) and 7–41 °C (*P. sedimentorum*) with optimum above 20 °C. They grow at pH from 4 to 9.5 and optimally at 7–8. Salinity ranges are 0.5–8 % for *P. pacifica* and slightly lower (up to 6 %) for *P. sedimentorum*, with optima between 2 % and 4 % NaCl. They are negative for nitrate reduction to nitrite. Both species are able to use glucose, maltose, citrate, L-serine and L-treonine, among others, as sole carbon and energy sources.

The G+C content of their DNA is 60–65.4 mol%.

Primorskyibacter

Primorskyibacter was described by Romanenko et al. (2011c) as a new genus on isolates obtained from the same source than the previous *Poseidonocella* spp. shallow sediments of the Sea of Japan. From a phylogenetic point of view, *P. sedentarius*, the type and sole species currently recognized in the genus, is a relative of *Marinovum algicola*, to which it merges in different analyses. The genus is defined as Gram negative, strictly aerobic, oxidase and catalase positive, rod shaped, and budding. It is chemoorganoheterotrophic and requires sodium ion for growth. The polar lipid profile includes PC, PE, PG, DPG, and one unidentified lipid. C18:1 ω7c and 11-methyl C18:1 ω7c are the major fatty acids and Q10 is the predominant respiratory quinone. The G+C content of the single species, *P. sedentarius*, is 60–62 mol%. The species produces nonmotile cells, is Bchl *a* negative, and is able to grow with only NaCl added to the medium. Growth occurs at salinities from 0.5 % to 8 % (optimally at 3–5 %) and at temperatures of 4–39 °C (optimum 25–30 °C). The pH range is 6.5–9.5 with its optimum at 7.5–8.5. It is unable to reduce nitrates or hydrolyze gelatin or starch. It uses glucose, maltose, L-rhamnose, L-arabinose, sucrose, fructose, cellobiose, raffinose, D-mannitol, L-ornithine, L-tyrosine, L-asparagine, citrate, acetate, fumarate, and malate as carbon and energy sources.

Profundibacterium

Profundibacterium mesophilum, the type and sole species of this recently described genus, was isolated from a deep sea sediment sample (Lai et al. 2013). The genus is described as Gram negative, strictly aerobic, chemoheterotrophic, slightly halophilic, and halotolerant. The cells are non-flagellated cocci. Oxidase and catalase tests are positive, while nitrate reduction is negative. Among the chemotaxonomic features, *Profundibacterium* shows Q10 as predominant quinone; its major fatty acids are C18:1 ω7C/ω6c, 11-methyl C18:1 ω7c, and C16:1 ω7c/ω6c. The DNA G+C content of the type species is 64 mol%. *P. mesophilum* is a slow-growing bacterium with huge spherical cells (5.0–8.0 μm diameter) that do not accumulate PHB. They require NaCl (0.5 %) and tolerate up to 20 % (optimum 2–6 %). Mesophilic and neutrophilic, they are unable to hydrolyze gelatin, casein, DNA, or starch and grow on few carbohydrates (D-galactose, D-xylose, D-glucose, glycerol), organic acids (pyruvate, succinate, citrate, propionate), and amino acids (L-glutamate, L-arginine) as sole carbon sources. Major polar lipids are PG and PE.

P. mesophilum is distantly related to *Hwanghaeicola* and *Maribius* species.

Pseudoruegeria

The genus *Pseudoruegeria* was described by Yoon et al. (2007e) with *P. aquimaris* as type species and emended recently (Jung et al. 2010a) to incorporate a second species, *P. lutimaris*. In addition to the common features shared with the vast majority of members of the *Roseobacter* group (Gram-negative, nonmotile, aerobic rods with Q10 as major quinone and C18:1 ω7c as dominant fatty acid). The G+C content is 67–73.5 mol%. The emended description of the genus states that PG plus an unidentified lipid and one aminolipid are the common polar lipids but the polar lipid profile is quite different between the two species: *P. aquimaris* shows PG, DPG, an aminolipid, and a lipid as major components while *P. lutimaris* contains PC, PG, PE, an aminolipid, a glycolipid, and a lipid (Jung et al. 2010a). The fatty acid composition is also very different, as none of the components of their profiles (see *Table 20.2* in Jung et al. 2010a) is common to both strains, with the only exception of C18:1 ω7c. DDH levels relating *P. aquimaris* and *P. lutimaris* DNAs are only 5 % (which is at the borderline of "noise"). Altogether, considering the high similarity in 16S rRNA gene sequences (96.6 %) and in *gyrB* sequences (79.4 %), Jung and col. (2010b) considered them members of the same genus.

P. aquimaris forms grayish-yellow colonies on Marine Agar, grows between 15 °C and 49 °C, and with up to 8 % NaCl (but not in the absence of this salt). Anaerobic growth with nitrate does not occur. Acid is produced from several carbohydrates, and fructose and malate are used as carbon and energy sources. *P. lutimaris* has a lower maximum temperature for growth (37 °C), requires not only sodium but also magnesium ions, and is able to grow in the absence of O_2 on Marine Agar (alone or with nitrate). Both species are positive for catalase and oxidase tests and are unable to hydrolyze gelatin, casein, starch, or Tweens.

The two species of the genus relate marginally to the subclade containing *Celeribacter*, *Vadicella*, and *Huaishuia* species.

Roseibacterium

Roseibacterium includes two species: *R. elongatum* (Suzuki et al. 2006) and *R. beibuensis* (Mao et al. 2012). The genus comprises bacteriochlorophyll-producing aerobes with a consistent phylogenetic relationship to *Dinoroseobacter shibae*, another AAP (*Fig. 20.5*). Phylogenies based on *pufM* gene sequences reveal a relationship between the photosynthetic genes of both species that is closer to *Jannaschia* sp. CCS1 than to *D. shibae* (Mao et al. 2012).

Roseibacterium species have been isolated from coastal sand and from surface marine water. The two species form pigmented colonies, pink to red, and their cells are nonmotile rods with monopolar growth and budding division. They are aerobic chemoorganotrophs and synthetize bacteriochlorophyll *a* under aerobic conditions. Oxidase and catalase are positive. C18:1 ω7c is the major cellular fatty acid and Q10 is the predominant quinone. While the type species *R. elongatum* requires sodium ion for growth (range 0.5–7.5 % NaCl), *R. beibuensis* is able to grow without NaCl, although it has its optimum at 3–4 % NaCl. Growth is optimal at 28–30 °C and pH is 7.5–8.0 for both species. They are urease positive and able to accumulate PHA but differ in the ability to reduce nitrates to nitrites and in the minor components of the fatty acid profile. The G+C content is 68–76 mol%.

A close phylogenetic neighbor of *Roseibacterium* was described recently (Csotonyi et al. 2011) and given the generic name of *Charonomicrobium*, a name without standing in nomenclature to date and lacking public available deposition of the type strain. *Charonomicrobium ambiphototrophicum* shows a 98.3 % 16S rRNA gene similarity in to *R. elongatum*. This level might be compatible with generic identity, but the species is described as unique and separated from other taxa in the vicinity due to its ability to grow as photoorganoheterotroph both in aerobic and anaerobic conditions in the light, a behavior not found in any of the phototrophic members of the family. EG17, the proposed type strain, produces LHI complex (expressed aerobically and anaerobically) and LHII complex (mostly anaerobically). It was found to yield proportionally the greatest aerobic photosynthetic biomass under oligotrophic conditions. Other features of *C. ambiphototrophicum* are oxidase negative, brown pigmentation, the requirement of yeast extract as growth factor, a salinity range of 2–16 % NaCl, and a G+C content of 65.6 mol%. Clearly, more studies are needed to assess the taxonomic relationships between this strain and members of the genus *Roseibacterium*.

Roseicyclus

Roseicyclus mahoneyensis, isolated from a meromictic saline lake from Canada, is currently the only species of the genus *Roseicyclus* and another AAP of the *Roseobacter* group (Rathgeber et al. 2005). In contrast with the majority of members of the family, cells of *Roseicyclus* are ring shaped (although rods and ovoid cells are also observed). They are similar to other AAP bacteria in the pigmentation (pink to purple), strictly aerobic character, lack of motility, and ability to accumulate PHA. They synthetize Bchl *a* and carotenoids and produce LHI and LHII complexes. They do not denitrify or ferment carbohydrates. *R. mahoneyensis* strains are able to grow with yeast extract, but also with acetate, pyruvate, butyrate, citrate, malate, succinate, lactate, fructose, glucose, or glutamate. They are mesophilic (4–37 °C) and slightly halophilic (0.5–10 % NaCl, sodium ion is required) and have a G+C content of 66 mol%.

The photosynthetic apparatus and photoinduced electron transfer of *R. mahoneyensis* strain ML6 have been analyzed recently (Rathgeber et al. 2012).

The species occupies an isolated position among the members of the *Roseobacter* group, as an independent lineage in the edge of the clade, with a distant connection to *Wenxinia marina* and the rubellimicrobia.

Roseisalinus

The hypersaline, meromictic, Antarctic Ekho Lake has been the source of several genera and species of the *Roseobacter* group, including *Roseisalinus antarcticus*, the only recognized species of the genus *Roseisalinus* (Labrenz et al. 2005). It is, as the previous genus, an AAP which synthetizes Bchl *a* and carotenoids in aerobic conditions, producing red colonies. The genus contains Gram-negative, motile rods which accumulate PHB and have complex ionic requirements. Growth in aerobic to microaerophilic conditions is positive with various carboxylic acids and sugars as carbon and energy sources. They do not grow photoautotrophically with H_2/CO_2, photoorganotrophically with glutamate or acetate or fermentatively with glucose. Oxidase, catalase, and peroxidase activities are present. Temperature range for growth is <3–33 °C, pH range is 5.5–9.5, and salinities allowing growth are 1–13 % artificial seawater. The peptidoglycan contains *m*-diaminopimelic acid. Polar lipids present are DPG, PG, and PC, but PE and phosphatidyl-momomethylethanolamine are absent. Dominant fatty acids are C18:1 ω7c and C16:0, with minor amounts of C18:0, C10:0 3OH, and C16:1 ω7c. The quinone system is Q10.

In addition to this generic profile, the species *R. antarcticus* is characterized by a strong tendency to form rosettes, monopolar growth that suggests budding division, and a DNA G+C content of 67 mol%.

The position of the species in the 16S rRNA gene tree suggests a moderate relationship to the type species of the genus *Oceanicola*, *O. granulosus*.

Roseivivax

The genus *Roseivivax* includes five species: *R. halodurans* and *R. halotolerans* (Suzuki et al. 1999b), *R. lentus* (Park et al. 2010), *R. isoporae* (Chen et al. 2012a), and *R. sediminis* (Xiao et al. 2012). Three of them (*R. halodurans*, *R. halotolerans* and *R. isoporae*) isolated from biological material (charophytes and stromatolites from a saline lake, coral tissues) synthetize Bchl *a* and form pink pigmented colonies. They form the core of the clade containing the five *Roseivivax* species (Fig. 20.5), while the other two members of the genus, *R. lentus* and *R. sediminis*, isolated from sediments from a tide flat and a salt mine crystallizer pond, respectively, do not produce Bchl *a* and develop grayish-yellow or cream-yellow colonies. The genus, as defined by Suzuki et al. (1999b) and emended by Park et al. (2010) and Chen et al. (2012a), includes Gram-negative chemoheterotrophic rods that, when motile, have subpolar flagella. Catalase and oxidase tests are positive. It may be aerobic or facultatively anaerobic (some species grow on Marine Agar under anaerobic conditions) and may synthetize Bchl *a* in aerobiosis. The quinone system is Q10. The major cellular fatty acid is C18:1 ω7c and the dominant polar lipids are PG, PE, and an unidentified phospholipid. G+C content of the DNA is 59–69 mol%. The species in the genus are mesophilic, neutrophilic, and variable in their preferred salinities: all of them tolerate salinities over 12 % (some up to 20 %) and two, including the type species *R. halodurans*, are able to grow without salt addition to the media; hence they have to be regarded as halotolerant rather than halophilic. They are able to use several sugars, organic acids, and some amino acids as sole carbon sources. Acid is produced from some carbohydrates and nitrate reduction to nitrite is variable among species. *R. isoporae* produces PC, DPG, phosphatidyl-dimethylethanolamine, and sulfo-quinovosil diacylglycerol, in addition to unidentified phospholipids, among its major polar lipids, exhibiting a more complex profile than the other *Roseivivax* species. In addition to the dominant fatty acid, C18:1 ω7c, other major components are C19:0 cyclo ω8c, 11-methyl C18:1 ω7c, C18:0, C16:0, and C12:0 3OH.

Roseivivax halodurans DSM 15395^T contains two large linear plasmids of 264 and 368 kbp and its *pufLM* genes are located in the chromosome (Pradella et al. 2004).

Roseovarius

Roseovarius is, together with *Loktanella*, the largest genus in the *Roseobacter* group, containing 13 species at present, but almost all phylogenetic analyses show that the genus is not coherent and comprises four different lineages dispersed among other roseobacters (Fig. 20.5): the true *Roseovarius*, grouped along with the type species *R. tolerans* (Labrenz et al. 1999) are *R. aestuarii* (Yoon et al. 2008), *R. mucosus* (Biebl et al. 2005b), *R. nanhaiticus* (Wang et al. 2010), and *R. nubinhibens* (González et al. 2003). Another group includes *R. crassostreae*

(Boettcher et al. 2005), causative agent of the juvenile oyster disease (JOD) or *Roseovarius* oyster disease (ROD), *R. halocynthiae* (Kim et al. 2012c), and *R. sediminilitoris* (Park and Yoon 2013). A third group is formed by *R. pacificus* (Wang et al. 2009b), *R. halotolerans* (Oh et al. 2009), *R. indicus* (Lai et al. 2011b), and *R. litoreus* (Jung et al. 2012b). This group merges with the "tolerans" group in ML analysis and both have *Pelagicola litoralis* marginally related (not shown). Finally, the species *R. marinus* (Jung et al. 2011) is kept apart from other *Roseovarius* species and very close to *Pacifibacter maritimus* (99.2 % 16S rRNA similarity), being a candidate for reclassification in this genus or even into the species (synonymy).

The genus description, not emended since the original publication, states that *Roseovarius* members are Gram-negative rods with one or both poles pointed, multiplying by monopolar growth (budding process). Motility and PHB accumulation may be positive, as well as Bchl *a* production and colony pigmentation. Temperature range enabling growth is from <3 °C to 43 °C, salinity from <1 % to 10 % NaCl, and pH from 5.3 to >9. They are heterotrophic, strict aerobes, and have no fermentative ability. They do not grow in anaerobiosis with nitrate and not able to grow photoautotrophically with H_2/CO_2 or photoorganotrophically with acetate or glutamate. Catalase, peroxidase, and cytochrome oxidase activities are positive, although the latter is weak. Cells contain the following polar lipids: DPG, PG, PC, PE, an unknown phospholipid, and an unknown lipid. The dominant fatty acid is C18:1 ω7c, accompanied by C18:2, C12:0 2OH, C12:1 3OH, C16:1, C16:0, and C18:0. Q10 is the major respiratory quinone. The G+C content of the type species is 62–64 mol%. The range of G+C content within the currently named species goes from 55.4 to 66 mol%. Some species require vitamins. Despite the absence of emendation to this description, some species of *Roseovarius* have been described as denitrifiers (*R. crassostreae*) or have different polar lipid profiles (*R. litoreus* lacks DPG). As a general rule, *Roseovarius* spp. require sodium ion for growth and some require also magnesium (*R. halocynthiae*, *R. marinus*, and *R. sediminilitoris*). The salinity range of some species reaches 20 % (*R. halotolerans*). Bchl *a* production is detected in strains of *R. tolerans* and *R. mucosus* (weakly in the later) and *pufLM* genes are present in the genome of *R. indicus* but absent for all other species except for *R. tolerans* and *R. mucosus* (Lai et al. 2011b). An outstanding activity of *R. nubinhibens* is its ability to demethylate dimethylsulfoniopropionate (DMSP), one of the key activities in the marine sulfur cycle.

DDH experiments between *Roseovarius* species have been performed for several pairs with the following results: González et al. (2003) reported 42 % between *R. nubinhibens* and *R. tolerans*; Boettcher et al. (2005) found 11 % relatedness between *R. crassostreae* and *R. tolerans* and 47 % between the former and *R. nubinhibens*; a 13 % DDH was found between *R. aestuarii* and *R. nubinhibens* by Yoon and coworkers (2008); *R. halotolerans* showed 1–5 % DDH relatedness to *R. tolerans*, *R. crassostreae*, and *R. nubinhibens* and 25 % to *R. mucosus*, according to Oh et al. (2009); the relationship between *R. indicus* and *R. halotolerans* and *R. pacificus* was 48 % and 44 %, respectively (Lai et al. 2011b); *R. halocynthiae* exhibited a 13 % relatedness to *R. crassostreae* (Kim et al. 2012c); and *R. litoreus* showed 33 % relatedness to *R. halotolerans* and 18 % to *R. pacificus* (Jung et al. 2012b). The recently described *R. sediminilitoris* was related to its neighbors *R. crassostreae* and *R. halocynthiae* by 16 and 22 % DDH, respectively (Park and Yoon 2013).

The genome of *R. nubinhibens* ISM^T has been sequenced and their general features are as follows: estimate genome size is 3.68 Mbp, estimated number of coding sequences is 3,547, and G+C content is 63.9 mol%. This strain has been the subject of several studies related to its activities on sulfur-containing organic molecules (González et al. 1999, 2003).

A "hidden" prophage has been reported in the genome of *R. nubinhibens* ISM^T (Zhao et al. 2010) that was unnoticed when employing methods aimed to classical prophage gene detection, but could be revealed through induction experiments.

Strains close to *R. tolerans* are able to produce free and organic iodine from iodide (Fuse et al. 2003), and iodide-oxidizing bacteria related to this species were isolated from iodide-rich natural gas brines and seawater (Amachi et al. 2005).

While members of the *Roseobacter* group are mostly non-pathogenic, a few exceptions could be found among *Roseovarius* species: *R. crassotreae* is involved in the juvenile oyster disease (JOD), also called *Roseovarius* oyster disease (ROD), a condition that causes seasonal mortalities among commercially produced eastern oysters (*Crassostrea virginica*) in the Northeastern coast of the USA. *R. crassotreae* is dominant among the bacterial consortia associated with the inner shell surface of JOD-affected animals. The polar attachment of the *R. crassostreae* cells to shell and conchiolin is believed to be related to polar fimbriae production and may protect the bacteria from hemocyte-mediated killing (Boardman et al. 2008). Culture-independent methods have revealed that strains similar to *R. crassostreae* are significantly associated to Australian Subtropical White Syndrome, an infectious, temperature-dependent disease of the coral *Turbinaria mesenterina*. The fact that this association is seen in a range of different types of disease lesions and on a range of different coral species suggests that these strains may be present simply as opportunists and are not directly responsible for causing the disease, but their possible role as pathogens cannot be ruled out (Godwin et al. 2012).

Rubellimicrobium

The genus *Rubellimicrobium* contains four species isolated from habitats other than the typical marine environments that inhabit most roseobacters. The first species described, *Rubellimicrobium thermophilum* (Denner et al. 2006), was isolated from colored biofilms formed in two fine-paper machines and a pulp dryer from the paper industry in Finland. The strains were slightly thermophilic, pigmented, and resistant to a common industrial biocide, 2,2-dibromo-3-nitrilopropionamide. Two other species, *R. mesophilum* (Dastager et al. 2008) and

R. roseum (Cao et al. 2010), were isolated from soil, while *R. aerolatum* was obtained from an air sample (Weon et al. 2009). In addition, field studies using culture-independent detection methods have revealed that *Rubellimicrobium* is a part of the characteristic soil communities of noncultivated soils, from which they disappear after agricultural use (Köberl et al. 2011). Along with *Acidobacteria*, they have been proposed as management indicator to discriminate between sustainable and non-sustainable agricultural practices (Figuerola et al. 2012). It has been also suggested that terrestrial hot springs might be a habitat for rubellimicrobia: isolate OSrt, enriched from Octopus Spring (Yellowstone Park, USA) and used as feed bacterium for the cultivation of the thermophilic amoeba *Echinamoeba thermarum*, is either a strain of *Rubellimicrobium thermophilum* or a closely related, unnamed species, based on 16S rRNA gene sequence similarity (>99 %) (Baumgartner et al. 2003; Denner et al. 2006).

Rubellimicrobium spp. form a well-defined subclade in the boundaries of the *Roseobacter* clade, to which *Roseicyclus mahoneyensis* and *Wenxinia marina* are loosely related (*Fig. 20.5*).

Defining features of the genus, as established by Denner et al. (2006), were as follows: Gram-negative, rod-shaped cells that produce carotenoids but not endospores, strict aerobes, positive for oxidase, and weakly positive for catalase. It is chemoorganoheterotrophic, using a large number of organic compounds for growth. Q10 is the major respiratory lipoquinone and DPG and PC are the major polar lipids, with minor amounts of PG. The predominant fatty acid is C19:0 cyclo ω8c, followed by C18:0 and C16:0. Main polyamines are spermidine, *sym*-homospermidine, and putrescine. DNA G+C content is 69–70 mol% for the type species, *R. thermophilum*, but the range for the four recognized species is 67–72 mol%. The type species differ from the rest by its moderate thermophily, having an optimum temperature for growth of 45–52 °C and a maximum of 56 °C, while the other three species are clearly mesophilic (28–30 °C optima, maxima 30–37 °C). Notable differences in polar lipid profile and cellular fatty acid composition are also found among species (probably as a consequence of the different growth conditions). In particular, the dominant fatty acids of the mesophilic rubellimicrobia are more similar to the typical major fatty acids of the rest of the roseobacters, with C18:1 ω7c as the most abundant one. Rubellimicrobia are non-halophilic, in consonance to their habitats; some of the species are sensitive to NaCl, which is not tolerated in the medium or only when lower than 1 %. All species form red colonies.

Draft genome of *R. thermophilum* DSM 16684^T, which is 3.16 Mb in size, contains 3,244 protein-coding genes.

Ruegeria

Ruegeria, one of the earliest described genera in the *Roseobacter* group, contains ten species. The history of this genus is an example of the taxonomic turmoil undergone at other parts of the group. The type species of the genus *R. atlantica* was formerly known as *Agrobacterium atlanticum*. Uchino and coworkers reclassified this and other species of the so-called marine agrobacteria (Rüger and Höfle 1992) in three new genera, *Stappia*, *Ahrensia*, and *Ruegeria* (Uchino et al. 1998). At that time, the genus comprised the species *Ruegeria atlantica* (resulting from the reclassification of *Agrobacterium atlanticum* and *Agrobacterium meteori*, both considered synonyms), *Ruegeria gelatinovora* (from *Agrobacterium gelatinovorum*), and *Ruegeria algicola* (from *Roseobacter algicola*). *R. gelatinovora* was later reclassified in the genus *Thalassobius* (Arahal et al. 2005) and *R. algicola* became *Marinovum algicola* (Martens et al. 2006), leaving the genus with only one species. Shortly after, Yi et al. (2007) proposed to transfer the two species of the genus *Silicibacter*, *S. lacuscaerulensis* (Petursdottir and Kristjansson 1999), and *S. pomeroyi* (González et al. 2003) to the genus *Ruegeria*, based on the close phylogenetic relationship between the three taxa (sequence similarities of 96.9–98.2 % on 16S rRNA gene, monophyletic clade), and emended the genus for a second time (a first emendation was proposed by Martens et al. 2006). The transfer has not been universally accepted, as some authors still support the maintenance of *Silicibacter* genus based on phenotypic differences (Muramatsu et al. 2007). Since, the following species have been described within the genus: *R. mobilis* (Muramatsu et al. 2007), *R. pelagia* (Lee et al. 2007c; found to be a later heterotypic synonym of *R. mobilis* by Lai et al. 2010a), *R. scottomollicae* (Vandecandelaere et al. 2008b), *R. marina* (Huo et al. 2011), *R. faecimaris* (Oh et al. 2011a), *R. halocynthiae* (Kim et al. 2012d), *R. arenilitoris* (Park and Yoon 2012b), and *R. conchae* (Lee et al. 2012b). All species have been isolated from marine samples, except for *R. lacuscaerulensis*, that were isolated from the water of the Blue Lagoon, a shallow geothermal lake in Iceland.

All *Ruegeria* species, including the two reclassified *Silicibacter*, merge in one clade that includes also *Sediminimonas* and *Salinihabitants* and have the clade *Phaeobacter caeruleus-Phaeobacter daeponensis-Leisingera sensu stricto-Nautella italica* as closest neighbor (*Fig. 20.5*).

After the last emendation, the genus is defined by the following traits: Gram-negative, chemoheterotrophic, strict aerobes, negative for Bchl *a* production and *puf* genes; they accumulate PHB and require sea salts for growth. Oxidase and catalase are positive. When motile, cells have polar flagella. Q10 is the dominant quinone, major fatty acids are C18:1 ω7c and 11-methyl C18:1 ω7c, and polar lipids include PC, PE, PG, and several phospholipids. The DNA G+C content is 55–68 mol%. Some exceptions to this profile can be found among currently recognized species; thus, *R. mobilis* and *R. marina* do not have a strict requirement of salt for growth, and PE is not detected among the polar lipids of several species (*R. faecimaris*, *R. halocynthiae*, *R. arenilitoris*, and *R. conchae*). Some species denitrify (*R. atlantica*, *R. lacuscaerulensis*); others are described as able to reduce nitrate or to grow with nitrate in anaerobic conditions, but denitrification ability is not confirmed (*R. faecimaris*, *R. arenilitoris*, *R. halocynthiae*). *R. lacuscaerulensis*

and *R. mobilis* produce tan or brown pigments, which may be related to antifouling/antimicrobial activities, in a way similar to that of *Phaeobacter* species (Porsby et al. 2008; Gram et al. 2010). Riclea et al. (2012) have identified five lactones in the volatile fraction of *R. pomeroyi* DSS-3. The structures of these lactones have been unambiguously assigned by comparison to synthetic standards that showed, in agar diffusion assays, specific activity against algae, but not against bacteria or fungi, suggesting that the lactones may have an ecological function in the interaction between the bacteria and the algae in fading algal blooms, similar to the recently described roseobacticides from *P. gallaeciensis*, which are active against *Emiliania huxleyi*.

Ruegeria species are relevant for the metabolism of DMSP in the marine environment, being *R. pomeroyi* one of the most studied contributors (González et al. 2003; Reisch et al. 2008, 2011; Todd et al. 2011, 2012).

The genomes of up to six *Ruegeria* strains have been sequenced (Roseobase), being *R. pomeroyi* type strain, DSS-3^T, the first of the *Roseobacter* clade that was completed and analyzed (Moran et al. 2004). It contains 4,283 coding sequences distributed between a chromosome of 4.11 Mbp and one megaplasmid of 491 Kbp. Three rRNA operons and 53 tRNA genes are present. Analysis of gene content revealed a metabolic strategy based on lithotrophic exploitation of carbon monoxide and sulfide, combined with heterotrophy. Abundant genes encoding for ABC-type transporters of peptides, amino acids, polyamines, and osmolytes (glycine betaine, DMSP) are also present, as well as multiple TRAP transporter systems. Other *Ruegeria* genomes also contain genes for carbon monoxide oxidation, namely, strain TM1040 (Moran et al. 2007) and TW15—now *R. conchae* (Lee et al. 2011b). Quorum-sensing related genes are also present in some *Ruegeria* genomes, including the one of *R. pomeroyi* DDS-3^T and *Ruegeria* sp. KLH11 (Zan et al. 2011).

An interesting approach by high-throughput proteogenomics has been conducted on *R. pomeroyi* DDS-3^T aiming at a better genomic annotation for the whole marine *Roseobacter* clade (Christie-Oleza et al. 2012). For this, a large dataset of peptides was obtained after searching over 1.1 million MS/MS spectra, from *R. pomeroyi* DDS-3^T cultivated under 30 different conditions against a six-frame translated genome database. The authors detected open reading frames that had not previously been annotated and genes that were wrongly annotated. By extending these re-annotations to the genomes of the other 36 *Roseobacter* isolates (20 different genera) available at that time, they proposed the correction of the assigned start codons of 1,082 homologous genes in the clade and reported the presence of novel genes within operons encoding determinants of the important tricarboxylic acid cycle, a feature characteristic of some *Roseobacter* genomes.

Bacteriophages infecting *R. pomeroyi* (Zhao et al. 2009) and *Ruegeria* sp. strain TM1040 (Chen et al. 2006) have been detected and characterized. The former were lytic phages isolated from seawater, while the later were obtained after induction with mitomycin C and were assumed to be attenuated phages representative of three of the five prophage-like elements detected in the genome of TM1040.

Sagittula

Sagittula stellata is the type species of the genus *Sagittula* (González et al. 1997), one of the oldest members of the *Roseobacter* group and distantly related to *Antarctobacter heliothermus*, *Ponticoccus litoralis*, and *Mameliella alba* (Fig. 20.5). The type strain E-37^T was isolated from a marine enrichment community obtained from salt marsh seawater in Georgia (USA) and grown on pulp mill effluent, rich in lignin.

The genus is defined by the following traits: cells are rod shaped and Gram negative, have a polar holdfast, and numerous vesicles on the surface, derived from the outer membrane. They form rosettes and aggregates. They are strict aerobes, oxidase and catalase positive, and grow on sugars, fatty acids, and amino acids. The type species also uses methanol and some aromatic compounds. They require sea salts for growth. In a recent emendation of the genus, Lee et al. (2013b) added to these generic properties the presence of Q10 as major respiratory quinone and a complex polar lipid profile: DPG, PC, PE, PG, and several unidentified (two ALs, one PL, and four Ls) polar lipids. These authors added a second species to the genus *S. marina*, which shows biochemical and physiological features similar to the ones of *S. stellata*: both species are mesophilic, neutrophilic, and grow up to 7 % NaCl; do not reduce nitrates; are able to use several carbohydrates, organic acids, and amino acids; and have C18:1 ω7c, C12:1 3OH, 11-methyl C18:1 ω7c, and C16:0 as major fatty acids. However, *S. marina* lacks the ability to degrade carboxymethylcellulose and to partially solubilize synthetic lignin in presence of glucose, defining properties of the genus according to González (2005), among other differences. The C+G content of the genus is 61–65 mol%.

The estimated genome size of E-37^T, type strain of *S. stellata*, is 5.26 Mbp and contains 5,067 coding sequences (Roseobase). *S. stellata* produces amphiphilic exopolymeric substances which induce self-assembly of marine dissolved organic matter and formation of microgels (Ding et al. 2008), and it is able to use dimethylsulfide oxidation as an anergy source, while growing on fructose or succinate (Boden et al. 2011).

Salinihabitans

Salinihabitans currently contains a single species, *S. flavidus* (Yoon et al. 2009b), represented by a single strain that shows optimal growth at 7 % NaCl and tolerates up to 17 % in the culture media. Thus, it is a true moderate halophile better adapted to the conditions of the isolation habitat, a marine solar saltern, than most other roseobacters. It forms pale yellow colonies on Marine Agar, is mesophilic, neutrophilic, and strictly aerobic. Chemotaxonomic features include Q10 as predominant quinone and a fatty acid composition that features C19:0 cyclo ω8c as the major fatty acid (46 % of the total), an atypical trait in the whole family (the usually dominant fatty acid is 18:1 ω7c, which represents only 18 % of the total in *S. flavidus* profile). This trait, being the only that clearly

differentiates this taxon from other related roseobacters, might be due to methodological bias (Yoon et al. 2009b).

Salinihabitans flavidus merges the *Ruegeria* clade in the complete analysis of the *Rhodobacteraceae*, along with *Sediminimonas qiaohouensis*.

Salipiger

The genus *Salipiger* was described based on an isolate from a saline soil bordering a saltern, at the Spanish Mediterranean coast (Martínez-Cánovas et al. 2004). To date, it contains a single species, *S. mucosus*, named after its ability to produce an exopolysaccharide. This polysaccharide incorporates notorious amounts of sulfates, an unusual trait in other bacterial counterparts, according to Llamas et al. (2010) who characterized its composition and properties.

The genus is related to *Tranquillimonas* and *Palleronia*, the later isolated from the same geographic area than *Salipiger mucosus* type strain.

Characters defining the genus are as follows: Gram-negative, nonmotile rods; strictly aerobic chemoorganotrophs; unable to grow in anaerobic conditions either by fermentation, nitrate or fumarate reduction, or photoheterotrophy; produce polyhydroxyalkanoates (PHA); and are oxidase and catalase positive. Strictly halophilic, they require Na ion for growth and display very low nutritional and biochemical versatility. Contain ubiquinone Q10 and present C18:1 ω7c and C16:0 as major cellular fatty acids.

The species *S. mucosus* forms encapsulated cells and mucoid colonies, growing optimally with 9–10 % sea salts added to the medium (total range 0.5–20 % NaCl), at 20–40 °C and at pH 6 to 10. Hydrolytic abilities are restricted to urea and Tween 20. It does not synthetize Bchl *a* and is unable to use any of the sole carbon and energy sources tested. The C+G molar content is 64.5 mol%. The draft genome of *S. mucosus* DSM 16094^T has 5.7 Mb.

Sediminimonas

Sediminimonas, described by Wang et al. (2009c), accommodates one species, *S. qiaohouensis*, a relative to the *Ruegeria* clade and to the genus *Salinihabitans*. The species was isolated from a salt mine sediment in China but has been also detected by DGGE in coastal seawater (South China Sea; Yang et al. 2012).

The genus contains Gram-negative, nonmotile rods that are aerobic and unable to synthetize Bchl *a*, do not produce PHB or exopolysaccharides, and are able to reduce nitrates to nitrites. It is chemoheterotrophic and strictly halophilic, require NaCl for growth, and are able to use a variety of carbon sources, including carbohydrates. Major fatty acids are C18:1 ω7c, C16:0, C18:1 ω9c, 11-methyl C18:1 ω7c, and C19:0 cyclo ω8c. Polar lipids include DPG, PG, PC, and four unknown PLs. Q10 is the only respiratory quinone and the G+C molar content of the type and only species is 63–64 mol%. The draft genome of *S. qiaohouensis* DSM 21189^T has 3.55 Mb.

S. qiaohouensis is able to grow between 0.25 % and 20 % NaCl content, having optimal growth between 1.5 % and 10 % NaCl. Colonies are faint brown to yellow colored. It is mesophilic and neutrophilic, positive for catalase and oxidase, able to use several sugars (D-glucose, D-fructose, D-galactose, maltose, D-mannose, sucrose, D-psicose, trehalose, turanose), sugar alcohols (glycerol, D-mannitol), and some amino acids (D- and L-alanine, L-glutamic acid, and L-serine).

Seohaeicola

Seohaeicola is another monospecific genus: *S. saemankumensis*, the only species recognized up to date, was described based on a single strain isolated from a tidal flat (Yoon et al. 2009c). It is close to the *Phaeobacter sensu stricto* clade. Main generic traits include the presence of Q10 as predominant quinone, C18:1 ω7c and 11-methyl C18:1 ω7c as major cellular fatty acids, and PC, PG, and PE plus an unidentified lipid as major polar lipids. The cells are Gram negative, ovoid to coccoid, and nonmotile. The species forms pale yellow colonies on Marine Agar and does not synthetize Bchl *a*. It is unable to growth without NaCl or with more than 7 %. Growth is possible between 4 °C and 40 °C. The strain grows anaerobically in Marine Agar with or without nitrate, which is reduced. Catalase and oxidase tests are positive. Acetate was used as sole carbon and energy source. The G+C molar content is 63.4 mol%.

Shimia

Shimia marina, the type species of the genus, was described by Choi and Cho (2006b) after the study of one isolate obtained from a fish farm biofilm. A second species, *S. isoporae*, was later described to accommodate novel isolates from the reef-building coral *Isopora palifera* (Chen et al. 2011b). The genus is related to the clade that contains all the *Thalassobius* species plus *Epibacterium ulvae*.

Traits defining the genus *Shimia* include presence of Q10 and C18:1 ω7c as dominant quinone and cellular fatty acid, respectively, absence of Bchl *a*, a positive response to oxidase and catalase tests, and a heterotrophic, strictly aerobic metabolism. Their cells are Gram negative, rod shaped, and do not contain cytoplasmic granules.

Shimia species are slightly halophilic (with salinity ranges of 1–5 %, *S. isoporae*, and 1–7 % NaCl, *S. marina*), neutrophilic (optimal growth at pH 7–8), and mesophilic (optimal growth at 30–35 °C, *S. marina*, or 25–30 °C, *S. isoporae*). They are motile by monopolar flagella. Both species of *Shimia* are related by DDH levels around 43 % (Chen et al. 2011b) and differ in their response to nitrate reduction, indole, arginine dihydrolase, lipase, lecithinase, and β-galactosidase activities, as well as in their ability to assimilate some sugars (glucose, maltose, and mannose).

Sulfitobacter

The genus *Sulfitobacter* is one of the oldest members of the *Roseobacter* group. It was described by Sorokin (1995) to encompass a new heterotrophic, marine species able to oxidize sulfite, *Sulfitobacter pontiacus*, isolated from the Black Sea. Currently, the genus contains nine species, including the former *Staleya guttiformis* that was reclassified as *Sulfitobacter guttiformis* (Yoon et al. 2007f). The nine species are grouped in a stable clade that also includes *Oceanibulbus indolifex* as a very close relative to the pair *S. delicatus* and *S. dubius*. Next to the clade two *Roseobacter* species appear as their closest neighbors. A deeply branching clade that contains *Sulfitobacter* (plus *Oceanibulbus*) and *Roseobacter* species is also recovered by analyzing 70 conserved, single-copy genes retrieved from 32 roseobacters genomes (Newton et al. 2010), confirming the solid nature of the *Sulfitobacter-Oceanibulbus-Roseobacter* grouping.

Members of the genus *Sulfitobacter* have rod-shaped cells, sometimes pointed for one pole and showing monopolar growth and budding division. Rosette formation is common. When motile, flagella are inserted subpolarly. Several species, including the type species, accumulate PHB granules. None of them synthetizes Bchl *a*, with the exception of some *S. guttiformis* strains, a trait that contributed to its former consideration as a different genus. Photosynthetic genes are plasmid located in *S. guttiformis* (Pradella et al. 2004), and the plasmid has an independent origin from the one in *Roseobacter denitrificans*, the other AAP with plasmid-encoded photosynthetic gene clusters (Petersen et al. 2012). Sulfite oxidation is displayed by five species, being *S. pontiacus* the one with higher tolerance to this compound (up to 60 mM). *S. pontiacus* derives energy from sulfite oxidation during growth on organic compounds as acetate. Thus, it can be considered a lithoheterotroph. It is also able to oxidize sulfur and thiosulfate. Ability to perform oxidation of sulfite to sulfate is dependent of an AMP-independent soluble sulfite dehydrogenase (Sorokin et al. 2005a). As obligate heterotrophs, sulfitobacters are able to assimilate a variety of organic acids and amino acids. They are strict aerobes and present oxidase and catalase activities. Peptidoglycan contains *m*-DAP in *S. guttiformis* and *S. brevis**. Common polar lipids of the genus are PC, PG, and PE (with low levels of DPG in some species and the occasional presence of one AL or one PL), and main cellular fatty acids correspond to C18:1 ω7c, C16:0, C10:0 3OH, and 11-methyl C18:1 ω7c. Predominant quinone is Q10 and the G+C content of their DNA is 55 to 64 mol%.

*[Gorshkova et al. (2007) reported a surprising finding in *Sulfitobacter brevis* KKM 6006: a teichoic acid containing glycerol, ribitol, and *N*-Acetyl-D-glucosamine. To the best of our knowledge, this is the first time a teichoic acid is found in Gram-negative bacteria].

The highest interspecific value of DDH between *Sulfitobacter* species relates the pair *S. pontiacus-S. mediterraneus* by 46 % (Pukall et al. 1999). Ivanova et al. (2004) determined the DDH values for the type strains of *S. dubius* and *S. delicatus* against *S. pontiacus*, *S. mediterraneus*, *S. brevis*, and *S. guttiformis*, with the higher figure relating *S. mediterraneus* and *S. dubius* (41 % DDH) and the lower *S. guttiformis* and *S. delicatus* (5 %). Yoon et al. (2007g) found values of 9–21 % DDH between *S. marinus* and the *Sulfitobacter* species previously described. *S. litoralis* and *S. pontiacus* are related by a 24 % DDH (Park et al. 2007) and *S. donghicola* and *S. guttiformis* show a 17 % DDH, according to Yoon et al. (2007f).

Sulfitobacter species are widespread in marine habitats: they have been detected/isolated from seawater, biofilms, sediments, marine animals, and algae and aquaculture environments. In addition to the original isolation from Black Sea waters (Sorokin 1995), they have been found as part of the bacterioplankton of polar seawater (Mergaert et al. 2001), deep layer oxycline at South Pacific waters (Stevens and Ulloa 2008), Adriatic seawater (Silović et al. 2012), near-shore mud in French Guiana (Madrid et al. 2001), biofilms formed in submersed glass (Kwon et al. 2002), and microbial mats in Antarctic lakes (Van Trappen et al. 2002), and they are enriched in oil-contaminated seawater (Brakstad and Lødeng 2005; Prabagaran et al. 2007; Jung et al. 2010b). As epiphytes, they have been found on diatoms (Shäfer et al. 2002; Hünken et al. 2008), marine brown and red algae (Beleneva and Zhukova 2006), or dinoflagellates—*Alexandrium fundyense* (Li et al. 2011b). Isolation from marine animals is also documented, both from wild and cultured fish and invertebrates: Griffiths et al. (2001) isolated *Sulfitobacter* strains from healthy haddock larvae; McIntosh et al. (2008) found them in cod larvae, and several invertebrates also show *Sulfitobacter* colonization—spiny lobster larvae (Payne et al. 2008), cultivated mollusks (Beleneva et al. 2007), sea anemones (Du et al. 2010), cnidarians (Schuett and Doepke 2010), and corals (Higuchi et al. 2012).

Sulfitobacter participates in the metabolism of diverse sulfur compounds in marine environments: they are among the bacteria that show elevated nucleic acid content when the water is amended with DMSP (Mou et al. 2005) and, in fact, are able to metabolize DMSP to DMS (Curson et al. 2008). Other interesting metabolic abilities of members of the genus are related to phthalate degradation (Iwaki et al. 2012b). *S. pontiacus* sulfite oxidase has been investigated with the aim of constructing a biosensor system for sulfite detection on food and beverages (Muffler and Ulber 2008).

The ethanol extract of strain P1-17B, an isolate close to *S. pontiacus* and collected from the interface of brine pools and sea water of the Red Sea, was among the most potent against tested cancer cell lines in a study of bioactive molecules with cytotoxic and apoptotic activity (Sagar et al. 2013).

Genomes of two *Sulfitobacter* strains have been sequenced: *Sulfitobacter* EE-36 has an estimated genome size of 3.55 Mbp with 3,474 coding sequences and a G+C molar content of 60.3 mol%. This strain is a host for a bacteriophage isolated from Baltimore Inner Harbor water (Zhao et al. 2009), similar to the one isolated from *Ruegeria pomeroyi* DSS-3 by the same authors. *Sulfitobacter* NAS-14.1, an isolate that was obtained

with DMSP as sole carbon source, has a genome of 4.0 Mbp in size that contains 3,962 coding sequences (Roseobase).

Tateyamaria

The genus *Tateyamaria* (Kurahashi and Yokota 2007) was raised to encompass a single species, *T. omphalii*, isolated from the shell of a molluskan collected in Japan coastal waters. Three years later, a second species was described, *T. pelophila*, on isolates obtained from tidal flat sediments from the German coast of the North Sea. The description of the second species was accompanied by an emendation of the genus (Sass et al. 2010). The pair of species is located nearby *Nereida*, *Lentibacter*, and the *Roseobacter-Sulfitobacter* clade, in the 16S rRNA-based tree (Fig. 20.5).

The emended description of the genus establishes that *Tateyamaria* members are Gram-negative coccoid or short rods that may be motile by polar flagella and require sodium chloride for growth. They are aerobic, mesophilic, and positive for oxidase, catalase, and phosphatase activities. They may produce Bchl *a*. Q10 is the predominant respiratory quinone. Cellular fatty acids comprise C18:1 ω7c, C16:0, 11-methyl C18:1 ω7c, C19:0 cyclo ω8c, C10:0 3 OH, and C12:0 3 OH. The G+C content of the two currently recognized species is 56.4–61.6 mol%.

T. omphalii and *T. pelophila* differ in several traits, as motility and the ability for Bchl *a* production, both positive in the second species. *T. pelophila* is also able to oxidize sulfite, thiosulfate, and hydrogen while growing lithoheterotrophically. Its salinity range is wider (0.3–10 % NaCl) than the one of *T. omphalii* (0.2–6 % NaCl), but the maximal temperature for growth is lower. Both species require biotin and pantothenate (plus thiamine in *T. pelophila*). Polar lipids have been determined only for *T. pelophila*, which shows PG and PE as major components and only trace amounts of PC and an unidentified lipid.

Tateyamaria is one of the genera recently isolated from soft corals and shown to display antimicrobial activities (Chen et al. 2012b).

Thalassobacter

The genus *Thalassobacter* (Macián et al. 2005b) is phylogenetically allocated in the vicinity of the genus *Jannaschia* (Fig. 20.5). It contains a single species, *T. stenotrophicus*, which includes the strain used for the genus description, along with the ones originally proposed as members of *Jannaschia cystaugens* (Adachi et al. 2004), later considered a synonym of *T. stenotrophicus* (Pujalte et al. 2005b).

The genus includes Gram-negative ovoid to irregular rods, motile by one polar flagellum. They are strict aerobes, chemoorganotrophic, and slightly halophilic, positive for catalase and oxidase. Cells show budding and binary division and accumulate PHB. Bchl *a* is produced. Seawater or a complex mixture of marine salts is required for growth. Mesophilic. No hydrolytic activities on polymeric substrates (proteins, polysaccharides, lipids, nucleic acids) are observed. Major polar lipids are PG, DPG, and PC. PE is absent. Major cellular fatty acids are C18:1 ω7c, 11-methyl C18:1 ω7c, C18:1 ω9c, and C20:1 ω7c. The G+C content of its DNA is around 59 mol%. The predominant respiratory quinone was determined by Adachi et al. (2004) to be Q10.

In 2009 a second species, *T. arenae*, was described by Kim et al., but it was later reclassified into the genus *Litoreibacter* as *L. arenae* (Kim et al. 2012b).

T. stenotrophicus grows on Marine Agar producing reddish to brown pigmentation and does not reduce nitrate to nitrite or gas. The type strain is able to use several organic acids and amino acids as sole carbon and energy source (pyruvate, acetate, 2-oxoglutarate, succinate, 3 hydroxybutyrate, L-glutamate, L-ornithine, L-citrulline, and putrescine) provided that the basal medium is supplemented with small amounts of yeast extract, a fact that suggests growth factor requirements. The preferred carbon sources of the species were confirmed in enrichment experiments by Gómez-Consarnau et al. (2012) who found that *Thalassobacter* sp. increased in relative abundance in seawater amended with pyruvate and amino acids.

The strains formerly known as *J. cystaugens* are able to inhibit cyst formation on toxic dinoflagellate *Alexandrium tamarense* (Adachi et al. 2002).

Thalassobius

The genus *Thalassobius* was established by Arahal et al. (2005) to account for two species, *T. mediterraneus* type species, isolated from seawater, and *T. gelatinovorus*, which corresponds to the reclassification of the former *Ruegeria gelatinovorans* (Uchino et al. 1998). Currently, two more species are included in the genus: *T. aestuarii* (Yi and Chun 2006) and *T. maritimus* (Park et al. 2012). The four species merge in a group that also includes *Epibacterium ulvae* (specifically related to *T. aestuarii*), both species of *Shimia*, *Thalassococcus* and *Octadecabacter* (Fig. 20.5), with *T. maritimus* being the more loosely related to the *Thalassobius* core species.

Thalassobius species present the following features: they are Gram-negative, strictly aerobic, chemoorganotrophic bacteria that divide by binary fission. Cells are coccoid to rod shaped and accumulate PHB. They require seawater or combined marine salts for growth and are slightly halophilic and mesophilic. They do not ferment carbohydrates and prefer organic acids and amino acids as carbon sources. Their G+C content ranges from 57–61 mol%. The predominant quinone is Q10. Major cellular fatty acid is C18:1 ω7c, with minor amounts of C16:0, C18:0, and 11-methyl C18:1 ω7c. Park et al. (2012) determined polar lipids for the four species, which include PE and PG and smaller amounts of PC plus an unidentified lipid.

T. aestuarii shows DDH values of 20 % and 43 % to *T. mediterraneus* and *T. gelatinovorus*, respectively (Yi and Chun 2006), while *T. maritimus* is related to *T. gelatinovorus* (its nearest species) by 17 % (Park et al. 2012). The four species could be differentiated by motility and nitrate reduction (both positive for *T. aestuarii* and *T. gelatinovorus*), a distinctive range of hydrolytic abilities on casein, gelatin, Tweens, and urea and differences on the carbon source pattern (Park et al. 2012).

Unidentified *Thalassobius* spp. have been related to epizootic shell disease (ESD) lesions on American lobster, *Homarus americanus*, and other crustacea. The lesions are colonized by a Bacteroidetes bacterium (*Aquimarina* sp.) altogether with *Thalassobius* sp. (Quinn et al. 2012; Chistoserdov et al. 2012). Algicidal activities have been also reported for strains tentatively identified as *Thalassobius* (Oh et al. 2011b; Wang et al. 2010b). A *Thalassobius* sp. strain able to utilize phthalate has been isolated from seawater (Iwaki et al. 2012b).

The genome draft of a strain of *Thalassobius* sp., R2A62, has been obtained (Roseobase) and reveals a genome size of 3.49 Mbp, 3,696 coding sequences, and a G+C content of 55 mol%, slightly below of the one of the species described so far.

Thalassococcus

Closely related to *Thalassobius* species, the genus *Thalassococcus* contained a single species *T. halodurans* (Lee et al. 2007b) until the recent proposal of *Thalassococcus lentus* (Park et al. 2013b). The type species was isolated from the surface of a marine sponge, *Halichondria panicea*, at the pacific coast of the USA.

Defining features of the genus are as follows: Gram-negative, ovoid-shaped, nonpigmented cells. They are nonmotile, oxidase and catalase positive, strictly aerobic, and halophilic. Q10 is the major respiratory quinone and C18:1 ω7c, C18:1 ω9c, C16:0, and C18:0 are the major cellular fatty acids. *T. halodurans* requires at least 2% NaCl for growth and is able to grow in the presence of up to 18 %. It is mesophilic and neutrophilic, lacks extracellular hydrolytic abilities, and reduces nitrates to nitrite, but not to N_2. It produces acid from some carbohydrates on API 50CH and is also able to use carbohydrates as carbon sources (glycerol, glucose, and galactose, among others). The G+C content of its DNA is 58.8 mol% (58 % for *T. lentus*, which is related by a 17 % DDH value to *T. halodurans*, according to Park et al. 2013b).

Tranquillimonas

This monospecific genus occupies an isolated position near *Salipiger mucosus* and *Palleronia marisminoris* in the 16S rRNA tree. Its type and single species, *Tranquillimonas alkanivorans* (Harwati et al. 2008), was isolated from seawater at the Semarang Port, Indonesia, during a search for hydrocarbon-degrading bacteria, and, as indicated by the species name, it is able to degrade alkanes ($C_{10–13}$). Its general characteristics fit the profile of the majority of roseobacters, with no other special trait: they are Gram negative, nonmotile, obligately halophilic, requiring Na ion for growth, oxidase and catalase positive, and pink pigmented on Marine Agar. Cells contain polyhydroxyalkanoates, Q10 as major respiratory quinone, and C18:1 ω7c, C19:0 cyclo ω8c, and C16:0 as major fatty acids. DNA G+C content is 69 mol%. *T. alkanivorans* is able to grow up to 13 % NaCl and from 10 °C to 50 °C, with an optimum at 43 °C. It uses a variety of carbon sources on Biolog plates, including carbohydrates, organic acids, and amino acids, and is able to reduce nitrate to nitrite.

Tropicibacter

In 2009, Harwati and colleagues proposed a new genus, *Tropicibacter*, to allocate a marine species able to degrade aromatic hydrocarbons. *Tropicibacter naphthalenivorans* (Harwati et al. 2009a) was isolated from Indonesian Semarang Port seawater and demonstrated to degrade hydrocarbons in crude oil (Harwati et al. 2007). The same study also originated the isolates later described as *Tropicimonas isoalkanivorans* (Harwati et al. 2009b). The type species of *Tropicibacter* was soon followed by new members of the genus, *T. multivorans* (Lucena et al. 2012b), *T. phthalicicus* (Iwaki et al. 2012a), *T. mediterraneus*, and *T. litoreus* (Lucena et al. 2013). *Tropicibacter* species are close to *Pelagimonas* and to the clade of *Phaeobacter sensu stricto* and relatives (*Fig. 20.5*).

The genus was described as containing Gram-negative, rod-shaped, peritrichously flagellated rods, but species described lately failed to show motility (*T. mediterraneus* and *T. litoreus*) or, when motile, displayed polarly flagellated cells (*T. multivorans*, *T. phthalicicus*). All species require sodium ion for growth and some of them also magnesium or calcium ions. The oxidase test is positive. Three of the species, including the type, are able to reduce nitrate to nitrite or to nitrogen gas. PHB accumulation is found only in *T. naphthalenivorans*. As it is usual among roseobacters, they contain Q10 as predominant quinone and their major cellular fatty acid is C18:1 ω7c, followed by C16:0 and 11-methyl C18:1 ω7c. Polar lipids have been determined in two species: they include PE, PG, PC, and AL and four PLs in *T. multivorans*, while *T. mediterraneus* contains PG, PE, and unidentified amino- and phospholipids, and lipids but lacks PC. The G+C content ranges from 58 to 64.6 mol%.

ANI values were used as alternative parameter to DDH for species delineation of *T. mediterraneus* and *T. litoreus*: the former species contains four strains that showed 97.5–99 % ANIb (98.9–99.7 ANIm) while interspecies values were 85–86 % ANIb (90 % ANIm) between both species (Lucena et al. 2013).

Tropicimonas

Harwati and coworkers described *Tropicimonas* after studying isolates obtained from the same location and samples that gave origin to the description of *Tropicibacter*, Semarang Port

seawater (Indonesia). The type species of their new genus, *Tropicimonas isoalkanivorans*, was able to degrade alkanes, branched alkanes, and alkylnaphthalenes (Harwati et al. 2009b). Two additional species have been recently added: *T. aquimaris*, which description was accompanied by an emended description of the genus (Oh et al. 2012), and *T. sediminicola* (Shin et al. 2012), both isolated from marine samples. Phylogenetic relatives of *Tropicimonas* species within the *Rhodobacteraceae sensu lato* are somewhat difficult to determine, as there is not always agreement between the trees obtained by different reconstruction methods. A relation with *Thioclava* was reported at the time of genus description and is recovered with NJ methods, but most parsimonious analyses fail to support this relation and locate the genus within *Roseobacter* group (this study, MP tree, not shown and LTP 111). In any case, all three species merge in a well-defined clade.

The genus contains members with the following features: cells are Gram negative, peritrichously flagellated (when motile), rod shaped, and oxidase positive. Catalase and PHA accumulation are variable. Halophilic, they require sodium ion for growth (but *T. sediminicola* is able to grow without NaCl). They grow optimally at 30–37 °C. Although Q10 is the most abundant respiratory quinone (57–60 %), it is accompanied by substantial amounts of others: 36 % of Q9 in *T. aquimaris* and two quinones of undetermined chain length in *T. isoalkanivorans*, accounting for 28 % and 14 % each. The major cellular fatty acids are C18:1 ω7c, C18:1 ω9c, and C16:0. Common major polar lipids are PC, PG, an unidentified aminolipid, and an unidentified lipid. G+C content of their DNA is 66.5–69.6 mol%.

All *Tropicimonas* species described so far are able to reduce nitrates to nitrites and *T. aquimaris* grows on Marine Agar incubated anaerobically, with and without nitrate supplementation. They grow at least up to 40 °C (*T. isoalkanivorans* up to 46 °C) and up to 6 % salinity. They produce acids from several carbohydrates and are able to assimilate a variety of carbon sources. *T. isoalkanivorans* is able to use decane, pristane, and methylnaphthalene for growth, but it is unable to grow on thiosulfate as energy source.

T. aquimaris shows a DNA-DNA relatedness of 12 % to the type species *T. isoalkanivorans* (Oh et al. 2012). On the other hand, *T. sediminicola* is related to *T. aquimaris* by DDH values of 46 %, while only a 6 % DDH could be found with *T. isoalkanivorans* (Shin et al. 2012).

Vadicella

The genus *Vadicella* contains a single species, *V. arenosi*, described after the study of several isolates obtained from a sandy sediment sample of the Sea of Japan (Romanenko et al. 2011d). The species has the genus *Celeribacter* as closest phylogenetic relative and belongs to the clade that also includes *Huaishuia* and *Pseudoruegeria* (Fig. 20.5). Basic properties defining the genus are as follows: they are rod shaped, Gram negative, strictly aerobic, oxidase and catalase positive, and chemoorganotrophic. They have an absolute requirement for sodium ion. They do not synthetize Bchl *a*. Their predominant quinone is Q10. Polar lipids include PC, PG, phosphatidic acid, an unknown aminolipid, and an unknown lipid; PE is present in minor amounts. Their major cellular fatty acids are C18:1 ω7c, 11-methyl C18:1 ω7c, C12:1, and C10:0 3OH. The only currently recognized species of *Vadicella* is nonmotile and nonpigmented, grows from 1 % to 7 % NaCl, from 4 °C to 37 °C, and from pH 5.5 to 9.5. It reduces nitrate and does not produces acid from carbohydrates. It uses a few sugars and organic acids as carbon and energy sources. The G+C content of its DNA is 56.7–60 mol%.

Wenxinia

Wenxinia marina represents the only recognized species so far in the genus *Wenxinia* (Ying et al. 2007). The type and single strain of this species was isolated from the sediment of an oil field (100 m depth) in the South China Sea. *Wenxinia* occupies a marginal position on the *Roseobacter* group, having a distant relationship to the genera *Rubellimicrobium* and *Roseicyclus*, at the edge of the clade.

The genus was described as containing Gram-negative, ovoid or short rods that are nonmotile, strictly aerobic, and heterotrophic. They require NaCl for growth and are slightly pigmented of pink, but do not produce Bchl *a*. Catalase and oxidase tests are positive. They reduce nitrates to nitrites. Their quinone system is Q10; they contain PG, PC, and an unidentified glycolipid as major polar lipids and have C18:1 ω7c and C16:0 as major cellular fatty acids.

W. marina is able to grow from 15 °C to 42 °C, from 0.5 % to 9 % NaCl, and at pH 6.5–8.5. It accumulates PHA and contains PE and an unidentified phospholipid as minor components of its polar lipid profile. It is able to produce acid from some carbohydrates and uses several sugars, organic acids, and amino acids. The C+G content of its DNA is 69.4 mol%. The draft genome of *W. marina* DSM 24838^T has 4.2 Mb.

Yangia

The genus *Yangia* belongs to the subclade that contains *Citreicella* and *Citreimonas* (Fig. 20.5). It was recognized as a new genus by Dai et al. (2006) and contains a single species, *Y. pacifica*, whose type and only characterized strain was isolated from a coastal sediment of the East China Sea. The genus is defined by the following properties: cells are Gram-negative, motile rods. They are aerobic, heterotrophic, and require NaCl for growth. They form slightly yellowish colonies on Marine Agar, which are positive for catalase and weakly positive for oxidase tests. Q10 is the predominant quinone, C18:1 ω7c and C16:0 are the major fatty acids, and C12:0 is also present.

Y. pacifica, the type species, does not produce Bchl *a*, accumulates PHB, is negative for nitrate reduction, and grows at 22–40 °C, with 1–10 % NaCl and with maltose, lactate,

malate, arginine, and glutamate as sole carbon sources. The DNA G+C content is 63.3 mol%.

In a survey about polyester production by halophilic and halotolerant bacterial strains obtained from mangrove soil samples located in Northern Vietnam, five strains (QN187, ND199, ND218, ND240, and QN271) phylogenetically close to *Y. pacifica* were found to accumulate PHAs in noticeable amounts. Strains QN187, ND240, and QN271 synthesized poly(3-hydroxybutyrate) (PHB) from glucose, whereas strains ND199 and ND218 synthesized poly(3-hydroxybutyrate-*co*-3-hydroxyvalerate) (PHBV) from this carbohydrate (Van-Thuoc et al. 2012).

Genera Not Belonging (Phylogenetically) to *Rhodobacteraceae Sensu Stricto*

The Stappia Group

The group formed by the genera *Stappia*, *Labrenzia*, *Nesiotobacter*, *Pannonibacter*, *Polymorphum*, *Pseudovibrio*, and *Roseibium* (Fig. 20.6) constitute the clearest candidate to the rank of new family in the currently heterogeneous *Rhodobacteraceae sensu lato*. These genera form a well-defined, stable, and neat clade, separated from *Rhodobacteraceae sensu stricto* by several other alphaproteobacterial branches that constitute families by themselves (*Hyphomonadaceae*, *Koordimonadaceae*, *Phyllobacterriaceae*, *Hyphomicrobiaceae*, etc., Fig. 20.1). The detachment of stappias from the rest of *Rhodobacteraceae* was already noted by Gupta and Mok (2007) in their phylogenomic study of the alphaproteobacteria, on the basis of signature proteins. These authors suggested the placement of *Labrenzia* (*Stappia*) *aggregata* among *Rhizobiaceae*, although more recent analysis based on 16S rRNA gene of the whole group indicates a separate position from this family (LTP111).

Stappias are aerobic or facultatively anaerobic and chemoorganotrophic but some species do contain *pufLM* genes (*Roseibium* spp., *Labrenzia alexandrii*, *Stappia stellulata*) and are able to synthetize Bchl *a*, although its amount may be very low in some species (Biebl et al. 2007). Members of the group display interesting activities related to the production of different bioactive compounds, carbon monoxide oxidation, aromatic ring cleavage, heavy metal detoxification, and oil degradation abilities. While several of the species are isolated from marine water and sediments, some were isolated from lake water, hot springs, or saline soil, as well as from marine invertebrates and surfaces of aquatic plants and algae. One species has been isolated from human blood samples and the other is related to an oyster disease affecting juveniles of *Crassostrea virginica* cultured in USA (Table 20.8).

Stappia

The genus *Stappia* has a history that parallels that of *Ruegeria*, in the *Roseobacter* group. As *Ruegeria*, *Stappia* was established as a new genus by Uchino et al. (1998) to accommodate species previously known as marine agrobacteria: *Agrobacterium stellulatum* and *Agrobacterium aggregatum* (Rüger and Höfle 1992). The new genus *Stappia* was phylogenetically distant to agrobacteria and was defined in terms of chemotaxonomic as well as physiological and biochemical properties (Uchino et al. 1998). After the description of two additional species, *S. alba* (Pujalte et al. 2005c) and *S. marina* (Kim et al. 2006b), Biebl and colleagues (2007) rebuilt the group by creating a new genus, *Labrenzia*, to which they transferred *S. alba* and *S. marina* as new combinations. Almost simultaneously, Weber and King (2007) proposed four new *Stappia* species which names have never been validated and thus have no standard in nomenclature (*S. meyerae*, *S. conradae*, *S. kahanamokuae*, and *S. carboxydovorans*). 16S rRNA genes of these species were analyzed by Lai et al. (2010b) who found they probably are more related to *Labrenzia* and *Pannonibacter* than to *Stappia*. The genus *Stappia* remained as monospecific until then with the description of *S. indica* (Lai et al. 2010b), and more recently *S. taiwanensis* (Kämpfer et al. 2013a) has also been proposed.

The emended description of *Stappia* by Biebl et al. (2007) defined the genus by the following properties: Gram-negative rods, motile by polar flagella, aerobic, and oxidase and catalase positive. They require seawater or Na ion for growth. Q10 is the predominant quinone. Polar lipid profile includes PG, DPG, PE, PMME, PC, and an aminolipid. The glycolipid SQDG is absent. Cellular fatty acids comprise C16:1 ω7c, C16:0, C18:1 ω7c, C18:0, 11-methyl C18:1 ω6t, C20:1 ω7c, C22:0, C22:1, and the hydroxy fatty acids C14:0 3OH (ester linked), C16:0 3OH, C18:1 3OH, C18:0 3OH, and C20:0 3OH (all amide linked). The G+C content of the type species is 59 mol% but extends up to 65.9 % in *S. indica*. *S. taiwanensis* contains spermidine and spermine as major polyamines. The draft genome of *S. stellulata* DSM 5886^T has 4.6 Mb.

DDH relatedness between *Stappia* species are reported by Lai et al. (2010b) for *S. indica* and *S. stellulata* (43 %) and Kämpfer et al. (2013a) for *S. taiwanensis* and *S. stellulata* (24–25 %) and *S. indica* (27 %).

Some *Stappia* contain *coxL* gene, being able to oxidize carbon monoxide (a common ability in members of the group) (Biebl et al. 2007), and some also present *pcaH* gene, encoding for a key ring-cleaving enzyme of the β-ketoadipate pathway (Buchan et al. 2001). *S. stellulata*-like strains have been related to a pathology of cultured oysters, JOD (juvenile oyster disease), that causes seasonal mortalities in *Crassotrea virginica* hatcheries, in the USA Northeast coast (Boettcher et al. 2000). *Stappia* spp. also participates in DMS production from DMSP, through a DMSP-lyase also present in several members of the *Roseobacter* group (Curson et al. 2008).

Labrenzia

Labrenzia was established as a new genus by Biebl et al. (2007), with the Bchl *a*-producing *L. alexandrii* as type species and the former *Stappia aggregata*, *S. marina*, and *S. alba* as new combinations. The four *Labrenzia* species were closely related according with the analysis of their 16S rRNA genes and only loosely related to *Stappia stellulata*, the type species of the genus *Stappia*, which joined to the clade only after *Roseibium spp.*,

Table 20.8
Species in the *Stappia* group and unaffiliated or isolated genera

Species (synonym)	Isolation/habitat	Metabolism[a]	Na^+ requirement, others	References
Stappia stellulata (*Agrobacterium*)	Marine sediment and water	AAP	Yes	Uchino et al. 1998
S. indica	Deep seawater, Indian Ocean	COH a	Yes	Lai et al. 2010b
S. taiwanensis	Coastal hot spring, Taiwan	COH a	Yes	Kämpfer et al. 2013a
Labrenzia alexandrii	Cultured dinoflagellate (*Alexandrium*), Germany	AAP	Yes	Biebl et al. 2007
L. aggregata (*Stappia*)	Sediment, Baltic Sea, Germany	COH a	Yes	Biebl et al. 2007; Uchino et al. 1998
L. alba (*Stappia*)	Oysters, Mediterranean coast, Spain	COH a	Yes	Biebl et al. 2007; Pujalte et al. 2005c
L. marina	Tidal flat, Yellow Sea, S. Korea	AAP	Yes	Biebl et al. 2007; Kim et al. 2006b
Nesiotobacter exalbescens	Hypersaline lake water, Hawaii, USA	COH	Yes	Donachie et al. 2006
Pannonibacter phragmitetus	Decomposing rhizomes of reed (Phragmites), from soda lake, Hungary	COH fac an	No, alkalitolerant	Biebl et al. 2007; Borsodi et al. 2003
P. indicus	Hot spring sediment, India	COH a	No	Bandyopadhyay et al. 2013
Polymorphum gilvum	Crude oil-contaminated, saline soil, China	COH fac an	No	Cai et al. 2011
Pseudovibrio denitrificans	Seawater, Taiwan	COH fac an	Yes	Shieh et al. 2004
P. ascidiaceicola	Ascidians (Polycitor and Botryllidae), Japan	COH fac an	Yes	Fukunaga et al. 2006
P. axinellae	Marine sponge, Axinella, Ireland	COH fac an	Yes	O'Halloran et al. 2013
P. japonicus	Coastal seawater, Japan	COH fac an	Yes	Hosoya and Yokota 2007b
Roseibium denhamense	Red algae (Botryocladia) surface, Australia	AAP	Yes	Biebl et al. 2007; Suzuki et al. 2000
R. hamelinense	Marine sand, Australia	AAP	No	Biebl et al. 2007; Suzuki et al. 2000
Unaffiliated				
Agaricicola taiwanensis	Mushroom (Agaricus), Taiwan	COH a	No	Chu et al. 2010

Rhodothalassium salexigens[c] (*Rhodospirillum*)	Salterns, hypersaline lakes, Oregon, USA	PNS	Yes	Venkata Ramana et al. 2013a; Imhoff et al. 1998

[a] *AAP* aerobic anoxygenic photoheterotroph, *COH* chemoorganoheterotroph, *COH a* chemoorganoheterotroph aerobic, *COH fac an* chemoorganoheterotroph facultative anaerobic, *PNS* purple non-sulfur anoxygenic photoheterotroph
[b] *Phyllobacteriaceae*
[c] *Rhodothalassiaceae*

Pannonibacter phragmitetus, two *Pseudovibrio spp.*, and *Nesiotobacter exalbescens*. The current phylogenetic tree, including all newly described members of the *Stappia* group, maintains the same large separation between *Stappia* and *Labrenzia* species (*Fig. 20.6*).

Members of *Labrenzia* are defined as having Gram-negative, rod-shaped cells that are motile by one to several polar flagella. They may produce small amounts of Bchl *a* in the dark and a pink colony pigment in appropriate conditions. They require NaCl for growth, which occurs optimally in 1–10 % NaCl concentrations. Optimum pH is 7 to 8.5. Nitrate reduction activity (to nitrite or to N_2) is variable. They are chemoheterotrophic and non-fermentative under aerobic or anaerobic conditions. Indole production is negative. The major respiratory quinone is Q10. Polar lipids include PG, DPG, PE, PMME, PC, SQDG, and an amino lipid. Fatty acids comprise C16:0, C18:1 ω7c, C18:0, 11-methyl C18:1 ω6t, and C20:1 ω7c and the following hydroxy fatty acids: C14:0 3OH, C18:0 3OH, and C20:0 3OH (all amide linked). The G+C content ranges from 56 to 60 mol%.

The four species are mesophilic and neutrophilic and some are denitrifiers and accumulate PHB (*L. alba*). *L. marina* and

L. alexandrii produce Bchl *a*, while *L. alba* and *L. aggregata* lack this ability and the *pufLM* genes. All four species contain *coxL* genes and are capable of carbon monoxide oxidation (Biebl et al. 2007; Weber and King 2007).

Labrenzia strains have been isolated from the dinoflagellate *Alexandrium lusitanicum* (*L. alexandrii*), marine sediment (*L. aggregata*), oysters (*L. alba*), and tidal flat (*L. marina*), but isolates pertaining to the genus have also been found on estuarine microbial mats (Villanueva et al. 2010), as endophytes on siphonous green seaweeds (Hollants et al. 2011) and in soft corals (Chen et al. 2012b). A putative new *Labrenzia* species has been isolated and extensively investigated in suboxic waters of the Arabian Sea, where they contribute actively to the removal of N_2O through its N_2O-reductase activity, developing in colonies of *Trichodesmium* spp. (Wyman et al. 2013). Some *Labrenzia* spp. draw attention because of their polyhydroxyalcanoate accumulation (Koller et al. 2011; Xiao and Jiao 2011) or because of the production of particular enzymes, as a new nitrilase from *L. aggregata*, interesting to the drug manufacturing industry (Zhang et al. 2012c).

The genome of *L. alexandrii* type strain, DFL-11^T, has been sequenced, bringing attention, among other traits, in the ability to form R-bodies (Fiebig et al. 2013). The genome size is 5.46 Mbp and comprises one chromosome (5.3 Mbp) and two plasmids. It contains 3 rRNA operons and 52 tRNA genes, and its G+C content is 56.4 mol%. Homologues to the three *Caedibacter taeniospiralis* genes determining R-body production were found in the chromosome. The draft genome of *L. aggregata* IAM 12614^T has 6.56 Mb and a G+C content of 59.4 mol%.

Nesiotobacter

Nesiotobacter contains a single species, *N. exalbescens*, isolated from hypersaline lake water in Hawaii (Donachie et al. 2006). The species occupies a position next to *Pseudovibrio* in the *Stappia* clade (Fig. 20.6). Strains belonging to *Nesiotobacter* are Gram-negative, motile rods, positive for oxidase and catalase tests, which reduce nitrates to N_2. They do not synthetize Bchl *a*. Their major fatty acid is C18:1 ω7c. The DNA G+C content of the only strain is 61 mol%.

N. exalbescens grows on Tryptone Soya Agar with 0.5–13.5 % NaCl added (but not at 0 % NaCl) and in Marine Broth with 1–17.5 % NaCl added. It is able to grow up to 45 °C but not at 50º, a behavior that was described as moderately thermophilic in the species description, but corresponds probably to a mesophile with a high upper temperature limit. It produces acid from several carbohydrates and hydrolyzes gelatin. DNA of the type strain showed 14–15 % DDH levels with type strains of *Roseibium denhamense* and *Labrenzia aggregata*, their closest neighbors at the time of the description. The draft genome of *N. exalbescens* DSM 16456^T has 4.16 Mb.

Pannonibacter

The type species of the genus *Pannonibacter*, *P. phragmitetus*, was isolated from rhizomes of reed (*Phragmites australis*) in a Hungarian soda lake (Borsodi et al. 2003). A few years later, Holmes et al. (2006) reported that the new genus and species have been isolated and characterized previously (as *Achromobacter* groups B and E) from blood samples of human origin. This makes *P. phragmitetus* one of the very few *Rhodobacteraceae* bacteria isolated from human clinical specimens, along with *Paracoccus yeei* and *Haematobacter* spp. (see above). The human strains were related to a case of replacement valve endocarditis and two septicemia cases (Holmes et al. 2006).

The original genus description was emended by Biebl et al. (2007), by adding information on their chemotaxonomic traits. It includes strains with Gram-negative, rod-shaped cells, which are motile by polar flagella, contain PHA, and are chemoorganotrophic and facultative anaerobic. They ferment glucose without gas production, are positive for oxidase and catalase, and reduce nitrate to dinitrogen gas. Bchl *a* is not synthetized. The dominant quinone is Q10. Polar lipid profile includes PG, DPG, PMME, PC, an amino lipid, and an unidentified lipid. PE is not detected (although it is a precursor of PMME). Phosphatidylserine and SQDG are absent. Cellular fatty acid comprise C16:1 ω7c, C16:0, C18:1 ω7c, C18:0, 11-methyl C18:1 ω6t, C20:1 ω7c, C22:0, and the hydroxy fatty acids C14:0 3OH (ester linked), C16:0 3OH, C18:1 3OH, C18:0 3OH, and C20:1 3OH (all amide linked). The peptidoglycan contains *m*-DAP. The G+C content of the species described so far is 63–64.6 mol%. The draft genome of *P. phragmitetus* DSM 14782^T has a size of 4.8 Mb.

P. indicus, the second species in the genus, shows DDH values of 34–55 % against different strains of *P. phragmitetus* (Bandyopadhyay et al. 2013) and, unlike the type species, is unable to grow anaerobically, does not reduce nitrates, and is able to grow up to 45 °C. It resembles *P. phragmitetus* in its alkalitolerant character and in the absence of salt requirements for growth.

Pannonibacter strains isolated from wastewater treatment plants have shown remarkable abilities for degradation of some undesired compounds as tert-butyl alcohol (Reinauer et al. 2008) or 4-aminobenzene sulfonate (Wang et al. 2009d; Zhang et al. 2011b), but the bulk of the literature on applied uses of *Pannonibacter* is related to its activity as a chromium (IV) reducing agent, which makes *Pannonibacter phragmitetus* (strains BB and LSSE-09, among others) an effective resource for contaminated soil bioremediation (Chai et al. 2009; Xu et al. 2011a, b, 2012; Wang et al. 2013a). It is also remarkable the tolerance to arsenate of the newly described species *P. indicus* (Bandyopadhyay et al. 2013), which type strain is able to grow in the presence of up to 500 mM of sodium arsenate. The strain was isolated from hot spring sediment in India. Other hot spring environments also contain *Pannonibacter* strains, as recently reported by Coman et al. (2013).

Polymorphum

The genus *Polymorphum* was recently described to accommodate a new species, *P. gilvum*, isolated from crude oil-contaminated saline soils, in China (Cai et al. 2011), the same samples from which *Rubrimonas shengliensis* was isolated and described. *Polymorphum's* closest taxon corresponds to the pair

of *Pannonibacter* species (*P. phragmitetus* and *P. indicum*) (Fig. 20.6, LTP111), to which they reassemble in their facultatively anaerobic character.

Cells of *Polymorphum* exhibit different morphologies, as suggested by the generic name, as short rods or dumb-shaped cells with different branches that occasionally aggregate in star-shaped groups. They are Gram negative, facultatively anaerobic, and motile (one polar flagellum is present in the cells of the type species). The predominant quinone is Q10; major fatty acids correspond to C18:1 ω7c, 11-methyl C18:1 ω7c, C18:0, C16:0, and C20:1 ω7c. The polar lipid profile includes DPG, PMME, PG, PC, SQDG, and unidentified aminolipids and phospholipids. The type species has a DNA G+C content of 65.6 mol%.

P. gilvum is able to grow from 4 °C to 50 °C, at pH 5–9, and with 0–6 % NaCl. Optimum growth occurs at 37 °C, pH 6.0, and 1 % NaCl. The species is positive for catalase activity but negative for oxidase, an atypical behavior in the group. It does not reduce nitrates. Bchl *a* is not synthetized and *pufLM* genes are absent. Acid is produced from several carbohydrates (glycerol, L-arabinose, D-ribose, D-xylose, D-glucose, D-fructose, D-mannose, and D-cellobiose, among others). The type strain SL003B-26A1^T is able to grow on crude oil as sole carbon source, an ability that justifies the interest in its complete genome sequence: Li et al. (2011c) found that the genome of this strain consists of a circular chromosome 4.65 Mbp in size and a plasmid of 69.6 kbp with 67 and 61 mol% G+C content, respectively. The chromosome contains 50 tRNA and two rRNA encoding operons. The genes for membrane-bound alkane monooxygenase and for cytochrome P450 (related to oil degradative capabilities in other bacteria) are not found, but *ladA*, coding for long chain-alkane hydroxylation, is present. This gene codes for an extracellular enzyme that can hydroxylate C_{15} to C_{36} alkanes. The authors suggest it might have been acquired by horizontal gene transfer.

Pseudovibrio

Four species have been described in the genus *Pseudovibrio* since Shieh et al. (2004) named the new genus: *P. denitrificans*, the type species, *P. ascidiaceicola* (Fukunaga et al. 2006), *P. japonicus* (Hosoya and Yokota 2007b), and *P. axinellae* (O'Halloran et al. 2013). All four contain strains of Gram-negative, straight, or curved rods, which are motile by one to several lateral/subpolar flagella. *P. ascidiaceicola* forms conspicuous rosettes. They are able to grow in anaerobic conditions, either by carbohydrate fermentation (glucose and mannose are fermented by the four species) or through denitrification, as all of them reduce nitrates to nitrogen gas. They are oxidase and catalase positive, mesophilic and halophilic, requiring NaCl for growth. Their fatty acid profile includes C18:1 ω7c as major component, accompanied by varying amounts of C16:0, C18:0, C19:0 cyclo ω8c, and the hydroxylated C14:0 3OH (as SF 2), C16:0 3OH, and C18:0 3OH (O'Halloran et al. 2013). The G+C content of their DNA is 50–52 mol%. The species could be differentiated by their fermentative and assimilative patterns as well as for the relative amounts of minor fatty acids. DDH values between *P. ascidiaeceicola* and *P. denitrificans* are lower than 30 % (Fukunaga et al. 2006); *P. japonicus* shows values of 35 % against *P. denitrificans* and 14–32 % against *P. ascidiaceicola* strains (Hosoya and Yokota 2007b). Finally, *P. axinellae* shows DDH values of 26 % with *P. ascidiaceicola*, 18 % with *P. denitrificans*, and 16 % with *P. japonicus* (O'Halloran et al. 2013).

Pseudovibrio species form a well-defined, tight clade, which closest relative is *Nesiotobacter exalbescens* (Fig. 20.6).

Although two of the species were isolated from seawater, most of the reports on isolation of pseudovibrios are associated to microbiota of marine invertebrates, with a significative dominance of sponges of very different geographic sites. Several reports document the production of bioactive metabolites from these sponge-, tunicate-, ascidian-, coral- or polychaetide-associated bacteria (Radjasa et al. 2007; Muscholl-Silberhorn et al. 2008; Riesenfeld et al. 2008; Kennedy et al. 2009; Santos et al. 2010; O'Halloran et al. 2011; Penesyan et al. 2011; Flemer et al. 2012; Margassery et al. 2012; Chen et al. 2012b; Rizzo et al. 2013). The genomes of two *Pseudovibrio* strains, isolated from a coral and a sponge, revealed a number of ORFs and gene clusters that seem to be involved in symbiont-host interactions: attachment and interaction with eukaryotic cell machinery, production of secondary metabolites, and supply of the host with cofactors (Bondarev et al. 2013). The size of these genomes, 5.73 and 5.92 Mb, are among the largest reported within the *Rhodobacteraceae*.

Roseibium

The genus *Roseibium* was described by Suzuki et al. (2000) to accommodate two new species of APPs isolated from algal surfaces and sand from coastal areas of Australia. *R. denhamense* and *R. hamelinense* synthetized Bchl *a* in aerobiosis and produced pink colonies. Their cells are Gram-negative rods, motile by means of peritrichous flagella. They are aerobic, chemoorganotrophic, and positive for catalase, oxidase, phosphatase, and nitrate reductase. Q10 is the predominant quinone and C18:1 ω7c is the major fatty acid. The G+C molar content of their DNA expands from 57.6 to 63.4 mol%. Biebl et al. (2007) emended the genus description, adding the polar lipid profile, which comprises PG, DPG, PE, PMME, PC, SQDG, and an amino lipid. They also added a more detailed fatty acid profile that includes C16:0, C18:1 ω7c, C18:0, 11-methyl C18:1 ω6t, and C20:1 ω7c and the hydroxy fatty acids C14:0 3OH (ester linked), C18:0 3OH, C20:0 3OH, and C20:1 3OH (amide linked).

Roseibium species are mesophilic and neutrophilic (optimal growth at 27–30 °C and pH 7.5–8.0). *R. hamelinense* does not require NaCl for growth (range: 0–10 % NaCl), in contrast to *R. denhamense* (range: 0.5–7.5 % NaCl). They are chemoorganotrophic and aerobic and unable to grow phototrophically under anaerobic conditions in the light. Their carbon sources include butyrate, L-glutamate, L-aspartate, and pyruvate. Acid is produced from some carbohydrates: D-glucose, D-fructose, D-ribose, and maltose. They produce indole and hydrolyze gelatin. DDH determinations related both species by values of 12–17 % (Suzuki et al. 2000).

Roseibium species have *Labrenzia* spp. as their closest phylogenetic relatives (Fig. 20.6). The draft genome of strain *Roseibium* sp. TrichSKD4 has 5.7 Mb and a G+C content of 53.9 mol%.

Agaricicola

The description of the genus *Agaricicola* and its only species, *A. taiwanensis*, was based on the study of a single strain, CC-SBAB117^T, isolated from the stipe of the edible mushroom *Agaricus blazei* in Taiwan. After analysis of the 16S rRNA gene sequence, a distant relationship was found to some members of the *Stappia* clade (*Pannonibacter phragmitetus*, 92.5 % sequence similarity; *Nesiotobacter exalbescens*, 91.5 %) and to *Prosthecomicrobium pneumaticum* (92.3 %) (Chu et al. 2010). Although some early analysis might suggest *Agaricicola* being a peripheral member of the clade *Stappia*, the more recent version of LTP, LTP111, shows *Agaricicola* paired with *Prosthecomicrobium pneumaticum* and clearly unrelated to the stappias. Thus, *Agaricicola* should be removed from *Rhodobacteraceae sensu lato*, as currently considered.

The genus is defined by the following traits: Gram-negative, strictly aerobic, nonspore-forming, motile, club-shaped cells that accumulate PHB granules as polar inclusions. Oxidase test is positive but catalase is negative. It contains the following polar lipids: DPG, PG, PC, and PE. SQDG and PMME are not detected. The major respiratory quinone is Q10. The predominant fatty acids are C18:1 ω7c, C19:0 cyclo ω8c, C16:0, and C18:0 whereas C10:0 3OH is absent.

The type and only species of the genus, *A. taiwanensis*, grows in Nutrient Agar forming circular, shiny, beige pigmented colonies. Growth is optimal at 30–35 °C and occurs between 20 °C and 40 °C, at pH 6.0–9.0 and with 1–4 % NaCl. NaCl is not required for growth. Cells have polar flagella. Nitrate reduction to nitrite or N_2 is negative and no growth is observed with nitrate in anaerobic conditions. Bchl *a* is not synthetized. No acid is produced from carbohydrates. It uses a few sugars and several organic acids as carbon sources, including acetate, pyruvate, propionate, and β-hydroxybutyric acid. The G+C content of its DNA is 62.7 mol%.

Ahrensia

The type species of the genus *Ahrensia*, *A. kieliensis*, was formerly known as one of the "marine agrobacteria," but its relation to the main group was considered ungranted by Rüger and Höfle (1992). Years later, Uchino et al. (1997) revised the phylogenetic position of the whole group of marine agrobacteria, including the non-validated species names, based on 16S rRNA sequence analysis: they found that *Agrobacterium kieliense* IAM 12618 sequence was positioned in the α-2 branch of *Proteobacteria* and recognized it should be classified as a species in new genera. Shortly after that, the proposal of *Ahrensia kieliense* (corrected *kielensis*) gen. nov., sp. nov., nom. rev. was published (Uchino et al. 1998), and since then *Ahrensia* has remained as a monospecific genus, distantly related to the other reclassified marine agrobacteria (*Stappia stellulata*, *Labrenzia aggregata*, *Ruegeria atlantica*, *Thalassobius gelatinovorus*). On recent times, the affiliation of *Ahrensia* to the family *Phyllobacteriaceae* has become evident: *A. kieliensis* merges with species of the genus *Hoeflea*, in particular, with *H. phototrophica* (LTP 111), to which it shows a 95.7 % 16S rRNA gene sequence similarity (Kim et al. 2012f). It should be noted that the type species of the genus *Hoeflea*, *H. marina*, is itself a reclassified marine agrobacterium (*A. ferrugineum* LMG 128).

Ahrensia displays the following generic features: Gram-negative rods, motile by polar flagella, aerobic, and they have a strictly respiratory type of metabolism with oxygen as terminal electron acceptor. Catalase and oxidase are positive. Nitrate is not reduced; gelatin, starch, chitin, and alginate are not hydrolyzed; and indole is not produced. Sodium ion is required for growth. Optimal temperatures are 20–30 °C (range: 5 °C to less than 37 °C). The major fatty acid is C18:1 ω7c and hydroxyl fatty acid is C12:0 3OH, while 2OH fatty acids are absent. Major respiratory quinone is Q10. The G+C content is 48 mol% (Uchino et al. 1998; Krieg 2005). *A. kieliensis* was isolated from seawater from the Baltic Sea.

The draft genome of *A. kieliensis* DSM 5890^T has 3.36 Mb and a G+C content of 48.1 mol%, whereas *Ahrensia* sp. R2A130 has similar size (3.73 Mb) but a considerably higher G+C content (56.9 mol%).

Rhodothalassium

The position of *Rhodothalassium salexigens* (Imhoff et al. 1998; formerly, *Rhodospirillum salexigens*) as a separate phylogenetic branch amid alphaproteobacterial families in the vicinity of *Rhodobacteraceae* was already stressed in the second edition of *Bergey's Manual of Systematic Bacteriology*, where it is classified as Genus *Incertae Sedis*. This unique position in the 16S rRNA tree is accompanied by a combination of chemotaxonomic features unlike other purple non-sulfur phototrophs in *Rhodobacteraceae*: presence of menaquinones (MK10), ornithine lipids, or carotenoids of the spirilloxanthine series. Only the lack of additional strains had prevented an earlier reclassification of the genus, but after the study of several *R. salexigens*-like strains obtained from a solar saltern in India, Venkata Ramana et al. (2013) had emended the description of *Rhodothalassium* and proposed *Rhodothalassiaceae* fam. nov. and *Rhodothalassiales* ord. nov. At the time of writing of this chapter, these names have not been yet validated.

The closest relatives to *Rhodothalassium*, according to the more recent 16S rRNA phylogenetic analyses, are *Kordiimonas* species (fam. *Kordiimonadaceae*, order *Kordiimonadales*), as can be seen in *Fig. 20.1* and LTP111 tree.

According to the emended description, the genus *Rhodothalassium* is defined by the following traits: cells are Gram negative, vibrioid to spiral shaped, motile by polar flagella, and multiply by binary fission. The intracytoplasmic photosynthetic membranes are lamellar stacks. Bchl *a* and carotenoids of the spirilloxanthin series are the major photosynthetic pigments. The quinone system is composed of ubiquinone Q10 and menaquinone MK10. Halophilic, they require NaCl or sea salts for growth. Optimum salinity is above the seawater salt content and tolerate up to 20 % total salts. Growth occurs

preferably photo-organotrophically under anoxic conditions in the light, but is generally possible under microoxic to oxic conditions in the dark (except in some strains). They may require amino acids or niacin and thiamine. Major polar lipids are DPG, PG, ornithine lipid (OL), an unidentified phospholipid, and an amino lipid. Major fatty acids are C18:1 ω7c, 11-methyl C18:1 ω7c, and C16:0, with minor amounts of C14:0, C18:0, C18:1 ω5c, and C16:1 ω7c/C16:1 ω6c. The G+C content of the DNA is 60–62.8 mol%. Hamana et al. (2001) reported aminopropylhomospermidine as the major polyamine in *R. salexigens* cells.

The only species currently recognized is *R. salexigens*. This species is able to grow with N_2 as nitrogen source, requires glutamate, and is unable to grow photoautotrophically with H_2, sulfide, or thiosulfate as electron donors. The temperature range is 20–45 °C (optimum 40 °C) and the salinity range is 5–20 % NaCl (optimum: 4–8 %). Their habitats include anoxic zones of hypersaline environments, such as salterns and partially evaporated seawater pools.

Addendum

The following new genera and species have been effectively published after completion of the manuscript and are not included in the phylogenetic trees and the main text, but their names might be eventually included in validation lists.

Genera:

- *Albirhodobacter marinus* gen. nov., sp. nov. (Nupur et al. 2013), affiliated to the *Rhodobacter* group.
- *Falsirhodobacter halotolerans* gen. nov., sp. nov. (Subhash et al. 2013), affiliated to the *Rhodobacter* group.
- *Litorisediminicola beolgyonensis* gen. nov., sp. nov. (Yoon et al. 2013c), affiliated to the *Roseobacter* group.
- *Paenirhodobacter enshiensis* gen. nov., sp. nov. (Wang et al. 2013b), affiliated to the *Rhodobacter* group.
- *Planktomarina temperata* gen. nov., sp. nov. (Giebel et al. 2013), affiliated to the *Roseobacter* group.
- *Pleomorphobacterium xiamenensis* gen. nov., sp. nov. (Yin et al. 2013), affiliated to the *Amaricoccus* group.
- *Sinorhodobacter ferrireducens* gen. nov., sp. nov. (Yang et al. 2013), affiliated to the *Rhodobacter* group.

Species:

- *Albimonas pacifica* (Li et al. 2013).
- *Defluviimonas aestuarii* (Math et al. 2013).
- *Gemmobacter lanyuensis* (Sheu et al. 2013b).
- *Gemmobacter megaterium* (Liu et al. 2013)
- *Litoreibacter halocynthiae* (Kim et al. 2013).
- *Loktanella sediminilitoris* (Park et al. 2013c).
- *Loktanella soesokkakensis* (Park et al. 2013d).
- *Pelagicola litorisediminis* (Park et al. 2013e).
- *Phaeobacter leonis* (Gaboyer et al. 2013).
- *Roseivivax pacificus* (Wu et al. 2013).
- *Roseovarius lutimaris* (Choi et al. 2013).
- *Roseovarius marisflavi* (Li et al. 2013).
- *Ruegeria intermedia* (Kämpfer et al. 2013b).
- *Shimia biformata* (Hameed et al. 2013).
- *Shimia haliotis* (Hyun et al. 2013).
- *Sulfitobacter porphyrae* (Fukui et al. 2013).
- *Thioclava dalianensis* (Zhang et al. 2013), with emended description of the genus.

Acknowledgments

The research of the authors on the taxonomy of *Rhodobacteraceae* has been founded through projects CGL2005-02292/BOS and CGL2010-18134/BOS (Spanish Government) and ACOMP06/177 and PROMETEO2012/040 (Generalitat Valenciana).

Abstract
Rhodobiaceae is a family within the order *Rhizobiales* of the class *Alphaproteobacteria*. This family embraces the genera *Afifella*, *Anderseniella*, *Lutibaculum*, *Parvibaculum*, *Rhodobium*, *Rhodoligotrophos*, *Tepidamorphus*, *and Bauldia*. With the exception of slightly thermophilic *Tepidamorphus gemmatus*, the other members of this family are mesophilic. The species of two genera of this family are photoheterotrophic when grown under anaerobic conditions in the light, while the species of the other genera are strictly chemoorganotrophic. The major fatty acids in all mesophilic species are straight chain, namely, $C_{18:1}\omega 7c$, $C_{16:0}$, and $C_{18:1}\omega 9c$, but in the slightly thermophilic *Tepidamorphus gemmatus*, the major fatty acid is $C_{19:0\ cyclo}\omega 8c$. The morphology of the species of the family is variable ranging from coccoid forms to rods, diving by budding asymmetric division; some possess prosthecae and complex structures. The members of this family have been isolated from a variety of environments, such as seawater, deep sea, hydrothermal vent, salterns, freshwater, hot springs, a mud volcano, activated sludge, and soil.

Taxonomy, Historical and Current

Short Description of the Family

The family *Rhodobiaceae* was described by Garrity et al. (2005b) based on the species of the genus *Rhodobium*. This family, as currently understood, is a rather diverse group of organisms, despite representing a monophyletic clade that comprises organisms that share mainly characteristics commonly encountered in many other *Alphaproteobacteria*, namely, fatty acids, polar lipids, and the respiratory quinones. Four of the species of this family possess bacteriochlorophyll *a*, are facultative photoheterotrophs, and may even be capable of anaerobic photolithotrophic growth. Other species are strictly chemoorganotrophic. The morphology is also diverse ranging from rod-shaped cells to cocci that divide by budding or asymmetric cell division. Some species produce prosthecae or form irregular appendages and hyphal-like budding structures.

The genus *Rhodobium* was initially described to include a species previously named *Rhodopseudomonas marina* (Imhoff 1983), as *Rhodobium marinum*, and the newly described species named *Rhodobium orientis* (Hiraishi et al. 1995). Later, Caumette et al. (2007) described a species that was named *Rhodobium pfennigii*. That same year the species *Rhodobium gokarnense* was described by Srinivas et al. (2007). These organisms have a marine origin, possess bacteriochlorophyll *a*, are phototrophic, and share morphological, physiological, and biochemical characteristics but actually belong to two clades. The taxonomy of the genus *Rhodobium* was later questioned because 16S rRNA gene sequence analysis showed that the validly named species of the genus *Rhodobium* did not form a monophyletic clade (Urdiain et al. 2008). These authors, therefore, proposed the genus *Afifella*, not only based on phylogenetic analysis but also based on the phenotypic and chemotaxonomic characteristics, for the species formerly named *R. marinum* and *R. pfennigii*, and now as *Afifella marina* and *Afifella pfennigii*.

The species now classified as *Bauldia consociata* and *B. litoralis* (Yee et al. 2010) were originally placed in the genus *Prosthecomicrobium*, as *P. consociatum* and *P. litoralum* by Bauld et al. (1983), and Vasil'eva et al. (1991). The classification of these organisms in the *Prosthecomicrobium* was based primarily on the presence of prosthecae and budding.

E. Rosenberg et al. (eds.), *The Prokaryotes – Alphaproteobacteria and Betaproteobacteria*, DOI 10.1007/978-3-642-30197-1_252,

The description of species of the genus *Parvibaculum* begins with the description of *P. lavamentivorans* by Schleheck et al. (2004) who were isolating organisms that degraded surfactants such as alkylbenzenesulfonate. The description of this organism was followed years later by the isolation of *P. indicum* and *P. hydrocarboniclasticum* (Lai et al. 2011; Rosario-Passapera et al. 2012). Two species, namely, *P. lavamentivorans* and *P. hydrocarboniclasticum*, are known to degrade and grow on surfactants and alkanes, respectively. These characteristics were not examined in *P. indicum*. It is noteworthy that *P. indicum* was considered by the authors to be a member of the family *Phyllobacteriaceae* (Lai et al. 2011).

The species *Anderseniella baltica* is a red-pigmented aerobic and chemoorganotrophic organism isolated from an anoxic marine sediment that forms pleomorphic rod-shaped cells and complex structures and short filaments with bulges (Brettar et al. 2007). *Tepidamorphus gemmat*us is the only extant slightly thermophic member of the family *Rhodobiaceae*. This organism, unlike most other species of the family, forms complex structures that in some cases resemble short hyphae.

The species *Rhodoligotrophos appendicifer* is a coccoid, red-pigmented, non-bacteriochlorophyll *a*-producing, aerobic, chemoorganotrophic organism that forms appendages that connect cells to each other (Fukuda et al. 2012). These authors show this species to be phylogenetically most closely related to the species of the genus *Parvibaculum* and belong to the family *Rhodobiaceae*.

The genus *Lutibaculum* comprises only one species named *L. baratangense* (Kumar et al. 2012). This rather nondescript, pale orange organism that forms coccoid- to rod-shaped cells is a mesophilic, aerobic, and chemoorganotrophic organism isolated from a marine mud volcano.

Rhodobiaceae Garrity et al. 2006

Rhodobiaceae (Rho.do.bi.a'ce.ae. N.L. neut. n. *Rhodobium*, type genus of the family; suff. *-aceae*, ending to denote family; N.L. fem. pl. n. *Rhodobiaceae*, the *Rhodobium* family).

The members of the family *Rhodobiaceae* of the order *Rhizobiales* stain Gram-negative and form rod-shaped cells, although more complex cellular structures appear in some genera such as *Tepidamorphus*. These organisms do not form endospores. Some species are strictly aerobic; others grow under aerobic conditions in the dark and under anaerobic conditions in the light. The species of the genera have ubiquinone 9, 10, 11 (U-9, U-10, U-11), and/or menaquinone 10 (MK-10) as the major respiratory lipoquinone. Unsaturated straight-chain fatty acids are the predominant acyl groups of the family; among these are $C_{18:1}\omega7c$, $C_{18:1}\omega9c$, $C_{19:0\ cyclo}\omega8c$, and $C_{18:1}\omega7c$ 11-methyl. $C_{16:0}$ is also a major fatty acid in *Rhodoligotrophos appendicifer*. Hydroxy fatty acids are also present in members of this family. The type genus of the family is *Rhodobium* (Hiraishi et al. 1995; Garrity et al. 2005b). *Afifella*, *Anderseniella*, *Lutibaculum*, *Parvibaculum*, *Rhodoligotrophos*, *Tepidamorphus*, and *Bauldia* are additional genera of the family (Albuquerque et al. 2010a; Brettar et al. 2007; Caumette et al. 2007; Fukuda et al. 2012; Schleheck et al. 2004; Kumar et al. 2012; Urdiain et al. 2008; Yee et al. 2010).

Phylogenetic Structure of the Family and Its Genera

The phylogenetic reconstruction of the family *Rhodobiaceae* shows a paraphyletic affiliation that is not supported by phenotypic characteristics. There are, in fact, pronounced differences in the public databases, on the genera that belong to this family, which do not agree entirely with the genera we consider to belong to the family *Rhodobiaceae* (*Fig. 21.1*). In the one hand, the species *Roseospirillum parvum* (Glaeser and Overmann 1999, 2001), which was later proposed to belong to the family *Rhodospirillaceae* (Garrity et al. 2005a), is classified in the family *Rhodobiaceae* in the List of Prokaryotic Names with Standing in Nomenclature (www.bacterio.cict.fr) and the NCBI Taxonomy Browser (http://www.ncbi.nlm.nih.gov/taxonomy). Despite the fact that some phenotypic characteristics are shared with the species of the genera *Rhodobium* and *Afifella*, the phylogenetic affiliation of this species clearly positions it within the family *Rhodospirillaceae*. On the other hand, the species of the genus *Bauldia* are not included in the family *Rhodobiaceae* by the List of Prokaryotic Names with Standing in Nomenclature and the NCBI Taxonomy Browser, and this genus is considered to be an unclassified member of the order *Rhizobiales*. However, our phylogenetic reconstruction affiliates the species of the genus *Bauldia* with a fairly high (about 93 %) 16S rRNA sequence similarity with *Rhodobium* spp.

Regarding the 16S rRNA identity, some lineages of the family *Rhodobiaceae* appear as closely related to genera included in other families as they are to genera of this family. Actually, only the neighbor-joining algorithm using the out-group-supporting sequences was the only analysis that showed all genera as monophyletic (*Fig. 21.1*). Alternative reconstructions using RAxML algorithm always gave paraphyletic topologies (data not shown). Four genera of this family are monospecific, namely, *Lutibaculum*, *Tepidamorphus*, *Rhodoligotrophos*, and *Anderseniella*; two genera comprise two species; the genus *Afifella* includes *A. pfennigii* and *A. marina*, while the genus *Rhodobium* comprises *R. orientis* and *R. gokarnense*. The genus *Parvibaculum* comprises three species, namely, *P. lavamentivorans*, *P. indicum*, and *P. hydrocarboniclasticum*. *Lutibaculum baratangense* is most closely related, based on 16S rRNA gene sequence analysis, to *Tepidamorphus gemmatus* (95 % similarity), *Bauldia consociata* (94.5 % similarity), and *Afifella pfennigii* (94.4 % similarity). The 16S rRNA gene sequence of *Anderseniella baltica* is most similar to the species of *Rhodobium* (92.6 %) and *Tepidamorphus gemmatus* (92.1 %). The two species of *Bauldia* share 96 % 16S rRNA gene sequence similarity and 95 % sequence similarity with *Lutibaculum baratangense*. The type strain of *Rhodobium*

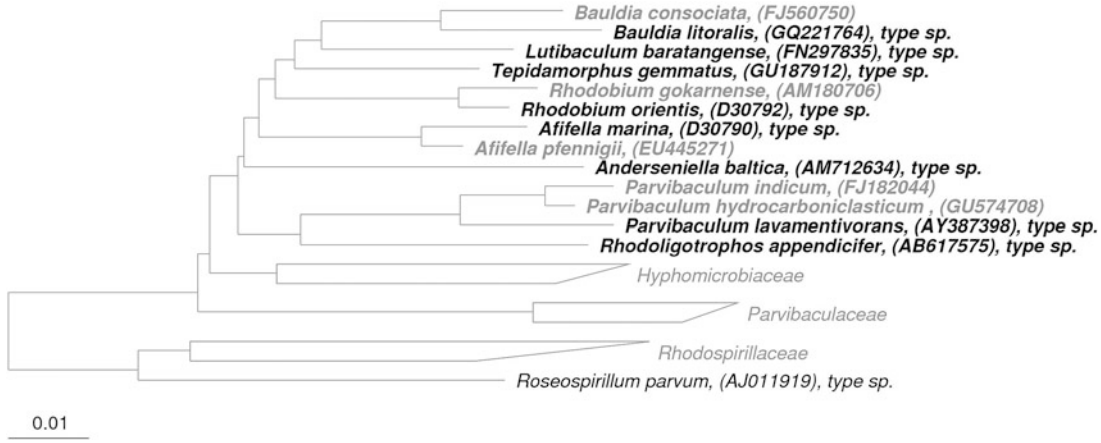

Fig. 21.1

Phylogenetic reconstruction of the family *Rhodobiaceae* based on 16S rRNA and created using the neighbor-joining algorithm with the Jukes-Cantor correction. The sequence datasets and alignments were used according to the All-Species Living Tree Project (LTP) database (Yarza et al. 2010; http://www.arb-silva.de/projects/living-tree). The tree topology was stabilized with the use of a representative set of nearly 750 high-quality type strain sequences proportionally distributed among the different bacterial and archaeal phyla. In addition, a 40 % maximum frequency filter was applied in order to remove hypervariable positions and potentially misplaced bases from the alignment. The scale bar indicates estimated sequence divergence

orientis (the type strain of the family) shares almost 99 % sequence similarity with the type strain of *Rhodobium gokarnense*. Despite the very similar 16S rRNA sequence between both type strains, the DNA: DNA hybridization is reported to have a relatedness of only 35.1 % (Srinivas et al. 2007), which would indicate that these organisms belong to two different species. The two species of the genus *Afifella* share about 98.3 % 16S rRNA sequence similarity with each other. The species *Rhodoligotrophos appendicifer* appears to be the most distantly related organism in the family *Rhodobiaceae* sharing only 92.7 % 16S rRNA sequence similarity with *Lutibaculum baratangense*.

Molecular Analyses

Genome Comparison

The only member of the family *Rhodobiaceae* to have the whole genome sequenced is *Parvibaculum lavamentivorans* strain DS-1^T, because it completely degrades laundry surfactants. In this respect the organism is potentially important for bioremediation (Schleheck et al. 2011). The genome is large with 3,914,745 bp and a total of 3,714 genes. The inability of the organism to assimilate several carbon sources examined is confirmed by the lack of candidate genes for ATP-dependent sugar uptake systems. There are no known homologues for amino acid or di-/oligopeptide transport systems. The organism has the genes necessary for the synthesis of all amino acids and essential cofactors. Most interestingly, the genome of *P. lavamentivorans* possesses a multitude of genes for alkyl-chain degradation.

Phenotypic Analyses

The main features of members of the family *Rhodobiaceae* are listed in *Table 21.1*. The main features of members of the genera *Afifella*, *Anderseniella*, *Lutibaculum*, *Parvibaculum*, *Rhodobium*, *Rhodoligotrophos*, *Tepidamorphus*, and *Bauldia* are listed in *Tables 21.2*, *21.3*, and *21.4*.

Afifella Urdian et al. 2009b

Afifella (A.fi.fel'la. N.L. fem. dim. n. *Afifella*, named after S. Afif, a British philosopher and painter in recognition of his expertise and guidance in the subject of the philosophical tendency of structuralism, essential for the development and understanding of taxonomy as a science).

Afifella forms motile rod-shaped cells that divide by budding and asymmetric cell division. Mesophilic, marine bacteria that require NaCl for growth and grow at seawater and environments with higher salinities. Chemoorganotrophic growth in the dark can occur aerobically or microaerobically and in some cases fermentatively. The organisms grow anaerobically in the light by photoheterotrophic metabolism and may be photolithotrophic on thiosulfate. Phototrophic grown cells contain intracytoplasmic membranes of the lamellar type together with bacteriochlorophyll *a* and carotenoids belonging to the spirilloxanthin series. The absorption maxima of living cells for *A. marina* and *A. pfennigii* are, respectively, 375, 483, 516, 533, 590, 803, and 883 nm and 395, 483, 512, 548, 594, and 909 nm. The major fatty acid is $C_{18:1}\omega7c$. When grown aerobically in the dark, species of this genus exhibit a quinone system with ubiquinone 10 (U-10) predominating and significant

Table 21.2

Comparison of selected characteristics of members of the genera of *Afifella*, *Anderseniella*, *Parvibaculum*, *Lutibaculum*, *Rhodobium*, *Rhodoligotrophos*, *Tepidamorphus*, and *Bauldia*. Some characteristics were examined in some species but not others as follows; in the Api ZYM tests, *Anderseniella baltica*, *Parvibaculum indicum*, and *P. lavamentivorans* are positive for alkaline phosphatase, esterase (C 4), esterase lipase (C 8), and leucine arylamidase and negative for α-*chymotrypsin*, α-galactosidase, β-glucuronidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, and α-fucosidase. *Afifella marina* assimilates caproate, ascorbate, and galactose. *Afifella pfennigii* assimilates glutamate, aspartate, cyclohexanecarboxylate, crotonate, 2-oxoglutamate, and cysteine, but does not assimilate caprylate, pelargonate, palmitate, gluconate, glycolate, gallate, nicotinate, catechol, *N*-acetylglucosamine, methionine, glycine betaine, thioacetamide, trehalose, and butanol. *A. marina* and *A. pfennigii* assimilate acetate, butyrate, pyruvate, succinate, casamino acids, and yeast extract, but does not assimilate benzoate and methanol. *A. baltica* does not assimilate D-arabinose, mannose, maltose, *N*-acetylglucosamine, caprate, phenylacetate, and gluconate; does not hydrolyse DNA, urea, chitin, starch, and casein; and does not produce acid from any carbon source in the Api 50CH. *P. indicum* and *P. lavamentivorans* assimilate L-arabinose and does not assimilate mannose, maltose, *N*-acetylglucosamine, caprate, phenylacetate, potassium gluconate, and trisodium citrate. In the biolog GN2 test, *A. baltica*, *P. indicum*, and *P. lavamentivorans* are negative for α-cyclodextrin, dextrin, *N*-acetyl-D-galactosamine, *N*-acetyl-D-glucosamine, adonitol, D-fructose, L-fucose, D-galactose, gentiobiose, α-D-glucose, α-D-lactose, lactulose, maltose, D-mannitol, D-mannose, D-melibiose, D-psicose, D-raffinose, L-rhamnose, D-sorbitol, sucrose, D-trehalose, turanose, xylitol, D-galactonic acid lactone, D-glucosaminic acid, D-glucoronic acid, *p*-hydroxybutyric, malonic acid, quinic acid, D-sacharic, bromosuccinic acid, D-alanine, L-alanine, L-asparagine, glycyl L-aspartic acid, glycyl L-glutamic acid, L-histidine, L-leucine, L-ornithine, L-phenylalanine, L-proline, L-pyroglutamic acid, D-serine, L-serine, L-threonine, DL-carnitine, uronic acid, inosine, thymidine, phenylethylamine, putrescine, 2-aminoethanol, 2,3-butanediol, α-D-glucose 1-phosphate, and D-glucose 6-phosphate. *P. indicum* and *P. lavamentivorans* are sensitive to erythromycin, gentamicin, kanamycin, carbenicillin, cefazolin, chloromycetin, cefobid, rifampicin, minomycin, piperacillin, and vibramycin and resistant to lincomycin, oxacillin, ofloxacin, cephradine, cefalexin, ciprofloxacin, and metronidazole

amounts of menaquinone 10 (MK-10). S*ym*-homospermidine (HSPD) is the predominate polyamine. The major polar lipids are diphosphatidylglycerol (DPG), phosphatidylglycerol (PG), phosphatidylcholine (PC), phosphatidylethanolamine (PE), an unknown aminolipid (AL), and an unknown glycolipid (GL); phosphatidylmonomethylethanolamine (PME) is also present. The DNA G+C content varies between 62.2 and 67.5 mol%. The species of this genus have been isolated from saline environments. The type species is *Afifella marina*. The type strain is DSM 2698^T (=BN 126^T =ATCC 35675^T =CIP 104405^T =NBRC 100343^T) (Imhoff 1983; Urdiain et al. 2008). *Afifella pfennigii* is the second species of this genus; the type strain is AR2102^T (=DSM 17143^T =ATCC BAA-1145^T), isolated from a benthic microbial mat in a brackish pond located on the rim of the Rangiroa atoll (French Polynesia) (Caumette et al. 2007; Urdiain et al. 2008).

For Symbols see *Table 21.1*

Anderseniella Brettar et al. 2007

Anderseniella (An.der.sen.i.el'la. N.L. fem. dim. n. *Anderseniella*, named in honor of the late marine scientist Valérie Andersen, Observatoire Océanologique de Villefranche sur Mer, France, in recognition of her valuable work on marine ecosystems).

Anderseniella forms rod-shaped to pleomorphic cells and is nonmotile. Strictly aerobic and chemoorganotrophic. Catalase and oxidase positive. Cells contain carotenoids but not bacteriochlorophyll *a*. Mesophilic requiring NaCl for growth. Predominant fatty acid is $C_{18:1}\omega7c$, and other major fatty acids are $C_{16:0}$ and $C_{19:0\ cyclo}\omega8c$. The organism does not produce acid from carbohydrates with the API 50CH and metabolizes few organic acids and L-arabinose on the Biolog GN2. The DNA G+C content of the type strain is 61.2 mol%. The type species is *Anderseniella baltica*. The type strain BA141^T (=CIP 109499^T =LMG 24028^T) was isolated from the surface layer of anoxic sediment in central Baltic Sea (Brettar et al. 2007).

Lutibaculum Kumar et al. 2012

Lutibaculum (Lu.ti.ba'cu.lum. L. n. *lutum*, mud; L. neut. n. *baculum*, rod; N.L. neut. n. *Lutibaculum*, rod from mud).

Lutibaculum forms oval to rod-shaped cells, motile by means of two monopolar flagella. Strictly aerobic and chemoorganotrophic. Catalase and oxidase positive. Cells contain carotenoids but not bacteriochlorophyll *a*. Mesophilic. Diphosphatidylglycerol (DPG), phosphatidylglycerol (PG), and phosphatidylethanolamine (PE) are the major polar lipids. Major fatty acid is $C_{18:1}\omega7c$. Ubiquinone-10 (U-10) is the major respiratory lipoquinone. The organism produces acid from several carbohydrates and assimilates several sugars and amino acids. The DNA G+C content of the type strain is 70.5 mol%. The type species is *Lutibaculum baratangense*. The type strain AMV1^T (=KCTC 22669^T =NBRC 105799^T) was isolated from a soil sample collected from a mud volcano of Baratang Island, Middle Andaman, India (Kumar et al. 2012).

Parvibaculum Schleheck et al. 2004

Parvibaculum (Par.vi.ba'cu.lum. L. adj. *parvus*, small; L. neut. n. *baculum*, stick; N.L. neut. n. *Parvibaculum*, small stick).

Parvibaculum forms motile rod-shaped cells. Strictly aerobic and chemoorganotrophic. Catalase and oxidase variable. The members of this genus assimilate a few carbon sources such as acetate and L-arabinose but seem to be capable of assimilating long-chain alkanes and derivatives like alkylbenzenesulfonate (LAS). Mesophilic and require NaCl for growth. Diphosphatidylglycerol (DPG), phosphatidylglycerol (PG), phosphatidylcholine (PC), and phosphatidylethanolamine (PE) are the major polar lipids. According to Schleheck et al. (2004), the predominant fatty acid of *P. lavamentivorans* is $C_{18:1}\omega7c$ and $C_{19:0\ cyclo}\omega8c$, while $C_{18:1}\omega7c$ 11-methyl was not detected; however, according to Lai et al. (2011), the predominant fatty acids of the same species are $C_{18:1}\omega7c$, $C_{18:1}\omega7c$ 11-methyl, and $C_{19:0\ cyclo}\omega8c$. Ubiquinone-11 (U-11) is the major respiratory lipoquinone. The DNA G+C content varies between 62.1 and 64.0 mol%. The type species is *Parvibaculum lavamentivorans*. The type strain is DS-1^T (=DSM 13023^T =NCIMB 13966^T) (Schleheck et al. 2004). *Parvibaculum indicum* is another species of this genus, and the type strain is P31^T (=LMG 24712^T =CCTCC AB 208230^T =MCCC 1A01132^T), isolated from deep-sea water of the Indian Ocean (Lai et al. 2011). More recently, the species *Parvibaculum hydrocarboniclasticum* was described based on strain EPR92^T (=DSM 23209^T =JCM 16666^T), which was isolated from hydrothermal vent fluids collected from the East Pacific Rise (Rosario-Passapera et al. 2012).

Rhodobium Hiraishi et al. 1995; Emend. Urdian et al. 2008

Rhodobium (Rho.do'bi.um. Gr. n. *rhodos*, rose; Gr. n. *bios*, life; N.L. neut. n. *Rhodobium*, red life).

Rhodobium forms rod-shaped cells. Cells divide by budding and asymmetric cell division and grow aerobically in the dark and anaerobically in the light; under these conditions the organisms are photoorganotrophic. Cells contain carotenoids and bacteriochlorophyll *a*. The absorption maxima of living cells for *R. orientis* and *R. gokarnense* are, respectively, 377, 468, 500, 530, 591, 802, and 870 nm and 370, 402, 488, 530, 590, 803, and 872 nm. Chemoorganotrophic in the dark depending on several single-carbon sources for growth such as organic acids, short-chain fatty acids, and a few sugars. Energy can be derived from reduced sulfur compounds. Mesophilic and require NaCl for growth. Phosphatidylglycerol (PG), diphosphatidylglycerol (DPG), phosphatidylcholine (PC), phosphatidylethanolamine (PE), and phosphatidylmonoethanolamine (PME) are the major polar lipids. Predominant fatty acid is $C_{18:1}\omega7c$. U-10 and MK-10 are the major respiratory lipoquinone. Spermidine (SPD) and spermine (SPM) are the predominate polyamines. The DNA G+C content varies between 65.2 and 65.8 mol%. The type species is *Rhodobium orientis*. The type strain MB312^T (=JCM 9337^T) was isolated from seawater samples with sediment mud (Hiraishi et al. 1995; Urdiain et al. 2008, 2009a, b). *Rhodobium gokarnense* is the second species of this genus; the type strain is JA173^T (=ATCC BAA-1215^T =DSM 17935^T =JCM 13532^T), isolated from a saltern in Gokarna, India (Srinivas et al. 2007; Urdiain et al. 2008, 2009a, b).

Rhodoligotrophos Fukuda et al. 2012

Rhodoligotrophos (Rho.do.li.go.tro'phos. Gr. n. *rhodon*, the rose; Gr. adj. *oligos*, little, few; Gr. masc. or fem. n. *trophos*, feeder, rearer, that which nourishes; N.L. masc. n. *Rhodoligotrophos*, red utilizer of few substrates).

Rhodoligotrophos forms nonmotile irregular coccoids cells. Chemoorganotrophic. Grows aerobically or microaerobically. Catalase and oxidase positive. Mesophilic. The organism assimilates a few organic acids and a few sugars. Predominant fatty acid is $C_{16:0}$, and other major fatty acids are $C_{18:1}\omega9c$ and $C_{18:1}\omega7c$. Ubiquinone 9 (U-9) and ubiquinone 10 (U-10) are the major respiratory lipoquinone. The DNA G+C content of the type strain is 61.1 mol%. The type species is *Rhodoligotrophos appendicifer*. The type strain 120-1^T (=JCM 16873^T =ATCC BAA-2115^T) was isolated from a freshwater lake in Skarvsnes, Antarctica (Fukuda et al. 2012).

Tepidamorphus Albuquerque et al. 2010b

Tepidamorphus (Te.pi.da.mor'phus. L. adj. *tepidus* -a -um, moderately warm, lukewarm, tepid; Gr. masc. adj. *amorphous*, without form, shapeless; N.L. masc. n. *Tepidamorphus*, an organism without a distinctive morphology that grows at warm temperatures).

Tepidamorphus forms motile irregular rod-shaped cells with hyphal-like structures; multiplies by budding. Strictly aerobic and chemoorganotrophic. Catalase and oxidase positive. Slightly thermophilic. Bacteriochlorophyll *a* is not present. Diphosphatidylglycerol (DPG), phosphatidylglycerol (PG), phosphatidylcholine (PC), phosphatidylethanolamine (PE), and phosphatidylmonoethanolamine (PME) are the major polar lipids. Major fatty acid is $C_{19:0\ cyclo}\omega8c$. Ubiquinone 10 (U-10) is the major respiratory lipoquinone. The organism produces acid from several carbohydrates and assimilates sugars, organic acids, and amino acids. The DNA G+C content varies between 65.6 and 66.9 mol%. The type species is *Tepidamorphus gemmatus*. The type strain CB-27A^T (=DSM 19345^T =LMG 24113^T) was isolated from a runoff of the hot spring known as Caldeira da Barrela, Furnas, on the Island of São Miguel in the Azores, Portugal. Strain CB-26A (=DSM 19344 =LMG 24114) is an additional strain of this species (Albuquerque et al. 2010a).

Bauldia Yee et al. 2010

Bauldia (Baul' di.a. N.L. fem. n. *Bauldia*, of Bauld, named in honor of John Bauld, an Australian microbiologist who isolated, investigated, and named members of the genus *Prosthecomicrobium* and *Planctomyces maris*).

Bauldia forms nonmotile budding prosthecate cells with short appendages. Strictly aerobic and chemoorganotrophic. Catalase and oxidase positive. Mesophilic. Several carbon sources can be used for growth including sugars, polyols, and organic acids. The DNA G+C content varies between 66 and 69 mol%. The type species is *Bauldia litoralis*. The type strain 524-16^T (=NCIB 2233^T = ATCC 35022^T) was isolated from littoral marine waters from the Washington coastlines, USA (Bauld et al. 1983; Yee et al. 2010). *Bauldia consociata* is the second species of this genus; the type strain is 11^T (=VKM B-2498^T =CCM 7594^T) and was isolated from the soil (Vasiléva et al. 1991, 2009; Yee et al. 2010).

Isolation, Enrichment, and Maintenance Procedures

Afifella marina was isolated from marine and moderately hypersaline waters and marine coastal sediments using DSM medium 27 http://www.dsmz.de/microorganisms/medium/pdf/DSMZ_Medium27.pdf with 3 % NaCl (Hiraishi et al. 1995; Imhoff 1983).

Afifella pfennigii was isolated from a red layer of a microbial mat in a brackish water pond on the rim of Rangiroa atoll, French Polynesia (Caumette et al. 2007). The salinity was 7 g L^{-1} and the temperature of the water above the mat was 34 °C (Mao Che et al. 2001). The organism was isolated from

deep-agar dilution series prepared from the red layer of the microbial mat. The medium, prepared according to Pfennig and Trüper (1992), contained the following (per liter deionized water): 0.35 g KH_2PO_4, 0.05 g $CaCl_2 \cdot 2H_2O$, 0.5 g NH_4Cl, 10 g NaCl, 0.7 g $MgCl_2 \cdot 6H_2O$, 0.35 g $MgSO_4 \cdot 7H_2O$, 1.5 g $NaHCO_3$, 1 mL vitamin solution V7 (Pfennig and Trüper 1981), 1 mL trace element solution SL12B containing (per liter of deionized water) 3 g $Na_2EDTA \cdot 2H_2O$, 1.1 g $FeSO_4 \cdot 7H_2O$, 0.3 g H_3BO_3, 0.19 g $CoCl_2 \cdot 6H_2O$, 0.05 g $MnCl_2 \cdot 4H_2O$, 0.042 g $ZnCl_2$, 0.024 g $NiCl_2 \cdot 2H_2O$, 0.018 g $NaMoO_4 \cdot 2H_2O$, 0.002 g $CuCl_2 \cdot 2H_2O$ (Overmann et al. 1992), 0.5 g yeast extract, 1.35 g (5 mM) disodium succinate, 0.68 g (5 mM) sodium acetate, and pH 6.8. For enrichments and to obtain better growth of pure cultures, the growth medium was supplemented with sodium ascorbate (0.5 g L^{-1}) to maintain reducing conditions. The cultures were incubated at 30 °C with a light intensity of 50 µmol quanta m^{-2} s^{-1} measured within the photosynthetically active radiation (16 h light, 8 h dark). Purity of cultures was checked by microscopic observations as well as through growth tests in oxygen gradients established in deep-agar AC medium (Difco), supplemented with thiosulfate (5 mM), and incubated in the dark. Pure cultures in liquid medium were stored in screw-capped bottles at 4 °C in the dark.

Anderseniella baltica was isolated from the black anoxic surface of sediment collected at a sampling site in the central Baltic Sea, station TEILI1, at a depth of 165 m (Brettar et al. 2007). The sediment sample was serially diluted with sterile seawater, spread on agar plates, and incubated in the dark for 3 weeks. Half-strength Zobell agar was used for enrichments (5 g Bacto peptone, 1 g yeast extract, 15 g Bacto agar, 250 mL aged seawater, 750 mL deionized water, pH 7.2) (Oppenheimer and ZoBell 1952). The strain grew well on half-strength Zobell agar, in half-strength marine broth 2216 (Difco), and on marine agar 2216 (Difco).

Lutibaculum baratangense was isolated from a soil sample collected from a mud volcano of Baratang Island, Middle Andaman, India (Kumar et al. 2012). The solid sample (100 mg) was suspended in water containing 1 % NaCl and plated on Zobell's marine agar medium containing (per liter of deionized water) 5 g Bacto peptone, 1 g yeast extract, 19.4 g NaCl, 8.8 g $MgCl_2$, 3.24 Na_2SO_4, 1.8 $CaCl_2$, 0.55 g KCl, 0.16 g $NaHCO_3$, 0.1 g $C_6H_5FeO_7$, 0.08 g KBr, 0.034 g $SrCl_2$, 0.022 g H_3BO_3, 0.008 g Na_2HPO_4, 0.004 g Na_2SiO_3, 0.0024 g NaF, 0.0016 g NH_4NO_3, and 15 g Bacto agar (Zobell 1941) and incubated at room temperature for 15 days.

Parvibaculum hydrocarboniclasticum was isolated from the Tica vent on East Pacific Rise at a depth of 2,513 m (Rosario-Passapera et al. 2012). Hydrothermal fluids were collected with titanium samplers. A sample (1 mL) was inoculated into 10 mL of artificial seawater minimal medium (ASW MM) containing (per liter of deionized water) 23.6 g NaCl, 0.64 g KCl, 4.53 g $MgCl_2 \cdot 6H_2O$, 5.94 g $MgSO_4 \cdot 7H_2O$, 1.3 g $CaCl_2 \cdot 2H_2O$, 43 mg $Na_2HPO_4 \cdot 7H_2O$, 0.22 g $NaNO_3$, and 0.65 g NH_4Cl (Crespo-Medina et al. 2009) and serially diluted in the same medium. Each tube was then supplemented with dodecane, as a single-carbon and energy source, and incubated at 28 °C. A pure culture was isolated by successive transfers on ASW MM solidified with 1.5 % (w/v) Noble agar (Sigma) with dodecane. The organism can be cultured in artificial seawater (ASW) medium containing (per liter of deionized water) 24 g NaCl, 0.7 KCl, 7 g $MgCl_2$, 3 g yeast extract, and 2.5 g peptone and in low-stretch ASW (LS ASW) medium (modified ASW) containing 0.01 % (w/v) yeast extract and 0.05 % (w/v) peptone at 35 °C.

Parvibaculum indicum was isolated from deep-sea water sample of the Southwest Indian Ridge (Lai et al. 2011). The sample was collected using Niskin bottles from a depth of 1,068 m. The water sample was enriched with a PAH mixture (final concentrations 200 p.p.m. each) of naphthalene, phenanthrene, anthracene, and pyrene dissolved in crude oil. 1 mL of the enrichment culture was transferred into 100 mL medium containing (per liter of water) 1 g NH_4NO_3, 0.5 g KH_2PO_4, and 2.8 mg $FeSO_4 \cdot 7H_2O$, with the PAH mixture as the only carbon and energy source. PAH stock solution in chloroform was added to the flasks to the same concentrations as above, and the flasks were then shaken at 160 r.p.m. for 2 days to evaporate the chloroform before inoculation. After 3 weeks of incubation at 28 °C with shaking at 160 r.p.m., 1 mL of the culture was transferred to the same medium for further enrichment (Lai et al. 2009). One strain was isolated on a 216-L marine agar containing (per liter of seawater) 1 g sodium acetate, 10 g tryptone, 2 g yeast extract, 0.5 g sodium citrate, 0.2 g NH_4NO_3, 15 g agar, and pH 7.5. The organism is routinely cultured on a 216-L medium.

Parvibaculum lavamentivorans was isolated from activated sludge and from American forest soil (Schleheck et al. 2000). Activated sludge as an inoculum for experiments was obtained from the urban sewage treatment plants in Konstanz and Radolfzell, Germany, and from the industrial plant in Ludwigshafen, Germany. Activated sludge obtained from urban sewage treatment plants and American forest soil was used as inoculums of phosphate-buffered minimal-salts medium. Enrichment cultures on LAS or LADPEDS as the sole source of carbon and energy for growth were performed with a 5 % (v/v) inoculum in 3-mL cultures screw cap tubes aerated at 30 °C on a roller. Cultures were deemed positive when growth occurred and substrate decreases as assessed by HPLC. Anaerobic mineral salts medium was supplemented with 1.0 mM LAS, 20 mM succinate, and 20 mM acetate, and cultures were incubated at 25 °C about 25 cm from a 40-W lamp. Enrichment cultures were streaked on selective agarose plates prepared by solidifying 1 mM LADPEDS-salts medium with 1 % agarose. Pinpoint colonies developed after 3 weeks at 30 °C in the dark. Single colonies were picked into selective liquid medium (1 mM LADPEDS-salts), e.g., 3-mL cultures with 10 mg of glass wool in 30-mL tubes aerated on a roller. The culture was subjected to two further rounds of plating and picking, and microscopic purity was confirmed by the absence of colonies on nutrient agar within 1 week.

Rhodobium gokarnense was isolated from a soil sample with a pH of 6.8 and a temperature 30 °C in a saltern in Gokarna, India (Srinivas et al. 2007). One strain was isolated from photoheterotrophic enrichments of the soil sample. Pfennig's

medium was used (Pfennig and Trüper 1992)—0.34 g KH_2PO_4, 0.34 g NH_4Cl, 0.5 g $MgSO_4 \cdot 7H_2O$, 0.05 g $CaCl_2 \cdot 2H_2O$, and 0.34 g KCl—supplemented with NaCl (2 % w/v) and pyruvate (0.3 % w/v) as single-carbon source and ammonium chloride (0.12 % w/v) as nitrogen source used for photoheterotrophic growth under light (2,400 lx) at 30 °C. Purification of the culture was done by using the repeated agar shake dilution method (Pfennig and Trüper 1992). Purified cultures were grown in completely filled screw cap test tubes (Srinivas et al. 2006).

Rhodobium orientis was isolated from seawater samples with sediment mud obtained from two different areas in Japan (Hiraishi et al. 1995). One of the samples was collected from the bottom of a tidal pool (30–50 cm) in Goto Island, Nagasaki, and the other was obtained from the bottom of a tidal pool (50–70 cm) in Makurazaki, Kagoshima. Enrichments were performed in screw cap 20-mL test tubes which contained 10 mL of mineral base (Hiraishi and Kitamura 1984) supplemented with 10 mM acetate, 10 mM succinate, 2 mM thiosulfate, 2 mM sodium ascorbate, 2.5 % (w/v) NaCl, 0.01 % (w/v) yeast extract, and 1 mL L^{-1} vitamin solution VA (10 mg biotin, 35 mg niacin, 30 mg thiamine HCl, 20 mg *p*-aminobenzoic acid, 10 mg pyridoxine HCl, 10 mg calcium pantothenate, 5 mg vitamin B_{12}, 100 ml deionized water) (Imhoff and Trüper 1992) and were inoculated with 0.1 or 1 mL samples of seawater samples with mud, completely filled with the same medium and incubated at 28 °C under light (2,000 lx). The agar shake technique (Imhoff and Trüper 1992) was used to isolate colonies from the enrichment cultures on the medium described above containing 0.8 % agar. Single colonies that were pink to red were picked from the tubes and then purified using agar plates and the GasPak anaerobic jars. The organism that was routinely cultured in MMYS-III medium contained mineral base RM2, 20 mM sodium DL-malate as the carbon source, 2 mM thiosulfate, 5 % (w/v) NaCl, and 0.1 % (w/v) yeast extract as the growth factor, anaerobically in the light in screw cap test tubes or bottles filled with medium.

Rhodoligotrophos appendicifer was isolated from freshwater samples collected at the bottom of a freshwater lake, Naga-ike, in Skarvsnes region, Antarctica (Fukuda et al. 2012). The sample was added to 0.1× Luria-Bertani (LB) medium containing (per liter of tap water) 1 g tryptone, 0.5 g yeast extract, and 5 g NaCl and incubated at 25 °C. The resulting culture was transferred to 0.1× LB medium solidified with 2 % agar (w/v). Red colonies were found on the plate medium after incubation. The isolate grew well in 0.25× LB medium; however, no growth was observed in medium containing organic compounds at high concentration (per liter of tap water) 7.5 g tryptone, 3.8 g yeast extract, and 5 g NaCl. The strain was able to grow in NZCYM medium containing (per liter of tap water) 10 g NZ amine, 5 g yeast extract, 1 g NaCl, 2 g MgSO4·7H_2O, and 1 g casamino acids or in half-strength marine broth 2216 medium (Difco) at 30 °C.

Tepidamorphus gemmatus was isolated from a hot spring at Caldeira da Barrela, Furnas, on the Island of São Miguel in the Azores, Portugal (Albuquerque et al. 2010a). Water samples were maintained without temperature control for 6 days, and then 10–100 mL were filtered through membrane filters (Gelman type GN-6; pore size 0.45 μm; diameter 47 mm). The filters were placed on the surface of solidified *Thermus* medium (Williams and da Costa 1992) containing (per liter of media) 1 g yeast extract (Difco), 1 g tryptone (Difco), 20 g agar (Difco), 100 mL of a macronutrients solution 10x concentrated, 10 mL of a trace elements solution 100x concentrated, and 10 mL of 0.17 mM $FeCl_3 \cdot 6H_2O$. The 10× concentrated macronutrients solution contained per liter 1 g nitrilotriacetic acid, 0.6 g $CaSO_4 \times 2H_2O$, 1 g $MgSO_4 \cdot 7H_2O$, 0.08 g NaCl, 1.03 g KNO_3, 6.89 g $NaNO_3$, and 1.11 g $NaHPO_4$. The 100x concentrated trace elements solution contained per liter 0.22 g $MnSO_4 \cdot H_2O$, 0.05 g $ZnSO_4 \cdot 7H_2O$, 0.05 g H_3BO_3, 0.0025 g $CuSO_4 \cdot 5H_2O$, 0.0025 g $Na_2MoO_4 \cdot 2H_2O$, and 0.0046 g $CoCl_2 \cdot 6H_2O$. The plates were wrapped in plastic to prevent evaporation and incubated at 50 °C for up to 4 days. Cultures were purified by subculturing on solidified *Thermus* medium at 50 °C. The strain was able to grow on solidified Degryse medium 162 (Degryse et al. 1978), containing 0.25 % (w/v) yeast extract and 0.25 % (w/v) tryptone. Degryse medium contained the following components per liter of media: 2.5 g yeast extract (Difco), 2.5 g tryptone (Difco), 20 g agar (Difco), 100 mL of a macronutrients solution 10× concentrated, 5 mL of a trace elements solution 100x concentrated, 0.5 mL of 0.01 M $C_6H_5O_7Fe \cdot 5H_2O$, 10 mL of 0.2 M KH_2PO_4, and 15 mL of 0.2 M $Na_2HPO_4 \cdot 12H_2O$. The 10x concentrated macronutrient solution contained per liter 1 g nitrilotriacetic acid, 0.4 g $CaSO_4 \cdot 2H_2O$, and 2 g $MgSO_4 \cdot 7H_2O$. The 100× concentrated trace elements solution contained per liter 0.22 g $MnSO_4 \cdot H_2O$, 0.05 g $ZnSO_4 \cdot 7H_2O$, 0.05 g H_3BO_3, 0.0025 g $CuSO_4 \cdot 5H_2O$, 0.0025 g $Na_2MoO_4 \cdot 2H_2O$, and 0.0046 g $CoCl_2 6H_2O$. The organism is routinely grown in *Thermus* or Degryse liquid medium or on solidified *Thermus* or Degryse medium at 45–50 °C.

Bauldia consociata was isolated from soil habitats and compost with high cellulolytic activity (Vasiléva et al. 1991; Yee et al. 2010).

Bauldia litoralis was isolated from littoral marine waters from the Washington State (USA) coastline (Bauld et al. 1983). The isolation of organism was achieved when small pieces of *Ulva* spp. fronds, located on rocks in the sampling area, were incubated in dilute peptone enrichment medium [0.01 % peptone (w/v)]. The incubation temperature for enrichments is not mentioned in the original paper.

Members of this family do not require special procedures for maintenance and long-term storage. Generally strains are maintained on the isolation medium at 4 °C for a few days and can be stored frozen at –70 °C in medium containing 15 % glycerol without loss of viability. Long-term preservation is by lyophilization.

Ecology

Habitat

Most of the species of the family *Rhodobiaceae* are of marine origin; only the strains of the species *Rhodoligotrophos*

appendicifer and *Tepidamorphus gemmatus* were isolated from freshwater: the first from a small freshwater lake in Antarctica and the latter from a hot spring in the Azorean Island of São Miguel venting freshwater.

Environmental clones with 16S RNA similar to cultured strains can add to our knowledge of the habitats colonized by phylogenetic relatives. For example, the most closely related 16S rRNA genes to *Rhodoligotrophos appendicifer* (JN391616, 94 % sequence similarity) have been retrieved from biofilm-activated sludge system for nitrogen and phosphorus removal. Sequences very closely related to *Tepidamorphus gemmatus* have been retrieved from (DQ23097, 99 % sequence similarity) the deep aquifer of the Kalahari Shield in South Africa (Gihring et al. 2006), which is low in salinity alkaline and has a temperature of 45 °C, and white plague disease-associated community of the Caribbean coral *Montastraea faveolata* (FJ202923, 98 % sequence similarity). The latter clone implies that organisms closely related to *Tepidamorphus gemmatus* also inhabit marine environments.

The species of the genus *Rhodobium* have been isolated from marine ecosystems; the species *R. gokarnense* was isolated from salterns in India. Environmental 16S rRNA clone sequences related to the genus *Rhodobium* have not been deposited in the databases; the most closely related being sequences JN391616 and FJ623370, both of which share 94 % sequence similarity with *R. gokarnense* and were isolated from activated sludge. The same is true of uncultured organisms related to *R. orientis* such as DQ230971 (94 % sequence similarity) from the subsurface water of the Kalahari Shield in South Africa, JN391616 (94 % sequence similarity) from an activated sludge and AB630707 (94 % sequence similarity) from biofilms of a freshwater Antarctic lake. There are only a few environmental sequences that have low similarity with the two *Afifella* spp. These are EU528243 retrieved from what appears to be a tributary of a Kentucky Reservoir (USA) with sequence similarities of 98 % to *A. marina* and 96 % to *A. pfennigii*. Sequence JF344261 with 94 % sequence similarity to both *Afifella* spp. was retrieved from marine sediment after an oil spill in Galicia (Spain).

In contrast to the paucity of 16S rRNA gene sequences to the above mentioned organisms, there are several clones that are closely related to *Anderseniella baltica*, many of which were obtained from mangrove environments or marine sediments, namely, AM176883, EF061946, GU180151, and EU700185, all with 98 % sequence similarity. Two other clones (EU700185 and DQ028258) were obtained from marine plankton and aquaculture ponds that also shared 98 % sequence similarity with this species.

Many environmental 16S rRNA sequences have been reported with similarities of 99 % with the type strain of the species *Parvibaculum lavamentivorans*. Many of these are of marine origin (GU474930, HM598180, HM598131, and FM242452); others are saline alkaline soils (HQ697798 and JF727690) or deep aquifers (AB478001), natural asphalt from the La Brea Tar Pits in California (EF157176), livestock manure (AB594043), and chromium-contaminated tannery sludge (HM468043). This wide distribution of organisms closely related to *Parvibaculum lavamentivorans* contrasts with the rarity of environmental sequences that are similar to the species *P. indicum* and *P. hydrocarboniclasticum*. Only one sequence with a similarity of 99 % (HQ326336) to both species was reported from seawater reverse osmosis (SWRO) filters and are deposited in the databases.

The species *Bauldia consociata* were isolated from the soil, while the species *Bauldia litoralis* was from leaves of the macroalga *Ulva* sp. Sequences with high similarity (97–98 %) with *Bauldia consociata* were retrieved from a freshwater lake in Antarctica (AB630694), highly alkaline saline soil of the former lake Texcoco in Mexico (FJ152803), soil (JQ978641, HQ864104), rock biofilms from an ancient gold mine (HE614829, FM253576), and perhaps more surprisingly inflammatory bowel disease (HQ755623). Sequences very closely related to *B. litoralis* have been retrieved from a freshwater lake in Antarctica (AB630712, 99 % sequence similarity) and sediment in the northern Bering Sea (EU925889, 97 % sequence similarity). There are no environmental clones that can be considered to be closely related to *Lutibaculum baratangense* deposited in the public databases.

Abstract

Rhodospirillaceae Pfennig and Trüper 1971, 17[AL]

Rhodospirillaceae are a family within the order *Rhodospirillales* in the subclass of *Alphaproteobacteria*. The family *Rhodospirillaceae*, the so-called purple non-sulfur bacteria, have the type genus *Rhodospirillum* and embrace a total of 34 genera: *Azospirillum*, *Caenispirillum*, *Constrictibacter*, *Defluviicoccus*, *Desertibacter*, *Dongia*, *Elstera*, *Ferrovibrio*, *Fodinicurvata*, *Inquilinus*, *Insolitispirillum*, *Limimonas*, *Magnetospira*, *Magnetospirillum*, *Magnetovibrio*, *Marispirillum*, *Nisaea*, *Novispirillum*, *Oceanibaculum*, *Pelagibius*, *Phaeospirillum*, *Phaeovibrio*, *Rhodocista*, *Rhodospira*, *Rhodospirillum*, *Pararhodospirillum*, *Rhodovibrio*, *Roseospira*, *Skermanella*, *Telmatospirillum*, *Thalassobaculum*, *Thalassospira*, *Tistlia*, and *Tistrella*. According to 16S rRNA gene sequence similarities, the genera within the *Rhodospirillaceae* can be grouped into three big clusters: *Azospirillum–Skermanella–Desertibacter–Rhodocista–Dongia–Elstera–Inquilinus, Magnetospirillum–Nisaea–Thalassobaculum–Oceanibaculum–Fodinicurvata–Pelagibius –Tistlia–Phaeospirillum–Telmatospirillum–Defluviicoccus–Tistrella–Constrictibacter–Rhodovibrio–Limimonas*, and *Rhodospirillum–Pararhodospirillum–Roseospira–Rhodospira–Phaeovibrio–Novispirillum–Marispirillum–Insolitispirillum–Caenispirillum–Thalassospira–Magnetospira–Magnetovibrio–Ferrovibrio*. Some genera in the family *Rhodospirillaceae* grow photoheterotrophically under anoxic conditions in the light and chemoheterotrophically in the dark, while others grow heterotrophically under aerobic/microaerobic conditions. The members of the *Rhodospirillaceae* stain Gram negative and form rod shaped to spirillum-formed cells. The chemoheterotrophs include the facultative anaerobic genera *Skermanella*, *Telmatospirillum*, *Caenispirillum*, *Thalassobaculum*, and *Nisaea* and the strictly aerobic and microoxic genera *Azospirillum*, *Conglomeromonas*, *Magnetospirillum*, *Thalassospira*, *Tistrella*, and *Inquilinus*. The genus *Azospirillum* contains several diazotrophic, plant-associated bacteria having plant growth-promoting potential with agricultural application. Other genera include strains with interesting biotechnological potentials. Some genera also harbor opportunistic pathogenic bacteria, whose risk potential is not yet clear.

Taxonomy, Historical and Current

Short Description of the Family

Rhodospirillaceae (*Rho.do.spi.ril.la´ce.ae*: M.L. neut. n. *Rhodospirillum*, type genus of the family; L. suff. -aceae, ending

to denote a family; N.L. fem. pl. n. *Rhodospirillaceae*, the *Rhodospirillum* family; Pfennig and Trüper 1971a).

Phylogenetically, the family of *Rhodospirillaceae* is a member of the order *Rhodospirillales*, subclass *Alphaproteobacteria* in the phylum Proteobacteria (Stackebrandt et al. 1988). According to the 16S rRNA gene sequence comparison of the type species, the next related family within the the order *Rhodospirillales* is the family *Acetobacteraceae* (Gillis and De Ley 1980). The family *Rhodospirillaceae* contain the genera *Azospirillum*, *Caenispirillum*, *Constrictibacter*, *Defluviicoccus*, *Desertibacter*, *Dongia*, *Elstera*, *Ferrovibrio*, *Fodinicurvata*, *Inquilinus*, *Insolitispirillum*, *Limimonas*, *Magnetospira*, *Magnetospirillum*, *Magnetovibrio*, *Marispirillum*, *Nisaea*, *Novispirillum*, *Oceanibaculum*, *Pelagibius*, *Phaeospirillum*, *Phaeovibrio*, *Rhodocista*, *Rhodospira*, *Rhodospirillum*, *Rhodovibrio*, *Roseospira*, *Skermanella*, *Telmatospirillum*, *Thalassobaculum*, *Thalassospira*, *Tistlia*, and *Tistrella*. Some genera of the family *Rhodospirillaceae* grow photoheterotrophically under anoxic conditions in the light and chemotrophically in the dark (Pfennig and Trüper 1971a), while others grow chemoheterotrophically under aerobic conditions. They stain Gram negative and form rod shaped to spirillum-formed cells. Members of *Rhodospirillaceae* have varying metabolic and nutritional properties, which include photoheterotrophs, photoautotrophs, and chemoheterotrophs. The major respiratory lipochinones are ubiquinones 9, 10, and 11 and/or menaquinone 10 (MK-10). Unsaturated straight chain fatty acids are the predominant acyl groups of the family; among these are summed feature 8 ($C_{18:1}$ ω7c and/or $C_{18:1}$ ω6*c*), summed feature 3 ($C_{16:1}$ ω7c and/or $C_{168:1}\omega$6c), and summed feature 2 (consisting of $C_{14:0}$ 3 OH and or iso-$C_{16:0}$ 3-OH). The polar lipids consist mainly of phosphatidylglycerol, phosphatidylcholine, and other lipids which differ from species to species level. The type genus of the family is *Rhodospirillum*.

Azospirillum–Skermanella–Desertibacter–Rhodocista–Dongia–Elstera–Inquilinus

The genus *Azospirillum* (Tarand et al. 1979) forms a subcluster within the family *Rhodospirillaceae* together with the genera *Skermanella, Rhodocista, Desertibacter, Dongia*, *Elstera*, and *Inquilinus* (*Fig. 22.1*). These bacteria belong to the large group of "hydrobacteria," a clade of prokaryotes that originated in marine environments (Battistuzzi and Hedges 2009). Nearly all known representatives of the family *Rhodospirillaceae* are found in aquatic habitats, suggesting that *Azospirillum* represents a lineage which might have transitioned to terrestrial environments much later than the Precambrian split of "hydrobacteria" and "terrabacteria" (Wisniewski-Dyé et al. 2011). *Azospirillum* spp. are members of the α-subclass of *Proteobacteria*, and this genus was initially described by Krieg and Döbereiner (1984) to include a species previously named as *Spirillum lipoferum* (Beijerinck 1925). The growth of a spirillum-like bacterium in nitrogen-deficient malate- or lactate-based media, which had been inoculated heavily with garden soil, was first observed by Beijerinck in 1925. When this new bacterium was cultivated in malate medium, the nitrogen content increased, which led to the original species name *Azotobacter spirillum*. Three years later, it was renamed into *Spirillum* genus. In 1978 a group of isolates was utilized in a detailed taxonomic study by Tarrand et al. (1978). Based on the DNA homology group II bacteria *Azospirillum lipoferum* genus and species were described. This group of isolates seemed to correspond in several ways to Beijerinck's original description of *Spirillum lipoferum*, particularly with regard to growth with glucose or mannitol and to the formation of spirillum-shaped cells under certain conditions (Krieg and Döbereiner 1984).

These bacteria are spiral or slightly curved rod-shaped non-spore-forming cells with polyhydroxybutyrate (PHB) granules, which can form cysts. The Gram staining is negative and the cells are very motile with a single polar flagellum and several lateral flagella, shorter in length. Cells are polymorphic and positive for oxidase as well as catalase reaction (Tarrand et al. 1978). *Azospirillum* has a large amount of $C_{18:1}$ ω7*c* lipids (55·3 %) and contains also 16:1ω7*c*, 16:0 as a major component; the major hydroxy fatty acids are 3-OH $C_{14:0}$ and 3-OH $C_{16:0}$. When grown aerobically, species of this genus exhibit a quinone system with ubiquinone 10 (Q-10). The polar lipids consist mainly of phosphatidylglycerol, phosphatidylcholine, and one unidentified phospholipid. The DNA G+C content varies between 64 and 71 mol%.

The occurrence of *Azospirillum* spp. is widespread in the environment and has significant agricultural importance specifically as aerobic nitrogen-fixing species with considerable plant growth-promoting abilities. *A. brasilense* and *A. lipoferum* are known to associate with, and stimulate the growth of, numerous grasses and cereals. Most of the species were described from plant roots and soil samples. These organisms have a plant root tissue origin, especially in soils of tropical and subtropical regions, but also in temperate regions (Lavrinenko et al. 2010). *Azospirillum lipoferum* and *A. brasilense* are the two species which were described at first. Later, Magalhães et al. (1983) described the third species, *A. amazonense*. Four years later, another species was described, *A. halopraeferens* (Reinhold et al. 1987) from Kallar grass (*Leptochloa fusca*) in Pakistan. In 1989, Khammas isolated the 5th species of this genus, *A. irakense*, using root samples of rice. The taxonomy of the species *Conglomeromonas largimobilis* subsp. *largomobilis hodobium* was questioned as its similarity of the species *A. lipoferum*. The strains of this species were renamed to a new *Azospirillum* species called *A. largomobilis* and then corrected to *A. largimobile* (Sly and Stackebrandt 1999). In 2001, a new species was described and received the name of the famous scientist Johanna Döbereiner, calling *A. doebereinerae* (Eckert et al. 2001). In 2005, another species was described in China, also from rice samples, *A. oryzae* (Xie and Yokota 2005). Again a new species was described using plant tissue collected in China, *A. melinis* (Peng et al. 2006), using roots and stem of a plant called *Melinis*

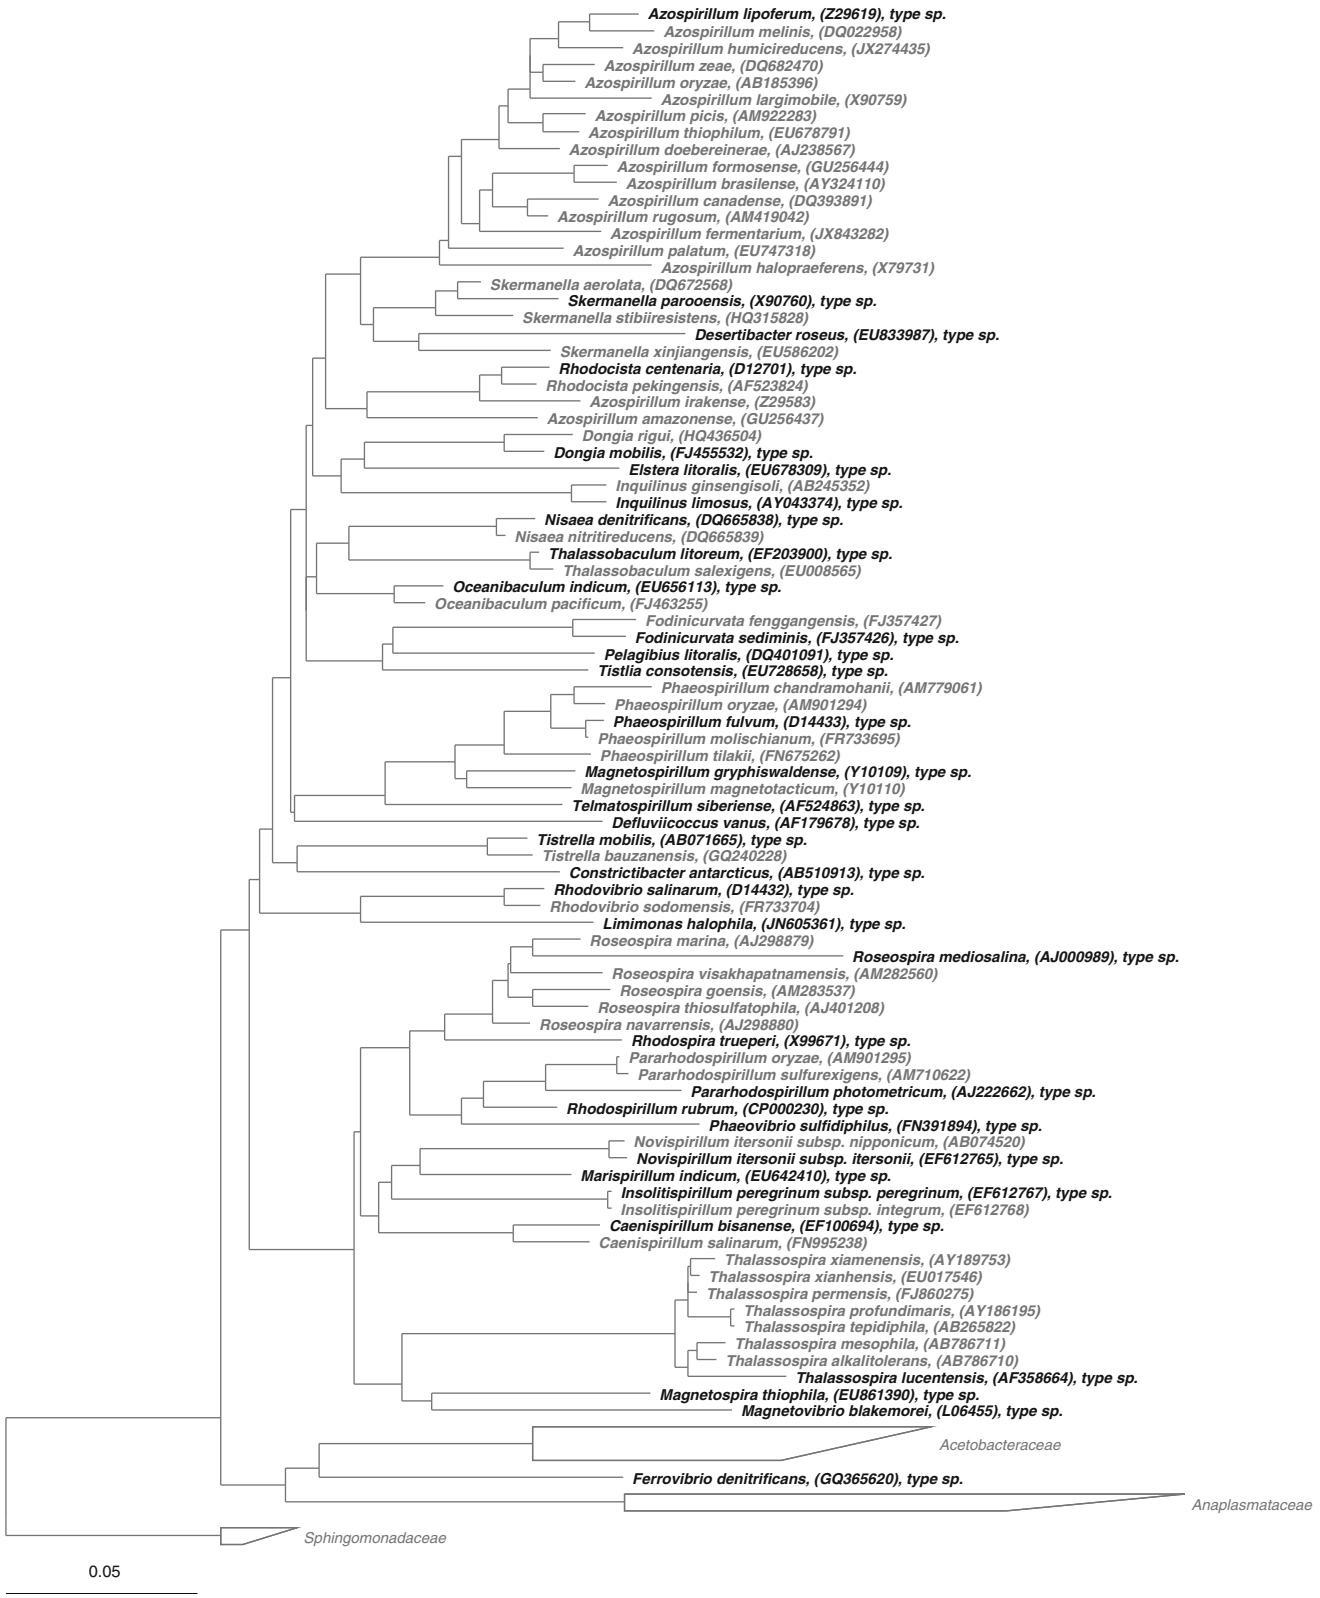

Fig. 22.1

Phylogenetic reconstruction of the family *Rhodospirillaceae* based on 16S rRNA and created using the neighbor-joining algorithm with the Jukes-Cantor correction. The sequence datasets and alignments were used according to the All-Species Living Tree Project (LTP) database (Yarza et al. 2010; http://www.arb-silva.de/projects/living-tree). The tree topology was stabilized with the use of a representative set of nearly 750 high quality type strain sequences proportionally distributed among the different bacterial and archaeal phyla. In addition, a 40% maximum frequency filter was applied in order to remove hypervariable positions and potentially misplaced bases from the alignment. Scale bar indicates estimated sequence divergence

minutiflora. In this case, a modification of the culture medium to a high pH contributed to discover not only this species but also two new ones: *A. canadense* (Mehnaz et al. 2007a) and *A. zeae* (Mehnaz et al. 2007b). In 2008, a new species was described using contaminated soils collected in Taiwan. This species was named *A. rugosum* as its colony morphology was different from the closely related ones (Young et al. 2008). This species was isolated from discarded road tar soil. In 2009, two new species were described: *A. palatum* (Zhou et al. 2009) and *A. picis* (Lin et al. 2009). *A. picis* was isolated from oil-contaminated soil samples in Taiwan, and it fixes nitrogen and possesses nitrate reduction activity, differing from *A. palatum*. Both species do not have indole production. *A. thiophilum* was isolated from sulfide spring collected in Russia (Lavrinenko et al. 2010). *A. formosense* was isolated from agricultural soil collected in Taiwan (Lin et al. 2012), and the last species, until to date (February 2014), is *A. humicireducens* that was isolated from microbial fuel cell and also fixes nitrogen. *A. fermentarium* was isolated from a fermentative tank in Taiwan.

More recently, the relatedness of *Roseomonas fauriae* and R. genomospecies 6 (originally members of the *Roseomonas* genus in the *Acetobacteraceae*) and *Azospirillum* spp. became apparent in comparative studies using phenotypic methods and molecular techniques. Conventional biochemical tests could not differentiate between the two taxa, and 16S rRNA and DNA–DNA hybridization experiments revealed rather high values for relatedness between *R. fauriae* with several type strains of *Azospirillum*. It was suggested that strains previously identified as *R. fauriae* and R. genomospecies 6 should be reclassified as *A. brasilense*, with the name *Roseomonas fauriae* as a later heterotypic synonym of *Azospirillum brasilense* (Helsel et al. 2006). Thus, *R. fauriae* and R. genomospecies 6, which possess a pink pigment like *A. brasilense*, were included into the genus *Azospirillum*; however, clinical isolates are also listed as *R. fauriae*.

Skermanella parooensis was first described as *Conglomeromonas largomobilis* subsp. *parooensis* together with *Conglomeromonas largomobilis* subsp. *largomobilis*. However, 16S rRNA comparison and nucleic acid hybridization (Falk et al. 1986; Ben Dekhil et al. 1997) showed that the latter was closely related to the genus *Azospirillum* and was therefore transferred as *Azospirillum largimobile* (Ben Dekhil et al. 1997) and *Conglomeromonas largomobilis* subsp. *parooensis* was elevated to *Conglomeromonas parooensis* (Ben Dekhil et al. 1997) since it was more distant from *Azospirillum* species. However, according to Rule 37a (1) of the International Code of Nomenclature of Bacteria, it should be classified in a different genus; thus, it was transferred to *Skermanella* gen. nov. as *Skermanella parooensis* gen. nov. (Sly and Stackebrandt 1999). New isolates from air (Weon et al. 2007) and soil from coal mine (Luo et al. 2012) made amendments to the genus description necessary as strictly aerobic (Weon et al. 2007), variable ability of ferment glucose and other phenotypic characteristics (Luo et al. 2012). The fourth species of genus was isolated from desert sand (An et al. 2009).

Recently, a bacterial isolate from sandy soil of the Taklimakan desert in Xinjiang, China, was described as a new genus, *Desertibacter roseus*. Based on 16S rRNA sequence comparison, it is more closely related to *Skermanella* than to *Azospirillum* (Liu et al. 2011).

Description of the genus *Rhodocista* was proposed by Kawasaki et al. (1992), to include a previously named *Rhodospirillum centenum* strain isolated from water of a hot spring (Favinger et al. 1989) as *Rhodocista centenaria* (Kawasaki et al. 1992). The presence of clearly distinct phenotypic, biochemical, and genetic properties from *Rhodospirillum rubrum* (type species of *Rhodospirillum* genus) supported the reclassification of this organism. The second species of this genus was described later by Zhang et al. (2003) that was named *Rhodocista pekingensis*, isolated from wastewater treatment plant. Rhodocista cells are vibrioid to spiral-shaped, anaerobic phototrophs or aerobic chemoorganotrophs; they are mesophilic and possess bacteriochlorophyll *a*. Colonies are pink pigmented, differentiating into dormant thermotolerant cysts when growing aerobically. *Rhodocista* type species form a close cluster with two species of the genus *Azospirillum* (*A. irakense* and *A. amazonense*, sharing 94.1 % and 91 % 16S rRNA gene sequence similarity). It encompasses 89.9 % 16S rRNA gene sequence similarity with the *Rhodospirillum rubrum* type species.

The bacterial genera *Dongia*, *Elstera*, and *Inquilinus* form a subcluster of strictly aerobic chemoheterotrophic bacteria. *Dongia mobillis* was isolated from freshwater wetland in Korea (Liu et al. 2010), while *Elstera litoralis* from biofilms on stones in the littoral zone of Lake Constance in Germany (Rahalkar et al. 2012). *Inquilinus* isolates are derived from clinical samples of, e.g., a cystic fibrosis patient (Coenye et al. 2001).

Magnetospirillum–Phaeospirillum–Nisaea–Thalassobaculum–Oceanibaculum–Fodinicurvata–Pelagibius–Tistlia–Telmatospirillum–Defluviicoccus–Tistrella–Constrictibacter–Rhodovibrio–Limimonas

According to the 16S rRNA gene sequence analysis (neighbor joining and maximum likelihood), a second branch of bacterial genera around *Magnetospirillum* and *Phaeospirillum* is evident (◉ *Fig. 22.1*).

Magnetotactic bacteria (MTB) is a general name used to group microorganisms capable of showing magnetotaxis and synthesizing intracellular organelles filled with crystals of a variety of mineral sources, named magnetosome. They are phylogenetically distributed into Alpha-, Gamma-, and Deltaproteobacteria classes of the Proteobacteria phylum, the Nitrospirae phylum, and the candidate division OP3, part of the Planctomycetes–Verrucomicrobia–Chlamydiae (PVC) bacterial superphylum (Bazylinski and Frankel 2004; Kolinko et al. 2012; Lefèvre et al. 2012a). Among the *Alphaproteobacteria* families, the *Rhodospirillaceae* comprises 3 genera representative of MTB: *Magnetospirillum*, *Magnetospira*, and *Magnetovibrio*. Characterization of the second isolated MTB that could be axenically cultivated, named MSR-1, and other

proteobacteria showed that it was closely related to *Aquaspirillum magnetotacticum* (94.1 %) than to *A. serpens* or to other reference organisms of the alpha subclass of *Proteobacteria* (84.1–88.9 %). Based on these results, Scheifer et al. (1991) proposed a new genus description, *Magnetospirillum*, in which both *A. magnetotacticum* and strain MSR-1 could be placed.

The genus *Phaeospirillum* was originally described as part of the study of Imhoff et al. (1998) which reclassified the *Rhodospirillum* species known so far into different genera mainly based on 16S rRNA gene sequence analysis. At this work *Rhodospirillum fulvum* (van Niel 1944) and *Rhodospirillum molischianum* (Giesberger 1947) were transferred to *Phaeospirillum fulvum* and *Phaeospirillum molischianum*, respectively. Reclassification of *Phaeospirillum* species was followed by the description of *P. chandramohanii*, *P. oryzae*, and *P. tilakii* (Kumar et al. 2009; Lakshmi et al. 2011a; Raj et al. 2012). These organisms were found in freshwater-rich environments such as mud and rhizosphere soil; are spiral shaped, mesophilic, and photoheterotrophic with photosynthetically grown cell suspension showing brown to brown-orange/brown-red color; present bacteriochlorophyll *a*, and major quinones are Q-9 and MK-9. *Phaeospirillum* type species share 94.4 % 16S rRNA gene sequence similarity with *Magnetospirillum* type species and 89.1 % 16S rRNA gene sequence similarity with *Rhodospirillum* type species.

A strain named P24 was shown to form a deep branch within the family *Rhodospirillaceae* based on comparative 16S rRNA gene sequence analysis (Lai et al. 2009a). The strain clustered closely to *Thalassobaculum litoreum* CL-GR58T (92.7 %), but the highest 16S rRNA gene sequence similarity was shared with strain SL3.14 (99 %), a bacterium isolated from the Silver Lake throughflow playa (Navarro et al. 2009; Lai et al. 2009a). Based on many peculiar phenotypic, biochemical, and molecular traits, a new genus, *Oceanibaculum* (Lai et al. 2009b emend. Dong et al. 2010) was proposed within the family *Rhodospirillaceae*. The type species is *Oceanibaculum indicum* P24^T (Lai et al. 2009b).

The genus *Pelagibius* was described by Choi et al. (2009) to include a marine bacterial strain isolated from seawater of the east coast of Korea. *Pelagibius* is a monospecific genus affiliated with the *Rhodospirillaceae* family according to 16S rRNA sequence analysis. The type species *Pelagibius litoralis* forms slightly curved or straight rods, is a mesophilic non-fermentative heterotroph, and is strictly aerobic forming circular, convex, and creamy colonies when grown on marine agar. The type species of *Pelagibius* share 92.9 % 16S rRNA gene sequence similarity with *Fodinicurvata* type species.

Tistlia consotensis is the only species decribed for this genus. This aerobic, slightly halophilic bacterium was recently isolated from a saline spring in Colombia (Diaz-Cárdenas et al. 2010).

Telmatospirillum siberiense was the first and only species described in the genus. Three isolates of this species were recovered from acidic wetland in Northern Russia. Based on 16S rRNA comparison, these isolates were allocated to *Telmatospirillum* nov. gen. as *Telmatospirillum siberiense*.

The genus *Rhodovibrio* comprises two species named *Rhodovibrio salinarum*, which is the type species, and *Rhodovibrio sodomensis* (Imhoff et al. 1998), formerly classified as *Rhodospirillum salinarum* and *Rhodospirillum sodomense*, respectively.

Rhodospirillum–Pararhodospirillum–Roseospira–Rhodospira–Phaeovibrio–Novispirillum–Marispirillum–Insolitispirillum–Caenispirillum–Thalassospira–Magnetospira–Magnetovibrio–Ferrovibrio

The genus *Rhodospirillum* is the type genus, and at present it consists of only one species, *Rhodospirillum rubrum* (Skerman et al. 1980; Molisch 1907; Imhoff et al. 1998), as the type species. The genus has ever contained other 11 species, including *Rhodospirillum photometricum*, *Rhodospirillum sulfurexigens*, *Rhodospirillum oryzae* (now *Pararhodospirillum photometricum*, *Pararhodospirillum sulfurexigens*, and *Pararhodospirillum oryzae*, respectively (Lakshmi et al. 2014)), *Rhodospirillum tenue* (now *Rhodocyclus tenuis* after (Imhoff et al. 1984)), *Rhodospirillum centenum* (presently *Rhodocista centenaria* after (Kawasaki et al. 1992)), and *Rhodospirillum fulvum*, *Rhodospirillum molischianum*, *Rhodospirillum salinarum*, *Rhodospirillum sodomense*, *Rhodospirillum salexigens*, and *Rhodospirillum mediosalinum* (these have been transferred respectively to *Phaeospirillum fulvum*, *Phaeospirillum molischianum*, *Rhodovibrio salinarum*, *Rhodovibrio sodomensis*, *Rhodothalassium salexigens*, and *Roseospira mediosalina* (Imhoff et al. 1998). The genus *Pararhodospirillum* consists of three species named *Pararhodospirillum photometricum*, *Pararhodospirillum sulfurexigens*, and *Pararhodospirillum oryzae* (Lakshmi et al. 2014), which have been classified previously as *Rhodospirillum photometricum*, *Rhodospirillum sulfurexigens*, and *Rhodospirillum oryzae*, respectively. *Pararhodospirillum photometricum* is the type species.

Roseospira mediosalina was first described as *Rhodospirillum mediosalinum* by Kompantseva and Gorlenko (1984). In 1998 Imhoff et al. based on comparison of the 16S rRNA sequence proposed to transfer it to *Roseospira* gen. nov. as *Roseospira mediosalina* comb. nov. Later Guyoneaud et al. (2002) classified 3 new isolates as new species of the genus (*R. marina* sp. nov., *R. navarrensis* sp. nov., and *R. thiosultatophila* sp. nov.) based on 16S rRNA gene sequence, DNA–DNA hybridization, and phenotypic characteristics. These authors also emended the genus description to take into account the characteristics of the new species. Chakravarthy et al. (2007) isolated from water of the fishing harbor at Visakhapatnam (India) strain JA131, later classified as *Roseospira visakhapatnamensis* sp. nov., and strain JA135 from sediment of Kurka saltern, Goa (India), which was classified as *Roseospira goensis* sp. nov.

Reallocation of *Aquaspirillum itersonii* and *Aquaspirillum peregrinum* (Hylemon et al. 1973) to the family *Rhodospirillaceae* leads to their reclassification into 2 new genera, *Novispirillum* and *Insolitispirillum* (Ding and Yokota 2002; Yoon et al. 2007b).

The species *Phaeovibrio sulfidiphilus*, the only species of this genus, was isolated from brackish water (Lakshmi et al. 2011b). Cells are vibrioid, mesophilic, strictly anaerobic, photoheterotrophic, and able to grow in a limited number of carbon substrates (acetate, pyruvate, and succinate). Chimeric internal membranes of lamellar stacks and vesicles are present in a single cell, and photosynthetically grown cultures are light brown. *Phaeovibrio* type species share 91.5 % 16S rRNA gene sequence similarity with *Rhodospirillum* type species and 80–91 % sequence similarity to *Rhodocista*, *Phaeospirillum*, *Rhodovibrio*, *Rhodospira*, and *Roseospira* type species.

The genus *Rhodospira* comprehends only one species named *Rhodospira trueperi* (Pfennig et al. 1997). This genus was assigned to describe a marine photosynthetic non-sulfur bacteria strain isolated from salt marsh that forms vibrioid- to spirilloid-shaped cells, and mesophilic, peach-colored photoheterotrophic cultures were observed under anoxic conditions. *R. trueperi* presents bacteriochlorophyll *b* and forms elemental sulfur globules outside the cells in the presence of sulfide, with Q-7 and MK-7 as major quinones. *Rhodospira trueperi* shares 93.9 % 16S rRNA gene sequence similarity with *Roseospira mediosalina* (type species) and 92.8 % 16S rRNA gene sequence similarity with *Rhodospirillum* type species.

Phylogenetic Structure of the Family and Its Genera

According to the phylogenetic relationship based on 16S rRNA gene sequence analyses within the order *Burkholderiales*, the family *Rhodospirillaceae* (Pfennig and Trüper 1971a) is moderately affiliated to the family *Acetobacteraceae* (Gillis and De Ley 1980). Extensive 16S rRNA gene sequence analyses of type species and strains constitute the phylogenetic structure within the family *Rhodospirillaceae* (Fig. 22.1).

Azospirillum–Skermanella–Desertibacter–Rhodocista–Dongia–Elstera–Inquilinus

The 16S rRNA gene sequence analysis within the genus *Azospirillum* reveals that *A. lipoferum, A. largimobile, A. brasilense, and A. halopraeferens* have 96.6 %, 96.6 %, 95.9 %, and 93.6 % similarity, respecticvely, with *A. doebereinerae* (Eckert et al. 2001). *A. formosense* is closely related to *A. brasilense* (98 % 16S rRNA similarity). *A. canadense* and *A. rugosum* are 96 % similar, while *A. thiophilum* and *A. picis* present a lower level of similarity (72 %). *A. halopraeferens* formed another cluster with 86 % of similarity to the above species described. *Skermanella aerolata* and *Skermanella parooensis* are included into the 16S rRNA tree as the closely related genus of *Azospirillum*. *A. amazonense* is the species with lower level of similarity together with *A. irakense* and forms a branch with *Rhodocista centenaria* and *Rhodocista pekingensis* (Lin et al. 2012). *A. fermentarium* strain CC-LY743^T revealed a high similarity level to *A. picis* DSM 19922^T (96.1 %), *A. oryzae* JCM 21588^T (96.0 %), and *A. rugosum* DSM 19657^T (96.0 %), while these values were lower (<96.0 %) for other species (Lin et al. 2013). The recently described *A. humicireducens* is closely related to *A. lipoferum* forming a subclade with 98 % similarity and also presents high levels to *A. thiophilum* (97.6 %) and *A. oryzae* (97.1 %) (Zhou et al. 2013).

Skermanella parooensis was originally classified as *Conglomeromonas largomobilis* subsp. *paraooensis*. The transfer of *Conglomeromonas largomobilis* subsp. *largomobilis* to the genus *Azospirillum* and the low 16S rRNA similarity (93 %) (Ben Dekhil et al. 1997) and DNA–DNA hybridization (5–12 %) between the two subspecies led to the elevation of the former to a new species *Skermanella parooensis* (Falk et al. 1986). Phylogenetic analyses of 16S rRNA gene sequences showed that species of the *Skermanella* genus form a cluster with *Desertibacter roseus* and are related phylogenetically to members of the genera *Azospirillum* and *Rhodocista* within the *Alphaproteobacteria*. Comparison of the 16S rRNA gene sequence of *Skermanella aerolata* 5416 T-32 showed highest level of similarity (96.2 %) with *S. parooensis* DSM 9527 but has lower levels of sequence similarity (<92 %) with respect to other species (Weon et al. 2007). *Skermanella xinjiangensis* strain 10-1-101 has the highest degree of similarity to *S. aerolata* 5416 T-32 (94.07 %) and *S. parooensis* DSM 9527 (92.74 %) (An et al. 2009). Partial 16S rRNA gene sequence (1,420 bp) of *Skermanella stibiiresistens* strain SB22T showed the highest degree of similarity to *S. aerolata* 5416 T-32 (97.3 % similarity), *S. parooensis* ACM 2042^T (95.8 %), and *S. xinjiangensis* 10-1 (92.9 %) (Luo et al. 2012). The phylogenetic analysis revealed that strain SB22T was closely related to the members of the genus *Skermanella* and grouped in the same cluster with *S. aerolata* 5416 T-32, *S. parooensis* ACM 2042^T, and *S. xinjiangensis* 10-1-101.

Phylogenetic analysis of the 16S rRNA gene sequence showed that the nearest phylogenetic neighbors of *Desertibacter roseus* 2622^T are species of the genus *Skermanella*. It shared 91.7 % and 90.1 % similarities to the type strains of *S. xinjiangensis* and *S. aerolata*, respectively. These values were lower (89.8–88.1 %) when compared to the type strains of the genus *Azospirillum* (Liu et al. 2011).

The 16S rRNA gene sequence analysis of the genus *Rhodocista* indicated that it forms a distinct phylogenetic branch within the *Rhodospirillaceae* family. In fact, the work of Kawasaki et al. (1992) clarified the phylogenetic positioning of spiral-shaped purple non-sulfur bacteria on the basis of 16S rRNA gene sequences, highlighting the heterogeneity of *Rhodospirillum* genus. The phylogenetic positioning of the *Rhodocista* species indicates a close cluster with *Azospirillum irakense* but quite distant from the other *Azospirillum* species. This very close relationship was also shown by Zhang et al. (2003), who described the second species *Rhodocista pekingensis*. *Rhodocista* species and *Azospirillum irakense* share about 96–97 % sequence similarity, although the latter is not phototrophic while the former did not grow using malate as carbon source.

Dongia mobilis LM22^T exhibited the highest 16S rRNA sequence similarity with *Inquilinus limosus* AU0476^T (90.4 %) and less than 90 % similarity with other members of the family *Rhodospirillaceae* such as *Skermanella*, *Azospirillum*, and *Rhodocista* (Liu et al. 2011). *Inquilinus ginsengisoli* Gsoil 080^T (Jung et al. 2011) was most closely related to *I. limosus* strains AU0476^T and AU1979 (Wayne et al. 1987) with 98.9 % 16S rRNA sequence similarity level. Recently, Baik et al. (2013) described a bacterium enrichment culture clone 04SU4-P as *Dongia rigui* 04SU4-P^T. A phylogenetic analysis based on 16S rRNA gene sequences showed that strain 04SU4-P^T forms an evolutionary lineage within the genus *Dongia* and its nearest neighbor is *Dongia mobilis* LM22^T (98.0 %). The 16S rRNA gene sequence analysis indicated that *Elstera litoralis* Dia-1^T was closely related to representatives of the genera *Azospirillum* (90–91 %), *Skermanella* (88–89 %), *Rhodocista* (87–88 %), and *Dongia* (88–89 %) (Rahalkar et al. 2012).

Magnetospirillum–Phaeospirillum–Telmatospirillum–Thalassobaculum–Nisaea–Oceanibaculum–Fodinicurvata–Pelagibius–Tistlia–Defluviicoccus–Tistrella–Constrictibacter–Rhodovibrio–Limimonas

Magnetotactic bacteria (MTB) is a general name used to group microorganisms capable of showing magnetotaxis and synthesizing intracellular organelles filled with crystals of a variety of mineral sources, named magnetosome. They are phylogenetically distributed into Alpha-, Gamma-, and Deltaproteobacteria classes of the Proteobacteria phylum, the Nitrospirae phylum, and the candidate division OP3, part of the Planctomycetes–Verrucomicrobia–Chlamydiae (PVC) bacterial superphylum (Bazylinski and Frankel 2004; Kolinko et al. 2012; Lefèvre et al. 2012a). Among the *Alphaproteobacteria* families, the *Rhodospirillaceae* comprises 3 genera representative of MTB: *Magnetospirillum, Magnetospira, and Magnetovibrio.* Based on 16S rRNA gene identity, it was shown that the closest organism of *Magnetospirillum bellicus* was *Magnetospirillum gryphiswaldense* MSR-1, with 96 % sequence similarity to strain VDY^T. The species *Dechlorospirillum anomalous* strain WD was shown to be closely related *to the* magnetotactic *Magnetospirillum species* (Michaelidou et al. 2000), but at the time, none of the *Magnetospirillum* species tested (*M. gryphiswaldense, M. magnetotacticum*, and *Magnetospirillum* strain AMB-1) could couple growth to the reduction of perchlorate or chlorate, but later on, the presence of a homolog of the cld gene in strains VDY, WD, and MS-1 was reported by Bender et al. (2004). Meanwhile, according to Lefèvre et al. (2013a), the magnetospirilla are a large group that appears to phylogenetically span a number of genera. Current evidences suggest that a detailed study considering the phylogenetic relationship between *Phaeospirillum* and *Magnetospirillum* would be necessary. The phylogenetic positioning of the *Phaeospirillum* type species is distributed in three sister clades. *P. fulvum* and *P. molischianum* form one clade with 99.1 % 16S rRNA gene sequence similarity. Another clade encompasses *P. chandramohanii* and *P. oryzae*, which shares 98.2 % similarity. The third clade harbors *P. tilakii* type strain sharing approximately 97 % similarity with *P. chandramohanii*/*P.oryzae* clade and around 96.7 % similarity with *P. fulvum*/*P. molischianum* clade. The clades *P. fulvum*/*P. molischianum* and *P. chandramohanii*/*P.oryzae* share approximately 97 % similarity. The 16S rRNA gene sequence similarities between *P. tilakii* JA492^T and the other *Phaeospirillum* type strains ranged from 96.5 % to 97.4 %. Besides the neighbors, strains *P. fulvum* DSM 113^T and *P. molischianum* ATCC 14031^T share the same branch with a 99.1 % 16S rRNA gene sequence similarity. Phylogenetic tree based on 16S rRNA gene sequences of strains of *Telmatospirillum siberiense* formed a separate cluster with purple non-sulfur bacteria of the genera *Phaeospirillum* and *Magnetospirillum*, within the family *Rhodospirillaceae.* Sequence similarity of *Telmatospirillum siberiense* strains between each other was 98.3–98.9 %, but only 90.9–92.5 % when compared to *Phaeospirillum* and *Magnetospirillum.* Comparison of partial amino acid sequence obtained from amplified *nifH* gene (148 residues) also showed that 2 strains (26-4b1 and K-1) of *Telmatospirillum siberiense* formed a separate branch with higher similarity to each other (97.0 % of amino acid sequence identity) than to their closest *Azospirillum* relatives (92.0–94.1 %). In addition, comparison of partial sequences of the "red-like" *cbbL* gene encoding large (catalytic) subunits of RuBisCO, corresponding to 231 amino acid residues, also showed close relationship of *Telmatospirillum siberiense* strains to each other (96.9 %), forming a separate branch in the phylogenetic tree. Their similarity with *Azospirillum lipoferum* (88.1–91.3 %) "red-like" *cbb*L gene was similar to other *Alphaproteobacteria* (77.9–94.2 %).

The 16S rRNA gene sequence of *Thalassobaculum litoreum* strain CL-GR58^T showed 90.9 % similarity to the type strain of *Azospirillum lipoferum*, 89.8 % to *Azospirillum oryzae*, 89.7 % to *Azospirillum canadense*, 89.5 % to *A. doebereinerae*, and 79.3–89.5 % to the other type species of the family *Rhodospirillaceae* (Zhang et al. 2008). The 16S rRNA sequence analysis of strain *Thalassobaculum salexigens* CZ41-10a^T showed that it was phylogenetically affiliated to the family *Rhodospirillaceae* (Urios et al. 2010) and presented variable similarity relatedness values to the relatives *Thalassobaculum litoreum* CL-GR58^T (99 %), *Nisaea nitritireducens* DSM 19540^T (94 %), and *Nisaea denitrificans* DSM 18348^T (93 %). *Oceanibaculum* is closely related to *Thalassobaculum litoreum* CLGR58 and *Nisaea*, but each of them forms a separate clade, as independent monophyletic cluster in the family *Rhodospirillaceae* (Urios et al. 2008; Lai et al. 2009a, b).

Phylogenetic analysis of almost-complete 16S rRNA gene sequences of *Fodinicurvata sediminis* strain YIM D82^T and *Fodinicurvata fenggangensis* YIM D812^T revealed that they formed a distinct lineage within the family *Rhodospirillaceae* (Wang et al. 2009). The similarity between the 16S rRNA gene sequences of the two strains was 98.2 %. The levels of 16S rRNA

gene sequence similarities between strain YIM D82^T and the type strains of *Rhodovibrio sodomensis* and *Rhodovibrio salinarum* were 90.6 % and 90.5 %, respectively, while the sequence similarity levels were 90.2 % and 90.1 %, respectively, against *Fodinicurvata fenggangensis* YIM D812^T. The single species of the *Pelagibius* genus formed a branch closely related to *Tistlia* type species (Díaz-Cárdenas et al. 2010) showing about 91 % of 16S rRNA gene sequence similarity (Choi et al. 2009). The 16S rRNA gene sequence analysis of strain *Tistlia consotensis* USBA 355^T indicated that it formed a distant phylogenetic line of descent with members of the genus *Thalassobaculumn* (90 % gene sequence similarity). This level was much lower when strain USBA 355T was compared to all other members of the family *Rhodospirillaceae* (Díaz-Cárdenas et al. 2010).

The species *Defluvicoccus vanus* showed 16S rRNA gene sequence similarity to the species *Rhodospirillum rubrum* (87.5 %), *P. fulvum* (88.5 %), *Magnetospirillum gryphiswaldense* (88.2 %), *Magnetospirillum magnetotacticum* (88.5 %), and *Rhodocista centenaria* (89 %). A comparison of the inferred 16S rRNA gene sequence nucleotide signature between members of *Alphaproteobacteria* supports the view that type strain Ben 114^T is not closely related to any of them (Maszenan et al. 2005).

The almost complete 16S rDNA sequence of *Tistrella mobilis* strain IAM 14872^T (Shi et al. 2002) showed sequence similarity values of 86.0 % to *Craurococcus roseus* JCM 9933 T and 90.1 % to *Phaeospirillum molischianum* ATCC 14031^T. Phylogenetic analysis using the neighbor-joining method showed that strain BZ78*T* (1,493 bp) formed a distinct cluster with *T. mobilis* IAM 14872 *T*, supported by a relatively high bootstrap value (98.3 % 16S rRNA gene sequence similarity) within the family *Rhodospirillaceae* (Zhang et al. 2011). A similar tree topology was also found in the tree generated using the maximum-likelihood method. Levels of 16S rRNA gene sequence similarities between strain BZ78*T* and the type strains of other species in the family *Rhodospirillaceae* were 90.1 %.

The 16S rRNA gene sequence of *Constrictibacter antarcticus* (strain 262-8^T) indicated high sequence similarities (99–90 %) with sequences of uncultured bacteria found in environmental samples worldwide. In comparative analysis with type strains, the most closely related neighbors of strain 262-8^T were *Stella vacuolata* DSM 5901 T (90.2 %), *Stella humosa* DSM5900T (90.2), and *Tistrella mobilis* IAM 14872 T (89.7 %). In agreement with Yamada et al. (2011), the low similarity values suggested that it would be difficult to analyze the phylogenetic position of strain 262-8^T by DNA–DNA hybridization.

The genus *Rhodovibrio* comprises two species named *Rhodovibrio salinarum*, which is the type species, and *Rhodovibrio sodomensis* (Imhoff et al. 1998), formerly classified as *Rhodospirillum salinarum* and *Rhodospirillum sodomense*, respectively. *Limimonas* 16S rRNA sequence showed similarity with *Rhodovibrio sodomensis* DSM 9895^T (91.6 %) and *Rhodovibrio salinarum* NCIMB 2243^T (91.2 %) forming an independent cluster with the halophilic members of the family *Rhodospirillaceae* although in a separate clade (Amoozegar et al. 2013).

Rhodospirillum–Pararhodospirillum–Phaeovibrio–Roseospira–Rhodospira–Novispirillum–Marispirillum–Insolitispirillum–Caenispirillum–Thalassospira–Magnetospira–Magnetovibrio–Ferrovibrio

Analysis of the 16S rRNA sequence of *Rhodospirillum rubrum* ATCC11170^T, *Pararhodospirillum photometricum* (formerly *Rhodospirillum photometricum*) strains DSM122^T and E11, *Rhodovibrio sodomensis* (formerly *Rhodospirillum sodomense*) strain ATCC51195^T, and *Rhodovibrio salinarum* (previously *Rhodospirillum salinarum*) strain ATCC35394^T resulted in the separation of these two later into a phylogenetic clade and the proposal of the new genus *Rhodovibrio* (Imhoff et al. 1998).

The 16S rRNA sequence analysis between *Pararhodospirillum sulfurexigens* (formerly *Rhodospirillum sulfurexigens*) strain JA143^T with *Rhodospirillum rubrum* ATCC11170^T and *Pararhodospirillum photometricum* (formerly *Rhodospirillum photometricum*) strain DSM122^T showed sequence similarity of 95.72 % and 95.58 %, respectively, which justified the description of the former as the type strain of the novel species (Kumar et al. 2008). In the same analysis, *Rhodovibrio sodomensis* (previously *Rhodospirillum sodomense*) strain DSI^T and *Rhodovibrio salinarum* (originally *Rhodospirillum salinarum*) strain ATCC35394^T were grouped into a clade apart. Later on, phylogenetic relationships based on the 16S rRNA gene sequence analysis of *Pararhodospirillum oryzae* (formerly *Rhodospirillum oryzae*) strain JA318^T with *Pararhodospirillum sulfurexigens* (formerly *Rhodospirillum sulfurexigens*) strain JA143^T, *Pararhodospirillum photometricum* (formerly *Rhodospirillum photometricum*) strain DSM122^T, and *Rhodospirillum rubrum* ATCC 11170^T indicated that the *P.oryzae* clustered with type strains of the genus *Rhodospirillum* (which was then included in the *Pararhodospirillum*) (Lakshmi et al. 2014). The highest sequence similarity for *Pararhodospirillum oryzae* strain JA318^T was found with the type strain of *Pararhodospirillum sulfurexigens* (99.9 %).

Comparative 16S rDNA sequence analyses of *Roseospira marina* CE2105, *Roseospira navarrensis* SE3104, *Roseospira thiosulfatophila* AT2115 (AJ401208), *Roseospira mediosalina*, *Roseospira visakhapatnamensis* JA131, and *Roseospira goensis* JA135 showed that these strains form a subgroup together with *Rhodospira trueperi* within the *Rhodospirillaceae* family of the *Alphaproteobacteria*, well separated from *Rhodospirillum* genus, their closest relatives. *Roseospira marina* CE2105, *Roseospira navarrensis* SE3104, and *Roseospira thiosulfatophila* AT2115 (AJ401208) have similar salt requirements that are phylogenetically closely related, with 16S rRNA similarity ranging from 97.6 % to 96.5 %, whereas *Roseospira mediosalina* requires a higher optimal salt concentration salinity and similarity ranging from 95.6 % to 94.7 % in comparison with the former three species (Guyoneaud et al. 2002). Comparison of 16S rRNA sequences of *Roseospira visakhapatnamensis* JA131 and *Roseospira goensis* JA135 showed that they are closest to *Roseospira navarrensis* (95.9 %), *Roseospira marina* (95.5 %), *Roseospira mediosalina* (94.2 %), and *Roseospira thiosulfatophila* (96.1 %).

Sequence similarity between *Roseospira visakhapatnamensis* JA131 and *Roseospira goensis* JA135T is 96.6 % (Chakravarthy et al. 2007).

Analysis of the phylogenetic positioning of the genus *Rhodospira* indicates its close relationship with the genus *Roseospira*, with 16S rRNA gene sequence similarity of about 93–94 %. However, the presence of bacteriochlorophyll *b* and tetrahydrospirilloxanthin as main pigments in *Rhodospira* differentiates this genus from *Roseospira* which contains Bchl *a* and carotenoids of the normal spirilloxanthin series as main pigments.

Phaeovibrio genus formed by the species *Phaeovibrio sulphidiphilus* branches separately from other *Rhodospirillaceae* genera. The highest similarities of the 16S rRNA gene sequences are observed with representatives from the *Rhodospirillum* genus, sharing approximately 91–92 % similarity.

Phylogenetic analysis based on 16S rRNA gene revealed that species previously named as *Aquaspirillum itersonii* and *Aquaspirillum peregrinum* (Hylemon et al. 1973) were more closely related to the *Alphaproteobacteria* than to the *Betaproteobacteria* group and formed distinct phylogenetic lineages leading to their reallocation to the family *Rhodospirillaceae* and creation of the genera *Novispirillum* and *Insolitispirillum* (Ding and Yokota 2002; Yoon et al. 2007b).

Representatives of the genera *Marispirillum*, *Insolitispirillum*, and *Novispirillum* cluster independently in the same branch of *Caenispirillum*, but apart from the *Rhodospirillum* and *Rhodospira*, representatives of the photosynthetic group of *Rhodospirillaceae*. Comparisons of 16S rRNA gene sequences showed that *Marispirillum indicum* type strain was most closely related to the type strains of two *Insolitispirillum peregrinum* subspecies (93.0–93.1 % sequence similarity), two *Novispirillum itersonii* subspecies (92.8–92.9 %), and *Caenispirillum bisanense* (91.7 %); sequence similarities with respect to other taxa were below 90.5 % (Lai et al. 2009a). The phylogenetic analysis based on 16S rRNA and the neighbor-joining algorithm showed that strains K92T and K93 of *Caenispirillum bisanense* joined a phylogenetic clade comprising *Novispirillum itersonii* (formerly *Aquaspirillum itersonii*) and *Insolitispirillum peregrinum* (formerly *Aquaspirillum peregrinum*) exhibiting the highest 16S rRNA gene sequence similarity values (91.3–91.5 %). Similar analysis indicated that *Caenispirillum salinarum* strain AK4^T was most closely related to *Caenispirillum bisanense* (96.6 %). In contrast, it shared less than 93.2 % sequence similarity with other members of the family.

Phylogenetic analysis based on the partial 16S rRNA gene sequencing of the type strain *Thalassospira lucentensis* QMT2^T indicated a high sequence identity (89 %) to the well-characterized species *Rhodospirillum rubrum*, *Novispirillum itersonii* (formerly *Aquaspirillum itersonii*), and *Terasakiella pusilla* (formerly *Oceanospirillum pusillum*) microorganisms, which are representatives of the α-subclass of the *Proteobacteria* (López-López et al. 2002). Analysis of 16S rRNA gene sequences of *Thalassospira xiamenensis* M-5^T and *Thalassospira profundimaris* WP0211^T indicated that both species were closely related to *Thalassospira lucentensis* (96.1 % and 96.2 % gene sequence similarities, respectively). The 16S rRNA gene sequence analysis of *Thalassospira tepidiphila* 1-1B^T showed a very high level of similarity to *Thalassospira profundimaris* WP0211^T (99.8 %), *Thalassospira xiamenensis* M-5^T (98.2 %), and *Thalassospira lucentensis* DSM 14000^T (98.1 %). However, the levels of DNA–DNA relatedness between strain 1-1B^T and these type strains were 50.7 ± 17.2, 35.7 ± 17.8, and 32.0 ± 21.1 %, respectively. Very high level of similarity was also observed between *Thalassospira alkalitolerans* MBE#61^T and *T. mesophila* MBE#74^T (98.9 % similarity), and these strains shared the highest levels of similarity with *T. lucentensis* QMT2T (99.0 % and 98.5 %, respectively). High levels of similarity were also detected when these strains were compared to *T. xianhensis* P-4^T (97.9 % and 97.7 %, respectively), *T. profundimaris* WP0211^T (97.7 % and 97.2 %, respectively), *T. xiamenensis* M-5^T (97.5 % and 97.2 %, respectively), and *T. tepidiphila* 1-1B^T (97.5 % and 96.9 %, respectively) (Tsubouchi et al. 2014). Neighbor-joining phylogenetic tree based on 16S rRNA gene sequences reveals that *Magnetospira thiophila* and *Magnetovibrio blakemorei* are closely related to *Thalassospira* spp. while other MTB representatives cluster closely to *Phaeospirillum* spp. within the second main group of *Rhodospirillaceae*. Lefèvre et al. (2012a) observed the same distribution when comparing their phylogenetic relationship based on 16S rRNA or Mam proteins cluster analysis and concluded that the evolution of MTB and magnetosomes is congruent, indicating that they were acquired by a common ancestor of the *Magnetospirillum* clade, except in one case. The congruency of the evolutionary path of MTB and magnetotaxis is also confirmed when composition and morphological properties of magnetosome minerals are taken into account (Lefèvre et al. 2013a; Pósfai et al. 2013).

Phylogenetic analysis, based on 16S rRNA gene sequence, showed that *Ferrovibrio denitrificans* Sp-1^T formed a cluster with members from two different orders: *Sneathiellales* and *Rhodospirillales* within the class *Alphaproteobacteria* (Sorokina et al. 2012). 16S rRNA gene sequence of strain Sp-1^T showed similarities with *Sneathiellales chinensis* (89.4 %) followed by *Inquilinus limosus* (89.0 %) and 88.9 % with both *S. glossodoripedis* and *I. ginsengisoli*.

Molecular Analyses

DNA–DNA Hybridization Studies

Almost all descriptions of the *Azospirillum* species include results of DNA–DNA hybridization (DDH) studies within the genus possessing approximately 64–71 mol% (Ben Dekhil et al. 1997). Only for the species *A. rugosum* the data are not available. In 1987, Reinhold et al. detected the generic relationship of *A. halopraeferens* and also confirmed the generic status of *A. amazonense* using the DNAs of five representative strains of the genus. The authors hybridized labeled rRNA from *A. brasilense* ATCC 29145^T. The strains Au 4^T and Au 5 of *A. halopraeferens* as well as the strains YI^T, Y9, and Y13 of *A. amazonense* are located at the same level on the *Azospirillum* rRNA branch, which forms

a trinity together with the rRNA branches of *Rhodospirillum rubrum* and some *Aquaspirillum* species obtained previously by De Smedt et al. (1980). Each of these branches deserved at least a separate generic rank. With Tm(e) values ranging from 73.4 °C to 75.3 °C, both *A. halopraeferens* strains are quite distinct from the *A. brasilense–Azospirillum lipoferum* cluster. One year earlier Falk et al. (1986) described the results of DNA–DNA hybridization of *Conglomeromonas largomobilis* subsp. *largomobilis* that proved the similarity to the species *A. lipoferum* althought the 47 % of this similarity was considered lower to the criteria of 70 % recommended by Wayne et al. (1987). Ben Dekhil et al. (1997) compared the binary sequence similarity values; corrected dissimilarity values indicate that *C. largomobilis* subsp. *largomobilis* is most closely related to *A. lipoferum* and *A. brasilense* with 97.1 % and 95.2 % similarities, respectively. Based on this comparison and also other features, they transfer the species into *Azospirillum largomobilis* comb. nov., and subsequently the name was corrected to *Azospirillum largimobile* by Sly and Stackebrandt (1999). Other study involving *Azospirillum* species was reported by (Peng et al. 2006). The DNA–DNA hybridization among strains of *A. melinis* isolated from molasses grass varied from 81 % to 95 %, with a mean of 88.7 %, indicating that they represented the same genomic species. As expected, the DNA–DNA relatedness was 54–57 % for *Azospirillum lipoferum* DSM 1691^T and 30–34 % for *Azospirillum brasilense* Sp 7^T hybridized against the three strains of *A. melinis*. The DNA–DNA hybridization value between *Skermanella stibiiresistens* SB22^T and *S. aerolata* KACC 11604^T (= 5416 T-32^T) was 43.3 %. DNA–DNA hybridization studies of *Roseospira marina* CE2105, *Roseospira navarrensis* SE3104, and *Roseospira thiosulfatophila* AT2115 (AJ401208) showed low homologies between them and supported the separation into three species (Guyoneaud et al. 2002). No data are available for the other species or genera. DDH analysis showed that *Inquilinus ginsengisoli* Gsoil 080^T exhibited 12 ± 3.2 % DNA–DNA relatedness with *Inquilinus limosus* AU0476^T, whereas reciprocal hybridization resulted in a higher value of 15 ± 2.7 %. DDH studies for the other genera are missing, and in many cases, the 16S rRNA has been used to create new species.

DNA–DNA hybridization study showed that a dissimilatory perchlorate-reducing bacteria (DPRB) strain VDY^T, described as *Magnetospirillum bellicus*, has only 46.2 % similarity with *Dechlorospirillum anomalous*, although 99 % similarity was observed in 16S rRNA gene sequence analysis (Thrash et al. 2007). No data about DNA–DNA hybridization is available for *Magnetospirillum* (*M. gryphiswaldense* and *M. magnetotacticum*). Studies of DNA–DNA hybridization (DDH) on *Phaeospirillum* type strains are available for *P. oryzae* and *P. tilakii* between the other type strains of the genus. The neighbors strain *P. oryzae* JA317T and *P. chandramohanii* JA145T which share 98.2 % 16S rRNA gene sequence similarity present 55 % DDH similarity, which is lower than the level generally accepted to distinguish species. In addition, values of DDH for *P. oryzae* and the type strains *P. fulvum* DSM 113 T and *P. molischianum* ATCC 14031 T are 42 % and 38 % similarities, while 16S rRNA gene sequence similarities are 97.1 % and 97.4 %, respectively (Lakshmi et al. 2011b). Studies perfomed by Raj et al. (2012) presented very low DDH values for *P. tilakii* JA492T and the other *Phaeospirillum* type strains: 10–12 %, 10.2–14.6 %, 35.3–39.5 %, and 35.3–38 % DDH similarities between DSM 113 T, ATCC 14031 T, JA317T, and JA145T, respectively. DDH analysis indicated DNA–DNA relatedness value of 66 ± 1 % between *Thalassobaculum litoreum* DSM 18839^T and *Thalassobaculum salexigens* strain CZ41-10a^T (Urios et al. 2010). DNA–DNA hybridization assays indicated that *Thalassospira lucentensis* QMT2^T was the closest phylogenetic neighbor, and *T. xiamenensis* M-5^T and *T. tepidiphila* 1-1B^T were distantly related neighbors. The species *T. alkalitolerans* MBE#61^T and *T. mesophila* MBE#74^T showed relatively high levels of DNA–DNA relatedness (%); however, they exhibited low levels of hybridization value with *T. lucentensis* QMT2^T (12.5–16.0 % and 7.1–11.0 %, respectively), with *T. xiamenensis* M-5^T (24.1–25.0 % and 8.0–15.8 %, respectively), and with *T. tepidiphila* 1-1B^T (11.3–19.4 % and 9.0–10.4 %, respectively). The DNA–DNA relatedness between *T. alkalitolerans* MBE#61^T and *T. mesophila* MBE#74^T is 7.3–15.1 %. Studies involving species of genus *Tristella* showed that the level of DNA–DNA relatedness between strains *T. bauzanensis* BZ78^T and *T. mobilis* JCM 21370^T was 37.3 %, which was well below the threshold value of 70 % recommended for the delineation of bacterial species. In the case of the genus *Tistlia*, the DNA **GC%** of strain USBA 355^T was calculated to be 71 ± 1 mol% (Díaz-Cárdenas et al. 2010). This GC% value is closer to the genera *Inquilinus* and *Caenispirillum* and in the same range of the genera *Azospirillum* and *Magnetospirillum*. In contrast, it is quite distant from the genera *Thalassospira* and *Nisaea*. DNA–DNA hybridization (DDH) performed between species *Fodinicurvata sediminis* YIM D82T and *Fodinicurvata fenggangensis* YIM D812T showed a DNA–DNA relatedness of 27.5 %.

DDH experiments carried out between strains JA318^T of *Pararhodospirillum oryzae* and JA143^T of *Pararhodospirillum sulfurexigens* and strains JA318^T of *Pararhodospirillum oryzae* and DSM122^T of *Pararhodospirillum photometricum* resulted in reassociation values of 52 ± 2 % and 45.1 ± 1 % (n = 5, including reciprocal analyses), respectively, and these hybridization values supported the classification of strain JA318^T as a distinct species (Lakshmi et al. 2014). There are no reports of DNA–DNA hybridization studies involving neither *Rhodospirillum rubrum* nor *Rhodovibrio* sp. DNA–DNA relatedness of 93 % was reported, when *Caenispirillum bisanense* strain K92T was hybridized with strain K93, suggesting that the two strains represent the same genomic species (Yoon et al. 2007a).

Riboprinting and Ribotyping

The use of the riboprinting and ribotyping methods for clustering and characterization of members of the *Rhodospirillaceae* family is scarce. So far, the methods have been used for clustering several strains from few *Azospirillum* species and *Phaeospirillum*. The intraspecific diversity of *Azospirillum amazonense* isolates was studied by Azevedo et al. (2005) and

Reis Junior et al. (2006). Both authors used the intergenic space of 16–23S rDNA as target region, where the applied restriction enzymes allowed a highly resolving diversity analysis. Azevedo et al. (2005) observed a genetic diversity within the *A. amazonense* species and divided the isolates into four clusters with 78 % of similarity using *Hae*III, *Alu*I, *Rsa*I, *Cfo*I, *Msp*I, and *Eco*RI restriction enzymes. Reis Junior et al. (2006) obtained two groups defined at 56 % of similarity using *Alu*I, *Rsa*I, and *Cfo*I for other strains from the same species. Peng et al. (2006) used the IS-PCR fingerprinting to discover a new species of *Azospirillum*, *A. melinis*.

Oda et al. (2002) studied the bacterial community of aquatic sediments using BOX-PCR, RFLP, and 16S rRNA gene sequencing and reported two *Phaeospirillum fulvum* isolates.

MALDI-TOF

The use of the MALDI-TOF method for genotypic characterization of members of the *Rhodospirillaceae* family is scarce. Recently the method was used to differentiate few species from the genus *Azospirillum* (Stets et al. 2013). The authors compared the *A. brasilense*, *A. amazonense*, and *A. lipoferum* species commonly found associated to grasses to validate the discriminatory and identification efficiency of the method; MALDI-TOF MS was proposed to classify also other bacteria isolated from wheat roots. Six strains (Sp7, Sp245, FP2, HM210, SF0, and SF5) of *A. brasilense*, two strains (Y2 and Y6) of *A. amazonense*, and one strain DSM 1691 of *A. lipoferum* were grown in DYGS medium and analyzed in biological triplicates following the same procedures used for wheat isolates. The three *Azospirillum* species were grouped into separated clusters, and the four derivative strains of *A. brasilense* Sp7 and Sp245 also clustered according to their parent strains. It is noteworthy that the replicates always clustered together, but different strains formed distinct branches, distinguishing parent and derivative strains of *A. brasilense*. The technique is still under development; therefore, new data are not available yet.

Rudney et al. (2010) identified peptides assigned to *Phaeospirillum molischianum* when studying the metaproteome of the salivary microbiota by tandem mass spectrometry (MS/MS) followed by a cation exchange step-gradient chromatography linked to a microcapillary reverse-phase liquid chromatography.

Genome Comparison

Azospirillum–Skermanella–Rhodocista–Inquilinus

The most studied strains of the *Azospirillum* genus belong to the *A. brasilense*, *A. lipoferum*, and *A. amazonense* species that have complete or draft genome sequences available. The first data on genome structure of *Azospirillum* was described by Martin-Didonet et al. (2000), and at that time only six species were described. The authors used 10 strains of five *Azospirillum* species: *A. brasilense*, strains Sp7 (ATCC 29145), Cd (ATCC 29710), FP2, and Sp245; *A. lipoferum*, strains Sp59b (ATCC 29707) and JA25; *A. amazonense*, strains Y2 (ATCC 35120) and Y6 (ATCC 35121); *A. irakense*; and *A. halopraeferens*. The results showed the presence of several megareplicons with molecular sizes ranging from 0.2 to 2.7 Mbp as determined by pulsed-field gel electrophoresis (PFGE). The PFGE DNA patterns differed within the same species, which indicates that they are strain specific. In all strains tested, the presence of 16S rDNA was detected in more than one replicon, suggesting that *Azospirillum* contains multiple chromosomes. This assumption was confirmed later on with the genomes of three members of the *Azospirillum–R. centenaria* group available: *Azospirillum* sp. B510 (Kaneko et al. 2010), *A. brasilense* Sp245 (http://genome.ornl.gov/microbial/abra/19sep08/), and *R. centenaria* SW (Lu et al. 2010) detailed below. *Azospirillum* is usually compared to *Rhodocista centenaria* (formerly *Rhodospirillum centenum*), since the latter species possesses multiple chemotaxis operons and is used as a model organism to study chemotaxis (Xie et al. 2010).

Plasmids are present in *A. lipoferum* and *A. brasilense* strains tested over several years. Some of the strains contain as many as six plasmids ranging in size from 4 MDa to over 300 MDa (Elmerich 1983, 1986). A plasmid with a size of 90 Mda is present in all strains of *A. brasilense* and in some of *A. lipoferum* (p90) and shares conserved regions and carries several genes involved in the *A. brasilense*–plant root interaction (Croes et al. 1991; Alexandre and Bally 1999). Another plasmid – also described in detail – is pRhico found in *A. brasilense* Sp7, responsible for the interaction with roots. The *A. amazonense* strain Y2 presents four replicons with the following estimated sizes: 2.7 Mb, 2.2 Mb, 1.7 Mb, and 0.75 Mb (Martin-Didonet et al. 2000).

The *A. brasilense* Sp245 genome carries seven replicons of 3, 1.76, 0.912, 0.778, 0.690, 0.191, and 0.167 Mbp (Wisniewski-Dyé et al. 2011). These genomes encode genes related to nitrogen/carbon metabolism, energy production, phytohormone production, quorum sensing, antibiotic resistance, chemotaxis/motility, and bacteriophytochrome biosynthesis, as well as those involved in nitrogen and carbon fixation.

The genome of *Azospirillum* spp. strain B510, isolated from surface-sterilized stems of rice plants (*Oryza sativa* cv. Nipponbare) in Japan (Xie and Yokota 2005), consists of a single chromosome and six circular plasmids (pAB510a (1, 455, 109 bp), pAB510b (723, 779 bp), pAB510c (681, 723 bp), pAB510d (628, 837 bp), pAB510e (537, 299 bp), and pAB510f (261, 596 bp)) with the total size of 7,599,738 bp with no linear plasmids that are present in *A. brasilense* and *A. lipoferum*. Also *A. lipoferum* has the largest number of chromids (intermediates between chromosomes and plasmids) among all prokaryotes sequenced, indicating a potential for genome plasticity (Wisniewski-Dyé et al. 2011).

One of the most surprising features of the *A. amazonense* Y2 genome sequenced recently (Sant'Anna et al. 2011) is the presence of a gene cluster implicated in carbon fixation (the Calvin–Benson–Bassham cycle). The main genes of this cluster are the genes *cbbL* and *cbbS*, and they encode, respectively, the large and

small subunits of ribulose-1,5-bisphosphate carboxylase (RuBisCO). At least *R. centenaria* (formerly *R. centenum*) and *A. lipoferum* are known to be capable of growing autotrophically by means of RuBisCO in contrast to *Azospirillum* sp. B510 and *A. brasilense* Sp245, which do not contain Form I or II of RuBisCOs ("true" RuBisCOs) encoded in their genomes (Sant'Anna et al. 2011).

In *A. brasilense*, at least three pathways for IAA biosynthesis exist, two tryptophan-dependent pathways (indole-3-acetamide (IAM) pathway and indole-3-pyruvate (IPyA) pathway) and one tryptophan-independent pathway (Steenhoudt and Vanderleyden 2000; Spaepen et al. 2007). Similarly, the genome of *Azospirillum* sp. B510 contains genes responsible for the IAM pathway and three putative plant hormone-related genes encoding tryptophan 2-monooxytenase (*iaaM*) and indole-3-acetaldehyde hydrolase (*iaaH*), which are involved in IAA biosynthesis (Kaneko et al. 2010). However, the *iaaM*, *iaaH*, and *ipdC* genes, related to the IAM or IPyA pathways, were not located in the *A. amazonense* genome, and no *ipdC* homologue and *iaaC* was found in the B510 genome (Kaneko et al. 2010; Sant'Anna et al. 2011), suggesting that another pathway is present in these bacteria. Comparison among genome sequences of *A. brasilense* strains Sp 245 (origin: Brazil), Az39 (origin: Argentina), and CBG497 (origin: Mexico); *A. lipoferum* 4 B (origin: France); *Azospirillum* sp. B510 (origin: Japan); and *A. amazonense* Y2 (origin: Brazil), using BLAST for putative genes involved in IAA biosynthesis, showed that ipdC is present in *A. brasilense*, aromatic aminotransferase hisC1 is absent only in *A. amazonense*, aldehyde dehydrogenase is present only in Sp245 and Az39 genomes and nitrilase is present in Sp245, Az39, and Y2 genomes (Cassán et al. 2013). Further analysis of the genome sequence of *A. amazonense* revealed a gene encoding a protein with about 70 % similarity to nitrilases from plant species, like *Arabidopsis thaliana* and *Zea mays*, which catalyze the conversion of indole 3-acetonitrile to IAA (Kriechbaumer et al. 2007; Vorwerk et al. 2001). Future studies may indicate if this gene is envolved in IAA biosynthesis in *A. amazonense*.

Other features are also described to the *Azospirillum* genus such as chemotaxis/motility (Bible et al. 2008) including flagellum gene distributions (Chang et al. 2007; Sant'Anna et al. 2011), type IV secretion system (Kaneko et al. 2010), quorum sensing (Lerner et al. 2009), transport (TonB-dependent transport), antibiotic resistance (multidrug resistance (MDR) transporters), and several others (Sant'Anna et al. 2011). All three *Azospirillum* species possess three chemotaxis operons that are orthologous to those in *R. centenum*; however, they also have additional chemotaxis operons that are absent from their close aquatic relative (Wisniewski-Dyé et al. 2011).

Two species of the genus *Skermanella*, namely, *Skermanella aerolata* KACC 11604 and *Skermanella stibiiresistens* SB22, are being sequenced, but no sequence is available to date (http://www.ncbi.nlm.nih.gov/bioproject/).

The genome of *Rhodocista centenaria* ATCC 43720 T (formerly *Rhodospirillum centenum* strain SW = ATCC 51521) was sequenced (INSDC ID CP000613.2) (Lu et al. 2010). The genome presents 4,355,548 bp, 4,003 proteins, and 4,102 genes with a DNA G+C content of 70.5 %. The G+C content determined by thermal denaturation method on purified DNA is 69.9 mol% (Kawasaki et al. 1992). Extrachromosomal elements were absent. Genome assembly presents a single circular chromosome containing 35 pseudogenes, 4,003 protein coding genes, and 64 genes coding for RNA (11 rRNA genes, 52 tRNA genes, and 1 miscellaneous RNA gene). Nitrogenase reductase genes include *nif*, *mod*, and *fix* clusters for nitrogenase biosynthesis, molybdenium transport, and electron transport respectively. The absence of nitrogenase enzymes DRAT and DRAG, which mediated posttranslational regulation of nitrogenase Fe protein, suggests different environmental requirements for nitrogen fixation by *R. centenaria*. Two forms of RuBisCO (subtypes IAq and IC) and a gene encoding PEPC reveal superior ability for carbon fixation. Two genes encoding bacteriophytochrome are present (*ppr* and RC1_3803), and two genes coding for flavin-binding photoreceptors (RC1_2193 and RC1_0351) are suggested to play a role in controlling the bacterial metabolism in response of light. The sequences of the four 16S rRNA gene copies in the genome of *R. centenaria* SW are identical. A total of 72 flagella genes distributed in five gene clusters were identified to accomplish for the dual flagella system of *R. centenaria*: a constitutive polar flagellum and an inducible lateral flagellum.

The first draft assembly genome sequence of *Inquilinus limosus* (INSDC AUHM00000000) was reported by Pino et al. (2012). This genome was 7,413,714 bp long with a 69.87 % GC content and contained 7,081 predicted genes with 6,998 protein coding genes and 83 RNA genes. Besides genes with unknown function (610; 9.34 %), the highest number of genes are involved in amino acid transport and metabolism (857; 13.12 %), followed by genes coding for general function prediction only (848; 12.98 %), transcription (627, 9.60 %), carbohydrate transport and metabolism (705, 10.79 %), and inorganic ion transport and metabolism (408; 6.25 %). Other 199 genes (3.05 %) were found to code for secondary metabolite biosynthesis, transport, and catabolism, and 85 (1.30 %) were found related to defense mechanisms. According to Pino et al. (2012) 89 genes are likely involved in susceptibility or resistance to antibiotics and toxic compounds. Up to 19 could be coded for multidrug resistance efflux pumps while 21 for different classes of β-lactam recognizing proteins as penicillin-binding proteins. From them, four are homologous to β-lactamases deposited in databases. No transposable elements or pathogenicity islands could be detected.

Magnetospirillum–Phaeospirillum–Oceanibaculum–Thalassobaculum–Nisaea–Fodinicurvata–Tistlia–Tistrella–Rhodovibrio

Complete genome sequences of magnetotactic spirilla, *Magnetospira* sp. QH-2 and *Magnetospirillum* sp. (*Magnetospirillum magneticum*) AMB-1, from marine and freshwater environment, respectively, raised very important data

Table 22.1

Morphological, physiological and molecular differentiating characteristics among the genera of the family *Rhodospirillaceae*

	Azospirillum	*Desertibacter*	*Dongia*
Morphology	Straight or slightly curved rods	Rods	Slightly curved to straight rods
Gram-stain	Negative	Negative	Negative
Motility	+	+	+
Metabolism	Aero- and microaerobic	Strictly aerobic	Strictly aerobic and heterotrophic
Nitrogen fixation	+	Negative	Negative
Nitrate reduction	+	+	+
Range for growth			
Temperature (°C)	5–42 optimum 30	47–40	30–35
pH	5–9 optimum 7.0	7–10	7.0–7.5
Major fatty acids	18:1ω7c, 16:1ω7c, 16:0	C18:1 ω7c, C16:0, C18:0	C18:1v7c, C19:0 cyclo v8c, C16:0 and C16:0 2-OH
Ubiquinone type	Q-10	Q-10	Q-10
Genome size	6.8–7.6		
G+C content	64–69.6	71.4	65.6
Habitat	Mainly rhizosphere soil of several plants specially members of *Poaceae* family	Sand soil	Reactor
Additional characteristics	Denitrification variable		

	Constrictibacter	*Defluviicoccus*	*Fodinicurvata*	*Limimonas*	*Magnetospirillum*	*Nisaea*
Morphology	Ovoid to rods	Cocci/coccobacilli in tetrads and clusters	Vibrioid and rod-shape	Rod	Helical (clockwise) spirilla	Rod
Gram-stain	Negative	Negative	Negative	Negative	Negative	Negative
Motility	+	–	–	–	+	+

Sensitive to 3.0 % NaCl, produces water-soluble yellowish green fluorescent or brown pigment, the last in presence of tyrosine and tryptophan	Non-fermentative. Brown pigmented under photoautotrophic growth	Anaerobically grown colonies are beige to peach-colored	Cells contain internal photosynthetic membranes as vesicles. Photosynthetic pigments are bacteriochlorophyll a (esterified with phytol or geranylgeraniol) and carotenoids of the spirilloxanthin series. Photoheterotrophs under anaerobiosis in the light, or photoautotrophs with molecular hydrogen or sulfide as electron donors, or chemotrophs under microoxic to oxic conditions in the dark, or fermentatives and oxidant-dependent	Cells contain internal photosynthetic membranes as lamellar stacks forming a sharp angle to the cytoplasmic membrane. Photosynthetic pigments are bacteriochlorophyll a and carotenoids lycopene and rhodopin. Strict anaerobes and obligate phototrophs with preference for neutral pH	NaCl concentration −0.2–15 %	Halophilic; growth up to 10 % NaCl

about peculiarities associated with their gene structural organization, ecosystem origin, and adaptative evolution (Matsunaga et al. 2005; Richter et al. 2007; Ji et al. 2013). A 130 kb region representing a putative genomic "magnetosome island" (MAI) of *M. gryphiswaldense* was shown to undergo frequent transposition and subsequent deletion under physiological stress conditions (Ullrich et al. 2005). In this region a great abundance of multiple copies of transposase genes that belongs to different families of IS elements was observed, suggesting that these mobile genetic elements play a major role in driving the hypervariability shown by the organizational differences in spontaneous magnetosome mutants obtained upon subculture in the laboratory. Comparison of magnetosome gene organization among some MTB of *Rhodospirillaceae* revealed that distinct variations in gene order and sequence similarity, as well as copy numbers, are present in the MAI of the MTB. Based on these data and on a detailed comparison study including MTB of other classes, it has been considered that at least a set of *mam* genes (*mamH, I, E, K, M, O, P, A, Q, L, B, S, T, C, D, Z*, and *X*), *mms6* and *mmsF* are universally shared by the MAI on MTB of the *Rhodospirillaceae* family (Richter et al. 2007; Lefèvre et al. 2013b). Genes for nitrogen fixation and assimilatory nitrate respiration are well conserved among freshwater magnetospirilla, but absent from the *Magnetospira* sp. QH-2 genome. As observed in the QH-2 genome by gene cluster synteny and gene correlation analyses, the insertion of the magnetosome island probably occurred after divergence between freshwater and marine magnetospirilla. The presence of a sodium-quinone reductase, sodium transporters, and other functional genes is evidence of the adaptive evolution of *Magnetospira* sp. QH-2 to the marine ecosystem. In contrast, marine *Magnetospira* sp. QH-2 neither has TonB and TonB-dependent receptors nor does it grow on trace amounts of iron (Ji et al. 2013). Further draft genome comparison of other *Magnetospirillum* spp. revealed that the genome size varies from 4,2 Mbp to 4,9 Mbp and annotated ORFs from 3,878 to 4,925 (Dzyuba et al. 2012). The presence of plasmid is indicated to *M. gryphiswaldense* type strain, and a 3.7-kb cryptic plasmid designated pMGT was found in *M. magneticum* MGT-1 (Bertani et al. 2001; Okamura et al. 2003).

The genome of *Phaeospirillum molischianum* strain DSM 120^T was sequenced (INSDC ID CAHP00000000.1) (Duquesne et al. 2012). The genome presents 3,805,617 bp, 3,803 protein sequences, and 3,888 genes with a G+C content of 61.5 %. The G+C content determined as buoyant density and by thermal denaturation was in this range (60.5–64.8 mol%) (Imhoff et al. 1998). Extrachromosomal elements were absent. The genome assembly presents 61 contigs (sizes of 522–416,194 bp), 11 pseudogenes, 3,803 protein coding genes, and 62 genes coding for RNA (5 rRNA genes, 49 tRNA genes, and 8 other miscellaneous RNA genes). Proteins involved in signal transduction include 60 histidine kinase-type sensors and 65 response regulators (*LuxR, Fis, CheY*, and *OmpR* families), which are believed to play important roles in the adaptability of *P. molischianum* to environmental changes. Nitrogenase reductase genes include two types of nitrogenases, a Mo-Fe-dependent nitrogenase and an alternative Fe-Fe nitrogenase. In addition, 5.89 % of the overall genome corresponds to repetitive sequences, and a total of 81 transposases were predicted. The genome of the *Phaeospirillum fulvum* strain MGU-K5, isolated from a lake mud in Khabarovsk (Russia), was fully sequenced, and the automatic annotation is available (AQPH00000000.1 at NCBI). The genome presents 3,789,403 bp, 3,462 proteins, and 3,510 genes with a DNA G+C content of 63.9 %. Nitrogenase reductase genes, including molybdenium–iron and vanadium–iron nitrogenase subunits, are present in the genome. A high number of proteins involved in signal transduction (including ~49 histidine kinase-type sensors), response regulators (including approximately 2 *LuxR*, 1 *Fis*, and 21 *CheY* families), and cell detoxification (including approximately 12 multidrug efflux pumps, 4 heavy metal efflux pumps, and 8 RND-related efflux transporters) are present.

Oceanibaculum indicum P24^T draft genome contains 3,952,792 bp corresponding to a total of 3,755 protein-coding and 45 tRNA genes. According to Lai and Shao (2012a), the proteins associated with amino acid transport and metabolism (COG initial, E) were the most abundant COG group (415 open reading frames (ORFs), 14.4 %), followed by the ones associated with inorganic ion transport and metabolism (P; 244 ORFs, 8.5 %) and transcription (K;216 ORFs, 7.4 %).

One ongoing draft genome sequencing project on *Thalassobaculum salexigens* strain DSM 19539 is available at the public GenBank (NCBI) with a total length of 5.08 Mb and a GC content of 67.4 %. No more information about the proteins and ribosomal genes is available.

The *Nisaea denitrificans* DR41_21^T genome sequenced (GenBank accession number AUFM00000000) by DOE Joint Genome Institute is represented by 20 scaffolds covering 4626718 bases; of this total 91.53 % are coding DNA (98.62 % of protein coding, 1.38 % of RNA, and 0.67 % of pseudogenes coding, that is not additive under total gene count since it could be counted as protein coding or RNA genes). Another draft genome related to this genus is that of *Nisaea* sp. BAL199 (GenBank accession number ABHC00000000), by J. Craig Venter Institute, that consists of a total of 69 DNA scaffolds covering 6102701 bases that represent 90.10 % of total DNA coding bases, and a total of 6182 genes (99.13 % protein coding and 0.87 % RNA coding). Up to date, although publically available at NCBI, no further details about these genomes have been published elsewhere.

Fodinicurvata sediminis DSM 21159 (YIM D82T) genome (INSDC ATVH00000000.1), analyzed in the course of the Genomic Encyclopedia of Bacteria and Archaea, showed 3,690,548 bp long with 60.63 % GC content. This value is similar to those determined by T_m and nuclease method performed on purified DNA (61 mol%, ❯ *Table 22.1*). Besides 28 pseudogenes, 3,551 genes have been predicted, of which 3,490 were protein-coding genes and 61 were RNA genes. The distribution of genes into clusters of orthologous groups (COGs) functional categories indicates that the highest number of genes is involved in amino acid transport and metabolism (435; 13.42 %), followed by genes coding for general function prediction only (403; 12.43 %), transcription (215, 6.63 %), energy production and conversion (176; 5.43 %),

and carbohydrate transport and metabolism (175, 5.4 %). A total of 141 genes (4.35 %) were found to code for secondary metabolite biosynthesis, transport, and catabolism, and 35 (1.08 %) were found related to defense mechanisms.

The genome of *Tistlia consotensis* was sequenced using the Roche GS FLX + System allowing for long sequence reads (Rubiano-Labrador et al. 2014). After assembling the 171,055 reads, 2,377 contigs were obtained comprising a total of 5,701,113 bp sequence. The high sequence coverage obtained (10.4×) indicates that the genome size should be slightly above 5.7 Mbp. Based on the nucleotide sequences, the G+C mole percentage was estimated at 70.4 %. Remarkably, this value is among the highest G+C ratio known for *Alphaproteobacteria*, but the GC content between 60 and 70 mol% is consistent with that reported to halophilic and halotolerant microorganisms in *Rhodospirillaceae* family (Rubiano-Labrador et al. 2014). A high GC content (above 60 %), as found in *T. consotensis*, could be a common feature in halophilic microorganisms, since it is correlated with the abundance of acidic residues, especially Asp, in halophilic proteins. The acidic nature of the proteins contributes to adaptation at high salt concentrations.

The complete genome sequence of *Tistrella mobilis* strain KA081020-065 totaling 6,513,401 bp was established by 454 pyrosequencing to reveal five replicons comprising a 3,919,492-bp circular chromosome and four circular plasmids ranging in size from 83,885 bp (pTM4) to 1,126,962 bp (pTM3); it has also a high average G+C content of 68 % (Xu et al. 2012). Its genome organization with three megaplasmids greater than 600 kb each is reminiscent of several other α-proteobacteria members such as the rice plant endophyte *Azospirillum* sp. B510 that harbors six plasmids, five of which are in excess of 500 kb.

One ongoing draft genome sequencing project on *Rhodovibrio salinarum* strain DSM 9154 is available at the public GenBank (NCBI) with a total length of 4.18 Mb and a GC content of 64 %. No more information about the proteins and ribosomal genes is available.

Rhodospirillum–Pararhodospirillum–Novispirillum–Caenispirillum–Thalassospira

The *Rhodospirillum rubrum* genome consists of a 4,352,825-bp-long chromosome with 65 % G+C content and a 53,732-bp plasmid with 60 % G+C content (Munk et al. 2011). A total of 3,850 protein-coding genes and 83 RNA genes were predicted, including four copies of rrn operon. The *Pararhodospirillum photometricum* genome consists of a 3,876,289-bp chromosome, which encodes 3,281 proteins and 3 rRNAs (Duquesne and Sturgis 2012).

Novispirillum itersonii subsp. *itersonii* ATCC 12639 draft genome (GenBank accession number ARMX00000000) corresponds to 34 scaffolds, including Clustered Regularly Interspaced Short Palindromic Repeats (CRISPR), covering a total of 4290651 number of bases; of this total only 88.58 % was assigned as base coding for proteins (98.13 %) and RNA (1.87 %) genes.

A draft genome sequence of *Caenispirillum salinarum* AK4T (INSDC ANHY00000000) is available and consisted of 61 contigs of 4,952,365 bp. A total of 4,574 coding regions were found in the genome, where 3,092 (67.8 %) were functionally annotated. The number of genes transcribed from positive strands was 2,276 and from negative strands were 2,327. Besides genes with unknown function (401; 10.11 %), the distribution of genes into clusters of orthologous groups (COGs) functional categories indicates that the highest number of genes is involved only in general function prediction (458; 11.55 %), followed by genes coding for amino acid transport and metabolism (353; 8.9 %) and energy production and conversion and signal transduction mechanisms (both 295; 7.44 %). A total of 124 genes (3.13 %) were found to code for secondary metabolite biosynthesis, transport, and catabolism, and 47 (1.19 %) were found related to defense mechanisms. In agreement with Khatri et al. (2013), the functional comparison of genome sequences available on the RAST server revealed the closest neighbors of *Caenispirillum salinarum* to be *Rhodospirillum rubrum* ATCC 11170 (score 533) followed by *Magnetospirillum magneticum* AMB-1 (score 520), *Rhodospirillum rubrum* (score 490), *Magnetospirillum gryphiswaldense* MSR-1 (score 472), and *Alphaproteobacterium* BAL199 (score 318).

The genome of *Thalassospira profundimaris* WP0211^T was sequenced and contains 4,040 candidate protein-encoding genes (with an average size of 958 bp), giving a coding intensity of 88.4 % (Lai and Shao 2012b). A total of 3,157 proteins could be assigned to clusters of orthologous groups (COG) families. Forty-three tRNA genes for 18 amino acids (lacking Asn and Lys) were identified. The proteins associated with amino acid transport and metabolism (COG initial, E) were the most abundant group among the COGs (412 open reading frames (ORFs), 13.1 %), followed by the proteins associated with transcription (K; 360 ORFs, 11.4 %) and inorganic ion transport and metabolism (P; 263 ORFs, 8.3 %).

Phenotypic Analyses

The main features of the members of *Rhodospirillaceae* are listed in ❯ *Table 22.1*.

Azospirillum Tarrand et al. 1979 (1980), Emend. Falk et al. 1985

A.zo.spi.ril'lum. French noun azote, nitrogen; Greek noun spira, a spiral; spillum, a small spiral; *Azospirillum*, a small nitrogen spiral.

Bacteria belonging to the genus *Azospirillum* are Gram negative, aerobic, curved, or slightly curved rods, spiral with diameter varying from 0.6 to 1.5 μm, and lengths vary with the species and culture medium from 1.0 to 7.0 μm. Motile by a single polar flagellum and lateral several smaller ones, shorter in length. Generally contains granules of poly-β-hydroxybutyrate (PHB). Oxidase, catalase, and urease activity is present in some species. Also nitrate–nitrite and denitrification is present in some species but not all three pathways together and a single species,

A. palatum, described as a non-nitrogen-fixing bacterium. Most bacteria of the genus *Azospirillum* grow aerobically, but three species were classified as facultative anaerobic such as *A. melinis, A. thiophilum*, and *A. humicireducens*. Sugars are oxidized but not fermented. It is considered a mesophilic genus with growth at 20–37 °C, optimum temperature at 30 °C. Some species can grow at 5 ° C and a maximum temperature of 41 °C was found for *A. halopraeferens*. The pH range can vary from 4.0 to 8.0, but neutral pH is the optimum for most of the species. Growth in 3 % NaCl is also variable, but it is a special feature for *A. halopraeferens*. Bacteria of this genus also utilize several carbon sources such as organic acids, sugars, amino acids, and sugar alcohols; the pattern of carbon utilization has been used for discriminatory purpose between the species of the genus. The use of the nitrogen-free NFb semisolid medium allows the enrichment and isolation of several species although new media can also be used. Several new isolates obtained from soil and other environments confirm that this genus is widespread in nature and in different regions of the world. *Azospirillum* lipids have a large amount of $C_{18:1}\omega7c$ (55.3 %) and also contain $C_{16:1}\omega7c$ and $C_{16:0}$ as major components; the major hydroxy fatty acids are $C_{14:0}$ 3-OH and $C_{16:0}$ 3-OH. When grown aerobically, the species of this genus exhibit a quinone system with ubiquinone 10 (Q-10). The polar lipids consist mainly of phosphatidylglycerol, phosphatidylcholine, and one unidentified phospholipid. The DNA G+C content varies between 64 and 71 mol%. This genus is closely related to *Rhodocista* and *Skermanella* based on the 16S rRNA gene sequence comparison. The type species of the genus is *A. lipoferum* and the type strain is 59b (= ATCC 29707 = CIP 106280 = DSM 1691 = JCM 1247 = LMG 13128 = NBRC 102290 = NCAIM B.01801 = NRRL B-14654 = VKM B-1519). Besides the type species, the genus embraces 16 other species, isolated either from the rhizosphere or from endophytic plant tissues, agricultural or contaminated soil samples, water, and fermented tank, as follows: *A.brasilense* (Tarrand et al. 1978), *A. amazonense* (Magalhães et al. 1983), *A. halopraeferens* (Reinhold et al. 1987), *A. irakense* (Khammas et al. 1989), *A. largimobile* (Ben Dekhil et al. 1997), *A. doebereinerae* (Eckert et al. 2001), *A. oryzae* (Xie and Yokota 2005), *A. melinis* (Peng et al. 2006), *A. canadense* (Mehnaz et al. 2007a), *A. zeae* (Mehnaz et al. 2007b), *A. rugosum* (Young et al. 2008), *A. picis* (Lin et al. 2009), *A. palatum* (Zhou et al. 2009), *A. thiophilum* (Lavrinenko et al. 2010), *A. formosense* (Lin et al. 2012), *A. humicireducens* (Zhou et al. 2013), and *A. fermentarium* (Lin et al. 2013). The type strains and additional characteristics for these species are listed in *Table 22.2*.

Conglomeromonas Skerman et al. 1983

Con. glom. e. ro. monas, L. pp. conglomeratus to form in a [rounded] mass; Gr. fem. n. monas a unit, monad; M. L. fem. n. *Conglomeromonas* monad forming in a [rounded] mass.

The genus *Conglomeromonas* has one species, *Conglomeromonas largomobilis*, and two subspecies, *Conglomeromonas largomobilis* subsp. *largomobilis* and *Conglomeromonas largomobilis* subsp. *parooensis*, as was proposed by Skerman et al. (1983). This genus was proposed to incorporate the strains described as follows: Gram-negative, non-spore-forming organisms which exhibit unicellular and multicellular phases of growth. Unicellular phase cells are rod shaped, with rounded or tapered ends and a straight or slightly curved axis; cells are arranged singly or in pairs. Motile cells have mixed flagellation, with a single polar flagellum and one or more distinctive lateral flagella of different thickness and length. The DNA G+C content was 67.0 mol%. Although these organisms were isolated from freshwater sources rather than from soil or plant roots and are not able to fix nitrogen under aerobic conditions, other characteristics suggested that they may be related to the genus *Azospirillum* (Skerman et al. 1983). Ben Dekhil et al. (1997) transferred the type species of the genus *Conglomeromonas largomobilis* subsp. *largomobilis* to the genus *Azospirillum* as *A. largomobile* on the basis of phylogenetic evidence based on16S rRNA gene sequence comparisons and earlier nucleic acid hybridization studies (Falk et al. 1986). Furthermore, the genus *Conglomeromonas* became invalid, and consequently, a new genus was required to accommodate *C. largomobilis* subsp. *parooensis*. Thus, Sly and Stackebrandt (1999) created a new genus *Skermanella* and transferred the subspecies of *C. largomobilis* subsp. *parooensis* as *Skermanella parooensis*.

Skermanella Sly and Stackebrandt (1999), Emended Weon et al. (2007) and Luo et al. 2012

Sker.ma.nel'la. M.L. dim. ending -ella; M.L. fem. dim. n. *Skermanella* named after V. B. D. Skerman who first isolated this bacterium, and in honor of his contribution to bacterial systematics.

Bacteria of this genus are Gram negative and non-spore forming, which exhibits unicellular and multicellular phases of growth. Unicellular-phase cells are rod shaped, with rounded or tapered ends and a straight or slightly curved axis, arranged singularly or in pairs. Motile cells have mixed flagellation, with a single polar flagellum and one or more distinct lateral flagella of different lengths. Multicellular conglomerates arise from single cells, which lose motility, become optically refractile, and reproduce by multi-planar septation. Under suitable conditions conglomerates dissociate into single motile cells, which produce water-clear colonies in which the sparse number of cells move in a sluggish manner. No filamentous structures are formed and no buds are produced. The bacterium is an obligate chemoorganotroph and strictly aerobic. All members of the genus are positive for catalase, oxidase, alkaline phosphatase, acid phosphatase, esterase (C4), naphthol-AS-BI-phosphohydrolase, and leucine arylamidase, but negative for α-galactosidase, β-galactosidase, α-mannosidase, β-fucosidase, N-acetyl-β-glucosaminidase, α-chymotrypsin, and trypsin. Carbohydrate metabolism is fermentative and glucose fermentation is variable. Cells do not fix dinitrogen under microaerophilic

conditions. Strains of this genus have a high DNA G+C content (65.0–69.6 mol%), and the major respiratory quinone is Q-10. The major polar lipids are diphosphatidylglycerol, phosphatidylcholine, phosphatidylethanolamine, phosphatidylglycerol, and an unknown aminolipid. The nearest phylogenetic relative is *Azospirillum largimobile* (93 % 16S rRNA gene sequence similarity). The type species is *Skermanella parooensis* and the type strain is ACM 2042 (= CIP 106994 = DSM 9527 = UQM 2042). The other species of the genus are *S. xinjiangensis* (An et al. 2009), *S. stibiiresistens* (Luo et al. 2012), and *S. aerolata* (Weon et al. 2007). The *S. stibiiresistens* strain SB22^T is highly resistant to antimony, growing in the presence of 4 mM Sb(III) in R_2A broth. The type strains and additional characteristics for these species are listed in ● *Table 22.3*.

Desertibacter Liu et al. 2011

De.ser.ti.bac'ter. L. n. *desertum* desert; N.L. masc. n. *bacter* rod; N.L. masc. n. *Desertibacter* a desert bacterium.

The cells are Gram-negative rods, motile by means of a single polar flagellum and strictly aerobic. They are catalase and oxidase positive and are able to reduce nitrate to nitrite. *Desertibacter* is not able to fix nitrogen. Colonies of the type strain 2622^T are pink, circular, and convex with regular margins. Cells contain PHB. Growth occurs at 12–42 °C (optimum 37–40 °C), at pH 7–10 (optimum pH 8), and at NaCl concentrations of up to 1.5 % (optimum 0.5 % NaCl). Hydrolyse aesculin and gelatin but not casein, tyrosine, or starch. In API ZYM tests, positive for alkaline phosphatase, esterase (C4), esterase/lipase (C8), leucine arylamidase, valine arylamidase, cystine arylamidase, naphthol-AS-BI-phosphohydrolase, β-galactosidase (weakly), and α-glucosidase (weakly) and negative for lipase (C14), trypsin, α-chymotrypsin, acid phosphatase, α-galactosidase, β-glucuronidase, N-acetyl-b-glucosaminidase, β-glucosidase, α-mannosidase, and α-fucosidase. API 20NE tests show positive reactions for nitrate reduction, aesculin hydrolysis, gelatin hydrolysis, urease, and β-galactosidase and negative reactions for arginine dihydrolase, indole production, and glucose fermentation. It does not assimilate D-glucose, L-arabinose, maltose, D-mannose, D-mannitol, N-acetylglucosamine, adipic acid, capric acid, malic acid, potassium gluconate, trisodium citrate, or phenylacetic acid. The DNA G+C content of strain 2622^T is 71.4 mol%. The type species is *Desertibacter roseus* and type strain 2622^T (= CCTCC AB 20812 T = KCTC 22436 T), isolated from a gamma-irradiated sand sample from the Taklimakan desert in Xinjiang, China. The type strains and additional characteristics for these species are listed in ● *Table 22.4*.

Rhodocista Kawasaki et al. 1994

Rho.do.ci'sta. L. fem. n. *rhodos* the rose; L. fem.n. *cista* a basket; M.L. fem.n., *Rhodocista* red basket.

Cells have vibrioid to spiral cell form with a size of 0.6–2 µm; they are motile by means of a polar flagellum. Growth is mesophilic. Photosynthetic membranes are present as lamellae lying parallel to cytoplasmatic membrane when cells are grown phototrophically. Growth occurs phototrophically under anaerobic conditions in the light and chemoheterotrophically under aerobic conditions in the dark. Anaerobically grown colonies are pink. Bacteriochlorophyll *a* and carotenoids of the spirilloxanthin series are present. Cells are converted to cysts under aerobic incubation, becoming resistant to desiccation and heat. The major cellular ubiquinone is ubiquinone Q-9. The DNA G+C content is 68.8–69.9 mol%. The type species is *Rhodocista centenaria* ATCC 43720^T (= DSM 9894^T = IAM 14193^T = NRBC 16667^T = JCM 21060^T) isolated from a water sample at the edge of a thermophilic hot spring at Wyoming, USA (Kawasaki et al. 1994). This species is a homotypic synonym of *Rhodospirillum centenum* (Favinger et al. 1989). *Rhodocista pekingensis* is the second species of the genus, and the type strain 3-p^T (= AS 1.2194^T = JCM 11669^T) was isolated from a municipal wastewater treatment plant at Beijing, China (Zhang et al. 2003). The type strains and additional characteristics for these species are listed in ● *Table 22.5*.

Dongia Liu et al. 2010

Don'gi.a. N.L. fem. n. *Dongia* after Professor Xiu-Zhu Dong, a bacteriologist and bacterial taxonomist in China.

The cells are Gram negative, 0.3–0.5 µm wide and 0.6–1.0 µm long, non-spore forming, motile, and slightly curved to straight rods. They have a strictly aerobic metabolism and are heterotrophic – never phototrophic. Internal membrane systems and bacteriochlorophyll a are absent. Cells reduce nitrate to nitrite and oxidase is variable. Dongia cells are negative for ß-galactosidase, urease, catalase, and production of indole and H_2S. They hydrolyze Tweens 20 and 80 weakly, but starch, L-tyrosine, casein, arginine, gelatin, and aesculin are not hydrolyzed. Using the standard mineral base according to Dong and Cai (2001), weak growth on L-arabinose, cellobiose, glucose, lactose, maltose, raffinose, sucrose, D-xylose,erythritol, glycerol, and D-glucitol was observed; no growth occurred with sodium acetate, casein, citrate, citric acid, inositol, malic acid, methanol, L-rhamnose, sorbitol, and succinic acid. API ZYM tests are positive for alkaline phosphatase, esterase (C4), esterase lipase (C8), leucine arylamidase, phosphatase acid, and naphthol-AS-BI-phosphohydrolase and weakly positive for lipase (C14), valine arylamidase, and cystine arylamidase. The type species of the genus is *Dongia mobilis*. Type strain is LM22^T (5CGMCC 1.7660 T 5JCM15798T), isolated from a sequencing batch reactor for the treatment of malachite green effluent. A second species, *Dongia rigui*, type strain 04SU4-P^T (KCTC 23341 = JCM 17521), was isolated from freshwater collected from the Woopo wetland, Republic of Korea (Baik et al. 2013). Both species have as majors fatty acids (>10 % of the total) $C_{19:0}$ω8c cyclo, $C_{16:0}$, and $C_{18:0}$ω7c. The major ubiquinone is Q-10. The DNA G+C content varies from 65.6 to 71.5 mol%. The type strains and additional characteristics for these species are listed in ● *Table 22.6*.

Elstera Rahalkar et al. 2012

Els'te.ra. N.L. fem. n. *Elstera* named after Hans-Joachim Elster, a German limnologist working on Lake Constance who was one of the first to establish the importance of the littoral zone for the lake ecosystem.

Cells are Gram-negative rods; they are catalase and oxidase positive. They grow chemoheterotrophically and use sugars, some organic acids, and alcohols as preferred substrates. Ubiquinone Q-10 is the dominant quinone and putrescine is the dominant polyamine. Cells are slightly curved rods, 1.0 × 2.0–5.0 μm in size, and nonmotile, with a minimum doubling time of approximately 40 h. Based on API 20NE and Biolog PM1 tests, cells are negative for the reduction of nitrate, sulfate, and iron (III); nitrogen fixation; and indole production from tryptophan. The cells grow in the presence of many carbon sources such as D-glucose, L-rhamnose, D-fructose, D-galactose, L-arabinose, D-xylose, D-mannitol, D-sorbitol, D-glucuronic acid, glycerol, ethanol, and L-malate. Weak or no growth was observed in the presence of trehalose, D-maltose, dulcitol, adonitol, D-saccharic acid, N-acetyl-β-*o*-mannosamine, glucuronamide, D-glucosaminic acid, formate, acetate, propionate, pyruvate, L-lactate, D-malate, fumarate, succinate, glycolate, glyoxylate, citric acid, m-tartrate, 2-oxoglutarate, and Tweens 20, 40, and 80. The DNA G+C content of strain Dia-1 is 61.0 ± 1.5 mol%. The type species is *Elstera litoralis* and type strain is Dia-1^T (= DSM 19532 T = LMG 24234 T). It was isolated from biofilms on stones in the littoral zone of Lake Constance, Germany. The type strains and additional characteristics for this species are listed in *Table 22.7*.

Inquilinus Coenye et al. 2002

In.qui'li.nus. L. masc. n., *Inquilinus* an inhabitant of a place that is not its own.

Cells are Gram negative, strictly aerobic, chemoorganotrophic, nonmotile, nonsporulating, and rod shaped; *I. ginsengisoli* has a cell size of 0.6–0.8 × 2.5–4.0 μm when grown for 2 days at 30 °C on R_2A agar. Catalase activity is present. Growth is observed at 25–42 °C and in 1 % NaCl. *I. ginsengisoli* cannot grow with 3 % (w/v) NaCl and at 37 °C. Growth is observed on BCSA at 32 °C. There are no denitrification and indole production. Based on RapID NF Plus (Remel) and API 20E (bioMerieux, Hazelwood, MO), lysine decarboxylase, ornithine decarboxylase, or arginine dihydrolase activities are negative. There are no pigment production, lipase, phosphatase, N-acetylglucosaminidase, β-glucosidase, proline aminopeptidase, pyrrolidonyl aminopeptidase, and tryptophan aminopeptidase; N-benzyl-arginine aminopeptidase activity may be present. Utilization of carbon sources (API 20NE and API ID 32 GN kits) is variable between species (Jung et al. 2011). The predominant ubiquinone is Q-10, and the majority of cellular fatty acids are $C_{18:0}$ω7c, $C_{18:1}$2-OH, and $C_{18:0}$3-OH. The G+C content of the genome is between 69.9 and 70.9 mol%. The genus *Inquilinus* was originally described by Coenye et al. (2002).

It comprises the species *Inquilinus limosus*, isolated from respiratory secretions of a cystic fibrosis patient in the USA (Coenye et al. 2002), and *Inquilinus ginsengisoli*, isolated from ginseng field soil (Jung et al. 2011). The *Inquilinus limosus* AU0476^T (= LMG 20952 T = CCUG45653T) is the type species. The type strains and additional characteristics for these species are listed in *Table 22.8*.

Magnetospirillum Scheifer et al. 1992

Mag.ne'to.spir.il'lum, Gr.n.magnes, magnet, comb. form magneto-, Gr.n.*spira* a spiral; M.L.dim.neut.n.*spirillum* a small spiral; *Magnetospirillum* a small magnetic spiral.

Bacteria are characterized by a helical (clockwise) spirillum cell shape; cells are 0.2–0.7 μm wide and 1.0–20.0 μm long. The cells have a Gram-negative cell wall and are motile by means of a single flagellum at each pole. Each magnetotactic cell contains membrane enveloped crystals, named magnetosomes, which are arranged in a chain within the cytoplasm. Mobility and magnetic behavior can be diminished or lost after several subcultivations. The cells are microaerophilic and chemoorganotrophic. Catalase and oxidase can be present or absent. Growth occurs on various organic acids; carbohydrates

are utilized only occasionally. *Magnetospirillum* is nitrogen fixation positive as indicated by acetylene reduction assay, *nif*HDK hybridization, and growth in N-free media (Bazylinski et al. 2000). The G+C content of DNA is 64–71 mol%. The type species is *Magnetospirillum gryphiswaldense* and the type strain is MSR-1 (= DSM 6361 = IFO – now NBRC 15271 = JCM 21280). The other species of the genus is *Magnetospirillum magnetotacticum*, type strain MS-1 (= ATCC 31632 = DSM 3856 = IFO – now NBRC 15272 = JCM 21281 = LMG 10894). This species is the basonym of *Aquaspirillum magnetotacticum* (Maratea and Blakemore 1981 emended by Scheifer et al. 1992). The type strains and additional characteristics for these species are listed in ➤ *Table 22.9*.

Phaeospirillum Imhoff et al. 1998

Phae.o.spi.ril´lum. Gr. adj. *phaeos*, brown; M.L. neut. n. *Spirillum*, a bacterial genus; M.L. neut. n., *Phaeospirillum*, brown *Spirillum*.

Phaeospirillum forms vibrioid- to spiral-shaped cells, 0.5–1.2 μm in size. The cells are motile by means of polar flagella. Carotenoid glycosides and bacteriochlorophyll *a* are present on intracytoplasmatic photosynthetic membranes as lamellar stacks. Growth is mesophilic. The major fatty acids are $C_{18:1}\omega7c$, $C_{16:0}$, and $C_{16:1}\omega6c$ and/or $C_{16:1}\omega7c$. Growth is preferably photo-organotrophically under anaerobic conditions in the light or in the dark under microaerobic conditions. Cell suspensions are dark brown to brown-orange/brown-red colored. Cells harbors ubiquinone Q-9 and menaquinone MK-9 as major components. The DNA G+C content is 60.5–64.8 mol%. This genus name was created by Imhoff et al. (1998) after reclassification of brown-colored spiral-shaped phototrophic purple non-sulfur bacteria formerly classified originally as *Rhodospirillum*, based on genetic and phenotypic characteristics. The species of this genus have been isolated from freshwater, mud, and rhizosphere soil and show no salt requirement for growth. The type species is *Phaeospirillum fulvum* and the type strain ATCC 15798^T (= ATCC 53113^T = DSM 113^T) was isolated from sewage pond (van Niel 1944; Imhoff et al. 1998). *P. molischianum* was described as the second species, and the type strain ATCC 14031^T (= DSM 120^T = LMG 4354^T) was isolated from mud from a ditch (Giesberger 1947; Imhoff et al. 1998). The third species is *P. chandramohanii*, type strain JA145^T (= JCM 14933^T = KCTC5703^T = NBRC 104961^T), isolated

from freshwater reservoir at Mudasarlova, India (Kumar et al. 2009). The fourth species described is *P. oryzae*, and the type strain JA317^T (= KCTC 5704^T = NBRC 104938^T) was isolated from rhizosphere soil of a paddy at Nadergul, India (Lakshmi et al. 2011); the fifth species of the genus is *P. tilakii*, and the type strain JA492^T (= KCTC 15012^T = NBRC 107650^T) was isolated from a water/mud from Nelapattu Bird Sanctuary, India (Raj et al. 2012). The type strains and additional characteristics for these species are listed in *Table 22.10*.

Nisaea Urios et al. 2008

Nis´ae.a. L. fem. n., *Nisaea* nymph of the sea (1 of the 50 daughters of Nereus and Doris), referring to the marine origin.

Cells are motile, Gram-negative rods growing optimally at 30 °C, pH 6.0, and 20 g l^{-1} NaCl. The major fatty acids are $C_{18:1}\omega7c$ (69.1 %), $C_{16:1}\omega7c$ (13.9 %), and $C_{16:0}$ (11.3 %). The cells harbor Q-10 and the polar lipid phosphatidylglycerol. On Biolog GN2 plates positive reactions are obtained for fructose, glucose, raffinose, acetate, γ-hydroxybutyrate, and propionate. Positive reactions with API ZYM are obtained for alkaline phosphatase, acid phosphatase, and leucine arylamidase. Oxidase and catalase are positive. The genus *Nisaea* was created after characterization of strains isolated from one of the major sites of water-column denitrification among the world's oceans (Urios et al. 2008). It comprises two species, the type species *Nisaea denitrificans* (type strain DR41_21 = OOB 129 = CIP 109265 = DSM 18348) and *N. nitritireducens* (type strain DR41_18 = OOB 128 = CIP 109601 = DSM 19540). The DNA G+C content is around 60.1–60.2 mol%. The type strains and additional characteristics for these species are listed in *Table 22.11*.

Thalassobaculum Zhang et al. 2008, Emend. Urios et al. 2010

Tha.las´so.ba.cu.lum. Gr. n. *Thalassa*, the sea; L. neut. n. *baculum*, stick; N.L. neut. n. *Thalassobaculum* rod-shaped bacterium from the sea.

Cells are Gram negative, slightly curved, and straight rod shaped; they are motile by means of a polar flagellum. Growth is heterotrophic and some of the strains are facultative anaerobes. Cells are positive for oxidase and catalase. Bacteriochlorophyll a is not present. Cells do not fix atmospheric N_2 under anoxic conditions. Optimal growth occurs at 30 °C, at pH 8.0, and at high salinity ranging from 34 to 40 g l^{-1}. Cells are tested positive for leucine arylamidase and valine arylamidase activities with the API ZYM kit. Carbon source utilization is variable according to the kit applied. The major fatty acids are $C_{18:1}\omega7c$, $C_{16:0}$, $C_{17:0}$, and summed feature 3 ($C_{16:1}\omega7c$ and/or iso-$C_{15:0}$ 2-OH). The isoprenoid quinone is Q-10. The G+C content of the DNA is 65–68 mol%. The type species of the genus is *Thalassobaculum litoreum* and type strain CL-GR58^T (= KCCM 42674^T = DSM 18839^T) that was isolated from coastal seawater, Korea (Zhang et al. 2008). The second species is *T. salexigens*, type strain CZ41-10a^T (= DSM 19539^T = CIP 109064^T = MOLA 84^T), isolated from the water column in the bay of Banyuls-sur-Mer, France (Urios et al. 2010). The type strains and additional characteristics for these species are listed in Table 22.12.

Oceanibaculum Lai et al. 2009, Emend. Dong et al. 2010

O.ce.a'ni.ba'cu.lum. Gr. n. *oceanus*, ocean; L. neut. n. *baculum*, stick; N.L. neut. n. *Oceanibaculum*, rod-shaped bacterium from the ocean.

The genus is characterized by rod-shaped cells, motile by means of a single polar flagellum. The cells stain Gram negative and are oxidase positive. Catalase activity and nitrate reduction are variable. The type species share similar characteristics of growth on 216 L agar plates, forming smooth, gray colonies with regular edges, 1–2 mm in diameter after 72 h incubation at 28 °C, and are nonpigmented and slightly raised in the center. The strains are unable to ferment glucose; they are moderately halophilic, but optimum NaCl concentration varies among them. The dominant fatty acids are $C_{16:1}\omega7c$, $C_{16:0}$, $C_{18:0}$, $C_{18:1}\omega7c$, $C_{18:1}$2-OH, and $C_{19:0}\omega8c$ cyclo. Bacteriochlorophyll *a* is not present. The DNA G+C content is 64.8–67.7 mol%. The type species is *Oceanibaculum indicum* and the type strain is P24 (= CCTCC AB 208226 = LMG 24626 = MCCC 1A02083).

The second species of the genus is *Oceanibaculum pacificum*, type strain LMC2up-L3 (= MC2UP-L3 = CCTCC AB 209059 = LMG 24859 = MCCC 1A02656), and was isolated from a hydrothermal field sediment of the southwest Pacific Ocean (Dong et al. 2010). The type strains and additional characteristics for these species are listed in *Table 22.13*.

Fodinicurvata Wang et al. 2009

Fo.di.ni.cur.va'ta. L. fem. n. *fodina*, mine; L. adj. curvatus -a -um curved; N.L. fem. n. *Fodinicurvata*, curved-shaped bacterium isolated from a mine.

Cells have a Gram-negative cell wall structure and a size of 0.2–0.5 × 0.5–1.5 μm. They are facultatively anaerobic, vibrioid, and rod shaped. Neither flagella nor endospores are present. Catalase and oxidase are positive. Colonies are cream–white, circular, convex, and opaque with irregular margins after growth on NA supplemented with 5 % at 28 °C for 5 days. Growth occurs under anaerobic conditions. The temperature range for growth is 15–42 °C (optimum, 28 °C), and the pH range for growth is 6.5–8.5 (optimum, 7.5). The carbon sources L-arabinose, D-mannitol, and sucrose are used by *F. sediminis*, while *F. fenggangensis* utilizes myoinositol. Growth occurs at NaCl concentrations of 1.5–20 % (w/v) (optimum, 5 %). Bacteriochlorophyll *a* is not present. Cells accumulate PHB granules and are able to reduce nitrate. The two species strains do not produce H_2S or L-phenylalanine deaminase. Biochemical tests for nitrate reduction, arginine dihydrolase, and urease are positive. Hydrolysis of aesculin and gelatin, indole production, glucose acidification, and phenylalanine deaminase and b-galactosidase are negative. The predominant polar lipids consist of diphosphatidylglycerol, phosphatidylmethylethanolamine, and phosphatidylcholine. Phosphatidylinositol is variable. The DNA G+C content varies from 61.5 to 62.3 mol%. The type species of the genus is *F. sediminis* and the type strains is YIM D82^T (= DSM 21159 T = KCTC22351T). The second species is *F. fenggangensis* strain YIM D812^T (= CCTCC AA 208037 T = DSM 21160 T). Both species were isolated from a salt mine of Fenggang in Yunnan, southwest China. The type strains and additional characteristics for these species are listed in *Table 22.14*.

Pelagibius Choi et al. 2009

Pe.la.gi.bi'us. L. n. *pelagus*, the sea; N.L. masc. n. *bius* from Gr. N. *bios* life; N.L. masc. N., *Pelagibius*, sea life.

Pelagibius forms slightly curved or straight rods, motile by means of a polar flagellum. Cells are strictly aerobic, non-fermentative heterotrophs; they require salt for growth. Cells are oxidase and catalase positive. Growth is mesophilic. Poly-β-hydroxybutyrate granules are formed. Dominant fatty acids are $C_{18:1}\omega7c$, $C_{18:0}$ 3-OH, and $C_{19:0}$ cyclo $\omega8c$. Ubiquinone 10 (Q-10) is the major isoprenoid quinone. Chemotactic and phenotypic characteristics differentiate *Pelagibius* from other related genera in the family *Rhodospirillaceae*, such as temperature range for growth (15–33 °C), pH 6–11, salt tolerance range (2–6 %), and absence of bacteriochlorophyll *a*. Amylase and gelatinase are not produced. Cells grow on L-tyrosine, but casein, hypoxanthine, Tween 80, and xanthine are not hydrolyzed. Cells reduce nitrate to nitrite. According to API ZYM substrate panel, the type strain produces alkaline and acid phosphatases, esterase (C4), leucine arylamidase, naphthol-AS-BI-phosphohydrolase, and β-galactosidase. Aesculin is hydrolyzed (API 20NE). Cells utilize L-arabinose, D-galactose, D-glucose, inositol, inulin, D-mannitol, D-mannose, pyruvic acid, succinate, tartrate, and D-xylose as sole carbon sources. The DNA G+C content of the type species is 66.3 mol%. The type species is *Pelagibius litoralis*, and the type strain CL-UU02^T (= KCCM 42323^T = JCM 15426^T) was isolated from seawater of the east coast of Korea (Choi et al. 2009). The type strains and additional characteristics for this species are listed in *Table 22.15*.

Tistlia Díaz-Cárdenas et al. 2010

Tistlia Tist'li.a. N.L. fem. n. *Tistlia* named after Tistl, honoring Michael Tistl, a geologist, for his rediscovery of the Salado de Consotá saline spring.

Cells of *Tistlia* are strictly aerobic, slightly curved to straight rods which do not possess pili or form spores. Gram reaction is negative. In *Tistlia consotensis* (Díaz-Cárdenas et al. 2010) cells reveal a Gram-positive cell-wall ultrastructure. Cell sizes are 0.6–0.7 × 3.0–3.5 μm. Cells multiply by binary fission and show tumbling motility. Growth is mesophilic and slightly halophilic with optimum growth occurring at 30 °C, pH 6.5–6.7, and a salinity of 0.5 % (w/v). Growth is chemoheterotrophic; cells grow on glucose or peptone as a sole carbon source. Yeast extract is not required for growth but increases the biomass yields. Growth occurs with pyruvate, butyrate, succinate, glucose, mannose, xylose, galactose, arabinose, trehalose, cellobiose, lactose, sucrose, rhamnose, fructose, maltose, peptone, casamino acids, tryptone, pepticase, gelatin, arginine, alanine, leucine, isoleucine, valine, glutamate, glycerol, inositol, and starch, but formate, acetate, methanol, lactate, citrate, α-ketoglutarate, ribose, raffinose, methionine, threonine, lysine, glycine, histidine, Tween 80, ethyl oleate, olive oil, benzoate, and cinnamate cannot be used as substrates. Cells are able to fix dinitrogen, showing very high acetylene reduction activity, and were found to possess the *nifH* gene. Urea, nitrate, and glutamate can serve as sole nitrogen sources. Q-10 is the predominant ubiquinone and $C_{19:0}\omega8c$ cyclo, $C_{18:1}\omega7c$, and $C_{18:0}$ are the dominant fatty acids. The DNA G+C content is 71 ± 1 mol%. The type species is *T. consotensis*, strain USBA 355 T (= JCM 15529 T = KCTC 22406 T), isolated from the Salado de Consotá saline spring, Colombia (Díaz-Cárdenas et al. 2010). The type strains and additional characteristics for this species are listed in *Table 22.16*.

Telmatospirillum Sizova et al. 2007

Tel.ma.to.spi.ril'lum Gr.n. *telma -atos*, marsh, swamp, fen; N.L. dim neut. n. *Spirillum*, a bacterial genus; N.L. neut. n. *Telmatospirillum*, a fen *Spirillum*.

Cells are Gram negative, vibrioid to spiral shaped, and motile by means of polar or subpolar flagella. Major cellular fatty acids are $C_{18:1}\omega7c$, $C_{17:0}$ cyclopropane, and $C_{16:0}$. Cells grow chemoorganotrophically under anoxic conditions or at low oxygen pressures in the dark as well autotrophically on $H_2 + CO_2$ at low oxygen pressure, being tolerant up to 5 kPa of oxygen. Cells are catalase and oxidase negative. The growth temperature range between 4 °C and 30 °C and the pH range is 4–7. Growth is supported by several organic acids and glucose. Cells can fix atmospheric N_2. Liquid medium is superior to solid agar medium. The G+C content of the DNA is 61.6–64 mol%. The type species is *Telmatospirillum siberiense*, and the type strain 26-4b1 (= ATCC BAA-1305 = KACC 11899) was isolated from northern acidic wetlands under *Sphagnum*. The type strains and additional characteristics for this species are listed in Table 22.17.

Defluvicoccus Maszenan et al. 2005

De.flu.vi.coc'cus. L. neut. n. *defluvium*, sewage; N.L. (Gr. derived) masc. n. *coccus*, berry (spherical microbe); N.L. masc. n. *Defluvicoccus*, a coccus from sewage.

Cells are Gram-negative, non-spore-forming, and nonmotile cocci; they grow chemoheterotrophically under aerobic conditions with a mean cell size of 1.5–4.0 μm. Cells are usually arranged in clusters or tetrads, stain very faintly, and appear empty after staining. Oxidase is negative and catalase is positive. It grew optimally at 25–30 °C and at a pH of 7.5–8.0. Urease and gelatin liquefaction are weakly positive. Many carbon sources (Biolog GN and GP systems), including adonitol, malate, and D-arabinose, are utilized by strain Ben 114^T as presented in description of species and summarized in Table 22.1. Cells are positive for the following enzyme activities as detected with the API ZYM system: alkaline phosphatase, esterase, esterase lipase, leucine arylamidase, acid

phosphatase, and naphthol-AS-BI-phosphohydrolase. The DNA G+C content is 66 mol%. The type species is *Defluvicoccus vanus* and the type strain is Ben 114 T (= NCIMB 13612 T = CIP107350T), isolated from a sample of biomass from an enhanced biological phosphorus removal (EBPR) activated sludge plant in the Czech Republic (Maszenan et al. 2005). The type strains and additional characteristics for this species are listed in *Table 22.18*.

Tistrella Shi et al. 2002

Tistr.el'la. M. L. dim. fem. ending -ella; N. L. fem. n. *Tistrella*, arbitrary name formed from the acronym of Thailand Institute of Scientific and Technological Research, TISTR, where the isolation of strain IAM 14872^T was performed.

Cells are Gram negative and rod shaped, with variable sizes (0.7–1.2 × 1.5–1.2 μm). They often occur in chains with a length of approximately 12 mm and are highly motile by means of a single polar flagellum. The cells show binary fission. Bacteria are strictly aerobic and chemoorganotrophic. They are non-photosynthetic and the cells lack intracytoplasmic membrane systems and bacteriochlorophyll a. Cells accumulate polyhydroxyalkanoates. Optimal growth temperatures and pH depend on the species and are between 25 °C and 30 °C and pH 7–7.4, respectively. The salt requirement is variable. Malic acid is readily used as carbon source. The use of other carbon sources such as

L-arabinose, D-mannitol, N-acetylglucosamine, and adipic acid is variable. The cells produce indole, reduce nitrate to nitrite, but do not fix dinitrogen. Aesculin, gelatin, and arginine are hydrolyzed. Cells are positive for catalase and oxidase. The major ubiquinone is Q-10. The major cellular fatty acid is $C_{18:1}\omega7c$. Both 2-hydroxy and 3-hydroxy fatty acids are present, and the major hydroxy fatty acids are $C_{18:0}$ 2-OH and $C_{14:0}$ 3-OH. The $C_{19:0}$ ω8c cyclo may be present. The G–C content of DNA is 65.8–67.5 mol%. The type species is *T. mobilis* and the type strain is IAM 14872 T (= TISTR 1108 T), isolated from wastewater in Thailand (Shi et al. 2002). A second species, named *T. bauzanensis*, type strain BZ78T (= DSM 22817 T = CGMCC 1.10188 T = LMG 26047 T), was isolated from hydrocarbon-contaminated soil in Bozen, South Tyrol, Italy, and was described by Zhang et al. (2011). The type strains and additional characteristics for these species are listed in ❯ *Table 22.19*.

Constrictibacter Yamada et al. 2011

Cons.tric.ti.bac'ter. L. adj. *constrictus*, compressed, contracted; N.L. masc. n. *bacter*, a rod; N.L. masc. n. *Constrictibacter*, rod with compressed parts.

Cells of *Constrictibacter antarcticus* are ovoid to rod shaped and often occur in pairs or chains. Cells are motile and do not form spores and grow aerobically or micro-aerobically; they have a diameter of 0.8–1.0 μm and a length of 1.5–2.0 μm. Colonies are white and circular, 0.2 mm in diameter on 0.256LB/MA agar. Biochemical characteristics, analyzed using the API 20NE and API ZYM, indicate that catalase is produced, but oxidase is not produced. Produces acid phosphatase, alkaline phosphatase, cystine arylamidase, esterase (C4), esterase lipase (C8),b-glucosidase, leucine arylamidase, lipase (C14), naphthol-AS-BI-phosphohydrolase, trypsin, and valine arylamidase. *Constrictibacter* cells reduce nitrate and complex nutrients (tryptone or yeast extract) are essential for growth. The respiratory quinones are Q-10 and Q-8. The major cellular fatty acids are $C_{18:1}$, $C_{16:0}$, and $C_{18:0}$. The DNA G+C content of the type strain/species is 69.8 mol%. The type species is *Constrictibacter antarcticus* 262-8^T (= JCM, ATCC16422T, BAA1906T) that was isolated from a cavity within white rock collected in the Skallen region of Antarctica. The type strains and additional characteristics for this species are listed in ❯ *Table 22.20*.

[a]*DHLYDG* Dihydroxylycopene diglucoside, *HLG* hydroxylycopene glucoside, *LY* lycopene, *RP* rhodopin, *SP* spirilloxanthin

Rhodovibrio Imhoff et al. 1998

Rho.do.vi'bri.o. Gr. n. *rhodon*, the rose; M.L. masc. n. *Vibrio*, a bacterial genus; M.L. masc. n., *Rhodovibrio*, the rose *Vibrio*.

Cells of the genus *Rhodovibrio* are vibrioid to spiral shaped, 0.6–0.9 µm in size. They are motile by means of polar flagella and multiply by binary fission (Imhoff et al. 1998; Imhoff 2005a). Cell staining is Gram negative. Internal photosynthetic membranes are present as vesicles. They contain bacteriochlorophyll a as well as carotenoids of the spirilloxanthin series. Cells harbor ubiquinones and menaquinones with 10 isoprene units (Q-10 and MK-10). Major cellular fatty acids are $C_{18:1}$ and $C_{18:0}$. The polyamines putrescine and spermidine may be present (Haitiana et al. 2001). Bacteria of this genus grow preferably photoheterotrophically under anoxic conditions in the light, but it is also possible to grow the cells chemotrophically under microoxic to oxic conditions in the dark (Imhoff et al. 1998; Imhoff 2005a). Complex nutrients are required, as no growth is observed in the complete absence of yeast extract or peptone. Under low concentration of yeast extract, lactate or casamino acids increase growth markedly in case of *R. salinarum*, while acetate, malate, succinate, or pyruvate has a similar effect in *R. sodomensis* (Nissen and Dundas 1984; Mack et al. 1993). These species are halophiles, require NaCl or sea salt for growth, and have salt optima above seawater salinity. Cell growth is mesophilic with the preference for neutral pH. Both species show best growth in the presence of 0.1 M Mg^{2+} (Mack et al. 1993). Their DNAs have G+C contents between 65 and 69 mol%. *R. salinarum* is the genus type species and the type strain is ATCC 35394^T (= DSM 9154). The type strain of the species *R. sodomensis* is DSI (= ATCC 51195 = DSM 9895). The type strains and additional characteristics for these species are listed in *Table 22.21*.

Limimonas Amoozegar et al. 2013

Li.mi.mo'nas. L. n. *limus*, mud; L. fem. n. *monas*, a unit, monad; N.L. fem. n. *Limimonas*, a unit (bacterium) isolated from mud.

Cells are Gram negative, strictly aerobic, nonmotile, and rod shaped. They are catalase and oxidase positive and extremely halophilic. Optimal growth occurs with 3.4 M NaCl, at pH 7.0 and 40 °C. The polar lipid pattern consists of phosphatidylglycerol,

diphosphatidylglycerol, four unidentified phospholipids, three unidentified amino lipids, and two other unidentified lipids. Ubiquinone Q-10 is the major isoprenoid quinone. The predominant fatty acids are $C_{19:0}$ω7c cyclo and $C_{18:0}$. The DNA G+C content of the type strain is 67.0 mol%. The type species is *Limimonas halophila* and the type strain is IA16^T (= IBRC-M 10018^T = DSM 25584^T). The type strains and additional characteristics for this species are listed in *Table 22.22*.

Rhodospirillum Molisch 1907, Emend. Lakshmi et al. 2013

Rho.do.spi.ril'lum. Gr. n. *rhodon*, the rose; M.L. neut. n. *Spirillum*, a bacterial genus; M.L. neut. n., *Rhodospirillum*, the rose Spirillum.

Cells of the genus *Rhodospirillum* are vibrioid to spiral shaped and motile by means of bipolar flagella and multiply by binary fission. They are Gram negative and mesophilic and prefer neutral pH. Cells contain internal photosynthetic membranes as vesicles. Photosynthetic pigments are bacteriochlorophyll *a* (esterified with phytol or geranylgeraniol) and carotenoids of the spirilloxanthin series, such as spirilloxanthin itself and rhodovibrin. Ubiquinones and rhodoquinones with 10 isoprene units are present. Main cellular fatty acids include $C_{18:1}$ω7c/$C_{18:1}$ω6c, $C_{16:1}$ω7c/$C_{16:1}$ω6c, $C_{16:0}$, $C_{14:0}$3-OH, and $C_{16:0}$3-OH. They grow generally well using fatty acids as carbon sources, except formate and propionate. No appreciable development occurs with tartrate, gluconate, or citrate (Van Niel 1944).

Ethanol is a good substrate, whereas carbohydrates and their corresponding polyalcohols are not utilized. Alanine, asparagine, and aspartic and glutamic acids result in satisfactory growth; glycine and leucine give rise, at best, to slight development. Bacteria of this genus grow preferably photoheterotrophically under anaerobic conditions in the light, but they can also grow photoautotrophically with molecular hydrogen and sulfide, but not with thiosulfate as photosynthetic electron donor. They also can grow chemotrophically under microoxic to oxic conditions in the dark. Fermentation and oxidant-dependent growth may occur. Their DNA has a G+C content between 63 and 66 mol%. *Rhodospirillum rubrum* is the type species of the genus and the type strain is S1^T (= ATCC 11 170^T = NCIB 8355^T) (Skerman et al. 1980, Pfennig and Trüper 1971b; Lakshmi et al. 2014). The type strains and additional characteristics for this species are listed in ❯ *Table 22.23*.

Pararhodospirillum Lakshmi et al. 2014

Pa.ra.rho.do.spi.ril'lum. Gr. prep. *para*, beside, alongside of, near, like; N.L. neut. n. *Rhodospirillum*, a bacterial generic name; N.L. neut. n. *Pararhodospirillum*, resembling *Rhodospirillum*.

Cells of the genus *Pararhodospirillum* are spiral shaped and motile by means of bipolar flagella and multiply by binary fission. They are Gram negative and grow under mesophilic conditions with preference for neutral pH. Cells contain internal photosynthetic membranes as stacks of lamellae that form a sharp angle to the cytoplasmic membrane. Photosynthetic pigments are bacteriochlorophyll *a* (esterified with phytol or geranylgeraniol) and carotenoids of the spirilloxanthin series, which include lycopene and rhodopin, although spirilloxanthin itself may be absent in some *P. photometricum* strains. Ubiquinones and rhodoquinones with 8 isoprene units are present. Main cellular fatty acids include $C_{18:1}\omega7c/C_{18:1}\omega6c$, $C_{16:0}$, $C_{14:0}$3-OH, $C_{15:0}$3-OH, and $C_{16:0}$3-OH. Bacteria of this genus are strictly anaerobes and obligate phototrophs. Growth factors are required for growth. Their DNA has a G+C content between 60.0 and 65.8 mol%. *Pararhodospirillum photometricum* is the type species of the genus (DSM 122^T = ATCC 49918^T). Other species are *Pararhodospirillum sulfurexigens* (JA143^T = DSM 19785^T = JCM 14885^T = NBRC 104433^T) and *Pararhodospirillum oryzae* (JA318^T = KCTC 5960^T = NBRC 107573^T). The type strains and additional characteristics for these species are listed in ❯ *Table 22.24*.

Roseospira Imhoff et al. 1998, Emend. Guyoneaud et al. 2003

Ro.se.o.spi'ra. L. adj. *roseus*, rosy; Gr. n. *spira*, the spiral; M.L. fem. n., *Roseospira*, the rosy spiral.

The cells of this genus are vibrioid or spiral shaped, 0.4–1.0 μm in size, and motile by means of polar or bipolar flagella and divide by binary fission. Cells are staining Gram negative. Intracytoplasmic photosynthetic membranes are present as vesicles and contain bacteriochlorophyll *a* as well as various carotenoids as photosynthetic pigments. *Roseospira* are slightly halophilic bacteria requiring NaCl or sea salt for growth. Optimum NaCl concentrations are between 0.5 % and 7 % (w/w). Growth occurs preferably photo-organotrophically under anoxic conditions in the light, but cells can also grow under microoxic conditions in the dark. Phototrophic grown cells contain intracytoplasmic membranes of the lamellar type together with bacteriochlorophyll *a* as well as carotenoids. Growth factors niacin, thiamine, *p*-aminobenzoic acid, and yeast extract are required. Their DNAs have G+C contents between 65.0 and 72.3 mol%. The type species of the genus is *Roseospira mediosalina* and type strain is strain BN 280. The genus embraces four other species: *R. marina*, *R. visakhapatnamensis*, *R. goensis*, and *R. navarrensis*. A new species, *R. thiosulfatophila*, has been proposed (Guyoneaud et al. 2002) but, to date,

the name has not been validated. The type strains and additional characteristics for these species are listed in *Table 22.25*.

Rhodospira Pfennig et al. 1997

Rho.do.spi'ra. Gr.n. *rhodos*, the rose; Gr.n. *spira*, the spiral; M.L. fem.n., *Rhodospira*, the rose spiral.

Cells are vibrioid to spirilloid with a size of 0.6–0.8 μm; they are motile by means of flagella. Growth is mesophilic. The major fatty acids are $C_{18:1}$, $C_{16:0}$, and $C_{14:0}$. Cells harbor photosynthetic membranes of the vesicular type. The cells grow preferably photoorganotrophically under anaerobic conditions in the light and microaerobically in the dark. Anaerobically grown colonies are beige to peach colored. Bacteriochlorophyll *b* and the carotenoid tetrahydrospirilloxanthin are present. The absorption maxima of living cells for *R. trueperi* type strain are 397, 458, 490, 600, 689, 801, 889, and 986 nm. Major quinone components are Q-7, MK-7, and RQ-7. Cell growth requires reduced sulfur compounds and extracellular sulfur depositions are produced. Biotin, thiamine, and pantothenate are required as growth factors. Cells do not grow in the absence of NaCl. The DNA G+C content is 65.7 mol%. The type species is *Rhodospira trueperi* 8316^T (= ATCC 700224^T), isolated from a peach-colored layer of a laminated microbial mat in a salt marsh at Massachusetts, USA (Pfennig et al. 1997). The type strains and additional characteristics for this species are listed in *Table 22.26*.

Phaeovibrio Lakshmi et al. 2011

Cells are vibrioid, 0.3–0.5 μm in size. They are motile by polar flagella and multiply by binary fission. They grow obligately phototrophic and strictly anaerobic. Growth is mesophilic. Bacteriochlorophyll a as well as carotenoids of rodopinal series are present in chimeric internal membranes of lamellar stacks and vesicles. The absorption maxima of living cells for *P. sulfidiphilus* type strain are 377, 488, 524, 593, 794, and 863 nm. Cells require biotin and *p*-aminobenzoic acid as growth factors; a limited number of organic substrates can be photoassimilated. Sulfide is required as sulfur source. Major fatty acids are $C_{18:1}\omega7c$ and $C_{16:0}$. The DNA G+C content of the type strain is 67.8–68.8 mol%. Phylogenetic information from 16S rRNA gene sequences differentiates *Phaeovibrio* from other related genera in the family *Rhodospirillaceae*. The type species is *Phaeovibrio sulfidiphilus* and the type strain JA480^T (= KCTC 5825^T = NBRC 106163^T = DSM 23193^T) was isolated from brackish water at Nagapattinam, India (Lakshmi et al. 2011b). The type strains and additional characteristics for this species are listed in *Table 22.27*.

Novispirillum Yoon et al. 2007b

No'vi.spi.ril'lum. L. adj. *novus*, new; N.L. dim. neut. n. *spirillum*, a small spiral; N.L. neut. n., *Novispirillum*, a new small spiral.

Cells are Gram negative and have spirillum, helical, and coccoid forms. The cell size ranges from 0.4 to 0.6 × 2.0 to 7.0 μm (diameter × length). Cells are motile by means of bipolar and fascicles flagella. Positive growth occurs on EMB, MacConkey, TSI, and Seller agars and in MR-VP broth; a predominance of coccoid bodies was observed in older cultures. Colonies are white, circular, and convex with smooth edges. The cells produce water-soluble yellowish green fluorescent or brown pigment, the last in presence of tyrosine and tryptophan. All strains are sensitive to 3.0 % NaCl, negative for hydrolysis of aesculin. They contain as predominant ubiquinone type Q-10. Cells contain esterase (C4) and esterase lipase (C8) activity and hydrolysis of tyrosine; they reduce nitrate if grown anaerobically with KNO_3. The strains grow on malate but only weakly on glycerol. DNA G+C content is 63–65 mol%. The genus *Novispirillum* comprises one species *Novispirillum itersonii* (previously *Aquaspirillum itersonii*) classified into two subspecies, subsp. *nipponicum* and subsp. *itersonii* (Yoon et al. 2007b). The type species of the genus is *Novispirillum itersonii* and the type strain is ATCC 12639 (= CCUG 49447 = CIP 105798 = JCM 21278 = JCM 21494 = LMG 4337 = NBRC 15648). The type strains and additional characteristics for this species are listed in *Table 22.28*.

Marispirillum Lai et al. 2009a

Ma.ri.spi.ril'lum. L. neut. n. *mare*, the sea; N.L. dim. neut. n. *spirillum*, a small spiral; N.L. neut. n., *Marispirillum*, a small spiral of the sea.

Cells are Gram negative, oxidase negative, catalase positive, and helical in shape. Cells are motile by means of polar flagella (three per cell) and moderately halophilic. Growth occurs at salinities of 0.5–12 % and at temperatures of 10–41 °C. The bacteria are capable of denitrification, but they are unable to degrade Tween 80 or gelatin. Major fatty acids are $C_{16:1}\omega7c$, iso-$C_{15:0}$ 2-OH, $C_{16:0}$, $C_{18:1}\omega7c$, $C_{18:0}$, and $C_{19:0}\omega8c$ cyclo. The G+C content of DNA is 67.3 mol%. The type species is *Marispirillum indicum* and the type strain is B142 (= CCTCC AB 208225 = LMG 24627 = MCCC 1A01235). The type strains and additional characteristics for this species are listed in *Table 22.29*.

Insolitispirillum Yoon et al. 2007b

In.so.li'ti.spi.ril'lum. L. adj. *insolitus*, unaccustomed; N.L. dim. neut. n. *spirillum*, a small spiral; N.L. neut. n., *Insolitispirillum*, an unaccustomed small spiral.

The cell form is helical, but in older cultures, coccoid, nonmotile organisms and microcysts predominate. The cell diameter is 0.5–0.7 μm and cell length varies from 5 to 22 μm. Cells are motile by means of bipolar fascicles of flagella that persist even in nonmotile forms. The predominant ubiquinone is Q-9. The bacteria are positive for hydrolysis of urea,

utilization of aesculin, and β-glucosidase activity; they are negative for utilization of malate, nitrate reduction, and anaerobic growth with KNO_3. A yellow, water-soluble pigment is formed from phenylalanine, but no pigments are formed from tryptophan or tyrosine. Growth in the presence of 1 % bile was achieved, but not in 1 % glycine. Growth occurs on EMB, TSI, and Seller agars, but not on MacConkey agar or in MR-VP broth. Maximum growth temperature is 39 °C. The pH conducive for growth ranges from pH 5.0 to 8.0. Colonies are finely granular, round, and 2–3 mm in diameter; the color on nutrient agar and potato glucose agar differs from grayish to yellowish, respectively. The G+C content of the DNA is 62–66 mol%. The type species is *Insolitispirillum peregrinum* (Pretorius 1963) and the type strain is ATCC 15387 (= CCUG 13795 = DSM 1839 = JCM 21450 = LMG 4340 = NBRC 14922). This species comprises 2 subspecies based on slightly higher G+C values and the development of cell coccoid forms in older cultures. The subsp. *integrum* (Terasaki 1973 emended Yoon et al. 2007b), basonym *Aquaspirillum peregrinum* subsp. *integrum* (Terasaki 1973; Terasaki 1979), type strain ATCC 33334 (= CCUG 49449 = DSM 11589 = JCM 21428 = LMG 5407 = NBRC 13617), was isolated from oxidation pond water. The type strain for the subsp. *peregrinum* (Pretorius 1963 emend Yoon et al. 2007b), basonym *Aquaspirillum peregrinum* subsp. *peregrinum* (Pretorius 1963; Hylemon et al. 1973), is ATCC 15387 (= CCUG 13795 = DSM 1839 = JCM 21450 = LMG 4340 = NBRC 14922). The type strains and additional characteristics for these species are listed in *Table 22.30*.

the API ZYM system, alkaline phosphatase, esterase (C4), and esterase lipase (C8) are present and naphthol-AS-BI-phosphohydrolase is weakly present. The type species K92^T is positive for catalase, oxidase, and aesculin hydrolysis and negative for Gram staining, indole production, and hydrolysis of casein and gelatin, while strain AK4^T was positive for oxidase, urease, and DNase activities but negative for gelatinase, catalase, ornithine decarboxylase, lysine decarboxylase, nitrate reduction, indole, and lipase activities. The predominant ubiquinone is Q-10. The major fatty acid is $C_{18:1}\omega7c$. The major respiratory quinone contains Q-10. Phosphatidylglycerol, diphosphatidylglycerol, phosphatidylethanolamine, and phosphatidylcholine are the major polar lipids. The DNA G+C content is 70.0–71.0 mol%. The type species is *Caenispirillum bisanense*, type strain K92^T (= KCTC 12839^T = JCM 14346^T). The second species is *C. salinarum*, type strain AK4^T (= JCM 17360 = MTCC 10963), and was isolated from a solar saltern lake (Ritika et al. 2012). The type strains and additional characteristics for these species are listed in *Table 22.31*.

Thalassospira López-López et al. 2002, Emend. Liu et al. 2007

Tha.las'so.spi.ra. Gr. fem. n. *thalassa*, the sea; Gr. fem. n. *spira*, a spire; N.L. fem. n. *Thalassospira*, spiral-shaped organism from the sea.

Bacteria are Gram negative and vibrioid to spiral shapedwith a cell size of 3–5 μm length and 0.6 μm width. Cells are nonmotile and nonflagellated or motile by a single polar flagellum. Some species can grow under anaerobic conditions by reducing nitrate. The bacteria are halophilic, require Na^+ ions for growth, and are able to grow in the presence of up to 12 % NaCl. No requirement exists for organic growth factors. Carbohydrates are used as sole carbon sources and both nitrate and ammonium are used as sole nitrogen sources. Principal fatty acids are $C_{18:1}\omega7c$, $C_{16:0}$, and $C_{18:0}$, while $C_{16:1}\omega7c$, $C_{14:0}$, $C_{16:1}\omega7c$, $C_{14:0}$, $C_{17:0}$, $C_{17:0}$, and $C_{19:0}$ cyclo are variable among species. The G+C content of the genomic DNA ranges from 47 to 61.2 mol%. The following additional species have been described: *T. lucentensis* (López-López et al. 2002), *T. xiamenensis* (Liu et al. 2007), *T. profundimaris* (Liu et al. 2007),

helical forms (Meldrum et al. 1993). Cells assimilate inorganic carbon (as CO_2) and grow chemolithoautotrophically with S_2O_3- as the electron donor, using the CBB cycle. The cells harbor form II RuBisCO (CbbM). They are motile by means of bipolar flagella (amphitrichous), with a single flagellum at each pole. *Magnetospira* cells exhibit only polar magnetotaxis and biomineralize a single chain of magnetosomes that contain elongated cuboctahedral magnetite crystals positioned along the long axis of the cell. The G+C content of the DNA was 47.2 mol%. The type species for genus *Magnetospira* is *M. thiophila*, type strain MMS-1 (= ATCC BAA-1438 = JCM 17960). The type strains and additional characteristics for this species are listed in *Table 22.33*.

Magnetovibrio Bazylinski et al. 2013

Ma.gne.to.vi'bri.o. Gr. n. *magnês -êtos*, a magnet; N.L. pref. magneto-, pertaining to a magnet; N.L. masc. n. *vibrio*, a vibrio; N.L. masc. n. *Magnetovibrio*, the magnetic vibrio, which references the vibrioid morphology and magnetotactic behavior of this bacterium.

Cells are Gram negative and vibrioid to helicoid in morphology; they are motile by means of a single polar flagellum. Cells assimilate inorganic carbon (as CO_2) and grow chemolithoautotrophically with thiosulfate and sulfide as the electron donors, using a form II ribulose-1,5-bisphosphate carboxylase/oxygenase (CbbM) and the CBB cycle. Cells of strain MV-1^T exhibit characteristics of both axial and polar magnetotaxis and biomineralize a single chain of magnetosomes that contain magnetite crystals of truncated hexa-octahedral habit, positioned along the long axis of the cell. Major polar lipids identified include phosphatidylethanolamine and phosphatidylglycerol. The G+C content of the DNA is 52.9–53.5 mol%. The type species is *M. blakemorei*, strain MV-1^T. The type strains and additional characteristics for this species are listed in *Table 22.34*.

Artificial seawater semi-solid agar medium was used for Carbon sources test (final concentration of 0.1%–wt/vol or vol/vol)

Ferrovibrio Sorokina et al. 2012

Fer.ro.vi'bri.o L. n. *ferrum*, iron; L. v. *vibrio*, move to and fro; N. L. masc. n. *vibrio*, which vibrates; N. L. masc. n. *Ferrovibrio*, an iron-oxidizing organism of vibrioid shape.

The cells are vibrioid and motile with one polar flagellum and 0.3 × 0.8–1.3 μm size. Division occurs by binary fission. The cell wall is of Gram-negative type. The cells have a facultative anaerobic metabolism. Growth occurs within the ranges of 5–45 °C and pH 5.5–8.0. Oxidase activity and low catalase activity are present. Organotrophic, mixotrophic, or lithoheterotrophic growth is possible owing to oxidation of Fe(II) coupled to reduction of NO_3^- or N_2O, with accumulation of Fe(III) oxides on the cell surface. Fe(II) may be used as an electron donor for anaerobic mixotrophic or lithoheterotrophic growth. Aerobic organotrophic growth occurs with acetate, butyrate, citrate, fumarate, glycerol, lactate, malate, propanol, propionate, pyruvate, succinate, peptone, and yeast extract as carbon and energy sources. Weak growth occurs on amino acids alanine, histidine, aspartate, and glutamate. Sugars, asparagine, benzoate, butanol, ethanol, formate, glutamine, leucine, oxalate, phenylalanine, proline, tryptophan, and casein hydrolysate are not utilized. Ammonium salts, NO_3^-, N_2O, urea, yeast extract, and peptone may be used as nitrogen sources. NO_2, histidine, aspartate, and casein hydrolysate are not used. Anaerobic growth does not occur with ClO_4^-, SO_4^{2-}, $S_2O_3^{2-}$, or $Fe(OH)_3$ as electron acceptor. In mineral medium with nitrate, H_2 is not used as an electron donor. The DNA G+C content is 64.2 mol%. The type species is *F. denitrificans* and the type strain is Sp-1^T (= LMG 25817 ^{T} = VKMB-2673 ^{T}) – isolated from a moderately thermal, iron-sulfide mineral spring of the Psekups mineral water deposit (Northern Caucasus, Russia). The type strains and additional characteristics for this species are listed in *Table 22.35*.

Isolation, Enrichment, and Maintenance Procedures

Azospirillum

The isolation of *A. lipoferum* and *A. brasilense* is based on the use of N-free semisolid medium, containing agar (1.75 g L^{-1}). The recipe contains (g L^{-1}) the following: malic acid, 5.0; K_2HPO_4, 0.5; $MgSO_4.7H_2O$, 0.2; NaCl, 0.1; $CaCl_2.2H_2O$, 0.02; micronutrient solution A, 2 mL; bromothymol blue (0.5 % in 0.2 N KOH), 2 mL; Fe-EDTA (solution 1.64 %), 4 mL; vitamin solution B, 1 mL; and KOH, 4.5 g; complete volume to 1,000 mL and adjust pH to 6.5–6.8. To semisolid medium, add 1.75–1.80 g agar L^{-1}. To solid medium, add 15 g agar L^{-1}. Micronutrient solution (g L^{-1}): $CuSO_4.5H_2O$, 0.04; $ZnSO_4.7H_2O$, 0.12; H_3BO_3, 1.40; $Na_2MoO_4.2H_2O$, 1.0; $MnSO_4.H_2O$, 1.175. Complete volume to 1,000 mL with distilled water. Store the solution in the refrigerator. Vitamin solution: biotin, 10 mg; pyridoxal HCl, 20 mg. Dissolve in hot-water bath. Complete to 100 mL adding distilled water. Store the solution in refrigerator.

These microaerobically nitrogen-fixing (diazotrophic) bacteria are selectively enriched because they can grow with N_2 as nitrogen source. Because azospirilla do not harbor powerful oxygen-protective mechanisms for the oxygen-sensitive nitrogen-fixing system, they are unable to grow on N_2 as sole N-source in N-free agar plates or liquid media because of too high oxygen levels in air. Microaerobic diazotrophs are aerotactic, and as a result, the nitrogen-fixing population collects in zones of reduced oxygen concentration. There, they form a thin pellicle or veil that moves upward as it becomes thicker (Döbereiner and Pedrosa 1987). After characteristic pellicles have formed, N_2 fixation can be checked by acetylene reduction activity, and active cultures are transferred to new vials

containing the same medium. As soon as a new pellicle is visible, the cultures are streaked out on agar plates containing the same medium with yeast extract (20 mg L^{-1}) added. The small amount of yeast extract permits the growth of small colonies on the surface of plates. Characteristic individual colonies are then transferred again to N-free semisolid media, and those that grow well are streaked out on potato agar for final purification.

The species *A. irakense* (Khammas et al. 1989) can also be isolated using the semisolid NFb medium containing up to 0.3 % NaCl, pH adjusted to 7.0–8.5 and incubation at 33 °C. Similarly, *A. doebereinerae* (Eckert et al. 2001) can be isolated using the NFb semisolid medium after incubation for 3–5 days at 30 °C. Further purification is done on NFb (supplemented with 50 mg yeast extract L^{-1}).

The species *A. oryzae* can be isolated using the M (malate) medium with the following composition in g L^{-1}: sodium malate, 5.0; $CaCl_2.2H_2O$, 0.02; $MgSO_4.7H_2O$, 0.2; K_2HPO_4, 0.1; KH_2PO_4, 0.4; NaCl, 0.1; $FeCl_3$,0.010, $Na_2MoO_4.2H_2O$, 0.002; yeast extract, 0.1; and biotin, 2 μg. Complete to 1,000 mL with distilled water and adjust the pH to 6.8. The NFG medium can also be used with the composition (g L^{-1}): glucose, 10.0; $CaCl_2.2H_2O$, 0.020; $MgSO_4.7H_2O$, 0.2; K_2HPO_4, 1.0; $CaCO_3$, 5.0; $FeSO_4.7H_2O$, 0.050; and $Na_2MoO_4.2H_2O$, 0.001. Complete to 1,000 mL with distilled water and adjust the pH to 7.3. Similarly, *A. zeae* and *A. canadense* can be isolated using the M medium by omitting the addition of biotin, and the pH of the medium is adjusted to 7.2–7.4. (Xie and Yokota 2005; Mehnaz et al. 2007a, b). Sub-cultivation is done on the same medium at 30 °C for 48–72 h.

The species *A. amazonense* (Magalhães et al. 1983) is isolated in a semisolid sucrose medium (LGI or Fam). Composition of LGI medium (g L^{-1}): sucrose, 5.0; K_2HPO_4, 0.2; KH_2PO_4, 0.6; $MgSO_4.7H_2O$, 0.2; $CaCl_2.2H_2O$, 0.02; $Na_2MoO_4.2H_2O$, 0.002; bromothymol blue (0.5 % in 0.2 N KOH), 5 mL; Fe-EDTA (solution 1.64 %), 4 mL; vitamin solution (see above), 1 mL. Complete volume to 1,000 mL with distilled water. Adjust pH to 6.0–6.2 with H_2SO_4. For semisolid medium, add 1.75–1.80 agar L^{-1} and 15 g agar L^{-1} for solid medium. FAM medium has the composition (g L^{-1}): sucrose, 5.0; KH_2PO_4, 0.12; K_2HPO_4, 0.03; $MgSO_4.7H_2O$, 0.2; $CaCl_2$, 0.02; Fe-EDTA, 0.066; NaCl, 0.1; $Na_2MoO_4.2H_2O$, 0.002; $MnSO_4$, 0.00235; H_3BO_3, 0.0028; $CuSO_4.5H_2O$, 0.00008; $ZnSO_4.7H_2O$, 0.00024; biotin, 0.0001; and pyridoxine-HCl, 0.0002 g. Complete volume to 1,000 mL with distilled water. For semisolid medium, add 1.75 g agar L^{-1} and adjust pH to 6.0.

The species *A. melinis* (Peng et al. 2006) can also be isolated in a semisolid LGI medium or a semisolid NFB medium after incubation at 28 °C for 3–5 days. Purification can be done by repeatedly streaking the isolates on plates of solid LGI or NFb medium.

The species *A. halopraeferans* (Reinhold et al. 1987) can be isolated in the semisolid SM medium supplemented with 1.5 % NaCl, pH adjusted to 8.5 and vials incubated at 41oC. Composition (g L^{-1}): DL-malic acid, 5.0; KOH, 4.8; NaCl, 1.2; $NaSO_4$, 2.4; $NaHCO_3$, 0.5; $CaCl_2$, 0.22; $MgSO_4.7H_2O$, 0.25; K_2SO_4, 0.17;

Na_2CO_3, 0.09; Fe-EDTA, 0.077; K_2HPO_4, 0.13; biotin, 0.0001; $MnCl_2.4H_2O$, 0.0002; H_3BO_3, 0.0002; $ZnCl_2$, 0.00015; $CuCl_2.2H_2O$, 0.000002; $Na_2MoO_4.2H_2O$, 0.002; distilled water, completed to 1,000 mL. The final pH of the medium is 8.5. Cells may grow to 1.2 µm length and 0.7–1.4 µm thick if the pH turns alkaline.

The non-nitrogen-fixing *A. palatum* (Zhou et al. 2009) can be isolated using a TYB medium containing 0.3 % yeast extract, 0.2 % beef extract, 0.6 % tryptone, 0.3 % NaCl, and 001 % $FeCl_3$, pH 7.0.

For rapid multiplication, many *Azospirillum* species can be grown in liquid media to which a combined nitrogen source has been added (NH_4Cl (1 g/l), KNO_3 (1 g/l), or yeast extract (0.4 g L^{-1})). Alternatively, complex media such as nutrient broth (NB) or 1/2 DYGS medium (D,L-malate (1 g L^{-1}), yeast extract (2 g L^{-1}), glucose (1 g L^{-1}), glutamate (1.5 g L^{-1}), peptone (1.5 g L^{-1}), $MgSO_4.7H_2O$ (0.5 g L^{-1})) can be applied (Rodrigues Neto et al. 1986). In such media, with rapid stirring or shaking, cell concentrations of 10^8 per ml are reached after 24–48 h. To stabilize the pH at the desired value upon prolonged growth, the addition of 50 mM MOPS (3-(N-morpholino)propanesulfonic acid) buffer (pH 6.8) or MES (2-(N-morpholino)ethanesulfonic acid) buffer (pH 6.0; for *A. amazonense*) is recommended. Alternatively, the *Azospirillum* minimal medium of Okon et al. (1977), which also contains high phosphate levels, can be used.

Storage of the cultures for many years at −80 °C or in liquid N_2 is also possible after adding 50 % glycerin or dimethyl sulfoxide (DMSO) to an exponentially growing culture. The cells can also be preserved by lyophilization according to the following protocol (Döbereiner et al. 1995). The cultures are grown to late log phase in the following medium: K_2HPO_4, 0.5 g; $MgSO_4.7H_2O$, 0.2 g; NaCl, 0.1 g; K-DL-malate (*A. brasilense*) or glucose (*A. lipoferum*), 5 g; yeast extract, 0.4 g; and 1 l of distilled water. The cells must then be collected by centrifugation and resuspended to a dense cell suspension with 10 % sucrose solution containing 5 % peptone. Then 0.1 ml portions are transferred into lyophilization ampoules, which are frozen and lyophilized according to the procedures recommended for *Rhizobium* spp. (Vincent 1970).

Caenispirillum, *Conglomeromonas*, *Constrictibacter*, *Defluviicoccus*, *Desertibacter*, *Dongia*, *Elstera*, *Ferrovibrio*, *Fodinicurvata*, and *Inquilinus*

Caenispirillum bisanense (Yoon et al. 2007a) was isolated from a sludge sample collected from the wastewater treatment plant of a dye works at Daegu, Korea. The type strains K92 and K93 were isolated on nutrient agar (Difco) and trypticase soy agar (TSA; Difco) at 30 °C, using standard dilution plating technique. Colonies on TSA are circular, raised, smooth, glistening, grayish yellow in color, and 1.5–2.5 mm in diameter after incubation for 2 days at 37 °C. *Caenispirillum salinarum* AK4T was isolated from a solar saltern at Kakinada, Andhra Pradesh, India (Ritika et al. 2012) using the same medium.

Constrictibacter antarcticus (Yamada et al. 2011), strain 262-8^T, was obtained from the white rock sample from the Skallen region in Antarctica. The white rock collected by the summer party of the 46th Japanese Antarctic Research Expedition in 2004–2005 was stored at 4 °C for 6 months. To screen for autotrophic bacteria, rock samples were crushed, added to BG-11 liquid medium (ATCC medium 616), and incubated at 25 °C in the light. Strain 262-8^T was able to grow in 0.25 × LB/MA, 0.25 × LB/ASW and marine broth 2216. After growth on 0.25 × LB/MA medium for 2 weeks, colonies were white and circular, with a diameter of 0.2 mm. Strain 262-8^T was able to form colonies microaerobically, but anaerobic growth could not be observed after 2 weeks in either light or dark conditions. No growth was observed in synthetic media. The type strain could be stored as a 20 % (v/v) glycerol suspension at −80 °C for at least 2 years.

Defluvicoccus vanus (Maszenan et al. 2005), a tetrad-forming organism, was isolated by micromanipulation from a sample of activated sludge biomass from an enhanced biological phosphorus removal (EBPR) plant in Pilsen, Czech Republic, in 1997 (Maszenan et al. 1997). For growth, freshly prepared GS medium (Williams and Unz 1985) was the most successful in supporting growth of this organism from activated sludge. Strain Ben 114^T grew very slowly on GS agar, taking 2–3 weeks to produce visible mucoid beige colonies of < 5 mm diameter. In GS broth dispersed growth was seen. Strain Ben 114^T was stored at −80 °C for 8 years.

Desertibacter roseus (Liu et al. 2011), gamma radiation-resistant bacterium, was isolated from the Taklimakan desert, Xinjiang, China. Sand was sampled from the Taklimakan desert, and 1-g samples were exposed to 10-kGy radiation at a dose of 300 Gy min at room temperature. After exposure, the samples were serially diluted in water (0.85 %, w/v, NaCl) and plated on different media TSA (Difco), nutrient agar (Difco), and R_2A agar (Difco). After incubation at 30 °C for 20 days, the type strain 2622^T was isolated on R_2A agar. Colonies were pink, circular, and convex with regular margins after growth on R_2A agar at 37 °C for 4 days at pH 8. Strain 2622^T was stored by lyophilization.

Dongia mobilis, strain LM22^T, was isolated during an investigation of the culturable microbial diversity in the activated sludge of a sequencing batch reactor for the treatment of malachite green effluent. A sludge sample was suspended in normal saline by vigorous vortexing, and 0.1 ml suspension was spread onto 1/10-diluted trypticase soy agar (TSA; Difco) and incubated at 30 °C for 1 week. A pure culture of strain LM22T was obtained after subcultivation on YP agar (Difco). Colonies on YP agar are white, transparent, smooth, circular, convex, and 0.5–1 mm in diameter after incubation at 30 °C for 3 days. Abundant growth was observed on R2A. No growth was seen on LB agar, NA, or TSA (Liu et al. 2010). Strain LM22^T was maintained on YP agar and stored in 15 % (w/v) glycerol at −80 °C.

Elstera litoralis (Rahalkar et al. 2012), a biofilm-associated bacterium, was isolated from the stones of the littoral zone (20–30-cm water depth) of Lake Constance, Germany, on 2006. The biofilm material was diluted and vortexed vigorously to disperse the bacteria. Strain Dia-1^T was isolated from the final plated dilution of the biofilm sample where EPS was used as the carbon source. It also grew well in 1:2-diluted nutrient broth supplemented with 10 mM glucose and in VM medium (pH 6.5–7.0) with ethanol as sole carbon source at room temperature (20–23 °C), both in liquid medium and on solid medium plates. In liquid VM media without shaking, the strain initially formed small aggregates or white flocks. On agar plates, milky white to cream-colored colonies were formed within 3–4 days, which turned light yellow at the periphery after extended incubations. Strain Dia-1^T grew well in VM-ethanol medium and did not grow in nutrient broth only, i.e., a sugar or ethanol was required for growth.

Ferrovibrio denitrificans (Sorokina et al. 2012) was isolated from freshly precipitated sediments from the redox zone at the FeS–Fe(OH)3 boundary in the bottom sediments of the Marka low-salinity iron-rich spring at its confluence with a sulfide spring located at the groundwater discharge zone of the Psekups mineral water deposit, Northern Caucasus (Krasnodar Krai, Russia). The cultivation medium was described by Sorokina et al. (2012) and contained 0.2 mL of a freshly prepared FeS suspension (Hanert 1981) that was added to each tube per 10 mL of the medium. The incubation time was 2–3 weeks. In agar medium, the bacteria formed small (2–3 mm in diameter), loose spherical colonies. The colonies are orange colored because of the presence of iron oxides. In liquid medium of the same composition, an ochreous precipitate is formed at the bottom of the vials. FeS, $FeSO_4$, and $FeCO_3$ are used as Fe(II) sources for lithotrophic growth.

Fodinicurvata sediminis (Wang et al. 2009) was isolated during the course of a study of the microbial diversity of the Fenggang salt mine in Yunnan, southwest China. The type strains YIM D82^T and YIM D812^T were isolated from a sediment sample collected from the salt mine by using a standard dilution-plating technique at 28 °C on Difco marine agar 2216 (MA; pH 7.2), supplemented with 3 % (w/v) NaCl. Pure cultures are maintained on nutrient agar (NA; Difco) supplemented with 5 % NaCl. Colonies are cream–white, circular, convex, and opaque with irregular margins after growth on NA supplemented with 5 % at 28 °C for 5 days. Growth occurred under anaerobic conditions. Pure cultures are maintained on nutrient agar (NA; Difco) supplemented with 5 % NaCl and stored as 20 % (v/v) glycerol suspensions at −80 °C.

Inquilinus limosus was isolated from respiratory secretions of cystic fibrosis patients in the USA in 1995 (Pitulle et al. 1999) and described by Coenye et al. (2002). The type strain AU0476^T grows on BCSA at 32 °C. During the course of a study on the culturable aerobic and facultatively anaerobic bacterial community of ginseng field soil in Pocheon Province, South Korea, a large number of bacteria were isolated (Im et al. 2005). One of these isolates, Gsoil 080^T, was identified as *I. limosus*. It was one of the several isolates that appeared on modified R_2A agar plates under aerobic conditions and was routinely cultured on R_2A agar (Difco) at 30 °C. After 2 days of incubation on R_2A agar, colonies are creamy white, round to slightly irregular, and 1.0–5.0 mm in diameter. It was routinely cultured on R_2A agar (Difco) at 30 °C and maintained as a glycerol suspension (20 %, w/v) at −70 °C.

Insolitispirillum–Limimonas–Magnetospira–Magnetospirillum–Magnetovibrio–Marispirillum–Nisaea–Novispirillum–Oceanibaculum

Magnetospirillum gryphiswaldense was isolated from water and the muddy upper layers of sediment collected from the eutrophic river Ryck near Greifswald, Germany, after magnetotactic enrichment collected from jars. Jars were filled with 100 ml mud and 200 ml water. Magnetotactic bacteria found near the magnetic pole were collected with a pipette over several weeks. After centrifugation, a drop of the cell concentrate was placed on one edge of a 5-cm-long and 1-mm-wide strip of sterile soft agar (2 g agar/I tap water) processed as describe by Scheifer et al. (1991) and used as inocula for the isolation medium consisting of 50 ml mud, 100 ml water, and 1.5 mg disodium succinate. It was filled into 200-ml bottles and sterilized at 121 °C for 20 min. The bottles were tightly sealed by rubber stoppers. The inoculated medium was incubated at 30 °C for 10 days.

Magnetospirillum magnetotacticum strain MS-1 was isolated from sediments collected in Cedar Swamp (Woods Hole, MA, USA) after enrichment of sampled material by application of steady, nonuniform magnetic fields as described by (Blakemore et al. 1979). The semisolid isolation medium consisted of (per 90 ml of distilled water) 10 ml of filtered swamp or bog water, 1 ml of vitamin elixir (23), 1 ml of mineral elixir (Wolin et al. 1963), and 0.5 mM potassium phosphate buffer (pH 6.7). To this mixture were added 5 g of vitamin B12, 25 mg of NH_4Cl, 10 mg of sodium acetate (anhydrous), 0.2 mg of resazurin, and 90 mg of Ionagar no. 2 (Oxoid). The pH was adjusted to 6.7 with NaOH. A well-isolated area of growth was homogenized, and cells were cloned by serial dilution into tubes containing molten, prereduced isolation medium containing 0.85 % (wt/vol) Ionagar no. 2. Well-isolated colonies which appeared in these tubes after 1 week at 30 °C were homogeneous as evidenced by microscopy. Strain MS-1 was maintained at 30 °C with weekly transfers in screw-capped culture tubes containing a semisolid growth medium consisting of (per 98 ml of distilled water) 1 ml of vitamin elixir, 1 ml of mineral elixir, 5 mM KH_2PO_4, 25 MuM ferric quinate, and 0.2 mg of resazurin. To this mixture were added (per 100 ml) 0.1 g of succinic acid, 20 mg of sodium acetate (anhydrous), 10 mg of $NaNO_3$, 5 mg of sodium thioglycolate, and 130 mg of agar (GIBCO Laboratories). The ferric quinate solution was prepared by combining 2.7 g of $FeCI_3$ and 1.9 g of quinic acid with 1 l of distilled water. Before adding the agar, the pH of the medium was adjusted to 6.7 with NaOH. The medium was boiled, and 12 ml was added to each

screw-capped tube (16 by 125 mm) containing approximately 0.1 ml of 5 % (wt/vol) sodium thioglycolate in distilled water. After autoclaving, the medium stands overnight for the establishment of O_2 gradients.

M. magneticum AMB-1^T is a magnetic bacterium capable of growing aerobically, isolated from freshwater sludges and sediments obtained from ponds at Koganei in Tokyo (Matsunaga et al. 1991). Separation of magnetic bacteria from sediment and water samples was achieved using an apparatus adapted from Matsunaga and Kamiya (1987). This apparatus allowed that magnetic bacteria migrated through the cotton plug toward the south pole of a samarium–cobalt (Sin-Co) magnet (produced by TDK, Tokyo, Japan) placed on the side of the sterile solution. Dark gray suspension around the magnet was sampled with a pipette and inoculated into the isolation medium. The isolation medium contained (per liter of distilled water) 2 ml Wolfe's mineral solution (Wolin et al. 1963), 0.2 g potassium dihydrogen phosphate, 0.12 g sodium nitrate, 0.02 g yeast extract, 0.02 g malt extract, and 0.05 g L-cysteine HC1. H_2O, 10 M ferric gallate (prepared in 100 ml distilled water containing 0.27 g $FeCI_3$ and 0.19 g gallic acid.), and 0.5 mg biotin. The medium was adjusted to pH 7.0, and after sterilization, 0.6 ml of 10 % glucose filter sterilized (pore size 0.45 m) solution was added to the medium.

The *Magnetospirillum* strains can be routinely grown microaerobically in semisolid (1.5 g l^{-1} agar Noble; Difco Laboratories) revised Magnetic Spirillum Growth Medium (MSGM) (American Type Culture Collection, 1989 – available at http://www.atcc.org). Bazilinski et al. (2000) proposed the following modifications to MSGM during a study of nitrogen fixation in *Magnetospirillum* strains: tartaric acid was omitted and the concentration of succinic acid was raised to 5 mM; ascorbic acid was replaced by 0.1 g l^{-1} sodium thioglycolate; the Wolfe's mineral solution added at 5 ml l^{-1} was modified by increases in the amounts of $Na_2MoO_4.2H_2O$ (from 0.01 g to 0.4 g l^{-1}) and $CuSO_4.5H_2O$ (from 0.01 g to 0.02 g l^{-1}) and by the addition of 0.01 g l^{-1} $NiCl_2.6H_2O$. They grow in the presence of NH_4Cl (4 mM), $NaNO_3$ (8 mM), and N_2 as sole nitrogen sources.

Magnetospirillum bellicus, the second dissimilatory perchlorate-reducing bacteria (DPRB), was isolated from the surface of a working electrode in an active perchlorate-reducing bioelectrical reactor (BER) that was inoculated with water from Strawberry Creek on the University of California, Berkeley, campus (Thrash et al. 2007). Perchlorate-reducing enrichments were established by transferring 1 g of electrode surface scrapings into 9 mL of prepared anoxic medium as indicated by Miller and Wolin (1974) under a gas stream of N_2-CO_2 (80:20; v/v). Acetate (590 mg L^{-1}) was the electron donor and perchlorate (990 mg L^{-1}) was the electron acceptor. Incubations were done at 30 °C in the dark. Positive enrichments were identified by visual increase in optical density and by microscopic examination. Once a positive enrichment was established, the perchlorate-reducing culture was transferred (10 % inoculum) into 9 mL of fresh anoxic medium. Isolated colonies were obtained from transfers of positive enrichments by the standard agar shake-tube technique with acetate (590 g L^{-1}) as the sole electron donor and perchlorate (990 mg L^{-1}) as the sole electron acceptor.

Magnetospirillum aberrantis was isolated from the coastal bottom sediment of the Ol'khovka River in the city of Kislovodsk (Gorlenko et al. 2011). Enrichment cultures were obtained by microaerobic incubation of the medium inoculated with the bottom sediments. The medium contained the following (g/l): KH_2PO_4, 0.4; NH_4Cl, 0.33; KCl, 0.33; $MgCl_2$, 0.33; Na_2SO_4, 0.25; $Na_2S_2O_3$, 0.25; $NaNO_3$, 0.33; $NaHCO_3$, 0.25; sodium acetate, 1.0; and yeast extract, 0.1, as well as Fe(III) citrate, 30 μM; resazurin, 0.5 mg/l; sodium thioglycolate, 50 mg/l; vitamin B12, 15 μg/l; and trace elements, 1 ml/l. The optimal oxygen concentration determined by cultivation in sealed Hungate tubes was from 1 % to 20 %. Magnetic separation was used to obtain pure bacterial cultures as described by Gorlenko et al. (2011). Bacteria were grown in 5-ml syringes under microaerobic conditions with a small air bubble at 30°C, pH 6.7. The same medium was used for the subsequent cultivation of the isolates.

Magnetospira thiophila strain MMS-1 was obtained from mud and water samples using the capillary magnetic racetrack technique (Wolfe et al. 1987). Concentrated magnetotactic cells were inoculated into ASW medium containing 5 ml of modified Wolfe's mineral elixir (Frankel et al. 1997), 0.25 g of NH_4Cl, and 100 μL of 0.2 % (wt/vol) aqueous resazurin. To produce an oxygen gradient, the medium was modified into semisolid by addition of 2.0 g of Agar Noble. Cultures were incubated at 25–28 °C and cells grew as a microaerophilic band at the oxic–anoxic transition zone of the tubes (pink/colorless interface). Cells also grew in this same medium when 3.7 mM sodium succinate replaced the thiosulfate. Separate colonies were obtained in a serial dilution of a culture in ASW solid medium shake tubes with succinate as the electron donor. Colonies were removed aseptically and the process was repeated three times and the purity of the cultures was determined using light microscopy as described in Williams et al. (2012). To achieve a sufficient yield of biomass cells, these authors grew MMS-1 chemolithoautotrophically in 2L glass bottles containing 850 ml using the same medium modified by the addition of thiosulfate ($S_2O_3^{2-}$) as the electron donor and O_2 as the terminal electron acceptor. After sterilization, the medium was cooled to room temperature, and the following solutions were injected (per liter) into the medium bottles, in order, from oxygen-free stocks (except for the cysteine, which was made fresh and filter sterilized directly into the medium): 1.5 ml of 0.5 M Potassium phosphate buffer, pH 6.9, neutralized cysteine HCl.H_2O to give a final concentration of 0.04 g l1, 10 ml of 25 % (wt/vol) $Na_2S_2O_3.5H_2O$, and 0.5 ml of vitamin solution (Frankel et al. 1997). The medium was allowed to become reduced (= colorless), after which 2.5 ml of 0.01 M $FeSO_4$ dissolved in 0.2 N HCl was injected. The medium was inoculated with several bands of cells from semisolid medium, after which sterile O_2 was introduced (0.4 % of the final headspace), and carefully placed at 25 °C for O_2 gradient establishment, indicated by pink color at the surface while the remaining medium

remained colorless. Growth initiated at the oxic–anoxic interface near the surface, and as growth increased, O_2 in the headspace was replenished up to a maximum of 4 % of the headspace every 24–48 h during 7–10 days.

Magnetovibrio blakemorei was isolated from shallow, brackish, salt-marsh pools near the Neponset River estuary in Milton, MA, USA. Samples were placed under dim light at room temperature, and after several days, formation of a horizontal "plate" of microorganisms in the water column was observed in one of the bottles. The characterization of the environmental conditions that favored the enrichment of this bacterium suggested that the gradient of sulfide was in the presence of an opposing gradient of oxygen diffusing from the surface to the bottom and thus the plate probably formed at the oxic–anoxic interface within the bottle at pH 7.5. Cells removed from the plate were used to inoculate sulfide–O_2 concentration gradient medium, prepared following the recipe of Nelson and Jannasch (1983) but modified by using diluted artificial seawater (ASW) solution rather than natural seawater and by the addition of 25 mM ferric quinate (Blakemore et al. 1979) and 200 µl 0.2 % aqueous resazurin per liter. The ASW was adjusted to approximately 23 % and consisted of (g l^{-1}) NaCl, 16.4; $MgCl_2.6H_2O$, 3.5; Na_2SO_4, 2.7; KCl, 0.47; and $CaCl_2.2H_2O$, 0.39. After enrichment into ASW modified medium, small amounts of magnetotactic cells were observed in a low percentage of the cultures forming microaerophilic bands of cells. For isolation of the strain, cells from these enrichment gradient cultures were inoculated in a dilution series of solid agar (13 g Agar Noble l^{-1}; Difco Laboratories) shake tubes of ASW [O_2]-gradient medium containing 5 ml modified Wolfe's mineral elixir containing 0.5 ml vitamin solution as described in Bazylinski et al. (2013). Anoxic conditions and the use of nitrous oxide (N_2O) at a pressure of 2 atm (202.7 kPa) were necessary to avoid contamination by nonmagnetic bacteria. After 2–3 weeks, shake tube black, lens-shaped colonies consisting of the magnetotactic vibrio individual colonies were removed and used as inocula for a second series of shake tubes, and the process was repeated once more to ensure purity of the culture. Since then, cells of *M. blakemorei* are routinely grown in oxygen-free liquid cultures of ASW modified medium containing 5 ml modified Wolfe's mineral elixir and N_2O at 1 atm as the terminal electron acceptor.

Species of the genera *Novispirillum* and *Insolitispirillum* are routinely grown on LMG medium no. 8 (composition per liter: 1 g succinic acid, 10 g peptone, 1 g $(NH_4)_2SO_4$, 1 g $MgSO_4.7H_2O$, 2 mg $FeCl_3.6H_2O$, 2 mg $MnSO_4.H_2O$, and 15 g agar, pH 7.0).

Nisaea spp. were isolated from one of the major sites of water-column denitrification among the world's oceans using filter-sterilized seawater from the isolation site for the preparation of media and dilution to extinction as described by Schut et al. (1993). After 1 month at 20 °C, positive cultures were plated on seawater R2A agar (Difco) and incubated at 20 °C for 1 week. After subculturing, two isolates forming cream-colored colonies on Marine Broth 2216 medium (MB; Difco) were obtained and designated as *N. denitrificans* DR41_21^T and *N. nitritireducens* DR41_18^T. According to genus description (Urios et al. 2008), growth occurs at 15–44 °C (optimum, 30 °C), at pH 5.0–9.0 (optimum, pH 6.0), and at salinities in the range 0–60 g l^{-1} (optimum, 20 g l^{-1}).

Marispirillum indicum was isolated from the seawater of the Southwest Indian Ridge, Indian Ocean (Lai et al. 2009a). Seawater sample was added with crude oil, as carbon and energy source, for enrichment of oil-degrading bacteria. After 2 months, 1 ml enrichment culture was transferred into 100 ml fresh MM medium as described in Lai et al. (2009b). Sequential transfers were performed three times at intervals of 2 weeks and incubation at 28 °C with shaking at 160 r.p.m. Bacteria were isolated using the plate screening method on 216 L medium (containing, per liter seawater: CH_3COONa, 1.0 g; tryptone, 10.0 g; yeast extract, 2.0 g; sodium citrate, 0.5 g; NH_4NO_3, 0.2 g; pH 7.5). The 216 L medium was used for all studies of strain B142^T.

Oceanibaculum species were isolated from deep seawater during a survey for PAH-degrading bacteria (Lai et al. 2009b; Dong et al. 2010). PAH-degrading bacteria media containing 1 % (v/v) sterilized crude oil and two different PAH mixtures were used for enrichment. *O. indicum* P24^{T}was isolated from the Southwest Indian Ridge, using PAH mixture containing naphthalene, phenanthrene, anthracene, and pyrene, at 200 p.p.m each, dissolved in crude oil as the carbon and energy source. *O. pacificum* strain LMC2up-L3^T was isolated from a hydrothermal field of the southwest Pacific Ocean, using PAH mixture containing naphthalene and phenanthrene at a final concentration of 100 p.p.m. and 20 p.p.m. of pyrene. After 2 months, 1 mL of each enrichment culture was transferred into 100 ml fresh seawater medium containing per liter 1.0 g NH_4NO_3, 0.5 g KH_2PO_4, and 2.8 mg $FeSO_4.7H_2O$, using the PAH mixture respective to each species, as the sole carbon and energy source. After 3 weeks of incubation at 28 °C with shaking at 160 r.p.m., each culture was transferred repeatedly to the same medium for further enrichment every 4 weeks three times. Bacteria were isolated by using the plate screening method on 216 L medium (per liter seawater: 1.0 g CH_3COONa, 10.0 g tryptone, 2.0 g yeast extract, 0.5 g sodium citrate, and 0.2 g NH_4NO_3; pH 7.5). For further studies of these species, the same medium has been used as described by Lai et al. (2009b) and Dong et al. (2010).

Limimonas halophila (Amoozegar et al. 2013) designated strain IA16^T was isolated using the modified growth medium (MGM) with 24 % (w/v) total salt concentration as described (Dyall-Smith 2008): 5 g peptone (Oxoid), 1 g yeast extract, and 200 ml pure water with 767 ml of a stock salt solution that contained (L^{-1}) 240 g NaCl, 35 g $MgSO_4.7H_2O$, 30 g $MgCl_2.6H_2O$, 7 g KCl, and 1 g $CaCl_2$. The pH of the medium was adjusted to pH 7.2–7.4 with Tris base, and agar was added to the medium to give a final concentration of 1.5 % (w/v). The isolation procedure consisted of spreading mud sample serial dilution in sterile 20 % (w/v) on plates of MGM agar. After growth development, achieved at 40 °C after 2 months under aerobic conditions, successive cultivation leads to pure isolate of IA16^T.

Pelagibius–Phaeospirillum–Phaeovibrio–Rhodocista–Rhodospira

Pelagibius litoralis was isolated from coastal seawater off the east coast of Korea. Autoclaved seawater (500 ml) supplemented with urea (100 mM) was inoculated with seawater (100 µl) and incubated at 20 °C in the dark for about 8 months. Incubated material was spread on a Marine Agar 2216 (Difco) plate (https://www.bd.com/europe/regulatory/Assets/IFU/Difco_BBL/212185.pdf) following incubation aerobically at 30 °C for 2 weeks. Purified cultures were obtained by subsequently streaking the isolated strain onto fresh MA plates at 30 °C under aerobic conditions. Pure cultures were stored in Marine Agar 2216 at 30 + C and in Marine Broth 2216 (Difco) supplemented with 30 % (v/v) glycerol at −80 °C (Choi et al. 2009).

In general, media and growth conditions for *Phaeospirillum* species can be the same applied for other freshwater photosynthetic non-sulfur bacteria such as *Rhodospirillum*, considering the need to establish and maintain reduced oxygen partial pressure. Cultures can be cryopreserved in liquid nitrogen or at −80 °C through standard techniques.

Phaeospirillum fulvum and *Phaeospirillum molischianum* were both isolated from an enrichment culture using mud or surface water as inoculum in a glass stoppered bottle. Carprylate or pelargonate (up to 0.04 % at pH 7.5) were added to the mineral salt media used to isolate *P. fulvum* (van Niel 1944; Imhoff et al. 1998) and can provide selective growth conditions for *P. fulvum* and *P. molischianum*. Hay was used as organic substrate to isolate *P. molischianum* (Giesberger 1947; Imhoff et al. 1998). Pure cultures were obtained by using successive dilutions of enrichment culture in agar medium under anaerobic conditions according to van Niel (1944).

Phaeospirillum chandramohanii was isolated from a photolithoheterotrophic enrichment of a water sample from a freshwater reservoir sampled at Mudasarlova (India), using mineral medium (Biebl and Pfennig 1981) supplemented with $Na_2S.9H_2O$ (1 mM) plus 0.3 % pyruvate (w/v), in anaerobiose (Kumar et al. 2009). Pure cultures were obtained by using the repeated agar shake dilution method (Pfennig and Truper 1992; Imhoff 1988) using the medium described by Pfennig and Truper (1974) supplemented with $Na_2S_2O_3$ (4 mM).

Phaeospirillum oryzae was isolated from an enrichment culture of the rhizosphere soil of a paddy (Nadergul, India), using a photoheterotrophic medium (Biebl and Pfennig 1981), pH 7.0, incubated at 2,400 lx, 28–30 °C for 7 days in fully filled screw-capped bottles (Lakshmi et al. 2011a). Pure cultures were obtained by repeated streaking on agar slants in test tubes (25 × 150 mm) sealed with butyl rubber corks and replacing the gas phase with argon to achieve anaerobic conditions. Purification media contained (g l^{-1}) KH_2PO_4 (0.5), $MgSO_4.7H_2O$ (0.2), NaCl (0.4), NH_4Cl (0.6), $CaCl_2.2H_2O$ (0.05), sodium pyruvate (0.5), sodium succinate (0.5), sodium acetate (0.5), yeast extract (0.3), ferric citrate (5 ml l^{-1} forms a 0.1 % w/v stock solution), and trace element solution SL 7 (1 ml l^{-1}; Biebl and Pfennig 1981).

Phaeospirillum tilakii was isolated from an enrichment culture of aquatic sediment (Nelapattu, India) using photoheterotrophic medium prepared according to Lakshmi et al. (2011b) containing the following: NH_4Cl (18 mM), $MgSO_4.7H_2O$ (1.2 mM), $CaCl_2.2H_2O$ (1.3 mM), KH_2PO_4 (3.6 mM), NaCl (17 mM), sodium succinate (7.4 mM), yeast extract (2.0 g l^{-1}), and Na_2HPO_4 (2 mM), pH 7.0. Enrichment cultures were incubated at 2,400 lx, 28–30 °C for 7 days in fully filled screw-capped bottles (Raj et al. 2012). Pure cultures were obtained by repeated streaking on agar slants in test tubes (25 × 150 mm) sealed with butyl rubber corks and replacing the gas phase with argon to achieve anaerobic conditions. Purification media contained (g l^{-1}) KH_2PO_4 (0.5), $MgSO_4.7H_2O$ (0.2), NaCl (0.4), NH_4Cl (0.6), $CaCl_2.2H_2O$ (0.05), sodium pyruvate (0.5), sodium succinate (0.5), sodium acetate (0.5), yeast extract (0.3), ferric citrate (5 ml l^{-1} forms a 0.1 % w/v stock solution), and trace element solution SL 7 (1 ml l^{-1}; Biebl and Pfennig 1981).

Phaeovibrio sulfidiphilus was isolated from sediment of a brackish shrimp pond (pH 8.2) at Vadkku Poigainallur (India). Enrichment culture was obtained in a photoheterotrophic medium containing the following: NH_4Cl (18 mM), $MgSO_4.7H_2O$ (1.2 mM), $CaCl_2.2H_2O$ (1.3 mM), KH_2PO_4 (3.6 mM), NaCl (17 mM), sodium succinate (7.4 mM), yeast extract (2.0 g l^{-1}), and Na_2HPO_4 (2 mM), pH 8.2. Cultures were incubated at 2,400 lx, 28–30 °C for 7 days in fully filled screw-capped bottles (Lakshmi et al. 2011b). Pure cultures were obtained by repeated streaking on agar slants in test tubes (25 × 150 mm) sealed with butyl rubber corks and replacing the gas phase with argon to achieve anaerobic conditions. Purification media contained KH_2PO_4 (3.6 mM), $MgSO_4.7H_2O$ (0.8 mM), NaCl (6.8 mM), NH_4Cl (11 mM), $CaCl_2.2H_2O$ (0.34 mM), sodium pyruvate (4.5 mM), sodium succinate (1.8 mM), sodium acetate (3.6 mM), yeast extract (0.3 g l^{-1}), Na_2S (1 mM), $NaHCO_3$ (100 mM), ferric citrate (0.2 mM), and trace element solution SL 7 (1 ml l^{-1}; Biebl and Pfennig 1981).

Rhodocista centenaria was isolated from a water sample collected at the edge of a hot spring (55 °C) at Wyoming (USA) (Favinger et al. 1989). Enrichment culture was at 40 °C using a procedure selective for anoxygenic N_2-fixing photosynthetic bacteria according to Guest et al. (1985). Maintenance of pure cultures can be achieved in SA agar medium kept at 10 °C in the dark (Kawasaki et al. 1992).

Rhodocista pekingensis originates from activated sludge from a municipal wastewater treatment plant in Beijing (China). Dilluted samples were inoculated in soft-agar (0.7 % agar) tubes using the following media modified from the AT medium (Imhoff and Trüper 1992): ATB medium with butyrate as sole carbon source, ATY medium with 0.05 % w/v yeast extract and removal of sodium hydrogen carbonate, and ATYP medium with addition of 0.03 % w/v peptone to ATY medium. Inoculated tubes were incubated anaerobically at 34–41 °C under incandescent illumination of 1,000–2,000 lx for 1 week. After incubation period, pink-reddish colonies were picked and streak onto agar plates (1.5 % agar) with the same medium and incubation conditions (Zhang et al. 2003).

Rhodospira trueperi was isolated from the peach-colored layer of a laminated microbial mat in Massachusetts (USA). Material was suspended in sterile seawater and inoculated in a deep-agar dilution series. Cultures were grown phototrophically in 100-ml screw-capped bottles with rubber seals, at 20–22 °C and a light intensity of 300–500 lx, using basal medium containing (g l^{-1}) KH_2PO_4 (0.25), NH_4Cl (0.4), KCl (0.35), NaCl (20.0), $MgSO_4.7H_2O$ (2.8), $CaCl_2.2H_2O$ (0.25), $NaHCO_3$ (1.5), $Na_2S.9H_2O$ (0.3), 1 ml vitamin solution (Pfennig and Trüper 1981), 1 ml trace element solution SL 12 (Overmann et al. 1992), 3 mM acetate, and 1 % w/v washed agar. Pure cultures were obtained after repeated deep-agar dilution series (Pfennig et al. 1997). Pure cultures were stored at 4 °C in the dark.

Rhodospirillum–Pararhodospirillum–Rhodovibrio

A number of media have been used for the isolation and enrichment of *Rhodospirillaceae* species (Biebl and Pfennig 1981; Imhoff and Trüper 1992). Among these, a mineral medium has been used for culturing the majority of "purple non-sulfur bacteria" (J. F. Imhoff 2005b): AT medium contains 1.0 g·L^{-1} KH_2PO_4, 0.5 g·L^{-1} $MgCl_2{\cdot}6H_2O$, 0.1 g·L^{-1} $CaCl_2{\cdot}2H_2O$, 1.0 g·L^{-1} NH_4Cl, 3.0 g·L^{-1} $NaHCO_3$, 0.7 g·L^{-1} Na_2SO_4, 1.0 g·L^{-1} NaCl, 1 mL of sulfate-free trace element solution SLA (Imhoff and Trüper 1977; Imhoff 1992), and 1 mL of vitamin solution VA (Imhoff and Trüper 1977; Imhoff 1992). Organic carbon sources include (routinely 10 mM) sodium malate, sodium succinate, sodium pyruvate, or sodium acetate and also, for oxygen-sensitive strains, 0.5 g·L^{-1} of sodium ascorbate or 0.25 g·L^{-1} thioglycolate, added separately. The initial pH is adjusted to 6.9. Vitamin solution VA, prepared in double distilled water, contains 0.01 % biotin, 0.035 % niacinamide, 0.03 % thiamine dichloride, 0.02 % p-aminobenzoic acid, 0.01 % pyridoxal hydrochloride, 0.01 % calcium pantothenate, and 0.005 % vitamin B12. The trace element solution SLA has the following composition: 1.8 g·L^{-1} $FeCl_2{\cdot}4H_2O$, 250 mg·L^{-1} $CoCl_2{\cdot}6H_2O$, 10 mg·L^{-1} $NiCl_2{\cdot}6H_2O$, 10 mg·L^{-1} $CuCl_2{\cdot}5H_2O$, 70 mg·L^{-1} $MnCl_2{\cdot}4H_2O$, 100 mg·L^{-1} $ZnCl_2$, 500 mg·L^{-1} H_3BO_3, 30 mg·L^{-1} $Na_2MoO_4{\cdot}2H_2O$, and 10 mg·L^{-1} $Na_2SeO_3{\cdot}5H_2O$; the pH of the solution is adjusted with HCl to 2–3.

Bacteria of the *Rhodospirillum* species can be isolated through standard techniques for anaerobes in agar dilution series and on agar plates, keeping oxygen-free conditions, especially for oxygen-sensitive species (Biebl and Pfennig 1981; Imhoff and Trüper 1992). This can be accomplished by adding 0.5 g·L^{-1} of sodium ascorbate or 0.25 g·L^{-1} thioglycolate to the growth medium in completely filled screw-capped bottles. Cell cultures can be maintained by standard techniques in liquid nitrogen or at −80°C (Imhoff 2005b).

Bacteria of the *Pararhodospirillum* species can be isolated through standard techniques for anaerobes in agar dilution series and on agar plates, keeping oxygen-free conditions, as these are oxygen sensitive (Biebl and Pfennig 1981; Imhoff and Trüper 1992). This can be accomplished by adding 0.5 g·L^{-1} of sodium ascorbate or 0.25 g·L^{-1} thioglycolate to the growth medium in completely filled screw-capped bottles. Cell cultures can be maintained by standard techniques in liquid nitrogen or at −80°C (Imhoff 2005b).

Rhodovibrio species require high salt concentrations and complex nutrients for growth (Imhoff 2005a). Thus, complex media with salt concentrations of ∼10 % and anaerobic incubation in the light constitute selective conditions for the enrichment of *Rhodovibrio* species. A suitable medium for both *Rhodovibrio* species, named DSIC$^-$ or SAL (Mack et al. 1993), contains per liter: 1 g yeast extract, 1 g sodium acetate, 125 g NaCl, 10 g $MgCl_2{\cdot}6H_2O$, 0.2 g $CaCl_2{\cdot}2H_2O$, 0.5 g NH_4Cl, 0.6 g KH_2PO_4, 2.5 g K_2SO_4, 1 g $NaHCO_3$, 0.1 g $Na_2S_2O_3{\cdot}5H_2O$, 2.1 g MOPS buffer, 20 µg vitamin B12, 1 ml trace element solution SLA (see above), and pH 7. To avoid precipitation, the magnesium and calcium salts, as well as the $NaHCO_3$, are autoclaved as separate solutions. *Rhodovibrio* species can be isolated through standard techniques for anaerobes in agar dilution series and on agar plates, keeping oxygen-free conditions (J. F. Imhoff and Trüper 1992; Imhoff 2005a). This can be achieved by photosynthetic growth, in completely filled screw-capped illuminated tubes, at 37°C. Cell cultures can be maintained by standard techniques in liquid nitrogen, by lyophilization, or storage at −80°C (Imhoff 2005a).

Roseospira–Skermanella–Telmatospirillum

Roseospira marina strain CE2105 was isolated from brackish Certes Fishponds (Arcachon Bay, French Atlantic coast), which are periodically flooded with seawater. Liquid enrichment cultures were prepared from the upper layer of the anoxic sediments (Guyoneaud et al. 2002). Enrichment and isolation of strain CE2105 were obtained by using a basal medium containing filtered (0.2-µm pore size) seawater, 750 ml; distilled water, 250 ml; NH_4Cl, 0.035 % (w/v); yeast extract, 0.04 % (w/v); and Fe citrate, 0.001 % (w/v). The medium was autoclaved and cooled under a gas mixture of N_2/CO_2 (90/10, v/v). Vitamin V7 solution (Pfennig and Truper 1992; 1 ml.l^{-1}), phosphate buffer (0.1 M, pH 6.8, 36 ml.l^{-1}), and Na ascorbate/cysteine HCl (0.25 % (w/v)/0.5 % (w/v) solution at pH 7.0, 0.2 ml.l^{-1}) were then aseptically added to the medium.

Roseospira navarrensis strain SE3104 was isolated from the surface of sulfide-rich sediment from a small saline pond in the Spanish Pyrenees, formed from the outflow of a saline spring (Salinas de Oro, Navarra, Spain) with salinity varying from 2 % to 10 % (total salinity) (Guyoneaud et al. 2002). This spring water is rich in chloride (46 % w/v), sodium (28 % w/v), sulfate (15 % w/v), calcium (5 % w/v), and potassium (4 % w/v). For enrichment and isolation of strain SE3104, the culture medium was prepared according to the method of Pfennig and Trüper (1992) which contained (per liter water) 0.35 g KH_2PO_4, 0.05 g $CaCl_2.2H_2O$, 0.5 g NH_4Cl, 10 g NaCl, 0.7 g $MgCl_2.6H_2O$, 0.35 g $MgSO_4.7H_2O$, 1.5 g $NaHCO_3$, 1 ml vitamin solution V7 (Pfennig and Trüper 1981), 1 ml trace element solution SL12B containing (per liter of deionized water) 3 g $Na_2EDTA.2H_2O$,

1.1 g $FeSO_4.7H_2O$, 0.3 g H_3BO_3, 0.19 g $CoCl_2.6H_2O$, 0.05 g $MnCl_2.4H_2O$, 0.042 g $ZnCl_2$, 0.024 g $NiCl_2.2H_2O$, 0.018 g $NaMoO_4.2H_2O$, 0.002 g $CuCl_2.2H_2O$ (Overmann et al. 1992), 0.5 g yeast extract, 1.35 g (5 mM) disodium succinate, 0.68 g (5 mM) sodium acetate, and pH 6.8 and supplemented with 5 % (w/v) NaCl and 1 % (w/v) $MgCl_2.6H_2O$.

Roseospira thiosulfatophila strain AT2115 was isolated from microbial mats in French Polynesia (Tetiaroa Atoll, Society Islands) (Guyoneaud et al. 2002). The culture medium used for enrichment and isolation of strain AT2115 contained filtered (0.2-µm pore size) seawater, 1,000 ml; NH_4Cl, 0.05 % (w/v); KH_2PO_4, 0.02 % (w/v); and yeast extract, 0.05 % (w/v). The medium was autoclaved and cooled under N_2/CO_2 (90/10, v/v). Vitamin V7 solution (1 ml.l–1), $NaHCO_3$ (0.15 % w/v), and $Na_2S.9H_2O$ (0.02 % w/v) were then aseptically added to the medium. The final pH for all media was adjusted to 6.8. The media were dispensed into sterile 50-ml screw-capped bottles. Organic substrates (5 mM sodium acetate and 5 mM disodium succinate) were added just before utilization. Pure cultures were obtained by repeated application of the deep-agar dilution method (Pfennig 1978). Deep-agar tubes were incubated at 25 °C under a light/dark cycle (16 h light/8 h dark) using tungsten lamps.

The pure cultures of *Roseospira marina, Roseospira navarrensis*, and *Roseospira thiosulfatophila* are cultivated, characterized and maintained in the synthetic media with the composition (per liter of distilled water): KH_2PO_4, 0.03 % (w/v); NH_4Cl, 0.05 % (w/v); $CaCl_2.2H_2O$, 0.005 % (w/v); $MgCl_2.6H_20$, 0.1 % (w/v) (0.3 % w/v for strain SE3104); $MgSO_4.7H_2O$, 0.05 % (w/v) (0.2 % w/v for strain SE3104); NaCl, 2 % (w/v) (5 % w/v for strain SE3104); trace element solution SL12 (Overmann et al. 1992), 1 ml; and yeast extract, 0.05 % (w/v). Media were autoclaved and cooled under N_2/CO_2 (90/10, v/v). Vitamin V7 solution (1 ml.l–1), Na ascorbate (0.05 % w/v), and $NaHCO_3$ (0.15 % w/v) were then aseptically added to the medium. The final pH was adjusted to 6.8–7.0 and the medium was dispensed into sterile 50-ml screw-capped bottles. Organic substrates (5 mM Na acetate and/or 5 mM di-Na succinate) were added as substrates before use. In addition, for strains SE3104 and AT2115, $Na_2S.9H2O$ (0.02 % w/v) was also added to the medium prior to utilization. Pure cultures were grown in 50-ml screw-capped bottles and stored at +4 °C in the dark for preservation.

Roseospira visakhapatnamensis strain JA131 was isolated from a water sample (pH ~6.8, 30°C, 2–3 % (w/v) salinity) collected on 25 March 2004 from the fishing harbor at Visakhapatnam, India (17° 41′ N 83° 18 E). *Roseospira goensis* strain JA135 was isolated from a sediment sample (pH ~6.8; 30°C, 6–7 % (w/v) salinity) collected on 12 February 2005 from Kurka saltern, Goa, India (15° 29′ N 73° 49 E). Original enrichments of both strains were from photolithoheterotrophic media (anaerobic, 1 mM $Na_2S.9H_2O$ + 0.3 % (w/v) pyruvate/malate). Strain JA131 was isolated from an enriched culture containing 2 % NaCl, and strain JA135 was isolated from an enrichment containing 8 % NaCl. Subsequent culturing, purification, and characterization were as described by Biebl and Pfennig (1981) medium with the following modifications (g per liter): 1 g $MgSO_4.7H_2O$, 0.15 g $CaCl_2.2H_2O$, and 20 g NaCl and supplemented with $Na_2S_2O_3.5H_2O$ (2 mM) (Chakravarthy et al. 2007).

Skermanella parooensis was isolated from the water of the Paroo Channel in southwest Queensland, Australia (Skerman et al. 1983). A drop of water was inoculated on the surface of lake water agar (LWA) (Franzmann and Skerman 1981) plates, air-dried, and incubated for periods of up to 3 weeks. Multicellular bodies developed on some plates were transferred by micromanipulation to fresh LWA, in which each conglomerate transformed after periods of 4–8 h to actively motile cells containing highly refractive granules. Further incubation led these cells to produce water-clear colonies. Single cells selected and cultured on LWA produced this colony form. After prolonged incubation, a few of the multicellular forms appeared among the dense population.

Skermanella aerolata was isolated from air samples (20–1,000 ml) collected with a MAS-100 air sampler (a single-stage, multiple-hole impactor; Merck) on the roof of Taean Lily Experimental Station (Chungnam Provincial Agricultural Research and Extension Services in the Taean district of Korea) on 16 April 2005 (Weon et al. 2007). The sampler contained Petri dishes with R2A agar (BBL) supplemented with 200 micrograms/milliliter cycloheximide and incubated in the dark at 28 ° C for 5 days.

Skermanella xinjiangensis was isolated from sand soil sample collected from Xinjiang (An et al. 2009). Strain 10-1-101^T was isolated after dilution and plating on 0.1 × trypticase soy broth (TSB) agar plates (Difco) at 28 °C. The isolate could also grow on R2A (Difco).

Skermanella stibiiresistens was isolated from soil collected from Jixi coal mine (45° 18′ N 130° 57′ E) of Jixi City, Heilongjiang Province, Northeast China (Luo et al. 2012). The soil texture was sandy with a pH of 7.2, and total As, Sb, Fe, and Cu concentrations were 0.04, 0.01, 18.0, and 0.09 $g.kg^{-1}$, respectively. Total C, N, P, S, and nitrate concentrations were 303.0, 3.8, 0.6, 0.2, and 0.04 g kg^{-1}, respectively. Sb-resistant bacteria were isolated using CDM medium (per liter): $MgSO_4.7H_2O$, 2.0 g; NH_4Cl, 1.0 g; Na_2SO_4, 1.0 g; K_2HPO_4, 0.013 g; $CaCl_2.2H_2O$, 0.067 g; sodium lactate, 5.0 g; $Fe_2SO_4.7H_2O$, 0.033 g; $NaHCO_3$, 0.798 g; and 15.0 g agar, pH 7.2 (Weeger et al. 1999) containing 0.1 mM $C_8H_4K_2O_{12}Sb_2.3H_2O$ (potassium antimony tartrate trihydrate).

Telmatospirillum siberiense was isolated by plating of acidotolerant methanogenic consortia from northern acidic peatlands on 1 % agarose N-free mineral medium (g per liter): K_2HPO_4, 0.25; KH_2PO_4, 1.0; $CaCl_2$, 0.1; $MgSO_4$, 0.4; Na-EDTA, 0.01; $FeCl_3 \cdot 6H_2O$, 1×10^{-3}; KI, 2×10^{-4}; $CoCl \cdot 6H_2O$, 2×10^{-4}; $MnCl_2 \cdot 4H_2O$, 8×10^{-4}; $ZnSO_4$, 8×10^{-4}; H_3BO_2, 1×10^{-4}; $Na_2MoO_4 \cdot 2H_2O$, 1×10^{-4}; $CuCl_2$, 1×10^{-4}; and $NiCl_2 \cdot 6H_2O$, 2×10^{-4}, with 0.6 mM Ti(III) citrate as reducing agent and H_2:CO_2:N_2 in the headspace. Brown colonies of non-methanogenic microorganisms formed after 5–7 months of anaerobic incubation. Intensive growth occurred in liquid Na citrate medium after complete utilization of citrate in 4–7 days.

Small brown, beige, and pink colonies formed on citrate-agar medium in 10–14 days. Colonies were subcultured at 28 °C on the same liquid medium supplemented with $(NH_4)_2SO_4$ and Na citrate instead of Ti(III) citrate under N_2 (Sizova et al. 2007).

Thalassobaculum

For isolating *Thalassobaculum litoreum* CL-GR58^T, coastal seawater and sediment samples were incubated in a 150-mm-diameter glass Petri dish for around 15 months at room temperature. Without disturbing the sediment, a 100-ml sample of seawater was removed from the surface and spread on a Marine Agar 2216 (MA; Difco) plate, which was then incubated at 30 °C for 1 week. Strain CL-GR58^T was isolated and subsequently purified on MA at 30 °C four times. The strain was maintained both on MA at 30 °C and in Marine Broth 2216 (MB; Difco) supplemented with 30% (v/v) glycerol at −80 °C (Zhang et al. 2008).

Thalassobaculum salexigens CZ41-10a^T was isolated from seawater samples. Subsamples were spread on nutrient agar plates (Bio-Rad) prepared with filtered seawater and incubated at 25 °C for 2 weeks. Colonies were picked and purified by three subcultures. Among these colonies, an isolate forming cream-colored colonies was obtained and designated strain CZ41-10a^T (Urios et al. 2010).

Thalassospira

For isolating *Thalassospira lucentensis*, the culture medium consisted of autoclaved and filtered seawater supplemented with cocktail FRV (at 0.01 g l^{-1}), which contains *Spirulina* (Sigma), fish meal, and *Artemia salina* (1 :1: 1). The pH of the medium was adjusted to 7.2. A 2-l bioreactor was completely filled up with the sample and incubated at 13 °C (in situ temperature) and with slow magnetic stirring. After 24 h, a flow rate was established to obtain a dilution rate of 0.0004 h^{-1}. The setup was maintained for three months. Weekly, 100 µl of enrichment was plated onto solidified FRV medium and incubated at 13 °C. Initially, bacteria grow as very small colonies on the complex oligotrophic FRV medium. After subculturing, they are able to grow in media containing a higher nutrient content than that of the medium used for initial isolation. In fact, the peptone-yeast extract-based media, marine agar, or YEA routinely used to culture fast-growing, copiotrophic marine bacteria allow fairly good growth.

For isolating *Thalassospira xiamenensis* M-5^T and *Thalassospira profundimaris* WP0211^T, bacteria were enriched by culturing in artificial seawater medium (ASM; Liu and Shao 2005), supplemented with 10 g diesel fuel l^{-1} (strain M-5^T) or 5 g pyrene l^{-1} (strain WP0211^T) as the sole carbon source. HLB medium (modified from Luria–Bertani medium by increasing the NaCl concentration to 30 g l^{-1}; Liu and Shao 2005) was used for routine cultivation of the isolates and for most of the phenotypic tests. All cultures were incubated at 28 °C with rotation at 200 r.p.m. unless noted otherwise. As was previously found for *Thalassospira lucentensis* QMT2^T (López-López et al. 2002), both strains formed very small colonies in the oligotrophic medium, but showed fairly good growth in the HLB media (Liu et al. 2007).

Thalassospira tepidiphila 1-1B^T was isolated from petroleum-contaminated seawater during a bioremediation experiment (Kodama et al. 2008). Seawater was collected from a bioremediation tank, serially diluted, and spread onto 1 % (w/v) Gelrite plates containing the artificial seawater medium ONR7a (Dyksterhouse et al. 1995). The plates were then coated with heat-treated Arabian light crude oil (0.2 %, w/v) (Kasai et al. 2002) and incubated at 20 °C. After incubation for 3 weeks, small colonies appearing on these plates were picked and streaked onto solid plates containing Marine Broth 2216 (MB; Difco) and 1 % (w/v) Gelrite for purification. MB was used for routine cultivation. Cells of strain 1-1B^T were stored at −80 °C in MB supplemented with 15 % (v/v) glycerol.

To isolate *Thalassospira xianhensis* P-4^T (Zhao et al. 2010), 5 % sea-salt defined medium (5 % SSDM; Zhao et al. 2009) and 5 % SSDM with 0.5 % yeast extract (5 % SSDMY) were used. Solid 5 % SSDMY medium was prepared with 1.5 % agar. A sample of oil-polluted saline soil (1 g) was added to 100 ml 5 % SSDM medium supplemented with phenanthrene (100 mg ml^{-1}) in a 300-ml Erlenmeyer flask. The culture was aerobically incubated at 30 °C in darkness on a rotary shaker operating at 200 r.p.m. After 2 weeks, 10 ml culture was transferred to 100 ml 5 % SSDM medium and incubated under the conditions described above. The enrichment was performed five or six times. Next, a culture broth dilution series was spread on 5 % SSDMY agar. After incubation for 2 days, single colonies were picked and cultivated in 5 ml 5 % SSDM using phenanthrene as the sole source of carbon and energy. These isolates developed a yellowish-orange or reddish-brown color, which is an indication of ring cleavage of polycyclic aromatic hydrocarbons (Guerin and Jones 1988) and, thus, phenanthrene-degrading activity.

For isolating *Thalassospira permensis* SMB34^T (Plotnikova et al. 2011), the enrichment culture was incubated aerobically at 28 °C with shaking in Raymond's mineral medium (RMM), containing (g l^{-1}) NH_4NO_3 (2.0), $MgSO_4{\cdot}7H_2O$ (0.2), KH_2PO_4 (2), Na_2HPO_4 (3), $CaCl_2{\cdot}6H_2O$ (0.01), Na_2CO_3 (0.1), 2 ml of 1 % $MnSO_4{\cdot}5H_2O$, and 2 ml of 1 % $FeSO_4{\cdot}7H_2O$ that was supplemented with naphthalene (0.1 %, w/v) and NaCl (6 %, w/v). Strain SMB34^T was isolated by plating the enrichment onto RMM agar supplemented with 0.5 % (w/v) tryptone, 0.25 % (w/v) yeast extract, and 3 % (w/v) NaCl (designated complete Raymond's medium, CRM). The strain was routinely cultured on CRM agar and Marine Agar 2216 (MA; Difco) at 28 or 30 °C (Plotnikova et al. 2011).

Thalassospira alkalitolerans MBE#61^T and *Thalassospira mesophila* MBE#74^T were isolated from a piece of sunken bamboo in the coastal area of Japan (Tsubouchi et al. 2014). Bamboo is a fast-growing plant and significant bioresource in the east and south area of Asia. A portion (approximately 1 g) of sinker was soaked in 2 ml of sterile artificial seawater (ASW; Nihon Pharmaceuticals, Japan) and shaken briefly on

a vortex at room temperature. The immersion fluid was incubated at 25 °C for 1 day and then spread on 1.5 % (w/v) agar containing milled Japanese timber bamboo (MJTB; 2 % (w/v) milled Japanese timber bamboo and 0.5 × ASW). Both strains were isolated after incubation at 25 °C for 10 days. After incubation, small colonies appearing on MJTB plates were picked and streaked onto solid plate containing Marine Broth (MB; BD Difco) for purification. For routine cultivation, MB was used.

Tistrella

Tistrella mobilis was isolated from samples of wastewater in mineral salt medium prepared with 0.81 mM $MgSO_4$, 0.58 mM $CaSO_4$, 18 mM $FeSO_4$, 1.0 mM $NaMoO_4$ in 5 mM potassium phosphate, 50 mM ferric citrate, 3 % glucose, and 15 mM ammonium acetate (pH 7.1) (Shi et al. 2002). The polyhydroxyalkanoate (PHA) content in bacterial colonies can be determined qualitatively by observing the presence of visible, intracellular granules using a phase-contrast microscope. To recognize PHA-rich colonies, colonies grown on nitrogen-deficient agar after 5-day incubation at 30 °C are stained with Sudan Black B (0.02 % in 96 % ethanol). The dye is removed after 20 min, and the plates are then treated for 1 min with 10 ml of 96 % ethanol. The colonies of PHA-rich cells retain the dye and appear dark blue, whereas those of PHA-deficient cells decolorize and appear light gray.

Tristella bauzanensis BZ78^T was isolated from soil containing high levels of heavy oil and heavy metals (Zhang et al. 2011). For that, 10-g soil was shaken with 90 ml of sterile 1 % sodium pyrophosphate for 20 min at 150 r.p.m. Appropriate dilutions, prepared with sterile saline solution (0.9 % NaCl), were plated (0.1 ml) on R2A agar (0.05 % yeast extract, 0.05 % peptone, 0.05 % casamino acids, 0.05 % glucose, 0.05 % starch, 0.03 % sodium pyruvate, 0.03 % K_2HPO_4, 0.005 % $MgSO_4$, 1.5 % agar; pH 7; Reasoner and Geldreich 1985) and incubated at 20 °C. Strain BZ78^T was routinely cultured in R2A liquid medium at 20 °C and maintained as a suspension in skimmed milk (10 %, w/v) at −80 °C.

Tistlia

For isolating *Tistlia consotensis*, water samples were collected aseptically from the Salado de Consotá spring in 2006 by filling sterile glass containers to the brim (Díaz-Cárdenas et al. 2010). Enrichments were initiated by inoculating a 2-ml water sample in 10-ml filter-sterilized saline spring water which had been amended with 0.1 % (w/v) starch (Sigma) and 0.02 % (w/v) yeast extract (Sigma). Turbidity was observed after 10 days incubation at 37 °C. Subsequent phase-contrast microscopy (Eclipse 50i; Nikon) revealed the presence of curved and rod-shaped cells. Several colonies developed from serial dilutions of the enrichment culture streaked onto the same medium fortified with 2 % (w/v) Noble Agar (Sigma) after 3 days of incubation at 37 °C. A beige colour and slightly raised, circular, mucoid colony (1-mm diameter) was selected and the culture derived from this, designated strain USBA 355^T. Then it was routinely cultured in a basal medium (BM) supplemented with 20 mM D-glucose and 0.1 % (v/v) yeast extract. BM contained (l^{-1} deionized water) 1 g NH_4Cl, 0.3 g K_2HPO_4, 0.3 g KH_2PO_4, 3 g $MgCl_2.6H_2O$, 0.1 g $CaCl_2.2H_2O$, 0.1 g KCl, 23 g NaCl, and 1 ml Zeikus' trace element solution (Zeikus et al. 1979); the pH of the medium was adjusted to 7.1 with 1 M NaOH. Cells were preserved at −20 °C in BM supplemented with 20 % (v/v) glycerol.

Ecology

The species belonging to the family *Rhodospirillaceae* present wide range of habitats. For example, *Azospirillum* genus was first described as bacterial colonizing plant tissues, but more recently has been reported in broad range of niches, such as oil-contaminated soil and discarded road and fermentative tank. Species from the other genera have the aquatic environment (freshwater, stagnant, anoxic, acid, or saline, petroleum-contamined seawater), ocean, and saline soil as the common habitats although the species *I. limosus* was isolated from respiratory secretions of cystic fibrosis patients and from ginseng field soil.

Azospirillum–Skermanella–Desertibacter–Rhodocista–Dongia–Elstera–Inquilinus

The nitrogen-fixing genera are widespread in agricultural soils, where they are frequently associated with grasses, cereals, and crops (Bally et al. 1983; Day and Dobereiner 1976; Kirchhof et al. 1997; Ladha et al. 1987; Patriquin et al. 1983; Baldani and Baldani 2005) grown especially in soils of tropical and subtropical and temperate regions (Lavrinenko et al. 2010). More detailed, *A. lipoferum* and *A. brasilense* followed by *A. amazonense* were the first three species described and found associated with many cereals and other grasses grown in different regions of Brazil (Magalhães et al. 1983; Baldani and Baldani 2005), while the species named *A. halopraeferens* was found exclusively associated with kallar grass (*Leptochloa fusca*) grown in saline soils in Pakistan (Reinhold et al. 1987). In 1989, Khammas and collaborators isolated the species *A. irakense* using root samples of rice grown in Iraq. Many other species were also found associated with plants: *A. doebereinerae* with washed roots and rhizosphere soil of *Miscanthus sinensis* cv. Giganteus and *Miscanthus sacchariflorus* grown in Germany (Eckert et al. 2001), *A. oryzae* (Xie and Yokota 2005) with rice roots, and *A. melinis* (Peng et al. 2006) with subtropical molasses grass plants collected in China. *A. canadense* (Mehnaz et al. 2007a) and *A. zeae* (Mehnaz et al. 2007b) had its origin in the rhizosphere of corn (Zea mays) plants grown in Canada. In contrast, *A. rugosum* (Young et al. 2008) and *A. picis* (Lin et al. 2009) were enriched from contaminated soils and discarded road tar collected in Taiwan. *A. palatum* (Zhou et al. 2009) was isolated from forest soil in Zhejiang province, China, while *A. thiophilum* had its origin from a sulfide spring in Russia

(Lavrinenko et al. 2010). *A. formosense* was isolated from agricultural soil collected in Taiwan (Lin et al. 2012) and the species *A. humicireducens* from microbial fuel cell in Guangdong, China. On the other hand, the *A. largomobile* (formerly *Conglomeromonas largomobilis* subsp. *largomobilis*) was enriched from a freshwater sample collected in Australia (Sly and Stackebrandt 1999), while *A. fermentarium* was isolated from a fermentative tank in Taiwan (Lin et al. 2013). All species of the *Azospirillum* genus fix nitrogen, except *A. palatum*, a nonvalidated species. The species described more recently are less studied, and the knowledge about their ecological distributions is restricted to the original description of the type species. Therefore, more new data on the ecology of *Azospirillum* species are needed.

The genus *Azospirillum* is widely known as containing free-living nitrogen-fixing plant-growth-promoting rhizobacteria (Okon and Labandera-Gonzalez 1994, Okon and Itzigsohn 1992, and many others), and the carbon source and N-metabolism in this genus make it well adapted to several conditions of the soil and competent to colonize the rhizosphere and in some cases the inner part of the plant tissue (Döbereiner 1992; Steenhoudt and Vanderleyden 2000). They predominantly colonize the root surface, and only a few strains are able to infect plants (Patriquin et al. 1983; Döbereiner et al. 1995). Some *Azospirillum* strains have specific mechanisms to interact with roots and colonize even the root interior, while others colonize the mucigel layer or injured root cortical cell (Baldani et al. 1986). The physiological basis for the observed invasiveness of *A. brasilense* and others is not known. Even species are known which possess enzymes degrading carbon polymer structures of plant host cells, such as in the case of *A. irakense*; a conclusive model of invasiveness is not established (Khammas et al. 1989). Usually, bacteria enter in inner part of the plant using opportunities such as disrupted cortical tissue at lateral root junction, lysed root hairs, or natural cracks on the plant tissue (Steenhoudt and Vanderleyden 2000). Mainly the data on *Azospirillum* interaction with plants are based on a single species and the most studied one: *A. brasilense*. Chemotaxis is the basis of attraction and primary interaction with the host and flagella and frimbriae are involved in the adhesion, anchoring phase and irreversible adsorption that involves polar flagellum (Croes et al. (1993) and extracellular polysaccharide production (Michiels et al. 1991; Skvortsov and Ignatov 1998).

Skermanella species seems to have a large range of habits, being isolated from air, freshwater, and soil. *S. aerolata* was isolated from air samples in Korea (Weon et al. 2007), whereas *S. parooensis* was isolated in a microbial survey of waters of the Paroo Channel, Queensland, Australia. The two other species, *S. xinjiangensis* and *S. stibiiresistens*, were isolated from soil. The former was isolated from desert soil sample from Xinjiang, China (An et al. 2009), while the latter was from coal mine soil and exhibits resistance up to 4 mM Sb(III) in R2A broth (Liu et al. 2011).

Desertibacter roseus was isolated from gamma-irradiated sand sample from the Taklimakan desert, Xinjiang, China. The high resistance of this organism against the lethal actions of DNA-damaging agents including ionizing radiation and ultraviolet light (UV) has been widely reported (Zhang et al. 2007). Radiation-resistant bacteria can survive severe damage from gamma radiation, which implies that they have high DNA repair efficiency (Sghaier et al. 2008) and are adept at detoxifying reactive oxygen species (ROS) (Zhang et al. 2007).

The species of the genus *Rhodocista* have been mainly found in freshwater ecosystems; *Rhodocista* sp. T4 (tentatively *Rhodocista hanoiensis*) was isolated from an enrichment culture from a wastewater pond in Vietnam (Do et al. 2007a). An additional record at NCBI taxonomy browser assigned *Rhodocista* to include *R. xerospirillum* (no standing in the taxonomy) isolated from an upland paddy soil in India (accession no. AM072288, 98.7 % sequence similarity to *R. centenaria*). *Rhodocista* sp. strain JA353 (AM999778, 99.3 % sequence similarity to *R. peckingensis*) was indeed isolated from rhizosphere soil in India. *Rhodocista* sp. strains AR2107 and AT2107 (AJ401217 and AJ401204, respectively) were isolated from microbial mats in Rangiroa Atoll at French Polynesia and share 99.6 % and 99.3 % sequence similarities to *R. centenaria*, respectively. *Rhodocista* sp. strain W38 (KC248056, 96.3 % and 95.7 % sequence similarities to *Azospirillum irakense* and *R. peckingensis*, respectively) was obtained from a water sample, although no further information about this isolate is available. Isolation of *Rhodocista* sp. strain CAJ2-2 from the digestive organ of the Asian lady beetle *Harmonia axyridis* (HQ876734, 92.6 % and 90.7 % sequence similarities to *R. peckingensis* and *Azospirillum irakense*, respectively) is intriguing, although this genus is phylogenetically close to some *Azospirillum*, which are found in association with several plant species. In addition, sequences assigned as *Rhodocista* isolates from saline/marine environments (EU374900, EF650482, and DQ658977) are rather related to other species. In this same sense, the isolate *Rhodocista* sp. M71 (KC464867) originating from rhizosphere soil is more closely related to *Azospirillum*/*Skermanella* genus than to *Rhodocista*. Environmental 16S rRNA clone sequences related to *Rhodocista* are scarce, nevertheless reinforce the preference of this organism to inhabit freshwater environments. Few environmental sequences have >97 % 16S rRNA gene sequence similarity to *R. centenaria*; these are JF739669 (97.5 % sequence similarity) retrieved from soil from peatlands at Indonesia and JF278043 (97.8 % sequence similarity) retrieved from a biofilm grown in flow cell of an urban water canal at Singapore. Environmental clones with 16S rRNA sequences that have low similarity to *Rhodocista* reference sequences include FJ572031 (95.5 % similarity) retrieved from lake water in China. The clone sequences JF412910, JF412944, JF413199, JF413867, JF413890, JF413920, and JQ700914 (88.7–92.1 % 16S rRNA gene sequence similarities to *R. pekingensis*) were retrieved from the aquatic microbial community from the enclosed Cuatro Cienegas Basin in Mexico. Clone sequences retrieved from the vaginal microbiota of HIV-infected women were unusually assigned as *Rhodocista* sp. (JF475184, JF478845, JF487499, JF487508, JF487548, JF487561, JF487568, JF487584, JF487604, JF487608, JF487611, JF487613); nevertheless, such sequences present ~50 % coberture and 81.6–93.3 % similarity

to *R. pekingensis* that has been more closely related to *Rhodovulum*, *Ancalomicrobium*, and *Yangia* species.

The species *Dongia mobilis* LM22^T was found associated with a batch reactor for the treatment of malachite green effluent. In addition, sequences of 16S rRNA with high similarity (94–99 %) with *D. mobilis* were retrieved from a marine hot spring from Kalianda Island, Indonesia (JX047098), in soils, and in the associated Fe–Mn nodules of four regions in China (JX493260, JX493549, JX493661, JX493873, JX494044) and marine coastal sediment in India (KF465352, KF465359).

Elstera litoralis Dia-1^T was isolated from biofilms on stones in the littoral zone of Lake Constance, Germany (Rahalkar et al. 2012). *E. litoralis* was found living associated with diatoms in photic biofilms. It is possible that the extracellular polysaccharides (EPS) produced by the diatoms are an important source of organic carbon for heterotrophic bacteria in such biofilms (Bruckner et al. 2008). So far, there are no environmental clones known closely related to *Elstera.*

The genus *Inquilinus* comprises the species *I. limosus* (Coenye et al. 2002) and *I. ginsengisoli* (Jung et al. 2011). *I. limosus* was isolated from respiratory secretions of cystic fibrosis patients in the USA while *I. ginsengisoli* from ginseng field soil in Pocheon Province, South Korea. Sequences very closely related to *Inquilinus* have been retrieved from polluted soil contaminated by Zn and Cd (Gomez-Balderas et al. 2014), tufa core sample formation (FM177000) water from long-term experimental oligotrophic mesocosms in Cuatro Cienegas in Mexico (JQ701641), soil (JN64589, EF662791, GU300421), and bronchoalveolar lavage fluid from human with cystic fibrosis (DQ188295).

Magnetospirillum–Nisaea–Thalassobaculum–Oceanibaculum–Fodinicurvata–Pelagibius–Tistlia–Phaeospirillum–Telmatospirillum–Defluviicoccus–Tistrella–Constrictibacter–Rhodovibrio–Limimonas

The occurrence of MTB, surprisingly, appears to not be dependent on particularly high concentrations of iron in the environment but on the presence of an oxygen/anoxic interface that represents, in most environments, opposing gradients of oxygen from the surface and reduced compounds (usually reduced sulfur species) in sediments or water columns (reviewed by Lefévre et al. 2013a). Siderophore production was not detected in the culture supernatants of *Magnetospirillum gryphiswaldense* (Schüler and Baeuerlein 1996). However, during the growth of *M. magnetotacticum* MS-1 and *M. magneticum* AMB-1 under iron-rich condition, iron is rapidly assimilated from the medium, and the initial high concentration is reduced to levels comparable to iron-deficient cultures, thereby triggering siderophore production and excretion (Paoletti and Blakemore 1986; Calugay et al. 2003; Calugay et al. 2006). Based on this characteristic and their participation in other biogeochemical processes, Simmons and Edwards (2007) suggested that representatives of this group show a great potential for iron, nitrogen, sulfur, and carbon cycling in natural environments. Since the discovery of MTB, several morphologically and metabolically diverse types of magnetotactic bacteria are detected worldwide and ubiquitously in sediments of freshwater, brackish, marine, and hypersaline habitats as well as in chemically stratified water columns of these environments (reviewed by Frankel 2009; Lefèvre and Bazylinski 2013). Although widely spread in different ecosystems worldwide, only few axenic cultures mostly isolated from aquatic environment are available.

The chemoheterotrophic bacterium *Thalassobaculum litoreum* CL-GR58^T was isolated from coastal seawater in Gori, Korea (Zhang et al. 2008). *Thalassobaculum salexigens* CZ41-10a^T was obtained from seawater samples collected at the SOLA station located in the bay of Banyuls-sur-Mer, France, at a depth of 3 m (Urios et al. 2010). *Nisaea* species were detected in marine denitrification sites (Urios et al. 2008). No further data about their distribution and ecological importance is available.

Both *Oceanibaculum* species were isolated from a PAH-degrading consortium from deep-seawater sample collected from the Indian Ocean and Pacific Ocean. A study to determine the compositions of the bacterial community associated with oil and water phases in a mesothermic oil field showed that sequences representative of *Oceanibaculum* associated to the pooled microbial community are associated with the aqueous phase (Kryachko et al. 2012). Noteworthy, *Oceanibaculum* strains are reported to consume both water-insoluble aromatic hydrocarbons and water-soluble substances, but their primary metabolic substrate(s) must be water soluble, as suggested for other microorganisms found associated with the aqueous phase. However, further studies are necessary to elucidate the ecology of this microorganism under environmental conditions.

Two *Fodinicurvata* strains, designated YIM D82^T and YIM D812^T, were isolated from a Fenggang salt mine in Yunnan, southwest China. No environmental 16S rRNA gene sequences resembling the genus *Fodinicurvata* were deposited in the public databases.

Species of *Pelagibius* genus have been cultured exclusively from marine environment, such as coastal seawater (Korea) or in association with the coral reef *Eunicea fusca* in the USA (accession no. KC545308, 93 % sequence similarity). Environmental clones with 16S rRNA gene sequences assigned as *Pelagibius* have been identified associated to the coral reef *Montastraea faveolata* in Puerto Rico (JQ516378, JQ515728, JQ515699, JQ515532), sediments of the Baltic Sea in Finland (FR820363), groundwater contaminated with chlorinated aliphatic hydrocarbon in the southwest of North China Plain (JQ279035), microbial fuel cell (JF522342), and oil sands tailings pond in Canada (HQ043938). Indeed, DGGE bands of 16S rRNA gene sequences retrieved from a study of diet-induced lesions in the shell of lobsters (JF297201, JF297191) were also assigned as *Pelagibius.* Although most of clone sequences indicate marine environment as the natural niche of *Pelagibius*, the sequences closely related retrieved from groundwater and from a microbial fuel cell suggest that this organism can also inhabit nonmarine

environments. Further information on ecological function of members of this genus is needed.

The aerobic, chemoheterotrophic, nitrogen-fixing bacterium *Tistlia consotensis* USBA 355^T was isolated from samples collected from the saline spring, Salado de Consotá, located in the Colombian Andes (64° 40′ 43.1″ N, 75° 31′ 34.3″ W) (Díaz-Cárdenas et al. 2010). Salado de Consotá is a neutral pH spring with a salt content of 4.5 % (w/v), close to seawater, and the dominant ions are Na^+, Ca^{2+}, and Cl^-.

The habitat of the genus *Phaeospirillum* appears to be freshwater-rich environments, since all type strains were isolated from mud and rhizosphere soil. Additionally, *P. fulvum* was isolated from lake mud in Russia and from the top layer of aquatic sediments in the Netherlands. Information regarding the occurrence of additional isolation of *P. molischianum* strains is scarce, although Paterek and Paynter (1988) identified the presence of *P. molischianum* – by using morphological and physiological approaches – in the anaerobic photosynthetic bacterial community of salt-marsh sediment in the USA. Despite the need for further evidence, Paterek and Paynter (1988) findings suggest the possibility that the bacteria of this genus can also colonize saline environments. The species *P. molischianum* has an additional record at NCBI taxonomy browser assigned as *Phaeospirillum* sp. strain AK-42, isolated from sediment from a lake in India (unpublished results, accession number HF562217, 98.2 % 16S rRNA gene sequence similarity). A single record of a *Phaeospirillum* sp. strain closely related to *P. oryzae* is available at NCBI taxonomy browser, in addition to the isolated strains obtained by Lakshmi et al. (2011b) from paddy soil. *Phaeospirillum* sp. strain MPA1 was obtained in a survey to characterize spiral-shaped purple non-sulfur bacteria from New Zealand thermal environments (unpublished results, accession number AF487433, 98.8 % 16S rRNA gene sequence similarity to *P. oryzae* type strain). Additional records of *Phaeospirillum* strains related to *P. tilakii* at NCBI taxonomy browser were presented by Hisada et al. (2007), who isolated *Phaeospirillum* sp. strain TUT3101 from the microbial community associated to *Chloroflexus* and cyanobacterial mats developing at 50–65 °C from a hot spring in Japan (accession number AB250624, 98.7 % sequence similarity to *P. tilakii* type strain). Environmental 16S rRNA clone sequences listed in the NCBI taxonomy browser – as well as some isolates such as *Phaeospirillum* sp. JA795 (accession no. HF559003) – related to *Phaeospirillum* include ambiguous assignments, as their relateness to *Phaeospirillum* reference sequences is lower than to other bacterial species. In this sense, although low identity to *Phaeospirillum* type species is mostly observed, few environmental sequences will be presented as putative members of this genus. These include KC994874 (identical to KC994669), retrieved from a metagenome survey of biofilms associated with the microalgae *Chlorella vulgaris* and *Scenedesmus obliquus* in a photobioreactor in Germany (Krohn-Molt et al. 2013), with a sequence similarity of 89.2 % to *P. chandramohanii*. Sequences KF523288 and JF340073 were obtained from agricultural soil in China and share 94.7 % sequence similarity to *P. chandramohanii* and 100 % sequence similarity to *P. fulvum*, respectively, even though the similarity to other few reference sequences was the same, probably due to the short size of these sequences (169 and 172 bases, respectively). The sequences JF278044 and HM371256, with 90.3 % and 90.7 % sequence similarities to *P. tilakii*, respectively, were retrieved from biofilm grown on polyethylene terephthalate water canal in Singapore and from the estuarine belt of Narmada River (India), respectively. Sequences DQ252395 and EU682492 with 94.5 % and 91.0 % sequence similarities to *P. fulvum*, respectively, were cloned from the indigenous microflora associated with the decomposition of jute stalks in India and from the surface of coastal marine sediments in Hong Kong, respectively. Sequence GQ257682 with 98.8 % sequence similarity to *P. oryzae* was retrieved from groundwater contaminated with the explosive compound RDX in the USA. In addition, Rudney et al. (2010) performed a metaproteomic survey from the human salivary microbiota and assigned one peptide to *P. molischianum*. Lenchi et al. (2013) used pyrosequencing analysis to assign 16S rRNA gene sequences to *Phaeospirillum* as part of the bacterial community associated with production waters from flooded wells and in injection waters used for flooding Algerian oilfields (temperature range 51–96 °C, salinity range 0.58–21.18 g NaCl l^{-1}). It is clear from the above data that *Phaeospirillum* species have a preference for freshwater environments and that its inhabitation in marine environments needs further experimental evidence.

Telmatospirillum siberiense was isolated from northern acidic waters from peatlands under *Sphagnum* moss mats (Sizova et al. 2007).

Defluvicoccus genus with only one species, *D. vanus* Ben 114^T, was isolated from a sample of biomass from an enhanced biological phosphorus removal activated sludge plant in the Czech Republic. Several clones closely related to *Defluvicoccus* were detected in marine samples (JQ516397, JQ793263, FN687095, and JN210804); others are from activated sludge (KC797679) or contaminated soils (HE974846) and gypsum-treated oil sands tailings pond (HQ044218, HQ041215, HQ042479, HQ042046); some are also related to human diseases as cystic fibrosis sinuses (JQ794646) and cutaneous microbiome (KF509289).

The type strain *Tistrella mobilis* IAM 14872^T was isolated from wastewater in Thailand and showed a good ability in producing polyhydroxyalkanoates (PHA) efficiently (Shi et al. 2002). *Tistrella bauzanensis* BZ78^T was isolated from soil containing high levels of heavy oil and heavy metals located in Bozen, South Tyrol, Italy (Zhang et al. 2011).

The unique species of *Constrictibacter*, *C. antarcticus* 262-8^T, was isolated from a cavity within white rock collected in the Skallen region of Antarctica. Environmental 16S rRNA clone sequences related to the genus *Constrictibacter* have not been deposited.

Limimonas is a genus of extremely halophilic microorganism in this family isolated from a saline mud sample collected from the hypersaline Lake Aran-Bidgol in Iran, and its characterization led to the description of the species

Limimonas halophila (Amoozegar et al. 2013). This microorganism is able to tolerate salt concentrations in the range of 15–30 % (w/v).

Rhodospirillum–Pararhodospirillum–Phaeovibrio–Roseospira–Rhodospira–Novispirillum–Marispirillum–Insolitispirillum–Caenispirillum–Thalassospira–Magnetospira–Magnetovibrio–Ferrovibrio

Stagnant and anoxic freshwater that is exposed to the light is the habitat of *Rhodospirillum* and most *Pararhodospirillum* species (Imhoff 2005b; Kumar et al. 2008; Lakshmi et al. 2014). A number of culture-dependent and culture-independent studies have shown that anoxic zones of saline or hypersaline environments such as seawater, brines, and salt lakes that are exposed to the light are the habitat of *Rhodovibrio* species (Nissen and Dundas 1984; Mack et al. 1993; Sørensen et al. 2005; Blazejak et al. 2006; Maturrano et al. 2006; Boutaiba et al. 2011; Atanasova et al. 2012; Makhdoumi-Kakhki et al. 2012; Liu and Liu 2013; Ntougias 2014; Schneider et al. 2013). Additional information on strains of *Phaeovibrio* is lacking, and the description of the species is the only source of ecological distribution (Lakshmi et al. 2011b). Environmental 16S rRNA sequences related to *Phaeovibrio* genus have not been deposited in the databases. Most closely related sequences are from *Rhodospirillum* (~93 % 16S sequence similarity).

Roseospira species are spiral-shaped purple nonsulfur bacteria which are slightly to moderately halophilic. The main habitat seems to be anoxic sediments in coastal waters such as brackish lagoons and saline springs. *R. navarrensis* was isolated from a microbial mat in Tetiaroa Atoll, Society Islands (Guyoneaud et al. 2002).

The description of the type species of *Rhodospira mediosalina* is the only source of ecological distribution (Pfennig et al. 1997), and information on additional strains of *Rhodospira* is lacking since environmental 16S rRNA sequences related closely to the genus *Rhodospira* have not been deposited in the databases. The available 16S rRNA gene sequences are HE797786 (94.5 % similarity), retrieved from anoxic photosynthetic biofilm from brackish water in France, and AM691104 (94.3 % similarity), retrieved from a hypersaline spring in Canada.

Marispirillum indicum strain B142^T is a marine bacterium isolated after enrichment from crude oil-contaminated seawater (Lai et al. 2009a). At the time of characterization, it showed the highest 16S rRNA gene sequence similarity (97.1 %) with an uncultured proteobacterial clone isolated from subsurface water from the Kalahari Shield in South Africa, but no further data about species distribution is available.

Species of *Novispirillum* and *Insolitispirillum* were isolated from primary oxidation pond water (Pretorius 1963; Hylemon et al. 1973).

The species of the genus *Caenispirillum* have been isolated from aquatic ecosystems; the species *C. bisanense* was isolated from sludge sample collected from the wastewater treatment plant of a dye works at Daegu, Korea, while *C. salinarum* from a sediment sample collected from a solar saltern at Kakinada, Andhra Pradesh, India. Uncultured 16S rRNA clone sequences related to *C. bisanense* K93 have been deposited in the NCBI databases. KF500423 (96 % sequence similarity) was obtained from the shrimp culture pond sediment in India and JF421153 (98 % sequence similarity) from a petroleum-contaminated saline–alkali soil with phytoremediation in China (unpublished).

Thalassospira lucentensis was isolated from offshore seawater samples obtained at 38° 06′87″ N, 0° 05′ 23″ W (21 nautical miles off Alicante, Spain) from a depth of 100 m by means of a Niskin bottle. For its isolation, enrichments in a continuous culture reactor designed to maintain extremely oligotrophic conditions such as those assumed to be found in the open ocean were carried out (López-López et al. 2002). *Thalassospira xiamenensis* M-5^T was isolated from surface water collected from a waste-oil pool at an oil storage dock in the city of Xiamen, Fujian Province, on the eastern coast of China (Liu et al. 2007). This seawater-based waste-oil pool had suffered long-term pollution with crude oil. *Thalassospira profundimaris* WP0211^T was retrieved from a deep-sea sediment sample, which was collected by a multi-core sampler from the West Pacific (region 973, station WP02-3; 147° 58′ 55″ E, 12° 59′ 54″ N; water depth 4,480 m) (Liu et al. 2007). *Thalassospira tepidiphila* 1-1B^T was isolated from petroleum-contaminated seawater in a beach-simulation tank during a bioremediation experiment (Kodama et al. 2008). *Thalassospira xianhensis* P-4^T originated from a saline soil contaminated by crude oil, collected from Xianhe, Shandong Province, China (Zhao et al. 2010). In 2011, Hütz et al. reported that bacteria affiliated with the genus *Thalassospira* were found to constitute a regular, low-abundance member of the bacterioplankton that can be detected throughout the water column of the Eastern Mediterranean Sea. A representative (strain EM) was isolated in pure culture and exposed to a strong positive chemotaxis toward inorganic phosphate that was induced exclusively in phosphate-starved cultures. Although *Thalassospira* sp. represents only up to 1.2 % of the total bacterioplankton community in the water column of the Eastern Mediterranean Sea, its chemotactic behavior potentially leads to an acceleration of nutrient cycling and may also explain the persistence of marine copiotrophs in this extremely nutrient-limited environment (Hütz et al. 2011). The halotolerant bacterium *Thalassospira permensis* SMB34^T was isolated from a naphthalene-utilizing bacterial consortium obtained from primitive technogeneous soil formed on salt-mine spoils at the Verchnekamsk deposit of potassium–magnesium salts (Berezniki, Perm region, Russia); this was located at the place of the ancient Permian sea about 280 Ma ago. In contrast to the majority of organisms of the genus *Thalassospira* which are marine inhabitants, it might be speculated that *Thalassospira permensis* or its ancestor also originally inhabited the ocean and then survived, being trapped within salt crystals, subsequently evolving as a terrestrial bacterium, together with other members of the local microbial community (Plotnikova et al. 2011). Recently, two new species

of marine bacteria were isolated from a piece of sunken bamboo in the marine environment in Japan (Tsubouchi et al. 2014): *Thalassospira alkalitolerans* MBE#61^T and *Thalassospira mesophila* MBE#74^T. These isolations were the result of searching for microbes that show high metabolizing activity against lignin-related compounds; indeed, they metabolize effectively lignin-related aromatic compounds.

For example, *Magnetovibrio blakemorei* strain MV-1 was isolated from sulfide-rich sediments in a salt marsh near Boston, MA (Bazylinski et al. 1988). Like many marine bacteria, strain MV-1 is euryhaline but has a growth requirement for salts, as it will not grow at very low concentrations of ASW or in freshwater media (Kaye and Baross 2004; Bazylinski et al. 2013). Magnetospira type strain "MV-4" (magnetic vibrio number 4) was isolated from a salt marsh in Woods Hole (Meldrum et al. 1993; Williams et al. 2012), but in contrast to their closest characterized magnetotactic relative, *M. blakemorei* and *M. thiophila* can use only a relatively small number of organic acids as carbon and energy sources.

The species *Ferrovibrio denitrificans* is able to use FeS, $FeSO_4$, and $FeCO_3$ as Fe(II) sources for lithotrophic growth and unable to use NO_2, ClO_4^-, S^0, $S_2O_3^{-2}$, and $Fe(OH)_3$ as electron acceptors for anaerobic growth. The incrustation phenomenon, which occurs not only at laboratory conditions but also in the natural habitats, indicates that this is a natural way of living under anaerobic conditions (Sorokina et al. 2012). No environmental 16S rRNA gene sequences resembling the genus *Ferrovibrio* are available yet.

Pathogenicity and Clinical Relevance

Analysis of the species belonging to the family *Rhodospirillaceae* indicates the presence of species that have been detected as opportunistic human pathogens. On the other hand, no plant related pathogenicity has been reported for the genera. Despite the large spectrum of antibiotic resistance among the species, the majority of them are nonpathogenic to human or no information is available.

Opportunistic Human Pathogen

Azospirillum – Recent analyses of 16S rRNA gene sequences and phenotypic characteristics suggested that *R. fauriae* was closely related to *Azospirillum brasilense* (Cohen et al. 2004; Han et al. 2003; Weyant and Whitney 2005). *Roseomonas* species are opportunistic pathogens and have been isolated from a range of human infections including septicemia, occurring primarily in patients with underlying medical conditions (Dé et al. 2004; Struthers et al. 1996). One single report was based on four phenotypically similar bacterial strains isolated from fungal, plant, and human sources that were identified as *Azospirillum* species (Cohen et al. 2004). Strains RC1 and LOD4 were isolated from the mycelium of the apple root pathogen *Rhizoctonia solani* AG 5 and from the rhizosphere of wheat grown in apple orchard soil, respectively. Strains C610 and F4626 isolated from human wounds were previously misclassified as *Roseomonas* genomospecies 3 and 6. All four strains demonstrated close similarities in 16S rRNA gene sequences, having greater than or equal to 97 % identity to *A. brasilense* type strain ATCC 29145 and <90 % identity to *Roseomonas gilardii*, the *Roseomonas* type strain. Authors also report that their results indicate a wide range of potential sources for *Azospirillum* spp. with the isolation of *Azospirillum* spp. from human wounds warranting further investigation. In 2013 another case was described related to *Azospirillum* infection in an immunocompetent middle-aged female manifesting as granulomatous tenosynovitis on the right hand (Serelis et al. 2013). A reclassification of *Roseomonas fauriae* and R. genomospecies 6 into the *A. brasilense* species has been suggested, mostly based on very close 16S rRNA gene similarities (Helsel et al. 2006). A case of peritonitis in a 65-year-old woman with ESRD was published in 2000 (Bibashi et al. 2000). McLean et al. (2006) described a 3-month-old girl suffering from stage III neuroblastoma who had experienced a 2-day history of fever, vomiting, and diarrhea. Blood cultures drawn through her catheter recovered *R. fauriae*. These cases may represent the first reported opportunistic human infections caused by the *Azospirillum*-related bacteria. Hogue et al. (2007) described that the overall mortality rate associated with these pink-pigmented bacteria (similar to *A. brasilense*) is essentially negligible and although a few deaths have been recorded (most notably in association with *Roseomonas*), these bacteria have not been conclusively demonstrated to be involved in the patient's demise. The relatedness of *R. fauriae* and *A. brasilense* is still a matter of debate, and whole genome comparisons are in progress to clarify this issue (A. Hartmann, unpublished results).

Inquilinus – *I. limosus* has been documented mainly in CF patients and was sometimes accompanied with exacerbation or respiratory decline. The pathogenic potential, the impact on respiratory function, and the risk of patient-to-patient transmission of *I. limosus* are still unclear, and the environmental habitat of this bacterium is unknown. It has been isolated in the USA, Germany, France, the UK, and Spain (Pitulle et al. 1999; Coenye et al. 2002; Schmoldt et al. 2006; Cooke et al. 2007; Wellinghausen et al. 2005; Salvador-García et al. 2013). *I. limosus* may represent a new threat to CF patients, as it has a mucoid phenotype (i.e., production of EPS), multiresistance to a wide number of antibiotics, and the ability to persist in the respiratory tract. In agreement with Kuttel et al. (2012), *I. limosus* secretes two uniques exopolysaccharides (EPS), α-(1→2)-linked mannan and β-(1→3)-linked glucan. They demonstrated that the mixture of these two EPS is able to inhibit the lytic action of antimicrobial peptides of the innate immune system and it is possible that the coexistence of the two different secondary structures could enhance this biological activity. Additionally, these EPS form an effective barrier to penetration of chemically reactive biocides, antibiotics, and antimicrobial agents.

Antibiotic Sensitivity

Azospirillum – Wild-type strains of *Azospirillum lipoferum* and *Azospirillum brasilense* were found to be naturally resistant to penicillin, a resistance that was attributed to β-lactamase activity (Franche and Elmerich 1981). Antibiotic resistance is also studied in *Azospirillum*, for example, the β-lactam antibiotics that cause cell envelope stress by inhibiting peptidoglycan biosynthesis, and nalidixic acid that inhibits DNA gyrase activity is present in *A. brasilense*. *Azospirillum lipoferum* RG20 was found to be naturally resistant to penicillins and cephalosporins (Boggio et al. 1989). This strain showed high resistance to benzylpenicillin, ampicillin, carbenicillin, cephalosporin C, cephaloridine, cephalothin, and cefotaxime (MIC 1,000 μg ml^{-1}), whereas it was more susceptible to oxacillin and cloxacillin (MIC = 200 μg ml^{-1}) (Boggio and Roveri 2003). *A. amazonense* strains showed similar resistance to *A. lipoferum* and *A. brasilense* such as penicillin and relative tolerance to chloramphenicol and tetracycline (Magalhães et al. 1983).

Inquilinus – *I. limosus* is sensitive to imipenem, ciprofloxacin, and meropenem, but resistant to aminoglycosides, piperacillin–tazobactam, cefotaxime, ceftazidime, cefepime, aztreonam, kanamycin, gentamicin, amikacin, fosfomycin, doxycycline, and colistin (Bittar et al. 2008; Chiron et al. 2005). This bacterium is multiresistant to several antimicrobial drugs, particularly colistin, which is widely used for treatment for *P. aeruginosa* colonization (as was the case for our four patients). Bittar et al. (2008) hypothesize that this bacterium is selected during the evolution of the disease.

Constrictibacter – According to ATB VET system (bioMérieux), the type strain of the genus is resistant to erythromycin, lincomycin, pristinamycin, tylosin, co-trimoxazole, sulfamethizole, nitrofurantoin, fusidic acid, metronidazole, penicillin, amoxicillin, oxacillin, cephalothin, cefoperazone, chloramphenicol, and tetracycline, but sensitive to colistin, flumequine, oxolinic acid, enrofloxacin, rifampicin, amoxicillin/clavulanic acid, streptomycin, spectinomycin, kanamycin, gentamicin, apramycin, and doxycycline.

Desertibacter–Dongia–Ferrovibrio–Desertibacter roseus is susceptible to erythromycin, vancomycin, streptomycin, acheomycin, and penicillin. *Dongia mobilis* is susceptible to vancomycin, gentamicin, carbenicillin, polymyxin B, streptomycin, kanamycin, ampicillin, neomycin, chloramphenicol, and penicillin and weakly sensitive to tetracycline, erythromycin, novobiocin and rifampicin, while the species *Ferrovibrio denitrificans* is sensitive to amikacin, lincomycin, neomycin, polymyxin, streptomycin, rifampicin, and nalidixic acid. The last species is resistant to ampicillin, bacitracin, vancomycin, gentamicin, kanamycin, mycostatin, novobiocin, penicillin, and tetracycline.

Novispirillum and *Insolitispirillum* – Strains from these species show susceptibility to streptomycin, chloramphenicol, gentamicin, tetracycline, kanamycin, and neomycin, but not to penicillin G, ampicillin, cephalothin, and oleandomycin (Ding and Yokota 2002; Yoon et al. 2007b). In addition, representatives of the genus *Novispirillum* are susceptible to novobiocin, only weakly susceptible to polymyxin B, and resistant to carbenicillin, but each subspecies can be differentiated based on their characteristic lincomycin susceptibility. Both species of the genus *Insolitispirillum* present susceptibility to polymyxin B and carbenicillin.

Marispirillum – *M. indicum* is susceptible to carbenicillin, chloramphenicol, ciprofloxacin, erythromycin, gentamicin, kanamycin, minocycline, neomycin, norfloxacin, ofloxacin, rifampicin, ceftriaxone, streptomycin, and doxycycline and resistant to ampicillin, cefalexin, cefazolin, cefoperazone, cefradine, clindamycin, co-trimoxazole, furazolidone, lincomycin, metronidazole, oxacillin, penicillin G, piperacillin, polymyxin B, tetracycline, and vancomycin (Lai et al. 2009a).

Oceanibaculum – The *Oceanibaculum* species differ from each other according to their characteristic sensitivity or resistance to several antibiotics (Lai et al. 2009b; Dong et al. 2010). The species are resistant to cefalexin, cefazolin, cefradine, clindamycin, erythromycin, furazolidone, lincomycin, metronidazole, norfloxacin, ofloxacin, oxacillin, and vancomycin. *Oceanibaculum indicum* is susceptible to ciprofloxacin, co-trimoxazole, kanamycin, neomycin, polymyxin B, and streptomycin, while *O. pacificum* is susceptible to ampicillin, carbenicillin, chloromycetin, ciprofloxacin, gentamicin, kanamycin, neomycin, penicillin G, polymyxin B, rifampicin, rocephin, streptomycin, tetracycline, and vibramycin.

Limimonas – *L. halophila* is susceptible to nitrofurantoin, novobiocin, and rifampicin, but resistant to amikacin, amoxicillin, bacitracin, carbenicillin, chloramphenicol, erythromycin, gentamicin, kanamycin, polymyxin B, streptomycin, tetracycline, cephalothin, nalidixic acid, tobramycin, and penicillin G (Amoozegar et al. 2013).

Rhodospirillum–Rhodovibrio–Pararhodospirillum – *R. rubrum* is resistant to penicillin, ampicillin, carbenicillin, and nalidixic acid, while it is sensitive to triclosan, chloramphenicol, tetracycline, kanamycin, streptomycin, and gentamicin (Weaver et al. 1975; Pycke et al. 2010), while *Rhodovibrio salinarum* is sensitive to chloramphenicol, tetracycline, kanamycin, streptomycin, rifampicin, and spectinomycin (Borghese et al. 2001). *Rhodovibrio* sp. (isolates GV-2 and GV-3) are sensitive to antimicrobial substances produced by the halophilic archaea *Haloferax* (Atanasova et al. 2013). *Pararhodospirillum photometricum* is sensitive to penicillin (Imhoff 2005b).

Thalassospira – The antibiotic sensitivity varies among the *Thalassospira* species. *T. xiamenensis* is sensitive to chloramphenicol, norfloxacin, furazolidone, co-trimoxazole, ofloxacin, midecamycin, ceftriaxone, polymyxin B, doxycycline, tetracycline, neomycin, kanamycin, gentamicin, amikacin, erythromycin, minocycline, carbenicillin, cefalexin, cefradine, ciprofloxacin, and cefuroxime, but resistant to cefoperazone, clindamycin, vancomycin, ceftazidime, cefazolin, penicillin, oxacillin, ampicillin, and piperacillin (Liu et al. 2007). *T. profundimaris* is sensitive to chloramphenicol, norfloxacin, furazolidone, co-trimoxazole, ofloxacin, midecamycin, ceftriaxone, polymyxin B, doxycycline, tetracycline, neomycin, kanamycin, gentamicin, amikacin, erythromycin, minocycline, carbenicillin, cefalexin, ciprofloxacin, cefoperazone, vancomycin, ceftazidime, cefazolin, penicillin, oxacillin, ampicillin, and piperacillin but

resistant to clindamycin, cefuroxime, and cefradine (Liu et al. 2007). *T. xianhensis* is sensitive to ampicillin, cephalothin, clarithromycin, clindamycin, erythromycin, penicillin, and vancomycin, but resistant to ceftriaxone, cefotaxime, ciprofloxacin, gentamicin, streptomycin, and tetracycline (Zhao et al. 2010). *T. alkalitolerans* is sensitive to kanamycin, gentamicin, chloramphenicol, penicillin G, polymyxin B, and carbenicillin, slightly sensitive to tetracycline, streptomycin, novobiocin, rifampicin, and erythromycin, but resistant to bacteriocin, vancomycin, neomycin, ampicillin, and lincomycin (Tsubouchi et al. 2014). *T. mesophila is* sensitive to kanamycin, neomycin, novobiocin, gentamicin, chloramphenicol, ampicillin, penicillin G, and carbenicillin, slightly sensitive to tetracycline, streptomycin, rifampicin, erythromycin, and polymyxin B, and resistant to bacteriocin, vancomycin, and lincomycin (Tsubouchi et al. 2014).

Thalassobaculum–Tistrella–Tistlia – Thalassobaculum litoreum is sensitive to streptomycin, gentamicin, vancomycin, kanamycin, penicillin, erythromycin, tetracycline, chloramphenicol, ciprofloxacin, and ampicillin (Zhang et al. 2008). *Tistrella bauzanensis* is sensitive to kanamycin, amikacin, rifampicin, and neomycin but resistant to chloramphenicol, tetracycline, and erythromycin (Zhang et al. 2011), while *Tistlia consotensis* is sensitive to ampicillin, streptomycin, chloramphenicol, tetracycline, and penicillin (Díaz-Cárdenas et al. 2010).

Application

The *Rhodospirillaceae* family is formed by bacterial species with very diverse metabolic functions, but so far, only *Azospirillum* species have already been applied as biofertilizer in the agriculture, while other genera have been exploited for industry and environmental application. Many species of other genera have shown biotechnological potential as suggested by the genome sequencing analyses, while others have not been exploited yet.

Agricultural Application

Members of the genus *Azospirillum* are commonly used in the field as biofertilizers and other field tests in many countries such as (alphabetical order): Argentina, Brazil, Colombia, Egypt, France, Israel, Turkey, South Africa, and many others (Okon and Labandera-Gonzalez 1994; Dobbelaere et al. 2001; Turan et al. 2012). Most of these applications are linked to the oldest species described, especially the commercial inoculants based on *A. brasilense* strains. At the beginning, only cereals were tested but recently its application is spread in co-inoculation of rhizobia in legumes such as soybean (Juge et al. 2012), *Vicia sativa* (Star et al. 2012), and beans. Also its single application was extended to other cultures such as lettuce (Fasciglione et al. 2012), cactus (Lopez et al. 2012) trees (Leyva and Bashan 2008), and even in microalgae (Choix et al. 2012).

Species from the *Azospirillum* genus has the capacity to produce several plant growth regulators such as abscisic acid, ethylene, gibberellic acid, indole 3-acetic acid, zeatin (Tien et al. 1979; Bashan et al. 2004), nitric oxide (NO) (Steenhoudt et al. 2001), polyamides (Thuler et al. 2003), and siderophores (Saxena et al. 1986). However, the bacteria also produce a wide variety of these signaling molecules and influence plant growth. *Azospirillum* is a well known bacterium that produces high amounts of auxins "in vitro," and different pathways are involved in this production but not in all species the indole production was determined such as *A. humicireducens* (Zhou et al. 2013). The best characterized pathway in *Azospirillum* auxin production is via indole-3-acetamide (IAM) and indole-3-pyruvate (IPyA) intermediates, both well described by Spaepen et al. (2007) to generate osmotic stress response in plants (Aziz et al. 1997) and solubilize phosphates (Seshadri et al. 2000). Several modifications of plant architecture and physiology of the cells were recorded: increased respiration rates of root cell in plants inoculated with *Azospirillum* such as maize and sorghum (Okon and Kapulnik 1986; Sarig et al. 1992); membrane proton efflux in wheat; increased mineral uptake (Bashan et al. 1989); and hydrolysis of conjugated phytohormones and flavonoids (Volpin et al. 1996). The main effect visually observed after inoculation is the root proliferation. This effect causes enhancement of the root surface activity to the plant that increases mineral nutrients and water (Spaepen et al. 2007). *Azospirillum* can contribute some nitrogen in cellulose-decomposing mixed cultures with Cellulomonas gelida (Halsall and Gibson 1985) or through the ability of straw decomposition by some specific N_2-fixing *Azospirillum* sp. isolates (Halsall et al. 1985). Another feature of *Azospirillum* is related to the accumulation of polybetahydroxyalkanoates (PHA) in the cells. It appears to be an important trait for root colonization and plant growth promotion, especially for A. brasilense inoculants where cells with high amounts of PHA play a better capacity of plant growth in field experiments carried out in South America with maize and wheat. These assays revealed that increased crop yields were consistently obtained using inoculants prepared with PHA-rich *Azospirillum* cells (Dobbelaere et al. 2001; Helman et al. 2011).

In the last years, *Azospirillum* spp. have been applied in consortium with other PGPR bacteria such as *Pseudomonas* in maize (Salamone et al. 2012), other nitrogen-fixing bacteria in sugarcane (Oliveira et al. 2006), or with mycorrhizal fungi (Couillerot et al. 2013). It has also been used as a biocontrol component in cotton inoculation (Marimuthu et al. 2013), or reported its activity in stressed conditions such as drought (Abbasi and Zahedi 2013; Bano et al. 2013) and saline conditions (Nakade 2013).

Two recently reported new species of the genus *Thalassospira*, *T. alkalitolerans* and *T. mesophila*, metabolize effectively lignin-related aromatic compounds, and therefore, their use is expected by the biochemical industries in the degradation of plant biomass (Tsubouchi et al. 2014).

Industrial Application

The species *Rhodospirillum rubrum* provides several potential biotechnological applications for the industry. It produces

polyhydroxyalkanoates (PHAs) composed of both short- and medium-chain-length monomers, and it can produce up to 50 % (dry weight) of the cell in PHAs (Brandl et al. 1989; Liebergesell et al. 1991; Ulmer et al. 1994). Because of its metabolic versatility, R. rubrum offers the potential for converting many different carbon sources to PHA (Do et al. 2007b; Smith et al. 2008). *R. rubrum* also provides the potential for hydrogen fuel production. It may produce H_2 growing photoheterotrophically using, for example, malate as carbon source and electron donor; growing anaerobically using fructose, lactate, acetate, or succinate as carbon source, and dimethyl sulfoxide (DMSO) or trimethylamine-N-oxide (TMAO) as electron donor; or fermenting fructose or pyruvate when an external electron acceptor is absent (Gest and Kamen 1949; Uffen 1973; Schultz and Weaver 1982). *R. rubrum* has been genetically modified in order to increase its capacity to produce hydrogen (Kars and Gündüz 2010); in this way, a Hup plus (uptake hydrogenase) mutant has been generated, and this showed a significant increase in H_2 production (Kern et al. 1994). Through an applied approach, *R. rubrum* has been grown on synthesis gas in order to produce both H_2 and PHA (Do et al. 2007b). *R. rubrum* offers the potential for production of the food additive coenzyme Q10 (CoQ10) and the carotenoid lycopene, which is also a natural colorant (Tiana et al. 2010; Wang et al. 2012). R. rubrum has been used as a heterologous expression system of membrane proteins (Butzin et al. 2010). No data are available for application of neither *Pararhodospirillum* nor *Rhodovibrio* species.

The biologically derived magneto-functional inorganic nanocrystals of magnetite have been used as carriers for enzymes and in immunoassay methods including those involving nucleic acids, antibodies, and targeted delivery of anticancer drugs (Naresh et al. 2012). The process of magnetosome synthesis has been used to develop novel tools for ligand–receptor interaction analysis, such as those applied for TRAb immunoassay in Graves' disease patients (Sugamata et al. 2013).

Ghosh et al. (2012) reported on lactose hydrolysis of milk by crude enzyme extracted from deep marine psychrophilic strain *Thalassospira* sp. 3SC-21. They showed that 80.18 % of lactose was hydrolyzed after 43 min of incubation at 20 °C, within a pH range of 6.5–7.5. This activity was also observed at 10 °C (65 %), indicating that this enzyme is useful at refrigerated temperature. From these findings, they conclude that *Thalassospira* sp. 3SC-21 is a source for the production of cold active β-galactosidase enzyme that can be applicable at cold temperature and might be considered in food industry including dairy industry on a larger scale.

Tistrella mobilis and *Tistrella bauzanensis* produce didemnins (antineoplastic agents) via unique post-assembly line maturation process (Xu et al. 2012). Complete genome sequence analysis of *T. mobilis* strain KA081020-065 revealed the putative didemnin biosynthetic gene cluster (*did*) on the megaplasmid pTM3. The *did* locus encodes a 13-module hybrid non-ribosomal peptide synthetase–polyketide synthase enzyme complex organized in a collinear arrangement for the synthesis of the fatty acylglutamine ester derivatives didemnins X and Y rather than didemnin B. Imaging mass spectrometry of *T. mobilis* bacterial colonies captured the time-dependent extracellular conversion of the didemnin X and Y precursors to didemnin B, in support of an unusual post-synthetase activation mechanism. Significantly, the discovery of the didemnin biosynthetic gene cluster may provide a long-term solution to the supply problem that presently hinders this group of natural products and pave the way for the genetic engineering of new didemnin congeners.

The bacterium *Tistlia consotensis*, isolated from a saline spring in the Colombian Andes, represents an interesting environmental model to be compared with extremophiles or other moderate organisms (Díaz-Cárdenas et al. 2010). To explore the halotolerance molecular mechanisms of the *T. consotensis*, through a proteogenomic approach, a large number of proteins were found to be produced in greater amounts when cells were cultivated in either hypo-osmotic or hyper-osmotic conditions (Rubiano-Labrador et al. 2014).

Other genera present biotechnological potential such as the *Phaeospirillum* species that have the photosynthetic apparatus of phototrophic bacteria (e.g., Mascle-Allemand et al. 2010) and evolutionary importance due its high amount of genes related to signal transduction (Duquesne et al. 2012). The close phylogenetic relationship of *Rhodocista centenaria* and *Rhodocista pekingensis* to *Azospirillum irakense/Azospirillum amazonense* also indicates scientific importance to this genus due to cyst-forming ability (Lu et al. 2010).

Environmental Application

New features are arising on the environmental application for the genus *Azospirillum*. *A. brasilense* strains Sp 7 and Sp245 are able to reduce selenium (IV) to elementary selenium (Tugarova et al. 2013), while *A. thiophilum* has the capacity for lithotrophic growth coupled oxidation for reduced sulfur compounds (Frolov et al. 2013).

Defluvicoccus vanus has been identified as glycogen-accumulating organisms (GAOs) (Meyer et al. 2006; Burow et al. 2007). According to Burow et al. (2007), the activity of glycogen-accumulating organisms (GAOs) in enhanced biological phosphorus removal (EBPR) wastewater treatment plants has been proposed as one cause of deterioration of EBPR. GAOs possess the ability to take up volatile fatty acids (VFA) under anaerobic conditions and convert them to polyhydroxyalkanoates (PHA), which are stored until the following aerobic period and then oxidized to CO_2 or transformed to glycogen.

Magnetotaxis and magnetosome productions are special traits shared by some magnetotactic and magnetosome bacteria that have been extensively employed for the development of new technology in the nanotechnology field. Besides the important role of nanobiotechnology to medicine, its application has already become a matter of study into many other applied sciences, such as environmental engineering and agricultural science. Ginet et al. (2011) demonstrated that functionalized magnetic nanoparticles efficient as a reusable nanobiocatalyst

for pesticide bioremediation in contaminated effluents can be produced by genetically modified magnetotactic bacteria.

The strains *Thalassospira xiamenensis* M-5^T and *Thalassospira profundimaris* WP0211^T were isolated separately from bacterial consortia that used hydrocarbons as their sole carbon sources; neither strain could degrade any of the hydrocarbons tested in their characterization tests (Liu et al. 2007). However, the analysis of 16S rRNA gene sequences obtained from various samples from marine environments has revealed that these two species and their close relatives were frequently detected in petrol-oil-degrading consortia. This suggests they may play some role in the degradation of petroleum hydrocarbons (Liu et al. 2007). However, no further study was done.

The strain T. profundimaris WP0211^T cannot use pyrene as the sole carbon source for growth, though it was isolated from a pyrene-degrading consortium. Its genome sequence analysis revealed a gene encoding a ring hydroxylating dioxygenase and therefore supports further characterization (Lai and Shao 2012b).

Thalassospira tepidiphila is considered to play important roles in marine spilled-oil bioremediation (Kodama et al. 2008). Polycyclic aromatic hydrocarbons (PAHs), hydrocarbons containing two or more fused aromatic rings, are released into the marine environment as a result of various anthropogenic activities such as marine seepage and accidental discharges during the transport and disposal of petroleum products and the use of fossil fuels (Sohn et al. 2004). Some PAHs are highly carcinogenic, genotoxic, and cytotoxic to marine organisms and may be transferred to humans through seafood consumption (Menzie et al. 1992). Therefore, removal of PAHs from contaminated marine environments is of considerable importance, hence the importance of isolating PAH-degrading bacteria such as *Thalassospira xianhensis* (Zhao et al. 2010). Recently, Um et al. (2013) reported that chemical investigation on the marine unicellular bacterium *Thalassospira* sp. led to the discovery of a new peptide, thalassospiramide G, along with thalassospiramides A and D. The peptides are structurally unique, with unusual γ-amino acids, such as 4-amino-5-hydroxy-penta-2-enoic acid (AHPEA) and 4-amino-3,5-dihydroxy-pentanoic acid (ADPA). In addition, thalassospiramide G bears a 2-amino-1-(1*H*-indol-3-yl) ethanone (AIEN) moiety, which is quite rare in a natural product. In the LPS-induced NO production assay, thalassospiramide D displayed more significant inhibition of NO production than thalassospiramide A, indicating its potential as an anti-inflammatory agent. The structural novelty and the biological activity of the secondary metabolites isolated from this marine α-proteobacterial taxonomic group suggest that marine unicellular bacteria, particularly α-proteobacteria, which have been overlooked in the search for new bioactive compounds, could potentially provide a rich source of chemically and pharmaceutically interesting natural products (Um et al. 2013).

Tistrella mobilis IAM 14872^T produces polyhydroxyalkanoates (PHAs) as intracellular granules (Shi et al. 2002). PHA is a biodegradable, biocompatible, and thermoplastic material, which has a potential role as a so-called biomass transducer, i.e., it can be used for the microbial transformation of carbohydrate feedstock via PHA into chiral depolymerization products (Seebach and Zuger 1984) or small-molecule organic chemicals by pyrolysis (Anderson and Dawes 1990). So far, these biodegradable PHAs, however, are not priced competitively mainly because of the high cost, which lies in both the use of glucose as a fermentation feedstock and the low product yield.

Tistrella sp. strain ZP5, isolated from soil samples contaminated with polycyclic aromatic hydrocarbon (PAH)-containing waste (Zhao et al. 2008), cannot degrade phenanthrene individually, but it can increase the speed of phenanthrene degradation together with *Sphingomonas* sp. ZP1. Such two strains may be useful for bioremediation applications.

Acknowledgements

The support of INCT-FBN, CNPq, FAPERJ, as well as EMBRAPA Agrobiologia and Helmholtz Zentrum München is greatly acknowledged. The chapter was prepared with contributions from all of the authors and they contributed equally.

[2]Departmento de Parasitologia, Universidade Federal Rural do Rio de Janeiro (UFRRJ), Seropédica, RJ, Brazil

Abstract
The *Rickettsiaceae* family is composed of two genera, *Rickettsia* and *Orientia*, which are obligate intracellular bacteria that belong to the order *Rickettsiales*. The species of these genera are divided into two groups based on antigenic, molecular, and ecological patterns: (1) the typhus group, composed of the species *Rickettsia prowazekii, Rickettsia typhi*, and *Orientia tsutsugamushi*, which are transmitted by lice, fleas, and mites, respectively; and (2) the spotted fever group (SFG), which is composed of more than 23 valid species. The transmission of great majority of species in SFG is associated with ticks, with the exception of *Rickettsia felis* and *Rickettsia akari*, which are associated with fleas and mites, respectively. Other *Rickettsia* species, such as *Rickettsia bellii* and *Rickettsia canadensis*, are not included in either of the two groups. In SFG, at least 12 species of *Rickettsia* cause infections in humans (*Rickettsia rickettsii, Rickettsia conorii, Rickettsia africae, Rickettsia parkeri, Rickettsia australis, Rickettsia honei, Rickettsia sibirica, Rickettsia japonica, Rickettsia massiliae, Rickettsia aeschlimannii, R. akari*, and *R. felis*). However, species of nonpathogenic rickettsiae or of unknown pathogenicity might have a key role in the natural history of the pathogenic species; ticks infected by a kind of rickettsia that is nonpathogenic to humans (e.g.: *Rickettsia montana, Rickettsia peacockii*) may become unable to maintain (via transovarial transmission) infection by other pathogenic species (e.g., *R. rickettsii*). This fact is of great practical importance because there are populations of ticks infected with nonpathogenic rickettsiae for which the infection rate is often higher compared to pathogenic rickettsiae.

Taxonomy, Historical and Current

Short Description of the Family and Their Genera

Rickettsiaceae (Pinkerton, 1936)

Members of this family are Gram-negative bacteria that grow only inside living cells and therefore are characterized as obligate intracellular parasites. They have high polymorphism and reside in the cytoplasm or nucleus in the host, where they divide by binary fission (Raoult and Roux 1997). They are classified as α-proteobacteria and belong to the order *Rickettsiales*. Within the *Rickettsiaceae* family, they currently have two genera: *Rickettsia* and *Orientia*, following Dumler et al. (2001). Based on their 16S rRNA and *groEL* genes, *Rickettsia* and *Orientia* represent very closely related evolutions of microorganisms in *Alphaproteobacteria* (Lee et al. 2003, Batra and Bakshi 2011).

The organisms identified as *Rickettsia* can be divided in two main groups by phylogenetic characteristics and clinical characteristics of disease: the typhus group (TG), composed of *Rickettsia typhi* and *Rickettsia prowazekii*, and the spotted fever group (SFG). SFG consists of more than 25 species, including *Rickettsia rickettsii* and *Rickettsia parkeri* in the American continent, *Rickettsia conorii* and *Rickettsia africae* in Europe and Africa, and *Rickettsia japonica* and *Rickettsia israeli* in Asia and the Middle East. However, new studies have shown that some species showed marked phenotypic differences and proposed two groups: the ancestral group (AG) composed of *Rickettsia bellii* and *Rickettsia canadensis* (of unknown pathogenicity in humans), and the transitional group (TRG), consisting of *Rickettsia akari*, *Rickettsia australis*, and *Rickettsia felis* (Gillespie et al. 2007). This newly proposed organization of rickettsial species was heavily based on a comparison of major conserved gene sequences (e.g. *ompB*, *gltA*) within the genus. In addition, because the best intrinsic aspects of bacterial growth temperature have a G + C content related to the genome of the bacterium, the ability to polymerize actin in the host cell (Heinzen et al. 1993; Teysseire et al. 1992), the cross-reaction of sera from a patient with rickettsial infection, the distribution of strains, and hemolytic activity are used to differentiate between different rickettsiae groups (Fournier and Raoult 2007).

The genus *Orientia* is classified in a single group, the scrub typhus group, represented by the species *O. tsutsugamuchi*.

E. Rosenberg et al. (eds.), *The Prokaryotes – Alphaproteobacteria and Betaproteobacteria*, DOI 10.1007/978-3-642-30197-1_263,

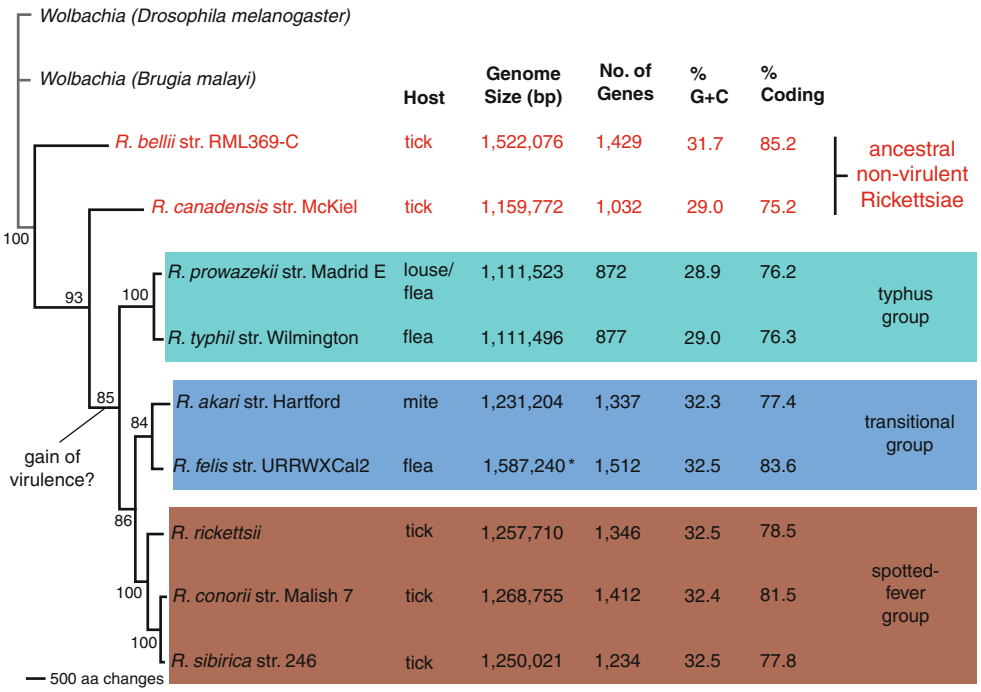

Fig. 23.1
Phylogeny estimation describing the four groups of the *Rickettsiaceae* family (Gillespie et al. 2007)

This organism was given its own genus designation because it is phylogenetically distinct from the other rickettsiae (Tamura et al. 1995).

This group of diseases affects humans through parasitism by blood-sucking arthropods, including ticks, fleas, lice, and mites (Hoogstraal 1967; Friedhoff 1990). These microorganisms thrive in nucleated cells from vertebrate and invertebrate, preferably a vertebrate host and endothelial cells (Weiss and Moulder 1984), and invertebrates, intestinal cells, salivary glands, and ovaries (Parola et al. 2005).

Regarding rickettsiosis, the genus *Rickettsia* is the most important due to the clinical and epidemiological aspects associated with human infections. The distribution of rickettsiae around the world is directly linked to their arthropod vectors, which includes a variety of species, described in regions of different countries from all continents (Parola et al. 2005).

Phylogenetic Structure of the Family and Its Genera

Previously, the original classification and phylogenic arrangement of the genus *Rickettsia* was determined by serological studies. The genus was subdivided into the conventionally well-defined TG and SFG, based mainly on phenotypic and serological features (Vitorino et al. 2007). Since the original organization, conserved genera-specific genes have been sequenced, compared among available *Rickettsia* species, and used to construct phylogenies based upon gene differences and their likely evolution (Reif 2009).

Many types of studies are realized throughout analysis of phylogenetic relation. According to the endosymbiont hypothesis, the mitochondria may be derived from an ancestral Alphaproteobacterium. Phylogenetic studies indicate that the mitochondrial ancestor is most closely related to the *Rickettsiales* (Brindefalk et al. 2011; Andersson et al. 1998). The most ancestral species of the genus appear to be *Rickettsia bellii* and *Rickettsia canadensis* (Stothard et al. 1994); because of their characteristics, these species have been recognized as belonging to ancestral group of *Rickettsiaceae*.

A reorganization of *Rickettsia* species within the genus *Rickettsia* has been proposed, based on phylogenetic analysis of a number of conserved genus-specific genes and the presence of a plasmid in *R. felis* (Gillespie et al. 2007). In this new arrangement, rickettsiae are organized into one of four groups: the ancestral group (AG; e.g. *R. bellii* and *R. canadensis*), the typhus group (TG; e.g. *Rickettsia typhi* and *Rickettsia prowazekii*), the transitional group (TRG; e.g. *Rickettsia felis* and *Rickettsia akari*), and the spotted-fever group (SFG; e.g. *Rickettsia rickettsii*, *Rickettsia sibirica*) (*Fig. 23.1*).

On account of phylogenetic studies based on the sequence of the 16S rRNA gene of members of the family *Rickettsiaceae*, it was initially observed that *Rickettsia tsutsugamushi*, the agent of scrub typhus, was found to be distinct enough by 16S rRNA gene sequence comparison to warrant transfer into the genus *Orientia*, which includes a single species, *Orientia tsutsugamushi* (Tamura et al. 1995) (*Fig. 23.2*). In addition, polymerase chain reaction (PCR) coupled with restriction fragment length polymorphism (RFLP) applied to the *gltA* and *ompA* genes showed

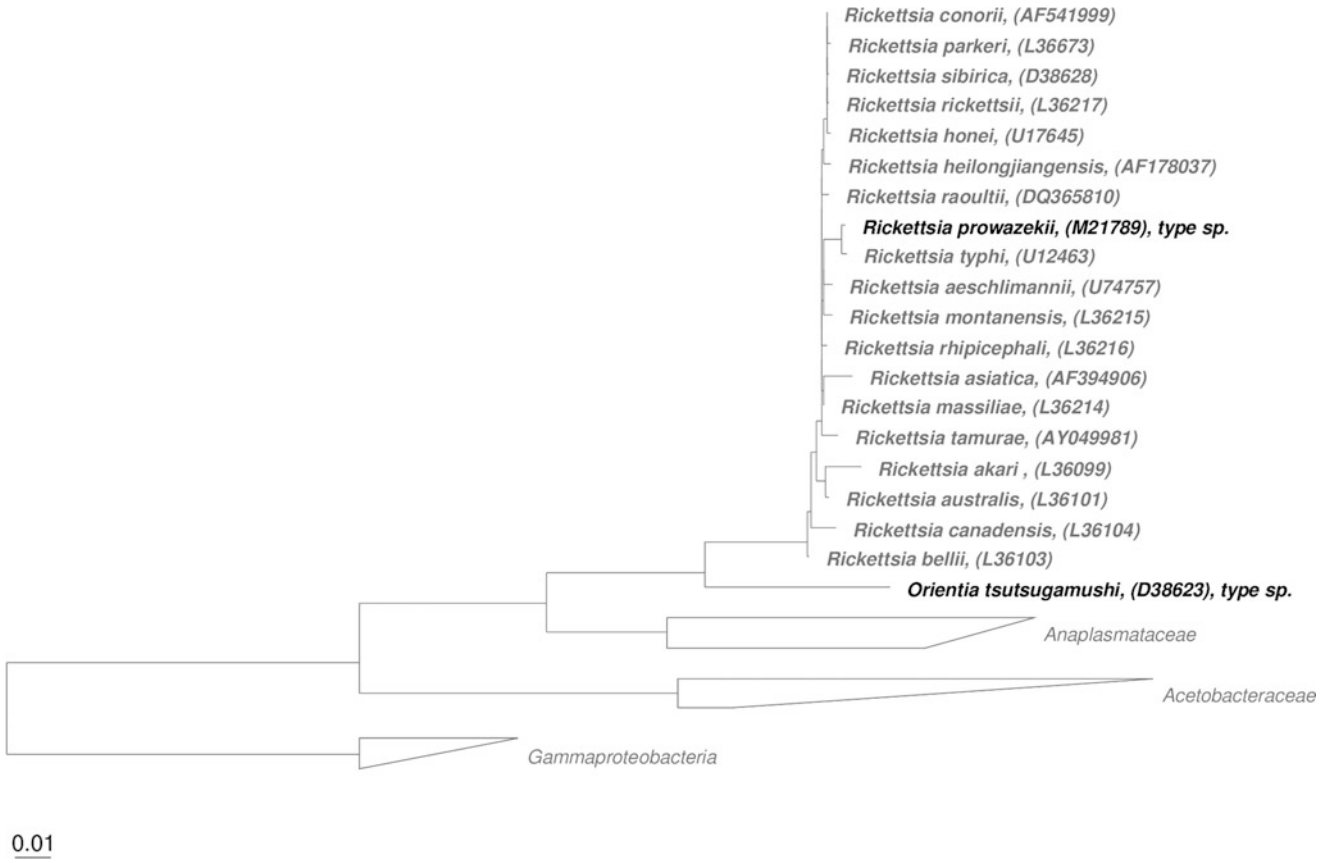

Fig. 23.2

Phylogenetic relationships of the organisms belonging to the *Rickettsiaceae* family in relation to the *Anaplasmataceae* family and others classes beyond *Alphaproteobacteria*, based on DNA sequences. The GenBank numbers are provided to the *right* of the species names

that *R. canadensis* and *R. bellii* occupied an intermediate position between the typhus and SFGs (*Table 23.1*).

- Phylogenetic reconstruction of the family *Rickettsiaceae* based on 16S rRNA and created using the maximum likelihood algorithm RAxML (Stamatakis 2006). The sequence dataset and alignment were used according to the All-Species Living Tree Project (LTP) database (Yarza et al. 2010; http://www.arb-silva.de/projects/living-tree). Representative sequences from closely related taxa were used as outgroups. In addition, a 40% maximum frequency filter was applied in order to remove hypervariable positions and potentially misplaced bases from the alignment. Scale bar indicates estimated sequence divergence.

In the *Rickettsiales* order are the *Anaplasmataceae* and *Rickettsiaceae* families, which are the most commonly studied. However, the *Holosporaceae* family was recently described by Görtz and Schmidt (2005); entered in that order were two new families, *Pelagibacteraceae* (Thrash et al. 2011) and *Midichloriaceae* (Montagna et al. 2013) (*Fig. 23.3*). According to Montagna et al. (2013), phylogenetic studies provided evidence for the deep branching of a lineage of the *Rickettsiaceae* that infects aquatic protista (Vaninni et al. 2005). Considering that current evidence, this places the family of ciliate-infecting bacteria *Holosporaceae* as the sister group of the lineage leading to *Rickettsiaceae*, *Anaplasmataceae*, and *Midichloriaceae*. There is evidence indicating that intracellular *Rickettsiales* were originally associated with aquatic/environmental protista that served (and potentially still serve) as an ecological and evolutionary reservoir for *Rickettsiales*-infecting animals (Montagna et al. 2013), based on phylogenetic studies.

Molecular Analyses

According to the genome project database of the National Center for Biotechnology Information (http://www.ncbi.nlm.nih.gov/genomes/lproks.cgi), 21 genomes of *Rickettsia* and one of *Orientia* species have been sequenced completely: *Rickettsia prowazekii* str. Breinl, *R. typhi* str. B9991CWPP, *R. conori* str. Malish 7, *R. rickettsii* str. Brazil, *R. parkeri* str. Portsmouth, *R. felis* URRWXCal2, *R. akari* str. Table 23.1
Brief description of the set of commonly sequenced genes used for phylogenetic studies in the *Rickettsiaceae* family

Gene	Characteristic of the gene	References
Citrate synthase gene (*gltA*)	The citrate synthase gene is one of the most common genes used to differentiate *Rickettsia* species from other bacterial species.	Bouyer et al. 2001, Regnery et al. 1991
16S rRNA gene	The 16S rRNA gene has stability as a housekeeping gene, which makes it less affected by host immune responses and other environmental stresses.	Reif 2009, Higgins et al. 1996
17-kDa protein gene (*htrA*)	The 17-kDa common antigen gene (*htrA*): The 17-kDa antigen found in all species of *Rickettsia* is an immunologically important surface protein and is one of the most characterized loci in any rickettsial genome. Only bacteria in the genus *Rickettsia* are known to possess the 17-kDa antigen gene; areas of divergence present in this gene between rickettsial species aided in the formation of the SFG and TG.	Anderson et al. 1987, 1988, Anderson and Tzianabos 1989, Tzianabos et al. 1989
OmpA protein gene (*ompA*)	The 190-kDa outer membrane antigen protein gene (*ompA*) is the major gene that defines the SFG. The immunodominant OmpA protein is believed to have a critical role in SFG rickettsial pathogenesis (e.g. cell adhesion and invasion) (Li and Walker 1998; Crocquet-Valdes et al. 2001). Antigenic variation in the conserved regions of this gene that flank tandemly repeated sequences are useful in differentiating *Rickettsia* species and strains within the SFG.	Regnery et al. 1991, Gilmore 1993, Zavala-Castro et al. 2005
OmpB protein gene (*OmpB)*	The 120-kDa protein outer-membrane protein B.	Eremeeva et al. 1994, Roux and Raoult 2000
groEL genes	The *groEL* genes, which encode the 60-kDa heat shock protein GroEL, are ubiquitous in both prokaryotes and eukaryotes and encode highly conserved housekeeping proteins that are essential for the survival of these cells. The *groEL* genes provide the defining evolutionary relationships among the members of the eubacterial lineage. *groEL* gene analysis is useful for the differentiation of STG strains and strains of the genus *Rickettsia.*	Lee et al. 2003
Gene D (*SCA4*)	'Gene D' is the PS120-protein-encoding gene, first described in *Rickettsia conorii* and *Rickettsia japonica.* 'Gene D' is considered as a complementary approach in phylogenetic studies of rickettsiae because it presents significant bootstrap values to the most of the nodes.	Sekeyova et al. 2001

different species belonging to a single genus enables comparative genomics to identify differences and commonalities among them.

The size, architecture, and composition of bacterial genomes vary incredibly. A common characteristic of bacteria of the family *Rickettsiaceae* is the small genome, ranging from 1.11 (*Rickettsia* sp.) to 2.13 Mb (*Orientia tsutsugamuschi*) (*Table 23.1*). One factor that clearly contributes to the genome reduction is the habitat. The genome reduction is probably related to adaptations to a parasitic and pathogenic lifestyle, in which certain functions are no longer required (Moran 1996), resulting in total dependence on host cells. In a study on the evolution of the *Rickettsiales*, it was demonstrated that evolution from a free-living lifestyle to an obligate intracellular one was associated with the loss of 2,135 genes (Georgiades et al. 2011a). Furthermore, the 12 deadliest epidemic species for humankind have significantly smaller genomes, with fewer open reading frames (ORFs), than less dangerous species (Georgiades et al. 2011b). One of the best examples of genomic reduction of epidemic bacteria is *R. prowazekii*, the agent of epidemic typhus. No virulence genes have been identified in its genome, and 24 % of its small genome is composed of pseudogenes and non-coding DNA (Andersson et al. 1998; Bechah et al. 2010). In fact, the genome of *R. prowazekii* (834 ORFs) represents a subset of *R. conorii* (1374 ORFs); it possesses almost no genes that are not present in *R. conorii*, with the exception of four TG-specific genes that also are present in *R. typhi* (RP624, RP338, RP164 and RP174) and absent from, or split in, other rickettsiae (Gillespie et al. 2008; Ammerman et al. 2009).

In *Listeria monocytogenes* and *Shigella* (Goldberg and Theriot 1995; Moliner et al. 2010), intracellular motility is considered a virulence factor. In *R. prowazekii*, this characteristic was not observed because the bacteria have no motility within cytoplasm (Andersson et al. 1998). In a study of comparative genomics between *R. rickettsii* and *R. africae*, pathogenicity development was associated with the loss of essential genes (Fournier et al. 2009). Studies of rickettsial genomics challenge traditional concepts of pathogenesis, which were based principally on the acquisition of virulence factors.

Another intriguing phenomenon about the reduced rickettsial genomes concerns the large fraction of non-coding DNA and

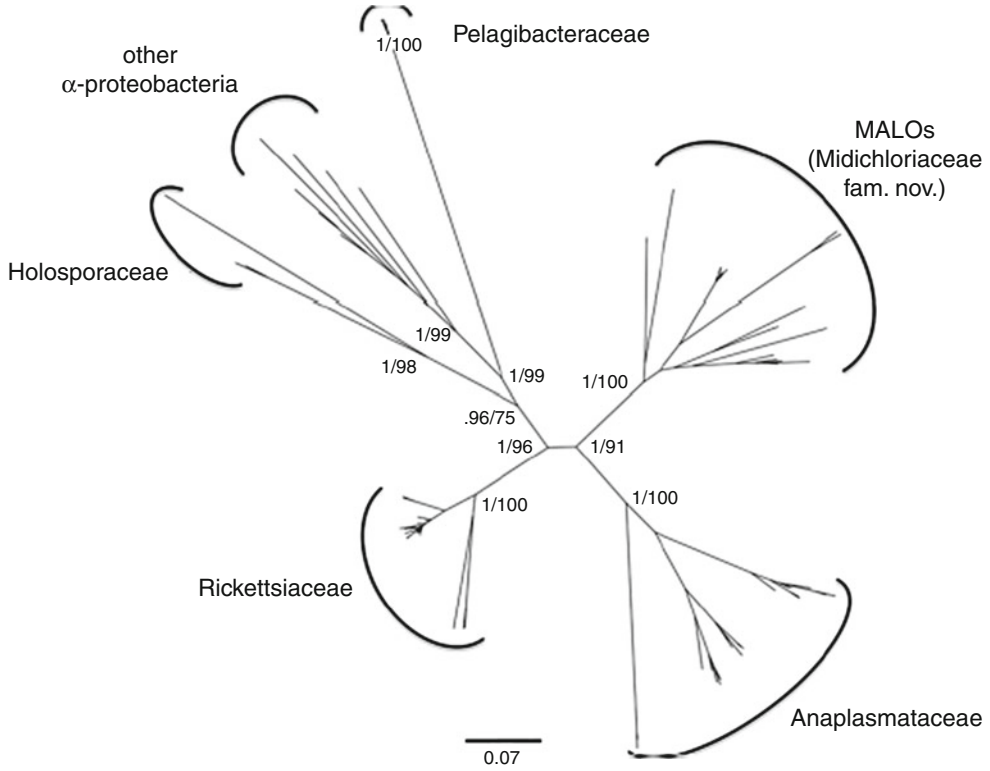

Fig. 23.3

An unrooted Bayesian phylogram of the *Rickettsiales* based on the 16S rRNA gene sequence. Bayesian posterior probability and ML (Maximum Likelihood) bootstrap values are reported for the main lineages (Montagna et al. 2013)

possible functionality of these "non-coding" sequences because of the high conservation of these regions. "Pathogenicity islands" (a set of genes coding for virulence traits) are present in many bacteria; however, they are not present in species of *Rickettsia* spp. vertebrate-pathogenic (Hacker and Kaper 2000). In many studies, the presence of plasmids in *Rickettsia* species does not appear to be directly associated with pathogenicity (Fournier et al. 2009; Ogata et al. 2005). However, it has been suggested that the genes encoding the proteins responsible for recognition, invasion, and pathogenicity are located in plasmids of some *Rickettsia* spp. species. The acquisition of new genes does not necessarily imply pathogenicity change, as has been shown in several studies on comparative genomics of *Rickettsia* sp. Furthermore, the emergence of virulent traits has occurred with the loss of gene function. In *Shigella* spp. and *Yersinia* spp., such events may provide a selective advantage, as noted by a series of genetic events that contribute to the emergence of virulence (Maurelli et al. 1998; Sun et al. 2008).

Compared with other bacteria species with sequenced genomes, the percentage of non-coding DNA in *Rickettsia* species not decreased, suggesting that the reduction of the genome is associated with the loss of genes (Rogozin et al. 2002). Genome analysis of various rickettsial genomes shows that the genome reduction process described for alpha-proteobacteria (Boussau et al. 2004) has occurred independently in different rickettsial lineages, leading to the existing species assemblage (Blanc et al. 2007b).

The changes in genome size may occur by gene duplication and the emergence of new sequences. In rickettsia, genomes have been found with repeating elements without defined cellular function (Ogata et al. 2000). In bacterial genomes, repeated elements are located in intergenic regions (Van Belkum et al. 1998). In some of these, variable numbers of tandem repeats (VNTR) represent an interindividual variability in the sequence length; some have been used for genetic typing (Eremeeva et al. 2006; Fournier et al. 2004).

In *Rickettsia* spp., elements palindromic repeat (EPR) of approximately 100–150 bp were found. These repetitions can invade coding and non-coding regions of the genome (Amiri et al. 2002; Claverie and Ogata 2003; Ogata et al. 2000). When inserted within genes encoding proteins, these repeats generated a new reading frame as a part of a preexisting gene. Therefore, the final gene product has an additional peptide segment (30–50 amino acids). Over evolutionary time, multiple random insertions of such elements within genes, followed by selection on the resulting peptide sequences within the context of different host proteins, may have contributed to the emergence of new protein sequences, domains, and functions. Thus, EPR enhance sequence diversity in coding regions of *Rickettsia* spp.

Mobile elements have been identified in the rickettsia genome by genome comparative studies. These elements mediate the DNA movement within and between genomes, by means of transposable elements, plasmids, bacteriophages, and genes associated with horizontal mobility. These mobile elements

Source: http://www.ncbi.nlm.nih.gov/genome/?term=Rickettsia

constitute "the mobilome" (Frost et al. 2005; Koonin and Wolf 2008). Some *Rickettsia* spp. contain transposases (Blanc et al. 2007a; Ogata et al. 2005), phage-related genes (Andersson et al. 1998; McLeod et al. 2004; Ogata et al. 2001, 2005, 2006), plasmids (Baldridge et al. 2007, 2008; Fournier et al. 2008; Ogata et al. 2005), and an apparatus for conjugation (*tra* genes) (Blanc et al. 2007a; Fournier et al. 2008; Ogata et al. 2005, 2006). In intracellular bacteria, the lateral gene transfer (LGT) phenomenon has long been considered rare (Audic et al. 2007); in rickettsiae, the discovery of the mobilome is possible. Ogata et al. (2006) described various mechanisms in rickettsial genomes for the influx of foreign DNA sequences. Further analysis of the rickettsial genome can identify candidates for LGT between *Rickettsiae* species.

The transfer of genes between chromosomes and plasmids was observed after analysis of *R. felis* genome. Eleven genes

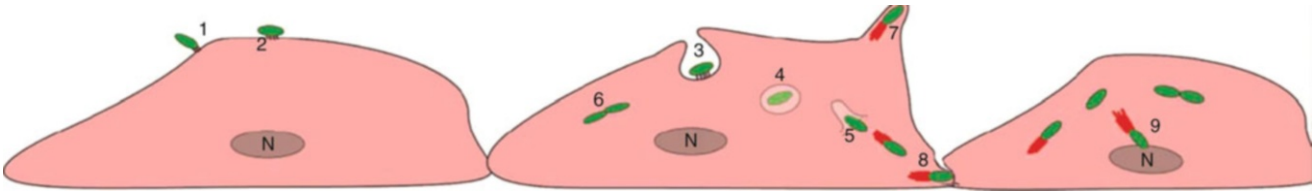

Fig. 23.4

Spotted fever group rickettsia–endothelial cell interaction. (*1*) Adhesion of bacteria to the cell membrane via adhesins; (*2*) Recruitment of more receptors; (*3*) Engulfment of the bacteria by cell extensions; (*4*) Inclusion of bacteria in phagocytic vacuoles; (*5*) Rickettsial enzymes lyse vacuolar membrane; (*6*) Replication by binary fission; (*7*) Host actin-based mobility; (*8*) Cell-to-cell spread; and (*9*) Invagination into the endothelial cell nucleus (*N*) (Walker 2007)

located on plasmid PRF exhibiting homologous chromosome of *R. felis* were observed. These two genes encoded heat shock proteins, thymidylate kinase, and patatin-like phospholipase transposase seven. All sequenced *Rickettsia* genomes exhibit patatin-like phospholipase-coded chromosome (pat1). In plasmid PRF, *R. felis* has a paralog additional pat2. Phylogenetic reconstruction among species of *Rickettsia* shows a close relationship for pat1 of *R. felis* and *R. Akari* pat2 with *R. felis*. This provides a clear case of transfer of genes from plasmid to chromosome; the chromosome was replaced by pat1 pat2 plasmid-encoded in the lineage, leading to the ancestor of *R. felis* and *R. akari* (Ogata et al. 2005).

The development of technologies for large-scale genome sequencing may modify the way we view microbiology, thus starting a postgenomic era in which the development of computational tools for the analysis of biological data is a priority. The genome comparative analysis of the family *Rickettsiaceae* with other bacteria has provided information about the bacteria-host relationship, pathogenicity, and evolutionary history. The ultimate understanding of the molecular mechanisms related to adaptation to different conditions requires the application of global approaches, including differential transcriptome analysis using platforms such as HiSeq 2000 (Illumina). Such a methodology has not yet been extensively applied for *Rickettsiaceae*, but we believe that experimental progress will make the technology more accessible in a few years. A better knowledge of a microorganism can also be gained by proteomic analysis.

Phenotypic Analyses

All the microorganisms of *Riackettsiaceae* are similar in the following aspects: they are obligate intracellular parasites, morphologically similar to gram-negative bacteria, and survive in vertebrates and arthropod hosts. When human infection occurs, this is mediated by arthropod vectors.

Bacteria of the genus *Rickettsia* and *Orientia* are small rods. *Rickettsia* measure 0.3–0.5 μm^2 in length and 0.8–2.0 μm^2 in width, whereas *Orientia* measure 0.5–0.8 μm^2 in length and 1.2–3 μm^2 in width, respectively. Generally, SFG members have an optimal growth temperature of 32 °C, whereas TG members have an optimum growth temperature of 35 °C. SFG members have 32–33 % GC content and TG members have nearly 29 % GC. In addition, only SFG members can enter the nucleus of parasitized cells (Heinzen et al. 1993; Teysseire et al. 1992).

Pathogenic *Rickettsiaceae* do not have flagella, although *Rickettsiae* of the SFG members move by a peculiar mechanism. They use the host cell actin to form a tail and move freely in the cytoplasm of the cell; however, this mechanism only occurs after escaping the phagocytic vacuole. The scientists suppose that the polymerization of actin and the tail formation play a fundamental role in the invasion movement from cell to cell in host infection; this could explain why *Rickettsiae* spreads rapidly in host organisms (Heinzen et al. 1993, 1999; Gouin et al. 1999) (*Fig. 23.4*). Concerning the polymerization of actin in the host cell, SFG members are capable and TG members are not capable.

The membrane structure of *Rickettsiaceae* is similar to those observed in gram-negative bacteria, in general. It has a trilamellar structure, as follows: a lipopolysaccharide outer membrane and inner membrane composed of a phospholipid bilayer, separated by a peptidoglycan layer in a periplasmic space. Furthermore, SFG members are surrounded by an electron-lucent slime layer when they are infecting a host cell (Raoult and Parola 2007; Quinn et al. 2011). One exception is *O. tsutsugamushi*, which lacks muramic acid, glucosamine, heptose, 3-deoxy D-mannooctulosonic acid (KDO), and hydroxy fatty acids—the basic components of peptidoglycan and LPS, so it is deficient of both in the cell wall (Amano et al. 1987). This fact explains why *O. tsutsugamushi* is resistant to beta-lactam antibiotics (Miyamura et al. 1989).

The major antigens of *Rickettsiae* are lipopolysaccharides, lipoproteins, outer membrane proteins of the surface cell antigen (SCA) family, and heat shock proteins. Other antigens have been characterized in *Rickettsiae* species, including a 17-kDa lipoprotein and members of the autotransporter protein family SCA, which includes the 120 kDa protein S-layer (OmpB or SCA5), OmpA (present only in SFG *Rickettsiae*), and Sca4 (Anderson et al. 1990; Blanc et al. 2005; Fournier et al. 1998b).

With light microscopy, the majority of *Rickettsiaceae* stains well with Giménez, Macchiavello, and Giemsa stains. *Rickettsia akari* does not stain with Giemsa or eosin-azure-based techniques, just with Macchiavelo, Giménez, and carbol basic fuchsin (Giménez 1964). In addition, *O. tsutsugamushi* does not stain with Macchiavello, and a modification of the Gimenez stain is

required (Timoney et al. 1992). Concerning microscopy fluorescence, it is possible to use acridine orange stain in cell culture or smears. Also, materials such as host tissue stains could be evaluated by immunohistochemistry or fluorescein-conjugated polyclonal antibodies (Raoult and Parola 2007).

Due to the strictly intracellular nature of *Rickettsiaceae*, traditional identification methods used in bacteriology cannot be applied. It must be cultivated in tissue culture or the yolk sac of developing chicken embryos (Teysseire et al. 1992). *Rickettsiaceae* can be isolated from decanted plasma, blood collected on heparin or citrate anticoagulant (because EDTA anticoagulant is harmful to the cell monolayers used for recovery of rickettsiae), skin biopsy, necropsy tissue, and arthropod samples (Brouqui et al. 2004). The material can be inoculated into experimental animals, in primary cultures of chicken embryo, HEL, MRC5, WI-38, LLC-MK2, BSC-1 or Hep-2 cells, further VERO cells, and L929 cells, which are used more often (Cox 1941; Cory et al. 1974; Brouqui et al. 2004). Today, cell culture systems have replaced the yolk sacs of developing chicken embryos and experimental animal inoculation, which were widely used in the past (La Scola and Raoult 1997). All of these procedures must be performed only in Biosafety Level 3 laboratories. The cultivation of *Rickettsiae* in cell monolayers is observed by the disruption of massively infected cells. SFG members form a plaque with a diameter of 2–3 mm in 5–8 days, while TG members form a plaque smaller than 1 mm in 8–10 days (Raoult and Parola 2007).

Concerning the metabolism of *Rickettsiaceae*, they do not use glucose as an energy source; rather, they use glutamate. Likewise, they do not synthesize or degrade nucleoside monophosphates (Raoult and Parola 2007).

Isolation, Enrichment and Maintenance Procedures

Isolation and Enrichment

Because of their intracellular binding, bacterial culture is one of the necessary procedures for cells' isolation. Another method for their isolation is the inoculation of biological material containing the bacteria in guinea pigs and embryonated eggs. However, cell culture is currently the most widely used system for primary isolation. Tissue culture requires prior disaggregation of the original tissue where the cells are grown and an adhesive layer on a solid substrate or suspended in culture medium.

For the isolation and cultivation of the parasite, samples used can be obtained from minced clot plasma, skin biopsy, and autopsy tissue samples (La Scola and Raoult 1997); arthropod material is collected and inoculated into cell lines (Paddock et al. 2010). It is important to note that performing routine laboratory cell isolation and cultivation of many of these rickettsial agents requires biosafety level 3 (BSL3) (Champman et al. 2006), which becomes impractical for implementation in many laboratories.

The cell cultivation may be performed in different lines, including Vero cells, MRC5 cells, L-929 cells, HEL cells, LLC-MK2, BSC-1, or Hep-2 (Cox 1941; Cory et al. 1974; Jonhson and Pedersen 1978; Dumler and Walker 2005). Vero or L929 cells have been shown to allow better and faster isolation of rickettsiae, especially from heavily infected samples, than HEL or MRC5 cells (Kelly et al. 1991; La Scola and Raoult 1997). However, these types of cell lines are established when an inhibition of cell division due to close contact occurs in the monolayer and may subsequently be used in a prolonged incubation.

The adaptation of the system shell vial employed for the detection of cytomegalovirus (Paya et al. 1987) has been successful for growing rickettsiae in VERO cells (La Scola and Raoult 1997), which may show multiplication of rickettsiae by the cytopathic effect (CPE). However, the cultivation of this technique has limitations because getting material from symptomatic patients is not always possible. Another important aspect of the isolation and cultivation of rickettsiae is the use of embryonic cell lineages of the tick, particularly for species struggling for multiplication in mammalian cell lines (Bell-Sakyi et al. 2007). Thus, using different strains of ticks, it is possible cultivation of different species of rickettsiae that have medical and veterinary importance (*Table 23.3*) (Bell-Sakyi et al. 2007).

Ecology

Rocky Mountain Spotted Fever (RMSF) is endemic to regions of North, Central, and South America. Cases have been reported from Canada to Argentina; however, some countries in these areas have not yet reported any cases. The greatest numbers of fatalities have been reported in the United States and Brazil. The distribution of RMSF reflects the distribution and abundance of the tick vectors *D. variabilis* (the American dog tick) and *D. andersoni* (*Table 23.4*).

The transmission of RMSF almost always results from rickettsiae infection in a human host by a tick as it obtains a blood meal from that host (McCalla 1908). Tick vectors of *R. rickettsii* include at least four species: *D. andersoni, D. variabilis, R. sanguineus*, and *Amblyomma cajenennse* (Parker 1933; Burgdorfer 1975; Demma et al. 2005). Because *R. rickettsii* is passaged transovarially and transstadially, all hematophagous stages of these ticks are potentially capable of transmitting rickettsiae to a susceptible host. Rare routes of transmission of *R. rickettsii* to human hosts include blood transfusion (Wells et al. 1978) and inoculation of rickettsiae through mucous membranes following contact with fingers contaminated during the crushing of infected ticks removed manually from a human or animal (Price 1954; Spencer and Parker 1930; Gordon et al. 1984).

Most of reported cases of RMSF occur during the months of April through September in the temperate United States (Kirkland et al. 1995; Gordon et al. 1984; Treadwell et al. 2000), because this period coincides with the greatest host-seeking activity of the *Dermacentor* spp. ticks (Clark et al. 1998;

Table 23.3
***Rickettsia* species propagated in tick cell lines since 1995 (Adapted by Bell-Sakyi et al. 2007)**

Rickettsia species	Mammalian host (disease caused)	Tick cell line (s) used
Rickettsia rickettsii	Human (Rocky mountain spotted fever)	IDE2, DALBE3, ISE6, IDE8,
Rickettsia peacockii	–	DAE 100, ISE6, BME26, DVE1, DAE3, DAE15, IDE12, IDE2, IDE8, IRE11, CCE3
Rickettsia monacensis	?	ISE6, IRE11, DAE100, IDE8
Rickettsia helvetica	Humans (fever, perimyocarditis?)	IRE11
Rickettsia montanensis	Various small mammals	IDE2, DALBE3
Rickettsia sp. (spotted fever group)	?	RAE25, IDE2, IDE8
Rickettsia felis	Humans (flea-associated spotted fever)	ISE6

Eads and Smith 1983). In Brazil, tick surveys in the county of Pedreira documented peak numbers of larvae and nymphs of *A. cajennense* between June and October, the months coinciding with the most reports of RMSF in Brazil (de Lemos et al. 1997).

African Tick-Bite Fever is transmitted by ixodid ticks of the genus *Amblyomma*: *Amblyomma variegatum* in West, Central, and East Africa and the eastern Caribbean, and *Amblyomma hebraeum* in southern Africa (Kelly and Mason 1991; Kelly et al. 1994; Parola et al. 2001). In contrast to most other ticks of human importance, *Amblyomma* ticks are hunter ticks and exhibit a notoriously aggressive behavior. Both tick species prefer semihumid habitats with tall grass or bush. Cattle, wild game, and other ungulates are the principal hosts, although young stages may also parasitize birds and rodents. *A. hebraeum* and *A. variegatum* are active all year, but their number peaks during and after the rainy season, from January to May (Norval 1983). Both species act as vectors of *R. africae* and are also reservoirs in which the infection is maintained through transstadial transmissions (Kelly and Mason 1991).

Mediterranean Spotted Fever (MSF) is caused by *R. conorrii* and transmitted by *R. sanguineus*, which probably has the most widespread distribution of all Ixodid ticks. Although *R. sanguineus* has a worldwide distribution, *R. conorii* is confined to particular regions of the world. *R. sanguineus* lives in peridomestic environments shared with dogs but has relatively low affinity for humans. Because of these circumstances, cases of MSF are sporadic and typically encountered in urban areas.

MSF is endemic in northern Africa, southern Europe, and the Mediterranean area. It is a reportable disease in Portugal (Bacellar et al. 2003), where there is an annual incidence rate of 9.8 cases per 100,000 persons (De Sousa et al. 2003). Overall, in endemic countries, fluctuation in incidence has been variable; this may be due to variations in climatic conditions, such as an increase in temperature and the lack of rainfall (Espejo-Arenas et al. 1986; Segura-Porta et al. 1989; Raoult et al. 1992). Sporadic cases in nonendemic countries are also frequently observed as a consequence of tourism (Rolain et al. 2004; Jensenius et al. 2004). Notably, although *R. sanguineus* is prevalent in North America, no cases of MSF were described until recently on that continent. In Europe, cases are encountered in late summer; this period is associated with the peak of activity of immature ticks, which are difficult to observe even when attached to the body (Raoult and Roux 1997).

Louse-Borne Epidemic Typhus has the most serious epidemic potential of all rickettsiae. It should be considered a serious threat, even in developed countries (Drancourt et al. 1995; Brouqui et al. 1996; Van Der Laan and Smit 1996; Brouqui et al. 1999). Epidemic typhus is currently considered as a potential bioterrorism agent (category B, Centers for Disease Control and Prevention). The human body louse is the only established vector for *R. prowazekii.* Lice die of their infection and do not transmit their infection to their progeny; because of this, the main reservoir appears to be humans. Bacteremia may occur and be prolonged to contaminate lice and allow transmission. Humans who contract typhus retain some rickettsiae for the rest of their lives, leading immunocompromised patients to relapse with Brill-Zinsser disease, a milder but bacteremic form of typhus (Green et al. 1990).

In the louse, rickettsiae only infect the epithelial cells of the first part of the louse's digestive tract (Weigl 1924; Houhamdi et al. 2002), where they multiply. As a result of its excessive growth, infected epithelial cells release the rickettsiae into the gut lumen (Houhamdi et al. 2002). Massive quantities of rickettsiae are discharged in the feces (Houhamdi et al. 2002). The rupture of digestive epithelium allows the ingested blood to diffuse through the intestine to the hemolymph and the louse becomes red (Burgess 1995); because of this, typhus has also been named "red louse disease". Because the ruptured epithelial cells are not replaced, infection with *R. prowazekii* leads to the death of the louse shortly thereafter (Houhamdi et al. 2002). *R. prowazekii* is the only *Rickettsia* species unable to be transmitted transovarially to its progeny in its vector.

Lice live in clothing, and their prevalence is determined by the weather, humidity, poverty, and lack of hygiene. They are more prevalent during the colder months; therefore, epidemic typhus is more frequently reported during winter and the early

Table 23.4

Species classified in SFG rickettsiae pathogenic for humans, SFG rickettsia never isolated from humans, the typhus group, and the genus *Orientia* (La Scola and Raoult 1997)

Group	Species	Disease	Associated arthropod	Distribution
SFG rickettsiae (human pathogens)	*Rickettsia conorii sensu stricto*	Mediterranean spotted fever	*Rhipicephalus sanguineus*	Mediterranean countries, Europe, Africa, Asia
	Rickettsia conorii complex	Israeli spotted fever	*Rhipicephalus sanguineus*	Israel
	Rickettsia conorii complex	Astrakhan spotted fever	*Rhipicephalus pumilo*	Russia
	Rickettsia rickettsii	Rocky Mountain spotted fever	*Dermacentor variabilis, D. andersoni, Rhipicephalus sanguineus, Amblyomma cajennense*	North and South America
	Rickettsia sibirica	Siberian tick typhus	*Dermacentor nuttalli, Dermacentor marginatus, Haemophysalis concinna*	Northern China, Pakistan (Asia Siberia)
	Rickettsia akari	Rickettsial pox	*Allodermanyssus sanguineus*	USA, Ukraine, Croatia, Korea
	Rickettsia africae	African tick bite fever	*Amblyomma hebraeum*	Southern Africa
	Rickettsia australis	Queensland tick typhus	*Ixodes hlocyclus*	Australia
	Rickettsia japônica	Japanese tick typhus	*Haemophysalis longicornis*	Japan
	Rickettsia honei	Finders Island tick typhus	*Aponomma hydrosauri*	Finders Islands
SFG rickettsiae (never isolated from humans)	*Rickettsia massiliae*		*Rhipicephalus turanicus, Rhipicephalus sanguineus, other Rhipicephalus spp.*	France, Greece, Spain, Portugal, central Africa.
	Rickettsia rhipicephali		*Rhipicephalus sanguineus*	USA, France, Portugal, central Africa
	Rickettsia parkeri		*Amblyomma maculatum*	USA
	Rickettsia Montana		*Dermacentor variabilis*	USA
	Rickettsia belli		*Dermacentor spp.*	USA
Typhus group	*Rickettsia prowazekkii*	Epidemic typhus	*Pediculus humanus corporis*	Worldwide (most in highlands areas of South America, Asia, Africa)
	Rickettsia typhi	Murine typhus	*Xenopsylla cheopis*	Worldwide
Scrub typhus	*Orientia tsutsugamushi*	Scrub typhus	*Leptotrombidium deliense*	Eastern Asia, northern Australia, western Pacific Islands

spring (Patterson 1993). Infestation with body lice and louse-transmitted diseases is also being increasingly reported in the inner cities of developed countries (Koehler et al. 1992; Van Der Laan and Smit 1996; Jackson and Spach 1996; Rydkina et al. 1999).

Murine Typhus is mainly transmitted by rat flea *Xenopsylla cheopis* (Azad 1990; Chaniotis et al. 1994); other flea species and arthropod vectors also have been reported to transmit *R. typhi*, including the cat flea *Ctenocephalides felis*, lice, mites, and ticks (Azad 1990; Sexton 2005; Raoult and Roux 1997). The flea remains infected for life after a blood meal from an infected rat (Azad 1990). The primary reservoirs are rats belonging to the subgenus *Rattus*, mainly *Rattus norvegicus* and *Rattus rattus* (Azad 1990). However, various rodents and other wild and domestic animals have also been occasionally seen to act as hosts. Rats serve not only as simple hosts but also as amplifying hosts (Azad 1990).

Rickettsia enters the midgut epithelial cells of the flea, where it multiplies without causing any damage and is excreted with the feces. The bacterium is additionally maintained in fleas by

transovarial and transstadial transmission (Raoult and Roux 1997) and is then transmitted back to a susceptible vertebrate host upon subsequent feeding (Azad 1990).

The role of humans in the natural cycle of *R. typhi* is secondary, as they are only accidental hosts. While feeding on a human host, the flea defecates; the irritation caused by the bite causes the host to scratch and thus inoculate the rickettsiae into the flea-bite site or skin abrasions. *Rickettsiae* are also thought to infect humans via inhalation or contamination of the conjunctiva (Azad 1990; Raoult and Roux 1997).

Many reports illustrate that murine typhus is an emerging disease with worldwide distribution, but it is most prevalent in warmer countries (Raoult and Roux 1997). Most cases occur in late summer or early autumn; this seasonal variation directly correlates with the abundance of the vector fleas (Azad 1990). A decline in the incidence of murine typhus occurs when rat and flea control programs are initiated by public health services (Azad 1990; Sexton 2005).

Scrub typhus Transmission occurs within an area bounded by the Asiatic and Australian continents, to the north by Siberia and the Kamchatka Peninsula, to the south by Queensland, and to the west by Afghanistan. The public health impact of *O. tsutsugamushi* infection is greatest for agricultural laborers in rural areas (Duffy et al. 1990), although disease transmission also has been reported in suburban areas (Fan et al. 1987). Travelers to endemic areas can become infected (Woodruff et al. 1988), but it is not common. The majority of scrub typhus cases go undiagnosed because commercial diagnostic tests are generally unavailable in the rural tropics. *O. tsutsugamushi* was documented to be the most common cause of acute fever in Malaysia and Thailand (Lorandos 1934; Binford and Ecker 1947).

Transmission occurs by mites in zones where the primary forest has been cleared and replaced. Humans are accidental hosts, acquiring *O. tsutsugamushi* during feeding of a larval trombiculid mite of the genus *Leptotrombidium*. These chiggers only feed on mammalian tissue fluid once in their lifetime (McLeod et al. 2004); the reservoir of infection is through transovarial transmission. Chigger activity is determined by temperature and humidity. Mites are normally maintained in nature by feeding on a variety of wild rodents, but rodents are not a reservoir of *O. tsutsugamushi*.

Leptotrombidium deliense is the most important vector species in Southeast Asia and southern China, whereas *L. akamushi, L. scutellare*, and *L. pallidum* are the main vectors in Korea and Japan (Duffy et al. 1990; McLeod et al. 2004). *L. chiangraiensis* is a newly described vector found in cultivated rice fields in Thailand (Schmiela and Millera 1999).

Pathogenicity and Clinical Significance

Rickettsiae are obligately intracellular organisms that do not replicate extracellularly. Organisms in this family generally target macrophages, leukocytes, and endothelial cells. The main target cells of rickettsiosis are endothelial cells, which are most likely the result of vascular location and hematogenous dissemination. The lungs and brain are the critical target organs determining the lethality of rickettsioses. The events are visible in the skin: vasodilatation, perivascular edema, and disruption of vascular integrity (Raoult and Parola 2007). The pathogenesis of diseases caused by *Rickettsia* and *Orientia* genera differ greatly, according to the species of bacteria:

Rocky Mountain Spotted Fever (RMSF), the most severe of all the spotted fever group (SFG), is caused by *Rickettsia rickettsii*. It is a disease of the capillary circulation, being the only organism in the genus that invades beyond the blood vessel lining of the endothelium; it also invades adjacent vascular smooth muscle cells, particularly in arterioles. This bacteria is transmissible from the blood of infected patients to healthy hosts. These bacteria have the capacity to infect and replicate in the cytosol, and occasionally in the nucleus of vertebrate cells (e.g., endothelium, vascular smooth muscle, and macrophages) and invertebrate cells (e.g., hemocytes and salivary gland epithelium) (Raoult and Parola 2007).

In vertebrate hosts, these organisms are found in apparently uninjured endothelium of normal vessels, in areas of proliferated endothelium of the intima of vessels, in hyaline necrosed intima of more advanced lesions, in apparently normal and necrosed smooth muscle fibers of vessels with lesions, and in endothelial cells in the perivascular zones of proliferation. The largest masses are seen in smooth muscle cells of affected arteries and veins (Wolbach 1916).

Infection by *R. rickettsii* causes a significant reduction in key enzymes involved in the protection of endothelial cells from oxidative injury (Devamanoharan et al. 1994), resulting in increased levels of intracellular peroxides accompanied by ultrastructural indications of cell injury (Hong et al. 1998). Endothelial cell infection by *R. rickettsii* activates the nuclear transcription factor, which exerts an antiapoptotic effect (Joshi et al. 2003) by inhibiting proteins in the caspase family, which mediate apoptosis (Joshi et al. 2004). Inhibition of apoptosis is essential for host cell survival and site persistence of active infection (Clifton et al. 1998).

RMSF is a systemic illness that can involve endothelial cells of capillaries of all tissues and organs; however, the first signs and symptoms of disease resemble many other infectious syndromes. Following the bite of an infected tick, the disease begins with abrupt onset of fever accompanied by headache, nausea, vomiting, anorexia, and generalized myalgia. Other findings were recorded but with low frequencies. The rash begins small, typically on the wrists, ankles, and forearms, then evolves. It spreads centrally, and the entire body may be involved in few hours (Ong and Raffeto 1940; Harrell 1949). Characteristics of the rash considered to be classic for RMSF—that is, petechial lesions and a distribution that includes the palms and soles—occur in most of patients (Hazard et al. 1969; Kaplowitz et al. 1981; Ong and Raffeto 1940; Harrell 1949). Children are less likely than adults to present without a rash (Helmick et al. 1984). The life-threatening pathophysiologic consequences of infection and inflammation are microvascular damage and increased vascular permeability, which results in edema, localized hemorrhage, and hypoperfusion of one or more organ systems.

The invertebrate hosts for *R. rickettsii* include several species of ticks from several genera, including *Dermacentor*, *Rhipicephalus*, and *Amblyomma* (Burgdorfer 1988; Guedes et al. 2005). In these hosts, rickettsiae infect and replicate in several cell types, such as ovaries, salivary glands, midgut epithelium, and hemocytes (Sonenshine 1993). Vertebrates host that these bacteria has been isolated include domestic dogs, field voles (*Microtus pennsylvanicus*) (Badger 1933; Price 1954), pine voles (*M. pinetorum*), white-footed mice (*Peromyscus leucopus*), cotton rats (*Sigmodon hispidus*), cottontail rabbits (*Sylvilagus floridanus*), Rocky Mountain cottontail rabbits (*S. nuttallii*), snowshoe hares (*Lepus americanus*), opossums (*Didelphis virginiana*), chipmunks (*Tamias amoenus*), and golden-mantled ground squirrels (*Spermophilus lateralis*) (Burgdorfer 1988; McDade and Newhouse 1986; Schriefer and Azad 1994). The importance of birds as reservoir hosts for *R. rickettsii* remains unproven (Burgdorfer 1975).

Most cases of severe rickettsial disease are confirmed by serologic testing and on this basis are attributed to RMSF caused by *R. rickettsii*. However, the recent description of *R. parkeri* as a cause of rash-associated febrile illness (Paddock et al. 2004) in the United States highlights the low reliability of the results of serologic tests.

Despite the current availability of effective treatment and advances in medical care, many patients still die from rickettsial diseases. The majority of deaths are attributable to delayed diagnosis and failure to initiate specific antibiotic treatment within the first several days of the illness (Dalton et al. 1995; Kirkland et al. 1995). The recommended therapy for RMSF is doxycycline (CDC 2006).

African Tick-Bite Fever is probably an ancient disease in sub-Saharan Africa caused by *Rckettsia africae*. This disease may be one of the most common causes of acute febrile disease in rural sub-Saharan Africa, particularly in visitors from abroad. *R. africae* is a spotted-fever group rickettsia closely related to *R. parkeri* in North America and *R. sibirica* in Northeast Asia. These bacteria are mainly transmitted by *Amblyomma variegatum* and *Amblyomma hebraeum* ticks (Kelly and Mason 1991; Kelly et al. 1994; Parola et al. 2001). Humans are usually attacked by ticks on the legs, typically on moist skin behind the knee, in the groin, the perineum, or the axilla.

The pathophysiological hallmark of African tick-bite fever is the formation of focal or disseminated vasculitis (Toutous-Trellu et al. 2003). *R. africae* primarily invades the endothelial cells of smaller blood vessels (Jensenius et al. 2003a) and results in intramural and perivascular inflammation composed mainly of polymorphonuclear leukocytes, T-cells, and macrophages (Lepidi et al. 2006). The clearance of *R. africae* from endothelial cells is characterized by increased circulating levels of cytokines and chemokines (Jensenius et al. 2003b).

Rickettsia africae infection is symptomatic in few cases (Jensenius et al. 2002). The clinical course typically includes an abrupt onset of fever, nausea, headache, and neck myalgia commencing days after a tick bite (Raoult et al. 2001; Jensenius et al. 2003b). Most patients develop a painless large black crust surrounded by a red halo at the site of the tick bite. A painful regional lymphangitis (Brouqui et al. 1997) is detected in half of the cases. The majority of patients with African tick-bite fever develop mild to moderately severe illness that either resolves spontaneously within 10 days or responds promptly to anti-rickettsial treatment (Raoult et al. 2001; Jensenius et al. 2003b; Fournier et al. 1998a; Smoak et al. 1996). Complications are rare and no fatalities have ever been reported.

R. africae is susceptible in vitro to tetracycline, chloramphenicol, rifampin, fluoroquinolones, newer macrolides, and ketolides (Rolain et al. 1998, 2000). Most patients respond quickly to doxycycline. Patients with mild symptoms may not require any treatment at all (Jensenius et al. 2003a).

Mediterranean Spotted Fever (MSF) was described in Tunisia and was soon reported in the Black Sea littoral, India, the Middle East, and southern Africa. The causative agent was named as *Rickettsia conorii*. It was thereafter also known as "boutonneuse fever" because of a papular rather than macular rash. The brown dog tick *Rhipicephalus sanguineus* was recognized as a vector in Europe (Brumpt 1932); this vector is found throughout the world, but *R. conorii* is found only in some regions.

This bacterium does not normally infect humans during its natural cycle between its arthropod and vertebrate hosts, dogs. After an asymptomatic incubation of 6 days (Raoult et al. 1986; Martin Farfan et al. 1985), the onset of MSF is abrupt. Typical cases present with high fever and flu-like symptoms such as headache, chills, arthromyalgia, and a black eschar at the tick-bite site (Raoult and Roux 1997; Anton et al. 2003). The eschar is usually localized on the trunk, legs, and arms and rarely occurs in multiples. The rash often involves the palms and soles, but not the face. Generally, patients will recover within 10 days without any sequelae.

R. conorii multiply in the endothelial cells of small to medium vessels in human hosts, causing a vasculitis that is responsible for the clinical and laboratory abnormalities occurring in MSF (Parola and Raoult 2001). After phagocytosis and internalization, the phagocytic vacuole is lysed and rickettsiae escape the phagocytic digestion to multiply freely in the host cell cytoplasm and nucleus (Raoult and Roux 1997).

Before confirmation of the diagnosis, early empirical antibiotic therapy should be prescribed in any suspected cases. Doxycycline remains the treatment of choice for MSF (Raoult and Roux 1997). In patients with severe hypersensitivity to tetracyclines, chloramphenicol can be considered as an alternate therapy (Shaked et al. 1989).

Murine typhus, also known as endemic typhus, is a flea-borne infectious disease caused by *Rickettsia typhi*. The disease occurs in environments where rats and humans live in close proximity and typically in temperate and subtropical seaboard regions. The illness is less commonly diagnosed in developed countries than in the developing part of the world due to improved hygiene and rat control efforts. It is difficult to establish the true incidence because of the difficulty in distinguishing murine typhus from other causes of rash and fever.

R. typhi is a member of the typhus group of rickettsiae that also includes the agent responsible for epidemic typhus, *R. prowazekii*. *R. typhi* (or *R. mooseri*) is carried by the rat flea *Xenopsylla cheopis* and typically infects humans in markets, grain stores, breweries, and garbage depots. It usually causes a mild form of illness, but severe forms of the disease can also occur.

Scrub typhus is a chigger-borne zoonosis that is of greatest public health importance in tropical Asia; the causative agent is *Orientia tsutsugamushi*. The chigger bite can occur on any part of the body, is painless, and is not usually remembered by the patient (Sayen et al. 1946). Humans are accidental hosts. It is not known whether organisms deposited in the skin spread to internal organs via the bloodstream, the lymphatics, or by another mechanism. The disease begins as a small papule, enlarges, undergoes central necrosis, and acquires a blackened crust to form a lesion resembling a cigarette burn. Atypical eschar is pathognomonic when viewed by a clinician experienced in scrub typhus diagnosis. The rash appears on the trunk and spreads peripherally; however, it is often difficult to detect on dark-skinned persons.

O. tsutsugamushi infection appears to be a vasculitis, but the host cell in human scrub typhus is not known with certainty. The basic histopathological lesions suggest that macrophages are a more important target cell than the endothelium (Park and Hart 1946). Scrub typhus bacteria have been demonstrated in a variety of cells in humans, including monocytes, macrophages, Kuppfer cells, cardiac myocytes, hepatocytes, and endothelial cells (Settle et al. 1945; Allen and Spitz 1945; Walsh et al. 2001; Moron et al. 2001). In fatal cases, histopathology showed chiefly disseminated focal vasculitis and perivasculitis in vessels of the skin, lungs, heart, and brain. Endovasculitis and focal hemorrhage may be present but are less prominent than in Rocky Mountain spotted fever and epidemic typhus (Settle et al. 1945). The most important lesions are interstitial pneumonia with alveolar edema, hemorrhage, and meningoencephalitis (Settle et al. 1945; Allen and Spitz 1945; Park and Hart 1946).

Fever and headache begin abruptly and are frequently accompanied by myalgia and malaise. Cough, sometimes accompanied by infiltrates on the chest radiograph, is one of the most common presentations of scrub typhus infection (Chaykul et al. 1988). In severe cases, tachypnea progresses to dyspnea, the patient becomes cyanotic, and full-blown acute respiratory distress syndrome (ARDS) may develop. ARDS is associated with older age and preceding infiltrates on chest radiographs (Tsay and Chang 2002). Respiratory failure is the most common cause of death in severe scrub typhus infection, but survivors recover without sequelae.

O. tsutsugamushi infection can be cured and prevented by chloramphenicol and safer tetracyclines (Smadel et al. 1950). The response of mild scrub typhus to treatment with doxycycline or chloramphenicol is typically so rapid that resolution of fever is used as a diagnostic test; if the temperature has not returned to normal within 48 h after beginning doxycycline treatment, then the infection is not due to *O. tsutsugamushi* (Watt et al. 1996).

24 The Family *Sneathiellaceae*

Brian Austin
Institute of Aquaculture, School of Natural Sciences, University of Stirling, Stirling, Scotland, UK

Abstract
Sneathiellaceae, a family in the order *Sneathiellales*, comprises the genera *Oceanibacterium* and *Sneathiella*. The cultures are Gram-negative asporogenous rods, which have been recovered from marine samples. The dominant fatty acids include $C_{18:1}\omega7c$ and $C_{16:0.}$ The G + C content of the DNA is ~57 mol%. 16S rRNA gene sequencing evidence was used principally to delineate the new order, family, and genera.

Taxonomy, Historical and Current

Short Description of the Family

Sneathiellaceae (Snea.thi.el.la'ceae. N.L. fem. N. *Sneathiella* type genus of the family; *-aceae* ending to denote a family; N.L. fem. N. *Sneathiellaceae* the family of *Sneathiella*).

LMG 23452^T, which became the type and so far only strain of *S. chinensis*, was recovered from coastal sediment in an aquacultural site located near Qingdao, China, in 2000. 16S rRNA gene sequencing pointed to its unique position with ~89 % sequence homology to *Devosia*, *Hyphomonas*, *Ensifer*, and *Chelatococcus*; phylogenetic examination of which showed that the culture formed a separate branch in the order *Rhizobiales*, recovered between the genera *Devosia* and *Ensifer* in the families *Hyphomicrobiaceae* and *Rhizobiaceae*, respectively. A second species, *S. glossodoripedis*, was described by Kurahashi et al. (2008) for a single isolate MKT133^T (= IAM 15419^T = KCTC 12842^T) from the nudibranch *Glossodoris cincta*, which was recovered from the sea of Aka island, Okinawa, Japan. However, these workers considered that *Sneathiella* formed a distinct phyletic lineage separate from all eight orders of the class *Alphaproteobacteria* and proposed a new family, i.e., *Sneathiellaceae*, in a new order *Sneathiellales*. A second genus, *Oceanibacterium* with a single species *O. hippocampi*, was described and added by Balcázar et al. (2012) for a single isolate BFLP-8^T (=CECT 7691^T = DSM 23444^T) obtained from the cutaneous mucus of wild long-snouted seahorse (*Hippocampus guttulatus*). The three cultures comprising the three species in the two genera of the family *Sneathiellaceae* are Gram-negative aerobic, asporogenous rods, which have been obtained from marine samples. The dominant fatty acids include $C_{18:1}\omega7c$ and $C_{16:0.}$ The G + C content of the DNA is ~57 mol%.

Phylogenetic Structure of the Family and Its Genera

Sequence similarity analyses involving the neighbor-joining algorithm revealed that *O. hippocampi* clustered most closely with uncultured bacterial clones (GenBank accession no. FJ202709 and FJ205319). The nearest culturable neighbors were *Oceanibaculum pacificum* MC2UP-L3^T, *S. glossodoripedis* IAM 15419^T, *S. chinensis* LMG 23452^T, and *Oceanibaculum indicum* P24^T with homologies of 91.5 %, 91.1 %, 90.9 %, and 90.5 %, respectively. The phylogenetic tree revealed that the *Sneathiella*, *Oceanibacterium*, and the uncultured bacterial clones form a distinct clade within the family *Sneathiellaceae* (*Fig. 24.1*).

Molecular Studies

The BLASTN search with the almost-complete (1,412 bp) 16S rRNA gene sequence of *S. chinensis* LMG 23452^T indicated that *Sneathiella* is phylogenetically related to members of the α-subgroup of the class *Proteobacteria*. The closest phylogenetic neighbors with similarities of 89 % were *Chelatococcus asaccharovorans* DSM 6462^T, *Devosia riboflavina* DSM 7230^T, and *Hyphomonas polymorpha* DSM 2665^T. The neighbor-joining tree showed that LMG 23452^T clustered most closely with an uncultured bacterial clone D101 that was found in deep-sea sediment of a western Pacific warm pool in China. LMG 23452^T was initially considered to form a separate branch in the order *Rhizobiales*, with <90 % 16S rRNA sequence homology with its neighbors (Jordan et al. 2007). However, Kurahashi et al. (2008) regarded that *Sneathiella* formed a separate and new phyletic lineage distinct from all eight orders, i.e., *Caulobacterales*, *Kordiimonadales*, *Parvularculales*, *Rhizobiales*, *Rhodobacterales*, *Rhodospirillales*, *Rickettsiales*, and

E. Rosenberg et al. (eds.), *The Prokaryotes – Alphaproteobacteria and Betaproteobacteria*, DOI 10.1007/978-3-642-30197-1_262,

Fig. 24.1

Phylogenetic reconstruction of the family *Sneathiellaceae* based on the neighbor-joining algorithm with the Jukes-Cantor correction. Sequence dataset and alignments, according to the All-Species Living Tree Project, release LTPs108 (Yarza et al. 2010). The tree topology was stabilized with the use of a representative set of 767 high quality type strain sequences proportionally distributed among the different bacterial and archaeal phyla. In addition, a 40 % maximum frequency filter was applied to remove hypervariable positions. The bar indicates 1 % sequence divergence

Sphingomonadales, of the class *Alphaproteobacteria*, segregating on a distinct and separate monophyletic 16SrRNA gene tree branch (Garrity et al. 2005; Kwon et al. 2005). Thus, the family *Sneathiellaceae* was proposed on the basis of phylogenetic analysis of 16S rRNA gene sequences (Kurahashi et al. 2008). *S. glossodoripedis* MKT133^T shared 97.2 % 16S rRNA sequence similarity with *S. chinensis* (Kurahashi et al. 2008). Moreover, the phylogenetic analysis revealed that the clade formed a distinct lineage with <90 % 15S rRNA sequence similarity to other orders in the *Alphaproteobacteria*. Therefore, it was proposed to elevate *Sneathiella* into a new order (*Sneathiellales*) and family (*Sneathiellaceae*). A second genus *Oceanibacterium* with *O. hippocampi* as the type and only species was added by Balcázar et al. (2012) after sequence similarities revealed 90.9 % and 91.1 % homology with *S. chinensis* and *S. glossodoripedis*, respectively.

DNA-DNA Hybridization Studies

The DNA-DNA relatedness between *S. chinensis* and *S. glossodoripedis* was ~22 % (Kurahashi et al. 2008).

Phenotypic Analyses

The main differential features of members of *Sneathiellaceae* are included in *Table 24.1*.

Table 24.1

Diagnostic properties in which the type strains of the species in the family *Sneathiellaceae* may be differentiated from each other

Taxon	Growth in/at:		Arginine dihydrolase	Urease production
	0 % (w/v) NaCl	45 °C		
O. hippocampi	–	–	+	+
S. chinensis	+	–	–	+
S. glossodoripedis	–	+	+	–

Oceanibacterium Balcázar et al. 2012

O.ce.an.i.bac.te'ri.um M.L. n. *oceanus* ocean; Gr. neut. Dim. N. *bakterium* a rod; N.L. n. *Oceanibacterium* rod-shaped bacterium from the ocean.

The single culture examined to date of the sole species *O. hippocampi* comprises slightly curved salt-requiring (1.0–6.0 % w/v) Gram-negative, aerobic, asporogenous rods of 0.4 × 1.0–16 μm in size that grow at 10–15 °C, and optimally at 25 °C on marine agar, and at pH 5.0–9.0, but not below pH 4.5 or above pH 9.5. Arginine dihydrolase, catalase, oxidase, and urease but not β-galactosidase or indole are produced. By means of API ZYM, acid, and alkaline phosphatases, esterase (C4), esterase lipase (C8), lipase (C14), cystine, leucine and valine arylamidases, and naphthol-AS-BI-phosphohydrolase were produced, but not α-chymotrypsin, α-fucosidase, α- or β-galactosidase, α- or β-glucosidase, β-glucuronidase, α-mannosidase, or trypsin. Adipate and malate are assimilated, but not D-glucose, L-arabinose, D-mannose, D-mannitol, *N*-acetyl-D-glucosamine, D-maltose, potassium gluconate, caprate, and citrate of phenyl acetate. Neither Aesculin nor gelatin is hydrolyzed. Nitrates are reduced to nitrite (Balcázar et al. 2012).

The ubiquinone system is Q-10; $C_{18:1}\omega7c$, $C_{19:0}$ cyclo $\omega8c$, $C_{16:0}$, $C_{18:1}$ 2-OH, and $C_{16:1}$ $\omega11c$ are the dominant fatty acids with smaller amounts of $C_{18:0}$, $C_{18:1}$ ω 9*c*, 11-methyl $C_{18:1}$ ω 7*c*, and $C_{18:0}$ 3-OH (Balcázar et al. 2012).

The G + C ratio of the DNA of the type strain is 57.8 mol% (T_m).

Sneathiella Jordan et al. 2007

Sneath.i.el'la N.L. fem. dim. n. *Sneathiella* honoring the British microbiologist P.H.A. Sneath for his contributions to bacterial taxonomy.

Cultures of the single isolate examined to date comprise aerobic, Gram-negative motile asporogenous rods. Growth occurs at 37 °C and in 1–3 % (w/v) NaCl. Catalase and oxidase are produced.

The major cellular fatty acids are $C_{18:1}$ ω7*c* and $C_{16:0}$.

After 48 h incubation, cultures of *S. chinensis* are butyrous and beige and 0.5–2.0 mm in diameter on marine agar, and comprise aerobic, Gram-negative motile asporogenous rods. *S. chinensis* grows in 0–3 % (w/v) NaCl, at 4–37 °C but not at 45 °C; reduces nitrate; hydrolyzes aesculin, casein, starch, tween 20, 40, 60, and 80; and deaminates tyrosine, but does not hemolyze horse blood. Alkaline phosphatase, leucine arylamidase, acid phosphatase, and naphthol-AS-BI-phosphohydrolase are produced, but not *N*-acetyl-β-glucosaminidase, α-chymotrypsin, esterase (C4), esterase lipase (C8), α-fucosidase, α- or β-galactosidase, β-glucuronidase, α-glucosidase, lipase (C14), α-mannosidase, cysteine or valine arylamidase, or trypsin. Neither glucose is assimilated nor arginine dihydrolase or urease produced; *p*-nitrophenyl-β-D-galactopyranoside, arabinan, cellulose, galactan, gelatin, pullulan, or xylan hydrolyzed; or *N*-acetylglucosamine, adipate, arabinose, caprate, citrate, gluconate, glucose, malate, maltose, mannitol, mannose, or phenylacetate assimilated. The major cellular fatty acids are $C_{18:1}$ ω7*c* and $C_{16:0}$, $C_{19:0}$ cyclo ω8*c*, $C_{16:1}$ ω7*c*, and $C_{17:1}$ ω6*c*. The G + C content of the type strain LMG 23452^T = CBMAI 737^T is 57.1 mol% (Jordan et al. 2007).

The single culture of *S. glossodoripedis* produces <1 mm diameter colorless, circular, convex, smooth colonies after 4–5 days incubation aerobically at 30 °C on marine agar and contains slightly curved rods of 0.2–0.3 × 0.7–1.0 μm in size with intracellular granules. Motility is by means of single polar flagella. Growth occurs at 17–45 °C [optimally at 40 °C], but not at 10 °C or 50 °C, and in 4 % (w/v) NaCl. Growth does not occur in 0 % (w/v) NaCl or anaerobically. Acid and alkaline phosphatase, arginine dihydrolase, esterase (C4) [weakly], esterase lipase (C8) [weakly], α-glucosidase [weakly], leucine arylamidase, *N*-acetyl-β-glucosaminidase, naphthol-AS-BI-phosphohydrolase, ornithine decarboxylase, trypsin [weakly], and tryptophan deaminase are produced but not α-chymotrypsin, α-fucosidase, α-or β-galactosidase, gelatinase, β-glucosidase, β-glucuronidase, H_2S, indole, lipase (C4), α-mannosidase, urease or cysteine, or valine arylamidase; the Voges-Proskauer reaction is positive, citrate is utilized, and nitrates are reduced to nitrite. Neither amygdalin, arabinose, D-glucose, inositol, D-mannose, melibiose, rhamnose, sorbitol nor sucrose is assimilated. The ubiquinone system is Q10. The dominant cellular fatty acids are $C_{18:1}$ω7*c*, $C_{16:0}$, $C_{17:1}$, and $C_{14:0}$ 3-OH. The G + C content of the type strain MKT13^T [IAM 15419^T = KCTC 12842^T) is 56.9 mol% (Kurahashi et al. 2008).

Isolation, Enrichment, and Maintenance Procedures

Isolation was achieved on marine agar with incubation at 20 °C [for *O. hippocampi* and *S. glossodoripedis*) or 28 °C [for *S. chinensis*] for 3–7 days. Subculturing was achieved on the same medium with incubation at room temperature to 30 °C for up to 7 days. Long-term preservation was at −70 or −80 °C in marine broth supplemented with 20 % or 30 % (v/v) glycerol (Kurahashi and Yokota 2002; Jordan et al. 2007; Kurahashi et al. 2008; Balcázar et al. 2012).

Ecology

Habitat

Isolates have been recovered from the marine environment. Thus, the single culture of *O. hippocampi* BFLP-8^T = CECT 7691 T = DSM 23444^T was obtained from cutaneous mucus of wild long-snouted seahorse (*Hippocampus guttulatus*) (Balcázar et al. 2012). *S. chinensis* LMG 23452^T = CBMAI 737^T was isolated from sediment within a coastal aquaculture site in China (Jordan et al. 2007). *S. glossodoripedis* was recovered from the foot epidermis of a nudibranch (*Glossodoris cincta*) from seawater at a depth of 4 m collected off the coast of Japan (Kurahashi et al. 2008).

Pathogenicity and Clinical Relevance

To date, there has not been any involvement with human or animal disease.

25 The Family *Sphingomonadaceae*

Stefanie P. Glaeser · Peter Kämpfer
Institute of Applied Microbiology, Justus-Liebig-University Giessen, Giessen, Germany

Abstract
Besides the *Erythrobacteraceae*, the family *Sphingomonadaceae* represents the order *Sphingomonadales*, which currently

E. Rosenberg et al. (eds.), *The Prokaryotes – Alphaproteobacteria and Betaproteobacteria*, DOI 10.1007/978-3-642-30197-1_302,

includes the genera *Sphingomonas, Sandaracinobacter, Blastomonas, Novosphingobium, Sphingobium, Sphingopyxis, Sandarakinorhabdus, Sphingosinicella, Stakelama, Sphingomicrobium, Sphingorhabdus, Parasphingopyxis*, and *Zymomonas*. The genus *Sphingomonas* is the type genus. The family was proposed based on the 16S rRNA gene sequence phylogeny and the presence of 2′hydroxymyristol dihydrosphingosine 1-glucuronic acid (SGL-1) as major sphingoglycolipid in the cellular lipids (Kosako et al. 2000). Originally the family embraced six genera, *Sphingomonas*, *Erythrobacter*, *Erythromicrobium*, *Prophyrobacter*, *Zymomonas*, and *Sandaracinobacter*. Because the genera *Erythrobacter*, *Erythromicrobium*, and *Prophyrobacter* formed a distinct monophyletic 16S rRNA gene sequence cluster, they were transferred to the family *Erythrobacteraceae*, supported by differences in the sphingoglycolipid composition. The genera *Blastomonas* (Sly and Cahill 1997) and *Erythromonas* (Yurkov et al. 1997) were first transferred to the genus *Sphingomonas*, then both to the genus *Blastomonas*. The type genus *Sphingomonas* was dissected into four genera based on clustering in the 16S rRNA gene sequence phylogeny and differences in the major polyamine and the 2-hydroxy fatty acid patterns; the genus *Sphingomonas sensu stricto* and the three new genera *Novosphingobium*, *Sphingobium*, and *Sphingopyxis*. The genus *Sphingopyxis* was further dissected by the proposal of the genus *Parasphingopyxis*.

Members of the family are defined by the presence of SGL-1 in their cellular lipids, ubiquinone-Q10 as the major respiratory quinone system, and the octadecenoic fatty acid (C18:1) as the major fatty acid in total extractable lipids. The presence of 2-OH fatty acids of different chain length (C14 to C16) and the absence of 3-OH fatty acids are characteristic. Either *sym*-homospermidine or spermidine are the predominant polyamines. Most of the *Sphingomonadaceae* are chemoorganotrophic. The genera *Blastomonas, Sandaracinobacter*,and *Sandarakinorhabdus* are facultative photoeterotrophic due to the bacteriochlorophyll a (BChl *a*) content. One species of the genus *Sphingomonas*, *Sphingomonas kaistensis*, also contains BChl *a*. *Sphingomonadaceae* are commonly isolated from soils, freshwater and marine habitats, activated sludge, or the plant phyllosphere or rhizosphere. Only a few *Sphingomonadaceae* are known to cause human infections (*Sphingomonas paucimobilis*) or to be plant pathogens (*S. suberifaciens*); some are antagonistic against plant pathogens and induce plant growth promotion. Several species can degrade xenobiotic and recalcitrant (poly)aromatic compounds of natural or anthropogenic origin. Sphingomonads are very interesting with respect to their applications for bioremediation. *Sphingomonas* species can produce exopolysaccharides (sphingans), which are gelling agents that are used for food, pharmaceutical, or industrial applications. The genus *Zymomonas* differs from other members of the *Sphingomonadaceae* because of its fermentative, obligate, or facultative anaerobic metabolism. *Zymomonas*, which can produce biofuels, is used in natural fermentation processes of cider or plan fruits but is also the causative agent of the secondary fermentation products in biotechnological processes.

Taxonomy; Historical and Current

Short Description of the Family

Sphingomonadaceae Kosako, Yabuuchi, Naka, Fijiwara and Kobayashi 2000b, 1953^{VP} (Effective Publication: Kosako, Yabuuchi, Naka, Fijiwara and Kobayashi 2000a, 563)

Sphing.o.mon.a.da'ceae. M.L. fem. n. *Sphingomonas* type genus of the family; *-aceae* ending to demote a family; M.L. fem. pl. n. *Sphingomonadaceae* the family of *Sphingomonas* (modified from *Bergey's Manual*). The description is an emended version of the description given in the *Bergey's Manual*, 2nd edition (Yabuuchi and Kosako 2005).

Sphingomonadaceae are phylogenetically assigned to the order *Sphingomonadales* (Yabuuchi and Kosako 2005), representing group-4 *Alphaproteobacteria*. The family currently contains 13 validated genera, the type genus *Sphingomonas* (Yabuuchi et al. 1990; emend. by Yabuuchi et al. 1999, 2002; Takeuchi et al. 2001; Busse et al. 2003; Chen et al. 2012a), and the genera *Zymomonas* (Kluyver and van Niel 1936), *Sandaracinobacter* (Yurkov et al. 1997), *Blastomonas* (Sly and Cahill 1997; emend. by Hiraishi et al. 2000), *Novosphingobium* (Takeuchi et al. 2001), *Sphingobium* (Takeuchi et al. 2001; emend. by Li et al. 2013), *Sphingopyxis* (Takeuchi et al. 2001; emend. by Baik et al. 2013), *Sandarakinorhabdus* (Gich and Overmann 2006), *Sphingosinicella* (Maruyama et al. 2006; emend. by Geueke et al. 2007; Yasir et al. 2010.), *Stakelama* (Chen et al. 2010), *Sphingomicrobium* (Kämpfer et al. 2012), *Parasphingopyxis* (Uchida et al. 2012), and *Sphingorhabdus* (Jogler et al. 2013).

The family was originally proposed by Kosako et al. (2000) based on the 16S rRNA gene sequence phylogeny and the presence of 2′hydroxymyristol dihydrosphingosine 1-glucuronic acid (SGL-1) as major sphingoglycolipid in the cellular lipids (Kosako et al. 2000). The family originally consisted of six genera, *Sphingomonas* (Yabuuchi et al. 1990), *Erythrobacter* (Shiba and Simidu 1982), *Erythromicrobium* (Yurkov et al. 1994), *Porphyrobacter* (Fuerst et al. 1993), *Zymomonas* (Kluyver and van Niel 1936), and *Sandaracinobacter* (Yurkov et al. 1997). The type genus is *Sphingomonas* (Yabuuchi et al. 1990).

Blastomonas, *Erythromonas*, and *Rhizomonas* were single species genera; the three respective species *Blastomonas natatoria* (Sly 1985), *Erythromonas ursincola* (Yurkov et al. 1997), and "*Rhizomonas*" *suberifaciens* (van Bruggen et al. 1990) were transferred to the genus *Sphingomonas* as "*Sphingomonas natatoria*", "*Sphingomonas ursincola*", and "*Sphingomonas suberifaciens*" by Yabuuchi et al. (1999). Later, the genus *Blastomonas* was revived and "*Sphingomonas natatoria*" and "*Sphingomonas ursincola*" were reclassified as *Blastomonas natatoria* and *Blastomonas ursincola* (Hiraishi et al. 2000). Based on the fact that "*Sphingomonas suberifaciens*" contained spermidine as the major polyamine (Takeuchi et al. 1995) and clustered in the 16S rRNA gene sequence phylogeny closest to *Sphingobium*

boeckii, the species was recently transferred from "*Sphingomonas suberifaciens*" to *Sphingobium suberifaciens* (Chen et al. 2013).

Rejection of the Genus "*Rhizomonas*"

The genus "*Rhizomonas*" was proposed by van Bruggen et al. (1990). Based on comparative 16S rRNA gene sequences analysis and the cellular content of sphingoglycolipids (SGLs), it was suggested that the genus *Sphingomonas* (Yabuuchi et al. 1990) is synonymous with the genus *Rhizomonas*. Based on Rule 24b of the bacteriological code, the genus *Rhizomonas* has nomenclatural priority but the name *Rhizomonas* is illegitimate (Laplace et al. 1992) and placed into the "Rejected names of genera and subgenera of bacteria (*nomina generum et subgenerum bacteriorum rejicienda*)" by the Judicial Opinion 14. The reason for the rejection was that it was figured out to be a later homonym of a name of a taxon of protozoa (*Rhizomonas*; Kent 1880). The type species of this single species genus "*Rhizomonas*" was transferred to the genus *Sphingomonas*, as "*Sphingomonas suberifaciens*" recently reclassified as *Sphingobium suberifaciens* (Chen et al. 2013).

The genera *Erythrobacter* (Shiba and Simidu 1982), *Erythromicrobium* (Yurkov et al. 1994), and *Porphyrobacter* (Fuerst et al. 1993) formed a distanced monophyletic cluster in phylogenetic trees based on 16S rRNA gene sequences. The genera were therefore transferred to a separate family, the *Erythrobacteraceae* (Lee et al. 2005), which is now the second family harboring Group-4 *Alphaproteobacteria* beside the *Sphingomonadaceae*. The dissection of the *Sphingomonadaceae* was supported by phenotypic and chemotaxonomic features including differences in the SGL composition, pigmentation, and content of BChl *a*. *Erythromonas*, *Erythromicrobium*,and *Prophyrobacter* are mainly orange to red in color and contain BChl *a*.

Members of the *Sphingomonadaceae* are Gram-negative, nonsporulating, rod-shaped bacteria differing in cell size. They are nonmotile or motile; if motile, it is most often by means of a polar flagella. Subpolar flagella or peritrichous flagella were also detected. Several species were motile only in the early exponential growth phase. *Sphingomonadaceae* are aerobic or partially facultative anaerobic chemoorganotrophs. Strains of the three genera *Blastomonas, Sandaracinobacter*, and *Sandarakinorhabdus* contain BChl *a* and are facultative prototrophs. BChl *a* was also detected in some strains of the species *Sphingomonas kaistensis* (Kim et al. 2007). Colonies of *Sphingomonadaceae* are most often yellow, but they may also be creamy, faint, or deep yellow; orange or brown-orange; red colored; or, rarely, uncolored. They contain carotenoids.

Sphingomonadaceae lack lipopolysaccharides in their outer membrane which are instead replaced by SGLs (Kawahara et al. 1991; Kawasaki et al. 1994). Beside the 16S rRNA gene sequence phylogeny, the presence of N-2′-hydroxymyristyl dihydrosphingosine 1-glucuronic acid (SGL-1) is the main commonly shared feature of all members of the family *Sphingomonadaceae*. Kosako et al. (2000) first determined SGL-1 in the alkaline stable lipid fraction using an acidic solvent system by type species of the genera *Sphingomonas*, *Erythrobacter*, *Erythromicrobium*, *Porphyrobacter*, and *Zymomonas* (Kosako et al. 2000). Two district SGL types were determined. The genera *Sphingomonas*, *Sphingobium*, *Novosphingobium*, *Sphingopyxis*, and *Zymomonas* contain monosaccharide type SGLs and one or more oligosaccharide-type SGLs, whereas the genera *Erythrobacter*, *Erythromicrobium*, and *Porphyrobacter* contain only monosaccharide-type GSLs. Those differences clearly supported the dissection of the *Sphingomonadaceae* and the proposal of the family *Erythrobacteraceae*.

Octadecenoic acid (C18:1) is the major fatty acid, 2-OH fatty acids of different chain lengths (mainly C14 to C16) occur, with genus specific differences in proportions; 3-hydroxy fatty acids are absence (the genus *Zymomonas* as exception). Further exceptions occur where minor to trace amounts of 3-OH fatty acid are detected. For example, minor amounts of 3-OH C13:0 were found in the fatty acid patterns of the type strains of *Novosphingobium stygium* and *Novosphingobium aromaticivorans* (Busse et al. 1999).

Members of the *Sphingomonadaceae* share ubiquinone-10 (Q-10) as the major respiratory quinone. Minor amounts of Q-9 and/or Q-8 were also detected in several type strains. The major polyamine is either *sym*-homospermidine or spermidine dependent of the investigated genus. The genera *Sphingomonas*, *Sphingosinicella*, and *Sphingomicrobium* contain *sym*-homospermidine as major polyamines; all other genera contain spermidine as the predominant polyamine. Only for the genus *Parasphingopyxis* are polyamines not detectable (Uchida et al. 2012). Polar lipid profiles are characterized by the presence of phosphatidylethanolamine (PE), phosphatidylglycerol (PG), diphosphatidylglycerol (DPG), and SGL in all members of the family. The majority of the *Sphingomonadaceae* also contain phosphatidylcholine (PC), phosphatidylmonomethylethanolamine (PME), and phosphatidyldimethylethanolamine (PDE). Several unidentified glycolipids (GL) and phospholipids (PL) are also present, which contribute significantly to the uniqueness of polar lipid profiles of different species (Busse et al. 1999). Quantitative and qualitative differences occurring between polar lipid profiles of different species can support the differentiation of species within the family.

The 16S rRNA gene signature pattern for the family, originally given by Kosako et al. (2000), is 105–116 (C-C), 433–422 (G-C), 750–754 (T-C), 855–858 (G-G), 1,334–1,336 (G-C) and 1,385 (G) (numbering according to *E. coli* numbering, Brosius et al. 1978). The G+C content of the genomic DNA is 59–68.5 mol% (expect: *Zymomonas mobilis*, 49.1 mol%).

Sphingoglycolipids

A characteristic feature for members of the *Sphingomonadaceae* is the content of SGLs. The presence of sphingolipids in eukaryotic and prokaryotic cells is well known; two main forms occur, sphingophospholipids and sphingoglycolipids. The central structure of sphingolipids is ceramide, which is composed of

sphingosine, a C18 amino alcohol with an unsaturated hydrocarbon chain, and a fatty acid. In SGLs, carbohydrates are linked to the alcoholic hydroxy base of sphingosine by a glycosidic bond. Sphingoglycolipids can be differentiated by the number (1–4) and kinds of linked carbohydrates (glucoronic acid, glucosamine, galactose, and mannose). Two novel SGLs were detected in *Sphingomonadaceae*, glucuronosyl-ceramide (SGL-1) (Yamamoto et al. 1978) and galacuturonosyl-ceramide (SGL-1′) (Naka et al. 2000). In *Sphingomonadaceae*, SGLs have an important physiological function because they replace lipopolysaccharides in the Gram-negative cell walls (Kawahara et al. 1991; Kawasaki et al. 1994). The localization of SGL-4 in the outer membrane of the type strain *Sphingomonas paucimobilis* was visualization by Gold-labeled immunoelectron microscopy. It was reported that SGLs can effect humans by stimulating phagocytosis and phagosome-lysosome fusion in human neutrophils and lead to the induction and release of monokine by SGL (reported for the type strain of *Sphingomonas paucimobilis*; Tahara and Kawazu 1994; Krziwon et al. 1995).

Detailed analysis of the GSL of the type strain of *Sphingomonas paucimobilis*, the type species of the type genus *Sphingomonas*, showed that *Sphingomonas paucimobilis* contains the monosaccharide-type SGL (SGL-1) commonly occurring in *Sphingomonadaceae* and additionally an oligosaccharide-type SGL, SGL-4A. SGL-4A was detected in the cell membranes of *Sphingomonas paucimobilis* IAM 12576^T, *Sphingomonas parapaucimobilis* JCM 7510^T, *Sphingomonas sanguinis* IFO 13937^T, and *Novosphingobium capuslatum*. Detailed analysis of the SGL composition was performed by Yabuuchi et al. (2002) for 22 *Sphingomonas* species, which were partially reclassified to the genera *Novosphingobium*, *Sphingobium*, and *Sphingopyxis*. Among those, only the type strains of *Sphingopyxis terrae*, *Sphingopyxis macrogoltabida*, *Sphingobium yanoikuyae*, and *Sphingomonas wittichii* contained SGL-1 (galacturonosyl ceramide) in their cellular lipids. A distinct phylogenetic relationship of those species, however, was not observed.

Carotenoids

Most of the *Sphingomonadaceae* are yellow or orange pigmented with several variations in color intensity, which is due to the relatively high content or carotenoids. The abundance and characteristics of carotenoids are often analyzed by absorption spectra measurements of acetone-extracted pigments resulting in comparable absorption peaks (λmax), which are specific for different carotenoids. More detailed analysis of the carotenoid composition by high-performance liquid chromatography analysis of extracted carotenoids was only done for few sphingomonads. Several carotenoids were thereby identified. The main found carotenoid in *Sphingomonadaceae* is nostoxanthin (Jenkins et al. 1979; Wu et al. 2011; Glaeser et al. 2009). Other carotenoids were found to be rather abundant in some species such as zeaxanthin in *Sphingomonas jaspsi* (Asker et al. 2007a) or astaxanthin in *Sphingomonas astaxanthinifaciens* (Asker et al. 2007b). Astaxanthin is a red carotenoid with a high antioxidative activity (Asker et al. 2009). Busse et al. (2003) investigated seven strains of orange-pigmented *Sphingomonas* species representing the genera *Sphingomonas aurantiaca*, *Sphingomonas aerolata*, and *Sphingomonas faeni*. The obtained absorption spectra were identical to those of several yellow pigmented species including *Sphingomonas paucimobilis*, the type species of the genus *Sphingomonas* (Jenkins et al. 1979). Polar lipid analysis, however, indicated the presence of several orange pigments present in the total lipid extract.

It was indicated recently that carotenoids may play an important role during the biodegradation of heterocyclic compounds (Liu et al. 2012), which is a metabolic feature shared by several species among the *Sphingomonadaceae*. Carotenoids can act as membrane-integrated antioxidants, changing the fluidity of membranes and protecting cells for oxidative stress. Oxidative stress occurs during the oxidative degradation of heterocyclic compounds because reactive oxygen species are formed within this process in the presence of molecular oxygen. Liu et al. (2012) showed that *Sphingobium yanoikuyae* XLDN2-5 enhances the synthesis of zeaxanthin if growing in the presence of heterocyclic compounds. In a similar manner, it is hypothesized that carotenoids may play an important role for the adaptation of *Novosphingobium acidiphilum* to the surface water of a humic lake because it is frequently exposed to reactive oxygen species, mainly singlet oxygen, during the photolysis of humic substances in the water column during sunlight exposure (Glaeser et al. 2010).

Dissection of Genus *Sphingomonas Sensu Lato* into Four Genera

The type genus *Sphingomonas* was proposed by Yabuuchi et al. (1990) based on five species (*S. adhaesiva*, *S. capsulatum*, *S. parapaucimobilis*, *S. paucimobilis* (type species), and *S. yanoikuyae*) as a genus of Gram-negative, rod-shaped bacteria that from yellow-pigmented colonies, harbor a strictly aerobic and chemoheterotrophic metabolism, and contain SGL-1. With the increasing number of described species and the transfer of *Blastomonas natatoria*, "*Erythromonas ursincola*", and "*Rhizomonas suberifaciens*" to the genus *Sphingomonas* (Yabuuchi et al. 1999) an increasing chemotaxonomic and phylogenetic heterogeneity was described. For example, *sym*-Homospermidine was given as a main polyamine only for a subgroup of *Sphingomonas* species, including *S. paucimonas*, *S. mali*, *S. pruni*, and *S. trueperi* (Kämpfer et al. 1997). Several authors described the formation of four specific subclusters by phylogenetic analysis based on 16S rRNA gene sequences (Stackebrandt et al. 1988; Takeuchi et al. 1994; Yurkov et al. 1997). Based on the formation of the four monophyletic clusters by 16S rRNA gene phylogeny, distinct polyamine pattern, differences in the content of 2-hydroxy fatty acids, and specific 16S rRNA gene sequence signature nucleotides, Takeuchi et al. (2001) proposed the subdivision of the genus *Sphingomonas*

Yabuuchi et al. (1990) into the genus *Sphingomonas sensu stricto*, including nine species (16S rRNA gene sequence cluster I) and three new genera—the genera *Sphingobium* (four species; cluster II), *Novosphingobium* (six species; cluster III), and *Sphingopyxis* (two species; cluster IV). The four clusters showed intracluster phylogenetic similarities of more than 95.8 % 16S rRNA gene sequence similarities but only 92.6–96.5 % intercluster sequence similarities. The differentiation of the clusters was supported by distinct pattern of signature nucleotides of the 16S rRNA gene sequences of the species within the separated cluster. All species shared C18:1 as major fatty acid followed by C16:0. Some considerable differences were obtained with respect to nonpolar fatty acids, but the differences could not be correlated with the distinction of the four clusters. However, distinct differences between the clusters were obtained with respect to the content of 2-hydroxyl fatty acids. The predominant 2-hydroxy fatty acids of members of the genus *Sphingomonas sensu stricto* (cluster I) were 2-OH C14:0 and/or 2-OH C15:0; for the genus *Sphingopyxis* (cluster IV), 2-OH C15:0 and/or 2-OH C16:0 were the predominant 2-OH fatty acids in addition to 2-OH C14:0. Species of the genera *Sphingobium* (cluster II) and *Novosphingobium* (cluster III) contained only 2-OH C14:0 as major 2-hydroxy fatty acids.

The species *Sphingomonas sensu stricto* could be clearly differentiated from the other three genera based on the polyamine pattern, with *sym*-homospermidine as the predominant polyamine for the genus *Sphingomonas sensu stricto* (cluster I), and spermidine for the other three genera. The dissection of the genus was supported by different physiological features. Later, Yabuuchi et al. (2002) proposed an emendation of the genus *Sphingomonas* (Yabuuchi et al. 1990) based on the argument that the dissection cannot be confirmed by clear physiological and biochemical characteristics, including cellular lipids and fatty acids. This proposal for emendation was not generally accepted. In several species descriptions, clear statements were given supporting the dissection of the genus *Sphingomonas sensu lato* into four genera. Busse et al. (2003) argued that the presence of *sym*-homospermidine as a clear distinctive chemotaxonomic feature was not considered by Yabuuchi et al. (1990, 2002), although it clearly supported the phylogenetic dissection of the genus *Sphingomonas sensu lato*. Therefore, these and several other authors proposed to retain the genus name *Sphingomonas* only for the members of cluster I as defined by Takeuchi et al. (2001). The overall acceptance of the dissection of the genus *Sphingomonas sensu lato* is illustrated by the proposal of 15 new *Sphingopyxis*, 16 *Novosphingobium*, and 28 *Sphingobium* species since 2002. The genera are also separately listed in the List of Prokaryotic Names with Standing in Nomenclature (LPSN, http://www.bacterio.net/; June 2013). Only the species of cluster I defined by Yabuuchi et al. (2001) remained in the species *Sphingomonas*, with 46 new species proposed since 2002. In this chapter, all species assigned to the genus *Sphingomonas sensu lato* (based on cluster I defined by Yabuuchi et al. 2001) will be treated as *Sphingomonas* species. All other species were treated as species of the genera *Novosphingobium*, *Sphingopyxis*, and *Sphingobium*, respectively.

Dissection of the Genus *Sphingopyxis* and Proposal of the Genus *Sphingorhabdus*

Just recently, the genus *Sphingopyxis* was further dissected by the proposal of the *genus Sphingorhabdus* (Jogler et al. 2013). Three species of the genus *Sphingopyxis*, *Sphingopyxis marina*, *Sphingopyxis litoris* (both Kim et al. 2008), and *Sphingopyxis flavimaris* (Yoon and Oh 2005) were thereby transferred to the genus *Sphingorhabdus* (Jogler et al. 2013) as *Sphingorhabdus marina*, *Sphingorhabdus litoris*, and *Sphingorhabdus flavimaris* (Jogler et al. 2013). The type species of the new genus is *Sphingorhabdus planktonica*. The new genus can be differentiated from the genus *Sphingopyxis sensu lato* by a clear separation based on the 16S rRNA gene sequence phylogeny (two monophyletic groups were formed) and differences in the G+C content, which was much lower for species of the genus *Sphingorhabdus* (52.6–57.8 mol%) compared to the species remaining in the genus *Sphingopyxis* (62.3–69.2 mol%). Furthermore, specific 16S rRNA gene sequence signature nucleotides were determined, which can distinguish the species of the two genera (Jogler et al. 2013).

History of the Proposal of the Species *Sandaracinobacter sibiricus*

Sandaracinobacter sibiricus was proposed by the reorganization of the genus *Erythromicrobium* (Yurkov et al. 1997). The type strain was originally described as the first obligately aerobic Bchl *a*-containing freshwater bacterium isolated from thin microbial mats near underwater hydrothermal vents of a river. The strain was assigned to the marine genus *Erythrobacter* (Shiba and Simidu 1982) as "*Erythrobacter sibiricus*" (Yurkov and Gorlenko 1990) based on the Bchl *a* content and the strict aerobiosis. Later on "*E. sibiricus*" was reclassified into the new genus *Erythromicrobium* that contained obligately aerobic anoxygenic photosynthetic bacteria from freshwater habitats (Yurkov and Gorlenko 1990; Yurkov et al. 1997). Beside differences in the 16S rRNA gene sequence phylogeny, differences in the carotenoid content, cell morphology and cell division, the photosynthetic reaction center and antenna complexes, differences in the ubiquinone content, and heterogeneity in DNA-DNA hybridization (DDH) and 5S rRNA sequences, "*Erythromicrobium sibiricus*" was dissected together with "*Erythromicrobium ursincola*" from the genus *Erythromicrobium*. Because the two species could be clearly differentiated from each other based on the 16S rRNA gene sequence phylogeny, two new genera were proposed and the two species were reclassified as *Sandaracinobacter sibiricus* and *Erythromonas ursincola*.

Comments on the Genera *Blastomonas* and *Erythromonas*

The genera *Blastomonas* (Sly and Cahill 1997) and *Erythromonas* (Yurkov et al. 1997) were proposed as single-species

genera. Despite the close phylogenetic relationship of the two type strains, Yurkov et al. (1997) proposed two distinct genera because of the differences in the photosynthetic properties between "*Erythromonas ursincola*" (formerly "*Erythromicrobium ursincola*") and *Blastomonas natatoria* (Sly 1985; Sly and Cahill 1997), "*Erythrobacter ursincola*" contains Bchl *a* incorporated in the photochemically active reaction center (RC) and one light harvesting complex. In *Blastomonas natatoria*,only carotenoids were detected but not BChl *a* (Yurkov et al. 1997). Based on the 16S rRNA gene sequence phylogeny and the presence of SGL in the cellular lipids, the two species *Blastomonas natatoria* and "*Erythromonas ursincola*" were then both transferred to the genus *Sphingomonas* as "*Sphingomonas natatoria*" (Sly 1985) and "*Sphingomonas ursincola*" (Yurkov et al. 1997) by Yabuuchi et al. (1999). Hiraishi et al. (2000) proposed to retain the reclassification by providing the evidence of photosynthetic properties in *Blastomonas natatoria*. The production of BChl *a* and the presence of structural genes of the type II photosynthetic reaction center (*pufM* and *pufL* genes) were proofed for both species, "*Sphingomonas natatoria*" and "*Sphingomonas ursincola*". At this time, no further photosynthetic active *Sphingomonas* species were described.

The two type strains also differ in other physiological properties, including colony color (orange- to red-colored colonies) and cell division properties (budding or asymmetric division as shown by electron microscopy). Because of the high 16S rRNA gene sequence similarity, the obtained common features regarding photosynthesis, and the fact that at that time photosynthesis genes were not determined in other *Sphingomonas* species, Hiraishi et al. (2000) emended the description of *Blastomonas natatoria* (Sly 1985) Yurkov et al. (1997) as an aerobic photosynthetic bacterium and thereby proposed the reclassification of "*Erythromonas ursincola*" to *Blastomonas ursincola*. Although both species shared a close phylogenetic relationship based on 16S rRNA gene sequence analysis and the same properties regarding photosynthesis, the species could be clearly differentiated by DDH and distinctive physiological properties. The name *Erythromonas* was changed to *Blastomonas* according to Rule 37a of the bacteriological code and the transfer of *Blastomonas natatoria* and "*Erythromonas ursincola*" (Yurkov et al. 1997) to the genus *Sphingomonas* proposed by Yabuuchi et al. (1999) was turned down (notes at LPSN; http://www.bacterio.net/b/blastomonas.html).

In the course of the recommendation to retain the genus *Sphingomonas sensu lato*, Yabuuchi et al. (2002) also suggested that the *Blastomonas* species should remain assigned to the genus *Sphingomonas*. The assignment of the two species is treated differently in the literature; for example, Kim et al. (2007) described the first additional *Sphingomonas* species, *Sphingomonas kaistensis*, containing pufML genes (amplified by polymerase chain reaction [PCR] using degenerated primers) and strain-dependent BChl *a* (not detected in the type strain). Phylogenetic analysis based on full-length 16S rRNA gene sequences provided in this chapter clearly shows that *Blastomonas natatoria* and *Blastomonas ursincola* form a separate branch distinct to species of the genus *Sphingomonas*. Therefore, the two species will be treated as *Blastomonas natatoria* and *Blastomonas ursincola*, as also listed in the LPSN database (http://www.bacterio.net/).

Molecular Analyses

Phylogeny of Type Strains of the Species

According to the 16S rRNA-based All-Species Living Tree (Release LTPs111, which contains all type strains of all species with validly published names up to August 2012), the family *Sphingomonadaceae* formed a monophyletic cluster within the Alphaproteobacteria. The *Sphingomonadaceae* branched together with the family *Erythrobacteraceae*, each forming two distinct monophyletic clusters. Based on this phylogenetic distinction, the dissection of the family *Sphingomonadaceae* and the proposal of the family *Erythrobacteraceae* were suggested previously by Lee et al. (2005), with the transfer of the three genera *Erythrobacter*, *Prophyrobacter*, and *Erythromicrobium* to the family *Erythrobacteraceae*. A phylogenetic tree including all type strains assigned to genera of the *Sphingomonadaceae* is provided in ❯ *Fig. 25.1*. The phylogenetic tree in ❯ *Fig. 25.1* clearly shows the distinction of species assigned to the four genera *Sphingomonas*, *Sphingobium*, *Sphingopyxis*, and *Novosphingobium*, which originate from the dissection of the genus *Sphingomonas sensu lato* based on the formation of four monophyletic clusters (clusters I to IV) proposed by Takeuchi et al. (2001).

Including all species assigned to the four genera since 2001, distinct monophyletic clusters were obtained for the genera *Sphingopyxis* and *Sphingobium*, harboring all of the species currently within the genera. Two species previously assigned to the genus *Sphingomonas*, "*Sphingomonas xenophaga*" (Stolz et al. 2000) and "*Sphingomonas taejonensis*" (Lee et al. 2001), were clustered either in the genus *Sphingopyxis* or *Sphingobium*. Their phylogenetic affiliation to the genera *Sphingopyxis* and *Sphingobium* was furthermore supported by spermidine as the major polyamine instead of *sym*-homospermidine. Therefore, the species were transferred to *Sphingobium xenophagum* and *Sphingopyxis taejonensis* by Pal et al. (2006). In a similar manner, the species *Sphingomonas suberfaciens* (Yabuuchi et al. 1999) (originally proposed as *Rhizomonas suberifaciens* van Bruggen et al. 1990; for more details, see above) was transferred to the genus *Sphingobium suberifaciens* by Chen et al. (2013). This species clusters together with the type strain of the newly proposed species *Sphingobium boeckii* (Chen et al. 2013) and shares spermidine as the predominant polyamine with species of the genus *Sphingobium* (Chen et al. 2013).

Within the monophyletic cluster of the genus *Sphingopyxis*, three separate branches or subclusters were formed. The first subcluster contained most of the *Sphingopyxis* species among those the type species *Sphingopyxis macrogoltabida*. Three species—*Sphingopyxis flavimaris* (Yoon and Oh 2005), *Sphingopyxis litoris*, and *Sphingopyxis marina* (both Kim et al. 2008)—formed

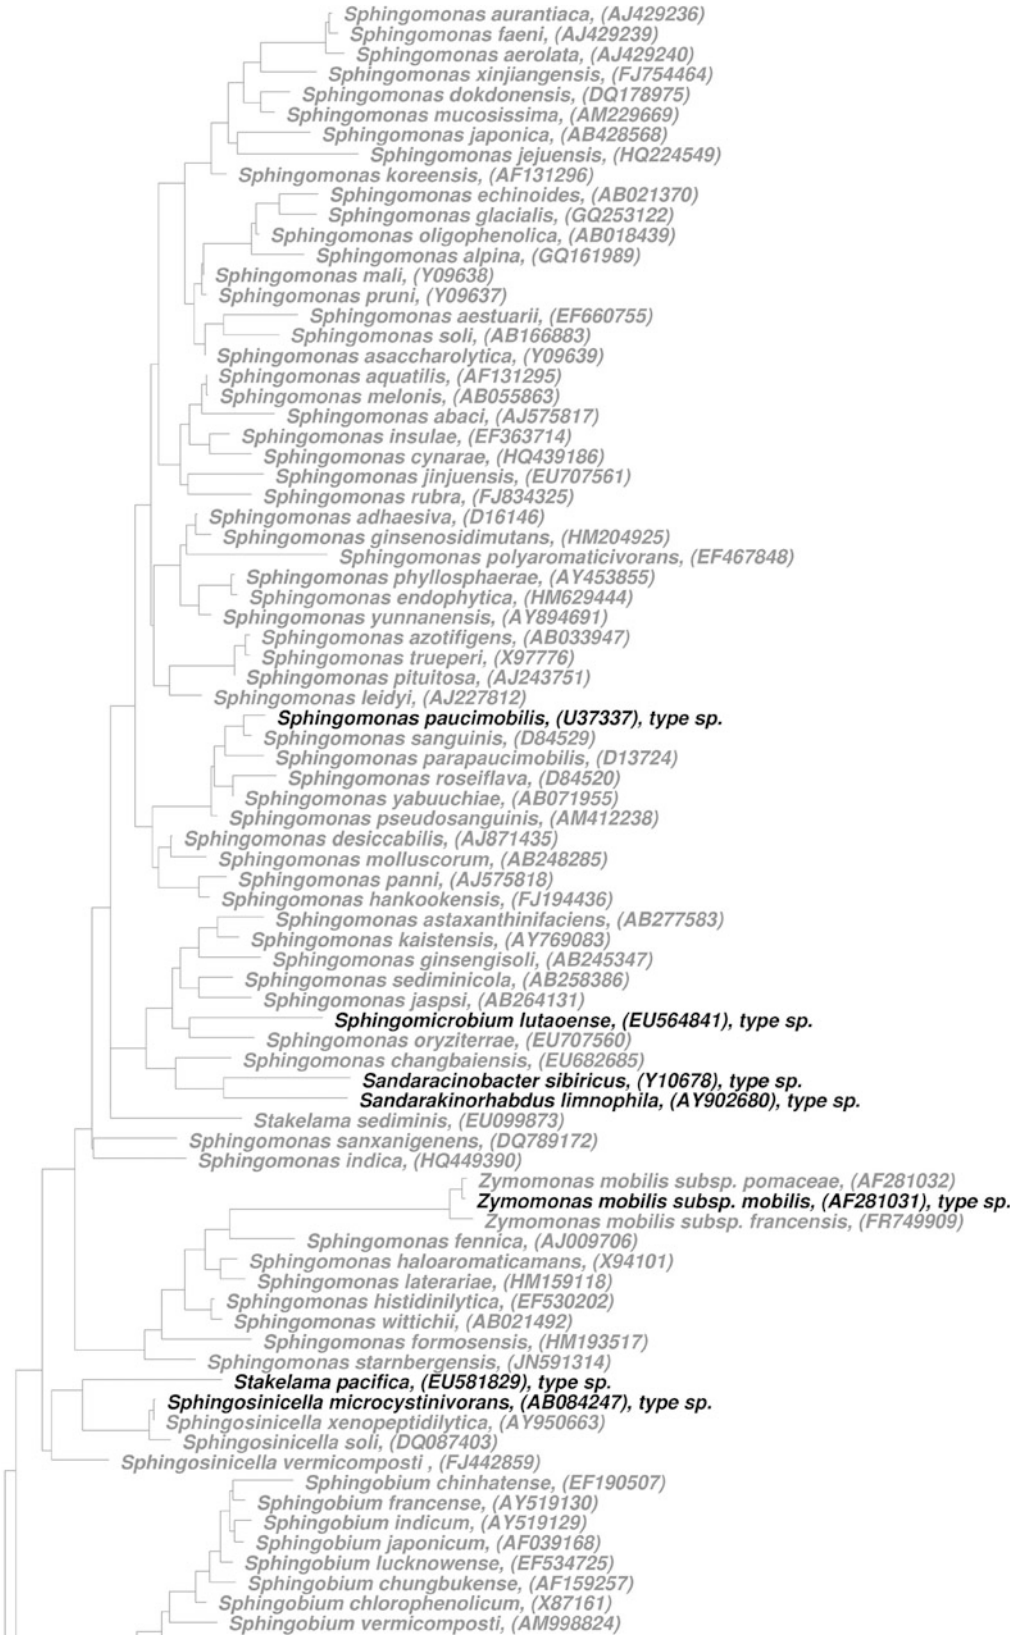

Fig. 25.1 (Continued)

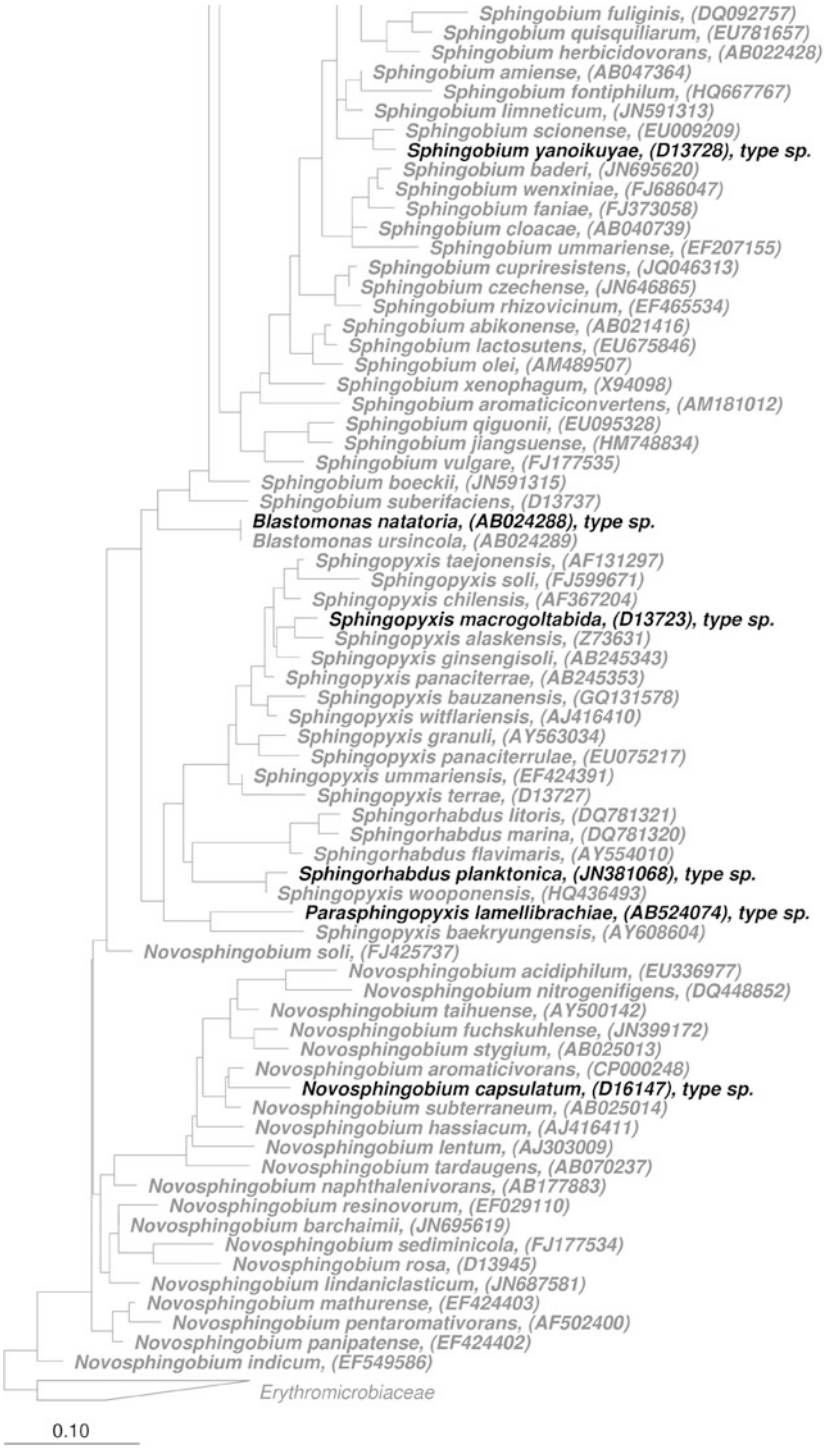

Fig. 25.1

Phylogenetic reconstruction of the family *Sphingomonadaceae* based on 16S rRNA gene sequences and created using the maximum likelihood algorithm RAxML (Stamatakis 2006). The sequence datasets and alignments were used according to the All-Species Living Tree Project database (Yarza et al. 2008; http://www.arb-silva.de/projects/living-tree). Representative sequences from closely related taxa were used as outgroups. Scale bar indicates estimated sequence divergence. In all, the tree includes 61 *Sphingomonas*, 34 *Sphingobium*, 22 *Novosphingobium*, 15 *Sphingopyxis*, 4 *Sphingosinicella*, 4 *Sphingorhabdus* species, 2 *Blastomonas*, 2 Stakelama, 1 *Sandaracinobacter*, 1 *Sandarakinorhabdus*, 1 *Sphingomicrobium*, and 1 *Parasphingopyxis* species. Furthermore, three subspecies of the genus *Zymomonas* are included. The three new species of the genus *Sphingomicrobium*—*Sphingomicrobium astaxanthinifaciens* (Shahina et al. 2013a), *Sphingomicrobium flavum*, and *Sphingomicrobium marinum* (Shahina et al. 2013b)—were not yet considered in the tree

the second subcluster. Just recently, Jogler et al. (2013) investigated a new strain, which clustered into the second subcluster. Base on the phylogenetic distinction of this subcluster and distinct differences in the G+C content of type strains assigned to the different subclusters, Jogler et al. (2013) suggested the dissection of the genus *Sphingopyxis* and proposed the genus *Sphingorhabdus* with the type species *Sphingorhabdus planktonica*. The three *Sphingopyxis* species of the second subcluster were reclassified as *Sphingorhabdus flavimaris*, *Sphingorhabdus marina*, and *Sphingorhabdus litoris*. The G+C content of species remaining in the genus *Sphingopyxis* ranged from 62.3 mol% to 69.2 mol%, whereas the G+C content of species assigned to the genus *Sphingorhabdus* were lower, ranging from 52.6 mol% to 57.8 mol%. The dissection of the genus *Sphingopyxis* was furthermore supported by distinct signature nucleotides of the 16S rRNA gene, which were shared by either the *Sphingopyxis* or *Sphingorhabdus* species. At the same time as the genera were dissected, two new *Sphingopyxis* species were proposed, *Sphingopyxis wooponensis* and *Sphingopyxis rigui* (Baik et al. 2013), which also showed a low G+C content (53.3 mol% and 53.7 mol%, respectively), as the *Sphingopyxis* species transferred to the genus *Sphingorhabdus*. The phylogenetic analysis provided in ❯ *Fig. 25.1* showed that the two species were placed phylogenetically within the new genus *Sphingorhabdus*. Together with the fact that those two species also shared the low G+C content with the species of the genus *Sphingorhabdus*, a reclassification of the two species is necessary.

One species of the genus *Sphingopyxis*, *Sphingopyxis baekryungensis*, branched separately from the two subclusters formed by other species of the genus *Sphingopyxis* and the genus *Sphingorhabdus*. The species was originally proposed as a *Sphingopyxis* species because the phylogenetic analysis in the proposal indicated its closest relationship to *Sphingorhabdus flavimaris* (formerly "*Sphingopyxis flavimaris*") (Yoon et al. 2005). The phylogenetic tree provided here (❯ *Fig. 25.1*) showed that *Sphingopyxis baekryungensis* formed a third subcluster within the original monophyletic *Sphingopyxis* cluster, together with the type strain of *Parasphingopyxis lamellibrachiae* (Uchida et al. 2012). A distinctive feature of the genus *Parasphingopyxis lamellibrachiae* compared to other *Sphingomonadaceae* is that no polyamines could be detected (Uchida et al. 2012). Polyamines were not analyzed for *Sphingopyxis baekryungensis* so far (Yoon et al. 2005). The genomic G+C content of both species is in the same range with 63 % and 60.1 % for *Sphingopyxis baekryungensis* and *Parasphingopyxis lamellibrachiae*, respectively (Yoon et al. 2005; Uchida et al. 2012). Further studies are necessary to clarify the phylogenetic position of *Sphingopyxis baekryungensis*.

At the time of writing, the genus *Novosphingobium* contained 23 species with validly published names. In contrast to the genera *Sphingopyxis* and *Sphingobium*, species of the genus *Novosphingobium* are not placed into a single monophyletic cluster. The original cluster of the genus *Novosphingobium* (cluster III; Takeuchi et al. 2001) only contains the type species *Novosphingobium capsulatum* and the originally proposed *Novosphingobium* species, *N. subarcticum*, *N. stygium*, *N. subterraneum*, and *N. aromaticivorans*,and some of the *Novosphingbium* species proposed after 2001, including *N. acidiphilum*, *N. hassiacum*, *N. tardaugens*, *N. nitrogenifigens*, and *N. lentum*. A few *Novosphingobium* species are only loosely associated with this original cluster III (Takeuchi et al. 2001). *Novosphingobium rosa* (originally proposed as "*Sphingomonas rosa*") and *N. sediminicola* are clustered separately from the other *Novosphingobium* species; in the same manner, the species *N. naphtalenivorans*, *N. resinovorum*, *N. panipatense*, *N. mathurense*, and *N. pentaromaticivorans* are also clustered separately.

The type genus *Sphingomonas* represents the largest genus of the *Sphingomonadaceae*, currently including 61 species (without considering "*S. natatoria*" and "*S. ursinicola*"). All species are clustered together, expanding the original cluster as defined by Takeuchi et al. (2001). The genus is paraphyletic, forming different subclusters between those branches where the genera *Sphingomicrobium*, *Sandaracinobacter*,and *Sandarakinorhabdus* are placed (❯ *Fig. 25.1*). The type strain of *Sphingomicrobium lutaoense* (Kämpfer et al. 2012) is clustered closest to *Sphingomonas oryziterra* (Chung et al. 2011) in a cluster separate from the main *Sphingomonas* cluster, together with *Sphingomonas astaraxanthinifaciens*, *Sphingomonas kaistensis*, *Sphingomonas gingengisoli*, *Sphingomonas sediminicola*, and *Sphingomonas jaspi*. In the original proposal of *Sphingomicrobium lutaoense*, a neighbor joining tree that only included species which shared more than 93.5 % 16S rRNA gene sequence similarities to the new species. The tree indicated a separate branching of *Sphingomicrobium lutaoense*. Phylogenetic analysis including all currently proposed *Sphingomonadaceae* and the phylogenetic analysis based on the maximum likelihood methods using the RAxML algorithm (❯ *Fig. 25.1*) did not support this distinct branching, but placed the species in a separate branch into the *Sphingomonas* cluster. Furthermore, the genus *Sphingomicrobium* shared *sym*-homospermidine as major polyamine as common chemotaxonomic feature with the genus *Sphingomonas*. However, the type strain of *Sphingomicrobium lutaoense* showed only a low 16S rRNA gene sequence similarity to species of the genera *Sphingomonas*, *Sphingopyxis*, and *Sphingosinicella* (<95.5 %; Kämpfer et al. 2012) and showed clear differences regarding the cellular fatty acid pattern with respect to 2-hydroxy fatty acids. High amounts of 2-OH C18:1 were detected, unlike in other Sphingomonadaceae. Furthermore, C14 to C16 2-OH fatty acids were not present in *Sphingomicrobium lutaoense*.

Recently, three new *Sphingomicrobium* species were proposed—*Sphingomicrobium astaxanthinifaciens* (Shahina et al. 2013a), *Sphingomicrobium marinum*, and *Sphingomicrobium flavum* (Shahina et al. 2013b), which form a distinct cluster with *Sphingomicrobium lutaoense* (Shahina et al. 2013b). They share the specific pattern of 2-OH fatty acids and the absence of phosphatidylmonomethylethanolamine (PME) and phosphatidyldimethylethanolamine (PDE) in the polar lipid profiles (see below) with *Sphingomicrobium lutaoense*, supporting the differentiation of the genus *Sphingomicrobium* from other genera of

the *Sphingomonadaceae*, including the genus *Sphingomonas*. The two single species genera *Sandarakinobacter* and *Sandarakinorhabdus* are clustered together with *Sphingomonas changbaiensis* (Zhang et al. 2010b) as a separate branch in the cluster containing *Sphingomicrobium lutaoense* and the six above-listed *Sphingomonas* species (Fig. 25.1).

An additional species that was first assigned to another family but phylogenetically placed within the *Sphingomonas* cluster was *Caulobacter leidyi*. The species was originally assigned to the genus *Caulobacter* (*Caulobacteraceae*) and was described as "*Caulobacter leidyi*" (Poindexter 1964) because of its morphological properties (dimorphic prosthecate cell structures) that are common for *Caulobacter* species. Subsequent 16S rRNA gene sequence analysis revealed that this strain is phylogenetically placed within the *Sphingomonadaceae* (Stahl et al. 1992; Garrity et al. 2005). As a consequence, "*Caulobacter leidyi*" was excluded from the genus *Caulobacter*, omitted from *Bergey's Manual of Systematic Bacteriology*, and moved to limbo (Garrity et al. 2005).

Chen et al. (2012a) performed a detailed genotypic and phenotypic analysis of the type strain of *Caulobacter leidyi* and a new freshwater strain that shared high 16S rRNA gene sequence similarity (99.6 %) and DDH relatedness (82.9 %). The two strains shared high 16S rRNA gene sequence similarity with the type strain of *Sphingomonas aquatilis*—which, however, represents another separate species (DDH values <70 %). "*Caulobacter leidyi*" and the new freshwater strain shared *sym*-homospermidine as the major polyamine, main fatty acids, and predominant polar lipids with the genus *Sphingomonas* (Jogler et al. 2013). As a consequence, the species "*Caulobacter leidyi*" was transferred to the genus *Sphingomonas* as *Sphingomonas leidyi* (Chen et al. 2012a). After the reclassification of "*Caulobacter leidyi*," another prosthecate *Sphingomonas* species was proposed, *Sphingomonas canadensis* (Abraham et al. 2013). This species shared 97.2 % with *Sphingomonas oligophenolica* S213^T (=DSM 17107^T) and 97.0 % with *Sphingomonas leidyi* DSM 4733^T. Low DDH values (10.3 % and 23.3 %) to *Sphingomonas oligophenolica* and *Sphingomonas leidyi* clearly indicate that the new strain represents a separate species.

The two species *Blastomonas natatoria* and *Blastomonas ursincola*, representing the genus *Blastomonas*, form a separate branch distinct to other genera of the *Sphingomonadaceae* (Fig. 25.1). This clearly supports the emendation of the genus *Blastomonas* and the transfer of "*Erythrobacter ursincola*" to the genus *Blastomonas* proposed by Hiraishi et al. (2000), which overturned the reclassification of the two species to the genus *Sphingomonas* (Yabuuchi et al. 1999), as previously discussed. A clearly separated monophyletic branch within the *Sphingomonadaceae* is formed by the genus *Sphingosinicella*, including all type strains of the four proposed species (Fig. 25.1).

The genus *Stakelama* contains two species, *Stakelama pacifica* (Chen et al. 2010) and *Stakelama sediminis* (Thawng et al. 2013). The type strains of the two species shared only 95.7 % 16S rRNA gene sequence similarity but formed a distinct cluster in the 16S rRNA gene sequence-based phylogenetic analysis provided by Thawng et al. (2013). This clustering was one of the main criteria for the assignment of the second species to the genus *Stakelama* (Thawng et al. 2013). 16S rRNA gene sequence analysis based on the neighbor-joining methods performed here confirmed the clustering of the two species if all *Sphingomonadaceae* type strains were considered (analogous to the analysis in Fig. 25.1; data not shown). However, if the maximum likelihood method was applied (Fig. 25.1), the two species would be distinctly-branched from each other. Tindall et al. (2010) recommended that the neighbor-joining method should not be applied for final phylogenetic analysis because this case is not an exception where a new strain was assigned to a specific genus or where a new genus was proposed based on a phylogenetic analysis performed with the neighbor-joining method.

The genus *Zymomonas* was originally assigned to *Sphingomonadaceae* based on the 16S rRNA gene sequences phylogeny (Balkwill et al. 1997), but it shows distinct differences in G+C content (with much lower values of 47.5–49.5 mol%) and different metabolic properties (anaerobic metabolism) compared to all other members of the family. The genus *Zymomonas* is represented by only one species, *Zymomonas mobilis*, which is divided into three subspecies: *Zymomonas mobilis* subsp. *mobilis* (De Ley and Swings 1976), *Zymomonas mobilis* subsp. *pomaceae* (De Ley and Swings 1976), and *Zymomonas mobilis* subsp. *francensis* (Coton et al. 2006). The three subspecies form a separate branch in the 16S rRNA gene sequence phylogeny (see Fig. 25.1), which is loosely associated with a cluster of *Sphingomonas* species separated from the main *Sphingomonas* cluster, including *Sphingomonas fennica, Sphingomonas haloaromaticamans* (both Wittich et al. 2007), *Sphingomonas laterariae* (Kaur et al. 2012), *Sphingomonas histidinilytica* (Nigam et al. 2010), *Sphingomonas wittichii* (Yabuuchi et al. 2001), *Sphingomonas formosensis* (Lin et al. 2012), and *Sphingomonas starnbergensis* (Chen et al. 2012b). The 16S rRNA gene sequence of *Zymomonas mobilis* subsp. *francensis* was just recently published within the framework of the Sequencing Orphan Species project (Yarza et al. 2013); it is included in phylogenetic tree shown in Fig. 25.1

DNA-DNA Hybridization Studies

Nearly all descriptions of *Sphingomonas*, *Novosphingobium*, *Sphingopyxis*, and *Sphingobium* species included DDH analysis of the investigated strains and closest related type stains—mainly those that shared more than 97 % 16S rRNA gene sequence similarity.

Within the genus *Sphingomonas*, most of the species were rather distantly related, as indicated by low DDH values that were most often between 10 % and 30 %, such as between *Sphingomonas dokdonensis* and six related species (9–17 % similarity; Yoon et al. 2006), between *Sphingomonas hankookensis* and four related species (15–28 %; Yoon et al. 2009),

Sphingomonas ginsenosidimutans and four related species (8–28 %, Choi et al. 2010a), *Sphingomonas alpina* and two related species (Margesin et al. 2012), and *Sphingomonas panni* and three related species (18–24 %; Busse et al. 2005). Only a few species showed a closer relationship (>40 % DDH similarity). Five *Sphingomonas* species—*S. paucimobilis*, *S. sanguinis*, *S. pseudosanguinis*, *S. parapaucimobilis*, and *S. yabuuchiae*—form a distinct cluster based on 16S rRNA gene sequence analysis and share DDH similarities between 39.6 % and 51.9 % (Kämpfer et al. 2007; Li et al. 2004). An exception is *Sphingomonas roseiflava*, which also clusters with those species based on 16S rRNA gene sequence phylogeny but shows much lower similarity values based on the genomic level (e.g., 24.4 % DDH similarity to *S. yabuuchiae*; Li et al. 2004). In a similar manner, the species *Sphingomonas endophytica*, *S. phyllosphaerae*, *S. yunnanensis*,and *S. rubra* cluster together based on 16S rRNA gene sequence phylogeny and show high DDH relatedness (37.9–59 %, Huo et al. 2011; Huang et al. 2012). As exception, *Sphingomonas abaci* shared only 12–19 % and 17 % DDH similarity with *Sphingomonas melonis* and *Sphingomonas aquatilis* (Busse et al. 2005); however, the species also clusters together with those species, showing the high genomic relatedness.

Genomic relationships among species of the genus *Sphingopyxis* varied from very low relationships with DDH values below 10 % (e.g. for *Sphingopyxis panaciterrulae* and *Sphingophyxis macrogoltabida*; Srinivasan et al. 2010) to high relationships with values of up to 50 % (e.g. for *Sphingopyxis chilensis* and *Sphingopyxis alaskensis*; Godoy et al. 2003). Most of the genomic relatedness values between *Sphingopyxis* species (obtained by DDH analysis) were in the range of 30–39 %. In a similar manner, DDH values for the genus *Novosphingobium* ranged from 8.5 % between *Novosphingobium maturense* and *Novosphingobium panipatense* (Gupta et al. 2009) to 55.2 % for *Novosphingobium hassiacum* and *Novosphingobium capsulatum* (Kämpfer et al. 2002a). Approximately the same range of DDH values was obtained for the genus *Sphingobium*, in which several closely related species shared a relatively low DDH relatedness (7–20 %), but most of the species shared a higher genomic relatedness between 30 % and 59 %. *Sphingobium* species with relative high DNA-DNA relatedness include *Sphingobium cupriresistens* and *Sphingobium rhizovicinum* (57.2 ± 0.6 %; Li et al. 2013) and *Sphingobium francense* and *Sphingobium chinhatense* (54 %; Dadhwal et al. 2009).

Only a few species were proposed based on more than one representative strain. The DDH relatedness among strains within a species ranged from only 67.7 to >100 %. The two strains of *Sphingomonas aurantiaca* shared 81–118 % DNA relatedness (DDH analysis); the two strain of *Sphingomonas aerolata* (Busse et al. 2003) shared 71–107 %; and the strains of the species *Sphingomonas azotifigens* (Xie and Yokota 2006) shared 78.9 –80.6 %. Intraspecies DDH values were lower for three strains of *Sphingomonas kaistensis* (67.7–73.1 %; Kim et al. 2007). DDH values of five *Sphingopyxis alaskensis* strains were between 89 % and 100 % (Godoy et al. 2003); between two strains of *Sphingomonas leidyi* 82.9 % (Chen et al. 2012a); between two strains of *Novosphingobium hassiacum* 86 % (Kämpfer et al. 2002a); and between two strains of *Sphingobium xenophagum* were 70.7 % (Stolz et al. 2000). In parallel-performed genomic fingerprint analyses, such as repetitive extragenic palindromic (rep)-PCRs as BOX-PCRs (derived from the boxA element), clearly showed genomic differences indicating that the investigated strains are different strains assigned to the same species. Clonality of the investigated strains was thereby excluded when different genomic fingerprint patterns were obtained.

A DDH value of 100 % between *Novosphingobium resinovorum* NCIMB 8767^T and *Novosphingobium subarcticum* KCTC 2890^T indicated that both type strains represent the same species. Therefore, *Novosphingobium subarcticum* (Nohynek et al. 1996; Takeuchi et al. 2001) was assigned as a later heterotypic synonym of *Novosphingobium resinovorum* ("*Flavobacterium resinovorum*" Delaporte and Daste 1956) (Lim et al. 2007).

DDH analysis clearly demonstrated the high relationship but also distinction of the type strains of *Blastomonas natatoria* and *Blastomonas ursincola*. The values were 54–68 % or 31–47 %, depending on the used hybridization temperature—42 °C and 44 °C, respectively (Hiraishi et al. 2000). In contrast, the two species showed very low DDH relatedness (2–5 %) to type species in the closest related genera, including *Sphingomonas paucimobilis*, *Erythromicrobium ramosum*, and *Prophysobacter neustonensis*, supporting the distinction of the genus *Blastomonas*. However, further genera and further species of the genus *Sphingomonas* were not included in the analysis.

DDH analysis was not applied for the single species genera *Sandaracinobacter*, *Sandarakinorhabdus*, and *Parasphingopyxis*, because 16S rRNA gene sequence similarities were clearly below 97 % for the closest related type strains of the neighboring genera.

For the genus *Sphingorhabdus* (Jogler et al. 2013), DDH values are available for the reclassified former *Sphingopyxis* species, *Sphingorhabdus marina*, *Sphingorhabdus litoralis*, and *Sphingorhabdus flavimaris*, which ranged from 20.7 % to 36.6 % (Kim et al. 2008).

For species of the genus *Sphingosinicella*, DDH analysis for *Sphingosinicella xenopeptidilytica* and *Sphingosinicella microcystinivorans* (Geueke et al. 2007) showed a relatively high genomic relatedness of 40.6 % (reciprocal, 51.9 %). *Sphingosinicella soli* showed much lower DNA relatedness to those two species, of only 27 % and 25 %, respectively (Yoon et al. 2008). Geueke et al. (2007) showed that DDH data are strongly affected by the applied method, with the microtiter plate method of Ziemke et al. (1998) resulting in much higher values (40.6, 51.9 %) compared to other standard methods used for DDH (33 %).

MLSA

Phylogenetic analyses provided for members of the family *Sphingomonadaceae* is thus far only based on 16S rRNA gene sequence data. Single or multilocus sequence analysis (MLSA) based on protein coding (housekeeping) genes has not been

applied to investigate the phylogenetic resolution between species and genera within the *Sphingomonadaceae* for taxonomic purposes.

Only *Zymomonas mobilis* subspecies were comparatively analyzed based on additional genes beside the 16S rRNA gene sequence analysis, including the 16S–23S rRNA gene intergenic spacer region (ISR) and two housekeeping genes, *hsp60*, encoding the 60-kDa heatshock protein (Hsp60) and *gyrB*, encoding the B subunit protein of the DNA gyrase (Coton et al. 2006). A total of three, four, and six strains were investigated for *Z. mobilis* subsp. *mobilis*, Z. *mobilis* subsp. *pomaceae*, and *Z. mobilis* subsp. *francensis*, respectively. Phylogenetic trees calculated based on ISR sequences (604–617 bp) and partial sequences of *hsp60* (592 bp) and *gyrB* (1,044 bp) clearly showed the formation of three distinct groups formed by the investigated strains of each subspecies. Groups representing strains of subspecies *Z. mobilis* subsp. *mobilis* and *Z. mobilis* subsp. *francensis* always clustered closer together, and the group of *Z. mobilis* subsp. *pomaceae* strains was more distantly related to those (Coton et al. 2006). This relationship was confirmed by the respective sequence similarities. Strains of *Z. mobilis* subsp. *francensis* shared 94 % ISR sequence similarity with strains of *Z. mobilis* subsp. *mobilis* but only 87 % with strains of *Z. mobilis* subsp. *pomaceae*. In a similar manner, 90 % similarity was obtained for strains of *Z. mobilis* subsp. *mobilis*, but only 84 % for strains of *Z. mobilis* subsp. *pomaceae* if partial *hsp60* sequences were investigated and 86 % similarity versus 80 % similarity if partial *gryB* sequences were investigated. Whole-cell protein analysis using sodium dodecyl sulfate polyacrylamide gel electrophoresis protein profiling, random amplified polymorphic DNA (RAPD)-PCR and rep-PCR genotyping confirmed the formation of distinct groups separating the three subspecies (Coton et al. 2006).

In an environmental study, Vaz-Moreira et al. (2011) analysed in addition to the 16S rRNA gene sequence-based phylogeny partial nucleotide sequence of the housekeeping gene *atpD* (encoding the beta subunit of membrane ATP synthase) to assign environmental isolates more precisely into the genera *Sphingomonas*, *Sphingopyxis*, *Novosphingobium*, *Sphingobium*, and *Blastomonas*. Thereby, the *atpD*-based phylogeny supported the 16S rRNA gene sequence-based phylogeny.

DNA Pattern, Ribotyping

Nucleic acid fingerprinting methods provide a resolution at the subspecies and/or strain level (Tindall et al. 2010). Techniques generating genomic DNA patterns were successfully applied for members of the *Sphingomonadaceae*, including RAPD-PCR and different repetitive element primed PCR techniques, directed to highly conserved, repetitive DNA sequences distributed in multiple copies over a genome. Successfully applied PCR methods were rep-PCR, enterobacterial repetitive intergenic consensus sequences (ERIC)-PCR, BOX-PCR, $(GTG)_5$-PCR, and Salmonella Enteritidis Repetitive Element (SERE-PCR; Louws et al. 1994; Versalovic et al. 1994; Rademaker et al. 1998; Rajashekara et al. 1998). The application of those methods in different studies of *Sphingomonadaceae* species proposals showed diverse fingerprint patterns, which allowed a good differentiation of strains within a single species and closely related species. For example, Busse et al. (2003) successfully applied two rep-PCR fingerprint methods, ERIC and BOX-PCRs, to differentiate three *Sphingomonas aurantiaca* strains, three *Sphingomonas aerolata* strains, and the type strain of *Sphingomonas faeni*,which all shared 99.3–100.0 % 16S rRNA gene sequence similarity (Busse et al. 2003). In the same manner, ERIC-PCR (Busse et al. 2005) and BOX-PCR (Balkwill et al. 1997; Yuan et al. 2009) were applied for other *Sphingomonas* and *Novosphingobium* species, respectively. Rivas et al. (2004) applied a two-primer RAPD fingerprinting for the differentiation of *Sphingomonas phyllosphaerae* strains and five rep-PCR methods, including BOX-, ERIC-, REP-, $(GTG)_5$, and SERE-PCR, were applied for the genus *Sphingosinicella* to support the differentiation of type strains of *Sphingosinicella* species (Geueke et al. 2007; Yoon et al. 2008).

RAPD-PCR and rep-PCRs including ERIC- and BOX-PCRs were also used to differentiate strains belonging to the three subspecies of the genus *Zymomonas*. Strains representing the three subspecies were clearly separated in three different groups by subsequent cluster analysis (Coton et al. 2006).

Riboprinting

Riboprinting was established as a tool for a rapid preliminary identification of sphingomonads by Busse et al. (2000). A riboprinting pattern of a strain was obtained after genomic DNA was restricted with the restriction enzyme EcoRI; the DNA fragments were separated on an agarose gel, transferred to a nylon membrane, and hybridized with phosphorescently tagged *E. coli* rrnB operon. In the study by Busse et al. (2000), a total of 43 sphingomonads were analysed. Most of the investigated type strains showed characteristic complex banding patterns. Bands appeared in the range of 1.1–48 kb and a strong band in the area of 3.5–3.9 kb. A single strong band in the range of 2.4–2.7 kb was obtained for *Sphingobium yanoikuyae* DSM 6900, *Sphingopyxis macrogoltabidus* IFO 15033^T, and *Sphingopyxis terrae* IFO 15098^T. For *Z. mobilis*,a strong band was obtained in the area of 1.1 kb. No bands were obtained for *Sphingobium suberifaciens* DSM 7465^T and *Sphingomonas witiichii* RW1^T except in the area of 48 kb. This suggests that the DNA of those two strains was not digested by EcoR1.

Ribotype patterns enabled all 40 species to be distinguished in the study by Busse et al. (2000). A high degree of riboprinting similarities were only observed among strains of the same species, such as *Sphingobium yanoikuyae*, *Novosphingobium aromaticivorans*, *Novosphingobium subarcticum*, and *Sphingomonas chlorophenolica*. However, strains of very closely

related species could clearly be differentiated, such as type strains of the species *Sphingomonas asaccharolytica*, *Sphingomonas mali*, and *Sphingomonas pruni*. Differentiation was possible by computer-based cluster analysis but also by visual analysis. Riboprinting was applied for the comparative analysis of the three closely related *Sphingomonas* species, *Sphingomonas aurantiaca* (3 strains), *Sphingomonas aerolata* (3 strains), and *Sphingomonas faeni* (1 strain), which shared 99.3–100.0 % 16S rRNA gene sequence similarity (Busse et al. 2003). A high degree of similarity in the riboprints was only observed for strains that represent the same species (>63 % and 76 %) but no significant similarities (<54 %) were detected between riboprints of strains from different species (supported by DDH analysis). Ribotyping was also applied by Koskinen et al. (2000) to characterize 38 sphingomonad strains isolated from biofilms in drinking water distribution systems. Two different restriction endonucleases, EcoRI and PvuII, were used for the analysis in this study. Riboprints obtained for isolated strains were compared with those of reference strains to assign the respective isolates to the species.

MALDI-TOF Analysis

Matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF MS) is generally not applied for the differentiation of species within the *Sphingomonadaceae*. Hotta et al. (2012) established a MALDI-TOF MS method using ribosomal subunit proteins coded in the S10-spc-alpha operon as biomarkers for the classification of environmental Sphingomonadaceae (S10GERM method). A total of nine ribosomal subunit proteins coded in the S10 and spc operons, L18, L22, L24, L29, L30, S08, S14, S17, and S19, were commonly detectable subunits by MALDI-TOF MS analysis of *Sphingomonadaceae* references. Sequence analysis of the S10 and spc operons from type strains of the genera *Sphingomonas*, *Sphingopyxis*, *Sphingobium*, and *Novosphingobium* confirmed the localization of the respective ribosomal proteins in this operon. A phylogenetic tree based on respective amino acids showed mainly the same phylogenetic relationships as what was obtained by 16S rRNA gene sequence analysis. However, a higher resolution was obtained by the S10Germ method among closely related strains.

Genomic and Phenetic Properties of the Taxa

Genome Structure, Genome Architecture, Number of Chromosomes, Genes, Plasmids, Integrons, Genomic Islands

In the integrated microbial genome database of the Joint Genome Institute or the National Center for Biotechnology Information (NCBI) genome database, currently 30 genomes represent strains assigned to the family *Sphingomonadaceae*. These genomes include several type strains, including three *Sphingomonas* species (*Sphingomonas melonis* DAPP-PG 224^T, *Sphingomonas phyllosphaerae* FA2^T, and *Sphingomonas wittichii* RW1^T), four *Novosphingobium* species (*Novosphingobium acidiphilum* DSM 19966^T, *Novosphingobium aromaticivorans* DSM 12444^T, *Novosphingobium nitrogenifigens* DSM 19370^T, and *Novosphingobium pentaromativorans* US6-1, DSM 17173^T), two *Sphingobium* species (*Sphingobium chlorophenolicum* L-1^T and *Sphingobium japonicum* UT26S^T), two *Sphingophyxis* species (*Sphingopyxis alaskensis* RB2256^T and *Sphingopyxis baekryungensis* DSM 16222^T), and *Sandarakinorhabdus limnophila* DSM 17366^T, as well as two *Zymomonas* subspecies (*Zymomonas mobilis* subspecies *mobilis* T.H.Delft 1, ATCC 10988^T and *Zymomonas mobilis* subspecies *pomaceae* Barker 1, ATCC 29192^T). The size of the genomes including draft genome data range from 2.6 to 5.9 Mbp, with a G+C content between 57 % and 68 % (Table 25.1). Exceptions are the genomes of *Zymomonas mobilis* strains, with a G+C content between 46 % and 51 %. The genomes contain one or two chromosomes and one to five plasmids of different sizes (Table 25.1). Many sphingomonads are able to degrade xenobiotic and recalcitrant (in particular, aromatic) compounds.

Genes involved in degradation pathways are often encoded on large plasmids with a size of 50–500 kb (Basta et al. 2004), but partially respective genes are also encoded on chromosomes. Evidence for horizontal gene transfer is given for several genomes (see below). Currently sequenced sphingomonads were mainly selected to investigate their specific metabolic features (e.g. degradation pathways) or were sequenced within the framework of the Genomic Encyclopedia of Bacteria and Achaea (GEBA) project (Wu et al. 2009).

The draft genome of ***Sphingomonas echinoides* ATCC 14820^T** had a size of 4.2 Mb, with a G+C content of 64.7 % (Shin et al. 2012). A total of 4,047 protein-encoding genes, 45 tRNA-encoding genes, and one rRNA operon have been predicted in the draft genome so far. A total of 2,781 (68.7 %) of the predicted protein-coding open reading frames (ORFs) were annotated to known proteins. Comparative analyses were performed with genome sequences available for *Sphingomonas* sp. strain SKA58 (score, 514), *Sphingobium japonicum* UT26S^T (score, 513), and *Sphingomonas wittichii* RW1^T (score, 476) as the closest related genome-sequenced sphingomonads.

***Sphingomonas elodea* ATCC 31461^T** was genome sequenced because it is able to produce gellan gum—a heteropolysaccharide used as a commercial gelling agent in several industries, including the food and pharmaceutical industries. The aim of the genome project was to identify genes and characterize metabolic pathways involved in the biosynthesis, regulation, and modification of gellan gum (Gai et al. 2011). The draft genome had a size of 4.1 Mb and a G+C content of 67.4 %. A total of 3,813 coding ORFs and 49 structural RNAs were predicted. Comparison with the genome sequences available on the RAST server suggested that the closest genome-sequenced neighbors

Chr Chromosome, *Plsm* Plasmid

are *Novosphingobium aromaticivorans* (score, 521), followed by *Sphingopyxis alaskensis* RB2256^T (score, 503), and *Sphingomonas wittichii* RW1^T (score, 475). A first insight into the genome showed that several genes (*pgmG*, *ugpG*, and *ugdG*) encoding enzymes involved in the synthesis of the nucleotide sugars (UDP-Glc and UDP-GlcA) from Glc-1-phosphate were found dispersed over the genome. A glycosyltransferase (involved in the synthesis of dTDP-l-Rha) and the proteins required for gellan polymerization and export were found to be located together in a gel cluster. At least 42 enzymes related to the metabolism of monosaccharides (such as mannose, D-galactonate, D-gluconate, ketogluconates, D-galacturonate, and D-glucuronate) were found, indicating the high metabolic versatility of the strain, which may be linked to the ability to synthesize heteropolysacchsarides (Gai et al. 2011).

The type strain of ***Sphingopyxis alaskensis* RB2256^T** was genome sequenced as a model for the investigation of oligotrophic (i.e., adapted to low nutrient concentrations) small marine bacteria (Lauro et al. 2009). The strain was isolated from Resurrection Bay in the Gulf of Alaska. The genome had a size of 3.9 Mb consisting of one chromosome (3.4 Mb, G+C 65.5 %, 3,165 proteins, one rRNA operon and 45 tRNAs) and one plasmid (28 kb, G+C 60.4 %, 30 proteins). The genome showed a high number of genes assigned to metabolic pathways for the degradation of aromatic compounds and a high number of genes assigned to detoxification reactions. The degradation of xenobiotic compounds and the catabolism of recalcitrant compounds are important for the use of carbon and energy in the habitat of this oligotrophic species. For example, genes involved in the degradation of beta-lactames, tyrosine, and catechol were determined. The cytochrome P450 gene was found to have six copies in the genome. Proteins of the P450 family are involved in a variety of oxidative reactions of exogenous and endogenous substrates, including fatty acid oxidation, bioconversion of recalcitrant organic compounds, and the synthesis of macromolecules.

***Sphingomonas wittichii* RW1^T** can degrade toxic dioxin pollutants and completely mineralize dibenzo-p-dioxin. The genome of this strain was sequenced to provide information on the production and regulation of enzymes involved in the degradation of dibenzo-p-dioxins and related compounds (Miller et al. 2010). The genome of *Sphingomonas wittichii* contained one chromosome (5.4 Mb, 68.4 % G+C, 4,941 ORFs, including 6 rRNAs and 48 tRNAs) and two megaplasmids, designated as pSWIT01 (310 kb, 64.1 % G+C, 288 ORFs) and pSWIT02 (222.8 kb, 61.2 % G+C, 210 ORFs). Parts of the larger plasmid, pSWIT01, showed high similarity to the plasmid pNL1 from *Novosphingobium aromaticivorans*. Specifically, a 17-kb regions shares highly similar proteins (50 % similarity cutoff), including a reverse transcriptase and a type IV pilus. All genes that were known to be required for dioxin degradation were located on the smaller megaplasmid, pSWIT02.

Three genomes of γ-hexachlorocyclohexane (HCH) degrading **Sphingobium species** were genome sequenced to investigate the genetic background of γ-HCH degradation: two *Sphingobium* type strains, *Sphingobium japonicum* UT26^T (Nagata et al. 2010) and *Sphingobium indicum* B90A^T (Anand et al. 2012) and a further *Sphingomonas* sp. strain MM-1 (Tabata et al. 2013). Differences in the genomic structures, including number of chromosomes and plasmids, were obtained. Clear differences were also obtained with respect to the localization of genes assigned to the γ-HCH degradation pathway.

The genome of ***Sphingobium japonicum* UT26^T** consists of two circular chromosomes and three circular plasmids (Nagata et al. 2010). Chromosome 1 had a size of 3.5 Mb, 64.8 % G+C, and 3,529 ORFs; the second chromosome was smaller in size (0.68 Mb) with a similar DNA G+C content (65.9 % G+C) and 589 ORFs. All three rRNA operons were determined, one at chromosome 1 and two at chromosome 2. Respectively, 51 and 4 tRNA genes were located on chromosomes 1 and 2. The genome contains one larger plasmid pCHQ1 (190 kb, 63.0 % G+C, 224 ORFs) and two smaller plasmids pUT1 (31 kb, 63.7 % G+C, 44 ORFs) and pUT2 (5.3 kb, 61.0 % G+C, 8 ORFs). Genes (*lin* genes) encoding for enzymes or transporters involved in the degradation pathway of γ-HCH (Nagata et al. 2011) were specifically analyzed. A total of 15 *lin* genes were found in the genome of strain UT26^T located either on chromosome 1 or 2 or on plasmid pCHQ1: Chr1 (*linA*, *linB*, *linC*, and *linKLMN*), Chr2 (*linF* and *linGHIJ*), and pCHQ1 (linRED). Comparative genome analysis of the genome of strain UT26^T and other sphingomonads (TM1) strains showed that the *lin* genes (*linA*, *linB*, *linC*, *linRED*, and *linF*) necessary for the conversion of γ-HCH to beta-ketoadipate were located in a DNA region that is unique for the genome of strain UT26^T. In contrast, *lin* genes necessary for the beta-ketoadipate pathway (*linGHIJ*, Nagata et al. 2007) or the ABC transporter system (*linKLMN*, Endo et al. 2005) are located in genome regions that are conserved in the compared *Sphingomonadaceae* (*Sphingomonas* sp. SKA58, *Sphingobium* sp. SYK-6, *Sphingomonas wittichii* RW1^T, *Sphingopyxis alaskensis* RB2256^T, and *Novosphingobium aromaticivorans* DSM 12444^T). The insertion sequence IS6100 was mainly found in close association with several of the *lin* genes (*linA*, *linC*, *linRED*, and *linF*) in the genome of UT26^T as it was also determined in other γ-HCH degraders. IS6100 has a size of 880 bp and carries the *tnp* gene encoding a transposase and 14-bp terminal inverted repeats (IR) at both ends (Mahillon and Chandler 1998). The insertion sequence IS6100 was often found in close proximity to *lin* genes and other HCH-degrading sphingomonads; it may be an important factor responsible for horizontal gene transfer (HGT) of *lin* genes (Böltner et al. 2005; Fuchu et al. 2008). Analysis of spontaneous *linA*-, *linC*-, and *linRED*-deletion mutants of strain UT26^T involved the role of IS6100 in deduced genome rearrangements, suggesting the importance of IS6100 in the dissemination of the *lin* genes and genome rearrangement (Nagata et al. 2011).

The draft genome of ***Sphingobium indicum* B90A^T** had a size of 4.08 Mb with a G+C content of 65 % and a total of 3,319 ORFs (Anand et al. 2012). Two rRNA gene operons were found; one of them had a doubled 23S rRNA gene sequence (arrangement: 16S-23S-23S-5S). The genome of stain B90A^T harbors nearly identical *lin* genes, as found in *Sphingobium japonicum* UT26^T. *Lin* genes were not integrated into a single operon that is constituently regulated but were dispersed over the genome. Seven copies of IS6100 were found, which were located in close proximity to the *lin* genes. In the same manner as *S. japonicum* UT26^T, the genome of strain B90A^T harbored a gene cluster for phenol- and pentachlorophenol-degradation pathways, but no homogentisate and anthranilate degradation pathways. For each *lin* gene—*linX*, *linA*, *linG*, *linH*, *linI*, and *linJ*—two copies were determined in the genome.

The genome of the third γ-HCH degrader ***Sphingomonas* sp. MM1** consists of one circular chromosome and five circular plasmids (Tabata et al. 2013). The chromosome is composed of 4.05 Mb with a G+C content of 67.2 % and 3,801 predicted ORFs. The chromosome carried 2 rRNA operons and 55 tRNAs. The five plasmids are pISP0 (275.8 kb, 63.5 % G+C, 251 ORFs), pISP1 (172 kb, 62.5 % G+C, 174 ORFs), pISP2 (53.8 kb, 62.9 % G+C, 51 ORFs), pISP3 (43.8 kb, 63.3 % GC, 44 ORFs), and pISP4 (33.2 kb, 63.0 % G+C, 39 ORFs). The *lin* genes determined in this genome were almost identical to those determined in *Sphingobium japonicum* UT26^T. However, in contrast to strain UT26^T, the *lin* genes were located on four out of the five plasmids and not on the chromosome. The *lin* gene distribution was as follows: pISP0 (*linF*), pISP1 (*linA*, *linC*, and truncated *linF*), pISP3 (*linRED*); and pISP4 (*linB*, *linC*, and truncated *linF*). Strain MM-1 harbored 15 copies of the IS6100 insertion sequence again associated with *lin* genes.

***Sphingobium chlorophenolicum* strain L-1** was genome sequenced because of its property to mineralize the toxic pesticide pentachlorophenol (PCP) (Copley et al. 2012). The genome consists of two chromosomes (Chr 1: 3.1 Mb, G+C content of 64 mol%, 2,940 ORFs including 1 rRNA operon and Chr 2: 1.4 Mb, G+C content 64 mol%; 1,159 ORFSs including 2 rRNA operons) and a small plasmid pSPHCH01 (123.7 kb; G+C content of 65 mol%, 125 ORFs). Most genes assigned to metabolic core processes are located at chromosome 1, whereas the smaller secondary chromosome encodes mainly genes associated with environmental adaptation processes. All genes of the PCP degradation pathway were located on the secondary chromosome. Some of the genes—*pcpB* (encoding a PCP hydroxylase) and *pcpD* (TCBQ reductase)—were located in one operon together with a further gene of the PCP degradation pathway, *pcpR*. The latter one encodes a LysR–transcriptional regulator involved in induction of the expression of *pcpB*, *pcpA*, and *pcpE* (Cai and Xun 2002). Further genes involved in the degradation pathway were not located in an operon but in close proximity to each other.

Different results were given on genes for PCP degradation as obtained by HGT. For example, *pcpB* and *pcpD* were located in a region of low GC content and PcpB shared a high amino acid sequence similarity (72–98 %) to PcpBs expressed by *Novosphingobium lentum* (Tiirola et al. 2002a) and other polychlorophenol-degrading sphingomonads (Tiirola et al. 2002b; Cassidy et al. 1999). The genome of strain L-1 showed a high structural similarity to the genome of *S. japonicum;* both had approximately the same size (4.57 and 4.46 Mb, respectively) with a similar number of ORFs (4,159 and 4,460, respectively) distributed on two chromosomes. Genes encoding for metabolic core processes (including the glycolysis, the tricarboxylic acid cycle, amino acid and nucleotide biosynthesis, fatty acid oxidation, DNA replication, transcription, and translation) were located in both genomes on the primary chromosome. The number of plasmids differed: a single plasmid in *Sphingobium chlorophenolicum* and three plasmids in *Sphingobium japonicum.* Homologues were determined for 1,931 genes on chromosome 1, 285 genes on the secondary chromosome, and 108 genes on plasmid pSphCh01 in the genome of *Sphingobium japonicum.* The comparative genome analysis furthermore indicated that the first three genes of the PCP degradation pathway, *pcpB*, *pcpA*, and *pcpC*, were acquired by HGT, whereas *pcpA* and *pcpE* seemed to originate from a common ancestor of *Sphingomonas chlorophenolicum* and *Sphingomonas japonicum.*

The genome of strain L-1 contained an integrated prophage which was indicated by a cluster of phage-related genes detected on chromosome 1. The cluster contained genes encoding a major capsid protein, a major tail protein, a phage portal protein, a pro-head peptidase, and some further conserved phage proteins of unknown function. Several distantly relate genes of the "phage integrase family" were determined to be distributed over both chromosomes. All shared a low GC content (between 48 mol% and 58 mol%). One of the phage integrase genes was located in the vicinity of a prophage gene (a CP4-57 regulatory protein), and two were adjacent to transposase genes. A total of 27 sequences annotated as "transposase," "transposase/integrase core domain," or "transposase and inactivated derivatives" were determined: 16 located on chromosome 1, nine on chromosome 2, and two on the plasmid. The transponases were assigned to different families of insertion elements and Tn3 family transposons, indicating a continuous gene exchange in the genome of strain L-1. PCP degradation genes, however, were not directly association with those genetic elements.

***Novosphingobium pentaromativorans* US6-1^T** was the first genome sequenced degrader of benzo(a)pyrene, a carcinogenic recalcitrant compound (Sohn et al. 2004). The draft genome comprises one chromosome (5.1 Mb; G+C content of 63.1 % with 4,948 ORFs, including one rRNA operon and 51 tRNAs) and two plasmids, pLA1 (188.5 kb, G+C content of 62.6 %, 199 ORFs) and pLA2 (60.1 kb, G+C content of 60.2 %, 87 ORFs) (Luo et al. 2012). The chromosome also contains an integrated phage. A total of 38 transposases and 13 phage integrases were found distributed all over the genome, indicating the ability of genetic rearrangement. A total of eight transponases and three phage interase copies were located on pLA1, with two transposases at pLA2. Those motile genetic elements indicate

the ability of genetic rearrangement in the genome of US6-1. The genome of strain US6-1^T showed a homology to the genome of *Novosphingobium aromaticivorans* DSM12444^T. The plasmid pLA1 of strain US6-1^T shared high similarity to the plasmid pCAR3 of *Sphingomonas* sp. strain KA1 and pNL1 of *Novosphingobium aromaticivorans* DSM 12444^T, with respect to the conjugative regions. Genes encoding proteins of the polycyclic aromatic hydrocarbon (PAH) degradation pathway were partially located on plasmid pLA1 and partially scattered on the chromosome. The genome harbors several genes encoding enzymes that commonly exist in aromatic-compound degrading bacteria as three sets of genes coding for aromatic-ring-hydroxylating dioxygenases: *bphA1a*, *bphA2a*, *bphA1b*, *bphA2b*, *bphA1e*, and *bphA2e* in *Sphingobium yanoikuyae* B1 (Chadhain et al. 2007); respective genes found on plasmid pNL1 of *Novosphingobium aromaticivorans* DSM12444^T (Romine et al. 1999); and *ahdA1a*, *ahdA2a*, *ahdA1b*, *ahdA2b*, *ahdA1e*, and *ahdA2e* in *Sphingomonas* sp. P2 (Pinyakong et al. 2003).

The type strain of ***Novosphingobium nitrogenifigens* Y88^T** was genome sequenced because of its specific metabolic properties linked to the ability of nitrogen fixation, production of poly-3-hydroxybutyrate (PHB), and the effective removal of Mn and Zn from model biorefinery effluents (Strabala et al. 2012). The strain was originally isolated from nickel-enriched pulp and paper mill wastewater (Addison et al. 2007). The draft genome had a size of 4.1 Mb, with a G+C content of 63 % and 3,801 ORFs, including 49 tRNAs. The genome harbors two small plasmids, py8 (5.9 kb) and py157 (5.7 kb), which both have a G+C content of 58 %. The plasmids encode genes for plasmid conjugation and replication and coding sequences (CDSs), which shared a high homology to CDSs on the plasmids pUT2 of *Sphingobium japonicum* UT26S^T. The genome contained all genes necessary for PHB synthesis (*phbA*, *phbB*, and *phaC*) and all genes encoding proteins involved in nitrogen fixation (*nifA*, *–D*, *–E*, *–H*, *–K*, *–N*, *–Q*, *–U*, *–W*, and *–X*, *fixA* and *fixU*, and various cofactor biosynthesis proteins). Thirteen CDSs were assigned to metal resistance, including putative metal resistance/efflux proteins for Ni, Cu, Hg, Co, and As resistance.

Sandarakinorhabdus

The first genome-sequenced strain of the genus *Sandarakinorhabdus* was ***Sandarakinorhabdus* sp. strain AAP62**, which shared 99.4 % 16S rRNA gene sequence similarity with the type strain of *Sandarakinorhabdus limnophila* (Zeng et al. 2013a). The orange-pigmented strain was isolated from surface waters of Lake Shahu (China) and was capable of producing BChl *a* under aerobic conditions (i.e., freshwater aerobic anoxygenic phototroph, AAP). The aim of the study was to characterize the metabolic potential and the composition of photosynthetic genes in freshwater AAPs.

The draft genome consisted of 22 contigs. A total genome length of 3.13 Mb with a G+C content of 65.5 %, containing 3,036 ORFs, and 46 tRNAs was thereby obtained. The strain harbored a photosynthesis gene cluster (PGC) with a total size of 44,237 bp, which was located at a 549,987-bp-long contig. The gene organization was as followed: *crtK-bchP-pucC-bchGFNBHLM-puhABC-lhaA-ORF-acsF-puhE-6xORFs-bchIDO-5xORFs-crtCDF-bchCXYZ-pufBALMC*. Genes of the pathway for autotrophic CO_2 fixation were not detected. Genes encoding enzymes of different catabolic pathways were detected, such as those of the pentose phosphate pathway, the Entner-Doudoroff pathway, and the tricarboxylic acid cycle. The first insight into the genome indicated a large metabolic versatility. Detailed studies of the genome should provide new insight into the metabolism and the ecology of AAPs. The genome of *Sandarakinorhabdus limnophila* DSM 17366^T is also being genome-sequenced as part of the GEBA project (Wu et al. 2009).

Blastomonas

For the genus *Blastomonas*, one genome sequence of an AAP strain, ***Blastomonas* sp. strain AAP53**, is available (Zeng et al. 2013b). The strain was genome sequenced to assess the metabolic potential and the photosynthesis gene composition of the *Blastomonas* species, which synthesizes BChl *a* under aerobic conditions. The yellow-pigmented strain AAP53 was isolated from surface waters of Lake Swan, a freshwater desert lake in Inner Mongolia, China, and shared 98.6 % 16S rRNA gene sequence identity with the type strain of *Blastomonas natatoria* DSM 3183^T. The draft genome was 3.6 Mb long with a G+C content of 63.6 % and 3,369 ORFs, including one rRNA operon and 42 tRNAs.

Genes of the PGC were located on two separate contigs. One contig contained the gene cluster *bchIDO-crtF-bchCXYZ-pufBALMC*. The other contig contained the other PGC genes in the following arrangement: *puhE-acsF-ORF-puhCBAlhaA-bchMLHBNF-ORF-ppsR-ORF-bchG-pucC-bchP-tspO*. *PufBLMC* genes showed a high sequence similarity (91 and 97 %) to the respective genes identified in the type strains of *B. natatoria* and *B. ursincola*. Genes for the autotrophic CO_2 fixation pathway were not found. The aerobic lifestyle of the *Blastomonas* strain was confirmed by the detection of several genes of the aerobic respiratory electron transport chain such as the NADH dehydrogenase, cytochrome c oxidase, and the succinate dehydrogenase, as well as a catalase.

Zymomonas

Strains of the species ***Zymomonas mobilis*** shared the metabolic capacity to ferment sugar to ethanol, which makes this species interesting for the industrial production of biofuel. Genomes of four *Zymomonas mobilis* subsp. *mobilis* strains, including the type strain *Zymomonas mobilis* subsp. *mobilis* T.H.Delft 1^T, ATCC 10988^T and the type strain of *Zymomonas mobilis* subsp. *pomaceae* Barker 1^T, ATCC 29192^T, are already available.

A comparative analysis of several further strains are under way at the U.S. Department of Energy Joint Genome Institute, in collaboration with the University of Athens. All genomes are relatively small in size, 2.1–2.2 Mb, with a G+C content between 44 % and 46.6 % and 1,807–1,978 ORFs. With exception of *Zymomonas mobilis* subsp. *mobilis* ZM4 (=ATCC 31821), all *Zymomonas* genomes contain several (2, 3, or 6) plasmids per genome. Evidence of plasmid DNA, however, was also given for strain ZM4 (Yang et al. 2009).

The first *Zymomonas* genome, the genome of *Zymomonas mobilis* ZM4 (ATCC 31821), was published in 2005 (Seo et al. 2005). Corrections to the genome annotation were given later (Yang et al. 2009). The genome consisted of a single circular chromosome (2.1 Mb, G+C content 46.3 %, and 1,998 predicted ORFs). Genes encoding for hexose-metabolizing enzymes were identified, such as invertases, a levansucrase, a glucokinase, glucose-6-phosphate isomerase, and glucose-fructose oxidoreductase to metabolize sucrose, fructose and glucose as well as probably mannose, raffinose, and sorbitol. Genes for lactose, maltose, or cellobiose utilization were not determined. Insight into the genome showed that glucose can only be metabolized by the Entner-Doudoroff pathway because key enzymes of other pathways are missing, such as the 6-phosphofructokinase of the EMP pathway.

A total of 54 ORFs were predicted to encode for transport and secretory proteins, transcriptional regulators, and oxidoreductases. Comparative microarray analysis indicated that several of the genes were absent in another *Zymomonas* species, ZM1, but most of the 54 ORFs were actively transcribed in ZM4 in association with ethanol production. Because *Z. mobilis* is a facultative anaerobe and therefore grows in the presence of oxygen, different oxidative stress-related genes were found in the genome, such as a glutathione reductase, a glutathione synthase, a γ-glutamylcysteine synthetase, a catalase, and a superoxide dismutase, as well as several additional genes that respond to oxidative stress.

A further genome sequenced *Zymomonas* strain is a flocculating mutant of ZM4, strain ZM401, which is able to perform a self-immobilization within a fermenter without the consumption of supporting materials, thereby forming a high-density culture improving ethanol productivity. The strain was also suitable for high-gravity fermentation, increasing the ethanol production per titer. Genome comparison of ZM4 and ZM401 showed the presence of 28 single-nucleotide polymorphisms (SNPs) in strain ZM401; 48.3 % were localized in coding regions and 51.7 % (30 in total) in noncoding regions (Zhao et al. 2012). Further details of transcriptome analysis of strain ZM401 are provided in the literature (Jeon et al. 2012).

A further genome sequence of the *Zymomonas mobilis* strain ATCC 29191 shared an average nucleotide identity of 97 % with ZM4. The genome of ATCC 29191 was 95.1 kb smaller than that of the ZM4. A total of 51 genes were unique for strain ATCC 29191 and 115 genes for ZM4. Genes unique in ATCC 29191 included a helicase, a transporter, and tellurium resistance genes (Desiniotis et al. 2012).

Nonchromosomal Genetic Elements, Such as Plasmids, Prophages, Phages, Superintegrons, Genomic Islands

Plasmids in Sphingomonads

Plasmids play an important role in sphingomonads because many genes of different degradation pathways are located on plasmids. For example, genes encoding enzymes involved in degradation pathways of biphenyl, naphthalene, m-xylene, and p-cresol were detected on megaplasmids in *Sphingomonas aromaticivorans* F199^{T} (184 kb) or other sphingomonads, which were isolated from the same habitat (Romine et al. 1999). Basta et al. (2005) investigated 17 different xenobiotic-degrading sphingomonad strains; all contained 2–5 plasmids in sizes of 50–500 kb. On several of those plasmids, genes for different metabolic degradation pathways were located.

The high-molecular-weight polycyclic aromatic hydrocarbon degrading *Sphingomonas aromaticivorans* F199 ^{T} contains two plasmids pNL1 (180 kb) and pNL2 (480 kb) (Romine et al. 1999). The smaller aromatic catabolic plasmid pNL1 was characterized in detail by full-length sequence analysis (Romine et al. 1999). Plasmid pNL1 encoded 186 ORFs. Among those, 76 genes were associated with functions related to aromatic compounds: aromatic catabolism, transport, and cell membrane alteration. Genes associated with the degradation pathways of biphenyl, naphthalene, m-xylene, and p-cresol were found to be localized in 15 gene clusters on the plasmids. Several ORFs of pNL1, distributed among the catabolic genes, showed high homology to gene coding for bacterial efflux pump genes, including genes encoding for cytoplasmic and outer membrane proteins and membrane fusion proteins as compounds of a typical efflux pump. The plasmid contained intron-associated maturases in the replication region, which suggested that the plasmid (pNL1) can perform integration and excision actions between the plasmid and the chromosome or among different plasmids with the chromosome and/or other portions of the plasmid. The plasmid harbors gene clusters of all genes necessary for a conjugative plasmid transfer to other bacteria. This was proven by Romine et al. (1999) with the transfer of the plasmid from the host *Sphingomonas aromaticivorans* F199^{T} to another *Sphingomonas* strain.

Ochou et al. (2008) isolated and characterized two small cryptic indigenous plasmids, pYAN-1 (4.9 kb) and pYAN-2 (4.7 kb), from *Sphingobium yanoikuyae* that contained genes encoding proteins with predicted functions associated with mobilization (*mob* genes) and replication (rep genes). Based on the detailed characterization of the two plasmids, Ouhou and coauthors were able to construct a shuttle vector between *E. coli* and sphingomonads, which was proven by the use of *Novosphingobium capsulatum* as a model host using electroporation-transformation. The construction vector enabled the genetic manipulation of sphingomonads. In a similar manner, Tani et al. (2011) characterized a small crypic plasmid pSM103mini that originated from *Sphingopyxis macrogoltabidus*

strain 103. The plasmid is 4.3 kb in size with a G+C content of 57.5 %. Only four ORFs were identified, including genes encoding a resolvase and the replication protein RepA. A complex repeat sequence and the other two ORFs are associated with the maintenance of the plasmid in a cell. Based on the plasmid, the authors constructed a shuttle vector (pHSG398-fused plasmid, pHSG-SN103mini) between *Sphingopyxis* strains. However, the plasmid was not stable in a tested *Sphingomonas* species, *Sphingomonas terrae*.

Indigenous plasmids in a size range of 1.5 kb to >40 kb have been described for *Zymomonas* spp. Antibiotic-resistant or heavy-metal-resistance genes were also found to be localized on these plasmids (for reference, see Sprenger et al. 1993). Plasmids that originate from *Zymomonas mobilis* strains were used for the constructing of shuttle vectors that can be used for homologous and heterologous gene expression in *Z. mobilis* for metabolic engineering (Conway et al. 1987; Sprenger et al. 1993).

Phenotypic Analyses

Table 25.2

Sphingomonas Yabuuchi, Yano, Oyaizu, Hashimoto, Ezaki, Yamamoto 1990; Emend. Yabuuchi et al. 1999; Yabuuchi et al. 2002; Busse et al. 2003; Chen et al. 2012a

The genus *Sphingomonas* was proposed by Yabuuchi et al. (1990) based on the 16S rRNA gene sequence phylogeny and the presence of a unique sphingoglycolipid and ubiquinone Q-10 as the major respiratory quinone. The proposal of the genus was based on five species: the type species *Sphingomonas paucimobilis* (previously "*Pseudomonas paucimobilis*"; Holmes et al. 1977), *Sphingomonas parapaucimobilis*, *Sphingomonas yanoikuyae*, *Sphingomonas adhaesiva*, and *Sphingomonas capsulatum*. At the time of writing (June 2013), the species *Sphingomonas* contained 61 species.

Cells are Gram-negative, non-sporulating, and ovoid to rod-shaped, including straight, oval, short, thin, slightly curved, or pleomorphic short rods. Cell size is between 0.3–1.1 × 0.8–5.0 µm. Strains are nonmotile or motile; for some strains, motility was only obtained in the early exponential growth phase. Cells are motile by means of (single) polar, subpolar or peritious flagella. Reproduction occurs by binary fission. Budding formation can occur (*Sphingomonas jaspsi*, Asker et al. 2007a). The presence of polar fimbriae leads to rosette-like aggregation in some species. One species shows a dimorphic life cycle, including a prosthecate stage, non-motile cell and a flagellated, motile cell stages (*Sphingomonas leidyii*; Chen et al. 2012a). Cells of *Sphingomonas molluscorum* (Romanenko et al. 2007) show plait-like structures on the cell surface.

Colonies are white, cream, pale-yellow, yellow, deep-yellow, yellow-orange, pink-yellow, orange, dark-orange, reddish, or red-colored, circular, and (slightly or low) convex. Some are smooth, have an entire margin, and are glistening; some are also mucoid and slimy. The colony diameter is in the range of 0.1–2 mm; mucoid or slimy colonies are often larger, with a diameter of 6–8 mm [e.g. *Sphingomonas sanxanigenens* (Huang et al. 2009a) or *Sphingomonas endophytica* (Huang et al. 2012)]. Acetone-extracted cellular pigments were characterized by λmax at 458 and 476/478 nm with a slight inflexion at 425 nm (Busse et al. 2003); λmax at 452–454 and 480–482 nm with a shoulder at 431 nm (Xie and Yokota 2006; Ohta et al. 2004); λmax at 451 nm with two shoulders at 423 and 475 nm (Huo et al. 2011); or λmax at 477 and 450 nm (An et al. 2013). Carotenoids were identified as zeaxanthin (λmax at 451 and 476 nm) and nostoxanthin (λmax at 449 and 475 nm) (Asker et al. 2007a) and for *Sphingomonas astaxanthinifaciens* as dihydroastaxanthin and astaxanthin (Asker et al. 2007b).

Strains are strictly aerobic with oxygen as the thermal terminal electron acceptor and chemo-organotrophic. They are catalase positive with one exception (*Sphingomonas oryziterrae*, Chung et al. 2011), and oxidase-positive or − negative. Aesculin is most often hydrolyzed, but a prolonged incubation can be necessary to obtain a positive reaction.

All strains grow at 15–28 °C—most up to 4 °C, often also at 37 °C, some at 42 °C, or even at 55 °C (*Sphingomonas laterariae*, Kaur et al. 2012). The pH range for growth can be between pH 4 and 12. The pH optimum for growth is between pH 6.5 and 9 (for most species, pH 7–8). Most strains grow without additional NaCl, 0 % (w/v). Several strains are not able to grow in the presence of 1 % or 2 % (w/v) NaCl; some can grow up to a NaCl concentration of 5 %. For some exceptions, growth occurs still at 8 % NaCl (*Sphingomonas rubra*, Huo et al. 2011).

Ubiquinone Q-10 is the predominant respiratory quinone; minor amounts of Q-9 and Q-8 can also be detected. The major nonpolar cellular fatty acids are $C_{18:1}\omega 9t$ and $C_{18:1}\ \omega 7c$, followed by saturated C16:0 and/or C17:1. The major 2-hydroxy fatty acids are 2-OH C14:0 or 2-OH C15:0. No 3-hydroxy fatty acids were detected. Sphingoglycolipids are present, replacing lipopolysaccharide (LPS) in the cell wall. The SGL types obtained are glucuronosyl-(1→1)-ceramide sphingoglycolipid (SGL-1), and galacturonosyl-β(1 → 1)-ceramide sphingoglycolipid (in several species). The major polyamine is *sym*-homospermidine. Minor to trace amounts of spermidine, spermine, putrescine, cadaverine, 1,3-diaminopropane, and agmatine occur in some species. *sym*-Homospermidine as major polyamine is a characteristic feature that clearly differentiated the genus *Sphingomonas sensu stricto* from the genera *Sphingobium*, *Novosphingobium*, and *Sphingopyxis* (Busse et al. 1999; Takeuchi et al. 2001). The genera *Sphingosinicella* and *Sphingomicrobium*, however, shared this chemotaxonomic feature (Geueke et al. 2007; Kämpfer et al. 2012), which hampered the differentiation of the genus *Sphingomonas* from those genera.

Besides sphingoglycolipid, the polar lipid profiles contain phosphatidylglycerol as the predominant lipid, with moderate to large amounts of phosphatidyl ethanolamine,

Table 25.2

BChl *a*, bacteriochlorophyll a, LH-I light harvesting complex I

[a]*Sphingomicrobium marinum* (Shahina et al. 2013b)

[b]*Sphingopyxis marina* DSM 22363^T (Kim et al. 2008)

[c]Two species *Sphingopyxis wooponensis* and *Sphingopyxis riguri*, which need to be reclassified to the genus *Sphingorhabdus* with respect to 16S rRNA gene sequence phylogeny

diphosphatidylglycerol, phosphatidyldimethylethanolamine, and phosphatidyl choline; different amounts of phosphatidylmonomethylethanolamine; and different amounts of unidentified polar lipids (Busse et al. 1999; Busse et al. 2003). Bacteriochlorophyll *a* was determined in one species, *Sphingomonas kaistensis* (Kim et al. 2007). However, a few species were investigated respectively. Detailed characteristics of the BChl *a* showed that three types are present in that species: BChl-a esterified with phytol (BChl a_P), esterified with farnesol (BChl *a*F), and esterified with geranylgeraniol (BChl *a*GG). In parallel genes for the photosynthetic type II reaction center, *pufL* and *pufM* genes were detected. The BChl *a* content was approximately 200 times lower as that determined for AAPs (Jiao et al. 2003; Kolber et al. 2001), with a ratio of 1:60–1:600 BChl *a* to carotenoid content (Kim et al. 2007).

Characteristic 16S rRNA gene signature nucleotides are at the following positions 52:359 (C:G), 134 (G), 593 (G), 987:1218 (G:C), and 990:1215 (U:G). The DNA G+C content ranges from 62 mol% to 68 mol%. The type species is *Sphingomonas paucimobilis* (formerly "*Pseudomonas paucimobilis*") (Table 25.3).

Habitats: Several environments of anthropogenic origin were found, including veterinary clinics, surfaces of air humidifiers, air samples from open buildings and the Russian space station Mir, whirled-up dust of cow farms, laboratory contaminants, wastewaters of a sequential batch reactor treatment and leather plants, wastewater treatment plants, HCH dump sites, hydrocarbon-contaminated soils, PCP-contaminated groundwater, 4,200-year-old ice, biological soil crust, the surface layer of desert soil, alpine soil, paddy soil, forest soil, topsoil of a cornfield and other agricultural soils (including soils of a ginseng field), glacier cryoconite collected from the Stubai Glacier, rhizosphere of a rice field, roots of *Malus* spp. (apple), *Oryza sativa*, or *Prunus persica* (peach), tissue of *Artemisia annua* L, ear of *Setaria viridis*, brown spots of yellow Spanish melon fruits, phyllosphere of *Cynara cardunculus* L. var. *sylvestris* or *Acacia caven*, specimen of the crab *Paralithodes camtschatica*, marine sponge, hymeniacidon flavia, millipede hind gut, marine bivalve (*Anadara broughtoni*), tidal flat sediment, water of freshwater lakes, natural mineral water, prealpine freshwater lakes, freshwater sediments, eutrophic fountains with algal blooms, and freshwater cyanobacterial mats of thermal springs.

Nitrogen Fixation

The capacity of nitrogen fixation was so far only detected for one *Sphingomonas* species, *Sphingomonas azotifigens*. The first evidence for nitrogen fixation was given for *Sphingomonas trueperi* NBRC 100456^T, which was formerly known as '*Pseudomonas azotocolligans*' (Anderson 1955). A later study, however, showed that the type strain was not able to fix nitrogen (Hill and Postgate 1969); this was supported by the study of Xie and Yokota (2006), in which neither acetylene reduction nor the *nifH* gene could be detected for the type strain of *S. trueperi*. A high capacity for acetylene reduction and amplification of the *nifH* gene was obtained for three strains (including the type strain) of *S. azotifigens*, which were all isolated from nonsterilized roots of *Oryza sativa*.

Sequence analysis of the partial *nifH* gene sequence showed the highest sequence similarities (98 %) to the respective sequences of uncultured diazotrophic bacteria detected in dead above-ground biomass of *Spartina alterniflora* (Lovell et al. 2001). Phylogenetic trees calculated based on partial *nifH* gene sequences showed that the *nifH* genes of the *S. azotifigens* strains cluster with *nifH* genes of one cluster of sequences originating either from *Alphaproteobacteria* or *Betaproteobacteria*,with highest sequence similarity to *nifH* genes of species from the genus *Bradyrhizobium*. This cluster was distinct from two monophyletic clusters of *nifH* genes of either nitrogen-fixing *Alphaproteobacteria* or *Gammaproteobacteria* (Xie and Yokota 2006).

The *nifH* gene sequences of *S. azotifigens* were distinct from those of many other *Alphaproteobacteria nifH* gene sequences. Based on this finding, Xie and Yokota (2006) concluded that the three strains of *S. azotifigens* may have obtained the *nifH* genes by lateral gene transfer. Further evidence for nitrogen fixing *Sphingomonas* spp. was given by Videira et al. (2009), who determined acetylene reduction and *nifH* gene sequences in 22 out of 42 isolates that were phylogenetically closely affiliated (based on 16S rRNA gene sequence) to the genus *Sphingomonas*. The strains were isolated from surface-sterilized plant tissue of roots and the aereal part of two rice varieties grown in two soils in Brazil. Four of the isolates showed *nifH* genes identical to the *nifH* gene found in the *S. azotifigens* isolates. The occurrence of nitrogen-fixing sphingomonads was suggested in several studies by the investigation of the rhizosphere of millet or sorghum (Hebbar et al. 1992), rice (Engelhard et al. 2000), and rice seeds (Mano et al. 2006). The ability of nitrogen fixation, however, was not proofed for the isolates. Engelhardt et al. (2000) suggested the abundance of nitrogen-fixing *Sphingomonas paucimobilis* bacteria in the rhizosphere of rice, but no nitrogenase activity was shown. Adhikart et al. (2001) amplified a partial *nifD* gene fragment form a single isolate of *Sphingomonas trueperi* but also did not show any nitrogenase activity.

Exopolysaccharides (Sphingans)

Some *Sphingomonas* species can produce water-soluble heteropolysaccharides by the fermentation of sugars that are excreted into the medium (exopolysaccharides, or EPSs). The characteristic feature of those EPSs is the ability to produce agar-like structures. The formation of EPSs was first described for *Pseudomonas* species (Kang et al. 1982); for *Sphingomonas* species, EPS formation was first reported by Pollock (1993), who described the release of so-called sphingans by the *Sphingomonas* species.

The two most studied sphingan-producing *Sphingomonas* species are *Sphingomonas paucimobilis* and *Sphingomonas elodea*, formerly described as "*Pseudomonas paucimobilis*" and

"*Pseudomonas elodea*". Several *Sphingomonas* strains were identified to produce sphingans of different structures. Phylogenetically, those *Sphingomonas* strains are closely related, forming a distinct cluster in 16S rRNA gene sequence-based trees (Fialho et al. 2008). *Sphingomonas* sp. ATCC 31555 produces welan (S-130), *Sphingomonas* strain ATCC 31961 rhamsan (S-194), S*phingomonas* sp. ATCC 53159 diutan (S-657), and *Sphingomonas* sp. ATCC 31554, ATCC 31853, and ATCC 21423 produce three different, yet-unnamed polysaccharides: S-88, S-198, and S-7, respectively (as reviewed by Fialho et al. 2008). All sphingans produced by those strains share the same backbone structure—a tetrasaccharide of (β1–3) or (β1–4) linked X–glucose–glucuronic acid–glucose–X subunits (where X can either be L-rhamnose or L-mannose) (Pollock 1993; Fialho et al. 2008). The most studied and commercially produced sphingan is gellan, which is composed of tetrasaccharides with repeating units of D-glucose, L-rhamnose, and D-glucuronic acid at a ratio of 2:1:1 with O-acetyl and L-glyceryl moieties on the D-glucosyl residue adjacent to the D-glucuronyl residues.

The heteropolysaccharide found in a culture of "*Pseudomonas elodea*" consists of a repeating linear tetrasaccharide of D-glucose, D-glucuronic acid, and L-rhamnose but without side chains (Jansson et al. 1983). The production of an unusual sphingan was recently described for *Sphingomonas cynarae* containing glucose, rhamnose, mannose, and galactose; glucuronic acid, commonly found in sphingans, was not detected (Talà et al. 2013). *Sphingomonas sanxanigenens* NX02^T produces the sphingan Ss (Huang et al. 2009a), which has the unique feature of precipitating by an increase of pH.

The biosynthesis of sphingans was most intensively studied for gellan. The respective biosynthetic pathway can be separated into three steps. In the first intracellular step, nucleotide sugar precursors are synthesized, followed by a second step in which the precursors are assembled. The formed tetrasaccharide units are thereby linked to the inner membrane. In a third step, the tetrasaccharides are translocated to the periplasmic space, polymerized, and exported through the outer membrane. More details with respect to the steps of the synthesis pathway can be found in Fialho et al. (2008). The genes responsible for the specific steps in the synthesis pathways have been identified. As shown by Fialho et al. (2008), a high homology was found between genes of synthesis gene clusters occurring in different *Sphingomonas* strains, *S. elodea* ATCC 31461 (gellan gene cluster; Harding et al. 2004), *Sphingomonas* sp. ATCC 31554 (S-88 sps cluster; Yamazaki et al. 1996), and from *Sphingomonas* sp. ATCC 53159 (diutan dps cluster; Coleman et al. 2008).

Blastomonas Sly and Cahill 1997

Gr. n. *blastos*, bud shoot; Gr. fem. n. *monas*, a unit, monad; N.L. fem. n. *Blastomonas*, a budding monad.

The genus *Blastomonas* was described initially by Sly and Cahill (1997) and Yurkov et al. (1997), and it was emended by Hiraishi et al. (2000). Currently (June 2013), two species, *Blastomonas natatoria* (Sly 1985; Sly and Cahill 1997) and *Blastomonas ursincola* (Yurkov et al. 1997; Hiraishi et al. 2000), are assigned to the genus.

Cells are Gram-negative, nonsporulating, and ovoid or rod-shaped. They are motile by means of a polar flagella. Reproduction occurs by budding or asymmetric cell division. Cells are single or paired; some form rosette-like aggregates. Stalks and prosthecae are not found. Colonies are yellow to orange-red colored, convex, smooth, and opaque. Carotenoids are present. Respective absorption spectra show characteristic λmax at 430, 458, and 485 nm (in vivo spectra). Members of the genus are strictly aerobic chemoorganotrophs and facultative photo-organotrophs. No growth occurs under anaerobic conditions in the light. Synthesis only light-harvesting complex I (LH-I)-type antenna with a λmax of 867 nm; LH-II is not present. Cells produce BChl *a*. Photosynthetic genes encoding proteins of RC/LH-1, *pufM*, and *pufL* genes are detectable by PCR amplification (sequence variation between the species of 4 % and 5 %) (Hiraishi et al. 2000)

Cells are catalase and oxidase positive. Nitrate is not reduced. No acid production occurs in Hugh-Leifson's OF medium. Optimal growth occurs at temperatures between 30 °C and 35 °C and pH 7.0–7.5. Growth in the presence of 3 % NaCl is variable. Strains can hydrolyze starch and tween 80. The hydrolysis of aesculin, casein, and gelatin is variable. Cells can utilize D-xylose, D-glucose, maltose, acetate, propionate, butyrate, succinate, fumarate, and glutamate. The utilization of L-arabinose, D-sorbitol, and malate is variable. Cells are negative for the utilization of D-fructose, D-mannose, cellobiose, lactose, methanol, propanol, formate, lactate, citrate, gluconate, phenylacetate, benzoate, p-cresol, dichlorophenol, dibenzofuran, dibenzo-p-dioxin, and naphthalene (Hiraishi et al. 2000). The type species is sensitive to tetracycline, polymyxin B, and chloramphenicol but resistant to penicillin, streptomycin, bacitracin, and kanamycin. Distinctive morphological and physiological characteristics are summarized in *Table 25.4*.

The predominant cellular fatty acid is C18:1 (d9). The major hydroxyl fatty acid is 2-OH C14:0. Further 2-hydroxyfatty acids can be detected in minor amounts, including 2-OH C15:0 and 2-OH C16:0; 3-hydroxy fatty acids are absent. The predominant polyamine is spermidine. Monosaccharide-type glycosphingolipids are present. Ubiquinone-10 is the major respiratory quinone; Q-9 was not detected. The genomic DNA G+C content is 64.8–65.2 mol%. The type species is *Blastomonas natatoria*. Habitates are freshwater environments.

Novosphingobium Takkeuchi, Hamana and Hiraishi 2001

No.vo.sphin.go´bi.um. L. adj. novus new; Gr. adj. sphingos of sphinx; Gr. n. bios life, living; N.L. fem. n. *Novosphingobium* new sphingosine-containing life.

The genus *Novosphingobium* was proposed by Takeuchi et al. (2001) based on six species (cluster III) of the genus *Sphingomonas sensu lato*, "*Sphingomonas rosa*", "*S. subarctica*", "*S. stygia*", "*S. subterranean*", "*S. aromaticivorans*" and "*S. capsulata*," which were reclassified as *Novosphingobium rosa*, *N. subarcticum*, *N. stygium*, *N. subterraneum*, *N. aromaticivorans*,

Data are from Hiraishi et al. (2000). + positive, (+) weakly positive, (–) negative reaction. Symbols for carbon nutrition tests: ++ good growth, + moderate growth, [+] poor growth, – no or only very less growth. Both strains were positive for catalase, oxidase, starch hydrolysis; Tween 80 hydrolysis; utilization of maltose, ++; acetate, +; propionate, +; butyrate, +; pyruvate, ++; succinate, [+]; fumarate, [+]; and glutamate, ++ and showed negative reactions for: indole production, H_2S production, nitrate reduction, phenylalanine deaminase, urease, gelatin liquefaction in gelatin tube, acid from glucose in OF test, chitin hydrolysis, and utilization of D-fructose, D-mannose, cellobiose, lactose, methanol, propanol, formate, lactate, citrate, gluconate, phenylacetate, benzoate, p-cresol, dichlorophenol, dibenzofuran, dibenzo-p-dioxin, and naphthalene

and *N. capsulatum*. At the time of writing (July 2013), 23 *Novosphingobium* species were described with validated names.

Cells are Gram-negative, nonsporulating, and rod-shaped. They are motile or nonmotile; for some strains, motility was only obtained in the early exponential growth phase. Cells are motile by the means of a polar flagella. Cell size is in the range of 0.1–1.0 × 0.6–4.0 µm. Colonies are off-white, pale-yellow, whitish-brown, yellow, or yellow-orange; mostly small, convex, circular, opaque, smooth; and have a diameter of 1–2 mm. Colonies can also be shiny, nontransparent, contain an entire margin, or have mucous. Methanol:acetone-soluble pigments have a characteristic λmax at 453 and 480 nm. The major carotenoid is nostoxanthin (Glaeser et al. 2009).

All strains grow at a temperature range between 15 °C and 32 °C; some also grow at 4 °C and 37 °C, with one growing at 41 °C (*Novosphingobium indicum*, Yuan et al. 2009) The optimum temperature for growth is 25 °C and 30 °C. Growth occurs at a wide pH range, from pH 4.5 to 10. The optimum pH for growth is pH 6.0–7.0. Salinity-dependent growth differs among species. Some are salt-sensitive (freshwater species, Glaeser et al. 2009, 2013) and can only grow at very low NaCl (%w/v) concentrations of ≤ 0.25 (0.5) % (w/v) NaCl. Other strains require at least 1 % NaCl and grow up to 6 % NaCl (*Novosphingobium pentaromativorans*; Sohn et al. 2004). Other strains grow in a range of 0–4 % and even 5 % (w/v) NaCl. Strains are strictly aerobic and chemo-organotrophic. A broad range of sugars and amino acids can be assimilated by different species. Morphological and physiological differences among the type strains are depicted in *Table 25.5*.

The predominant respiratory quinone is ubiquinone Q-10; minor to trace amounts of Q-9 have also been detected. The predominant saturated fatty acid is C18:1; C16:0 is present as a minor component. The major 2-hydroxy fatty acid is 2-OH C14:0. Other 2-hydroxy fatty acids, 2-OH C12:0, 2-OH C13:0, 2-OH C15:0, and 2-OH C16:0 were also detected in minor to trace amounts. GSLs are present. Spermidine is the major polyamine component. Minor to trace amounts of putrescine, spermine, cadaverine, 1,3-diaminopropane, or agmatine can be present. *sym*-Homospermidine was not detected at all. Polar lipid profiles share sphingoglycolipids, phosphatidylgylcerin, and phosphatidylethanolamine; most often diphosphatidylglycerol, phosphatidylcholine, phosphatidyldimethylethanolamine, and phosphatidylmonomethyl ethanolamine are also present as well as phosphor-, glycol-, and aminolipids. Some species contained a yellow pigment in the polar lipid profile, positive stained with α-naphthol (Glaeser et al. 2009, 2013; Kämpfer et al. 2002a).

Characteristic 16S rRNA signature nucleotides are present at positions 52:359 (U:A), 134 (G), 593 (U), 987:1218 (A:U) and 990:1215 (U:G). Two species (*Novosphingobium acidiphilum* and *Novosphingobium nitrogenifigens*) contain a characteristic 21-bp signature gap in the 16S rRNA gene sequence between base positions 1256 and 1278 (*E. coli* numbering, Brosius et al. 1978) (Addison et al. 2007; Glaeser et al. 2009). This 21-bp gap is not recognized in any other species of the family *Sphingomonadaceae*, but it occurred frequently in other members of the class *Alphaproteobacteria* (Glaeser et al. 2009). The type species is *Novosphingobium capsulatum* (Yabuuchi et al. 1990). The DNA G+C content is in the range of 60–67 mol%.

Habitats include saturated Atlantic coastal plain terrestrial subsurface sediments, roots of rose trees, clinical specimens, stocked distilled water, surface water and sediments of

freshwater lakes, sewage ponds, deep-sea water, fluidized-bed bioreactor treating PCP-contaminated groundwater, HCH-contaminated dumpsites, oil-, polychlorinated dibenzo-p-dioxins (PCDD)/F- and PAH-contaminated soils and sediments, activated sludge of a sewage treatment plant, and pulp and paper wastewater.

Nitrogen Fixation The ability to fix nitrogen was observed for one species in the genus *Novosphingobium*, *Novosphingobium nitrogenifigens* (Addison et al. 2007). The type strain Y88^T (originally isolated from pulp and paper wastewater), grown on nitrogen-limited mineral medium, showed a positive reaction for acetylene reduction and *nifH* was detected with degenerated primers (Addison et al. 2007). All genes required for nitrogen fixation were determined in the genome of the strain, *nifA*, *–D*, *–E*, *–H*, *–K*, *–N*, *–Q*, *–U*, *–W*, and *–X*, and *fixA* and *fixU* as well as genes encoding cofactors of the biosynthesis proteins (Strabala et al. 2012). Along with *S. azotifigens, N. nitrogenifigens* is one of the two species of the *Sphingomonadaceae* in which nitrogen fixation was proven.

Sphingobium Takkeuchi, Amana and Hiraishi 2001 Emend Li et al. 2013

Sphin.gobi.um. Gr. adj. Sphingos of sphinx; Gr. n. bios life, living; N.L. fem. n. Sphingobium sphingosine-containing life.

The genus *Sphingobium* was proposed based on three species of the genus *Sphingomonas sensu lato*, "*Sphingomonas yanoikuyae*", "*Sphingomonas herbicidovorans*", and "*Sphingomonas chlorophenolica*" representing the cluster IV of the genus *Sphingomonas sensu lato*, which were reclassified as *Sphingobium yanoikuyae*, *Sphingobium herbicidovorans*, and *Sphingobium chlorophenolica* (Yabuuchi et al. 2001). At the time of writing (July 2013), the genus contained 34 species (http://www.bacterio.net/).

Cells are Gram-negative, nonsporulating, and rod-shaped. Cell size is in the range of 0.1–1.5 × 0.7–3.5 μm. Cells can be nonmotile or motile by means of a polar, single lateral, or peritrichious flagella. Colonies are white, whitish-brown, pale, and creamy-yellow, yellow, circular, and smooth; some colonies are also convex, domed, or slimy. Two species, *Sphingobium indicum* and *Sphingobium chungbukense*, produce a water-soluble brown pigment (λmax = 532 nm; Pal et al. 2005). Some strains from rosette structures on complex medium and branched thread or hypha-like aggregates on selective media (*Sphingobium aromaticiconvertens*). Capsules can be formed under specific growth conditions; for example, cells of *Sphingobium aromaticiconvertens* from capsules after growth on dibenzofuran. Cells are strictly aerobic and have a chemo-organotrophic metabolism. Most grow at temperatures between 15 °C and 30 °C (optimal growth is mainly at 28–30 °C); most also grow at 37 °C, and some also at 40 °C. The pH range of growth is between pH 5 and 10, with an optimum at pH 7.0. Salinity-dependent growth occurs in a range of 0–5 % (w/v) NaCl; some only grow at low salinity, whereas others require at least 2 % (w/v) NaCl. Most species are positive for catalase activity and negative for nitrate reduction (Li et al. 2013).

Morphological and physiological features differentiating *Sphingobium* species are summarized in ❯ *Table 25.6*. The predominant respiratory quinone is ubiquinone Q-10, but minor to trace amounts of Q-9 can also be detected. The dominant fatty acid is C18:1; C16:0 occurs in minor amounts. The major 2-hydroxy fatty acid is 2-OH C14:0. In some species, 2-OH C15:0 and 2-OH C16:0 were also detected. The major polyamine is spermidine. Minor to trace amounts of putrescine, spermine, cadaverine, 1, 3-diaminopropane, and agmatine can be present. The major polar lipids are diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylglycerol and sphingoglycolipids, with only a few exceptions. Phosphatidyldimethylethanolamine, phosphatidylmonomethyl ethanolamine, and phosphatidylcholine are also found among species of the genus. Characteristic 16S rRNA signatures are present at positions 52:359 (U:A), 134 (G), 593 (U), 987: 1218 (A:U) and 990:1215 (U:G). The DNA G +C content is 58.2–67.0 mol% (values below 60 °C were only detected for *Sphingobium suberifaciens* and *Sphingobium rhizovicinum*). The type species is *Sphingobium yanoikuyae* (Takeuchi et al. 2001).

Habitates include oil-, chlorophenol-, and HCH-contaminated soils, γ-HCH-treated upland soils, HCH dumpsite sides, hydrocarbon-contaminated sawmill soil, chemically contaminated freshwater sediment, sewage-treatment wastewater, homemade kitchen-waste vermicompost, copper mine soil, activated sludge, fly ash dumping site of a thermal power plant, wastewater treatment system in a pesticide manufactory, rhizosphere soil of rice or *Fortunella hindsii* (Champ. ex Benth.) swingle, corked lettuce roots, spring water, river water or sediment, freshwater lake surface water, and sediments. Type strains of several *Sphingobium* species were isolated from HCH-contaminated sides and show HCH-degrading activities in different proportions regarding overall and HCH-isomere-specific degrading activities.

Sphingopyxis Takkeuchi, Hamana and Hiraishi 2001 Emend Baik et al. 2013

Sphin.go.pyx´is. Gr. adj. sphingos of sphinx; Gr. n. pyxis jewel box; N.L. fem. n. Sphingopyxis jewel box of sphingolipid-containing life.

The genus *Sphingopyxis* was proposed based on two species of the genus *Sphingomonas sensu lato*, "*Sphingomonas macrogoltabidus*" and "S*phingomonas terrae*," representing the cluster IV of the genus *Sphingomonas sensu lato*. The species were reclassified as *Sphingopyxis macrogoltabidus* and *Sphingopyxis terrae*. Three *Sphingopyxis* species, *Sphingopyxis marina*, *Sphingopyxis litoris* (both Kim et al. 2008), and *Sphingopyxis flavimaris* (Yoon and Oh 2005), were recently transferred to the new genus *Sphingorhabdus* by Jogler et al. (2013). At the time of writing (July 2013), the genus *Sphingopyxis* contained 16 species with validated names (http://www.bacterio.net/).

Cells are Gram-positive, nonsporulating, and ovoid to rod-shaped. Cell size is in the range of 0.2–0.9 × 0.5–3.0 μm. Ultrasmall cells (<0.1 μm^3) are characteristic for strains of *Sphingopyxis alaskensis*, which represents oligotrophic marine

ultramicrobacteria. Cells may be motile or nonmotile; motility by means of a single polar or subpolar flagella. Intracellular accumulation of polyhydroxyalkanoates (mainly 3-hydroxybutyric acid, with minor amounts of 3-hydroxyvaleric acid) was obtained during growth in mineral medium containing 0.1 % glucose for *Sphingophyxis chilensis*, *S. macrogoltabidus*, and *S. alaskensis* (Godoy et al. 2003). The three species can be differentiated from *Sphingomonas adhaesiva*, which accumulated, under the same conditions, 60 % 3-hydroxybutyric acid and 3 % 3-hydroxyvaleric acid (Godoy et al. 2003).

Colonies are beige, yellowish, yellow or orange pigmented, circular, convex with entire margins, smooth, opaque, glistening, and/or nonglossy, with a diameter between 0.8 and 5 mm. Acetone-soluble pigments for bright-yellow pigmented cells of *Sphingopyxis witflariensis* are characterized by λmax at 452 and 478 nm (Kämpfer et al. 2002b). Strains are strictly aerobic and chemo-organotrophic. Strains of *Sphingopyxis alaskensis* were obligate oligotrophic after the first isolation, but they turned out to be facultative oligotrophic (Schut et al. 1993, 1995). Cells are catalase-variable (Baik et al. 2013); nitrate reduction is variable.

All strains grow at temperatures between 10 °C and 30 °C; some also at 35–37 °C and 42 °C (*Sphingopyxis ginsengisoli*, Lee et al. 2008; *Sphingopyxis soli*, Choi et al. 2010b) and even at 48 °C (*Sphingopyxis alaskensis*, Godoy et al. 2003). One species is psychrophilic and cold-adapted (*Sphingopyxis bauzanensis*) and grows at temperatures between 1 °C and 25 °C (Zhang et al. 2010). Growth occurs at a wide pH range (pH 4.5 to 11), with optimal growth between pH 6 and 8. Salinity requirements depend on the original habitat of strains. Most strains grow in the presence of 0–3 % (w/v) NaCl. Freshwater species (*Sphingopyxis rigui* and *Sphingopyxis wooponensis*) show optimal growth at 0 % and in the presence of up to 1 % (w/v) NaCl. For marine species (*Sphingopyxis alaskensis* or *Sphingopyxis baekryungensis*), growth occurs up to 5–10 % NaCl (w/v), with an optimum between 2 % and 3 % (w/v) NaCl. Morphological and physiological characteristics differentiating *Sphingopyxis* and *Sphingorhabdus* species are listed in *Table 25.7*.

The predominant respiratory quinone is ubiquinone Q-10; minor amounts of ubiquinone Q-9 and Q-8 can also be present. The major cellular fatty acids are C18:1, C16:0, and C16:1. The major 2-hydroxy fatty acids are 2-OH C14:0, 2-OH C15:0, and/or 2-OH C16:0. GSLs are present. The major polar lipids are diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylglycerol, sphingoglycolipid, and different unknown glycolipids and/or phospholipids. Some also contain phosphatidylcholine and minor amounts of phosphatidylmonomethylethanolamine. Spermidine is the major polyamine; some also contain minor to trace amounts of putrescine or spermine, as well as cadaverine or 1,3-diaminopropane. Characteristic 16S rRNA signatures are present at positions 52:359 (C:G), 134 (G), 593 (U), 987:1218 (G:C), and 990:1215 (U:G).

The type species is *Sphingopyxis macrogoltabida* (Takeuchi et al. 1993, 2001). The DNA G+C content is 63–69.2 mol%. Lower values of 53.3–57.3 mol% were obtained for *Sphingopyxis wooponensis* and *Sphingopyxis rigui* (Baik et al. 2013). Habitats include underground water, seawater, soil partially contaminated with hydrocarbons or HCH, ginseng field soil, river-sediment contaminated with chlorophenolic compounds, wetlands, freshwater, mineral water, wastewater treatment plant granules, or activated sludge.

Biodegradation of recalcitrant natural and anthropogenic xenobiotic and polyaromatic compounds by *Sphingomonas*, *Sphingobium*, *Sphingopyxis*, and *Novosphingobium* species A specific feature of sphingomonads of the genera *Sphingomonas*, *Sphingobium*, *Sphingopyxis*, and *Novosphingobium* is the ability to degrade recalcitrant compounds of natural or anthropogenic origin, including biphenyl, naphthalene, fluorene, and several substituted variants of those compounds; phenanthrene(s), pyrene, as well as diphenylether, furan, dibenzo-p-dioxin, and several chlorinated variants; carbazole, estradiol, polyethylene glycols, chlorinated phenols, nonylphenols, and different herbicides and pesticides (reviewed by Stolz 2009). The specific adaptation of sphingomonads to the degradation of those compounds is indicated by the high frequency in which sphingomonads are isolated from respective contaminated habitats. The replacement of LPS in the outer membrane by SGLs and the excretion of anionic EPS (sphingans) are important features, which contribute to the ability of sphingomonads to degrade aromatic compounds that are often strongly hydrophobic (Stolz 2009).

For example, the type strain of *Sphingobium yanoikuyae* B1^T degrades anthracene, toluene, naphthalene, phenanthrene, biphenyl, and m-xylene (Yabuuchi et al. 1990; Khan et al. 1996); *Novosphingobium aromaticivorans* F199^T degrades naphthalene, toluene, cresols, biphenyl, fluorene, and dibenzothiophene, whereas another *N. aromaticivorans* strain was capable of degrading 2-methylnaphthalene, 2,3-dimethylnaphthalene, acenaphthene, anthracene, fluoranthene, and phenanthrene (Shi et al. 2001). The type strains of *Novosphingobium subterraneum* and *Novosphingobium stygium* were capable of degrading biphenyl, toluene, dibenzothiophene, and fluorene (Balkwill et al. 1997; Takeuchi et al. 2001). Several other *Sphingomonas* sp. were found to degrade differently methylated naphthalenes (Bramucci et al. 2002; Sabaté et al. 1999, 2003), acenaphthene, or acenaphthylene (Pinyakong et al. 2004; Kouzuma et al. 2006) or several other bi- or polycyclic aromatic compounds such as phenanthrene (Dutta et al. 1998; Liu et al. 2004; Pinyakong et al. 2000), fluorene (Wattiau et al. 2001), chrysene (Willison 2004), tetralin (1,2,3,4-tetrahydronaphthalene; Hernáez et al. 1999), or carbazole (Habe et al. 2002; Kilbane et al. 2002; Shepherd and Lloyd-Jones 1998). Other sphingomonads were found to degrade compounds that are problematic because of their estrogenic activity, which can be quite frequently found in effluents of sewage plants; for example, 17ß-estradiole can be degraded by a *Novosphingobium tardaugens* strain (Fujii et al. 2003a). Type strains of *Sphingopyxis macrogoltabidus*, *Sphingopyxis terrae*, and *Sphingomonas sanguinis* were capable of degrading polyethylene glycols (PEG)

Data were taken from references added to the species name or as otherwise indicated by labeling the result respectively: [a]Kim et al. (2005); [b]Kämpfer et al. (1997, 2002); [c]Zhang et al. (2010); [d]Baik et al. (2013); [e]Lee et al. (2008); [f]Srinivasan et al. (2010); [g]Choi et al. (2010b); [h]Sharma et al. (2010); [i]Jogler et al. (2013); [j]Uchida et al. (2012)

(Takeuchi et al. 1993). An overview of several more compounds degraded by sphingomonads is given in ❯ *Table 25.8*, which was adapted from Stolz (2009).

One important feature of sphingomonads is the degradation of insecticides and herbicides. One of the most studied insecticides that can be degraded by several sphingomonads is y-hexachlorocyclohexane (HCH; lindane). The degradation of HCH (1, 2, 3, 4, 5, 6–hexachlorocyclohexane) is a common feature of several sphingomonads that were isolated from HCH-contaminated or HCH-dumping sites; among those eight *Sphingobium* species with validated names, *Sphingobium baderi* (Kaur et al. 2013), *Sphingobium chinhatense* (Dadhwal et al. 2009), *Sphingobium czechense* (Niharika et al. 2013a), *Sphingobium francense* (Pal et al. 2005), *Sphingobium japonicum* (Pal et al. 2005), *Sphingobium lactosutens* (Kumari et al. 2009), *Sphingobium lucknowense* (Garg et al. 2012), *Sphingobium quisquiliarum* (Bala et al. 2010), and *Sphingobium ummariense* (Singh and Lal 2009). Beside *Sphingobium* species strains phylogenetically placed into the genera *Sphingomonas*, *Novosphingobium* and *Sphingopyxis* are also HCH-degrading sphingomonads, including the species *Novosphingobium lindaniclasticum* (Saxena et al. 2013), *Novosphingobium barchaimii* (Niharika et al. 2013b), and *Sphingopyxis ummariensis* (Sharma et al. 2010).

Hexachlorocyclohexane is an organochlorine insecticide that has been applied since the 1940s. Two forms are available. First, technical-grade HCH which is a mixture of mainly four isomers, α-, β-, γ-, and δ-HCH. Only γ-HCH thereby shows the insecticidal activity; however, all isomers are persistent in the environment and toxic for insects, birds, and mammals. Gamma-HCH only makes up 6–10 % of the technical-grade HCH (Willett et al. 1998; Alvarez et al. 2012). The second form of HCH is lindane, which is almost pure γ-HCH. The degradation pathways of HCH isomers were mainly studied for three *Sphingobium* species, *Sphingobium japonicum* UT26^T, *Sphingobium indicum* B90A ^{T}, and *Sphingobium francense* Sp + (Böltner et al. 2005; Nagata et al. 2007). All currently compared sphingomonads shared the same genes involved in the degradation pathway (Lal et al. 2006; Nagata et al. 2007). The degradation pathway of y-HCH was primarily studied for *Sphingobium japonicum* UT26^T.

Gene-coding enzymes or other proteins involved in the degradation pathways are called lin-genes (*linA* to *linN*). Several of those genes were cloned and characterized in detail. *LinA* is a dehydrochlorinase (Imai et al. 1991) involved in the first steps of the upstream degradation pathways (Lal et al. 2006). Different variants of the genes are known (*linA*/*linA1*/*linA2*; Lal et al. 2006). The stereo selectivity of LinA is responsible for the selective declorination of HCH isomers, including α-, γ-, and δ-HCH but not β- or ε-HCH (Lal et al. 2006). Further enzymes involved in the next steps of the upstream pathway are a halidohydrolase (haloalkane dehalogenase) coded by *linB* (Nagata et al. 1993b) and a dehydrogenase coded by *linC* or *linX* variants (Nagata et al. 1994).

The initial steps of the degradation pathway of different HCH isomers can be more or less complex depending on the isomers partially including both enzymes LinA and LinB (Sharma et al. 2006; Nagata et al. 1993a; Trantirek et al. 2001; Wu et al. 2007). Genes involved in the downstream pathway of HCH degradation are *linD* coding a reductive dechlorinase (Miyauchi et al. 1998), *linE* coding a ring-cleavage oxygenase (Miyauchi et al. 1999), and *linF* coding a maleylacetate reductase. The genes *linG* and *linH* code the alpha and beta-subunits of an acyl-CoA transferase and *linJ* codes a thiolase (Nagata et al. 2007). Two *lin* genes were identified to be transcriptional regulators of the LysR-family (*linR;* Miyauchi et al. 2002) and the IclR-family (*linL*; Nagata et al. 2007). The gene cluster *lin*KLMN was found in a homologous arrangement in several sphingomonads strains; it codes a putative ABC transporter involved in the HCH degradation pathway (Endo et al. 2005; Nagata et al. 2007). The structure of the ABC transporter was predicted as followed: the membrane protein LinK was localized in the inner membrane linked to a cytoplasmic ATPase (LinL). *LinM* codes a periplasmatic protein and *linN* a lipoprotein located at the outer membrane associated with LinK (Nagata et al. 2007).

Sphingobium spp. have been the most investigated HCH-degrading bacteria so far. Genome sequence analysis (see above) of the three most studied strains showed that *lin* genes are either located on the chromosomes and/or on plasmids, which varied between the different strains. Several of the *lin* genes were associated with an insertion element (IS6100), which is a genetic mobile element that may explain the spread of *lin* genes among several different *Sphingobium* species by horizontal gene transfer (see the genome section within this chapter). It was furthermore discussed that the presence of glycosphingolipids in the outer membrane instead of lipopolysaccharides might facilitate the assimilation of hydrophobic HCH because SGLs provide a membrane surface of higher hydrophobicity (Lal et al. 2006).

Other sphingomonads were found to degrade herbicides as carbofuran (Feng et al. 1997a; Kim et al. 2004; Yan et al. 2007), isoproturon (Sørensen et al. 2001; Bending et al. 2003), or further insecticides as chlorpyrifos (Li et al. 2007). The type strain of *Sphingobium herbicidovorans* was capable of the complete degradation of both enantiomers of the herbicide 2-(4-chloro-2-methylphenoxy)propionic acid (mecoprop) in an enantio selective manner (Zipper et al. 1996). An intensively studied *Sphingomonas*-type strain degrading nitrodiphenyl ether herbicides is *Sphingomonas wittichii* RW1^T, which is able to degrade PCDD, dibenzofurans (DF), and diphenyl ethers. Those compounds are occur worldwide in water and soil pollutants; they are considered to be potential mutagens and endocrine disruptors. The aerobic PCDD and DF degradation pathway of strain RW1^T has been intensively studied (e.g. Wittich et al. 1992; Bünz and Schmidt 1997; Wittich 1998; Hong et al. 2002; Nam et al. 2005; Keum et al. 2008).

Polyphenol degradation was obtained for the type strain of *Sphingophyxis chilensis*, Godoy et al. 2003, which was isolated from a sediment of a chlorophenol-polluted river (Godoy et al. 1999). The type strain of *Sphingobium chlorophenolicum* (formerly *Sphingomonas chlorophenolica*) was isolated from

Table 25.8

Overview of xenobiotic and recalcitrant compounds degraded by sphingomonads strains

Strains	Degraded compounds	Reference

soils contaminated with wood-preserving chlorophenols and was intensively studied because it is one of the most effective bacteria capable of a complete degradation pathway of pentachlorphenols (PCP) (Saber and Crawford 1985). The initial step of PCP mineralization is an oxidative dechlorination of PCP to tetrachlorop-benzoquinone (TeCB) by a 4-monooxygenase (PcpB). In the following step, the intermediate product TeCB is reduced by a tetrachlorobenzoquinone reductase (PcpD) to tetrachloro-p-hydroquinone (TeCH), which is further converted to 2,3,6-trichloro-p-hydroquinone (TCH) and 2,6-dichloro-p-hydroquinone (DiCH) by reductive dehalogenase (PcpC) and reductive dechlorination. A ring cleavage of DiCH by a 1,2-dioxygenase (PcpA) leads to the formation of 2-chloromaleylacetate (2-CMA), which is subsequently converted to succinyl-CoA and acetyl-CoA by a reductive dechlorination via a maleylacetate reductase (PcpE). Succinyl-CoA and acetyl-CoA can then be further mineralized through the Kreb's cycle (Pathway description: Orser and Lange 1994; Chanama and Chanama 2011).

Sandarakinobacter Yurkov et al (1997)

San.da.ra.ci.no.bac'ter. Gr. adj. sandaracinos, orange-colored; Gr. n. bacter, rod; M.L. masc. n. *sandaracinobacter*, orange-colored rod.

The genus contains only one species, *Sandaracinobacter sibiricus* (formerly "*Erythromonas sibricius*," formerly "*Erythrobacter sibiricum*"). The type strain was originally isolated as the first obligately aerobic Bchl *a*-containing freshwater bacterium from thin microbial mats that were formed near underwater hydrothermal vents in a river (Shiba and Simidu 1982).

Cells are Gram-negative, nonsporulating, and rod-shaped. Rods are thin and long and can form chains. Cells are motile by means of subpolar flagella (up to three). Cell size is in the range of 0.3–0.5 × 1.5–2.5 μm or longer. Cells divide by binary vision. Colonies are intensively yellow-orange pigmented. Carotenoid and Bchl *a* are produced. In vivo absorption spectra show absorption peaks with λmax at 424, 450, and 474 nm for carotenoids. The photosynthetic apparatus consists of a RC with a tightly bound tetraheme cytochrome c (cyt c) and a LH-I complex. The RC and LH-I are located in the cytoplasmatic membranes and showed absorption peaks with λmax at 750, 799, and 857 nm and λmax at 867 nm, respectively. The tetraheme cyt c is characterized by a molecular weight of 44.0 kDa and represents an immediate electron donor. Additionally, a soluble cyt c of 14.0 kDa and a membrane-bound cyt c of 30.0 kDa (cyt of bc_1 complex) are present (Yurkov et al. 1997). Storage compounds are polyphosphates, polysaccharide, and poly-β-hydroxybutyrate.

Cells have aerobic chemoorganotrophic and facultative photoheterotrophic metabolisms. They cannot grow anaerobically in the light. Cells are oxidase-positive and catalase-negative. A ribulose-bisphosphate carboxylase is not detectable. Fermentation or denitrification activities were not detected.

The optimal temperature for growth is 25–30 °C. Growth is strongly inhibited in the presence of 1.0 % (w/v) NaCl (salt-sensitive). The optimum pH is between 7.5 and 8.5. *Sandaracinobacter sibiricus* grows best on butyrate, sucrose, casein hydrolysate, and yeast extract; well on acetate and maltose; and shows weak growth on media containing glucose, fructose, pyruvate, propionate, or glycerol. Ribose, sorbitol, benzoate, fumarate, formate, succinate, citrate, malate, methanol, and ethanol are not utilized. Tween 60 is hydrolyzed but not gelatin or starch. Morphological and physiological characteristics differentiating *Sandaracinobacter sibiricus* and *Sandarakinorhabdus limnophila* are depicted in *Table 25.9*. *Sandaracinobacter sibiricus* is

Table 25.9

Data from Yurkov and Gorlenko (1990) for *Sandaracinobacter sibiricus* and Gich and Overmann (2006) for *Sandarakinorhabdus limnophila*. *nd* not determined. All strains were isolated from freshwater environments. No information on enzymic activities (other than those involved in glycolysis and the tricarboxylic acid cycle)

resistant to chloramphenicol, fusidic acid, streptomycin, amikacin, bacitracin, kanamycin, neomycin, and novobiocin. It is sensitive to penicillin, ampicillin, tetracycline, polymyxin B, erythromycin, nalidixic acid, lincomycin, mycostatin, aureomycin, and vancomycin. A high level of tellurite resistance occurs depending on the carbon source in the medium. Up to 1,200 pg mL^{-1} tellurite can be tolerated in a medium containing acetate or yeast extract as a sole organic source. Tellurite is reduced and transformed into metallic tellurium, which is accumulated inside the cells.

Ubiquinone Q-9 and Q-10 are the major respiratory quinones. Enaquinones are not present (Gogotov and Gorlenko 1995). The DNA base composition is 68.5 mol% G+C (determined by thermal denaturation). The habitat is freshwater algobacterial mats near hydrothermal sulfide-containing vents along a river bottom.

Sandarakinorhabdus Gich and Overmann 2006

San.da.ra´ki.no.rhab´dus. Gr. adj. *sandarakinos* of orange colour; Gr. fem. n. *rhabdos* rod; N.L. fem. n. *Sandarakinorhabdus* orange-coloured rod.

The genus *Sandarakinorhabdus* contains only one species, *Sandarakinorhabdus limnophila*—a phototrophic, Bchl *a* containing planktonic freshwater species. The type strain so42^T and two further strains of *Sandarakinorhabdus limnophila* were isolated from a mesotrophic freshwater lake, Lake Starnberger See in Bavaria, Germany (Gich and Overmann 2006).

Cells are Gram-negative, non-spore-forming, rod-shaped, and nonmotile. They grow as single cells. Capsules are not present. Cell division occurs by binary fission. Colonies are orange–red-pigmented with smooth surfaces; they form a mucilaginous texture on agar plates and have a diameter of 1–3 mm. Cells absorb at 430–490 nm (λmax at 420, 460, and 480 nm) and at 800–865 nm (λmax at 800, 837 and 865 nm), indicating the presence of carotenoids and BChl *a*P, respectively. Nostoxanthin was identified as the main carotenoid. Two unidentified carotenoids containing keto groups are also present. In some strains, keto-nostoxanthin was detected as an additional carotenoid.

Absorption maxima at 800 and 865 nm and a shoulder at 837 nm indicated the presence of two photosynthetic complexes—the photosynthetic, light-harvesting complexes LH-I (865 nm) and LH-II (800–837 nm, B800–830 type LH-II). Cells can contain polyphosphate granules and exhibit strong enzymatic activity for acid and alkaline phosphatases. They are cytochrome-oxidase negative and catalase positive. Strains are obligatory

aerobic and chemoorganoheterotrophic. Fermentation or anaerobic growth with nitrate or sulfate was not detected. Strains are facultative oligotrophs that grow in the presence of a number of short-chain organic acids and amino acids as electron donors and carbon sources. Cells grow well in media containing 0.1 % peptone or yeast extract.

The predominant respiratory lipoquinone is ubiquinone Q-10; minor amount of ubiquinone Q-9 was also detected. The major polar lipids are diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylglycerol, phosphatidylcholine, glycolipids, and two sphingoglycolipids (SGL-1 and SGL-2). Polyamines were not analyzed. The predominant cellular fatty acids are C16:1 ω7c and C18:1 ω7c, followed by C16:0. The most abundant 2-hydroxy fatty acid is iso-2-OH C14:0; minor to trace amounts of 2-OH C15:0 and 2-OH C16:0 and trace amount of a 3-hydroxy fatty acid iso-3-OH C16:0 were also detected. The G+C content of the genomic DNA is 64.3 mol% (determined by high-performance liquid chromatography).

Sphingocinicella Maruyama, Park, Ozawa, Tanaka, Sumino, Hamana, Hiraishi and Kato 2006, Emend Geueke et al. 2007; Yasir et al. 2010

Sphin.go.si´ni.cel´la. N.L. n. *sphingosinum* sphingosine; L. fem. n. cella a store-room and in biology a cell; N.L. fem. n. *Sphingosinicella* sphingosine-containing cell.

The genus *Sphingosinicella* was proposed by Maruyama et al. (2006) and comprised four species at the time of writing (July 2013): *Sphingosinicella microcystinivorans* (Maruyama et al. 2006), *Sphingosinicella xenopeptidilytica* (Geueke et al. 2007), *Sphingosinicella soli* (Yoon et al. 2008), and *Sphingosinicella vermicomposti* (Yasir et al. 2010).

Cells are Gram-negative, non-spore-forming, and rod-shaped. Cell size is the range of 0.3–0.8 × 0.6–4.0 μm. Cells are motile by means of polar flagella. Colonies are yellow or pale-yellow, circular, convex, smooth, sticky, or glistening with a diameter between 0.5 and 1.0 mm (either investigated on tryptone soy agar [TSA] or half-strength R2A). Acetone/methanol-soluble pigments are characterized by λmax 448–449 and 476 nm (*Sphingosinicella xenopeptidilytica*, Geueke et al. 2007). Strains are strictly aerobic and chemoorganotrophic. All strains are oxidase positive. They are variable with respect to catalase activity, nitrate reduction, and aesculin hydrolysis.

Growth conditions shared by all members of the genus are growth at temperatures between 10 °C and 37 °C with an optimal growth temperature around 30 °C; no growth is obtained at 44 °C. Growth occurs at pH values between 6.0 and 9.5, but not above pH 11. The optimal pH for growth was between 7.5 and 8.0. All strains grow with 0–1 % (w/v) NaCl, but not in the presence of >2.5 % (w/v) NaCl. Specific metabolic features are the ability to degradation microcystin (*Sphingsinicella microcystinivorans*, Maruyama et al. 2006) or beta-peptides, H-βhVal-βhAla-βhLeu-OH, or H-βhAla-βhLeu-OH, which is shared by strains of the species *Sphingosinicella microcystinivorans* and *Sphingosinicella xenopeptidilytica* (Geueke et al. 2007). The ability of beta-peptide degradation is associated with beta-peptidyl aminopeptidase activity, which is variable among species (Yasir et al. 2010). Species-differentiating physiological characters are summarized in *Table 25.10*.

The predominant respiratory quinone is ubiquinone Q-10; minor amounts of Q-8 and Q-9 can be present. The major polyamine is *sym*-homospermidine as determined for the genus *Sphingomonas*. The major fatty acids are C18:1 ω7c and C16:1 ω7c (by gas chromatographical analysis using the Sherlock MIDI software detected as summed feature C16:1 ω7c and/or iso-C15:0 2-OH), and minor amounts of C16:0. The predominating 2-hydroxy fatty acid is 2-OH C14:0, but trace amounts of 2-0H C12:0, 2-0H C15:0, 2-0H C16:0, and 2-0H C16:1 can also occur. 3-Hydroxy fatty acids are absent. Glycosphingolipids are produced. All strains share diphosphatidylglycerol (partially in low amounts), phosphatidylethanolamine, phosphatidylmonomethylethanolamine, and sphingoglycolipid in their polar lipid patterns; differences can be found in the content of unidentified phospholipids and the presence of glycolipids.

The characteristic 16S rRNA gene sequence signature nucleotides are the same as for the genus *Sphingomonas*: 52:359 (C:G), 134 (G), 593 (G), 987:1218 (G:C), and 990:1215 (U:G). The signature nucleotides in the 16S rRNA gene sequence described previously (Geueke et al. 2007) are variable from species to species within the genus *Sphingosinicella* (Yasir et al. 2010). The DNA G+C content ranges between 59.4 mol% and 65.0 mol% (including G+C values for all species). The type species is *Sphingosinicella microcystinivorans* (Maruyama et al. 2006).

Members of the genus *Sphingosinicell*a were isolated from the water of a toxic *Microcystis* blooming lake (Maruyama et al. 2006), an aeration tank of a wastewater treatment plant (Geueke et al. 2007), alkaline soil (Yoon et al. 2008), and vermicompost (Yasir et al. 2010).

Microcystin Degradation The ability to degrade microcystin is shared by several strains of the species ***Sphingosinicella microcystinivorans***. Microcystin is a hepatotoxic substance produced by several cyanobacteria of the genera *Microcystis*, *Anabaena*, *Nostoc*, and *Oscillatoria* (=Planktothrix); it can cause serious diseases in humans and animals (Jochimsen et al. 1998; Kuiper-Goldman et al. 1999).

The species was proposed based on three freshwater strains all capable of microcystin degradation. The type strain Y2^T was isolated from the eutrophic freshwater lake (Lake Suwa, Japan) during a bloom of toxic *Microcystis* (Park et al. 2001); the other two strains (MDB2 and MDB3) were isolated from the Tenryu River in Japan (Maruyama et al. 2006). Detailed characterization of the type strain showed that it is able to use microcystin as a sole carbon source and degrades several types of microcystin: microcystin-RR, –YR, –LR, and its isomer 6(Z)-Adda (Park et al. 2001). All strains contain the gene *mlrA* encoding a microcystinase; the hydrolytic enzyme opens the cyclic peptide of microcystin. MlrA is therefore necessary for the initial steps in microcystin degradation (Saito et al. 2003).

Microcystin degradation and *mlrA* genes were not detected in the other *Sphingosinicella* species (Geueke et al. 2007;

Table 25.10

Data from Yasir et al. (2010) unless indicated otherwise. + positive, – negative, *w* weak positive, *PCR* polymerase chain reaction

Yoon et al. 2008; Yasir et al. 2010). However, *mlrA* charring sphingomonads were also detected in other genera of the *Sphingomonadaceae*, such as the strains most closely related (>99 % 16S rRNA gene sequence similarity) to the type strain of *Sphingopyxis alaskensis* (Ho et al. 2012) or other *Sphingopyxis* and also *Novosphingobium* type strains (Ho et al. 2007).

***Stakelama* Chen, Zheng, Wang, Yan, Hao, Du and Jiao 2010**
Sta.ke.la´ma. N.L. fem. n. *Stakelama* arbitrary name derived from State Key Laboratory of Marine Environment Science.

The genus *Stakelama* comprises two species, *Stakelama pacifica* (type species; Chen et al. 2010) and *Stakelama sediminis* (Thawng et al. 2013). The type strain of *Stakelama pacifica* JLT832^T was isolated from surface water of the Pacific Ocean and the type strain of *Stakelama sediminis* CJ70^T from a tidal flat sediment in Korea.

Cells are Gram-negative, non-spore-forming, and rod-shaped. They are weakly motile by means of a flagella or non-motile. Colonies are gold–yellow, circular, small (about 1 mm in diameter), smooth or glossy, and opaque. Acetone-soluble pigments are characterized by λmax at 455 and 485 nm (*Stakelema sediminis*). All strains have a strictly aerobic metabolism. Cells are positive for catalase and variable for oxidase activity. Aesculin is hydrolyzed if tested (only for *Stakelama sedimins*).

Strains are negative for the hydrolysis of gelatin and starch and negative for indole production. Growth generally occurs between 5 °C and 20 °C up to 37 °C (optimal growth between 28 °C and 30 °C); at a pH ranges between pH 6 and 9 or pH 5.0 and 10.0 (optimal pH range from pH 6 to 8); and in the presence of 0–5 % (w/v) NaCl (with different optima between 0–1 % and 2 %). Further species-differentiating physiological properties are given in Table 25.11.

The respiratory quinone is ubiquinone Q-10; other ubiquinones were not detected. The predominant polyamine is spermidine; minor amounts of cadaverine and putrescine and trace amounts of spermine and 1,3-diaminopropane are partially present. *sym*-Homospermidine is absent. The major polar lipids are sphingoglycolipid, diphosphatidylglycerol, phosphatidylglycerol, phosphatidylethanolamine, phosphatidylcholine and one phospholipid (data from Thawng et al. 2013). The polar lipid profile can either contain only SGL (*Stakelama pacifica*) or SGL1 and 2 (*Stakelama sediminis*). The species can be further differentiated by the presence of specific aminophospholipids. The predominant fatty acids are C18:1 ω7c, 2-OH C14:0, and C16:0. Trace amounts of 2-OH C15:0 are also detected (Thawng et al. 2013). No further 2-hydroxy and no 3-OH fatty acids are present. The DNA G+C content ranges between 61.4 mol% and 66.5 mol%. The type species is *Stakelama pacifica*.

Sphingomicrobium Kämpfer, Arun, Young, Busse, Kassmannhuber, Rosselló-Móra, Geueke, Rekha and Chen 2012

Sphin.go.mi.crob´i.um. N.L. n. *sphingosinum* (from Gr. gen. n. *sphingos* of sphinx, and suff. *-ine*) sphingosine; N.L. pref. *sphingo-* pertaining to sphingosine; N.L. neut. n. *microbium* microbe; N.L. neut. n. *Sphingomicrobium* a sphingosine-containing microbe.

The genus *Sphingomicrobium* contained four species at the time of writing: *Sphingomicrobium lutaoense* (Kämpfer et al. 2012), *Sphingomicrobium astaxanthinifaciens* (Shahina et al. 2013a), *Sphingomicrobium marinum*, and *Sphingomicrobium flavum* (Shahina et al. 2013b).

Cells are Gram-negative, non-spore-forming, and rod-shaped; they are either nonmotile or motile and flagellated. Cell size is in the range of 0.3–1.1 × 1.2–3.1 μm. Colonies are round, with a diameter of approximately 0.5 mm, and light to bright yellowish or orange-reddish colored. The orange-reddish color is specific for the type strain of *Sphingomicrobium astaxanthinifaciens*, which is able to produce high amounts of astaxanthin (40 μg g^{-1} dry weight; Shahina et al. 2013a).

Cells are oxidase and catalase positive. An aerobic metabolism is observed. They grow on MA 2,216 but not on TSA; some species could weakly grow on R2A or nutrient agar (NA). Growth occurs between 20 °C and 40 °C (optimum at 30–37 °C); *Sphingomicrobium flavum* can also grow at 10 °C and *Sphingomicrobium marinum* even at 45 °C (Shahina et al. 2013b). The pH range of growth is pH 6.5–10 (only *Sphingomicrobium flavum* can grow up to pH 9); the growth is optimum between pH 6.5 and 8.5. Salinity-dependent growth is species-dependent between 1–2 % and 1–7 % (w/v) NaCl; all species grow at 1–2 % NaCl, with optimum growth at 1 %. Species-differentiating morphological and physiological characteristics are given in Table 25.12.

The major respiratory quinone is ubiquinone Q-10; minor amounts of Q-9 can also be present. The predominant polyamines are *sym*-homospermidine and (for *Sphingomicrobium marinum*) *sym*-homospermidine and spermidine (Shahina et al. 2013a, b). Minor amounts of spermidine, putrescine, caderverine, and trace amounts of spermine can also be detected. *sym*-Homospermidien, as the main polyamine, is shared with the genera *Sphingomonas* and *Sphingosinicella* but clearly distinguishes the genus from other genera of the *Sphingomonadaceae* (Busse et al. 1999; Takeuchi et al. 2001; Geueke et al. 2007; Kämpfer et al. 2012). The predominant polar lipids are diphosphatidylglycerol, phosphatidylglycerol, phosphatidylethanolamine, sphingoglycolipid, and three to eight unidentified glycolipids (GL 1–8). Some species also contain aminolipids (*Sphingomicrobium flavum* and *Sphingomicrobium marinum*; Shahina et al. 2013b) or lipids that are not stained with the staining reagents for amino-, phosphate- or glucosyl-groups).

Phosphatidylmonomethylethanolamine and phosphatidyldimethylethanolamine were not detected. The absence of phosphatidylmonomethylethanolamine and phosphatidyldimethylethanolamine was only reported for a few species of the genus *Sphingomonas*, including *Sphingomonas haloaromaticamans* (Wittich et al. 2007) and *Sphingomonas glacialis* (Zhang et al. 2011); it therefore distinguished species of the genus *Sphingomicrobium* from other genera. The predominant fatty acids of *Sphingomicrobium* species are C18:1 ω7c and 2-OH C18:1, which was not obtained by any other *Sphingomonadaceae*. The 2-hydroxy fatty acids 2-OH C14:0, 2-OH C15:0, and 2-OH C16:0 were not detected, in contrast to all other genera of the *Sphingomonadaceae*. No 3-hydroxy fatty acids were detected, as obtained from all other genera of the *Sphingomonadaceae*. DNA G+C content is 63.4–65.2 mol% (only higher for *Sphingomicrobium astaxanthinifaciens*, 70.6 %; Shahina et al. 2013a). The type species is *Sphingomicrobium lutaoense* (Kämpfer et al. 2012).

Habitats include coastal hot springs (*Sphingomicrobium lutaoense*) or seawater of 10 cm depth (*Sphingomicrobium astaxanthinifaciens*, S. *marinum*, and *S. flavum*) in Taiwan.

The type strain of *Sphingomicrobium lutaoense* (Kämpfer et al. 2012) was not able to hydrolyze the b-peptide H-bhVal-bhAla-bhLeu-OH, which clearly distinguished it from *Sphingosinicella xenopeptidilytica* (Geueke et al. 2007).

Sphingorhabdus Jogler et al. 2013

Sphin.go.rhab´dus. N.L. n. *sphingosinum* (from Gr. gen. n. *sphingos* of sphinx and suff. -ine) sphingosine; N.L. pref. *sphingo-* pertaining to sphingosine; Gr. fem. n. *rhabdos* rod; N.L. fem. n. *Sphingorhabdus* a sphingosine-containing rod.

The genus *Sphingorhabdus* is represented by four species (as of July 2013): *Sphingorhabdus planktonica* (type species) and three species that were formerly described as members of the genus *Sphingopyxis*, "*Sphingopyxis marina*", "*Sphingopyxis*

Both type strains were positive for β-glucuronidase; negative for acid production of L-xylose, methyl β-D-xylopyranoside, D-fructose, L-sorbose, methyl α-D-mannopyranoside, potassium gluconate and positive for acid production from starch. They were positive for the utilization of D-fructose, D-mannose, methyl β-D-glucoside, turanose, succinic acid monomethyl ester, bromosuccinic acid, L-alaninamide, L-glutamic acid, glycyl L-glutamic acid, and L-serine; and negative for α-ketobutyric acid. Data were from Thawng et al. (2013), except for the G+C content of *Stakelama pacifica*, which was taken from Chen et al. (2010)

litoris" (both Kim et al. 2008), and "*Sphingopyxis flavimaris*" (Yoon and Oh 2005), which were reclassified as *Sphingorhabdus marina*, *Sphingorhabdus litoris*, and *Sphingorhabdus flavimaris* by Jogler et al. (2013). The type strain of the species *Sphingorhabdus planktonica* G1A_585^T was isolated from an alpine oligotrophic freshwater lake (Walchensee, near Kochel in Bavaria, Germany; Jogler et al. 2013). Type strains of the other species were isolated from water samples of marine systems.

Cells are Gram-negative, non-spore-forming, and rod-shaped. Cell size is in the range of 0.7–1.0 × 0.4–2.5 μm. Cells are motile or nonmotile. Colonies are circular and convex with

+ positive reaction, – negative reaction, *w* weak reaction. All strains are positive for catalase, oxidase, alkaline phosphatase, esterase (C4), esterase lipase (C8), leucine arylamidase, and naphthol-AS-BI-phosphohydrolase activities; as well as assimilation of D-glucose, D-mannitol, acetyl-glucosamine, D-maltose, and phenylacetic acid. All strains are negative for: D-glucose fermentation; reduction of nitrate to nitrite; DNase, α-chymotrypsin, β-glucuronidase, α-fucosidase, α-mannosidase, o-nitrophenyl-β-D-galactopyranoside, p-nitrophenyl-β-D463 galactopyranoside, arginine dihydrolase, lysine decarboxylase, ornithine decarboxylase, urease and tryptophane deaminase activities; citrate utilization; indole and H_2S production; assimilation of capric acid; oxidation/fermentation of mannitol, inositol, sorbitol, rhamnose, saccharose, melibiose, amygdalin and arabinose; hydrolysis of gelatin, chitin, xylan, CMC, casein and Tween-80; growth on TSA and R2A. Data were taken from Kämpfer et al. (2012) and Shahina et al. (2013a, b)

a diameter of 0.7–1.0 mm; they are yellow to yellowish (marine species) or orange and transparent (*Sphingorhabdus planktonica*). The carotenoid content is characterized by λmax at 427 (shoulder), 453 and 481 nm (peaks; *Sphingorhabdus planktonica*; Jogler et al. 2013). Cells are oxidase and catalase positive. All strains show an aerobic metabolism. Only a broad spectrum of substrates can be utilized.

Growth conditions differ depending on the origin of the type strains. The type strain of the freshwater species (*Sphingorhabdus planktonica*, Jogler et al. 2013) only grows

between 18 °C and 24 °C, but not at 11 °C and 27 °C, with NaCl concentration between 0 % and 2 % (w/v) NaCl. Marine species grow either between 15 °C and 34 °C (opt. 24–31 °C) or between 4 °C and 30 °C, but not at 37 °C. The marine species require sea salt in the medium, at least 2–3 % (w/v), with an optimum content between 2–3 % and 3–5 %; they can partially grow in the presence of up to 7 % sea salt content. Further differentiating morphological and physiological characteristics are given in Table 25.7 for the comparison between the type strains of the genera *Sphingopyxis* and *Parasphingopyxis*.

The major respiratory quinone is ubiquinone Q-10; trace amounts of Q-9 were also detected. The main polyamine is spermidine and (for one species) spermidine and agmatine (*Sphingopyxis marina* DSM 22363^T; Kim et al. 2008). All species share minor to trace amounts of putrescine and spermine, and some species contain also trace amounts of agmatine and cadaverine or 1,3-diaminopropane. Major nonpolar fatty acids are summed feature 8 (C18:1 ω7c and/or C18:1ω6c) and summed feature 3 (C16:1ω7c). The main 2-hydroxy fatty acid is 2-OH C14:0. Polar lipids shared by all species are diphosphatidylglycerol, phosphatidylglycerol, phosphatidylethanolamine, and sphingoglycolipids; some species also contain phosphatidylcholine, phosphatidyl monomethylethanolamine, phosphatidyldimethylethanol amine, and glycolipids. The characteristic 16S rRNA gene sequence signature nucleotides are at position 990:1215 (U:A) (Jogler et al. 2013). The G+C content is between 52.6 mol% and 57.8 mol%, including values for type strains of currently proposed *Sphingorhabdus* species. The type species is *Sphingorhabdus planktonica* (Jogler et al. 2013)

The four *Sphingorhabdus* species form a separate phylogenetic branch among members of the *Sphingomonadaceae* (based on the 16S rRNA gene sequence phylogeny) and can be distinguished form the genus *Sphingopyxis* by lower G+C values: 52.6–57.8 mol% for the genus *Sphingorhabdus* compared to 63–69.2 mol% for species remaining in the genus *Sphingopyxis*.

Habitates include surface water of freshwater lakes and marine habitats.

Parasphingopyxis Uchida et al. 2012

Pa.ra.sphin.go.py´xis. Gr. prep. *para* beside, alongside of, near, like; N.L. fem. n. *Sphingopyxis* a bacterial generic name; N.L. fem. n. *Parasphingopyxis* beside *Sphingopyxis*.

The genus *Parasphingopyxis* is currently represented by only one species, *Parasphingopyxis lamellibrachiae*. The type strain of *Parasphingopyxis lamellibrachiae*, strain JAMH 0132^T, was isolated from the trophosome of a tubeworm (*Lamellibrachia satsuma*) of the Kagoshima Bay, Japan. The closest related type strain is *Sphingopyxis baekryungensis* SW-150^T (95.1 % 16S rRNA gene sequence similarity). Sequence similarities to all other type strains of the genera *Blastomonas, Sphingomonas*, *Sphingosinicella*, and *Novosphingobium* are below 95 %.

Cells are Gram-negative, non-spore-forming, and rod-shaped. Cell size is 0.5–0.6 × 1.0–2.0 μm. Cells are motile. Colonies are orange–yellow. Optimal growth occurs at 28–30 °C, pH 6.5–7.5, and a salt concentration of 2 % (w/v) NaCl. Growth generally occurs at 5–36 °C, pH 6.0–9.5, and a salt concentration of 0.5–5 % (w/v) NaCl. No growth occurs in a medium containing less than 0.5 % (w/v) NaCl. Cells are oxidase positive and catalase negative. Aesculin is not hydrolyzed, but nitrate is reduced to nitrite. Differentiating morphological and physiological characteristics are given in Table 25.7 in comparison to type strains of the genera *Sphingopyxis* and *Sphingorhabdus*.

The predominant respiratory quinone is ubiquinone Q-10. Polyamines, including putrescine, spermidine, spermine, *sym*-homospermidine, cadaverine, and agmatine, were not detected. This clearly distinguishes this species/genus from all other members of the *Sphingomonadaceae*. The major fatty acids are C18:1 ω7c, C16:0 and 11-methyl C18:1 ω7c. 2-OH C14:0 is absent. The main 2-hydroxy fatty acid is 2-OH C16:0. The major polar lipids are phosphatidylethanolamine, diphosphatidylglycerol, phosphatidylglycerol, phosphatidylcholine, and sphingoglycolipid. The type species is *Parasphingopyxis lamellibrachiae* (Uchida et al. 2012). The DNA G+C content of the respective type strain JAMH 0132^T is 60.1 mol%.

Zymomonas Kluyvera and Van Niel, 1936 Emend. Coton et al 2006

Gr. n. *zumê*, leaven, ferment; Gr. fem. n. *monas*, a unit, monad; N.L. fem. n. *Zymomonas*, intended to mean fermenting monad.

The genus *Zymomonas* contains only one species, which is represented by three subspecies: *Zymomonas mobilis* subsp. *mobilis* (Lindner 1928b; De Ley and Swings 1976), *Zymomonas mobilis* subsp. *pomaceae* (Millis 1951; De Ley and Swings 1976), and *Zymomonas mobilis* subsp. *francensis* (Coton et al. 2006). The latter subspecies was described in 2006 after a polyphasic analysis of *Zymomonas mobilis* strains isolated from French framboise ciders compared to several strains of the other subspecies, including the type strains.

Cells are Gram-negative, non-spore-forming, and rod-shaped. Rods are straight with rounded or ovoid ends, occasionally ellipsoidal, and single. Cell size measures 2–6 × 1.0–1.4 μm. Rosette-like cell aggregations, cell chains, and curved or U-shaped cells can occur. Usually, cells are nonmotile; some are motile by the means of one to four polar flagella. Motility can occur spontaneously. Membranes contain pentacyclic triterpenoids of the hopane series (Sahm et al. 1993). Intracellular lipids, glycogen, or poly-β-hydroxybutyrate were not obtained. Deep colonies are lenticular, regular, and contain entire edges; they are butyrous, white or cream colored, and have a diameter of 1–2 mm. Anaerobic surface colonies are spreading, contain entire edges, are convex or umbonate, and have a diameter of 1–4 mm (Swings and De Ley 1977). When incubated aerobically, colonies reach a maximum diameter of 1.5 mm or appear as microcolonies (Swings et al. 1997).

Cells are oxidase negative and catalase positive. They are negative for gelatinase activity but postitve for superoxide dismutase activity; negative for nitrate reduction and indole production; and negative for the hydrolysis of gelatin, Tween 60, and Tween 80. *Zymomonas* are facultative anaerobic; some strains are obligatory anaerobic and have a fermentative metabolism. They can grow chemoorganotrophic on glucose and fructose and ferment glucose or fructose to ethanol and CO_2,

as well as some organic acids such as lactic acid. Some strains can also utilize sucrose, but other carbon sources are not used. Gluconate can be degraded but does not serve as sole carbon or energy source (Strohdeicher et al. 1988). Sorbitol and gluconolactone are formed when grown on sucrose or mixtures of glucose and fructose by a so-far unique enzyme, glucose-fructose oxidoreductase.

Optimal growth occurs at 25–30 °C, reduced growth at 38 °C (74 % of the strains can grow), and weak growth at 40 °C (De Ley and Swings 1976; Swings and De Ley 1977). Slow growth occurs at 15 °C and no growth occurs at 4 °C (Millis 1951; Dadds et al. 1973). Growth at 36 °C can be used for phenotypic differentiation of the *Z. mobilis* subspecies, *Z. mobilis* subsp. *mobilis* (positive), *Z. mobilis* subsp. *pomaceae* (negative), and *Z. mobilis* subsp. *francensis* (negative or weak positive) (Swings et al. 1977; Coton et al. 2006). Further phenotypic features for subspecies differentiation is growth in the presence of 0.5 % (w/v) NaCl and 0.2 % bile salts: *Z. mobilis* subsp. *mobilis* (positive), *Z. mobilis* subsp. *pomaceae* and *Z. mobilis* subsp. *francensis* (negative) (Coton et al. 2006).

Zymomonas species are acid tolerant and grow in a pH range of pH 3.5–7.5. Most of *Zymomonas* strains (90 %) are able to grow between pH 3.8 and 7.5. At pH 3.5, at least 43 % of *Zymomonas* strains showed growth (Swings and De Ley 1977). In liquid standard medium, *Zymomonas* cannot grow at pH 3.0. A mixture of amino acids is required for optimal growth conditions; however, a specific single amino acid seemed not to be essential. *Zymomonas* requires biotin and pantothenate for growth.

The tightness of the subspecies is reflected by high DDH similarities (>76 % between *Z. mobilis* subsp. *mobilis* and *Z. mobilis* subsp. *pomaceae*) and high phenotypic similarity (Ssm ≥88 %) between those subspecies (De Ley and Swings 1976). *Zymomonas* subspecies have a very similar G+C content of 47.5–49.5 mol%. In contrast to other *Sphingomonadaceae* (mainly the genus *Sphingomonas*) 2-OH C14:0 is absent in *Zymomonas* species (Yabuuchi et al. 1990; Takeuchi et al. 1993; Balkwill et al. 1997).

Several genotypic features can be used to differentiate *Zymomonas mobilis* subspecies, including partial *gyrB* and *hsp60* and 16-23S rRNA ISR sequences, as well as genomic fingerprinting methods as RAPD-PCR with primer 1 and rep-PCR analysis with BOX and ERIC-PCRs as described in detail by Coton et al. (2006). The type species is *Zymomonas mobilis* (Lindner 1928a; previously "*Thermobacterium mobile*" Lindner 1928b). The genomic DNA G+C content is 47.5–49.5 mol%, which is much lower compared to all other members of the *Sphingomonadaceae*.

The natural habitats of *Zymomonas* include sugar-rich plant saps where *Zymomonas* ferments sugar to ethanol. Natural niches of the genus are acid palm wines, ciders, and beers, which fits well to the acidic tolerance obtained for *Zymomonas*. *Zymomonas* are used as fermenting agents in Agave sap, palm sap, and sugarcane juice; it occurs as a spoiler in beers, ciders, and perries; in honeybees and in opening honey.

Glucose and fructose metabolism *Zymomonas* ferment glucose anaerobically by the Entner-Doudoroff pathway (for references, see Conway 1992), followed by a pyruvate decarboxylation and reduction of acetaldehyde. Dissimilation of glucose under aerobic conditions leads to the formation of ethanol, acetaldehyde, and acetate. *Zymomonas* grow well in liquid media containing either D-glucose or D-fructose at 30 °C. The final pH of the medium reaches 4.8–5.2 by growth at 30 °C; a stronger acidification can be obtained by growth at higher temperatures. Half of the strains grow in the presence of up to 40 % glucose (Swings and De Ley 1977). Sucrose can also be fermented and used for growth by many strains (for references, see Preziosi et al. 1991; Sprenger 1996). However, the property to grow on sucrose can be lost if *Zymomonas* were subcultured on D-glucose (Shimwell 1950). Sucrose fermentation is also inducible (Dadds et al. 1973).

With respect to the industrial applications of *Zymomonas* species, both the glucose and sucrose metabolism of the genus *Zymomonas* were intensively studied but will not be discussed in detail here.

Ethanol Tolerance *Zymomonas* are characterized by a high tolerance to ethanol; strains can grows in the presence of 5 % ethanol, and even at higher concentrations (Swings and De Ley 1977). In batch cultures, up to 13 % (w/v) ethanol can be produced by *Zymomonas* (Rogers et al. 1982). Humanoids, pentacyclic triterpeniods, in the membranes of *Zymomonas* are thought to have a protective function against the produced ethanol. Up to 3 % of the membrane's dry weight or 40–50 % of total lipid content are humanoids (Sahm et al. 1993).

Sphingomonas, *Novosphingobium*, *Sphingopyxis*, and *Sphingobium* species

Isolation, Enrichment, and Maintenance Procedures

Members of the *Sphingomonadaceae* grow on a wide range of complex standard media, most often better in diluted variants. *Sphingomonadaceae* originate from a variety of habitats, including different soil habitats that are contaminated with (poly) aromatic compounds, freshwater and marine ecosystems, habitats associated with plants or eukaryotic hosts, or man-made environments. Based on this broad range of habitats, specifically adapted media are somewhat necessary to enrich and isolate sphingomonads.

Most members of the genera *Sphingomonas*, *Novosphingobium*, *Sphingobium*, and *Sphingopyxis* can be grown on R2A (Difco or Oxoide; containing 0.05 % (w/v) yeast extract, 0.05 % peptone, 0.05 % Casamino acids, 0.05 % glucose, 0.05 % starch, 0.03 % sodium pyruvate, 0.03 % K_2HPO_4, 0.005 % $MgSO_4$, and 1.5 % agar; pH, 7.2), nutrient agar (NA, Difco), TSA (Difco), 0.3 % PYE agar (containing 0.3 % peptone from casein and 0.3 % yeast extract, pH 7.2), or

peptone yeast extract glucose agar (PYGV; containing 0.025 % w/v of yeast extract and glucose; 5 mL L^{-1} of a vitamin solution, and 1.5 % agar; Staley 1968), Luria–Bertani agar (LB; containing per L: 10 g tryptone, 5 g yeast extract, 5 g NaCl, 1 g D-glucose, and 15 g agar), or HD medium (0.05 % casein peptone, 0.01 % glucose, 0.025 % yeast extract, in w/v). Some strains can be grown on full-strength medium, whereas others need to be grown on 2-fold, 5-fold, or 10-fold diluted variants of the listed complex media.

Species isolated from freshwater habitats are often very salt-sensitive and can only be grown on low-salt media, such as R2A or PYE, or in diluted variants of those. Another medium recommended for routine growth of freshwater *Novosphingobium* species is K7 medium, which contains per liter 1 g peptone, 1 g yeast extract, and 1 g glucose (Glaeser et al. 2009). For pH adjustment, it is recommended to use KCl instead of NaCl to avoid the input of sodium ions, which can inhibit growth.

Species from marine habitats grow well on marine agar 2216 or the respective marine broth (all from Difco); again, 2-, 5-, or 10-fold diluted variants may be necessary. Alternatively, a modified rich organic (RO) medium can be used (Yurkov et al. 1999). The RO medium contains per liter distilled water 1 g peptone, 1 g yeast extract, 1 g NaCl, 1 g sodium acetate, 0.3 g KCl, 0.5 g $MgSO_4 \cdot 7H_2O$, 0.05 g $CaCl_2 \cdot 7H_2O$, 0.3 g NH_4Cl, 0.3 g K_2HPO_4, 20 µg vitamin B12, and 1.0 mL element solution, and is adjusted to pH 8.0 (Chen et al. 2010). Most of the strains can grow at a pH around pH 7.0. Some strains that originate from acidic environments need a lower pH for growth. Incubation conditions that cover growth of most of the strains are 25–28 °C in the dark.

Many species originally isolated from soil or freshwater habitats as well as several other habitats, including human-impacted anthropogenic habitats, can be isolated by common serial dilution plating on R2A, NA, LB, TSA, or diluted variants of those media, and 1 % PTYG medium. Most often, incubation temperatures for primary isolation were in the range of 25–30 °C. Several strains that were isolated on diluted standard media could later be grown on undiluted media. Some strains were isolated on media supplemented with antibiotics. *Sphingomonas glacialis* was isolated on R2A supplemented with 100 µg mL^{-1} cycloheximide (Zhang et al. 2011). *Sphingomonas histidinilytica*, *Sphingopyxis ummariensis*, *Novosphingobium lindaniclasticum*, and *Sphingobium quisquiliarum* were isolated on LB agar amended with nystatin (30 µg mL^{-1}) and streptomycin (200 µg mL^{-1}) (Nigam et al. 2010; Sharma et al. 2010; Bala et al. 2010; Saxena et al. 2013). *Sphingopyxis witflariensis* was isolated on PTYG agar (Balkwill and Ghiorse 1985) containing 16 mg L^{-1} aztreonam (Kämpfer et al. 2002b). *Novosphingobium mathurense* and *Novosphingobium panipatense* were isolated on a minimal salt medium (MSM; Mohn et al. 2006; Vanbroekhoven et al. 2004) that was supplemented with 200 µg mL^{-1} streptomycin (Gupta et al. 2009). *Sphingomonas endophytica* was isolated on sodium propionate-asparagine agar (pH 7.2; Qin et al. 2009) contained nalidixic acid (25 mg L^{-1}), nystatin (50 mg L^{-1}), and cycloheximide (50 mg L^{-1}) (Huang et al. 2012).

Many freshwater species (*Sphingomonas starnbergensis*, *Sphingomonas leidyii*, *Novosphingobium acidiphilum*, *Sphingobium boeckii*, *Sphingobium limneticum*, and *Sphingorhabdus planktonica*) can be enriched using a basic synthetic freshwater medium (Bartscht et al. 1999). The basic medium is composed of 10 mM NH_4Cl, 10 mM KH_2PO_4, 100 mM KNO_3, 200 mM $MgSO_4 \cdot 7H_2O$, 100 mM $CaCl_2 \cdot 2H_2O$, 250 mM $CaCO_3$, 1 ml L^{-1} of SL 10 trace elements (Tschech and Pfennig 1984), and 10 ml L^{-1} vitamin solution (Balch et al. 1979) buffered with 10 mM HEPES (Bartscht et al. 1999) and supplemented with 20 amino acids, glucose, pyruvate, citrate, 2-oxoglutarate, and succinate (200 µM each), Tween 80 (0.001 % v/v), formate, acetate, and propionate (200 µM each) (Jaspers et al. 2001), For the enrichment of *Sphingomonas starnbergensis* (Chen et al. 2012b) and *Sphingorhabdus planktonica* (Jogler et al. 2013) signal molecules (cAMP, N-butyryl homoserine lactone, N-oxohexanoyl-di-homoserine lactone and ATP) were added at a 10 µM final concentration to stimulate growth (Bruns et al. 2002). For the isolation and purification of freshwater species on agar plates, it is recommended to used prewashed agar (12 g L^{-1}; washed three times with distilled water). The recommended agar media for isolation and cultivation are the basic synthetic freshwater medium, 1:10 diluted HD medium (0.05 % casein peptone, 0.01 % glucose, 0.025 % yeast extract, w/v), or YPG agar (0.075 % (w/v) yeast extract, 0.15 % glucose, and 0.075 %, 1.2 % pre-washed agar) supplemented with 5 % (v/v) 0.22-µm filter-sterilized or autoclaved habitat water. Several freshwater species were enriched using a dilution-to-extinction cultivation (Button 1993) in 96-well plates (Glaeser et al. 2009, 2013; Baek et al. 2010, 2011). *Novosphingobium sediminicola* and *Sphingobium vulgare* were enriched by dilution-to-extinction cultivation in unsupplemented lake water and were then purified on 10-fold diluted R2A (Baek et al. 2010, 2011). For dilution-to-extinction cultivation of freshwater, *Novosphingobium* species synthetic freshwater medium as described above or autoclaved lake water supplemented with 2.5 % (v/v) autoclaved YPG concentrate (3 % yeast extract, 6 % peptone, and 3 % glucose, adjusted to pH 6.5) can be used (Glaeser et al. 2009, 2013).

Marine *Sphingomonas* and *Sphingopyxis* species can be isolated on marine agar 2,216 (Difco, USA; e.g. *Sphingopyxis baekryungensis*; Yoon et al. 2005) or the half-strength variant with 1 % (w/v) additionally applied NaCl (*Sphingomonas jejuensis*, Park et al. 2011), or it can be pre-enriched in 0.22-µm filtered-autoclaved seawater (FAS) or synthetic seawater medium containing less than approximately 1 mg carbon per liter (*Sphingopyxis alaskensis*; Vancanneyt et al. 2001). *Sphingomonas molluscorum* was isolated on seawater medium containing (per liter) 5 g peptone, 2.5 g yeast extract, 1 g glucose, 0.2 g K_2HPO_4, 0.05 g $MgSO_4$, and 15 g agar in 750 ml seawater/250 ml distilled water (Romanenko et al. 2007).

Sphingomonas mucosissima and *Sphingomonas desiccabilis* originate from biological soil crusts and were isolated on BG11-PGY medium containing 10 % BG-11 mineral medium, 0.25 % peptone, 0.25 % yeast extract, 0.25 % glucose, and 15 %

agar (Reddy and Garcia-Pichel 2007). The BG-11 base is composed of $NaNO_3$ (1.5 g L^{-1}) $K_2HPO_4 \cdot 3H_2O$ (40 mg L^{-1}), $MgSO_4 \cdot 7H_2O$ (75 mg L^{-1}), $CaCl_2 \cdot 2H_2O$ (36 mg L^{-1}), citric acid (6 mg L^{-1}), ferric ammonium citrate (6 mg L^{-1}), EDTA (disodium magnesium) (1 mg L^{-1}), Na_2CO_3 (20 mg L^{-1}), and 1 mL L^{-1} trace metal solution, pH 7.4 (Rippka et al. 1979).

Sphingobium species inhabiting contaminated soils or dump sites can be isolated on a mineral salt medium supplemented with the respective contaminants. For example, S*phingobium abikonense*, *Sphingobium lactosutens*, and *Sphingobium ummariense* were isolated on MSM medium containing $(NH_4)_2HPO_4$ (10.5 g L^{-1}), $MgSO_4 \cdot 7H_2O$ (0.2 g L^{-1}), $FeSO_4 \cdot 7H2O$ (0.01 g L^{-1}), K_2HPO_4 (0.1 g L^{-1}), and $Ca(NO_3)_2$ (0.01 g L^{-1}) supplemented with 5 µg mL^{-1} HCH (Kumari et al. 2009; Singh and Lal 2009). *Sphingopyxis chilensis* was enriched from contaminated river sediment by the incubation of 20 % river water in chloride-free minimal saline medium supplemented with 2,4,6-dichlorophenol (TCP) (Godoy et al. 1999, 2003); *Novosphingobium naphthalenivorans* was enriched in dibenzofuran-containing liquid medium and isolated on dibenzofuran-coated agar plates (Futamata et al. 2004; Kubota et al. 2005) and *Novosphingobium pentaromativorans* in MM2 broth containing (per liter of aged sea water, pH 7.2; ZoBell 1946) 18 mM $(NH_4)_2SO_4$, 1 µM $FeSO_4 \cdot 7H_2O$, and 100 µL 1 M KH_2PO_4/Na_2HPO_4 buffer solution, supplemented with 1,000 p. p.m. of a final mixture of PAHs consisting of equal quantities of naphthalene, fluorene, phenanthrene, anthracene, fluoranthene, and pyrene (Sohn et al. 2004).

Strains can be stored lyophilized for years or can be preserved at − 80 °C after suspension in standard liquid medium supplemented with 7 % DSMO or 15–20 % glycerol after shock freezing in liquid nitrogen.

Blastomonas

The type strain of *Blastomonas natatoria* was isolated from a swimming pool using a Millipore *Pseudomonas* Count Water Tester (Sly and Hargreaves 1984). *Blastomonas* can be grown on diluted media, such as Staley's peptone yeast glucose agar, on which *Blastomonas* form pink colonies or on nutrient or R2A, on which *Blastomonas natatoria* form yellow colonies (Sly 1985). Recommended media for the cultivation of *Blastomonas* are DSM medium 364 (PYEA, containing per L 10 g peptone, 10 g yeast extract, 5 g NaCl, and 15 g agar; adjusted to pH 7.2), 535 (trypticase soy broth; 30 g L^{-1}), 1,015 (YPGA; yeast extract, peptone, glucose each 7 g L^{-1}). The recommended incubation temperature is 28 °C (http://www.straininfo.net/strains/36294/browser).

Cultures of *Blastomonas* can be preserved for long-term storage at − 80 °C in cryo-cultures containing liquid cultures grown in sucrose peptone broth, mixed with 10 % glycerol, and shock frozen in liquid nitrogen. Media for *Blastomonas ursincola* require a supplementation with 20 µg mL^{-1} vitamin B12 (Yurkov et al. 1997).

Sandaracinobacter

Sandaracinobacter sibiricus was isolated from a thin microbial mat, which was formed around underwater hydrothermal vents on a river bottom (Yurkov and Gorlenko 1990). *Sandaracinobacter sibiricus* was isolated by direct inoculation of homogenized diluted mat samples on agar plates of rich organic (RO) medium (Yurkov et al. 1994) containing yeast extract (1 g L^{-1}), Bacto peptone (1 g L^{-1}), sodium acetate (1 g L^{-1}), KCl (0.3 g L^{-1}), $MgSO_4 \cdot 7H_2O$ (0.5 g L^{-1}), $CaCl \cdot 2H_20$ (0.05 g L^{-1}), NH_4CL (0.3 g L^{-1}), and K_2HPO_4 (0.3 g L^{-1}) supplemented with 20 mg L^{-1} vitamin B12 and 1.0 mL L^{-1} trace elements. Incubation was at 30 °C and pH 7.6–7.8.

Sandaracinobacter sibiricus in liquid cultures taken from late logarithmic growth phase and agar surface cultures remain viable after storage at 4 °C for at least 2 months. For long-term storage, cultures need to be frozen in liquid nitrogen and stored at − 70 °C after 30 % glycerol is added to a culture of mid-logarithmic growth phase. The species can also be preserved lyophilized.

Sandarakinorhabdus

The genus *Sandarakinorhabdus* is only represented by one freshwater species, *Sandarakinorhabdus limnophila*. The species was isolated as described for several other freshwater *Sphingomonadaceae* in synthetic freshwater medium buffered with 10 mM HEPES and supplemented with formate, acetate, propionate, succinate, citrate, α-ketoglutarate, and pyruvate (200 µM each; all sodium salts); an amino acid mixture containing all 20 amino acids (200 µM each); 0.001 % Tween 80, and 40 µM glucose (Jaspers et al. 2001). Dilution-to-extinction cultivation (Bartscht et al. 1999) or application of the MicroDrop cultivation technique may be required (Bruns et al. 2003) to enrich *Sandarakinorhabdus* species. Purification can be done on plates containing synthetic freshwater medium and a 10-vitamin mixture (Bartscht et al. 1999) and 1 % (w/v) peptone. For routine cultivation, half-strength R2A (=DSM medium 830; http://www.dsmz.de/catalogues/catalogue-microorganisms/culture-technology/list-of-media-for-microorganisms.html) and incubation at 15 °C are recommended. Strains can be at maintained at − 80 °C resuspendend in growth medium containing 50 % glycerol or 7 % DMSO for at least 7 months.

Sphingorhabdus

The genus *Sphingorhabdus* contains species that originate either from freshwater or from marine habitats. The freshwater species, *Sphingorhabdus planktonica* (represented by one strain) (Jogler et al. 2013), can be pre-enriched as described for other freshwater sphingomonads in basic synthetic freshwater medium buffered with 10x HEPES and supplemented with formate, acetate,

propionate, succinate, citrate, α-ketoglutarate, and pyruvate (200 µM each; all sodium salts); an amino acid mixture containing all 20 amino acids (200 µM each); 0.001 % Tween 80, and 40 µM glucose (Jaspers et al. 2001). Additional supplementation with 10 µM of the inducers cAMP, N-butyryl homoserine lactone, and N-oxohexanoyl-DL-homoserine lactone (Bruns et al. 2002) may be necessary. Subsequent isolation can be done on agar (1 %, w/v) containing artificial freshwater, 1:10 diluted HD medium (0.05 % casein peptone, 0.01 % glucose, 0.025 % yeast extract; w/v), and 10 mM HEPES buffer (pH 7). Incubation temperature is 20 °C. For cultivation, it is recommended to used freshwater HD medium adjusted to pH 8.3 (=DSM medium 1312; http://www.dsmz.de/catalogues/catalogue-microorganisms/culture-technology/list-of-media-for-microorganisms.html) at 20 °C. It is required to keep the agar surface moist; an incubation time of 10–15 days is needed. The species cannot grow on R2A, NA, or CASO agar (Jogler et al. 2012).

The marine *Sphingorhabdus* species (*Sphingorhabdus marina*, *Sphingorhabdus litoris*, and *Sphingorhabdus flavimaris*) were isolated on marine agar 2216 (MA; Difco) incubated at 30 °C. The same medium and growth conditions are recommended to maintain those strains. For long-term preservation, MA cultures suspended with 20 % (w/v) glycerol can be stored at − 80 °C.

Sphingosinicella

Most of the *Sphingosinicella species* were isolated on NA or diluted NA (Yoon et al. 2008; Yasir et al. 2010; Maruyama et al. 2006). Pre-enrichments may be necessary; *Sphingosinicella vermicomposti* was pre-enriched in nutrient broth of 0.08 g L^{-1} (Difco) supplemented with 20 % (w/v) 0.2-µm filter-sterilized aqueous extract of vermicompost (Yasir et al. 2010). *Sphingosinicella xenopeptidilytica* can be pre-enriched in mineral salt medium supplemented with β-peptides as carbon source (Schreiber et al. 2002; Geueke et al. 2005, 2007). Beside nutrient agar (NA), *Sphingosinicella* species can grow on several complex media including R2A or the half-strength variant and TSA. Pre-enrichments and subcultivations can be done at 30 °C.

Stakelama

Species of the genus *Stakelama* were isolated from different environments and therefore different isolation conditions are required. The marine species *Stakelama pacifica* can be isolated on seawater medium (SW) containing, per liter of 0.22 µm-filtered seawater, 1 g peptone, 1 g yeast extract, 20 µg vitamin B12, and 1 ml of a trace element solution (ES) and cultured on modified rich organic (RO) medium (Yurkov et al. 1999) containing, per liter of distilled water, 1 g peptone, 1 g yeast extract, 20 g NaCl, 1 g sodium acetate, 0.3 g KCl, 0.5 g $MgSO_4 \cdot 7H_2O$, 0.05 g $CaCl_2 \cdot 7H_2O$, 0.3 g NH_4Cl, 0.3 g K_2HPO_4, 20 µg vitamin B12, and 1.0 ml ES, adjusted to pH 8.0 at 28 °C (Chen et al. 2010). The same conditions are recommended for cultivation of this species.

The second species, *Stakelama sediminis*, can be isolated and routinely grown on R2A at 30 °C (Thawng et al. 2013). Cultivation on LB and nutrient agar is also possible, but not on TSA. The species can be maintained at − 80 °C as a suspension in R2A broth supplemented with 20 % (v/v) glycerol.

Sphingomicrobium

Sphingomicrobium species were isolated from coastal or marine surface waters using marine agar 2,216 (MA; Difco) at temperatures between 30 °C and 45 °C (Kämpfer et al. 2012; Shahina et al. 2013a, b). The same media and growth conditions are also recommended for subsequent cultivation. Furthermore, it is recommended to grow the species on modified MA medium (=DSM medium 514a; http://www.dsmz.de/catalogues/-catalogue-microorganisms/culture-technology/list-of-media-for-microorganisms.html) at 28 °C; the addition of a vitamin solution can thereby accelerate growth. Strains can be preserved lyophilized or by the addition of 20 % glycerol to fresh cultures, shock freezing in liquid nitrogen, and storage at − 80 °C.

Parasphingopyxis

The type strain of *Parasphingopyxis lamellibrachiae* (single strain of this genus) was isolated from the *Trophosome* tissue of a marine annelid tubeworm (*Lamellibrachia satsuma*). The tissue was homogenized in normal-strength artificial seawater (ASW) containing NaCl (27.5 g L^{-1}), KCl (0.7 g L^{-1}), $MgCl_2 \cdot 6H_2O$ (5.4 g L^{-1}), $MgSO_4 \cdot 7H_2O$ (6.8 g L^{-1}), $CaCl_2 \cdot 2H_2O$ (1.4 g L^{-1}), and $NaHCO_3$ (0.2 g L^{-1}) (Miyazaki et al. 2008) and spread on marine agar 2,216 (MA; Difco) diluted with 10-fold 1× ASW and supplemented with 1.2 % (w/v) agar and incubated at 20 °C. For cultivation of *Parasphingopyxis lamellibrachiae*, marine agar 2,216 or the respective broth and incubation at 20 °C are recommended.

Zymomonas

The growth medium recommended for *Zymomonas* species is the *Zymomonas* DSM medium 10 (http://www.dsmz.de/catalogues/catalogue-microorganisms/culture-technology/list-of-media-for-microorganisms.html) containing in Bacto peptone (10.0 g L^{-1}), yeast extract (10.0 g L^{-1}), glucose (20.0 g L^{-1}), and, if required, agar (15 g L^{-1}). A medium for *Zymomonas* enrichment and detection in breweries is the *Zymomonas*

detection medium described by Dadds (1971), containing malt extract (3 g L^{-1}), yeast extract (3 g L^{-1}), D-glucose (20 g L^{-1}), peptone (5 g L^{-1}), and actidione (0.02 g L^{-1}) in distilled water. The pH should be adjusted to 4.0. Ethanol should be added in a final concentration of 3 % (v/v). An enrichment at 30 °C is recommended. The enrichment of *Zymomonas* is indicated by gas production after 2–6 days of incubation.

Further media recommended to grow *Zymomonas mobilis* in liquid culture contains glucose (20 g L^{-1}) and yeast extract (5 g L^{-1}). Incubation at 30 °C is recommended. *Zymomonas mobilis* strains can grow on zymomonads-pimaricine (ZP) agar (Coton and Coton 2003) under anaerobic conditions at 30 °C (incubation time of ~5 days). The medium contains glucose (20 g L^{-1}), peptone (5 g L^{-1}), yeast extract (3 g L^{-1}), malt extract (3 g L^{-1}), and agar (15 g L^{-1}). The pH should be adjusted to 4.8 using 10 % citric acid. If the medium is used to enrich and isolate *Zymomonas mobilis*,the growth of yeast and lactic acid bacteria can be inhibited by the addition of 100 mg L^{-1} pimaricine and 30 mg L^{-1} penicillin (ZPP medium; Coton and Coton 2003).

Zymomonas strains grow easily in liquid media containing either D-glucose or D-fructose. The nitrogen source for growth can be supplied as peptone, yeast extract, nutrient broth, beer, palm juice, or apple juice or a mixture of 20 amino acids. Groups of amino acids, individual amino acids, NH_4Cl, or $(NH_4)SO_4$ can also serve as nitrogen sources, but they are not verified for different *Zymomonas* strains. Growth factors required by the *Zymomonas* strains are biotin and pantothenate. Only some strains need additional growth factors, such as vitamin B2, lipoic acid, riboflavin, and folic acid for growth (Van Pee et al. 1974). *Zymomonas* can be maintained as living cells in standard medium at room temperature if they are transferred every 2–3 weeks. Lyophilized cells can be maintained over years.

Ecology

Sphingomonads, especially *Sphingomonas*, *Novosphingobium*, *Sphingopyxis*, and *Sphingobium* species were isolated from a broad range of habitats. Some of the most abundant habitats are explored here in more detail.

Habitats Contaminated with Recalcitrant (Poly)Aromatic Contaminants

Several sphingomonads were isolated in high proportions from a broad range of soils or other habitats contaminated with different recalcitrant (poly)aromatic compounds of anthropogenic origin. Potential reasons for the adaptation of sphingomonads to those habitats and their metabolic versatility for the degradation of a broad range of contaminants were already discussed in this chapter.

Sphingomonadaceae in Aquatic Systems

Freshwater Habitats

Sphingomonads represent typical members of freshwater bacterioplankton communities (Glöckner et al. 2000; Zwart et al. 2002; Newton et al. 2011; Gich et al. 2005). Several species of the genera *Sphingomonas*, *Novosphingobium*, and *Sphingopyxis* were isolated from freshwater systems, such as *Sphingomonas aquatilis* and *Sphingomonas koreensis* (Lee et al. 2001), *Sphingomonas jaspsi* (Asker et al. 2007a), *Sphingomonas astaxanthinifaciens* (Asker et al. 2007b), *Sphingomonas starnbergensis* (Chen et al. 2012b), *Sphingopyxis taejonensis* (Lee et al. 2001), *Sphingopyxis rigui* and *Sphingopyxis wooponensis* (Baik et al. 2013), *Novosphingobium acidiphilum* (Glaeser et al. 2009), *Novosphingobium fuchskuhlense* (Glaeser et al. 2013), *Sphingobium boeckii* and *Sphingobium limneticum* (Chen et al. 2013), and *Sphingobium xenophagum* (Stolz et al. 2000). All or several species of the genera *Blastomonas*, *Sandaracinobacter*, *Sandarakinorhabdus*, and *Sphingosinicella* were also isolated from freshwater systems. *Sandaracinobacter sibiricus* was isolated from a freshwater algobacterial mat near a hydrothermal vent (Yurkov et al. 1997). *Sandarakinorhabdus limnophila* and *Sphingorhabdus planktonica* were isolated from two freshwater lakes located in Germany (Gich and Overmann 2006; Jogler et al. 2012). The type species *Sphingosinicella microcystinivorans* was isolated from another freshwater lake during a toxic *Microcystis* bloom (Maruyama et al. 2006).

A broad range study of environmental 16S rRNA gene sequences ubiquitously occurring in freshwater habitats was performed by Newton et al. (2011), covering all freshwater 16S rRNA gene sequences of the primary databases. The study provided an excellent overview of *Sphingomonadaceae* phylotypes (linked to proposed species if available), which were found to be unique in freshwater systems. Two lineages of freshwater *Alphaproteobacteria* were phylogenetically placed into the *Sphingomonadaceae*. The lineage alfIII represented environmental sequences phylogenetically placed into the genus *Sphingomonas sensu stricto*. The linage alfIV, which was much more abundant with respect to the freshwater sequences, showed an overlaps with the genus *Novosphingobium*. Two tribes NovoA1 and NovoA2 (both of the lineage alfIV-A) represent the two freshwater species *Novosphingobium acidiphilum* (Glaeser et al. 2009) and *Novosphingobium fuchskuhlense* (Glaeser et al. 2013), respectively. The fourth-abundant sphingomonads freshwater tribe was Phyx (alfIV-B), which phylogenetically shows an overlap with the genus *Sphingopyxis*. Another tribe was assigned, including further *Sphingomonadaceae*-related phylotypes.

Several studies of surface water bacterioplankton showed the abundance of *Sphingomonadaceae* in freshwater systems in more detail. The abundance and persistence of the *Novosphingobium* species *Novosphingobium acidiphilum* (Glaeser et al. 2009) in the small humic-acid rich Lake Grosse Fuchskuhle was shown in several environmental studies by molecular cultivation-independent and cultivation-dependent studies

(Glöckner et al. 2000; Burkert et al. 2003; Allgaier and Grossart 2006; Hutalle-Schmelzer et al. 2010; Glaeser et al. 2009, 2010). The ecological niche of this species seemed to be linked to the utilization of small organics substances formed by the degradation (photolysis by sunlight exposure) of humic substances, which are highly abundant in the lake. The adaptation to reactive oxygen species, especially the short-lived singlet oxygen, seemed to play an important role in the adaptation of the species to this ecosystem (Glaeser et al. 2010).

A high diversity of freshwater sphingomonads was found by Jogler et al. (2011), who investigated the population structure of *Sphingomonadaceae* in two freshwater lakes in Germany, Lake Walchensee and Lake Starnberger See. The authors determined several different phylotypes based on 16S rRNA gene sequence analysis; among those, several subpopulation were found represented by different 16S -23S rRNA gene internal transcribed spacer (ITS)-types. Cultivation of representative strains of different ITS types of the predominant phylotype (G1A, later on described as *Sphingorhabdus planktonica*; Jogler et al. 2013) showed high physiological diversity regarding substrate utilization; however, this could not be linked to niche separation of the specific subpopulations (ecotypes).

A second predominant genotype obtained in the study of Jogler et al. (2011), genotype GA7, represents the species *Sandarakinorhabdus limnophila* (Gich and Overmann 2006). Several mechanisms for niche separation of closely related *Sphingomonadaceae* were discussed, including differences in the ability to degrade refractory high-molecular weight compounds, resistance to ultraviolet light, planktonic or sessile lifestyles, aerobic oxygenic phototrophic, or differences in the susceptibility of bacteriophage attach. Freshwater sphingomonads were also found associated with higher freshwater organisms, such as the green algae *Desmodesmus armatus* and the diatom *Stephanodiscus minutulus* (Eigemann et al. 2013). The detected phylotypes were phylogenetically most closely related to the genera *Sphingomonas* and *Sphingopyxis*. An ecological molecular cultivation-independent study of aerobic anoxygenic phototrophs in the surface waters of freshwater lakes targeting the *pufM* gene gave evidence for freshwater-associated *Sphingomonadaceae* of the genera *Blastomonas* and *Sphingomonas* containing *pufM*, indicating that phototrophy may be a common metabolic feature of freshwater *Sphingomonas* in different lakes (Salka et al. 2011).

Marine Habitats

Marine species were mainly found in the genus *Sphingopyxis* (Godoy et al. 2003; Yoon et al. 2005), the dissected genus *Sphingorhabdus* (Yoon and Oh 2005; Kim et al. 2008), and the genus *Sphingomicrobium*, *Sphingomicrobium lutaoense* (Kämpfer et al. 2012), and *Stakelama pacifica* (Chen et al. 2010). The species *Sphingopyxis alaskensis* (Godoy et al. 2003), formerly described as "*Sphingomonas alaskensis*" (Vancanneyt et al. 2001), is thereby one of the most well-investigated marine sphingomonads, representing a model organism for an oligotrophic marine lifestyle. Seven strains representing this species were isolated from seawater of the Resurrection Bay, a deep fjord of the Gulf of Alaska (Vancanneyt et al. 2001). The strains were oligotrophic ultramicrobacteria (<0.1 m^3), which were adapted to the nutrient-limited marine habitats (oligotrophs).

A genome-sequencing approach was performed to understand the lifestyle of this marine species in detail. In particular, carbon and nitrogen utilization were investigated with respect to the ability to adapt to heterotrophic growth under nutrient-depleted (oligotrophic) conditions (Williams et al. 2009). It was found that *Sphingopyxis alaskensis* has the physiological capacity to exploit an increase of an ambient nutrient availability and can thereby achieve high-population densities in its marine habitat. Several further metabolic features and adaptation mechanisms of marine bacteria to their environment were also investigated using *Sphingopyxis alaskensis*, as a model taxa, such as the adaptation to cold marine environments or the response to solar irradiation studied by quantitative proteomics (Ting et al. 2010; Matallana-Surget et al. 2009), as well as the adaptation to UV exposure investigated in detail by analysis of the effects of growth temperature and starvation state of the bacterium (Matallana-Surget et al. 2010)

Other marine sphingomonads were found in association with higher marine organisms. For example, *Sphingomonas jejuensis* was isolated from the marine sponge *Hymeniacidon flavia* (Park et al. 2011), *Sphingomonas molluscorum* from the marine bivalve *Anadara broughtoni* (Romanenko et al. 2007), and *Sphingomonas japonica* from the marine crustacean *Paralithodes camtschatica* (Romanenko et al. 2009). Sphingomonads were also found to be the dominating fraction of epiphytic bacterial biofilm communities that inhabit the surfaces of the green macroalgae *Ulvacean marine*, which is found worldwide in coastal tidal and subtidal ecosystems (Burke et al. 2011). The detected sphingomonad phylotypes were phylogenetically closely related to the genus *Sphingopyxis*. In that comparative study, however, *Sphingomonadaceae* were not detected in the surrounding seawater.

A marine *Novosphingobium* isolate was found to be able to grow on the aromatic part of fuels as a carbon and energy source. A detailed investigation of the substrate utilization of the strain showed that it could grow in a surprisingly wide range of aromatic compounds, including mono-, bi-, tri-, and tetracyclic aromatic hydrocarbons and heterocyclic compounds (Notomista et al. 2011).

Phyllosphere and Rhizosphere/Root-Associated Sphingomonads

Several species of the genus *Sphingomonas* were isolated from habitats associated with plants, including the phyllosphere and rhizosphere as well as root compartments. Some *Sphingobium* species were also isolated from the rhizosphere. *Sphingomonas cynarae* was isolated from the phyllosphere of *Cynara*

cardunculus, a wild cardoon, which is a native Mediterranean plant that is considered to be a wild ancestor of the artichoke and cultivated cardoon (Talà et al. 2013). *Sphingomonas phyllosphaerae* was isolated from the phyllosphere of *Acacia caven* (Rivas et al. 2004) and *Sphingomonas roseiflava* from the ear of *Setaria viridis* (*Gramineae*) (Yun et al. 2000). *Sphingomonas asaccharolytica* was isolated from roots of a *Malus* spp. (apple) (Takeuchi et al. 1995), strains of *Sphingomonas azotifigens* from roots of *Oryza sativa* (Xie and Yokota 2006), and *Sphingomonas jinjuensis* and *Sphingomonas oryziterrae* were both isolated from the rhizosphere of rice growing in a conventionally-managed rice field (*S. jinjuensis*) and a no-tillage rice field (Chen et al. 2011). *Sphingomonas pruni* was isolated from roots of *Prunus persica* (peach) (Takeuchi et al. 1995). The *Sphingobium* species isolated from the rhizosphere include *Sphingobium indicum*, which was isolated from the rhizosphere of rice in India (Pal et al. 2005), and *Sphingobium rhizovicinum*, which was isolated from the rhizosphere soil of *Fortunella hindsii* (Champ. ex Benth.) Swingle (Young et al. 2008).

Several studies investigating bacteria inhabiting the phyllosphere of plants reported the abundance of *Sphingomonas* species in this habitat (Kim et al. 1998; Idris et al. 2004; Enya et al. 2007; Fürnkranz et al. 2008). A metaproteogenomic approach of natural microbial communities growing in the phyllosphere of *Arabidopsis thaliana* and agriculturally grown clover and soybean plants indicated that *Sphingomonas* species occur in high abundance as natural inhabitants in the phyllosphere of several plant species beside methylotrophic bacteria (Delmotte et al. 2009). In a subsequent study, the antagonistic potential of *Sphingomonas* strains isolated from the respective phyllosphere samples were tested with the plant-pathogen model *Arabidopsis thaliana* and *Pseudomonas syringae* pv. *tomato* DC3000. Several of the investigated *Sphingomonas* isolates prevent disease symptom formation and kept the cell numbers of the pathogens lower compared to axenic plants. Similar effects were obtained for several plant-derived *Sphingomonas* species, including *Sphingomonas melonis* and *Sphingomonas phyllosphaerae*, which were tested in parallel. Based on those results, the authors concluded that a competitive phyllosphere colonization and suppression of pathogen growth in the phyllosphere may be a common trait of phyllosphere colonizing *Sphingomonas*.

Plant protection by *Sphingomonas* was also shown against *Xanthomonas campestris* pv. *campestris* LMG 568, another well-established plant pathogen (Buell 2002). Concurrence for photo-assimilates leaked by the plant leaves, such as glucose, fructose, and sucrose, was determined to be one of the important antagonistic features for protecting *Sphingomonas* against *P. syringae* pv. tomato DC3000, which metabolized the same substrates. This is supported by the fact that membrane proteins assigned to *Sphingomonas* spp. and involved in transport processes of various carbohydrates were abundant proteins in the metaproteomic approach (Delmotte et al. 2009).

Sphingomonas also occurs as endophytes in plant root tissue. One endophytic *Sphingomonas* species was already described—*Sphingomonas endophytica* (Huang et al. 2012), which was isolated from surface-sterilized tissue of *Artemisia annua* L. An endophytic strain that showed plant-growth promotion is *Sphingomonas* strain YM22. This strain was isolated from surface-sterilized roots of a copper-resistant plant of the species *Commelina communis*. The strain showed a high tolerance to Cu (0.5 mM), Pb (5 mM), and Zn (10 mM); it produced indol acetic acid (IAA) and high amounts of siderophores, and shows 1-aminocyclopropane-1-carboxylate (ACC) deaminase activity (Sun et al. 2010). Plant growth promotion of this strain was shown in a pot inoculation experiment with maize (*Zea mays*) plants, indicated by an increase of the plant biomass (including root and above-ground tissues) compared to noninoculated controls (Sheng et al. 2012). Furthermore, the strain was able to colonize the rhizosphere of maize and increase the proportion of water-extractable copper in the rhizosphere soil after the application of $Cu_2(OH)_2CO_3$.

Another endophytic plant growth promoting *Sphingomonas* strains (S12) was isolated from surface-sterilized rice roots (Adhikari et al. 2001). The strain was phylogenetically closely related to *Sphingomonas trueperi*. Pot experiments showed an increase in plant height and dry weight of inoculated rice seedlings compared to the nontreated seedlings. Furthermore, a reduced disease incidence was obtained for inoculated plants. Strain S12 was also capable of fixing nitrogen, which was proved by the detection of *nifD* and the ability to reduce acetylene. Further endophytic *Sphingomonas* were isolated from surface-sterilized chili pepper seeds (*C. annuum* L. cv. Bukang) (Kang et al. 2007). *Sphingomonas* were also detected in the mycorrhizosphere involved in mineral weathering in a forest soil (Uroz et al. 2007).

Sphingomonads in Activated Sludge

Several sphingomonads were isolated from activated sludge, including *Sphingomonas hankookensis* (Yoon et al. 2009), *Sphingopyxis terrae* (Takeuchi et al. 1993), *Sphingopyxis witflariensis* (Kämpfer et al. 2002b), and *Novosphingobium tardaugens* (Fujii et al. 2003a), *Sphingobium faniae* is a pyrethroid-degrading bacterium isolated from activated sludge treating wastewater from pyrethroid manufacture (Guo et al. 2010), *Sphingobium wenxiniae* a synthetic pyrethroid (SP)-degrader isolated from activated sludge of an SP-manufacturing wastewater treatment facility (Wang et al. 2011), or *Sphingobium jiangsuense* isolated from a wastewater treatment system in a pesticide manufacture (Zhang et al. 2012).

Fluorescence in situ hybridization (FISH) studies of activated sludge samples of different wastewater treatment plant targeted *Sphingomonadaceae* by the use of a specific fluorescent probes (Neef et al. 1999). Up to 50 % of the detected sphingomonads cells were located in flogs or the activated sludge. The ability to produces slime and/or capsules and the release of EPS in general, as well as the hydrophobicity of the outer cell layer (due to the presence of SGLs), suggested that sphingomonads contribute to the formation of aggregates in activated sludge.

Zymomonas

Zymomonas mobilis was isolated from different alcoholic beverages. *Zymomonas* spp. were either considered to be the active agent in natural fermentation processes as in agave or palm sap or the active agent in bioreactors for ethanol and acetaldehyde production. However, *Zymomonas* spp. are also considered to be spoilage bacteria in ciders, beers, and perries (Swings and De Ley 1977; Buchholz et al. 1987; Coton and Coton 2003).

Pathogenicity and Clinical Relevance *[Including Antibiotic Sensitivity]*

Only a few *Sphingomonas* species are known to be clinically relevant—mainly ***Sphingomonas paucimobilis*** (formerly "*Pseudomonas paucimobilis*") and (in lower abundance) *Sphingomonas parapaucimobilis*. Those species are known as primary opportunistic bacteria that are proposed to be persistent nosocomial infecting agents (Ryan and Adley 2010). *Sphingomonas paucimobilis* was isolated from several different clinical specimens, such as wounds, blood, cerebrospinal or peritoneal fluids, urine, the vagina, and the cervix (Holmes et al. 1977; Morrison and Shulman 1986; Reina et al. 1991; Lin et al. 2010; Mutlu et al. 2011; Lanoix et al. 2012; Souto et al. 2012). Clinical isolates identified as *Sphingomonas parapaucimobilis* were also isolated from clinical specimens, including sputum, urine, and the vagina (Yabuuchi et al. 1990).

Reported clinical syndromes associated with *Sphingomonas paucimobilis* are primary bacteremia and septicemia, bloodstream infections, intravascular catheter infections, peritoneal dialysis-associated peritonitis, urinary tract infections, biliary tract infection, cutaneous infection, ventilator-associated pneumonia, peritonitis, meningitis, myositis, osteomyelitis, septic arthritis, endophthalmitis, cervical adenitis, bromohidrosis, and diarrheal disease (Toh et al. 2011; Ryan and Adley 2010; Maragakis et al. 2009; Lin et al. 2010). Reported infections caused by *Sphingomonas paucimobilis* were either hospital acquired or related to nosocomial outbreaks. Infections were often caused by contaminated solutions of distilled water, hemodialysis fluid, or sterile drug solutions (Ryan and Adley 2010). With respect to neonatal infections in intensive care units, Lemaitre et al. (1996) isolated *Sphingomonas paucimobilis* from the tracheal secretions of mechanically ventilated babies (84 individuals) at a neonatal intensive care unit over a 2-year period. The ventilator equipment was thereby identified as source of maintenance and spread of *Sphingomonas paucimobilis*.

No literature reports were found where *Sphingomonas paucimobilis* infections were linked to the death of patients (Ryan and Adley 2010; Lin et al. 2010). *Sphingomonas paucimobilis* is reported to have a low clinical virulence, but infection can lead to a septic shock. Both, healthy and immune-compromised individuals, can be infected (Lin et al. 2010). Community-acquired infections, diabetes mellitus, and alcoholism were identified as significant risk factors for primary bacteremia caused by *Sphingomonas paucimobilis* (Toh et al. 2011).

Clinically relevant *Sphingomonas* strains were reported to be susceptible to tetracycline, chloramphenicol, trimethoprim-sulfamethoxazole, and aminoglycosides, but only partially susceptible to other antimicrobial agents, such as fluoroquinolones (Fass and Barnishan 1980; Hsueh et al. 1998; Reina et al. 1991). Ammendolia et al. (2004) investigated in detail the interaction of *Sphingomonas paucimobilis* with epithelial cells. The contact of *Sphingomonas paucimobilis* with the epithel cells altered the cell surface, caused numerous microvilli extensions, and membrane ruffles occurred. Confocal laser scanning microscopy showed that actin microfilaments were involved in the attachment and entry of the bacteria into the HeLa cells.

A further *Sphingomonas* isolate was reported to be associated with a clinical infection of a woman with sickle cell disease—***Sphingomonas mucosissima*** (Angelakis et al. 2009). Minimum inhibitory concentration (MIC) values were determined for several antibiotics: cefotaxime (1 mg L^{-1}), amoxicillin–clavulanic acid (1 mg L^{-1}), vancomycin (2–3 mg L^{-1}), imipenem (0.064 mg L^{-1}), ceftazidime (4–5 mg L^{-1}), amikacin (1 mg L^{-1}), ciprofloxacin (3 mg L^{-1}), and trimethoprim-sulfamethoxazole (0.047 mg L^{-1}). The patient was successfully treated with intravenous administration of ceftriaxone for 5 days. The intravenous catheter of the patient was thought to be the source of the infection.

Plant Pathogens

Few *Sphingomonas* were identified to be plant pathogens. ***Sphingomonas melonis*** was described as the causative agent of the brown-spot disease of yellow Spanish melons (*Cucumis melo* var. *inodorus* Naud.) cultivated in greenhouses in Almeria, Spain (Buonaurio et al. 2002). After infection of yellow Spanish melon fruits and leaves with cells of the type strain of *S. melonis*, desease symptoms were observed on the fruits. ***Sphingobium suberifaciens*** (formerly "*Rhizomonas suberifaciens*" or "*Sphingomonas suberifaciens*") was isolated and described as the causative agent of corky root rot of lettuce (van Bruggen et al. 1989, 1990). Initial symptoms are yellow bands occurring on young roots, which later form dark greenish-brown and corked areas that cover most of the tap root and main lateral roots. The infected roots became brittle and break off easily (van Bruggen et al. 1988). Furthermore, ***Novosphingobium rosa*** (formerly *Sphingomonas rosa*, "*Agrobacterium rhizogenes*") was isolated from hairy roots of *Rose* sp. and described as a plant pathogen (Sawada et al. 1993).

Zymomonas

For the genus *Zymomonas*, humans, animals, or plants pathogens are not currently known. However, antagonistic activity of *Zymomonas* spp. is indicated. Lindner (1929, 1931) recommended to use *Zymomonas* spp. as a supplement for

human nutrition, such as in form of yoghurt additives. For some *Zymomonas* strains, antagonistic activity against bacteria and fungi was determined in vitro, and the therapeutic application of *Zymomonas* for chronic enteric and gynecological infections was reported (Swings and De Ley 1977; Falcao de Morais et al. 1993). In mice, *Zymomonas mobilis* showed 60 % protection to an experimental infection with *Schistosoma mansoni* after oral application of *Zymomonas* cultures (Santos Jde et al. 2004).

Antibiotic Sensitivity

Sensitivities to antibiotics were studied for a broad range of *Sphingomonadaceae*. A total of 33 type strains were tested by Yabuuchi et al. (2001), including type strains of the genera *Sphingomonas* (12), *Sphingobium* (6), *Novosphingobium* (6), *Sphingopyxis* (2), and *Blastomonas* (2) species. In all, 38 antibiotics were tested. The type strains resisted to up to 58 % of the tested antibiotics. A total of 91–100 % was susceptible to tetracylines, amikacin, gentamicin, panipenem, and imipenem. Differences in susceptibilities to amoxicillin (67 %) and amoxicillin/clavulanic acid (91 %) suggest the presence of penicillinase in these species. Genera-dependent differences were obtained for antibiotics of the chinolone/fluorochinolone group. All type strains of the genus *Novosphingobium* were at least somewhat resistant to norfloxacin, ciprofloxacin, ofloxacin, and levofloxacin.

Vaz-Moreira et al. (2011) studied the antibiotic-resistance pattern of 86 *Sphingomonadaceae* isolated from drinking water systems, such as drinking water treatment plants, tap water, cup filters of dental chairs, demineralization filters, including antibiotics of fife classes, several beta-lactams and aminoglycosides, a fluoroquinolone, a polymyxin, and a sulfonamide. As identified by 16S rRNA gene and *atpD* sequence analysis, 27 *Sphingomonas*, 28 *Sphingobium*, 12 *Novosphingobium*, 7 *Sphingopyxis*, and 12 *Blastomonas* strains were investigated in the study. The antibiotic resistance level was especially high for colistin (90 %) and beta-lactam antibiotics. The highest prevalence values for antibiotic resistance were obtained for strains phylogenetically assigned to the genera *Sphingomonas* and *Sphingobium* with respect to beta-lactams, ciprofloxacin, and cotrimoxazole. Resistance patterns were mainly linked to species rather than to strains or isolation size. *Sphingomonadaceae* in water systems may be a source of clinically relevant antibiotic resistance. For example, a high prevalence of polymyxin (polymyxin B) and beta-lactams resistance was determined for clinical isolates of *Sphingomonas paucimobilis* (Sader and Jones 2005) (*Table 25.13*).

Applications

Sphingomonadaceae, especially of the genera *Sphingomonas* and *Sphingobium*,are biotechnologically interesting for two main reasons. First, sphingomonads have the potential to be applied for bioremediation of contaminated aquifers or soils because several sphingomonads can degrade a variety of xenobiotic compounds. Second, sphingomonads produce agar-like EPS, sphingans, which are of interest for food, pharmaceutical, and industrial applications.

Bioremediation by *Sphingomonas*

A variety of sphingomonads were found to be candidates for bioremediation of wastewater or contaminated dumping sites. For example, *Sphingomonas wittichii* RW1^T was used for bioremediation of PCDD in contaminated incinerator fly ash (Nam et al. 2005). In that study, a reduction of 75.5 % was obtained for the toxic of PCDDs after 15 days of treatment. Because sphingomonads that will be used for bioremediation need to cope with several environmental stress factors, further study is needed to overcome related problems. For example, the effects of changes in the water potential and respective adaptive responses of *Sphingomonas wittichii* RW1^T was investigated in detail by Johnson et al. (2011) using transcriptome and membrane fatty acid analysis. Bioengineering can be applied to increase the efficiency of the degradation pathways.

Sphingomonas strain sp. FG03 isolated from phenol-contaminated soils was positively tested for phenol degradation. The strain showed a high efficiency of phenol degradation with a removal rate of 95 % within 3 h in the presence of 800 mg L^{-1} phenol. Both free suspended and immobilized cells showed the respective activity. However, immobilized cells showed a better performance and were thereby indicated to be applicable for treating phenol-contaminated wastewater (Liu et al. 2009). The alkylphenol-degrading *Sphingomonas* sp. strain TTNP3 was proven for bioaugmentation in a membrane bioreactor of nonylphenol (Kolvenbach and Corvini 2012). The ability of *Sphingomonas* sp. TTNP3 to degrade a variety of alkylphenols, with potential reverse effects on living organisms by actin with the endocrine system, were summarized by Kolvenbach and Corvini (2012).

Production and Application of Exopolysaccharide (Sphingans)

Extracellular polysaccharides (EPS) produced by *Sphingomonas* species (sphingans) are gelling agents that are of interest for food, pharmaceutical, and industrial applications, including environmental bioremediation processes. A broad range of patents were published in recent years with respect to gellans. Fialho et al. (2008) reported of more than 800 patents worldwide.

Gellan gum produced by *Sphingomonas elodea* is one of the most important sphingans; it is commercially procured by C.P. Kelco in Japan and the USA (Prajapati et al. 2013). The strain used for production was isolated from the surface of a plant of the genus *Elodea* as an outcome of an extensive screening approach performed by Kelco (Kang and Veeder 1981). Gellan is produced in a fermentative process at a laboratory scale. The production of gellan is a growth-dependent process with a final

yield of approximately 10 g gellan L^{-1}. By the release of gellan into the growth medium, the viscosity of the medium increases, which makes it difficult to separate the produced gellan from the cells. Gellan can be precipitated from diluted cell cultures by the use of isolpropyl alcohol. Thereafter, gellan is suspended in water, further purified by dialysis, and finally lyophilized. Then, it can be suspended in water to produce gels.

The physical properties of gellan are dependent on the EPS concentration, the temperature, the water content, and the concentration of monovalent and divalent cations in the medium. Gels are formed with various cations. An important role in the rheology of the gellan gel matrix is therefore played by the acyl substituents. Deacylation of the native gellan gum can be used to modify the characteristics of gellan to produce either soft, elastic, and thermoreversible or hard-to-rough gels (Rinaudo and Milas 2000). Gellases can be used to modify native gellans; gellan lyasis (described as shinganases) are produced by several gram-positive and gram-negative bacteria as extracellular eliminase-type endoenzymes that cleave ß-D-glucosyl (1- > 4) ß-D-glucuronysyl linkages of the EPS and can thereby degrade EPS, used in biotechnolocially gellan production to modifiy the viscosity of EPS (Giavasis et al. 2000; White et al. 1996).

Gellan is applied as a gelling, stabilizing, and suspending agent in the food and medical industries in the United States and Europe. The advantage of gellan is its thermal and acid stability, the ability to adjust gel elasticity and rigidity, its high transparency, and good flavor. The stage of acyl content—no, low, or high acyl content—differentiates the commercially available gellan forms. The main products are Gelrite®, Kelcogel® F, or Kelcogel® LT100. Gelrite is an alternative gelling agent to agar, which is often applied in plant tissue cultures or used for the cultivation of thermophilic bacteria (Lin and Casida 1984). It also can be used by the process of biodegradation as a gel agent to encapsulate bacteria for bioaugmentation (Moslemy et al. 2003, 2004). Kelcogels is applied as a gelling, stabilizing, and suspending agent in the food industry (E number E418) or in the personal care industry as a supplement for lotions, creams, and toothpastes (Sutherland 2001). In the biomedical sector, gellan is applied as a pharmaceutical excipient to several different drugs, with several more possible applications also being tested (for more details, see Fialho et al. 2008).

The sphingan Ss, produced by *Sphingomonas sanxanigenens* $NX02^T$ (Huang et al. 2009a), can be precipitated by acidification (pH 3.0). This allows for much more cost-effective production compared to gellan, which cannot be precipitated as easily (Huang et al. 2009b). The sphingan produced by *Sphingomonas sanxanigenens* was used in China to recover petroleum by water flooding; thereby, it acts as a mud and thickening agent (Huang et al. 2009b).

Bioethanol Producing Capacity of *Zymomonas mobilis*

Zymomonas mobilis was originally used in tropical areas to produce spirituous beverages from plant sap (Swings and De Ley 1977). The unique metabolic capacity of *Zymomonas mobilis* to efficiently produce ethanol from simple sugars compounds made this species interesting for a biotechnological application to produce ethanol. *Zymomonas mobilis* has thereby several advantages compared to yeast: *Z. mobilis* cells have higher specific rates of glucose uptake and ethanol production; the yield of produced ethanol is higher compared to a low yield of bacterial biomass, anaerobic production is possible, and *Zymomonas* spp. are able to grow in the presence of relatively high amounts of ethanol. Some authors have studied extensively the kinetics of ethanol fermentation in both batch and continuous cultures at high glucose concentrations (Lee et al. 1979; Rogers et al. 1982). Attempts to broaden the narrow substrate and product spectrum of *Z. mobilis* have yielded strains that can utilize carbon sources such as mannitol (Buchholz et al. 1988) after chemical mutagenesis. Introduction of heterologous genes from various microorganisms has led to strains that can utilize D-xylose (Feldmann et al. 1992; Zhang et al. 1995), D-mannose (Weisser et al. 1996), L-arabinose (Deanda et al. 1996), β-glucosides, or lactose (Sprenger 1993).

Because *Zymomonas mobilis* is genetically assessable, severally metabolically engineered strains of *Zymomonas mobilis* were constructed for efficient bioethanol production. In the mid-1980s several heterologous genes were cloned to extend the substrate spectrum of *Zymomonas mobilis* (for review, see Rogers et al. 2007). With the elucidation of the enzymatic background of the Entner–Doudoroff pathway of *Zymomonas mobilis* in the 1980s, genes of complete pathways were introduced into *Zymomonas* cells to enable the utilization of further sugar compounds xylose and arabinose for ethanol production via the Entner-Doudoroff pathway. For example, Zhang and co-workers (1995) introduced genes encoding the xylose isomerase, xylulokinase, transaldolase, and transketolase to produce a functional metabolic pathway of xylose utilization. The introduction of this metabolic pentose pathway enabled *Zymomonas* strains to convert xylose to central intermediates of the Enter-Doudoroff pathway and to ferment it thereby to ethanol.

Another example is the introduction of five *E. coli* genes encoding L-arabinose isomerase, L-ribulokinase, L-ribulose-5-phosphate-4-epimerase, transaldolase, and transketolase generating an L-arabinose fermenting strain (Deanda et al. 1996). Glucose, xylose, and arabinose co-fermenting strains were later constructed by Mohagheghi et al. (1998). Several other strains were produced by genetic engineering. For example, Yanase et al. (2012) developed a genetically engineered *Zymomonas mobilis* strain that was able to produce bioethanol from complex cellolytic material (wood hydrolysates rich in glucose, mannose, and xylose as major sugar components) by the introduction of genes encoding enzymes from the catabolic mannose and xylose metabolism of *E. coli* into *Zymomonas mobilis*. Several recombinant plasmids harboring *E. coli*-derived genes (*xylA*, *xylB*, *tal*, and *tktA*) are necessary to ferment several further sugar substrates, including mannose, xylose, and glucose.

With the publication of the complete genome sequence of *Z. mobilis* ZM4 in 2005 (Seo et al. 2005), the ability for genetic

modification further increased. Besides the genetically engineered *Zymomonas mobilis*, bacteria genes of *Zymomonas* are also used for the genetic engineering of other bacteria. Codon-optimized genes encoding the pyruvate decarboxylase and alcohol dehydrogenase of *Z. mobilis* were introduced into *Lactococcus lactis* to enable a high-yield ethanol formation by this model species (Solem et al. 2013).

Beside ethanol production, *Zymomonas mobilis* can also be used for the production of other substances, such as L-alanine (Uhlenbusch et al. 1991), carotenoids (Misawa et al. 1991), and sorbitol (Liu and Blaschek 2010). A recombinant strain containing a plasmid for the overexpression of glucose–fructose oxidoreductase (GFOR) significantly increased the yield of sorbitol and gluconic acid from glucose and fructose. By the application of divalent metals as Zn^{2+} to this process, enzymes of the Entner–Doudoroff pathway were inhibited and the yield of ethanol as byproduct could be decreased, increasing in parallel the yield of sorbitol.

26 The Family *Xanthobacteraceae*

Aharon Oren
Department of Plant and Environmental Sciences, The Institute of Life Sciences, The Hebrew University of Jerusalem, Jerusalem, Israel

Abstract
The family *Xanthobacteraceae*, established in 2005 on the basis of 16S rRNA phylogeny, is affiliated with the *Alphaproteobacteria*. Currently (May 2012) it encompasses 7 genera (*Xanthobacter* [type genus], *Ancylobacter*, *Azorhizobium*, *Labrys*, *Pseudolabrys*, *Pseudoxanthobacter*, and *Starkeya*) and 28 species. All members grow as aerobic chemoheterotrophs, but facultative chemolithoautotrophy with hydrogen and/or reduced sulfur compounds is found in many species. Nitrogen fixation is widespread; the genus *Azorhizobium* entirely consists of N_2-fixing symbionts that live in association with leguminous plants. Some species can grow on unusual substrates such as alkenes, halogenated aliphatic and aromatic compounds, terpenes, thiophenes, or polyaromatic compounds. Representatives of the family can be found worldwide in freshwater lakes and streams, soils, wetlands, and in polluted sites.

Taxonomy, Historical and Current

Family *Xanthobacteraceae* Lee, Liu, Anzai, Kim, Aono, and Oyaizu 2005, 1916[VP]

Xan.tho.bac.te.ra'ce.ae. N.L. masc. n. *Xanthobacter*, type genus of the family; suff. *–aceae*, ending to denote a family; N.L. fem. pl. n. *Xanthobacteraceae*, the *Xanthobacter* family.

Gram-negative, rod-shaped chemoorganotrophic or facultatively chemolithoautotrophic bacteria, motile or nonmotile. Do not form spores. Some species fix N_2. The major isoprenoid quinone is Q-10. The family *Xanthobacteraceae* was circumscribed on the basis of phylogenetic analysis of 16S rRNA sequences. The family is phenotypically, metabolically, and ecologically diverse.

Type genus: *Xanthobacter*.

The mol% G+C of the DNA varies between 61 and 69.

The family *Xanthobacteraceae* was created in 2005, based on 16S rRNA sequence comparisons (Lee et al. 2005). At the time of writing (May 2012), the family contained 7 genera with 28 species (Tables 26.1–26.7): *Xanthobacter* [type genus] (8 species, the names of 2 of which were thus far effectively but not validly published), *Ancylobacter* (7 species, including one whose name was effectively but not yet validly published), *Azorhizobium* (2 species), *Labrys* (7 species), *Pseudolabrys* (1 species), *Pseudoxanthobacter* (1 species), and *Starkeya* (2 species).

The genus *Xanthobacter* was established by Wiegel et al. (1978) based on numerical taxonomy comparisons of organisms assigned at the time to the genus *Corynebacterium*. The species *Corynebacterium autotrophicum* (Baumgarten et al. 1974) was renamed *Xanthobacter autotrophicus*, and proposed as the type species of the new genus. A comparative study showed that the

E. Rosenberg et al. (eds.), *The Prokaryotes – Alphaproteobacteria and Betaproteobacteria*, DOI 10.1007/978-3-642-30197-1_258,

Table 26.1
The genera classified within the family *Xanthobacteraceae*, as of May 2012

Genus	Number of species	Type species	General properties
Xanthobacter [type genus]	8[a]	*Xanthobacter autotrophicus*	Rod-shaped, sometimes twisted or pleomorphic cells. Refractile (polyphosphate) and lipid (poly-β-hydroxybutyrate) bodies are evenly distributed in the cells. Aerobic, with a strictly respiratory type of metabolism. Colonies are opaque and generally slimy, yellow due to the presence of zeaxanthin dirhamnoside. Nearly all strains can grow chemolithoautotrophically in mineral media under an atmosphere of H_2, O_2, and CO_2, as well as chemoorganoheterotrophically on methanol, ethanol, n-propanol, n-butanol, and various organic acids as carbon sources. The carbohydrate utilization spectrum is limited. Some strains can use substituted thiophenes as sole carbon, energy, and sulfur sources. N_2 is fixed under a decreased O_2 pressure
Ancylobacter	7[a]	*Ancylobacter aquaticus*	Curved rods. Rings are occasionally formed prior to cell separation. Cells are encapsulated. Some strains produce gas vesicles. Generally nonmotile or motile by means of a single polar flagellum. Obligately aerobic with a strictly respiratory type of metabolism. Colonies are white to cream colored. Chemoorganotrophic, using a variety of sugars or salts of organic acids as carbon sources. Chemolithotrophic growth has been reported on molecular hydrogen. Some strains are facultatively methylotrophic, using methanol and formate
Azorhizobium	2	*Azorhizobium caulinodans*	Motile, short, rod-shaped cells, showing peritrichous flagella on solid medium and one or more lateral flagella in liquid medium. Obligately aerobic. N_2 is fixed under microaerobic conditions. Among sugars, only glucose is oxidized; the favorite carbon substrates are organic acids such as lactate or succinate. Grow also on malonate and on proline. Starch is not hydrolyzed. Denitrification is not observed. Nodulate the stems and roots of leguminous plants of the genus *Sesbania*
Labrys	7	*Labrys monachus*	Motile or nonmotile cells; may or may not possess triangular radial symmetry. They may have two to three short prosthecae, can be aerobes or facultative anaerobes. Cells divide by budding. Most strains are obligately aerobic, chemoorganotrophic. Use carbohydrates and some organic acids as sole carbon and energy sources. May be facultative methylotrophs
Pseudolabrys	1	*Pseudolabrys taiwanensis*	Non-motile, short, rod-shaped cells that multiply by division and not by budding. Methanol, methylamine, formaldehyde, and formamide are not used as sole carbon sources
Pseudoxanthobacter	1	*Pseudoxanthobacter soli*	Motile, short, rod-shaped cells that accumulate poly-β-hydroxybutyrate as polar inclusion bodies
Starkeya	2	*Starkeya novella*	Nonmotile, short, rod-shaped cells. Strictly aerobic facultative chemolithoautotrophs that grow on thiosulfate and tetrathionate but not on elemental sulfur or thiocyanate. Neutrophilic and mesophilic. Growth is also observed with formate. Some strains may degrade methylated sulfides

[a]Including species whose names have been effectively but not yet validly published

nitrogen-fixing facultative chemolithotrophic isolate known as *Mycobacterium flavum* strain 301 (Federov and Kalininskaya 1961) can be classified within the new genus as *Xanthobacter flavus* (Malik and Claus 1979). Later 16S rRNA sequence comparison confirmed the phylogenetic relationship. Based on 16S rRNA phylogeny, the species *Blastobacter viscosus* 7d (Loginova and Trotsenko 1980) and *Blastobacter aminooxidans* 14a (Doronina et al. 1984) were moved from the genus *Blastobacter* (*Bradyrhizobiaceae*) to the genus *Xanthobacter* as *X. viscosus* and *X. aminoxidans* (Doronina and Trotsenko 2003).

The genus name *Ancylobacter* was proposed by Raj (1983) as a substitute for the genus name *Microcyclus* (Ørskov 1928). The name *Microcyclus* was earlier used for a fungus in 1904, and therefore the name was considered illegitimate, even though it appeared in the Approved Lists of Bacterial Names of 1980. The strain described by Ørskov as the type of *Microcyclus aquaticus* has been lost. Subsequently, new similar strains were isolated by Ørskov, and one of these strains (ATCC 25396) was proposed as the neotype strain of *M. aquaticus*, now *A. aquaticus* comb. nov. (Ørskov 1957; Larkin and Borrall 1979; Staley et al. 2005).

Ancylobacter vacuolatus (Xin et al. 2006) was earlier described as *Renobacter vacuolatum* (Nikitin 1971).

Taxonomic rearrangement of obligately or facultatively chemolithoautotrophic organisms that oxidize reduced sulfur compounds, earlier classified as members of the genus *Thiobacillus*, led to the removal of *T. novellus* (Starkey 1934) (a member of the *Alphaproteobacteria*) from the genus *Thiobacillus* (*Betaproteobacteria*) and its reclassification as *Starkeya novella* gen. nov., comb. nov. (Kelly et al. 2000).

Phylogenetic Structure of the Family and Its Genera

Figure 26.1 shows a Neighbor Joining tree of the type strains of the 28 species of the family *Xanthobacteraceae*. The family is associated with the *Alphaproteobacteria*, close relatives being the families *Hyphomicrobiaceae*, *Bradyrhizobiaceae*, *Beijerinckiaceae*, *Methylocystaceae*, and *Acetobacteraceae*.

The family *Xanthobacteraceae*, originally with five genera (*Xanthobacter*, *Azorhizobium*, *Ancylobacter*, *Labrys*, and *Starkeya*) was proposed by Lee et al. (2005) based on 16S rRNA comparisons of the members of the *Alphaproteobacteria*. It is interesting to note that in an earlier phylogenetic analysis that did not include *Xanthobacter* spp., *Labrys monachus* did not cluster with *Starkeya novella* (*Thiobacillus novellus*) and with *Ancylobacter aquaticus* (Fritz et al. 2004). The close phylogenetic relationship between *Xanthobacter* and *Azorhizobium* was first reported in 1996 (Rainey and Wiegel 1996; Wiegel 2005). Already then, it was noted that members of *Xanthobacter* and *Azorhizobium* are intermixed in the tree, as seen also in *Fig. 26.1*. A Maximum Likelihood (RAxML) tree constructed (not shown) placed the two species of *Azorhizobium* on a single branch surrounded by members of the genus *Xanthobacter*. Both the Neighbor Joining and the Maximum Likelihood trees place the two *Starkeya* species between the *Ancylobacter* branches.

Genome Analysis

At the time of writing (May 2012), three genome sequences of members of the *Xanthobacteraceae* had been published (*Table 26.8*): the type strain of *Azorhizobium caulinodans* (Lee et al. 2008), the type strain of *Starkeya novella*, and *Xanthobacter autotrophicus* Py2, a strain that can grow on alkenes (van Ginkel and de Bont 1986) and has many interesting physiological and biochemical features as described below. The chromosomes are 4.77–5.37 Mbp in length and contain 4,483–4,847 predicted genes. *X. autotrophicus* Py2 in addition contains a 316-kb plasmid encoding 308 predicted proteins. Of the 4,717 predicted proteins encoded by the 5.37 Mbp genome of *A. caulinodans*, 3.7 % are unique for this organism. Most nodulation functions as well as a putative type-IV secretion system are found in a distinct "symbiosis region" (Lee et al. 2008).

Phages

Wilke and Schlegel (1979) described three phages infecting *Xanthobacter autotrophicus* strain GZ29. Two lytic phages CA1 and CA2 have heads of 61–68 nm diameter and tails of 98–100 and 166–175 nm length, respectively. A third phage designated CA3, with a head diameter of 37–43 nm, a 43–50 nm tail, and a small DNA molecule of 3.3 kDa, did not form plaques and was detected only by its transducing activity and by electron microscopy.

Forty-three plaque-forming phages against the stem-nodulating *Azorhizobium caulinodans* were isolated from rhizosphere soil of different leguminous plant species. They all had a head and short (14–18 nm) non-contractible and non-flexible tails and were assigned to the *Podoviridae* (Sharma et al. 2008).

Phenotypic Analyses

The Properties of the Genera and Species of *Xanthobacteraceae*

Phenotypically the members of the family *Xanthobacteraceae* are quite diverse. With the other members of the *Alphaproteobacteria*, they share a Gram-negative type of cell wall, presence of ubiquinone Q-10 as the major respiratory quinone (with Q-9, Q-8, and Q-11 sometimes found in minor amounts), and other chemotaxonomic traits such as the types of fatty acids present. Predominant polyamines are putrescine and *sym*-homospermidine, as characterized in *Xanthobacter autotrophicus* 7c and CB2, *Azorhizobium caulinodans*, and *Labrys wisconsinensis* (Hamana et al. 1990; Wiegel 2006; Albert et al. 2010). They are all aerobes, although *Labrys wisconsinensis* was described as a facultative anaerobe as growth was obtained anaerobically on plate count broth supplemented with 0.075 % agar (Albert et al. 2010). Chemolithoautotrophic growth is widespread within the family, with hydrogen and/or reduced sulfur compounds serving as electron donor and energy source. Another property found in many of the genera is the ability to fix N_2.

Genus *Xanthobacter* Wiegel, Wilke, Baumgarten, Opitz, and Schlegel 1978, 580[AL]

Xan.tho.bac'ter Gr. adj. *xanthos*, yellow; N.L. masc. n. *bacter*, rod, staff; N.L. masc. n. *Xanthobacter*, yellow rod.

Rod-shaped, sometimes twisted cells, 0.4–1.0 × 0.8–6.0 μm, nonmotile or motile by peritrichous flagella. Gram-negative type of cell wall. Pleomorphic cells are sometimes produced on media containing succinate and other tricarboxylic acid cycle intermediates, whereas coccoid cells as well as cells up to 10 μm long are produced on media containing an alcohol as the sole

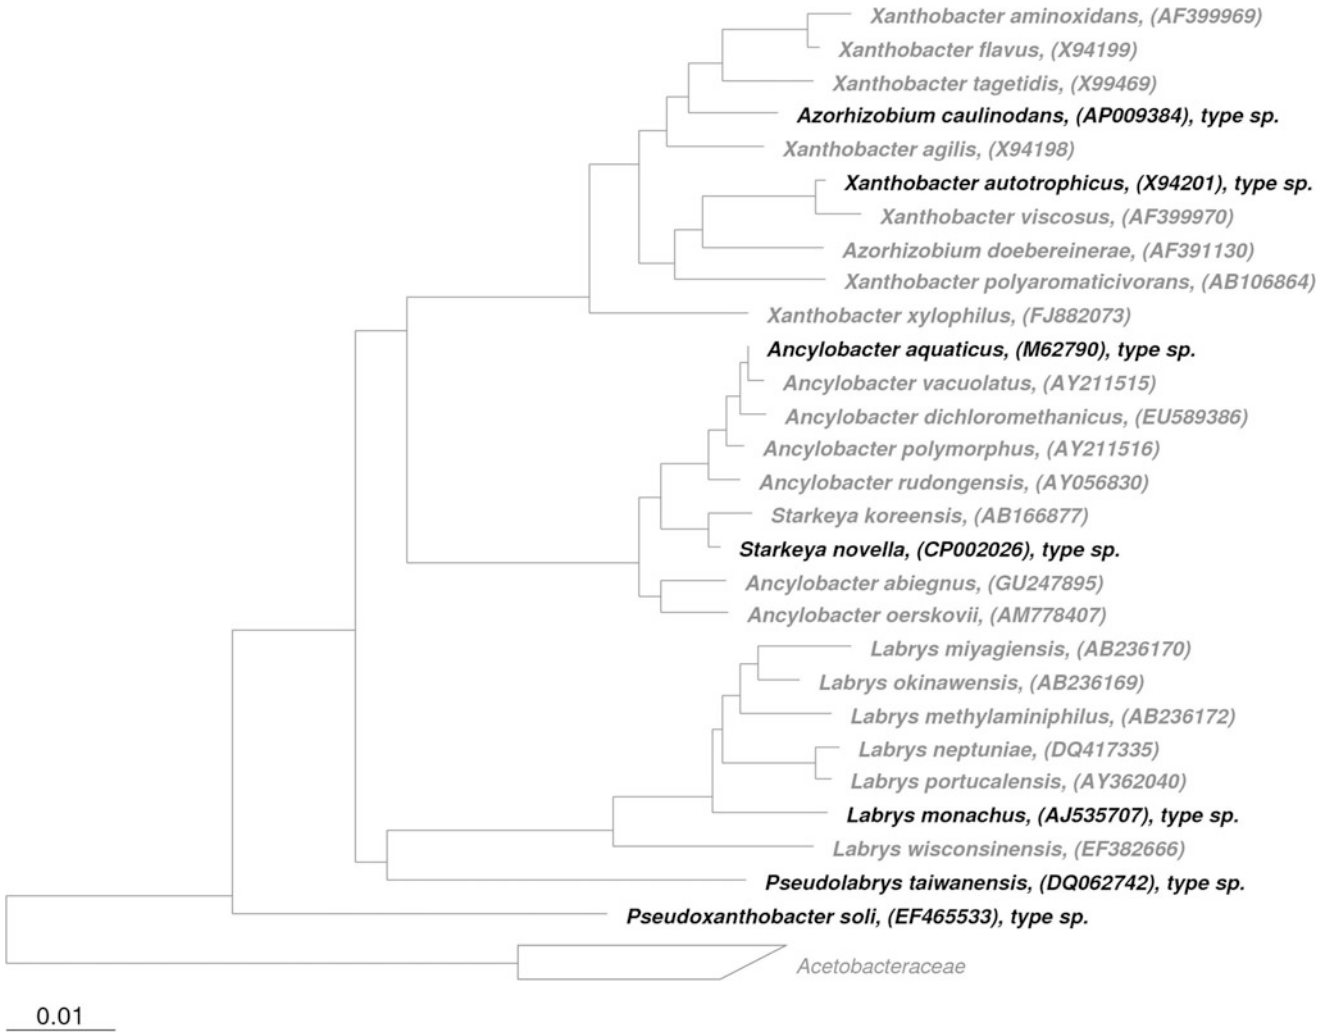

Fig. 26.1

Phylogenetic reconstruction of the family *Xanthobacteraceae* based on 16S rRNA and created using the neighbor-joining algorithm with the Jukes-Cantor correction. The sequence dataset and alignment were used according to the All-Species Living Tree Project (*LTP*) database (Yarza et al. 2010; http://www.arb-silva.de/projects/living-tree). The tree topology was stabilized with the use of a representative set of nearly 750 high-quality type strain sequences proportionally distributed among the different bacterial and archaeal phyla. In addition, a 40 % maximum frequency filter was applied in order to remove hypervariable positions and potentially misplaced bases from the alignment. *Scale bar* indicates estimated sequence divergence

carbon source. Refractile (polyphosphate) and lipid (poly-β-hydroxybutyrate) bodies are evenly distributed in the cells. Due to polyphosphate granules, the Gram reaction frequently appears falsely to be positive or variable. Aerobic, with a strictly respiratory type of metabolism. Neutrophilic and mesophilic. Colonies are opaque and generally slimy, yellow due to the presence of zeaxanthin dirhamnoside. Most strains can grow chemolithoautotrophically in mineral media under an atmosphere of H_2, O_2, and CO_2, as well as chemoorganoheterotrophically on methanol, ethanol, n-propanol, n-butanol, and various organic acids as carbon sources. The carbohydrate utilization spectrum is limited. Some strains can use substituted thiophenes as sole carbon, energy, and sulfur sources. When degrading aliphatic epoxides, tested strains contain coenzyme M, which otherwise is a typical coenzyme of the obligate anaerobic methanogenic archaea. N_2 is fixed under a decreased O_2 pressure.

The mol% G+C of the DNA is 65–70.

Type species: *Xanthobacter autotrophicus*.

The genus *Xanthobacter* currently contains eight species: *X. autotrophicus*, *X. agilis*, *X. aminoxidans*, *X. flavus*, *X. polyaromativorans* (a name effectively but not yet validly published), *X. tagetidis*, *X. viscosus*, and *X. xylophilus* (a name effectively but not yet validly published). The main features of the members of the genus *Xanthobacter* are summarized in *Table 26.2*.

Table 26.8
Properties of the sequenced genomes of members of the *Xanthobacteraceae* (as of May 2012)

[b]Data taken from Lee et al. (2008)
NR not reported

Additional comments:

- Irregular twisted cells (*X. tagetidis*) and branched cells (*X. autotrophicus*, *X. flavus*) are commonly found during growth on tricarboxylic acid cycle intermediates. Branching cells do not show septa at the branching points (Wiegel 2005).
- Most members of the genus multiply by symmetric division, but *X. viscosus* and *X. aminoxidans* reproduce by budding (Doronina and Trotsenko 2003). *X. polyaromaticivorans*, a species that degrades polycyclic and heterocyclic aromatic compounds, is atypical as it shows no autotrophic growth (Hirano et al. 2004).
- *X. flavus* was originally described as nonmotile. However, reexamination of the type strain showed peritrichous flagella in exponential cultures grown on methanol, ethanol, *n*-propanol, isopropanol, butanol, or gluconate, but not in media containing citrate, fumarate, malate, succinate, glutamate, glutamine, yeast extract, or in cells growing autotrophically on $H_2 + CO_2$ (Reding et al. 1992).
- Cellular fatty acids are high in $C_{18:1}$ and include $C_{18:0}$, 3-OH $C_{16:0}$, and (in *X. agilis*) $C_{19:0}$ cyclo ω7*c* (Urakami et al. 1995).
- *X. polyaromaticivorans* is slightly pinkish-orange, probably due to a zeaxanthin with terminal substitutions different from zeaxanthin dirhamnoside (Wiegel 2006).
- *X. xylophilus*, isolated from acidic low-salinity dystrophic water with decaying spruce wood, is moderately acidophilic, and uses organic acids (citrate, oxalate, succinate, gluconate), as well as xylose and xylan (Zaichikova et al. 2010a).
- *X. tagetidis* is associated with the roots of marigold (*Tagetes*) plants, which accumulate high concentrations of thiophenes. It grows on substituted thiophenes, and also is a facultative autotroph that can grow on H_2, thiosulfate, or sulfide as electron donors. It fixes CO_2 using ribulose bisphosphate carboxylase/oxygenase (Padden et al. 1997).
- All strains of *X. autotrophicus* and *X. flavus* produce an α-polyglutamine capsule located between the cell wall and the slime (Wiegel 2005).
- Two methanol degrading isolates 25P and 32P, classified as strains of *X. autotrophicus*, were described by Doronina et al. (1996).

Genus *Ancylobacter* Raj 1983, 397^{VP}

An.cy.lo.bac'ter. Gr. adj. *ankulos*, crooked, curved; N.L. masc. n. *bacter*, rod; N.L. masc. n. *Ancylobacter*, a curved rod.

Curved rods, 0.3–1.0 × 1.0–3.0 μm. Rings (0.9–3.0 μm outer diameter) are occasionally formed prior to cell separation. Cells are encapsulated. Some strains produce gas vesicles. Gram-negative. Generally nonmotile or motile by means of a single polar flagellum. Obligately aerobic with a strictly respiratory type of metabolism. Colonies are white to cream colored. Oxidase and catalase positive. Chemoorganotrophic, using a variety of sugars or salts of organic acids as carbon sources. Chemolithotrophic growth has been reported on molecular hydrogen. Some strains are facultatively methylotrophic, using methanol and formate.

The mol% G+C of the DNA is 66–69.

Type species: *Ancylobacter aquaticus*.

The genus *Ancylobacter* currently contains seven species: *A. aquaticus*, *A. abiegnus* (a name effectively but not yet validly published), *A. dichloromethanicus*, *A. oerskovii*, *A. polymorphus*, *A. rudongensis*, and *A. vacuolatus*. The main features of the members of the genus *Ancylobacter* are summarized in *Table 26.3*.

Additional comments:

- Overviews of the biology of *Ancylobacter* were published by Raj (1989) and by Staley et al. (2005).

- Staley et al. (2005) consider the type strain of *A. aquaticus* to be avacuolate, despite a claim to the contrary (Raj 1977).
- Autotrophic growth of several strains was reported with hydrogen (Namsaraev and Nozhevnikova 1978; Malik and Schlegel 1981) or with thiosulfate as energy source (Stubner et al. 1998). CO_2 fixation is mediated by ribulose bisphosphate carboxylase/oxygenase (Loginova et al. 1978; Firsova et al. 2009).
- *A. dichloromethanicus*, isolated from contaminated soil, uses dichloromethane, methanol, formate, formaldehyde, and a range of larger carbon sources (Firsova et al. 2009).
- The major fatty acid of *A. aquaticus* is $C_{18:1}$; further present $C_{16:0}$, $C_{18:0}$ $C_{19:0}$ cyclo. The major respiratory quinone is Q-10, with minor amounts of Q-9 and Q-11 (Urakami and Komagata 1986).

Genus *Azorhizobium* Dreyfus, Garcia, and Gillis 1988, 97[VP]

A.zo.rhi.zo'bi.um. N.L. n. *azotum* [from Fr. n. *azote* (from Gr. prep. *a*, not; Gr. n. *zôê*, life; N.Gr. n. *azôê*, not sustaining life)], nitrogen; N.L. pref. *azo-*, pertaining to nitrogen; N.L. neut. n. *Rhizobium*, a bacterial generic name; N.L. neut. n. *Azorhizobium*, a nitrogen (using) *Rhizobium*.

Motile, short, rod-shaped Gram-negative cells, showing peritrichous flagella on solid medium and one or more lateral flagella in liquid medium. Obligately aerobic. N_2 is fixed under microaerobic conditions when nicotinic acid is provided. Oxidase- and catalase-positive; urease-negative. Among sugars, only glucose is oxidized; the favorite carbon substrates are organic acids such as lactate or succinate. Grow also on malonate and on proline. Starch is not hydrolyzed. Denitrification is not observed. Nodulate the stems and roots of leguminous plants of the genus *Sesbania*.

The mol% G+C of the DNA of the type species is 66.

Type species: *Azorhizobium caulinodans*.

The genus *Azorhizobium* currently contains two species: *A. caulinodans* and *A. doebereinerae*. The main features of the members of the genus *Azorhizobium* are summarized in *Table 26.4*.

Additional comments:

- Overviews of the properties of nitrogen-fixing stem nodules of *Sesbania* and the biology of *Azorhizobium* were published by Dreyfus and Dommergues (1981), Dreyfus et al. (1984), Goormachtig et al. (1998), and Kuykendall (2005).
- *A. doebereinerae* was isolated from root nodules of Brazilian woody species *Sesbania virgata*. Its colonies on YMA agar are similar to those of *A. caulinodans*: scant extracellular polysaccharide, fast to intermediate growth rate, and causing alkalinization of the medium. Neither *A. caulinodans* nor *A. doebereinerae* use mannitol or sucrose, compounds used by most *Rhizobium*, *Sinorhizobium*, *Mesorhizobium*, and *Bradyrhizobium* spp. However, they can use DL-lactate. *A. doebereinerae* differs from *A. caulinodans* as it does not use either L-leucine or D-glucose (de Souza Moreira et al. 2006).

Genus *Labrys* Vasilyeva and Semenov 1985, 375[VP] (Effective Publication: Vasilyeva and Semenov 1984, p. 92 (Russian edition)); Emended Islam, Kawasaki, Nakagawa, Hattori and Seki, 2007, 556; Emended Albert, Waas, Langer, Pavlons, Feldner, Rosselló-Mora and Busse, 2010, 1757)

La'brys. N.L. masc. n. *Labrys* (from Gr. n. *labrus*), double-headed ax, an organism resembling a double-headed ax by the shape of the cell.

Motile or nonmotile cells; can be rod-shaped, and may or may not possess triangular radial symmetry. They may have two to three short prosthecae and can be aerobes or facultative anaerobes. Cells divide by budding. Buds are produced directly from the mother cell at the tip of the triangle that lacks prosthecae. In this stage, the cell resembles a double-headed ax. Most strains are aerobic, chemoorganotrophic. Use carbohydrates and some organic acids as sole carbon and energy sources. Oxidase and catalase positive. May be facultative methylotrophs. The primary polar lipids are diphosphatidylglycerol, phosphatidylmonomethylethanolamine, and phosphatidylcholine. The predominant fatty acids are $C_{19:0}$ cyclo ω8*c*, $C_{16:0}$, $C_{18:0}$, and $C_{18:1}$ω7*c*. The major ubiquinone is Q-10, and the major polyamine is *sym*-homospermidine.

The mol% G+C of the DNA is 61–68.

Type species: *Labrys monachus*.

The genus *Labrys* currently contains seven species: *L. monachus*, *L. methylaminiphilus*, *L. miyagiensis*, *L. neptuniae*, *L. okinawensis*, *L. portucalensis*, and *L. wisconsinensis*. The main features of the members of the genus *Labrys* are summarized in *Table 26.5*.

Additional comments:

- *L. neptuniae* was isolated from root nodules of the pan-tropical aquatic legume *Neptunia oleracea* (Chou et al. 2007).
- *L. portucalensis* is a fluorobenzene-degrading bacterium obtained from industrially contaminated sediment in northern Portugal. Fluorobenzene is used as a solvent in the pharmaceutical industry, as an insecticide, and as a reagent for plastic and resin polymers production (Carvalho et al. 2005, 2008).
- *L. okinawensis* and *L. miyagiensis* are budding bacteria isolated from rhizosphere habitats in Japan (Islam et al. 2007).
- *Labrys methylaminiphilus* was isolated from freshwater Lake Washington sediment following enrichment on

methylamine. It also uses a variety of mono- and disaccharides, organic acids, aromatic compounds, and alcohols. Methanol is not used. It also grows on polymers such as agarose and humic acid (Miller et al. 2005).
– Some species accumulate considerable amounts of poly-β-hydroxybutyrate (Vasilyeva 2005).

Genus *Pseudolabrys* Kämpfer, Young, Arun, Shen, Jäckel, Rosselló-Mora, Lai, and Rekha 2006, 2470[VP]

Pseu.do.la'brys. Gr. adj. *pseudês* false; N.L. masc. n. *Labrys* a bacterial genus name; N.L. masc. n. *Pseudolabrys* the false *Labrys*.

Nonmotile, short, rod-shaped Gram-negative cells that multiply by division and not by budding. Methanol, methylamine, formaldehyde, and formamide are not used as sole carbon sources. The major fatty acids are $C_{16:0}$, $C_{18:1}\omega7c$, and $C_{19:0}$ cyclo ω8*c*.

The mol% G+C of the DNA of the type species and only species described is 67.

Type species: *Pseudolabrys taiwanensis*. The main features of the single member of the genus *Pseudolabrys* are summarized in Table 26.6.

Genus *Pseudoxanthobacter* Arun, Schumann, Chu, Tan, Chen, Lai, Kämpfer, Shen, Rekha, Hung, Chou, and Young 2008, 1573[VP]

Pseu.do.xan.tho.bac'ter. Gr. adj. *pseudês* false; N.L. masc. n. *Xanthobacter* a bacterial genus name; N.L. masc. n. *Pseudoxanthobacter* the false *Xanthobacter*.

Motile, short, rod-shaped Gram-negative or Gram-variable cells that accumulate poly-β-hydroxybutyrate as polar inclusion bodies. The major quinone is Q-10. The characteristic diamino acid of the peptidoglycan is *meso*-diaminopimelic acid. Polar lipids are diphosphatidylglycerol, phosphatidylglycerol, phosphatidylethanolamine, phosphatidylcholine, phosphatidylmonomethylethanolamine, phosphatyidyldimethylethanolamine, and an unknown aminolipid. The predominant fatty acids are $C_{16:0}$, $C_{18:1}\omega7c$ and $C_{19:0}$ cyclo.

The mol% G+C of the DNA of the type species and only species described is 68.

Type species: *Pseudoxanthobacter soli*. The main features of the single member of the genus *Pseudoxanthobacter* are summarized in Table 26.6.

Additional comments:

– *P. soli* is a nitrogen-fixing species isolated from soil. Its major respiratory quinone is Q-10, with minor amounts of Q-9 and Q-8. The organism can fix N_2 and multiplies by budding (Arun et al. 2008).

Genus *Starkeya* Kelly, McDonald, and Wood 2000, 1800[VP]

Star.key'a. N.L. fem. n. *Starkeya*, named after Robert L. Starkey, who made important contributions to the study of soil microbiology and sulfur biochemistry.

Nonmotile, short, rod-shaped Gram-negative cells. Colonies grow on thiosulfate agar. Biotin is required. Strictly aerobic and facultative chemolithoautotrophic. Oxidize and grow on thiosulfate and tetrathionate but not on elemental sulfur or thiocyanate. Neutrophilic and mesophilic. Contain ubiquinone Q-10. Major cellular fatty acids are $C_{18:1}$ and $C_{19:0}$ cyclo. Growth is also observed with formate. Some strains may degrade methylated sulfides. Isolated from soils and presumably widely distributed.

The mol% G+C of the DNA is 67–69.

Type species: *Starkeya novella*.

The genus *Starkeya* currently contains two species: *S. novella* and *S. koreensis*. The main features of the members of the genus *Starkeya* are summarized in Table 26.7.

Additional comments:

– For optimal autotrophic development, biotin is required. When grown on formate, high levels of ribulose bisphosphate carboxylase/oxygenase are expressed (Kelly and Wood 2005).
– *S. novella* uses a variety of sugar alcohols, amino acids, carboxylic acids, and fatty acids for heterotrophic growth; reduced sulfur compounds serving as electron donors include thiosulfate, tetrathionate, dimethylsulfide, and dimethylsulfoxide (Kelly et al. 2000).
– A *S. novella* isolate from sewage was shown to oxidize methanethiol, dimethylsulfide, and dimethyldisulfide (Cha et al. 1999).

Isolation, Enrichment, and Maintenance Procedures

Strategies for the enrichment and isolation of *Xanthobacter* species can be based on the ability to fix N_2 under chemolithoautotrophic growth conditions under a gas mixture of H_2 (10 %), N_2 (70–75 %), CO_2 (10 %), and air (5–10 %), and on the specific yellow color and the characteristic "fried-egg" appearance of colonies caused by slime production on media containing 1 % succinate and nutrient broth, and the appearance of branched cells in such colonies (Wiegel 2005, 2006). Some isolates were obtained by chance, such as *X. autotrophicus* strain 7c, which was isolated from an enrichment for propane-oxidizing bacteria, using black mud of a pond in Germany as inoculum; the *Xanthobacter* obtained did not use propane. *X. tagetidis* can be reproducibly enriched from *Tagetes* (marigold) roots using thiophene-2-carboxylate or thiophene-2-acetate as substrates (Padden et al. 1997).

For enrichment and isolation of gas-vacuolated strains of *Ancylobacter*, 100 ml of a freshwater source can be added to a sterile aluminum foil-covered beaker containing 10 mg Bacto peptone (Difco). After 2 weeks incubation, at room temperature the culture is plated onto a hydrolysate medium containing glucose (Van Ert and Staley 1971; Staley et al. 2005). For the isolation of motile variants of gas-vacuolate strains of *Ancylobacter aquaticus*, selection on soft agar plates can be used: Growth radiating from the center of the colony consists of motile cells (Lara and Konopka 1987).

Ancylobacter oerskovii and two strains of *Ancylobacter polymorphus* were isolated from soil after enrichment with oxalate. All known species of the genus appear to use oxalate as the sole source of carbon (Lang et al. 2008), a finding that can probably be used as the basis for selective isolation procedures. Enrichment on dichloromethane as carbon and energy source, amended with a low concentration of yeast autolysate, was successfully applied for the isolation of *A. dichloromethanicus* (Firsova et al. 2009).

Azorhizobium grows well on nitrogen-free agar media, distinguishing the genus from other legume-nodulating bacteria (*Bradyrhizobium*, *Mesorhizobium*, *Rhizobium*) (Dreyfus et al. 1988). Lactate and succinate are preferred substrates for growth (Kuykendall 2005). Selective inhibitors are also useful in studies of *Azorhizobium* and related plant-associated nitrogen-fixing bacteria: *Azorhizobium* is resistant to carbencillin; nalidixic acid inhibits *Azorhizobium* but allows growth of *Rhizobium* (Robertson et al. 1995).

Low nutrient concentrations may favor growth of *Labrys* spp. in enrichment cultures. This, *L. miyagiensis*, isolated from grassland soil in Japan, grows in 1/100 diluted nutrient broth but is inhibited by full-strength nutrient broth medium (Islam et al. 2007). *L. methylaminiphilus*, a facultatively methylotrophic bacterium obtained from sediment of Lake Washington, WA, USA, was enriched using mineral medium with 0.01 % methylamine (Miller et al. 2005). The type strain of *L. monachus* was isolated from silt samples from Lake Mustjarv (Estonia) using horse manure extract, obtained by heating 1 % (w/v) dry manure in distilled water. The sediment is left to settle and a liquid medium is prepared from the supernatant (Vasilyeva 2005). Some other *Labrys* species were obtained on nonselective media. *L. neptuniae* was isolated from root nodules of the tropical aquatic legume *Neptunia oleracea* on yeast extract —mannitol agar (Chou et al. 2007). Finally, *L. wisconsinensis* was isolated from Lake Michigan water as a colony that grew on Difco Plate Count Agar—a nonselective general medium for heterotrophic bacteria (Albert et al. 2010).

The type strains (and thus far only isolates) of the soil bacteria *Pseudoxanthobacter soli* and *Pseudolabrys taiwanensis* were both isolated as colonies on nutrient agar, without any prior enrichment or selection procedure (Arun et al. 2008; Kämpfer et al. 2006).

No selective isolation procedures for *Starkeya* spp. have yet been tested. Vitamins may be important in determining the outcome of enrichment and isolation experiments: For optimal autotrophic growth, *S. novella* requires biotin, and for optimal heterotrophic growth yeast extract, biotin, or other vitamins such as pantothenate may be required, depending on the substrate (Kelly et al. 2000). *S. koreensis* was isolated from rice straw using R2A agar, a nonselective general low-nutrient plating medium (Im et al. 2006).

Maintenance

Cultures can be maintained if they are refrigerated at 4 °C for a number of weeks. For long-term preservation, lyophilization is recommended.

Physiological and Biochemical Features

Physiologically and biochemically there are a number of noteworthy features within in the family *Xanthobacteraceae*: the ability of some strains of *Xanthobacter*, *Ancylobacter*, and *Labrys* to degrade chlorinated and brominated alkanes, alkenes, and aromatic compounds; the degradation of thiophenes by *X. tagetidis*; the ability of *Xanthobacter* spp. to grow on polyaromatic compounds; and the growth of some *X. autotrophicus* strains to grow on ethylene, propylene, and other alkenes.

Xanthobacter autotrophicus GJ10 was isolated on 1,2-dichloroethane as the sole carbon and energy source. It possesses a hydrolytic haloalkane dehydrogenase with a broad substrate specificity that degrades dichloroethane to 2-chloroethanol. This intermediate is further metabolized via chloroacetaldehyde to chloroacetic acid, which is dechlorinated by a second dehalogenase to glycolate. A similar strain GJ11 was isolated from sediment of the River Rhine (Janssen et al. 1984, 1985). *Xanthobacter* sp. strain TM1, isolated from a wastewater treatment plant receiving domestic and pharmaceutical effluent in Portugal, degrades dichloromethane, chloroacetic acid, dichloroethane, 2-chloroethanol, 2-fluorobenzoate, 3-fluorobenzoate, 4-fluorobenzoate, 2-chlorobenzoate, 4-chlorobenzoate, and methanol (Emanuelsson et al. 2009). *Xanthobacter* sp. strain ENV481, isolated from a microcosm model with aquifer soil and groundwater from a landfill, New Jersey, can degrade bis (2-chloroethyl) ether, a compound used as a solvent for fats and greases, a cleaning fluid for textiles, a constituent of paints and varnishes, and an insecticide (McClay et al. 2007). *Xanthobacter flavus* strain 14p1, isolated from river sludge in Germany, degrades 1,4-dichlorobenzene but no other aromatic or chloroaromatic compounds. The degradation pathway starts with dioxygenation, followed by ring opening via *ortho* cleavage of dichlorocatechol to 2,5-dichloro-*cis*,*cis*-muconic acid (Spiess et al. 1995; Spiess and Görisch 1996; Sommer and Gorisch 1997). *X. autotrophicus* strain GJ10 grows on 1,2-dichloroethane,

bromochloromethane, dibromomethane, and 1-bromo-2-chloroethane. A novel pathway of degradation of dihalomethanes to formaldehyde was proposed. Cells growing on 1,2-dichloroethane converted 2-fluoroethanol and 1-chloro-2-fluoroethane to 2-fluoroacetate (Torz et al. 2007). *Labrys portucalensis* can grow on fluorobenzene (Carvalho et al. 2008). Co-metabolism of chlorinated compounds may also occur: *X. autotrophicus* strains GJ10 and Py2 degrade trichloroethylene during growth on propene (Reij et al. 1995; Inguva and Schreve 1999). When grown on propylene, *Xanthobacter* strain Py2 can degrade trichloroethylene, 1-chloroethylene (vinyl chloride), 1,3-dichloropropylene, 2,3-dichloropropylene, and other related compounds. Addition of propylene oxide, propionaldehyde, and glucose enhanced the rate of degradation of chlorinated alkenes (Ensign et al. 1992).

Several isolates of the genus *Ancylobacter* degrade chlorinated aliphatic compounds. *A. dichloromethanicus* uses dichloromethane (Firsova et al. 2009). *A. aquaticus* strain GJ10 (Janssen et al. 1984, 1985) and strains AD25 and AD27, isolated from slurries of brackish water sediment and activated sludge, respectively (van den Wijngaard et al. 1992), degrade 1,2-dichloroethane. Strains AD25 and AD27 also use 2-chloroethylvinylether as sole carbon and energy source. Such chlorinated ethers are synthesized for the production of anesthetics, sedatives, and cellulose ethers (van den Wijngaard et al. 1993). Other chlorinated compounds broken down by *Ancylobacter* strains include 2-chloroethanol, chloroacetate, and 2-chloropropionate (Staley et al. 2005; van den Wijngaard et al. 1992). The organochlorine fungicide pentachloronitrobenzene (PCNB) could be degraded by *Labrys portucalensis* strain pcnb-21, isolated from a PCNB-polluted soil in China (Li et al. 2011). *Labrys* sp. strain Wy1, isolated from soil in a rubber estate in Malaysia, can use the herbicide 2,2-dichloropropionate (2,2-DCP) as sole source of carbon (Wong and Huyop 2011).

Xanthobacter tagetidis was isolated from the roots of marigold (*Tagetes*) plants. *Tagetes* species accumulate thiophenes in the roots at concentrations up to 1 % of the root mass. *X. tagetidis* grows on thiophenes such as thiophene-2-carboxylate, thiophene-3-carboxylate, on analogs of these compounds (pyrrole-2-carboxylate, furan-2-carboxylate), and on the condensed thiophene dibenzothiophene (Padden et al. 1997).

Xanthobacter polyaromaticivorans 127 W grows on a range of polycyclic and heterocyclic aromatic compounds under extremely low oxygen concentrations. Polycyclic aromatic hydrocarbons used include anthracene, fluorene, naphthalene, phenanthrene, dibenzothiophene, dibenzofuran, and biphenyl. It also degrades dibenzothiophene (Hirano et al. 2004). Another *Xanthobacter* strain, isolated from forest soil in the UK by enrichment with cyclohexane vapor as the carbon source, metabolizes cyclohexane via cyclohexanol, cyclohexanone, and 1-oxa-2-oxocycloheptane (ε-caprolactone) to adipic acid (Trower et al. 1985).

Biochemically one of the most interesting processes performed by some *Xanthobacter* isolates is the degradation of alkenes. Alkene-utilizing *Xanthobacter* strains were obtained from enrichment cultures with propene and 1-butene. A monooxygenase was found to be involved, forming 1,2-epoxyalkanes as intermediate (van Ginkel and de Bont 1986). Alkene degradation and the metabolism of the epoxide intermediates was studied in-depth in *X. autotrophicus* strain Py2, which grows on ethylene, propylene, and butylene (Small and Ensign 1997). The involvement of coenzyme M (2-mercaptoethanesulfonate) in the process came as a big surprise. Coenzyme M has been known for many decades as a central component of the biochemical pathway of methanogenesis in archaea, but it was never before found in any other organisms. *Xanthobacter* strain Py2 possesses a linear megaplasmid that encodes enzymes of aliphatic alkene and epoxide metabolism and coenzyme M biosynthesis. Epoxidation of propylene to epoxypropane is followed by a sequence of three reactions resulting in epoxide ring opening and carboxylation to form acetoacetate. Coenzyme M plays a central role in epoxide carboxylation by serving as the nucleophile for epoxy ring opening and as the carrier of the C_3 unit that is finally carboxylated to acetoacetate, releasing the coenzyme (Sluis and Ensign 1997; Krum and Ensign 2001; Krishnakumar et al. 2008; Pandey et al. 2011). Shotgun proteomics revealed proteins specific to growth on propylene, including the enzymes necessary for the biosynthesis of coenzyme M (Broberg and Clark 2010).

Another substrate metabolized via an epoxide intermediate is the terpene limonene, used by *Xanthobacter* sp. C20. This strain was isolated from the River Rhine using cyclohexane as the sole carbon and energy source. It possesses a novel bioconversion pathway in which limonene is converted to limonene-8,9-epoxide in a reaction that involves cytochrome P-450 (van der Werf et al. 2000).

Ecology

Members of the genus *Xanthobacter* may be ubiquitous in wet soil and sediments. They can be found in freshwater (*X. agilis*), wet soil containing decaying organic material (*X. autotrophus*, *X. flavus*), compost of root balls of *Tagetes* (*X. tagetidis*) (Padden et al. 1997), and they are associated with plant roots including wetland rice (Oyaizu-Masuchi and Komagata 1988; Reding et al. 1991; Wiegel 2005, 2006). One *X. flavus* originated from marine sediment (Lidstrom-O'Connor et al. 1983; Meijer et al. 1990). *X. xylophilus* is moderately acidophilic (opt. 5.5, range 4.8–6.8) and was found in acidic low-salinity dystrophic water with decaying spruce wood (Zaichikova et al. 2010a). *Xanthobacter* species may play an important role in the degradation of toxic organic compounds in polluted environments. *X. viscosus* and *X. aminoxidans* were found in activated sludge of a water treatment plant processing paper mill pulp (Loginova and Trotsenko 1980; Doronina et al. 1984; Doronina and Trotsenko 2003). *X. autotrophicus* was suggested to be involved in the biodegradation of toluene in a freshwater stream in Delaware (Tay et al. 1999).

Ancylobacter aquaticus is found in freshwater habitats, including ponds, creeks, and lakes (Van Ert and Staley 1971; Konopka et al. 1976) and in rice paddies and soil environments (Stubner et al. 1998). *A. abiegnus* was isolated from dystrophic

Species: *1 Xanthobacter autotrophicus*, *2 X. agilis*, *3 X. flavus*, *4 X.tagetidis*, *5 X. xylophilus*, *6 Ancylobacter abiegnus*, *7 A. dichloromethanicus*, *8 A. oerskovii*, *9 Labrys methylaminiphilus*, *L monachus*, *10 L. myagiensis*, *11 L. neptuniae*, *12 L. okinawensis*, *13 L. portucalensis*, *14 Pseudoxanthobacter soli*, *15 Starkeya koreensis*
+ sensitive, – resistant, *NR* not reported
Data were derived from the species descriptions (see *Table 26.2–26.7*) and from Wiegel (2005, 2006)

waters with decaying spruce wood (Zaichikova et al. 2010b). *Ancylobacter* species may also be involved in the degradation of toxic compounds. *A. dichloromethanicus*, a facultatively methylotrophic bacterium that can grow on dichloromethane, was isolated from contaminated soil in Russia (Firsova et al. 2009). *Ancylobacter* sp. strain XJ-412-1 degrades the herbicide metsulfuron-methyl. It was isolated from an agricultural soil in China, which had been exposed to sulfonylurea herbicides for many years (Lu et al. 2011).

Azorhizobium is associated with stem- or root nodules of *Sesbania* and some other leguminous plants (Dreyfus and Dommergues 1981; Dreyfus et al. 1984, 1988; Kuykendall 2005; de Souza Moreira et al. 2006). A comparative study of rhizosphere and non-rhizosphere soils in four vegetation zones of Senegal showed *Azorhizobium* to be more abundant on leaves and stems than *Rhizobium* in three out of the four vegetation zones. Approximately 90 % of the stem nodules and 39–48 % of the root nodules on *S. rostrata* were formed by *Azorhizobium* (Robertson et al. 1995).

Little is known about the distribution of *Labrys* species in nature. They have been recovered from unpolluted freshwater environments (Vasilyeva 2005; Albert et al. 2010) as well as from polluted sites (e.g., the fluorobenzene-degrading *L. portucalensis* (Carvalho et al. 2008). *L. neptuniae* was isolated from root nodules of the aquatic pan-tropical legume *Neptunia oleracea*, but it probably is not the dominant bacterium there: Over 95 % of the colonies of *Neptunia*-associated bacteria in Taiwan that developed on yeast extract—mannitol agar belonged to *Allorhizobium undicola* (Chou et al. 2007).

Hardly anything is known about the distribution and the ecological role of the genera *Pseudolabrys* and *Pseudoxanthobacter*. It is also known little about the ecological niches where *Starkeya* species may be important. The type strains of *S. novella* and *S. koreensis* were isolated from soil and from rice straw, respectively (Starkey 1934; Im et al. 2006), not from environments rich in sulfide.

Pathogenicity, Clinical Relevance

No pathogenic bacteria are known within the *Xanthobacteraceae*. The plant-associated species of the genus *Azorhizobium* that colonize the stems of *Sesbania* and some other leguminous plants live in symbiosis with their host, and they were never shown to cause harm to their plant hosts (Dreyfus et al. 1984; Kuykendall 2005).

Table 26.9 summarizes data on the sensitivity of members of the *Xanthobacteraceae* to different antibiotics. Such data are not available for all members of the family, and the information present does not show any clear patterns, possibly except for the fact that all species tested were sensitive to erythromycin. Wiegel (2006) commented that the available data do not suggest antibiotic typing as a valid method for identification of *Xanthobacter*. This may be the case for other genera of the family as well. The resistance of *Azorhizobium* to carbencillin was mentioned above and allows the selective isolation with the exclusion of *Rhizobium* (Robertson et al. 1995).

Application

As shown above, many representatives of the genera *Xanthobacter*, *Ancylobacter*, and *Labrys* degrade toxic compounds: chlorinated alkanes, alkenes, polyaromatic compounds, thiophenes, etc., and the bacteria may be involved in the biodegradation of such compounds in polluted environments. Many such stains were isolated from sites polluted with such chemicals. However, no applications based on the use of such bacteria in bioremediation operations are known.

The polysaccharide slime produced by *Xanthobacter* species may have interesting biotechnological applications. Wiegel (2006) mentioned the possible use of these polysaccharides as drag-reducing substances for minimizing friction in turbulent flows in pipelines and water turbines or as viscosifiers in oil fields.

An intriguing application of gas-vacuolated *Anyclobacter aquaticus* was proposed: Mosquitocidal toxin genes from *Bacillus sphaericus* and *Bacillus thuringiensis* var. *israelensis* were introduced into *Ancylobacter* by electroporation. The transformed cells exhibited significant toxicity toward mosquito larvae. Such transgenic *Ancylobacter* could be released in water bodies infested with mosquito larvae, and due to the buoyancy of the cells conferred by the gas vesicles the toxin will accumulate at the water surface (Yap et al. 1994). No information could be found whether this interesting idea has ever been developed into field applications.

Starkeya novella, due to its potential to oxidize sulfide and methylated sulfur compounds, and its adaptability to a broad pH range (5–10), could be applied in biofilters for the removal of bad-smelling sulfur compounds, for example, from piggery wastewater (Chung et al. 1997).

Betaproteobacteria

27 The Family *Alcaligenaceae*

Brian Austin
Institute of Aquaculture, School of Natural Sciences, University of Stirling, Stirling, Scotland, UK

Abstract
Alcaligenaceae, a family in the order *Burkholderiales* of the β-*Proteobacteria*, comprises the genera *Achromobacter*, *Advenella*, *Alcaligenes*, *Bordetella*, *Brackiella*, *Candidimonas*, *Castellaniella*, *Derxia*, *Kerstersia*, *Oligella*, *Paenalcaligenes*, *Paralcaligenes*, *Parapusillimonas*, *Pelistega*, *Pigmentiphaga*, *Pusillimonas*, and *Taylorella*. The cultures are Gram-negative asporogenous rods, which have been recovered from a variety of habitats, including animals and human diseases, e.g., *Bordetella pertussis* from whooping cough, and the terrestrial and aquatic environments. The major isoprenoid quinone is Q-8. The dominant fatty acids include $C_{16:0}$ and $C_{17:0}$ cyclo. The G+C content of the DNA is 36–73 mol%. 16S rRNA gene sequencing evidence has been used to delineate members of the family.

Taxonomy, Historical and Current

Short Description of the Family

Alcaligenaceae (Al.ca.li.ge.na'ce.ae. M.L. masc. N. *Alcaligenes* type genus of the family; M.L. masc. Pl. N. *Alcaligenaceae* the *Alcaligenes* family).

The family *Alcaligenaceae* was proposed by DeLey et al. (1986) to accommodate *Alcaligenes* and *Bordetella*, with the former as the type genus, which were regarded as closely related by a numerical phenotypic study. 16S rRNA sequencing with support from chemotaxonomic and phenotypic differences pointed to two distinct lineages within *Alcaligenes*, the first comprising *Alc. alcaligenes* and *Alc. faecalis* and the second the *Alc. defragrans* lineage, which was proposed as a new genus, *Castellaniella* (Kämpfer et al. 2006). Separately, a polyphasic study of nine *Alc. faecalis*-like organisms from human clinical material led to the recognition of a new genus, *Kerstersia* (Coenye et al. 2003b). Then, *Advenella* was named after a polyphasic study of 14 isolates obtained from human and veterinary samples (Coenye et al. 2005). Other additions included *Oligella*, which was proposed as a new genus to include taxa previously recognized as *Moraxella urethralis* (= *Oligella urethralis*) and CDC Group IVe (=*Oligella ureolytica*) (Rossau et al. 1987). *Parapusillimonas granuli* was recovered from environmental samples, i.e., granules in a wastewater-treatment bioreactor associated with alcohol fermentation (Kim et al. 2010). *Taylorella* was proposed as a new genus to accommodate organisms previously classified as *Haemophilus equigenitalis*, which were originally equated with *Haemophilus* because of the

E. Rosenberg et al. (eds.), *The Prokaryotes – Alphaproteobacteria and Betaproteobacteria*, DOI 10.1007/978-3-642-30197-1_397,

G+C ratio of the DNA (Taylor et al. 1978; Sugimoto et al. 1983). Moreover, the pattern of respiratory quinones and cellular fatty acids was different to *Haemophilus* (Sugimoto et al. 1983). Most recently, *Candidimonas* was proposed to accommodate two strains from sewage sludge compost that were equated with the family but could not be placed in any of the current genera (Vaz-Moreira et al. 2011).

Phylogenetic Structure of the Family and Its Genera

The phylogenetic tree revealed that the *Alcaligenaceae* belongs in the β-*Proteobacteria*, forming a distinct clade within the order *Burkholderiales* (Fig. 27.1) with component taxa revealing >95 % 16S rRNA sequence homology (Coenye et al. 2005). Comparative 16S rRNA sequencing pointed to two lineages within *Alcaligenes*, with *Alc. defragrans* comprising a second line, which was subsequently elevated to a new genus, as *Castellaniella* (Kämpfer et al. 2006).

Molecular Studies

Many studies have addressed 16S rRNA sequence homologies of organisms now regarded as members of the *Alcaligenaceae*. Homologies of <99 % have often been used to justify new species designations. Thus, sequence similarities between strain Se-1111R^T (=*Bor. petrii*) and other *Bordetella* spp. were in the range of 97.9–98.6 %, which supported the delineation of a new species, i.e., *Bor. petrii* (Von Wintzingeroda et al. 2001). Yet, *Bor. holmesii* F5101 was 99.5 % similar to *Bor. pertussis* (Weyant et al. 1995).

Five isolates were subjected to sequencing of the 16S rRNA gene and determined to show 93.5–95.3 % homology with *Alcaligenaceae* representatives leading to the proposal for a new genus, *Tetrathiobacter* (Ghosh et al. 2005), which were later reclassified to *Advenella* (Gibello et al. 2009). Sequencing of the 16S rRNA gene revealed that five isolates, LMG 22250^T, R-16599, R-20008, R-18191, and R-20007, which were named as *Advenella*, i.e., *A. incenata*, formed a single, stable phylogenetic lineage. RAPD and protein profiling data indicated multiple albeit as yet unnamed species which shared >97 % 16S rRNA gene sequence homology (Coenye et al. 2005). A 98.5 % sequence homology with *Adv. kashmirensis* was instrumental in leading to the delineation of DPN7^T as a new species, *Adv. mimigardefordensis* (Wübbeler et al. 2006).

Sequence data highlighted two lineages within *Alcaligenes*, with the second proposed as a new genus, *Castellaniella* (Kämpfer et al. 2006). Moreover, Ho-11^T shared a sequence homology of 97.8 % with *Cas. denitrificans* and was elevated into a new species as *Cas. caeni* (Liu et al. 2008). *Cas. daejeonensis* was closest in terms of homology to other castellaniellas; specifically there was 98.6 % 16S rRNA sequence homology with *Cas. denitrificans* (Lee et al. 2010a). DCT36^T shared 98.4 % homology with *Cas. caeni* and was elevated to a new species as *Cas. ginsengisoli* (Kim et al. 2009).

Sequence homology revealed that GT was most closely related to *Alc. faecalis* at 98.7 % homology leading to the delineation of a new subspecies, i.e., *Alc. faecalis* subsp. *parafaecalis* (Schroll et al. 2001). Furthermore, *Alc. faecalis* subsp. *faecalis* ATCC 8750^T shared 97 % and 96 % sequence similarity with *Alc. faecalis* sub. *phenolicus* and *Alc. faecalis* subsp. *parafaecalis* type strains, respectively (Rehfuss and Urban 2005). SC-089^T and SC-092^T were equated with *Alcaligenaceae*, but not with any of the existing genera leading to the description of *Candidimonas* (Vaz-Moreira et al. 2011). Subsequently, B59^T was reported to have 97.7 % and 97.6 % 16S rRNA gene sequence homology with *Can. nitroreducens* and *Can. humi*, respectively, leading to the recognition of a new species, i.e., *Can. bauzanensis* (Zhang et al. 2012). Separately, 16S rRNA gene sequencing of *Brackiella oedipodis* showed 92–93 % homology with other members of the family (Willems et al. 2002). Moreover, HL-12^T belonged in *Derxia* and displayed 98.8 % and 99.1 % sequence homology with two isolates of *D. gummosa*, leading to the description of a new species, *D. lacustris* (Chen et al. 2013). Meanwhile, comparative examination of 16S rRNA gene sequences of an organism revealed <95 % similarity with other groups in the *Alcaligenaceae*, the discrimination of which was supported by chemotaxonomy and led to the description of *Paenalcaligenes* (Kämpfer et al. 2010). Similarly, sequence analyses of a representative strain of *Pel. europaea* revealed that *T. equigenitalis* was the nearest neighbor (similarity = ~94.8 %) (Vandamme et al. 1998). Sequence data for *T. asinigenitalis* revealed high intraspecific homology between three isolates (>99.8 %) and a value of 97.6 % homology with *T. equigenitalis* (Jang et al. 2001).

16S rRNA gene sequencing of *K. gyiorum* LMG 5906^T with LMG 5890 revealed 99.3 % similarity (Vandamme et al. 2012). Use of the *gyrB* gene revealed gene sequence homologies of 98.9–99.2 % between *K. gyiorum* LMG 5906^T with LMG 5890, the latter strain of which was elevated into a new species as *K. similis* (Vandamme et al. 2012).

16S rRNA gene sequencing data served to link a single isolate, GR24-5^T, with the family *Alcaligenaceae*, revealing the highest similarity with *Parapusillimonas granuli* (homology = 97.1 %) leading to the proposition for a new taxon, i.e., *Paralcaligenes ureilyticus* (Kim et al. 2011). *Parapusillimonas granuli* was described after a polyphasic study including the results of 16S rRNA gene sequencing pointed to a relationship with *Pus. noertemannii* (similarity = 97.30 %). The original culture, B201^T, of *Pus. harenae* was most closely related to *Pus. ginsengisoli* with a 98.6 % 16S rRNA sequence homology (Park et al. 2011). Sequencing of the 16S rRNA gene revealed that *Pusillimonas* was related to the *Alcaligenaceae* albeit at 94–96 % homology (Stolz et al. 2005).

Pig. kullae demonstrated a 95–96 % 16S rRNA sequence homology with *Achromobacter*, *Alcaligenes*, and *Bordetella* pointing to membership of *Alcaligenaceae* (Blümel et al. 2001). K110^T demonstrated a 99.4 % sequence homology with *Pig. kullae* and was named as a new species, *Pig. daeguensis* (Yoon et al. 2007). *Pig. litoralis* was most closely related to other

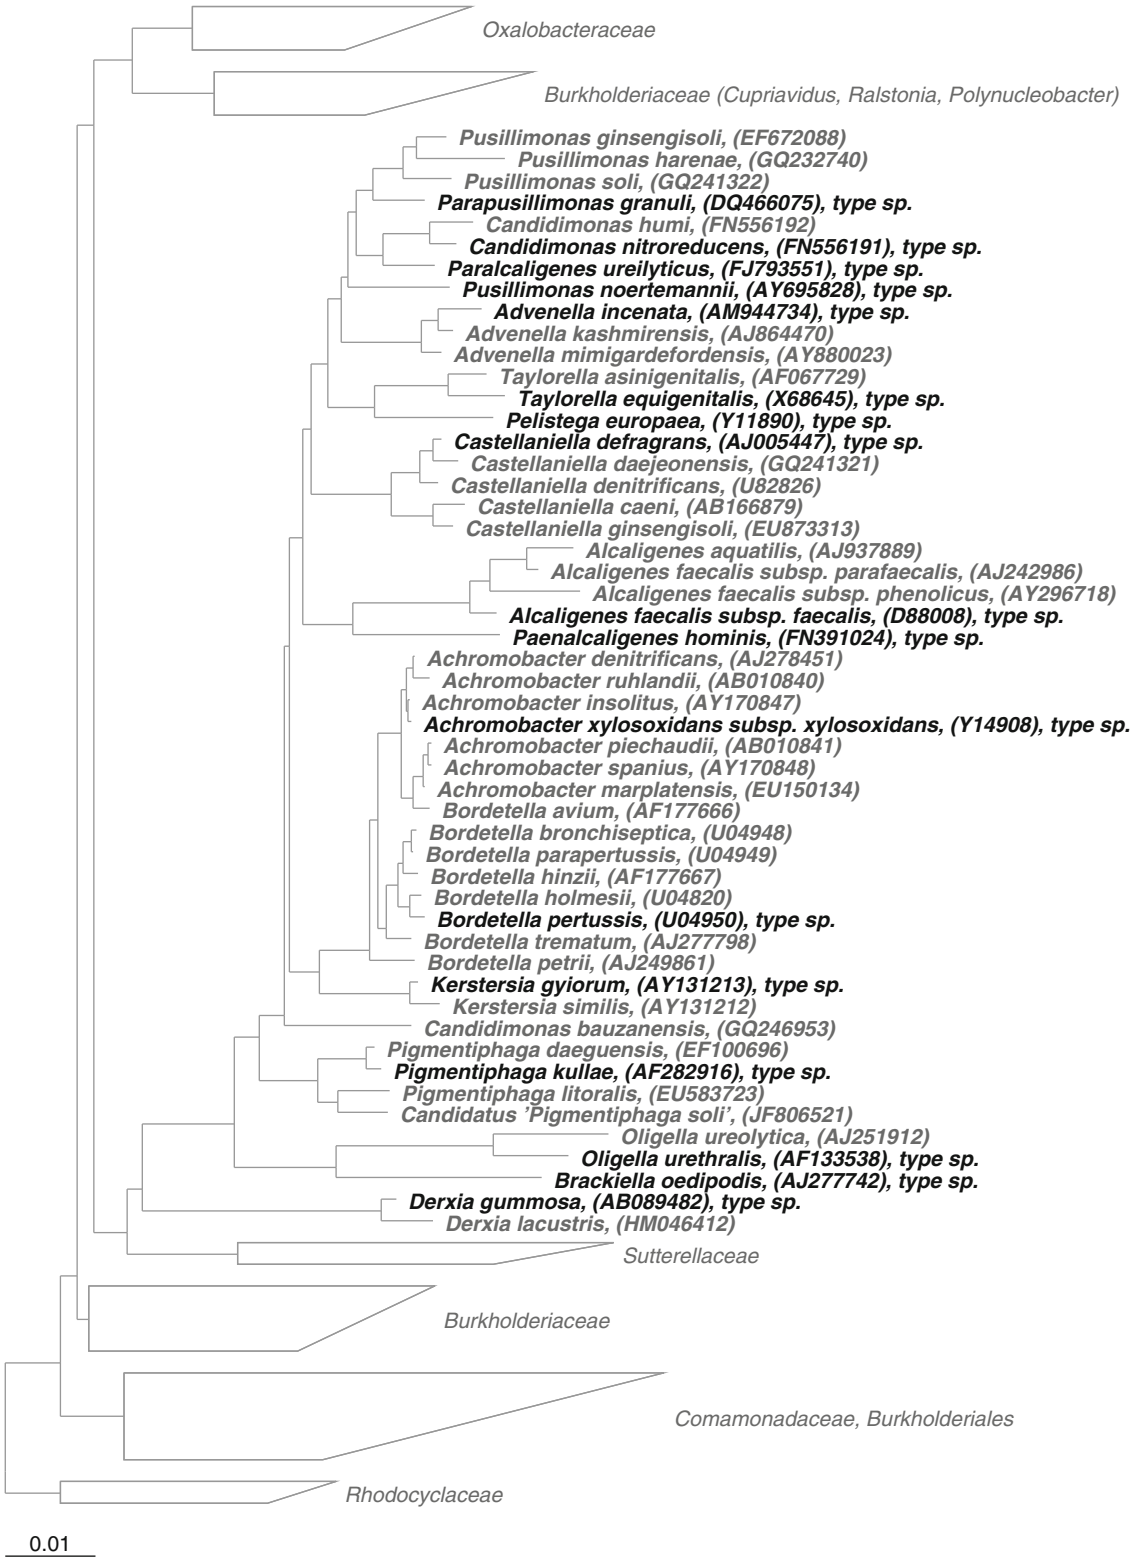

Fig. 27.1

Phylogenetic reconstruction of the family *Alcaligenaceae* based on 16S rRNA and created using the neighbor-joining algorithm with the Jukes-Cantor correction. The sequence datasets and alignments were used according to the All-Species Living Tree Project (LTP) database (Yarza et al. 2010; http://www.arb-silva.de/projects/living-tree). The tree topology was stabilized with the use of a representative set of nearly 750 high-quality type strain sequences proportionally distributed among the different bacterial and archaeal phyla. In addition, a 40 % maximum frequency filter was applied in order to remove hypervariable positions and potentially misplaced bases from the alignment. *Scale bar* indicates estimated sequence divergence

pigmentiphaga (Chen et al. 2009). The highest similarity of BS12^T was with *Pig. litoralis* (98.3 %) and led to the delineation of a new species, i.e., *Pig. soli* (Lee et al. 2011).

DNA-DNA Hybridization Studies

Numerous hybridization studies have involved representatives of the *Alcaligenaceae*. Thus, DNA:DNA confirmed the separation of *Ach. insolitus* from *Ach. spanius* and other achromobacters (Coenye et al. 2003a). *Adv. mimigardefordensis* shared 41 % homology with *Adv. kashmirensis* and much lower values with other representatives of the family (Wübbeler et al. 2006). Hybridization data pointed to the association of *Alc. denitrificans* with *Achromobacter*, leading to its reclassification as *Ach. denitrificans* comb. nov. (Coenye et al. 2003b). A DNA reassociation of 56 % was recorded between *Alc. faecalis* subsp. *parafaecalis* G^T and the type strain of *Alc. faecalis* (Schroll et al. 2001). Similarly, data for *Alc. faecalis* subsp. *phenolicus* J^T revealed homology values of 59.5 % and 60.2 % with *Alc. faecalis* subsp. *faecalis* ATCC 8750^T and *Alc. faecalis* subsp. *parafaecalis* G^T, respectively, thus indicating the distinctiveness of J^T from the other subspecies (Rehfuss and Urban 2005).

DNA:DNA hybridization suggested a close relationship between *Bordetella bronchiseptica*, *Bor. parapertussis*, and *Bor. pertussis* (DeLey et al. 1986) [Kloos et al. (1981) considered these taxa to be inseparable by DNA:DNA hybridization] but pointed to the uniqueness of other genera, notably *Parapusillimonas* which shared a homologies of <62 % with other taxa in the family (Kim et al. 2010). *Bor. petrii* shared 22.5–35.1 % DNA:DNA homology with other bordetellas (Von Wintzingeroda et al. 2001), which was well below the threshold of 70 %, which is taken as evidence of including within a species (Wayne et al. 1987). Similarly, *Bor. hinzii* demonstrated low binding homologies with other bordetellas and alcaligenes (Vandamme et al. 1995). *Bor. trematum* was distinct from other bordetellas; the highest DNA:DNA homology was with *Bor. bronchiseptica* at 30 % (Vandamme et al. 1996).

D. lacustris was related at 48.6 % and 51.5 % DNA homology with *D. gummosa* pointing to separate species status (Chen et al. 2013). The DNA:DNA relatedness of *Paralcaligenes ureilyticus* GR24-5^T was 23 % with *Parapusillimonas granuli* (Kim et al. 2011). *T. equigenitalis* hybridized with *T. asinigenitalis* to 23 % and 24 % indicated separate species status (Jang et al. 2001). Incidentally, *T. equigenitalis* displayed negligible DNA homologies with *Haemophilus* in which the organism was originally classified (Sugimoto et al. 1983). DNA:DNA relatedness between *Pus. harenae* and *Pus. ginsengisoli* and *Pus. soli* was 30.2 ± 5.4 % and 4.9 ±1.8 %, respectively, pointing to the distinction between the three species (Park et al. 2011).

DNA:DNA homology values of 23.7 2 % and 21.5 3.5 % between BZ59^T and *Can. nitroreducens* SC-089^T and *Can. humi* SC-092^T, respectively, were well below the threshold to justify inclusion with the same species (Wayne et al., 1987). The outcome was the recognition of a new species, i.e., *Can. bauzanensis* (Zhang et al. 2012).

Ribotyping

Ribotyping has been effective in epidemiological studies by distinguishing between different species and strains. Using 113 cultures from 11 host species worldwide, *Bor. bronchiseptica* was characterized by ribotyping with restriction enzyme *PvuII*, resulting in the recognition of 16 ribotypes containing 5–7 restriction fragments of 1.8–5.6 kb in size. Most [88 %] isolates from pigs were equated with ribotype 3 whereas those from dogs [74.1 %] belonged in ribotype 4, although there was not any correlation with geographical origin (Register et al. 1997). Furthermore, ribotyping with restriction enzyme *PvuII* was effective in allowing diagnostic laboratories to discriminate avian [=turkey]-respiratory-disease-causing *Bor. avium* from *Bor. hinzii* (Register et al. 2003).

Genome Sequencing

The genome sequences have been published for a range of *Alcaligenaceae* representatives, including *Ach. piechaudii* (Trimble et al. 2012), *Ach. xylosoxidans* (Jakobsen et al. 2010; Strnad et al. 2011), *Alc. faecalis* subsp. *faecalis* (Phung et al. 2012), *Bor. avium*, *Bor. bronchiseptica*, *Bor. parapertussis* (Sebaihia et al. 2006), *Bor. pertussis* (Zhang et al. 2011), *Pusillimonas* (Cao et al. 2011), *T. asinigenitalis*, and *T. equigenitalis* (Hebert et al. 2011; Hauser et al. 2012). The draft sequences of *Ach. piechaudii* HLE and *Alc. faecalis* subsp. *faecalis* NCIMB 8687 indicated genomes of 6.89 Mb (Trimble et al. 2012) and 3.9 Mb in 186 contigs, respectively (Phung et al. 2012). *Bor. avium* strain 197 N was reported to possess the smallest genome [3,732,255 bp] and gene complement [3417 predicted coding sequences] of any of the *Bordetella* sequenced to date (Sebaihia et al. 2006). >1,000 genes encoding surface and secreted proteins including genes for the synthesis of a type I secretion system, hemagglutinins, a polysaccharide capsule, two large genes for secreted proteins, and unique genes for both lipopolysaccharide and fimbria biogenesis in *Bor. avium* were absent from *Bor. bronchiseptica* (Sebaihia et al. 2006). The *T. asinigenitalis* genome comprises a single circular chromosome of 1,638,559 bp and 1,534 coding sequences (Hebert et al. 2012). The *T. equigenitalis* genome encodes many proteins associated with pathogenicity, including hemagglutinin-related proteins and a type IV secretion system (Hebert et al. 2012).

Phages

Bacteriophages have been recognized in *Achromobacter* (Jones and Pretorius 1981), *Alc. eutrophus* (Walthermauruschat and Mayer 1978; Faelen et al. 1993), and *Bordetella* (Paloheimo et al. 1987; Dai et al. 2010; Yuan et al. 2013). For example, a non-plaque forming prophage with 42 kb double-stranded DNA was recovered from *Alc. eutrophus* (Faelen et al. 1993).

Phenotypic Analyses

A comparison of *Alcaligenaceae* genera is given in Table 27.1.

Achromobacter Yabuuchi and Yano 1981

A. chro. mo. bac' ter Gr. adj. *Achromus* colorless; M. L. n. *bacter* the masc. equivalent of Gr. neut. N. *bactrum* a rod or staff; M. L. masc. N. *Achromobacter* colorless rodlet.

Cultures comprise straight obligately aerobic asporogenous chemoorganotrophic, motile by means of peritrichous flagella Gram-negative rods of 0.8–1.2 × 2.5–3.0 μm in size. Catalase and oxidase are produced, but not arginine dihydrolase, lysine or ornithine decarboxylase, or phenylalanine deaminase. DNA, gelatin, and urea are not degraded. Carbohydrates are usually not utilized. The dominant polyamines are putrescine and 2-hydroxyputrescine. The respiratory quinone is Q-8. The major fatty acids are $C_{12:0}$ 2OH, $C_{14:0}$ 3OH, $C_{16:0}$, $C_{16:1}$, and $C_{17:0}$ cyclo. The G+C ratio of the DNA is 65–70 mol%. The type species is *Achromobacter xylosoxidans* (Yabuuchi and Yano 1981). The distinguishing traits of *Achromobacter* species are given in Table 27.2.

Ach. xylosoxidans was divided into two subspecies, namely, *denitrificans* and *xylosoxidans*. The former was reclassified to *Ach. denitrificans* initially from *Alc. denitrificans* (Rüger and Tan 1983) and subsequently from *Ach. xylosoxidans* subsp. *denitrificans* (Yabuuchi et al. 1998).

Ach. xylosoxidans subsp. *xylosoxidans* comprises strictly aerobic, asporogenous motile by peritrichous flagella straight Gram-negative rods of 0.8–1.2 × 2.5–3.0 μm in size. Catalase and oxidase are produced, but not arginine dihydrolase or lysine decarboxylase. Nitrates are reduced. Simmons citrate is utilized. Neither [rabbit] blood DNA, gelatin, nor urea is degraded. Acid is produced slowly and weakly from D-arabinose, galactose, glucose, and mannose. The respiratory quinone is Q-8. The major fatty acids are $C_{12:0}$ 2OH, $C_{14:0}$ 2OH, $C_{14:0}$ 3OH, $C_{16:0}$, $C_{16:1}$, and C_{17} cyclo. The G+C ratio of the DNA is 65–70 mol%. The type strain is ATCC 27061^T (Yabuuchi and Yano 1981).

Ach. denitrificans comprises Gram-negative rods that are motile by peritrichous flagella. Acylamidase, catalase, and oxidase are produced, but not arginine dihydrolase, H_2S, lysine or ornithine decarboxylase, or phenylalanine deaminase. Growth occurs at 25–41 °C, in 0–5 % (w/v) NaCl and on MacConkey agar. Nitrates are reduced to gas. Neither aesculin, blood, DNA, gelatin, starch, Tween 80, nor urea is degraded. Simmons citrate but not malonate is utilized. Acid is produced from ethanol and glycerol, but not from adonitol, D-arabinose, L-arabinose, cellobiose, dulcitol, fructose, galactose, glucose, inositol, inulin, lactose, maltose, mannitol, melezitose, melibiose, raffinose, rhamnose, ribose, salicin, sorbitol, sucrose, trehalose, or xylose. Adipic acid, DL-malic acid, phenylacetate, and sodium citrate are assimilated, but not *N*-acetyl-D-glucosamine, L-arabinose, *n*-capric acid, glucose, maltose, D-mannitol, D-mannose, or potassium gluconate. The dominant respiratory quinone is Q-8. The type strain is 15173^T, which has a G+C ratio of the DNA of 68.5 mol% (Yabuuchi et al. 1998).

Ach. insolitus produces white to light brown flat or slightly convex colonies with smooth edges that comprise Gram-negative, small (1–2 μm in length), and coccoid cells that occur singly, in pairs, or in short chains. Motility may occur. Growth occurs at 28–37 °C and in 0–4.5 % (w/v) NaCl. Catalase, esterase (C4), leucine arylamidase, and oxidase are produced, but not *N*-acetyl-β-glucosaminidase, arginine dihydrolase, chymotrypsin, cysteine or valine arylamidase, ester lipase (C8), α-fucosidase, α- or β-galactosidase, α- or β-glucosidase, β-glucuronidase, H_2S, indole, lipase (C14), lysine or ornithine decarboxylase, α-mannosidase, phosphoamidase, or trypsin. Neither aesculin, blood, DNA, gelatin, starch, nor urea is degraded. Nitrates are reduced. Growth occurs on acetamide. Acetate, aconitate, adipate, azelate, butyrate, citraconate, citrate, L-cysteine, fumarate, gluconate, glutarate, DL-glycerate, L-histidine, DL-3-hydroxybutyrate, isobutyrate, isovalerate, itaconate, DL-lactate, L-leucine, D- and L-malate, mesaconate, L-norleucine, pimelate, L-proline, pyruvate, sebacate, L-serine, suberate, succinate, *meso*-tartrate, L-threonine, tryptamine, L-tryptophan, *n*-valerate, and L-valine are assimilated, but not *N*-acetylglucosamine, adonitol, amygdalin, D- or L-arabinose, arbutin, cellobiose, diaminobutane, dulcitol, D-fructose, galactose, D-glucose, glycerol, inositol, inulin, lactose, maltose, mannitol, D-mannose, D-melezitose, melibiose, raffinose, L-rhamnose, ribose, salicin, sucrose, D-tartrate, trehalose, or D-xylose. The major cellular fatty acids are $C_{12:0}$, $C_{12:0}$ 2-OH, $C_{14:0}$, $C_{16:0}$, $C_{17:0}$ cyclo, $C_{18:0}$, $C_{18:1}$ *ω7c*, and summed features 2 and 3. The G+C content of the DNA is 64.9–65.5 mol%. The type strain is LMG 6003^T = API 201-3-84^T = CCUG 47057^T, which has a G+C ratio of the DNA of 64.9 mol% (Coenye et al. 2003a).

Ach. marplatensis comprises asaccharolytic, motile Gram-negative rods of 0.5–1.0 μm in length. Growth occurs at 15–40 °C, but not at 4 °C or 42 °C, and on MacConkey agar, but not in 6.5 % (w/v) NaCl. Acid and alkaline phosphatases, catalase, leucine arylamidase, oxidase, and phosphoamidase are produced, but not *N*-acetyl-β-glucosaminidase, arginine dihydrolase, α-chymotrypsin, cysteine or valine arylamidase, esterase (C4), esterase (C8), esterase lipase, α-fucosidase, α- or β-galactosidase, α- or β-glucosidase, β-glucuronidase, H_2S, indole, lipase (C14), lysine or ornithine decarboxylase, α-mannosidase, trypsin, or tryptophan deaminase. Nitrates and nitrites are reduced. The Voges-Proskauer reaction is negative. Tyrosine but not aesculin, casein, DNA, elastin, gelatin, lecithin, starch, Tween 80, or urea is degraded. Citrate, gluconate (weakly), malate, and phenylacetate are assimilated. Growth does not occur with *N*-acetylglucosamine, amygdalin, arabinose, arginine, caprate, glucose, inositol, lactose, lactulose, maltotriose, maltose, mannitol, mannose, melibiose, *p*-nitrophenyl β-D-galactopyranoside, raffinose, rhamnose, sorbitol, or sucrose. The predominant fatty acids are $C_{16:0}$, $C_{16:1}$ *ω7c*, and $C_{17:0}$ cyclo. The type strain is CCM 7608^T = CCET 7342^T = CCUG 56371^T (Gomila et al. 2011).

Table 27.1
Comparison of the phenotypic traits of *Alcaligenaceae* genera

Character	*Achromobacter*	*Advenella*	*Alcaligenes*	*Bordetella*	*Brackiella*	*Candidimonas*
Micromorphology	Gram-negative straight rods	Gram-negative small rods	Gram-negative rods and coccobacilli	Gram-negative coccobacilli	Gram-negative coccobacilli	Gram-negative short rods
Growth media	TSA	NA, TSA	LB, TSA	Complex, often with blood	Columbia agar	PCA
Growth temperature (°C)	28–37	30–37	23–35	(25)–37–(42)	30–37	10–40
Tolerance to NaCl [% w/v]	0–4	0–3				0–3
Metabolism	Obligately aerobic; chemoorganotrophic	Aerobic [acid is not always produced]	Obligately aerobic; chemoorganotrophic [produces alkali from organic acids and amides]	Strictly aerobic or facultatively anaerobic	Aerobic to microaerophilic	Aerobic or anaerobic; chemoorganotrophic
Motility	+ [peritrichous flagella]	variable	+ [peritrichous flagella]	+ or – [peritrichous flagella]	–	+ or –

Ach. piechaudii produces small (1 mm in diameter) unpigmented, smooth colonies with entire edges on tryptone soya agar (TSA) after 48 h incubation and comprises obligately aerobic, straight asporogenous, nonencapsulated, motile with 2–8 peritrichous flagella Gram-negative rods of 0.5–1.0 x 1.0–1.5 µm in size that occur singly. Growth occurs at room temperature to 37 °C [optimally at 28–30 °C] but not at 5 °C or 42 °C and in 0–7 % (w/v) NaCl. Catalase, H_2S, and oxidase are produced, but not arginine dihydrolase, β-D-galactosidase, indole, lysine or ornithine decarboxylase, phenylalanine deaminase, or phosphatase. Tributyrin and tyrosine are degraded, but not aesculin, casein, DNA, gelatin, starch, Tween 20 or 80, or urea. Nitrates are reduced to nitrite. Utilizes citrate, but not malonate. Assimilates D-gluconate, isovalerate, itaconate, mesaconate, and *n*-valerate, but not carbohydrates. Produces acid from ethanol, but not adonitol, L-arabinose, D-cellobiose, dulcitol, D-fructose, D-glucose, glycerol, *m*-inositol, lactose, maltose, mannitol, raffinose, L-rhamnose, salicin, D-sorbitol, sucrose, trehalose, or D-xylose. The dominant polyamines are putrescine and 2-hydroxyputrescine. The fatty acid profile comprises $C_{12:0}$ 2OH, $C_{14:0}$, $C_{14:0}$ 3OH, $C_{16:0}$, $C_{16:0}$ 2OH, $C_{17:0}$ cyclo, $C_{18:0}$, $C_{18:1}$, and $C_{19:0}$ cyclo. The type strain is CIP 60.75^T = ATCC 43552^T = IAM 12591^T = LMG 1873^T, which has a G+C ratio of the DNA of 64–65 mol% (Kiredjian et al. 1986; Yabuuchi et al. 1998).

Ach. ruhlandii comprises asporogenous, nonfermentative motile with peritrichous flagella Gram-negative rods that grow on MacConkey agar, and at 41 °C, and in the presence of 5 % (w/v) NaCl. Growth occurs autotrophically with hydrogen. Catalase and oxidase are produced, but not arginine dihydrolase, lysine or ornithine decarboxylase, or phenylalanine deaminase. Nitrate is reduced to nitrite. Aesculin, DNA, gelatin, starch, Tween 80, and urea are not degraded. Adipic acid, capric acid, citrate, gluconate, glucose, malic acid, and phenylacetate are assimilated. Alkali is produced in Simmons citrate. Acid is produced from D- and L-arabinose, glucose, D-ribose, and D-xylose, but not from adonitol, cellobiose, dulcitol, fructose, galactose, glycerol, inositol, inulin, lactose, maltose, mannitol, melezitose, melibiose, raffinose, salicin, sorbitol, sucrose, or trehalose. The type strain is ATCC 15749^T = DSM 653^T = IAM 12600^T, which has a G+C ratio of the DNA of 68.1 mol% (DeLey et al. 1986; Yabuuchi et al. 1998).

Ach. spanius produces white to light brown flat or slightly convex colonies with smooth edges that comprise small (1–2 µm long) Gram-negative coccoid cells that occur singly, in pairs, and as short chains. Motility may occur. Catalase, esterase (C4), leucine arylamidase, and oxidase are produced, but not *N*-acetyl-β-glucosaminidase, arginine dihydrolase, chymotrypsin, cysteine or valine arylamidase, ester lipase (C8), α-fucosidase, α- or β-galactosidase, α- or β-glucosidase, β-glucuronidase, H_2S, indole, lipase (C14), lysine or ornithine decarboxylase, α-mannosidase, phosphoamidase, or trypsin. Nitrates are reduced to nitrites. Neither aesculin, blood, DNA, gelatin, starch, nor urea is degraded. Growth occurs at 28–37 °C and in 0–4 % (w/v) NaCl, but does not occur on acetamide. β-alanine, DL-3-aminobutyrate, diaminobutane, 2-ketoglutarate, tryptamine, and L-tyrosine are assimilated, but not acetate, *N*-acetylglucosamine, aconitate, adipate, adonitol, aesculin, amygdalin, D- or L-arabinose, arbutin, benzoate, butyrate, caprate, *n*-caproate, cellobiose, citrate, L-citrulline, dulcitol, erythritol, D-fructose, D- or L-fucose, fumarate, galactose, gluconate, D-glucose, glycerol, glycine, heptanoate, L-histidine, *p*-hydroxybenzoate, inositol, inulin, isobutyrate, L-isoleucine, DL-kynurenine, lactose, L-leucine, L-lysine, maltose, mannitol, D-mannose, D-melezitose, melibiose, mesaconate, L-methionine, L-ornithine, pelargonate, L-proline, propionate, pyruvate, raffinose, L-rhamnose, ribose, salicin, L-serine, sorbitol, succinate, sucrose, L-threonine, trehalose, or D-xylose. The major fatty acids are $C_{12:0}$ 2-OH, $C_{14:0}$, $C_{16:0}$, $C_{16:0}$ 2-OH, $C_{17:0}$ cyclo, $C_{18:0}$, $C_{18:1}$ $\omega7c$, and summed features 2 and 3. The G+C content of the DNA is 64.9 mol%. The type strain is LMG 5911^T = API 198-2-84^T = CCUG 47062^T, which has a G+C ratio of the DNA of 64.9 mol% (Coenye et al. 2003a).

Advenella Coenye et al. 2005

Ad.ven.el'la. L. n. *advena a* stranger, a foreigner; L. dim. ending –*ella*; N. L. fem. n. *Advenella* the little stranger—the source of the cultures is unknown.

Cultures comprise Gram-negative small (1–2 µm in length) rods or coccoid-shaped cells that occur singly, in pairs, or short chains. Motility may occur. Colonies on nutrient agar are light brown and flat or slightly convex with smooth edges. Cultures do not always produce acid in the oxidative-fermentative test medium, but produce catalase, leucine arylamidase, and oxidase, but not amylase, arginine dihydrolase, chymotrypsin, C_{14}-lipase, α-fucosidase, α- or β-galactosidase, α- or β-glucosidase, *N*-acetyl-β-glucosidase, β-glucuronidase, H_2S, indole, lysine or ornithine decarboxylase, α-mannosidase, trypsin, or valine arylamidase. Neither aesculin, blood, DNA, gelatin nor Tween 80 is degraded. Citrate is utilized. Growth occurs at 30 °C and 37 °C in 0–3 % (w/v) NaCl. The dominant fatty acids are $C_{12:0}$, $C_{16:0}$, $C_{17:0}$ cyclo, $C_{18:1\omega7c}$, and summed features 2 and 3. The G+C ratio of the DNA is 53.6–57.7 mol%. The type species is *Advenella incenata*

(Coenye et al. 2005). The distinguishing traits of *Advenella* species are given in *Table 27.3*.

Adv. incenata cultures match the genus description and also produce alkaline phosphatase and utilize L-malate, but do not reduce nitrates. Adipate, D-arabinose, D- and L-fucose, galactose, gluconate, glycerol, 2-ketogluconate, rhamnose, ribose, and D- and L-xylose are assimilated, but not D-adonitol, D- or L-arabitol, dulcitol, erythritol, D-fructose, gentiobiose, glycogen, inositol, inulin, D-lyxose, melezitose, melibiose, methyl β-D-glucopyranoside, methyl α-D-mannopyranoside, methyl β-D-xylopyranoside, raffinose, sorbitol, L-sorbose, starch, sucrose, tagatose, trehalose, turanose, or xylitol. The G+C ratio of the DNA is 54.0–54.5 mol%. The type strain is LMG 22250^T = CCUG 45225^T (Coenye et al. 2005; Gibello et al. 2009).

Twelve cultures were classified into a newly described genus, *Tetrathiobacter*, as *Tet. kashmirensis* (Ghosh et al. 2005) but were subsequently reclassified to *Advenella* as *Adv. kashmirensis* (Gibello et al. 2009). Characteristics include the ability to reduce nitrate to nitrite and to utilize ammonium salts and urea but not glutamate, aspartate, or nitrate as nitrogen sources. Neither yeast extract nor vitamins are required for growth. Growth occurs in 1 M NaCl. Esterase (C4) and acid [weakly] and alkaline phosphatase are produced, but not cystine arylamidase or esterase lipase (C8). Acetate, adipate, D- and L-arabinose, citrate, L-cysteine, D-fructose, D- and L-fucose, D-galactose, gluconate, D-glucose, L-glutamate, D-lactose, L-lysine, malate, rhamnose, ribose, succinate, and D- and L-xylose are assimilated chemoorganotrophically, but not D-adonitol, D- or L-arabitol, benzoate, dulcitol, erythritol, gentiobiose, glycerol, glycogen, L-histidine, inositol, inulin, L-isoleucine, 2-ketogluconate, L-leucine, D-lyxose, *myo*-DL-lactate, D-mannitol, melezitose, melibiose, methyl β-D-glucopyranoside, methyl α-D-mannopyranoside, methyl β-D-xylopyranoside, oxalate, D-raffinose, L-serine, sorbitol, L-sorbose, starch, sucrose, tagatose, L-threonine, trehalose, turanose, L-tyrosine, or xylitol. There is strain-dependent utilization of L-arginine, L-aspartic acid, D-maltose, D-mannose, and L-tryptophan and as the sole source of carbon. The major fatty acids are $C_{16:0}$, $C_{18:1}$ *ω7c*, and summed feature 3. The type strain is LMG 22695^T = MTCC 7002^T, which has a G+C content of the DNA of 55.1 mol% (Ghosh et al. 2005).

Tet. mimigardefordensis (Wübbeler et al. 2006) was reclassified as *Adv. mimigardefordensis* (Gibello et al. 2009). Colonies are white to lime yellow becoming yellower with age, circular and flatter than convex, and comprising oxidative, motile Gram-negative coccoid rods of 1.5–2 μm in length. Growth occurs at 15–40 °C and is best at 30–37 °C. Alkaline [weakly] and acid phosphatase, catalase, esterase lipase (C8), and oxidase are produced, but not cystine arylamidase or esterase (C4). Adipate, D-arabinose, D and L-fucose, D-galactose, gluconate, glycerol, DL-lactate, melezitose, ribose, and D- and L-xylose are assimilated, but not D-adonitol, D- or L-arabitol, dulcitol, erythritol, D-fructose, gentiobiose, glycogen, inositol, inulin, 2-ketogluconate, D-lyxose, melibiose, methyl β-D-glucopyranoside, methyl α-D-mannopyranoside, methyl β-D-xylopyranoside, raffinose, D-rhamnose, sorbitol, L-sorbose, starch, sucrose, tagatose, trehalose, turanose, or xylitol. The major fatty acids are $C_{16:0}$, $C_{18:1}$ *ω7c*, and $C_{16:1}$ *ω7c* and/or iso-$C_{15:0}$ 2-OH. The type strain is DSM 17166^T = LMG 22922^T, which has a G+C ratio of the DNA of 55.1 mol% (Wübbeler et al. 2006; Gibello et al. 2009).

Alcaligenes Castellani and Chalmers 1919

Al.ca.li'ge.nes Arabic *al* the; Arabic n. *gally* the ash of saltwort; French n. *alkali* alkali; Gr. v. *gennaio* to produce; M. L. masc. N. *Alcaligenes* alkali-producing [bacteria] (Castellani and Chalmers 1919).

Cultures on nutrient agar are nonpigmented and comprise obligately aerobic, chemoorganotrophic [alkali is produced] motile with 1–9, occasionally up to 12, peritrichous flagella Gram-negative rods/coccobacilli of 0.5–1.2 × 1.0–3.0 μm in size that occur mostly singly. Poly-β-hydroxybutyrate may be accumulated intracellularly. Catalase and oxidase are produced, but not indole. Aesculin, cellulose, DNA, and gelatin are not degraded. Carbohydrates are not usually utilized. Chemoorganotrophic. Alkali is produced from organic salts and amides. The dominant respiratory quinone is Q-8. The predominant polyamines are putrescine and

2-hydroxyputrescine. The major fatty acids are $C_{12:0}$ 2OH, $C_{14:0}$ 3OH, $C_{16:0}$, and $C_{17:0}$ cyclo. The G+C ratio of the DNA is 56–60 mol%. The type species is *Alcaligenes faecalis* with *Alc. faecalis* subsp. *faecalis* as the type subspecies (Kersters and DeLey 1984). The distinguishing traits of *Alcaligenes* species are given in Table 27.4.

Alc. faecalis is subdivided into subspecies, namely, *faecalis*, *parafaecalis*, and *phenolicus*.

Alc. faecalis subsp. *faecalis* produces nonpigmented to grayish-white colonies with irregular edges that comprise asporogenous Gram-negative peritrichously flagellated rods. Catalase and oxidase are produced. Neither gelatin, starch, Tween 80, nor urea is degraded. Nitrites but not nitrates are reduced. 2-hydroxyputrescine is present in the polyamine pattern. Acid is not produced from D-glucose or D-xylose. Acetate is used as a source of carbon, but not *N*-acetylglucosamine, adipate, adonitol, amygdalin, L-arabinose, cellobiose, D-fructose, D-fucose, D-galactose, D-gluconate, D-glucose, inulin, itaconate, lactose, maltose, D-mannitol, D-mannose, melezitose, melibiose, L-rhamnose, D-ribose, pimelate, salicin, suberate, sucrose, *m*-tartrate, trehalose, or D-xylose. The major fatty acids are $C_{16:0}$, $C_{17:0}$ cyclo, $C_{18:0}$ $\omega 7c$, and summed features 2 and 3. The G+C ratio of the DNA is 55.9–59.4 mol%. The type strain is ATCC 8750^T = DSM 30030^T = NCIMB 8156^T = CCM 1052^T = CIP $60\text{-}80^T$ (Schroll et al. 2001; Van Trappen et al. 2005).

Cultures of *Alc. faecalis* subsp. *parafaecalis* develop circular, entire, low-convex, smooth colonies with irregular edges and a diameter of ≤2 mm after incubation at 37 °C for one day and comprise alkali-producing asporogenous, motile Gram-negative rods of 0.75–1.0 μm × 1.5–3.0 μm in size. L-alanine aminopeptidase, acid and alkaline phosphatase, catalase, esterase (C4), lipase (C8) [weakly], lipase (C14) [weakly], leucine and valine arylamidase, naphthol-AS-BI-phosphohydrolase, and oxidase are produced, but not *N*-acetyl-β-glucosaminidase, chymotrypsin, cystine arylamidase, α-fucosidase, α- or β-galactosidase, α- or β-glucosidase, β-glucuronidase, H_2S, indole, lysine or ornithine decarboxylase, α-mannosidase, trypsin, or tryptophan deaminase. Growth occurs on MacConkey agar, and not at 42 °C. The Voges-Proskauer reaction is negative. Nitrates are not reduced. Citrate is utilized. Gelatin is degraded, but not casein, DNA, Tween 80, or urea. Acetate, butyrate, γ-butyrolactone, citrate, ethanol, heptanoate, γ-hydroxybutyric acid, L-lactate, propionate, and valerate are assimilated. The major respiratory isoprenoid quinone is Q-8. The main component in the polyamine pattern is putrescine. The major fatty acids are $C_{16:0}$, $C_{16:1}$, and $C_{17:0}$ cyclo (Schroll et al. 2001; Van Trappen et al. 2005). The G+C content of the DNA is 56 mol%. The type strain is DSM 13975^T = CIP 106866^T.

Alc. faecalis subsp. *phenolicus* produces white, translucent, irregular colonies with spreading edges on TSA plates and comprises asporogenous, alkali-producing motile [by peritrichous flagella] Gram-negative coccobacilli of 0.75–1.5 × 0.6–0.8 μm in size. Growth occurs at 23 °C, 30 °C, 37 °C, and 42 °C [optimally at 30 °C]. Grows on M9 mineral medium in 0.5 % (v/v) phenol as a sole source of carbon. Catalase is produced. Nitrites [anaerobically] but not nitrates are reduced. Acetate, D-alanine, L-alanine, L-asparagine, L-aspartic acid, butyrate, *cis*-aconitic acid, citrate, ethanol, L-glutamic acid, L-histidine, β-hydroxybutyric acid, γ-hydroxybutyric acid, *p*-hydroxyphenylacetic acid, α-ketoglutaric acid, α-ketovaleric acid, L-lactate, D,L-lactic acid, L-leucine, malonic acid, L-ornithine, phenol, L-phenylalanine, L-proline, propionate, pyruvate, succinic acid, and L-tryptophan are used as sole sources of carbon, but not *N*-acetyl-D-glucosamine, *N*-acetyl-D galactosamine, adonitol, L-arabinose, D-arabitol, D-cellobiose, citric acid, α-cyclodextrin, dextrin, *i*-erythritol, formic acid, D-fructose, L-fucose, D-galactose, gentiobiose, glycogen, α-D-glucose, α-hydroxybutyric acid, *m*-inositol, itaconic acid, α-ketobutyric acid, α-D-lactose, lactulose, maltose, D-mannitol, D-mannose, D-melibiose, β-methyl-D-glucoside, D-raffinose, L-rhamnose, D-serine, L-serine, D-sorbitol, sucrose, L-threonine, thymidine, D-trehalose, turanose, or xylitol. Acid is not produced from arabinose, cellobiose, galactose, glucose, lactose, maltose, D-mannitol, raffinose, sorbitol, sucrose, or D-xylose. The major fatty acids are $C_{12:0}$, $C_{12:0}$ 2-OH, $C_{16:0}$, $C_{17:0}$ cyclo, $C_{18:0}$, $C_{18:1}$ $\omega 7c$, and summed features 2 and 3. The type strain is DSM 16503^T = NRRL B-41076^T, which has a G+C ratio of the DNA

of 54.8 mol% (Rehfuss and Urban 2005; Van Trappen et al. 2005; Rehfuss and Urban 2005).

Alc. aquatilis produces non- and yellow-pigmented, circular, low-convex, and smooth colonies with spreading, irregular edges of 2–5 mm in diameter after incubation on TSA at 28 °C for 48 h. Cultures comprise motile by peritrichous flagella Gram-negative rods of 0.7–1.1 × 1.0–2.5 μm in size. Growth occurs at 4–35 °C [optimally at 18–24 °C]. Catalase [mostly] and oxidase are produced, but not arginine dihydrolase, β-galactosidase, H_2S, indole or lysine, or ornithine decarboxylase. Nitrates are not reduced, but some strains reduce nitrite. Aesculin, gelatin, starch, and urea are not degraded. Alkali is produced from asparagine, citrate, and glutamine. Sodium acetate and sodium citrate are mostly utilized. In most cases, acids are not produced from carbohydrates. Growth does not occur on *N*-acetylglucosamine, adipate, L-alanine, L-arabinose, L-fucose, gluconate, glucose, 3-hydroxybutyrate, 4-hydroxybenzoate, inositol, itaconate, 2-ketogluconate, 5-ketogluconate, malonate, maltose, mannitol, mannose, D-melibiose, L-proline, propionate, rhamnose, D-ribose, salicin, D-sorbitol, and D-sucrose. Growth is observed on acetate, caprate (mostly), citrate, glycogen, histidine, 3-hydroxybenzoate, DL-lactate, malate, phenylacetate, L-serine, suberate, and valerate. The dominant fatty acids are $C_{16:0}$, $C_{17:0}$ cyclo, $C_{18:1}$ *ω7c*, and summed features 2 and 3. The type strain is LMG 22996^T = CCUG 50924^T, which has a G+C ratio of the DNA of 56 mol% (Van Trappen et al. 2005).

Bordetella Moreno-Lòpez 1952

Bor. de. tel' la. M. L. dim. Ending *–ella*; M. L. fem. N. *Bordetella* after Jules Bordet, who first isolated the pertussis organism jointly with O. Gengou (Moreno-López 1952).

The emended description of *Bordetella* is that cultures comprise nonmotile or motile by peritrichous flagella Gram-negative, catalase-positive, coccobacilli of 0.2–0.5 × 0.5–2.0 μm in size that occur singly, in pairs, and occasionally in chains and may exhibit bipolar staining. Cultures grow strictly aerobically, facultatively anaerobically, and nonfermentatively. One species, *Bor. petrii*, is able to grow anaerobically under conditions favoring respiratory nitrate and selenate reduction. Citrate is assimilated aerobically; one species assimilates D-gluconate. The major respiratory isoprenoid quinone is Q-8. The type species of the genus is *Bordetella pertussis*. The G+C content of the DNA is 60–69 mol% (Von Wintzingeroda et al. 2001). The distinguishing traits of *Bordetella* species are given in Table 27.5.

Bor. pertussis produces minute colonies on potato glycerol blood agar and comprises nonmotile encapsulated coccobacilli of 0.2–0.5 × 0.5–1.0 μm in size. Growth does not occur at 25 °C or 42 °C or on MacConkey agar. Chymotrypsin, ester lipase (C8), naphthol-AS-BI-phosphohydrolase, oxidase, serine arylamidase, and possibly catalase are produced, but not alkaline phosphatase, cystine or valine arylamidase, glutamic decarboxylase, or trypsin. Nitrates are not reduced. Neither gelatin nor urea is degraded. DL-alanine, DL-aspartic acid, L-glutamic acid, glycine, L-proline, and L-serine are utilized, but not citrate. The major fatty acids are $C_{16:0}$ and $C_{16:1}$ *ω7c*. The G+C ratio of the DNA is 66–70 mol%. The type strain is ATCC 9797^T.

Bor. avium produces unpigmented colonies that comprise strictly aerobic, chemoorganotrophic capsulated rods of 0.4–0.5 × 1–2 μm in size that occur singly or in pairs and are motile by peritrichous flagella. Either of two distinct colony types may occur, namely, a small [<1 mm in diameter] glistening colony with entire edges after incubation for 24 h or larger, circular, smooth convex colonies with entire edges. Growth occurs

optimally at 37 °C and on MacConkey agar, nutrient agar (NA), and salmonella-shigella agar. Nitrates are not reduced. Acid and alkaline [weakly] phosphatase, catalase, esterase (C4), esterase lipase (C8) [weak], oxidase, and phosphoamidase are produced, but not *N*-acetyl-β-D-glucosaminidase, α-L-fucosidase, α- or β-D-galactosidase, α- or β-D-glucosidase, β-D-glucuronidase, indole, lipase (C14), α-D-mannosidase, phenylalanine deaminase, or trypsin. Neither aesculin, gelatin, nor urea is degraded. Growth occurs on L-aspartate, citrate, fumarate, L-glutamate, glutarate, α-ketoglutarate, L-malate, L-proline, pyruvate, and succinate, but not *N*-acetyl glucosamine, adonitol, aesculin, amygdalin, D- or L-arabinose, arbutin, L-arginine, benzoate, butyrate, D-cellobiose, dulcitol, D-fructose, D-galactose, D-gentiobiose, D-gluconate, D-glucose, glycine, glycogen, inulin, L-histidine, *m*-inositol, itaconate, lactose L-leucine, L-lysine, D-malate, malonate, D-maltose, D-mannitol, D-mannose, D-melezitose, D-melibiose, L-methionine, L-ornithine, L-phenylalanine, raffinose, L-rhamnose, D-ribose, salicin, L-serine, sorbitol, sucrose, L-threonine, trehalose, D- or L-tryptophan, L-valine, or D- or L-xylose. The G+C content of the DNA is 61.6–62.6 mol %. The type strain is ATCC 35086^T, which has a G+C ratio of the DNA of 61.6 mol% (Kersters et al. 1984).

Bor. bronchiseptica comprises motile Gram-negative coccobacilli, which grow on blood and MacConkey agar and at 25 °C and 42 °C. Catalase, oxidase, and serine arylamidase are produced, but not chymotrypsin, cystine, proline or valine arylamidase, lipase (C14), phosphatase, or trypsin. Nitrates are reduced to nitrite. Urea is degraded, but not gelatin. Tetrazolium is reduced. DL-alanine, DL-aspartic acid, citrate, L-glutamic acid, glycine L-proline, and L-serine are utilized. The major fatty acids are $C_{16:0}$, $C_{16:1}$ *ω7c*, and $C_{17:0}$ cyclo. The G+C content of the DNA is 67–79 mol%. The type strain is ATCC 19395^T (Vandamme et al. 1996).

Bor. hinzii may produce two distinct colony types including round, raised, glistening, grayish colonies of ~2 mm in diameter after incubation for 48 h at 37 °C in 5 % CO_2. The second type is characterized by the presence of flat, dry, crinkled colonies that are ≤5 mm in diameter. Cultures comprise Gram-negative, asporogenous rods that are motile by peritrichous flagella. Oxidase and catalase are produced, but not arginine dihydrolase, β-galactosidase, or indole. Nitrates are not reduced. Neither aesculin nor gelatin is degraded. Urease activity is strain dependent. Alkali is produced from acetamide, adipate, malonamide, malonate, valerate, and propionamide. Production of alkali from glycine is strain dependent. Acid is not produced from glucose. Adipate, citrate, malate, and phenylacetate are assimilated, but not *N*-acetyl-glucosamine, L-arabinose, D-gluconate, D-glucose, maltose, D-mannitol, or D-mannose. Assimilation of caprate is strain dependent. Q-8 and trace amounts of Q-9 are the respiratory quinones. The major fatty acid components are $C_{16:0}$, $C_{17:0}$ cyclo, and summed feature 3. The DNA base composition is 65–67 mol%. The type strain is LMG 13501^T, which has a G+C content of the DNA of 66 mol% (Vandamme et al. 1995).

Bor. holmesii, formerly known as CDC nonoxidizer group 2, produces brown, soluble, pigmented [diffusing around the colonies on heart infusion tyrosine agar], round, punctate, convex, semi-opaque colonies on rabbit blood agar after incubation at 35 °C for 3 days and comprises asaccharolytic, nonmotile, small, Gram-negative coccoid cells/rods; longer rods are observed sometimes. Growth occurs sometimes slowly on MacConkey agar. Catalase is produced weakly or not at all; oxidase is not produced. Urea is not degraded, nor are nitrates reduced. Carbohydrates are not utilized. The major fatty acids are $C_{16:0}$ and $C_{17:0}$ cyclo, with smaller quantities of $C_{18:0}$. The G+C ratio of the DNA is 61.5–62.3 mol%. The type strain is CDC F5101 = ATCC51541^T, which has a G+C ratio of the DNA of 61.9 mol% (Weyant et al. 1995).

Bor. parapertussis comprises strictly aerobic, nonmotile, Gram-negative rods, which produce brown diffusible pigment on peptone agar. Growth occurs on blood and MacConkey agars. Catalase is produced, but not oxidase or phosphatase. Nitrates are not reduced. Urea is degraded, but not gelatin. DL-alanine, DL-aspartic acid, citrate, L-glutamic acid, glycine, L-proline, and L-serine are utilized. The major fatty acids are $C_{16:0}$ and $C_{17:0}$ cyclo. The G+C ratio of the DNA is 66–70 mol%. The type strain is ATCC 15311^T, which has a G+C ratio of the DNA of 68.6 mol%.

Bor. petrii produces white/cream colonies comprising Gram-negative, asporogenous, nonmotile, circular to rod-shaped cells of 0.4–0.7 × 1.0–2.8 μm in size that have fimbria of different diameters. Catalase and oxidase is produced, but not indole or urease. Neither aesculin, blood, nor gelatin is degraded. Tetrazolium is reduced. Nitrates are not reduced. Growth occurs aerobically, microaerophilically, and anaerobically, the latter of which is nonfermentative, possibly attributed to denitrification or to the reduction of selenate to elemental sulfur. Growth occurs at 30 [aerobically] and 37 °C [aerobically and microaerophilically] and on MacConkey agar. The Voges-Proskauer reaction is negative. Adipate, citrate, D-gluconate, and L-malate are assimilated, but not *N*-acetylglucosamine, adonitol, amygdalin, L-arabinose, arbutin, caprate, cellobiose, erythritol, gentiobiose, D-glucose, glycerol, glycogen, inositol, inulin, lactose, maltose, mannose, mannitol, melezitose, melibiose, methyl β-D-xyloside, methyl α-D-glucoside, raffinose, rhamnose, ribose, saccharose, salicin, sorbitol, starch, trehalose xylitol, and L- and D-xylose. The major respiratory isoprenoid quinone is Q-8. The type strain is DSM 12804^T = CCUG 43448 T, which has a G+C ratio of the DNA of 63.8 mol% (Von Wintzingeroda et al. 2001).

Bor. trematum produce convex, circular, and grayish cream-white colonies with entire edges on blood agar, which comprise motile by peritrichous flagella, asporogenous, encapsulated Gram-negative rods of 0.5–0.6 × 1–1.8 μm in size; the longest rods are ≤2.4 μm long in 16–24 h cultures. Alkaline phosphatase, ester lipase (C8), naphthol-AS-BI-phosphohydrolase, and serine and valine arylamidase are produced, but not cystine or proline arylamidase, lysine decarboxylase, oxidase, or trypsin. Growth occurs microaerophilically but not anaerobically, and on MacConkey agar, and at 25 °C and 42 °C. Urea is not degraded. Adipate, aesculin, L-malate, and phenylacetate are assimilated, but not D-gluconate, caprate, D-glucose, or D-xylose. The major fatty acids are $C_{16:O}$, $C_{17:O}$ cyclo, and summed feature 3. The G+C ratio of the DNA is 64–65 mol%. The type strain is LMG 13506^T, which has a G+C ratio of the DNA of 65 mol% (Vandamme et al. 1996).

Brackiella Willems et al. 2002

Bra'cki.ella L. n. *Brackiella* after Manfred Brack, a German pathologist.

Cultures of *Bra. oedipodis* comprise aerobic to microaerophilic nonmotile Gram-negative asporogenous slightly ovoid coccobacilli of 0.9 × 1.1 μm; actively growing cells before dividing were up to 1.8 μm in length. Cells are surrounded by densely studded fimbriae of 280 nm in length. Growth occurs at 30–37 °C, but not at 4 °C, 40 °C, or 42 °C, on 5 % (v/v) sheep blood agar but without evidence of hemolysis. Two colony types are observed after 24 h, namely, small (up to 0.5 mm in diameter) and large (up to 1 mm in diameter), but after 4 h all colonies are of 1–2 mm in diameter. Catalase and oxidase is produced. Nitrates are reduced to nitrites. Urea is attacked. Acid is produced from maltose and D-mannose. Acetate is not utilized. One major outer membrane protein (OMP) of 45 kDa and three smaller and minor OMPs have been identified. The lipopolysaccharide profile comprises a ladder of repeating units with two strong bands at 8.4 kDa and other bands at 10 and 12 kDa and minor bands at 21–26 kDa. The major fatty acids are $C_{19:0\ cyclo}$ ω8*c*, $C_{18:1}$ ω7*c*, and $C_{16:0}$.

The type species is *Brackiella oedipodis*, which in addition to the genus characteristics produces L-alanine aminopeptidase and ornithine decarboxylase, degrades starch, and is positive for the methyl red test, but does not produce arginine dihydrolase, β-D-galactosidase, β-D-glucuronidase, indole, H_2S, phenylalanine deaminase, pyrase, or lysine decarboxylase; decompose aesculin, DNA, gelatin, or Tween 80; produce acid from adonitol, L-arabinose, cellobiose, dulcitol, erythritol, glycerol, *myo*-inositol, lactose, mannitol, melibiose, methyl-α-D-glucoside, mucate, raffinose, L-rhamnose, saccharose, salicin, D-sorbitol, trehalose, or D-xylose; utilize Simmons citrate or the Voges-Proskauer reaction; and grow on MacConkey agar, on KCN, or in 6.5 % (w/v) NaCl. The type strain is LMG 19451^T = DSM = 13743^T = NCIMB 13739^T.

Candidimonas Vaz-Moreira et al. 2011

Can.di.di.mo'nas. L. adj. *Candidus -a –um* white; L. fem. N. *monas* a unit, monad; N.L. fem. No. *Candidimonas* a unit (rod) that produces white colonies.

Cultures contain asporogenous, motile or nonmotile, Gram-negative short-curved rods. Catalase and oxidase are produced. Mesophilic or psychrophilic. Chemoorganotrophic. Respiratory metabolism. Nitrates are reduced. Amino acids and organic acids are utilized as the sole sources of carbon. Ubiquinone Q-8 is the respiratory quinone. The polar lipids are phosphatidylethanolamine, phosphatidylglycerol, phosphatidylmonomethylethanolamine, and diphosphatidylglycerol. The major fatty acids are $C_{16:0}$, $C_{17:0}$ cyclo, and summed feature 3. The G+C content of the DNA is 64–65 mol%. The type species is *Candidimonas nitroreducens* (Vaz-Moreira et al. 2011; Zhang et al. 2012). The distinguishing traits of *Candidimonas* species are given in Table 27.6.

Table 27.6
Differentiating phenotypic properties of *Candidimonas*

Characteristics	*Can. nitroreducens*	*Can. bauzanensis*	*Can. humi*
Anaerobic growth	+ [slow and weak]	+	–
Motility	–	+	–
Nitrate reduction to nitrate	+	+	–

Can. bauzanensis produces smooth, round, convex, cream-white colonies of 1–1.5 mm in diameter after incubation on R2A for 5 days. Colonies comprise Gram-negative rods of 0.7–0.9 × 1.2–1.9 μm in length. Growth occurs facultatively, anaerobically, and at 1–37 °C but not at 42 °C, at pH 6–8, and in 0–3 % (w/v) NaCl. Nitrates are reduced to nitrogen gas. Esterase (C4), esterase lipase (C8) [weakly], acid phosphatase [weakly], naphthol-AS-BI-phosphohydrolase, and leucine arylamidase are produced, but not *N*-acetyl-β-glucosaminidase, alkaline phosphatase, arginine dihydrolase, α-chymotrypsin, α-fucosidase, α- or β-galactosidase, α- or β-glucosidase, β-glucuronidase, H_2S, indole, lysine or ornithine decarboxylase, α-mannosidase, trypsin, or tryptophan deaminase. The Voges-Proskauer reaction is negative. Urea, but not aesculin, gelatin, skimmed milk, or starch, is degraded. Citrate is not utilized. Adipic acid, L-arabinose, D-glucose, malic acid, potassium gluconate, and trisodium citrate (weakly) are assimilated, but not *N*-acetylglucosamine, L-alanine, L-arabinose, capric acid, citrate, L-fucose, D-glucose, glycogen, L-histidine, inositol, maltose, D-mannitol, D-mannose, or phenyl acetic acid. Neither amygdalin, L-arabinose, D-glucose, inositol, D-mannitol, melibiose, L-rhamnose, D-sorbitol, nor sucrose is fermented. The polyamines are dominated by putrescine and spermidine. The isoprenoid quinone is Q-8. The major polar lipids are phosphatidylethanolamine, phosphatidylglycerol, phosphatidylmonomethylethanolamine, and diphosphatidylglycerol. The predominant fatty acids are $C_{16:0}$, $C_{17:0}$ cyclo, and summed feature 3. The type strain is BZ59^T = DSM 22805^T = LMG 26046^T = CGMCC 1.10190^T, which has a G+C ratio of the DNA of 61.6 mol% (Zhang et al. 2012).

Can. nitroreducens produces circular, convex, white colonies of ~1 mm in diameter after incubation on plate count agar for 48 h. Colonies comprise Gram-negative coccobacilli of 0.53 ± 0.11 μm in length. Growth occurs anaerobically [slowly] and at 15–40 °C [optimally at 30 °C], at pH 5–8 [optimally at pH 7], and in up to 3 % (w/v) NaCl [optimally in 1 % w/v NaCl]. Nitrates are reduced to nitrites. Esterase (C4), esterase lipase (C8), acid and alkaline phosphatase, naphthol-AS-BI-phosphohydrolase, and leucine and valine arylamidase are produced, but not *N*-acetyl-β-glucosaminidase, arginine dihydrolase, α-chymotrypsin, cystine arylamidase, α-fucosidase, α- or β-galactosidase, α- or β-glucosidase, β-glucuronidase, H_2S, indole, lipase (C14), lysine or ornithine decarboxylase,

α-mannosidase, trypsin, or tryptophan deaminase. The Voges-Proskauer reaction is negative. Neither aesculin, gelatin, nor urea is degraded. Simmons citrate is not utilized. Glucose is oxidized, but not amygdalin, L-arabinose, inositol, D-mannitol, melibiose, L-rhamnose, D-sorbitol, or sucrose. Adipate, 3-hydroxybenzoic acid, 4-hydroxybenzoic acid, 3-hydroxybutyric acid, itaconic acid, lactic acid, malate (weakly), phenylacetate, potassium gluconate (weakly), propionic acid, sodium acetate, and valeric acid are assimilated, but not *N*-acetylglucosamine, L-alanine, L-arabinose, capric acid, citrate, L-fucose, D-glucose, glycogen, L-histidine, inositol, maltose, D-mannitol, D-mannose, melibiose, potassium 2-ketogluconate, potassium 5-ketogluconate, L-proline, L-rhamnose, D-ribose, salicin, L-serine, sodium malonate, D-sorbitol, suberic acid, sucrose, or trisodium citrate. The predominant fatty acids are $C_{16:0}$, $C_{17:0}$ cyclo, $C_{18:1}$ *ω7c*, and summed feature 2. The type strain is SC-089^T = CCUG 55806^T = LMG 24812^T, which has a G+C ratio of the DNA of 64 mol% (Vaz-Moreira et al. 2011).

Can. humi produces circular, convex, white colonies of ~1 mm in diameter after incubation on plate count agar (PCA) for 48 h. Colonies comprise Gram-negative coccobacilli of 0.5 ± 0.09 μm in size. Growth occurs at 15–40 °C [optimally at ~30 °C], at pH 5–8 [optimally at pH 7], and in up to 3 % (w/v) NaCl [optimally in 1 % w/v NaCl]. Anaerobic growth does not occur. Nitrates are not reduced. Esterase (C4), esterase lipase (C8), acid and alkaline phosphatase, α-chymotrypsin, naphthol-AS-BI-phosphohydrolase, and leucine and valine arylamidase are produced, but not *N*-acetyl-β-glucosaminidase, arginine dihydrolase, cystine arylamidase, α-fucosidase, α- or β-galactosidase, α- or β-glucosidase, β-glucuronidase, H_2S, indole, lipase (C14), lysine or ornithine decarboxylase, α-mannosidase, trypsin, or tryptophan deaminase. Simmons citrate is not utilized. The Voges-Proskauer reaction is negative. Neither aesculin, gelatin, nor urea is degraded. Adipate, citrate 3-hydroxybenzoic acid, 3-hydroxybutyric acid, itaconic acid, lactic acid, phenylacetate, potassium 2-ketogluconate, propionic acid, sodium acetate, trisodium citrate, and valeric acid are assimilated, but not *N*-acetylglucosamine, L-alanine, L-arabinose, capric acid, L-fucose, D-glucose, glycogen, L-histidine, 4-hydroxy benzoic acid, inositol, malate, maltose, D-mannitol, D-mannose, melibiose, potassium gluconate, potassium 5-ketogluconate, L-proline L-rhamnose, D-ribose, salicin, L-serine, sodium malonate, D-sorbitol, suberic acid, or sucrose. The major fatty acids are $C_{16:0}$, $C_{18:1}$ *ω7c*, and summed features 2 and 3. The type strain is SC-092^T = CCUG 55807^T = LMG 24813^T, which has a G+C ratio of the DNA of 65 mol% (Vaz-Moreira et al. 2011).

Castellaniella Kämpfer et al. 2006

Cas.tel.la'ni.el.la. N. L. fem. dim. n. *Castellaniella* named after Sir Aldo Castellani, an Anglo-Italian bacteriologist who first described *Alcaligenes*.

On NA with incubation at 25–30 °C for 24 h, cultures comprise Gram-negative, facultatively anaerobic and denitrifying, motile rods of 1.3–2.0 × 0.2–0.8 μm. Polar lipids comprise phosphatidylglycerol and diphosphatidylglycerol with minor quantities of two unknown aminolipids and an unknown polar lipid. The polyamines consist mostly of putrescine with moderate amounts of 2-hydroxyputrescine. The main component of the quinone system is ubiquinone Q-8. The major fatty acids are $C_{16:0}$, $C_{16:1}$*ω7c*, $C_{17:0}$ cyclo, $C_{18:1}$ *ω7c*, and/or $C_{14:0}$ 3-OH (Kämpfer et al. 2006). The type species is *Cas. defragrans*. The distinguishing traits of *Castellaniella* species are given in Table 27.7.

Cas. defragrans (basonym = *Alcaligenes defragrans*) matches the genus description. The type strain is CCUG 39790^T = DSM 12141^T = CIP 105602^T which has a G+C ratio of the DNA of 66.9 mol% (Kämpfer et al. 2006).

Cas. caeni produces brownish 1–2 mm diameter smooth, transparent, circular, convex colonies on R2A agar after 2 days, which contain facultatively anaerobic, Gram-negative, nonmotile rods of 0.3–0.5 × 1.2–2.0 μm in size. Oxidase is produced but not arginine dihydrolase, catalase, β-galactosidase, H_2S, indole, lipase, lysine and ornithine decarboxylase, or tryptophan deaminase. The Voges-Proskauer reaction is positive. Growth occurs on MacConkey agar, NA, and TSA, at 10–37 °C [optimally at 30 °C] and at pH 5.0–8.5 [optimally at pH 6.5–7.0]. NaCl is not required for growth, but cultures can grow in 5 % (w/v) NaCl. Nitrates are reduced to nitrogen anaerobically. Aesculin is degraded, but not carboxymethylcellulose, casein, chitin, DNA, gelatin, starch, urea, or xylan. Acetate, adipate, D-adonitol, L-alanine, D-arabinose, L-arginine, L-asparagine, L-aspartate, caprate, cellobiose, L-cysteine, formate, fumarate, L-fucose, D-galactose, D-glucose, L-glutamate, L-glutamine, glutarate, glycine, glycerol, L-histidine, DL-3-hydroxybutyrate, L-isoleucine, lactate, L-lysine, malate, methanol, phenylacetate, L-proline, propionate, L-serine, suberate, succinate, L-threonine, L-valine, and valerate are utilized, but not *N*-acetylglucosamine, amygdalin, L-arabinose, benzoate, citrate, dextran, dulcitol, ethanol, fructose, gluconate, glycogen, 3-hydroxybenzoate, 4-hydroxybenzoate, inositol, inulin, itaconate, 2-ketogluconate, 5-ketogluconate, D-lactose, L-leucine, D-lyxose, maleic acid, malonate, maltose, D-mannitol, mannose, melibiose, L-methionine, oxalate, L-phenylalanine, pyruvate, raffinose, L-rhamnose, D-ribose, salicin, D-sorbitol, L-sorbose, sucrose, tartrate, trehalose, L-tryptophan, L-tyrosine, xylitol, L-xylose, or D-xylose. Acid is not produced from amygdalin, L-arabinose, glucose, inositol, D-mannitol, melibiose, L-rhamnose, D-sorbitol, or sucrose. The polar lipids are phosphatidylethanolamine, diphosphatidylglycerol, and phosphatidylglycerol. The major fatty acids are summed features 4 and 7. The type strain is KCTC 12197^T = LMG 23411^T, which has a G+C content of the DNA of 63.5 mol% (Liu et al. 2008).

Apart from the genus characteristics, colonies of *Cas. denitrificans* are beige and circular with an entire edge. Growth occurs at 30–42 °C but not at 4 °C. A wide range of compounds are utilized as sole sources of carbon and include acetate, *cis*-aconitate, *trans*-aconitate, L- and β-alanine, 4-aminobutyrate, L -aspartate, citrate, fumarate, D-gluconate (weak), glutarate, DL-3-hydroxybutyrate, itaconate, DL-lactate, L-leucine, L-malate, mesaconate, L-ornithine, 2-oxoglutarate, L-proline, propionate,

pyruvate, and L-serine, but not *N*-acetylgalactosamine, *N*-acetylglucosamine, adipate, adonitol, L-arabinose, L-arbutin, D-cellobiose, D-fructose, D-galactose, D-glucose, L-histidine, 3-hydroxybenzoate, *i*-inositol, D-maltose, D-mannitol, D-mannose, α-D-melibiose, phenylacetate, L-phenylalanine, putrescine, L-rhamnose, D-ribose, salicin, L-serine, D-sorbitol, D-sucrose, D-trehalose, L-tryptophan, or D-xylose. Acid is not produced from adonitol, L-arabinose, D-arabitol, cellobiose, dulcitol, erythritol, glucose, inositol, lactose, maltose, D-mannitol, D-mannose, methyl D-glucoside, melibiose, raffinose, rhamnose, salicin, sorbitol, sucrose, trehalose, or D-xylose. The type strain is DSM 11046^T = CCUG 39541^T (Kämpfer et al. 2006).

Cas. daejeonensis produces 0.5–2.0 mm diameter circular, smooth, convex, shiny, transparent, yellowish colonies on R2A agar after incubation at 30 °C. Cultures comprise facultatively anaerobic, Gram-negative, asporogenous, motile rods, 0.3–0.5 × 1.4–1.7 μm in size. Catalase and oxidase are produced, but not acid or alkaline phosphatase, cysteine or valine arylamidase, α-fucosidase, β-galactosidase, α-mannosidase, or naphthol-AS-BI-phosphohydrolase. Growth occurs on Luria-Bertani (LB) agar, R2A agar, NA, and TSA at 30–42 °C [optimally at 30 °C] but not at 20 °C or 45 °C and at pH 5.0–9.0 [optimally at 6.5–7.0]. Nitrate is reduced to nitrogen gas. Gelatin and casein (weakly) are degraded, but not so chitin, DNA, hydroxyethyl cellulose, starch, or xylan. Acetate, adipate, L-alanine, caprate, gluconate, D-glucose, L-histidine, 3-hydroxybenzoate, 4-hydroxybenzoate, inositol, 2-ketogluconate, L-proline, malonate, D-mannitol, D-mannose, phenylacetate, L-rhamnose, D-ribose, L-serine, D-sorbitol, and valerate are assimilated, but not *N*-acetyl-D-glucosamine, citrate, itaconate, L-fucose, or suberate. Acid is produced from D-arabitol, erythritol, gluconate, mannose, and lactose. The major fatty acids are $C_{16:0}$ and summed features 4 and 7. The principle respiratory quinone is Q-8. Putrescine is the dominant polyamine. The major polar lipids are phosphatidylethanolamine, diphosphatidylglycerol, and phosphatidylglycerol. The type strain is KCTC 22454^T = JCM 16240^T, which has a G+C ratio of the DNA of 66.2 mol% (Lee et al. 2010a).

Cas. ginsengisoli produces yellow, smooth, circular, convex colonies on R2A after 3 days and comprises Gram-negative, motile rods of 0.7–0.8 × 1.6–2.5 μm in size. Growth occurs on LB agar, NA, R2A agar, and TSA at 25–42 °C [optimally at 30 °C in LB broth] and at pH 5.0–9.0 [optimally at pH 6.5–7.0 in LB broth]. Acid and alkaline phosphatase, catalase, esterase (C4), esterase lipase (C8), β-glucosidase, leucine arylamidase, naphthol-AS-BI-phosphohydrolase, and oxidase are produced, but not *N*-acetyl-β-glucosaminidase, arginine dihydrolase, α-chymotrypsin, cystine arylamidase, lipase (C14), α- and β-galactosidase, α- and β-glucosidase, β-glucuronidase, α-mannosidase, or trypsin. Nitrates are reduced to nitrogen gas. Neither gelatin nor urea is degraded. Acetate, *N*-acetyl-D-glucosamine, adipate, L-alanine, L-arabinose, caprate, citrate, gluconate, D-glucose, 3- and 4-hydroxybenzoate, DL-3-hydroxybutyrate, lactate, L-malate, maltose, D-mannose, D-mannitol, phenylacetate, L-proline, propionate, L-serine and *n*-valerate are utilized, but not L-fucose, glycogen, L-histidine, inositol, itaconate, 2- or 5-ketogluconate, malonate, melibiose, L-rhamnose, D-ribose, salicin, D-sorbitol, sucrose, or suberate. The polar lipids are phosphatidylethanolamine, diphosphatidylglycerol, and phosphatidylglycerol. The major fatty acids are $C_{16:0}$, $C_{18:1}\omega7c$, and summed feature 4. The type strain is KCTC 22398^T = JCM 15515^T, which has a G+C ratio of the DNA of 63.7 mol% (Kim et al. 2009).

N-acetyl-β-glucosaminidase[a]	+	–

[a]Data from API ZYM

Derxia Jensen et al. 1960

Derx' i. a. M.L. fem. N. *Derxia* after H.G. Derx, a Dutch microbiologist.

Cultures are initially slimy and semitransparent becoming larger, opaque and wrinkled, and dark brown in color. These comprise aerobic (strictly respiratory), Gram-negative, motile [polar flagella], pleomorphic rods of 1.0–1.2 × 3.0–6.0 μm in size that occur singly or in short chains and fix molecular nitrogen. Growth occurs at 15–40 °C but not at 50 °C [optimally at 25–35 °C], at pH 5.5 ~9.0 but not at pH 4.4. Catalase is not produced. The G+C ratio of the DNA is 69.2–72.6 mol%. The type species is *Derxia gummosa* (Jensen et al. 1960). The distinguishing traits of *Derxia* species are given in Table 27.8.

D. gummosa produces yellow irregular colonies with curled edges on R2A agar and comprises obligately aerobic, encapsulated, motile by single polar flagella Gram-negative rods, which contain intracellular poly-β-hydroxybutyrate granules. Growth occurs at 10–45 °C [optimally at 20–30 °C] and in 0–2 % (w/v) NaCl [optimally in 1 % w/v NaCl]. *N*-acetyl-β-glucosaminidase and esterase lipase (C8) are produced, but not catalase. Molecular nitrogen is fixed aerobically and in decreased oxygen levels. Growth occurs as a facultative hydrogen autotroph. Adipate, arabinose, and mannitol are assimilated. The major respiratory quinone is Q-8. The dominant fatty acids are $C_{12:0}$ 3-OH, $C_{14:0}$ 2-OH, $C_{14:0}$ 3-OH, $C_{16:0}$, $C_{18:1}$ *ω7c*, and summed feature 3. The G+C ratio of the DNA is 69.2–72.6 mol%. The type strain is ATCC 15994^T, which has a G+C ratio of the DNA of 69.2 mol% (Jensen et al. 1960; De Smedt et al. 1980; Xie and Yokota 2004; Chen et al. 2013).

D. lacustris produces round, convex, smooth, light-yellow [becoming brownish yellow and brownish red with further incubation], glistening, translucent colonies with entire edges of 0.4–1.8 mm in diameter on R2A agar after incubation at 25 °C for 48 h. These comprise asporogenous, aerobic, motile encapsulated with a thick capsule Gram-negative rods of 1.0–1.2 × 2.0–4.0 μm in size, which contain intracellular poly-β-hydroxybutyrate granules. Molecular nitrogen is fixed microaerophilically. Growth occurs at 15–40 °C [optimally at 25–35 °C], at pH 6.0–7.0 [optimally at pH 6.0], and in 0–4 % (w/v) NaCl [optimally in 0–1 % w/v NaCl]. Alkaline and acid phosphatase, catalase, esterase (C4), β-glucosidase, leucine and valine arylamidase, naphthol-AS-BI-phosphohydrolase, and oxidase are produced, but not *N*-acetyl-β-glucosaminidase, arginine dihydrolase, α-chymotrypsin, cystine arylamidase, esterase lipase (C8), α-fucosidase, α- or β-galactosidase, α-glucosidase, β-glucuronidase, indole, lipase, α-mannosidase, or trypsin. Nitrates are not reduced. Tween 60 is degraded, but not aesculin; casein; DNA; gelatin; Tween 20, 40, or 80; or urea. Gluconate, glucose, and malate are assimilated, but not *N*-acetylglucosamine, adipate, arabinose, caprate, citrate, maltose, mannitol, mannose, or phenylacetate. Acid is not produced from glucose. The major respiratory quinone is Q-8. The polar lipid profile comprises phosphatidylethanolamine, phosphatidylglycerol, diphosphatidylglycerol, two unknown aminophospholipids, and 7 unknown phospholipids. The major fatty acids are $C_{12:0}$ 3-OH, $C_{14:0}$ 2-OH, $C_{14:0}$ 3-OH, $C_{16:0}$, $C_{18:1}$ *ω7c*, and summed feature 3. The type strain is BCRC 80208^T = KCTC 23311^T, which has a G+C ratio of the DNA of 72.0 mol% (Chen et al. 2013).

Kerstersia Coenye et al. 2003b

Kers.ters'ia. N.L. fem. n. *Kerstersia* after K. Kersters, an eminent Belgian microbiologist.

Cultures on NA are white to light brown, flat or slightly convex with smooth edges, and comprise small (1–2 μm) coccoid cells that occur singly, in pairs, and as short chains. Motility may occur. Catalase is produced, but not β-galactosidase, oxidase, or urease. Growth occurs at 28 °C and 42 °C. The fatty acid profile includes $C_{14:0}$, $C_{14:0}$ 2-OH, $C_{16:0}$, $C_{17:0}$ cyclo, $C_{18:0}$, $C_{18:1}$ *ω7c*, $C_{19:0}$ cyclo *ω8c*, and summed features 2 and 3. The G+C content of the DNA is 61.5–62.9 mol%. The type species is *Kerstersia gyiorum*. The distinguishing characteristics of *Kerstersia* species are included in Table 27.9.

K. gyiorum matches the genus description, and in addition caprylate is assimilated, but not aconitate, adipate, L-cysteine, glutarate, isobutyrate, L-isoleucine, isovalerate, 2-ketoglutarate, L-leucine, L-methionine, pimelate, L-threonine, or L-valine. The G+C content of the DNA is 62.7–62.9 mol%. The type strain = LMG 5906^T = CCUG 47000^T and has a G+C content of 62.9 mol% (Coenye et al. 2003b).

K. similis produces white to light brown flat or slightly convex colonies with a swarming appearing on NA that comprise nonmotile, Gram-negative coccobacilli of ~0.3–0.5 × 0.85–1.3 μm in size that occur singly or in pairs. Growth occurs at 28–42 °C and in 0–4.5 % (w/v) NaCl. Catalase is produced, but not arginine dihydrolase, β-galactosidase, H_2S, lysine or ornithine decarboxylase, or oxidase. Neither aesculin, DNA, gelatin, starch, or urea is degraded. Nitrates are not reduced. Acetate, α-D-alanine, α-L-alanine, L-aspartate, butyrate, caprate, *n*-caproate, citrate, fumarate, L-glutamate, heptanoate, *p*-hydroxybenzoate, DL-3-hydroxybutyrate, 2-ketoglutarate [weakly], DL-lactate, D-malate, L-malate, L-norleucine, L-ornithine, pelargonate, phenylacetate, L-phenylalanine, L-proline, propionate, pyruvate, succinate, L-tryptophan, L-tyrosine, and *n*-valerate are assimilated, but not adonitol, aesculin, amygdalin, D-arabinose, L-arabinose, arbutin, cellobiose, dulcitol,

Table 27.9

Characteristic	*K. gyiorum*	*K. similis*
Assimilation of 2-ketoglutarate	–	+ [weak]
Oxidation of D-galacturonic acid	+	–
Oxidation of D-glucuronic acid	+	–
Oxidation of D-serine	–	+

erythritol, D-fucose, L-fucose, galactose, D-glucose, inositol, inulin, 2-ketogluconate, 3-ketogluconate, lactose, malate, malonate, maltose, mannitol, D-mannose, melezitose, melibiose, oxalate, raffinose, L-rhamnose, ribose, salicin, sorbitol, starch, sucrose, trehalose, or D-xylose. The fatty acid profile includes $C_{14:0}$, $C_{14:0}$ 2-OH, $C_{16:0}$, $C_{17:0}$ cyclo, $C_{18:0}$, $C_{18:1}$ $\omega 7c$, $C_{19:0}$ cyclo $\omega 8c$, and summed features 2 and 3. The type strain = LMG 5890^T = CCUG 46999^T and has a G+C content of 61.5 mol% (Vandamme et al. 2012).

Oligella Rossau et al. 1987

O.lig.el'la. Gr. Adj. *Oligos*, little; scanty; M.L. dim. Ending *–ella*; M.L. fem. N. *Oligella*, referring to a small bacterium with limited nutritional properties.

Cultures comprise slowly developing, aerobic, noncapsulated, asporogenous, small, Gram-negative oxidase and usually catalase-positive rods of $\leq$1 μm in length, which are often in pairs. Cells are mostly nonmotile, but some (*O. ureolytica*) are motile by peritrichous flagella. Carbohydrates are not fermented or oxidized. H_2S and indole is not produced, nor is gelatin attacked. The major fatty acids are $C_{16:0}$ and $C_{18:1}$. The G+C content of the DNA is 47 ± 1 mol%. The type species is *O. urethralis*.

Cultures of *O. urethralis* comprise Gram-negative, aerobic, nonmotile coccobacilli, which grow at 42 °C but do not produce acid in the oxidative-fermentative medium and do not attack urea, reduce nitrates, or grow on *p*-hydroxybenzoate. Neither acetamide, aesculin, starch, or Tween 80 is attacked, nor is arginine hydrolase or arginine or ornithine decarboxylase produced. The type strain is ATCC 17960^T, and the G+C content of the DNA is 46.1–47.5 mol%.

Cultures of *O. ureolytica* contain motile cells that reduce nitrate to nitrite, utilize citrate, and produce urease and grow on *p*-hydroxybenzoate but not at 42 °C. $C_{19:cyc}$ is present in moderate quantities. The type strain is ATCC 43534^T = CCUG 1465^T = LMG 6519^T, and the G+C content of the DNA is 46–47 mol%.

Paenalcaligenes Kämpfer et al. 2010

Pa. en. al. ca. li' ge. nes. L. adv. *paene* nearly, almost; N. L. masc. n. *Alcaligenes* a bacterial genus name; N. L. masc. n. *Paenalcaligenes* almost *Alcaligenes*.

After 24 h incubation on NA, cultures comprise Gram-negative, motile rods of 1.3–2.0 × 0.2–0.8 mm in size, which have a respiratory metabolism and produce oxidase. The quinone system is ubiquinone Q-8 with smaller amounts of Q-7. Polar lipids contain diphosphatidylglycerol, phosphatidylglycerol, phosphatidylethanolamine, and an unidentified phospholipid. The major fatty acids are $C_{16:0}$, $C_{17:0}$ cyclo, and summed feature 3. The type species is *Paenalcaligenes hominis*.

Pae. hominis has the genus characteristics, and additionally on NA, colonies are beige and circular and have an entire edge. Growth occurs at 30–42 °C but not at 4 °C. L-alanine-*p*-nitroanilide is hydrolyzed, but not *p*-nitrophenyl (pNP) β-D-galactopyranoside, pNP β-D glucuronide, pNP α-D-glucopyranoside, pNP β-D-glucopyranoside, pNP β-D-xylopyranoside, bis-pNP phosphate, bis-pNP phenylphosphonate, bis-pNP phosphorylcholine, L-aniline pNA, γ-L-glutamate pNA, and L-proline pNA. Acetate, *cis*- and *trans*-aconitate, pyruvate, fumarate, DL-3- hydroxybutyrate, and DL-lactate are used as sole sources of carbon, but not *N*-acetylgalactosamine, *N*-acetylglucosamine, adipate, adonitol, L-alanine, β-alanine, 4-aminobutyrate, L-arabinose, L-arbutin, L-aspartate, cellobiose, citrate, D-fructose, D-galactose, D-glucose, D-gluconate, glutarate, L-histidine, 3-hydroxybenzoate, L-malate, L-leucine, maltose, D-mannose, α-melibiose, L-ornithine, L-phenylalanine, L-proline, propionate, L-rhamnose, D-ribose, L-serine, sucrose, salicin, trehalose, D-xylose, myo-inositol, maltitol, D-mannitol, phenylacetate, D-sorbitol, or L-tryptophan. Acid is not produced from adonitol, L-arabinose, D-arabitol, cellobiose, dulcitol, erythritol, glucose, inositol, lactose, maltose, D-mannitol, D-mannose, melibiose, methyl D-glucoside, raffinose, rhamnose, salicin, sorbitol, sucrose, trehalose, or D-xylose (Kämpfer et al. 2010). The type strain is CCUG $53761A^T$ = CCM 7698^T, which has a G+C content of the DNA of 57 mol%.

Paralcaligenes Kim et al. 2011

Par.al.ca.li'ge.nes. Gr. Prep. *para* beside; M.L. masc. n. *Alcaligenes* a bacterial genus name; M.L. masc. n. *Paralcaligenes* beside *Alcaligenes*.

Cultures comprise Gram-negative motile (with a single polar flagellum) strictly aerobic catalase- and oxidase-positive rods. The isoprenoid quinone is Q-8. The polar lipids are diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylglycerol, phosphatidylmethylethanolamine, and an unknown aminophospholipid. The major polyamines are cadaverine, putrescine, and 2-hydroxyputrescine. The dominant fatty acids are $C_{16:0}$, $C_{17:0}$ cyclo, and summed feature 1. The type species is *Paralcaligenes ureilyticus*.

After incubation on R2A agar plates at 28 °C for 2 days, colonies of *Paralcaligenes ureilyticus* are white, circular, and convex and comprise rods of ~1.2–1.8 × 0.4–0.5 μm. Acid and alkaline phosphatase, catalase esterase (C4), leucine arylamidase, naphthol-AS-BI-phosphohydrolase, and urease are produced, but not *N*-acetyl-β-glucosaminidase, arginine dihydrolase, α-chymotrypsin, cystine or valine arylamidase,

esterase lipase (C8), α-fucosidase, α- or β-galactosidase, α- or β-glucosidase, β-glucuronidase, indole, lipase (C14), α-mannosidase, oxidase, or trypsin. Nitrates are not reduced. Growth occurs at 10–30 °C (optimally at 28 °C) and at pH 4.0–8.0 (optimally at pH 6.0–7.0) and in 0–2 % (w/v) NaCl (optimally at 0–1 %). Aesculin, casein, carboxymethylcellulose, DNA, gelatin, tyrosine, and starch are not degraded. Glucose is not fermented. 3-hydroxybutyric acid, itaconic acid, lactic acid, potassium 2-ketogluconate, L-proline, propionic acid, sodium acetate, and valeric acid are assimilated, but not *N*-acetylglucosamine, adipic acid, L-alanine, L-arabinose, capric acid, L-fucose, D-glucose, glycogen, L-histidine, 3-hydroxybenzoic acid, 4-hydroxybenzoic acid, inositol, malic acid, D-maltose, D-mannitol, D-mannose, D-melibiose, phenylacetic acid, potassium gluconate, potassium 5-ketogluconate, L-rhamnose, D-ribose, D-saccharose, salicin, L-serine, sodium malonate, D-sorbitol, suberic acid, or trisodium citrate. The type strain is KACC 13888^T = DSM 24591^T, which has a G+C ratio of the DNA of 55.1 mol% (Kim et al. 2011).

Parapusillimonas Kim et al. 2010

Pa.ra.pu.sil.li.mo' nas. Gr. prep. *Par* a like; N.L. fem. n. *Pusillimonas* name of bacterial genus; N.L. fem. n. *Parapusillimonas* a bacterium like *Pusillimonas*.

Cultures comprise Gram-negative rods, which produce catalase and oxidase. Ubiquinone Q-8 is present. The major cellular fatty acids are $C_{16:0}$, $C_{17:0}$ cyclo, and summed features 3 and 5. The major polyamine is putrescine. The polar lipids are phosphatidylethanolamine, phosphatidylglycerol, and diphosphatidylglycerol. The G+C content of the DNA is 67.9 ± 0.1 mol%. The type species is *Parapusillimonas granuli*.

Parapusillimonas granuli matches the genus description, and when grown on R2A agar at 30 °C for 5 days, colonies are beige and circular with a diameter of 2 mm and comprise facultatively anaerobic rods of 0.9 × 1.5 μm in size, which are motile by means of three flagella per cell and possess fimbriae. Arginine dihydrolase, esterase (C4 and C8), leucine and valine arylamidase, and urease are produced, but not H_2S, indole, *N*-acetyl-ß-glucosaminidase acid or alkaline phosphatase, α-chymotrypsin, cystine arylamidase, α-fucosidase, α- or ß-galactosidase, ß-glucuronidase, α- or ß-glucosidase, lipase (C14), α-mannosidase, naphthol-AS-BI-phosphohydrolase, or trypsin. Nitrates are not reduced. Growth occurs at 25–37 °C [optimally at 30 °C] and at pH 6.5–7.5 [optimally at pH 7]. Utilizes adipate, L-alanine, citrate, gluconate, D-glucose, glycogen, L-histidine, 3-hydroxybenzoic acid, 4-hydroxybenzoic acid, 3-hydroxybutyric acid, inositol, lactic acid, malate, phenylacetate, potassium 2-ketogluconate, L-proline, propionic acid, L-serine, sodium acetate, D-sorbitol, and valeric acid, but not L-arabinose, caprate, L-fucose, maltose, D-mannitol, melibiose, potassium 5-ketogluconate, L-rhamnose, D-ribose, salicin, sodium malonate, or sucrose. The type strain is KCTC 12668^T = LMG 24012^T, which has a G+C ratio of the DNA of 67.9 ± 0.1 mol% (Kim et al. 2010).

Pelistega Vandamme et al. 1998

Pe.li'ste.ga. Gr. n. *peleia* pigeon; Gr. fem. n. *stege* house, stay, residence; M.L. fem. n. *Pelistega* refers to the bacteria living in pigeons.

Cultures comprise Gram-negative, asporogenous, encapsulated, microaerophilic, nonmotile cells with variable morphologies. The major fatty acid components are $C_{12:0}$, $C_{14:0}$, $C_{16:0}$, $C_{16:1}$ *ω7c*, $C_{16:1}$ *ω5c*, $C_{16:0}$ (3-OH), and summed features 3 and 7. The G+C ratio of the DNA is ~42–43 mol%. Type species is *Pelistega europaea*.

Pel. europaea produces gray-white to yellowish, convex, circular, smooth colonies with entire edges on blood agar and comprises microaerophilic, nonmotile, Gram-negative, asporogenous, capsulated cells with variable morphologies of 0.2–0.4 × 1–2 μm in size. Special growth factors are not required. Growth does not occur on MacConkey agar. Growth occurs at 37 °C and 42 °C, but not at 24 °C. Alkaline and acid phosphatase, catalase, esterase C4, ester lipase C8 and alanine, arginine, L-aspartic acid, glycine and leucine arylamidase, and oxidase are produced universally, whereas arginine dihydrolase, lipase, naphthol-AS-BI-phosphohydrolase, proline, pyroglutamic acid and tyrosine arylamidase, and urease are strain dependent, and *N*-acetyl-β-glucosaminidase, chondroitin sulfatase, chymotrypsin, cystine, leucyl glycine, glutamyl glutamic acid, histidine, phenylalanine, serine and valine arylamidase, α-fucosidase, α- and β-galactosidase, α- and β-glucosidase, β-glucuronidase, hyaluronidase, indole, lipase C14, lysine or ornithine decarboxylase, α-maltosidase, α-mannosidase, phenylalanine deaminase, and trypsin not at all. Nitrates are not reduced. The Voges-Proskauer reaction and methyl red test is negative. Aesculin and gelatin (mostly) are degraded, but not DNA or lecithin. Glucose is oxidized to alkali. Simmons citrate is utilized by some strains, but not malonate. L-malate is assimilated, but not *N*-acetyl-D-glucosamine, adipate, L-arabinose, caprate, D-gluconate, D-glucose, maltose, D-mannose, D-mannitol, or phenylacetate. Acid is not produced from *N*-acetyl-D-glucosamine, adonitol, L-arabinose, D- and L-arabitol, cellobiose, dextrin, dulcitol, D-fructose, D-galactose, galacturonate, D-glucose, inositol, lactose, lactulose, maltose, D-mannitol, D-mannose, *myo*-inositol, palatinose, rhamnose, salicin, D-sorbitol, L-sorbose, sucrose, trehalose, or D-xylose. The major fatty acid components are $C_{12:0}$, $C_{14:0}$, $C_{16:0}$, $C_{16:1}$ *ω7c*, $C_{16:1}$ *ω5c*, $C_{16:0}$ (3-OH), and summed features 3 and 7. Four genomovars are recognized. The type strain is LMG 10982 T, which has a G+C content of the DNA of 43 mol% (Vandamme et al. 1998).

Pigmentiphaga Blümel et al. 2001

Pig.men'ti.pha.ga. L. n. *pigmentum* dye; Gr. n. *phagos* eater; N.L. fem. adj. *Pigmentiphaga* eating dyes.

The genus and type species description were combined by Blümel et al. (2001) and amended by Yoon et al. (2007) to comprise cells that are motile or nonmotile. The common major

polar lipid is phosphatidylethanolamine. The G+C content of the DNA is 67.4–68.8 mol%. The type species is *Pigmentiphaga kullae*. The distinguishing traits of *Pigmentiphaga* species is given in Table 27.10.

Pig. kullae produces opaque, circular, and convex colonies, which comprise catalase- and oxidase-positive, Gram-negative, motile, asporogenous rods of 1.3–4 × 0.7–1.2 μm in size. Growth occurs at 30–42 °C, but not at 4 °C. L-alanine-*p*-nitroanilide is hydrolyzed, but not *p*-nitrophenyl β-D-galactopyranoside, *p*-nitrophenyl β-D-glucuronide, *p*-nitrophenyl α-D-glucopyranoside, *p*-nitrophenyl β-D-glucopyranoside, *p*-nitrophenyl β-D-xylopyranoside, bis-*p*-nitrophenyl phosphate, bis-*p*-nitrophenyl-phenylphosphonate, bis-*p*-nitrophenyl phosphorylcholine, L-aniline *p*-nitroanilide-L-glutamate-*p*-nitroanilide, or L-proline *p*-nitroanilide. Acetate, *cis*-aconitate, *trans*-aconitate, adipate, L-aspartate, azelate, citrate, fumarate, glutarate, 3-hydroxybenzoate, 4-hydroxybenzoate, DL-3-hydroxybutyrate, itaconate, DL-lactate, mesaconate, 2-oxoglutarate, propionate, pyruvate, and suberate are used as sole sources of carbon, but not *N*-acetylgalactosamine, *N*-acetylglucosamine, adonitol, L-alanine 4-aminobutyrate, L-arabinose, L-arbutin, D-cellobiose, D-fructose, D-galactose, gluconate, D-glucose, L-histidine, *i*-inositol, L-leucine, maltitol, D-maltose, D-mannitol, D-mannose, α-D-melibiose, L-ornithine, phenylacetate, L-phenylalanine, putrescine, L-rhamnose, D-ribose, D-sorbitol, D-sucrose, salicin, L-serine, D-trehalose, L-tryptophan, or D-xylose. Acids are not produced from adonitol, L-arabinose, D-arabitol, cellobiose, dulcitol, erythritol, glucose, inositol, lactose, maltose, D-mannitol, D-mannose, melibiose, methyl D-glucoside, raffinose, rhamnose, salicin, sorbitol, sucrose, trehalose, or D-xylose. The major isoprenoid quinone is ubiquinone Q-8. The major polar lipid is phosphatidylethanolamine, with lesser amounts of phosphatidylglycerol and diphosphatidylglycerol. The major fatty acids are $C_{10:0}$ 3-OH, $C_{14:0}$ 2-OH, $C_{16:0}$, $C_{16:0}$ 2-OH, $C_{17:0}$ cyclo, $C_{19:0}$ cyclo *ω8c*, and summed features 3 and 7. The type strain is DSM 13608^T = NCIMB 13708^T, which has G+C content of the DNA of 68.5 ± 0.3 mol% (Blümel et al. 2001).

Pig. daeguensis produces yellow-white circular to slightly irregular 1.0–2.0 mm diameter colonies on TSA after incubation at 37 °C for 3 days and contains Gram-negative, nonmotile, asporogenous rods of 0.3–0.6 × 0.7–2.5 μm in size. Growth occurs at 15–46 °C [optimally at 37 °C] and not at all at 10 °C or 47 °C, at pH 5.0–9.0 [optimally at pH 7.0–8.0] and not at pH 4.5 or 9.5, and in 0–5 % (w/v) NaCl [optimally in 0.5 % (w/v) NaCl]. Anaerobic growth does not occur on TSA or on TSA supplemented with nitrate. Arginine dihydrolase (weakly), catalase, α-chymotrypsin, esterase (C4), esterase lipase (C8), leucine arylamidase, naphthol-AS-BI-phosphohydrolase (weakly), and oxidase are produced, but not *N*-acetyl-β-glucosaminidase, acid or alkaline phosphatase, cystine or valine arylamidase, α-fucosidase, α- or β-galactosidase, β-glucuronidase, α- or β-glucosidase, lipase (C14), lysine or ornithine decarboxylase, α-mannosidase, trypsin, or tryptophan deaminase. Nitrates are not reduced. Hypoxanthine is degraded, but not aesculin; casein; gelatin starch; Tween 20, 40, 60, and 80; tyrosine; urea; or xanthine. Adipate, adonitol, citrate, and malate are utilized, but not *N*-acetylglucosamine, aesculin, amygdalin, L-arabinose, D-arabinose, D- and L-arabitol, arbutin, caprate, cellobiose, dulcitol, erythritol, fructose, D- and L-fucose, gentiobiose, galactose, gluconate, glucose, glycogen, glycerol, inositol, inulin, 2-ketogluconate, 5-ketogluconate, lactose, D-lyxose, maltose, mannitol, mannose, melezitose, melibiose, methyl α-D-glucoside, methyl α-D-mannoside, methyl β-D-xyloside, phenylacetate, raffinose, rhamnose, ribose, salicin, sorbitol, sorbose, starch, sucrose, D-tagatose, trehalose, D-turanose, xylitol, D-xylose, or L-xylose. The predominant ubiquinone is Q-8. The major polar lipids are phosphatidylglycerol, phosphatidylethanolamine, and two unidentified aminolipids. The major fatty acids are $C_{16:0}$, $C_{17:0}$ cyclo, and cyclo $C_{19:0}$ *ω8c*. The type strain is KCTC 12838^T = JCM 14330^T, which has a G+C ratio of the DNA of 67.4 mol% (Yoon et al. 2007).

Pig. litoralis produces yellow-pigmented, convex, non-translucent, glistening, circular colonies with slightly irregular edges of 1–2 mm in diameter after incubation on TSA at 28 °C for 3 days. Cultures comprise nonmotile, asporogenous, facultatively anaerobic, Gram-negative, straight to slightly curved rods of ~1.0–2.5 × 0.5–0.8 μm in size. Acid and alkaline phosphatase, arginine dihydrolase, catalase, cystine arylamidase, esterase lipase (C8), α- and β-glucosidase, lysine and ornithine decarboxylase, naphthol-AS-BI-phosphohydrolase, and oxidase are produced, but not *N*-acetyl-β-glucosaminidase, α-chymotrypsin, esterase (C4), α-fucosidase, α- or β-galactosidase, β-glucuronidase, H_2S, indole, leucine arylamidase, lipase (C14), α-mannosidase, trypsin, or valine arylamidase. Growth occurs at 4–35 °C [optimally at 25–30 °C] at pH 5.0–10.0 [optimally at pH 7.0] and in 0–5 % (w/v) NaCl [optimally at 0.5–1 %]. Aesculin is degraded, not but casein; gelatin; hypoxanthine; starch; L-tyrosine; Tween 20, 40, 60, and 80; urea; or

xanthine. The Voges-Proskauer reaction is positive. Nitrate is not reduced. Citrate is utilized. Arabinose, glucose, inositol, malate, maltose, mannitol, mannose, rhamnose, sorbitol, and sucrose are utilized, but not *N*-acetylglucosamine, adipic acid, amygdalin, capric acid, gluconate, melibiose, or potassium phenylacetic acid. Acid is produced from D-fructose, D-glucose, glycerol, D-lactose, maltose, D-mannitol, D-ribose, sucrose, trehalose, and D-xylose. The predominant respiratory quinone is ubiquinone Q-8. The polar lipids are phosphatidylethanolamine, phosphatidylglycerol, and an unidentified phospholipid. The dominant fatty acids are $C_{16:0}$, $C_{16:1}$, cyclo $C_{17:0}$, and $C_{18:1}\omega7c$. The type strain is JSM 061001^T = CCTCC AA207034^T = KCTC 22165^T, which has a G+C ratio of the DNA of 65.5 mol% (Chen et al. 2009).

Pig. soli produces pale yellow circular, convex, smooth colonies on LB after 3 days, which comprise short aerobic, motile [single subterminal flagella] Gram-negative rods of 0.7–1.0 × 0.5–0.7 μm in size. Growth occurs strongly on TSA, LB, and NA and weakly on R2A agar, at 15–42 °C but not at 4 °C [optimally at 30 °C], at pH 5–8, and up to 3 % (w/v) NaCl. Acid and alkaline phosphatase, catalase, esterase (C4), esterase (C8), leucine and valine arylamidase, naphthol-AS-BI-phosphohydrolase, and oxidase are produced, but not *N*-acetyl-β-glucosaminidase, arginine dihydrolase, α-chymotrypsin, cysteine arylamidase, α-fucosidase, α- and β-galactosidase, α- and β-glucosidase, β-glucuronidase, indole, lipase (C14), protease (gelatin), α-mannosidase, trypsin, and urease. Nitrates are not reduced. Growth occurs on acetate, adipate, caprate, citrate, D-glucose, glycogen, D,L-3-hydroxybutyrate, 4-hydroxybenzoate, L-malate, and suberate, but not *N*-acetyl-D-glucosamine, L-alanine, L-arabinose, gluconate, L-fucose, L-histidine, 3-hydroxybenzoate, itaconate, 2-ketogluconate, 5-ketogluconate, D,L-lactate, D-maltose, D-melibiose, malonate, D-mannitol, D-mannose, myo-inositol, propionate, L-rhamnose, D-ribose, salicin, L-serine, D-sorbitol, D-sucrose, phenylacetate, L-proline, or *n*-valerate. Acid is produced in D-adonitol, aesculin, amygdalin, erythritol, ferric citrate, glycerol, 2-ketogluconate, 5-ketogluconate, D-lyxose, α-methyl-D-glucopyranoside, β-methyl-D-xylose, salicin, and L-xylose, but not from *N*-acetyl-glucosamine, amidon, D-arabinose, L-arabinose, D-arabitol, L-arabitol, arbutin, D-cellobiose, dulcitol, D-fructose, D-fucose, L-fucose, D-galactose, gentiobiose, gluconate, D-glucose, glycogen, inositol, inulin, D-lactose, D-maltose, D-mannitol, D-mannose, D-melibiose, α-methyl-D-mannopyranoside, D-melezitose, D-raffinose, L-rhamnose, D-ribose, D-sucrose, D-sorbitol, L-sorbose, D-tagatose, D-trehalose, D-turanose, xylitol, or D-xylose. The major quinone is Q-8. The major polar lipids are phosphatidylethanolamine and phosphatidylglycerol. The predominant cellular fatty acids are $C_{16:0}$, $C_{17:0}$ cyclo, and summed features 3 and 8. The type strain = KCTC 23577^T = JCM 17666^T = KEMB 9004-082^T, which has a G+C ratio of the DNA of 67.3 mol% (Lee et al. 2011). Since its description in the Journal of Microbiology, the name has not been validated in the International Journal of Systematic and Evolutionary Microbiology.

Pusillimonas Stolz et al. 2005

Pu.sil.li.mo' nas. L. adj. *pusillus* very small/min; Gr. fem n. *monas* unit/monad; N.L. fem. n. *Pusillimonas* very small monad/unicell, referring to the small size of cells and colonies of the type species.

Cultures comprise small Gram-negative, oxidase-positive oxidative rods. The major isoprenoid quinone is ubiquinone Q-8. Putrescine, spermidine, and 2-hydroxyputrescine are the major polyamines. Major polar lipids are two unknown aminolipids, phosphatidylglycerol, diphosphatidylglycerol, and phosphatidylethanolamine (Stolz et al. 2005). The major fatty acids are $C_{16:0}$, $C_{17:0}$ cyclo, and summed feature 2 (Park et al. 2011). The G+C content of the DNA is in the range of 53.1–61.8 mol% (Park et al. 2011). The type species is *Pusillimonas noertemannii* (Stolz et al. 2005). The distinguishing traits of *Pusillimonas* species are given in Table 27.11.

Pus. noertemannii develops brownish circular colonies with entire edges on NA and comprises Gram-negative polarly flagellated rods of 1–1.5 × 0.5–0.8 μm in size, which grow at 30–42 °C but not 4 °C. L-alanine-*p*-nitroanilide is hydrolyzed, but not L-aniline-*p*-nitroanilide, γ-L-glutamate-*p*-nitroanilide, *p*-nitrophenyl β-D-galactopyranoside, *p*-nitrophenyl β-D-glucuronide, *p*-nitrophenyl α-D-glucopyranoside, *p*-nitrophenyl β-D-glucopyranoside, bis-*p*-nitrophenyl phosphate, bis-*p*-nitrophenyl-phenylphosphonate, bis-*p*-nitrophenyl-phosphoryl choline, *p*-nitrophenyl β-D-xylopyranoside, or L-proline–*p*-nitroanilide. Acetate, 4-hydroxybenzoate, DL-3-hydroxybutyrate, DL-lactate, 2-oxoglutarate propionate, and pyruvate are used as the sole sources of carbon, but not *N*-acetylgalactosamine, *N*-acetylglucosamine, *cis*-aconitate, *trans*-aconitate, adipate, adonitol, L-alanine, 4-aminobutyrate, L-arabinose, L-arbutin, L-aspartate, D-cellobiose, citrate, D-fructose, fumarate, D-galactose, gluconate, D-glucose, glutarate, L-histidine, 3-hydroxybenzoate, *i*-inositol, itaconate, L-leucine, L-malate, maltitol, D-maltose, D-mannitol, D-mannose, α-D-melibiose, L-ornithine, phenylacetate, L-phenylalanine, putrescine, L-rhamnose, D-ribose, salicin, L-serine, D-sorbitol, D-sucrose, D-trehalose, L-tryptophan, or D-xylose. Acid is not produced from adonitol, L-arabinose, D-arabitol, cellobiose, dulcitol, erythritol, glucose, inositol, lactose, maltose, D-mannitol, D-mannose, melibiose, methyl D-glucoside, raffinose, rhamnose, salicin, sorbitol, sucrose, trehalose, or D-xylose. The dominant fatty acids comprise $C_{16:0}$, $C_{17:0}$, and $C_{19:0}$ cyclo $\omega8c$. The type strain = DSM 10065^T = NCIMB 14020^T, which has a G+C content of the DNA of 61.8 mol% (Stolz et al. 2005).

Pus. ginsengisoli produces pale yellow, circular colonies with entire edges after growth on NA at 30 °C for 5 days and comprises Gram-negative, aerobic, motile rods of 0.5–0.8 × 0.3–0.6 μm. Grows at 15–40 °C (optimally at 30 °C), but not at 4 °C or 42 °C, and at pH 5.5–9.0 (optimally at pH 7.0). Acid and alkaline phosphatase, catalase, α-chymotrypsin, cystine and leucine and valine arylamidase, esterase (C4), esterase (C8), naphthol-AS-BI-phosphohydrolase, oxidase, and trypsin are produced, but not *N*-acetyl-β-glucosaminidase, arginine

dihydrolase, α-fucosidase, α- or β-galactosidase gelatinase, α- or β-glucosidase, β-glucuronidase, lipase (C14), α-mannosidase, or urease. Acetate, adipate, L-alanine, citrate, 3-hydroxybutyrate, itaconate, DL-lactate, L-malate, phenylacetate, L-proline, propionate, L-serine, and *n*-valerate are assimilated, but not *N*-acetyl-D-glucosamine, L-arabinose, caprate, L-fucose, gluconate, D-glucose, glycogen, L-histidine, 3-hydroxybenzoate, 4-hydroxybenzoate, 2-ketogluconate, 5-ketogluconate, maltose, D-mannitol, D-mannose, melibiose, *myo*-inositol, L-rhamnose, salicin, D-sorbitol, suberate, or sucrose. The predominant quinone is Q-8. The predominant polar lipids are phosphatidylethanolamine and phosphatidylglycerol. The major fatty acids are $C_{19:0}$ cyclo *ω8c*, $C_{14:0}$, $C_{16:0}$, $C_{18:0}$, and summed features 2 and 8. The type strain is KCTC 22046^T = JCM 14767^T, which has a G+C ratio of the DNA of 57.3 mol% (Srinivasan et al. 2010).

Pus. harenae develops ivory, round, convex colonies with entire edges on R2A agar and comprises strictly aerobic, Gram-negative, motile [with two lateral flagella] rods of 0.5–0.7 × 0.6–0.9 μm in size. Growth occurs at 15–45 °C [optimally at 30 °C], at pH 5.0–9.0 [optimally at pH 6.0–7.5], and in 0–6 % (w/v) NaCl [optimally in 0–3 % w/v NaCl]. Acid phosphatase, alkaline phosphatase (weak), catalase, α-chymotrypsin (weak), esterase (C4), esterase lipase (C8), cysteine, leucine and valine arylamidases, naphthol-AS-BI-phosphohydrolase, oxidase, and trypsin (weak) are produced, but not *N*-acetyl-β-glucosaminidase, arginine dihydrolase, α-fucosidase, α- or β-galactosidase, α- or β-glucosidase, β-glucuronidase, α-mannosidase, indole, or lipase (C14). Nitrates are not reduced. Urea is degraded, but not aesculin or gelatin. Adipic acid and malic acid are assimilated, but not *N*-acetylglucosamine,

L-arabinose, capric acid, D-glucose, maltose, D-mannitol, D-mannose, phenyl acetic acid, potassium gluconate, or trisodium citrate. Acid is not produced from glucose. The major cellular polar lipids are diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylglycerol, an unidentified phospholipid, and three aminolipids. The major acids are $C_{16:0}$, $C_{17:0}$ cyclo, $C_{19:0}$ cyclo *ω8c*, and summed feature 2. The type strain is KACC 14927^T = JCM 16917^T, which has a G+C ratio of the DNA of 53.1 mol% (Park et al. 2011).

Pus. soli comprises asporogenous Gram-negative catalase- and oxidase-positive motile rods of 0.7–1.0 × 0.3–0.5 μm in size. Growth occurs optimally at 30 °C and at pH 6.5–7.0 [range = pH 5.0–9.0]. Nitrates are reduced to gaseous nitrogen. Neither casein, cellulose, chitin, DNA, starch, nor xylan is attacked. Acetate, DL-3-hydroxybutyrate and DL-lactate are utilized, but not *N*-acetyl-D-glucosamine, L-arabinose, L-fucose, gluconate, D-glucose, glycogen, 2-ketogluconate, 5-ketogluconate, maltose, D-mannitol, D-mannose, melibiose, salicin, or sucrose. Esterase (C4) and esterase lipase (C8) are produced, but not *N*-acetyl-β-glucosaminidase, α-fucosidase, α- or β-galactosidase, α- or β-glucosidase, β-glucuronidase, lipase (C14), or α-mannosidase. The major polar lipids are phosphatidylethanolamine, phosphatidylglycerol, diphosphatidylglycerol, and two unknown aminolipids. The major fatty acids are $C_{16:0}$, $C_{17:0}$ cyclo, and $C_{19:0}$ cyclo *ω8c*. The type strain = KCTC 22455^T = JCM 16386^T, which has a G+C ratio of the DNA of 59.4 mol% (Lee et al. 2010b).

Taylorella Sugimoto et al. 1983

Tay.lor. el'la M. L. gen. n. *Taylorella*, named after C.E.D. Taylor who first studied the organism.

Cultures comprise microaerophilic [growth in 5–10 % CO_2], chemoorganotrophic, asporogenous, nonmotile, Gram-negative coccobacilli to rods that do not grow on conventional media, and poorly if at all on blood agar. Good growth occurs on chocolate agar but is not stimulated with X- and V-factors. Growth occurs at 30–42 °C [optimally at 35–37 °C]. Catalase, oxidase, phosphatase, and phosphoamidase are produced, but not arginine dihydrolase, H_2S, indole, or lysine or ornithine decarboxylase. Nitrates are not reduced. Neither DNA, gelatin, lipids, nor urea is degraded. Acid is not produced from carbohydrates. The type strain is *T. equigenitalis*. The distinguishing traits of *Taylorella* species is given in Table 27.12.

T. equigenitalis matches the genus description. In addition, cultures produce circular, convex, smooth, gray-white colonies with entire edges of 1.0–1.5 mm diameter on Eugon agar supplemented with heated blood after incubation for 3–4 days. Leucine and lysine arylamidase are produced, but not *N*-acetyl-glucosaminidase, chymotrypsin, esterase (C4 and C8), α- or β-fucosidase, α- or β-galactosidase, α- or β-glucosidase, β-glucuronidase, α-mannosidase, phenylalanine deaminase, or trypsin. The G+C ratio of the DNA is 36.5–37.0 mol% (Sugimoto et al. 1983). The type strain is NCTC 11184^T (Sugimoto et al. 1983).

Naphthol-AS-BI-phosphohydrolase[a]	+ [weak]	–

[a]Data from API ZYM

T. asinigenitalis produces tan colonies of ~1 mm in diameter that are entire, convex, opaque, and sometimes viscid in consistency after growth on ECA for 48 h. Cultures comprise Gram-negative, nonmotile coccobacilli that are catalase- and oxidase-positive and asaccharolytic and do not reduce nitrate. Alkaline phosphatase and leucine arylamidase are produced, but not indole and urease; aesculin is not degraded, nor is the methyl red test or Voges-Proskauer reaction positive. Growth does not occur on MacConkey agar or ECA medium incubated in air or anaerobically at 37 °C. Growth occurs microaerophilically and in air with 5–7 % CO_2 at 37 °C, but not at 24 °C or 42 °C. Growth is not stimulated by hemin or NAD. The major fatty acids are $C_{16:0}$, $C_{18:0}$, $C_{19:0}$ 10-methyl, and summed features 3, 4, and 7. The type strain is ATCC 700933^T = LMG 19572^T, and the G+C ratio of the DNA is 37.8 mol% (Jang et al. 2001).

Isolation, Enrichment, and Maintenance Procedures

Comparatively simple to complex media may be needed to isolate and culture the component taxa of *Alcaligenaceae*. Many representatives grow well on TSA with incubation at 25–37 °C for 1–2 days. Examples include *Ach. insolitus*, *Ach. spanius* and *Alc. denitrificans*, *Advenella*, *Kerstersia*, *Bor. avium*, *Bor. hinzii*, *Bor. trematum*, and *Pig. daeguensis* (Kersters et al. 1984; Vandamme et al. 1995; 1996; 2012; Coenye et al. 2003a, b; 2005; Van Trappen et al. 2005; Yoon et al. 2007). *Pel. europaea* needed microaerophilic conditions with TSA incubated at 36–37 °C (Vandamme et al. 1998). *Pig. litoralis* produced colonies on TSA prepared in 50 % seawater with incubation at 28 °C for 14 days (Chen et al. 2009). NA supported the growth of *Castellaniella* with incubation at 30 °C (Kämpfer et al. 2006). *Candidimonas* was cultured on PCA or R2A agar with incubation at 25–30 °C for 48 h (Vaz-Moreira et al. 2011; Zhang et al. 2012). *Pig. kullae* produced colonies on LB agar within 3 days at 37 °C (Blümel et al. 2001) whereas *Alc. faecalis* subsp. *parafaecalis* needed 48 h incubation (Schroll et al. 2001), and *Pus. soli* involved incubation at 30 °C for 2 weeks (Lee et al. 2010b). *Alc. faecalis* subsp. *phenolicus* and *Parapusillimonas granuli* were cultured on R2A agar with incubation at 30 °C (Rehfuss and Urban 2005; Kim et al. 2010). Similarly, *D. lacustris* was isolated on R2A agar after incubation at 25 °C for

3 days (Chen et al. 2013), whereas *Paralcaligenes ureilyticus* involved incubation at 28 °C for 5 days (Kim et al. 2011). Subculturing was achieved on nutrient agar but rarely on TSA and not at all on MacConkey agar (Kim et al. 2011). *Pig. soli* and *Pus. ginsengisoli* grew initially and were isolated on tenfold dilute R2A with incubation at 30 °C (Srinivasan et al. 2010; Lee et al. 2011). *Bra. oedipodis* was found using Columbia agar with cultivation aerobically at 37 °C for 24 h (Willems et al. 2002). *Cas. caeni* and *Cas. daejeonensis* were recovered on R2A agar with incubation at 30 °C for 2 weeks (Liu et al. 2008; Lee et al. 2010a). Also, *Cas. ginsengisoli* was recovered on R2A agar and was routinely cultured on LB agar with incubation at 30 °C (Kim et al. 2009). *Bor. bronchiseptica* may be isolated on Levine eosin-methylene blue agar (Smith and Baskerville 1979) whereas *Bor. petrii* was recovered anaerobically on RAMM medium of Shelton and Tiedje (1984) with incubation at 30 °C for 7 days (Von Wintzingeroda et al. 2001). *Pus. harenae* was recovered using marine 2216E agar with incubation aerobically at 25 °C for 5 days and grown routinely on R2A agar at 30 °C for 3 days (Park et al. 2011).

D. gummosa was recoverable on a nitrogen-free mineral medium supplemented with mannitol (Jensen et al. 1960). *Ach. marplatensis* was isolated in a mineral salt basal medium supplemented initially with 5 mg L^{-1} increasing to 100 mg $L^{-1}$of pentachlorophenol as the sole source of carbon (Gomila et al. 2011). *Adv. kashmirensis* was recovered from soil supplemented with 5 % sodium thiosulfate and 5 % elemental sulfur powder with incubation at 30 °C for 2 weeks with intermittent moistening with sterile water (Ghosh et al. 2005). The enriched samples were added to a modified basal and mineral salts solution (MSTY) with 20 mM sodium thiosulfate and 0.05 % yeast extract with incubation at 30 °C on a rotary shaker until phenol red indicator turned from red to yellow. Serial dilutions were plated on MSTY agar within incubation at 30 °C. The cultures were maintained in LB broth (Ghosh et al. 2005). *Adv. mimigardefordensis* was recovered by enrichment culture of mature compost involving a mineral salts medium supplemented with 0.5 % (w/v) 3, 3′-dithiodipropionic acid as the sole source of carbon with incubation at 30 °C for ∼1 week. Afterwards, serial dilutions were spread over mineral salts medium agar plates incorporating 0.5 % (w/v) 3, 3′-dithiodipropionic acid with incubation at 30 °C for 7 days (Wübbeler et al. 2006).

Richer media were required for some bordetellas, namely, *Bor. avium*, which grew well on Columbia agar supplemented with 7 % (v/v) defibrinated ox blood and on veal infusion agar (Kersters et al. 1984; Vandamme et al. 1995; 1996). *Bor. holmesii* was cultured on heart infusion agar supplemented with 5 % (v/v) rabbit blood in a candle jar at 35 °C (Weyant et al. 1995). *Bor. pertussis* and *Bor. parapertussis* were recoverable from human specimens on brilliant green medium modified with 16–20 % blood with incubation at 35–37 °C for up to 7 days (Kendrick and Eldering 1969). *Oligella* grew slowly on nutrient agar especially supplemented with blood, serum, or yeast autolysate (Rossau et al. 1987). *Pae. hominis* was discovered using blood agar with incubation at 37 °C with subculturing on nutrient agar at 30 °C for 24 h (Kämpfer et al. 2010). *Pus. noertemannii* grew strongly on chocolate-blood agar with incubation at 37 °C for 3–4 days, less well on sheep blood agar, and weakly on LB and NA (Stolz et al. 2005). *T. asinigenitalis* was cultured in 5–7 % CO_2 on Eugon agar supplemented with 10 % (v/v) laked horse blood and containing clindamycin and trimethoprim (Jang et al. 2001). In comparison, *T. equigenitalis* grew on Eugon agar with 5 % (v/v) Fildes digested sheep blood (Sugimoto et al. 1983).

Ecology

Habitat

Alcaligenaceae representatives occupy a diverse range of ecological niches from water and soil to animals and display a range of roles including the degradation of macromolecules, nitrogen fixation, and pathogenesis. *Ach. marplatensis* came from soil contaminated with pentachlorophenol in Argentina (Gomila et al. 2011), whereas *Adv. kashmirensis* was recovered from orchard soil and characteristically oxidized reduced sulfur compound, namely, tetrathionate and thiosulfate (Ghosh et al. 2005). *Adv. mimigardefordensis* was associated with compost and was capable of utilizing 3,3′-dithiodipropionic acid (Wübbeler et al. 2006). *Alcaligenes* spp. have been found in soil, water, hospitals, and clinical material (Coenye et al. 2003b). In particular, *Alc. aquatilis* was cultured from estuarine sediment and a salt marsh in Germany and the USA, respectively (Van Trappen et al. 2005). A solvent-tolerant strain capable of converting acetone-butanol residues into poly-β-hydroxybutyrate was recovered from water in a eutrophic garden pond, and identified as a new center of variation in *Alc. faecalis*, and named as *Alc. faecalis* subsp. *parafaecalis* (Schroll et al. 2001). In comparison, *Alc. faecalis* subsp. *phenolicus* is a phenol-degrading denitrifier, which was first identified in a graywater bioprocessor in the Johnson Space Center (Rehfuss and Urban 2005). *Bor. petrii* was recovered from an anaerobic dechlorinating bioreactor enriched from river sediment and was capable of aerobically reducing selenate to elemental selenium (Von Wintzingeroda et al. 2001). *Can nitroreducens*, *Can. humi*, and *Can. bauzanensis* were present in sewage sludge compost and soil, respectively (Vaz-Moreira et al. 2011; Zhang et al. 2012). *Cas. defragrans* was cultured from soil and demonstrated the ability to utilize alkenoic monoterpenes (Foss et al. 1998) and degrade phenol and taurine (Baek et al. 2003; Ruff et al. 2003). The denitrifier *Cas. caeni* was found in sludge in a leachate treatment plant in South Korea (Liu et al. 2008) whereas *Cas. daejeonensis* and *Cas. ginsengisoli* were isolated from oil-contaminated soil and ginseng field surface soil also in South Korea (Kim et al. 2009; Lee et al. 2010b). *D. gummosa* and *D. lacustris* were isolated initially from soil and lake water, respectively, and demonstrated nitrogen-fixing traits (Jensen et al. 1960; Chen et al. 2005). *Par. granuli* was obtained from environmental samples, namely, granules within a wastewater-treatment bioreactor in an alcohol fermentation factory in South Korea (Kim et al. 2010). *Pig. daeguensis* originated from wastewater from a dye works in South Korea (Yoon et al. 2007).

Moreover, *Pig. kullae* decolorized azo dyes, i.e., 1-(4′-carboxyphenylazo)-4-naphthol, as the sole source of carbon and energy (Blümel et al. 2001). *Pig. litoralis* was recovered from tidal flat sediment in China (Chen et al. 2009), and *Pig. soli* was found in South Korean soil (Lee et al. 2011). *Pus. harenae* was initially present in beach sand from the Taean coast of South Korea (Park et al. 2011). In comparison, *Pus. noertemannii* was isolated from river water and degraded 5-aminosalicylate (Stolz et al. 2005). Another member of the same genus, *Pus. soli* was recovered from farm soil (Lee et al. 2010b) whereas *Pus. ginsengisoli* was cultured from soil in a ginseng field located in South Korea (Srinivasan et al. 2010). *Paralcaligenes ureilyticus* was isolated from soil cultivated with Korean ginseng (Kim et al. 2011).

Bordetella spp. have been often isolated from epithelial cilia of the respiratory tract and from blood, being pathogenic for warm-blooded animals including humans. Thus, *Bor. holmesii* was obtained from blood cultures of young human adults (Weyant et al. 1995). *Bra. oedipodis* was recovered from the enlarged heart of a cotton-topped tamarind (*Saguinus oedipus*), which was devoid of disease signs and had died suddenly after a tooth extraction (Willems et al. 2002). *Kerstersia* was originally recovered from human clinical material (Coenye et al. 2003b) whereas *O. urethralis* was cultured from human urine, being considered as commensals of the genitourethral tract (Rossau et al. 1987). *T. asinigenitalis* was described from the genital tract of male donkeys in the USA (Jang et al. 2001).

Pathogenicity, Clinical Relevance

Many *Alcaligenaceae* representatives have been recovered from animals, with some taxa associated with disease as opportunists and primary pathogens. *Ach. insolitus* and *Ach. spanius* have been recovered from human clinical samples, with the former from wounds and urine and the latter from blood (Coenye et al. 2003a). *Bor. hinzii* has been recovered from humans and the respiratory tracts of poultry, but not necessarily linked with pathogenicity (Vandamme et al. 1995). Also, *T. asinigenitalis* was isolated from the genital tract of male donkeys but there was not any evidence of disease (Jang et al. 2001). *Ach. xylosoxidans* may be pathogenic of compromised patients (Yabuuchi and Yano 1981), including the cause of respiratory tract infections in cystic fibrosis patients (Lambiase et al. 2011) and prosthetic valve endocarditis in catheterized dialysis patients (Ahmed et al. 2009), and may be attributed with specific infections, such as osteomyelitis (Ozer et al. 2012) and ocular infections (Reddy et al. 2009). *Alc. faecalis* has been recovered from chickens and linked with respiratory disease (Berkhoff et al. 1984). Of the more serious pathogens, *Bor. pertussis*, *Bor. parapertussis*, *Bor. bronchiseptica*, *Bor. avium*, and *Bor. holmesii* are the causal agents of whooping cough, a milder form of disease, a severe respiratory disease mostly in dogs [= kennel cough] and pigs, coryza (= rhinotracheitis) in turkey poults and other birds, and septicaemia in humans, respectively (LeLey et al. 1986; Weyant et al. 1995; Willems et al. 2002). *Bor. avium* has been recovered initially from the respiratory tracts of turkeys and other birds, being associated with coryza/rhinotracheitis in turkey poults (Kersters et al. 1984). *Pel. europaea* was associated with respiratory disease in pigeons (Vandamme et al. 1998). The first cultures of *Bor. trematum* was obtained from wound and ear infections (Vandamme et al. 1996) whereas *Bra. oedipodis* was cultured from an enlarged heart [= endocarditis] of a cotton-topped tamarind, which died suddenly after a tooth extraction (Willems et al. 2002). *Kerstersia* was recovered from human clinical material, namely, leg/ankle wounds, sputum, feces, and neck abscess (Coenye et al. 2003b; Vandamme et al. 2012), whereas *Pen. hominis* was sourced from human blood of an 85-year-old male (Kämpfer et al. 2010). Finally, *T. equigenitalis* was associated with contagious equine, which is a serious venereal disease of horses (Platt et al. 1977; Sugimoto et al. 1983).

Application

Waste Treatment and Removal

Alc. faecalis, which were recovered from green water, nitrified heterotrophically ammonia into nitrite via formation of hydroxyl amine. This was oxidized to nitrous oxide using oxygen or nitrite as electron acceptor (Velusamy and Krishnani 2013). *Bordetella* Sulf-8 metabolized thiosulfate or sulfide into sulfate and degraded H_2S in a biotrickling filter system. In batch experiments, sulfur was removed at a rate of 88 mg S g^{-1} cells h^{-1} (Nisola et al. 2010). *Pigmentiphaga*-related DNA sequences were associated with naphthalene and phenanthrene degradation in contaminated soil (Jones et al. 2011). *T. kashmirensis*, which was recovered from soil, tolerated 64 mM selenite and detoxified it by aerobic reduction to insoluble elemental red selenium (Hunter and Manter 2008). Tannin-degrading *T. kashmirensis* was considered to have a role in the composting of olive mill waste (Federici et al. 2011).

Bioremediation

A thermophilic isolate of *Alc. faecalis*, which was recovered from crude oil-contaminated soil in India, produced a new class of glycolipid biosurfactant in medium supplemented with 2 % (v/v) diesel as the carbon and energy source. The biosurfactant demonstrated high emulsifying activity against hydrocarbons and was considered to have potential value in the bioremediation of hydrocarbon spillages (Bharali et al. 2011). *Achromobacter* was identified as part of a microbial consortium of six isolates involved in the bioremediation of hydrocarbon-rich industrial wastewater effluents, with possible value to petroleum refineries and the petrochemical industry (Gargouri et al. 2011). Also, *Achromobacter* in the presence of mineral salts solution was associated with 92 % bioremediation of polycyclic aromatic hydrocarbon-contaminated soil within 20 days; there was 99 % remediation after 8 weeks (Cutright and Lee 1994).

Family representatives have been attributed with a range of other bioremediation activities, including involvement in the aerobic degradation of glyphosate-contaminated soils by *Achromobacter* (Ermakova et al. 2010), the decoloration of dark brown-colored distillery effluent [due to the presence of high concentrations of melanoidin, which is an amino carbonyl polymer, phenolics, heavy metals, and sulfate] by *Ach. xylosoxidans* (Chaturvedi et al. 2006), the biotransformation of the herbicide with 100 $\mu g\ L^{-1}$ of terbuthylazine in a groundwater microcosm by *Adv. incenata* (Caracciola et al. 2010), the degradation of naphthalene and toluene in liquid culture by *Bor. petrii* (Bianchi et al. 2005), the mineralization of 1.2,4-trichlorobenzene in soil by *Bor. petrii* (Wang et al. 2007), and the in situ removal of nitrate in groundwater by *Castellaniella* (Spain et al. 2007).

Formation of Added-Value Products

Adv. mimigardefordensis SHX22 was genetically modified to produce poly(3-mercaptopropionic acid) (PMP) homopolymer. SHX22 accumulated PMP to ~25 % (w/w) of cell dry weight when grown in a mineral salts medium containing glycerol as the carbon source in addition to 3,3′-dithiodipropionic acid as a precursor (Xia et al. 2012).

Enzymes

Alcaligenaceae representatives are associated with the production of a diverse range of enzymes. For example, *Achromobacter* has been described as producer of collagenolytic enzymes, i.e., zinc-containing metalloenzymes, which have importance in biotechnology and medicine (Demina and Lysenko 1996).

28 The Family *Burkholderiaceae*

Tom Coenye
Laboratory of Pharmaceutical Microbiology, Ghent University, Ghent, Belgium

Abstract
The family *Burkholderiaceae* belongs to the order *Burkholderiales* within the class *Betaproteobacteria*. It contains the genera *Burkholderia* (the type genus), *Chitinimonas*, *Cupriavidus*, *Lautropia*, *Limnobacter*, *Pandoraea*, *Paucimonas*, *Polynucleobacter*, *Ralstonia*, *Thermothrix*, and *Wautersia*. The family is characterized by the presence of ecologically extremely diverse organisms and contains truly environmental saprophytic organisms, phytopathogens, opportunistic pathogens, as well as primary pathogens for humans and animals.

Taxonomy: Historical and Current

Short Description of the Family

Burk.hol.de.ri.a'ce.ae. M.L. fem. n. *Burkholderia* type genus of the family, *-aceae* ending to denote family; M.L. pl. n. *Burkholderiaceae*, the *Burkholderia* family.

The description is an emended version of the description given in *Bergey's Manual*, 2nd edition (Garrity et al. 2005). Family is phenotypically, metabolically, and ecologically extremely diverse and includes both strict aerobic and facultatively anaerobic chemoorganotrophs, as well as obligate and facultative chemolithotrophs. Based on phylogenetic analysis of 16S rRNA gene sequences, the family *Burkholderiaceae* contains the genera *Burkholderia* (the type genus), *Cupriavidus*, *Lautropia*, *Limnobacter*, *Pandoraea*, *Paucimonas*, *Polynucleobacter*, *Ralstonia*, and *Thermothrix*. In addition to these genera, the family also contains the more recently described genera *Chitinimonas* and *Wautersia*. Together with the families *Alcaligenaceae*, *Comamonadaceae*, and *Oxalobacteraceae*, the family *Burkholderiaceae* belongs to the order *Burkholderiales* within the class *Betaproteobacteria*.

Taxonomic History and Phylogenetic Structure of the Family and Its Genera

Historically, the taxonomy of the family *Burkholderiaceae* has its basis in studies on the genus *Pseudomonas* (reviewed by Kersters et al. 1996). Due to its broad and vague phenotypic definition, a lot of incompletely characterized, polarly flagellated, rod-shaped, aerobic, Gram-negative bacteria were placed in the genus *Pseudomonas*, but following results obtained by rRNA-DNA hybridizations, the genus was divided into five so-called rRNA groups by Palleroni et al. (1973). Later De Vos et al. (1985) demonstrated that these five groups were only distantly

E. Rosenberg et al. (eds.), *The Prokaryotes – Alphaproteobacteria and Betaproteobacteria*, DOI 10.1007/978-3-642-30197-1_239,

related to each other and that the genuine genus *Pseudomonas* had to be restricted to the group containing the type species *Pseudomonas aeruginosa* (rRNA group I or the *Pseudomonas fluorescens* rRNA branch). The seven species ([*Pseudomonas*] *solanacearum*, [*Pseudomonas*] *pickettii*, [*Pseudomonas*] *cepacia*, [*Pseudomonas*] *gladioli*, [*Pseudomonas*] *mallei*, [*Pseudomonas*] *pseudomallei*, and [*Pseudomonas*] *caryophylli* belonging to rRNA group II (the so-called solanacearum rRNA branch)) were transferred to the new genus *Burkholderia* in 1992 by Yabuuchi et al. [*Burkholderia*] *pickettii* and [*Burkholderia*] *solanacearum* were subsequently transferred to the novel genus *Ralstonia* (Yabuuchi et al. 1995). The genus *Burkholderia* belongs to rRNA superfamily III *sensu* De Ley (1992) or subgroup beta-3 of the *Betaproteobacteria sensu* Woese (1987). In the last decades, the genus *Burkholderia* has been expanded considerably, now containing well over 60 species (see http://www.bacterio.cict.fr/b/burkholderia.html for an up-to-date overview). The closest neighbor of the genus *Burkholderia* is the genus *Pandoraea*, described by Coenye et al. in 2000. Besides the previously described species [*Burkholderia*] *norimbergensis*, the genus initially contained four other species (*Pandoraea apista*, *Pandoraea pnomenusa, Pandoraea pulmonicola*, and *Pandoraea sputorum*) and was more recently expanded with the species *Pandoraea thiooxydans* (Anandham et al. 2010) and *Pandoraea oxalativorans*, *Pandoraea faecigallinarum*, and *Pandoraea vervacti* (Sahin et al. 2011). Besides these named species, the genus *Pandoraea* also contains four unnamed genomospecies (Coenye et al. 2000; Daneshvar et al. 2001).

A second major phylogenetic cluster within the family contains the genera *Cupriavidus, Ralstonia*, and *Wautersia*. As already mentioned above, the genus *Ralstonia* was created to accommodate two misclassified *Pseudomonas* species (*Ralstonia pickettii* and *Ralstonia solanacearum*) as well as a misclassified *Alcaligenes* species (*Ralstonia eutropha*) (Yabuuchi et al. 1995). Over the next few years, a number of other *Ralstonia* species were described (either novel species or previously misclassified taxa), including *Ralstonia basilensis* (Steinle et al. 1998; Goris et al. 2001), *Ralstonia campinensis* (Goris et al. 2001), *Ralstonia gilardii* (Coenye et al. 1999), *Ralstonia insidiosa* (Coenye et al. 2003), *Ralstonia mannitolilytica* (De Baere et al. 2001), *Ralstonia metallidurans* (Goris et al. 2001), *Ralstonia oxalatica* (Sahin et al. 2000), *Ralstonia paucula* (Vandamme et al. 1999), *Ralstonia respiraculi* (Coenye et al. 2003b), *Ralstonia syzygii* (formerly known as [*Pseudomonas syzygii*]) (Vaneechoutte et al. 2004), and *Ralstonia taiwanensis* (Chen et al. 2001). In 2004 Vaneechoutte et al. reported that two sublineages (>4 % dissimilarity in the 16S rRNA gene sequence) could be distinguished within the genus *Ralstonia* and proposed to reclassify the species belonging to the so-called *Ralstonia eutropha* lineage (*R. basilensis*, *R. campinensis*, *R. eutropha*, *R. gilardii*, *R. metallidurans*, *R. oxalatica*, *R. paucula*, *R. respiraculi*, and *R. taiwanensis*) in the novel genus *Wautersia*, with *Wautersia eutropha* as the type species. However, in 2004, Vandamme and Coenye demonstrated that *W. eutropha* (the type species of the genus *Wautersia*) is a later heterotypic synonym of *Cupriavidus necator* (the type species of the genus *Cupriavidus*, described by Makkar and Casida in 1987). According to Rule 37a of the Bacteriological Code, this meant that the name *Wautersia* had to be replaced by *Cupriavidus*, and all *Wautersia* species were renamed as *Cupriavidus* species. Only a single species remains in the genus *Wautersia, Wautersia numazuensis* (described in 2005 by Kageyama et al.), but its close phylogenetic relationship with *Cupriavidus* species strongly suggests it should be reclassified in this genus. Since its creation, three novel species were added to the genus *Cupriavidus*, namely, *Cupriavidus pinatubonensis* and *Cupriavidus laharis* (Sato et al. 2006) and *Cupriavidus pampae* (Cuadrado et al. 2010). Estrada-de Los Santos et al. (2012) recently proposed the name *Cupriavidus alkaliphilus* for plant-associated isolates. At the time of writing, this name has not been validated yet.

Besides the *Burkholderia/Pandoraea* group and the *Cupriavidus/Ralstonia/Wautersia* group, several other genera belong to the family *Burkholderiaceae*, namely, the genera *Chitinimonas*, *Lautropia*, *Limnobacter*, *Paucimonas*, *Polynucleobacter*, and *Thermothrix*.

The genus *Chitinimonas* (Chang et al. 2004), containing the species *Chitinimonas taiwanensis* (Chang et al. 2004) and *Chitinimonas koreensis* (Kim et al. 2006), forms a separate branch in the 16S rRNA-based phylogenetic tree and is only distantly related to other members of this family. Actually, this genus appears to be more closely related to members of the *Neisseriaceae* and its exact phylogenetic affiliation probably will need to be revised.

Limnobacter and *Lautropia* species (*Limnobacter thiooxidans, Limnobacter litoralis*, and *Lautropia mirabilis*) (Gerner-Smidt et al. 1994; Spring et al. 2001; Lu et al. 2011) occupy a position between both major phylogenetic groups but are more closely associated with the *Burkholderia/Pandoraea* group.

The genus *Paucimonas* (containing a single species, *Paucimonas lemoignei*) (Jendrossek 2001) appears to occupy a position somewhat between the *Burkholderiaceae* and the *Oxalobacteraceae*.

The genus *Polynucleobacter* contains five species (*Polynucleobacter acidophilus, Polynucleobacter cosmopolitanus, Polynucleobacter difficilis, Polynucleobacter necessarius* [with subspecies *necessarius* and *asymbioticus*], and *Polynucleobacter rarus*) (Heckmann and Schmidt 1987; Hahn et al. 2009, 2010, 2011a, b, 2012). Although it occupies a distinct position within the tree, its closest relatives are members of the *Cupriavidus/Ralstonia/Wautersia* group.

Finally, the genus *Thermothrix*, containing the species *Thermothrix azorensis* and *Thermothrix thiopara* (Odintsova et al. 1996; Caldwell et al. 1976), appears to be unrelated to any other member of this family and its deep-branching position suggests it should be reclassified.

Molecular Analyses

DNA-DNA Hybridization Studies

The vast majority of descriptions of species of the genera belonging to the family *Burkholderiaceae* include results of

DNA-DNA hybridization experiments. Overall species can easily be distinguished from each other as DNA-DNA binding values between representatives of different species are below 30 %. However, within the *Burkholderia cepacia* complex, representatives of different species generally have DNA-DNA hybridization values between 30 % and 60 %, while values obtained from strains belonging to the same species are generally higher than 70 %. DNA-DNA binding values obtained with other *Burkholderia* species are generally below 30 % (Coenye et al. 2001). The same appears to be true to some extent for *Pandoraea* species (with values up to 45 % between strains from different species) (Coenye et al. 2000) and certain *Ralstonia* species, e.g., hybridization values up to 58 % between *Ralstonia pickettii* and *Ralstonia mannitolilytica* (De Baere et al. 2001).

Phylogenetic Analysis Based on Housekeeping Genes

Ribosomal RNA genes evolve slowly, and due the associated limited taxonomic resolution, analysis of the 16S rRNA gene often does not allow to reliably distinguish between closely related species (Fox et al. 1992; Palys et al. 2000). This problem is most obvious in the genera *Burkholderia* (especially in the *Burkholderia cepacia* complex) and in the genus *Pandoraea* (*Fig. 28.1*). The sequencing of several "housekeeping" genes (i.e., protein-coding genes with an essential function) (e.g., *gyrB*, *rpoB*, *infB*, and *recA*) has been proposed to complement the phylogenetic information obtained from sequencing the 16S rRNA gene (Eisen 1995; Yamamoto and Harayama 1995, 1998; Venkateswaran et al. 1998; Hedegaard et al. 1999; Maréchal et al. 2000). The housekeeping genes most often used in phylogenetic analyses of taxa of the family *Burkholderiaceae* are *recA* (encoding recombinase A) and *gyrB* (encoding gyrase B).

Phylogenetic analyses based on the *recA* gene have played an important role in taxonomic studies of the genus *Burkholderia* and in the development of diagnostic PCR assays (see below), especially for the *Burkholderia cepacia* complex (Mahenthiralingam et al. 2000; Payne et al. 2005). In phylogenetic trees based on (nearly) complete *recA* sequences, most *Burkholderia cepacia* complex species will form discrete clusters that can easily be discerned from other species, unlike in trees based on 16S rRNA gene sequences. A notable exception is *Burkholderia cenocepacia*, in which four different *recA* lineages (designated IIIA through IIID) can be found (Vandamme et al. 2003; Vanlaere et al. 2009). Other protein-coding housekeeping genes that have been used for deducing relationships between *Burkholderia* species include *hisA* (encoding a 1-(5-phosphoribosyl)-5-[(5-phosphoribosylamino)methylideneamino]imidazole-4-carboxamide isomerase involved in histidine biosynthesis) (Papaleo et al. 2010) and *parB* and *repA*, two genes involved in the partitioning and replication, respectively, of the multireplicon *Burkholderia cepacia* complex genomes (Drevinek et al. 2008).

Sequence analysis of the gene encoding the gyrase B protein (*gyrB*) was shown to be very useful to deduce phylogenetic relationships between *Pandoraea* species. Sequence analysis of *gyrB* confirmed the separate status of *Pandoraea* genomospecies 1, 3, and 4 and suggested a close relationship between *Pandoraea* genomospecies 2 and *Pandoraea sputorum* (Coenye and LiPuma 2002; Sahin et al. 2011).

Multilocus Sequence Analysis

Initially developed as a typing tool, the sequence analysis of multiple (protein-coding) housekeeping genes (multilocus sequence analysis, MLSA) has emerged as a powerful taxonomic tool (Gevers et al. 2005; Coenye et al. 2005). Within the genus *Burkholderia*, MLSA schemes have been developed for the *Burkholderia pseudomallei/Burkholderia mallei/Burkholderia thailandensis* group (Godoy et al. 2003) and the *Burkholderia cepacia* complex (Baldwin et al. 2005). In order to keep up with the increasing taxonomic complexity of the *Burkholderia cepacia* complex and to be able to include other *Burkholderia* species, an "expanded" MLSA scheme was developed and published in 2009 (Spilker et al. 2009). The use of degenerate primers allowed expansion of the *Burkholderia cepacia* complex MLSA scheme to include other clinically relevant (e.g., *Burkholderia gladioli*) or important environmental (e.g., *Burkholderia glumae*) species. In the *Burkholderia cepacia* complex MLSA scheme, the following genes are used: *atpD* (encoding ATP synthase β chain), *gltB* (large subunit of glutamate synthase), *gyrB* (gyrase B), *recA* (recombinase A), *lepA* (GTP-binding protein), *phaC* (acetoacetyl-CoA reductase), and *trpB* (subunit B of tryptophan synthase). In the *Burkholderia pseudomallei* MLSA scheme, the following genes are used: *aceA* (encoding acetyl coenzyme A reductase), *gltB* (large subunit of glutamate synthase), *gmhD* (ADP glycerol-mannoheptose epimerase), *lepA* (GTP-binding elongation factor), *lipA* (lipoic acid synthetase), *narK* (nitrite extrusion protein), and *ndh* (NADH dehydrogenase).

MALDI-TOF MS

Matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS) of intact cells has recently emerged as a powerful tool for the characterization and identification of microorganisms. Most studies so far have focussed on the *Burkholderia cepacia* complex. In their pioneering study, Vanlaere et al. (2008) demonstrated that MALDI-TOF MS is a powerful approach for the rapid identification of *Burkholderia cepacia* complex bacteria. Seventy-five strains belonging to the nine at that time established *Burkholderia cepacia* complex species as well as some species commonly misidentified as belonging to the *Burkholderia cepacia* complex were included. All *Burkholderia cepacia* complex strains clustered together and could be separated from non-*Burkholderia cepacia* complex strains. Within the *Burkholderia cepacia* complex, most strains

Fig. 28.1

Phylogenetic reconstruction of the family *Burkholderiaceae* based on 16S rRNA and created using the neighbor-joining algorithm with the Jukes-Cantor correction. The sequence datasets and alignments were used according to the All-Species Living Tree Project (LTP) database (Yarza et al., 2010; http://www.arb-silva.de/projects/living-tree). The tree topology was stabilized with the use of a representative set of nearly 750 high quality type strain sequences proportionally distributed among the different bacterial and archaeal phyla. In addition, a 40% maximum frequency filter was applied in order to remove hypervariable positions and potentially misplaced bases from the alignment. Scale bar indicates estimated sequence divergence

grouped in species-specific clusters, except for *Burkholderia anthina* and *Burkholderia pyrrocinia* strains which constituted a single cluster. Subsequent studies in the context of cystic fibrosis microbiology confirmed that MALDI-TOF MS is a useful addition to the toolbox to identify *Burkholderia cepacia* complex species and related taxa (including *Ralstonia* and *Cupriavidus* species) (Degand et al. 2008; Minan et al. 2009; Fernández-Olmos et al. 2012; Desai et al. 2012). Two recent studies also demonstrated that this technique is appropriate for the confirmation of *Burkholderia pseudomallei* (Inglis et al. 2012; Lau et al. 2012).

PCR-Based Assays for Identification of Species Belonging to the Family *Burkholderiaceae*

Several candidate PCR assays have been developed for the identification of the *Burkholderia cepacia* complex species, but most of these assays were developed before the recognition that several species constitute the *Burkholderia cepacia* complex, and most relied on published DNA sequence data derived from analyses of culture collection strains that, in retrospect, are poorly representative of the total diversity within this group. However, in 1999, LiPuma et al. and Bauernfeind et al. (1999) presented rRNA-gene-based PCR assays which allowed the identification of *Burkholderia multivorans* and *Burkholderia vietnamiensis* and *Burkholderia cepacia, Burkholderia cenocepacia*, and *Burkholderia stabilis* as a group (but the latter three species could not be differentiated from each other). They also developed a PCR assay that, in retrospect, showed a positive reaction for the majority of *Burkholderia, Ralstonia, Cupriavidus, and Pandoraea* isolates investigated (unpublished data). Around the same time, Whitby et al. (2000) described an rRNA-gene-based PCR assay for the identification of *Burkholderia gladioli*. Vermis et al. (2004) developed a 16S rRNA-based assay for the identification of *Burkholderia dolosa*. 16S rRNA-gene-based PCR assays with excellent sensitivity and specificity were also developed for the genus *Pandoraea* as a whole and a number of individual *Pandoraea* species (*Pandoraea sputorum, Pandoraea norimbergensis, Pandoraea pnomenusa, and Pandoraea apista/Pandoraea pulmonicola*) (Coenye et al. 2001a). Similar assays were developed for *Ralstonia pickettii* and *Ralstonia mannitolilytica* (Coenye et al. 2002) and *Ralstonia insidiosa* (Coenye et al. 2003a).

Due to the inherent limitations imposed by the use of the 16S rRNA gene, the possibility to use alternative targets for PCR-based identification tools has been explored. The *recA* gene was identified as such a target that turned out to be extremely useful for the differentiation of *Burkholderia* species, including members of the *Burkholderia cepacia* complex. Analysis of *recA* sequences from a large number of isolates enabled the design of a *Burkholderia* genus-specific *recA* PCR as well as the design of a *Burkholderia cepacia* complex-specific *recA* PCR (Mahenthiralingam et al. 2000; Payne et al. 2005). In addition, PCR assays were developed for a number of individual *Burkholderia cepacia* complex species, including *Burkholderia cepacia, Burkholderia multivorans, Burkholderia cenocepacia, Burkholderia stabilis* and *Burkholderia vietnamiensis* (Mahenthiralingam et al. 2000), *Burkholderia ambifaria* (Coenye et al. 2001), and *Burkholderia dolosa* (Vermis et al. 2004). A thorough evaluation by Vermis et al. (2002) (508 *Burkholderia cepacia* complex isolates representing nine species) revealed that the *recA*-based assays for the identification of *Burkholderia multivorans, Burkholderia cenocepacia*, and *Burkholderia ambifaria were most efficient but that the assay directed against Burkholderia cepacia* lacked sensitivity and cross-reacted with all *Burkholderia pyrrocinia* isolates examined. In an attempt to develop a single PCR assay to distinguish all *Burkholderia cenocepacia* subgroups from other *Burkholderia cepacia* complex species, Drevinek et al. (2008) explored the sequence diversity in the *parB* and *repA* genes. The *Burkholderia cenocepacia repA* sequences were distinct from other species, which enabled the design of a species-specific multiplex PCR that allowed to identify the former species with 100 % sensitivity and 93 % specificity.

Ribotyping and Riboprinting

In ribotyping, chromosomal restriction fragment length polymorphisms (RFLP) are detected by probing restriction-digested genomic DNA with rRNA (Stull et al. 1988; Bingen et al. 1994) and RFLPs result mainly from nucleotide sequence variation in regions flanking rRNA genes. A modification of ribotyping, referred to as PCR ribotyping, employs PCR to amplify the 16S–23S intergenic spacer region of the bacterial rRNA operon to detect sequence length polymorphisms therein (Kostman et al. 1995). Both ribotyping and PCR ribotyping were used in early investigations of *Burkholderia cepacia* complex epidemiology (LiPuma et al. 1988, 1990, 1994; Dasen et al. 1994). Moissenet et al. (2001) evaluated PCR ribotyping as a tool for species and strain differentiation within the genera *Ralstonia* and *Cupriavidus* but concluded that the resolution was insufficient. The generation of RiboPrint patterns for *Burkholderiaceae* using the RiboPrinter microbial characterization system has been evaluated in a limited number of studies. Brisse et al. (2000) showed that this method was potentially useful for species-level identification within the *Burkholderia cepacia* complex. The method was also evaluated for typing of *Burkholderia pseudomallei* (Inglis et al. 2002) and *Burkholderia mallei* (Grif et al. 2003). Riboprinting has occasionally been used for other taxa within this family, including *Cupriavidus pauculus* (Clermont et al. 2001).

REP-PCR

The genomes of most bacteria contain specific conserved repetitive sequences. Versalovic et al. (1991) showed that these repeats can be used to amplify the intervening DNA sequences. Three main sets of repeats have been used for typing: (i) repetitive extragenic palindromic (REP) elements

Table 28.1
Selection of strains of the family *Burkholderiaceae* for which a complete genome sequence is available. Data obtained from the Genome Atlas Database (http://www.cbs.dtu.dk/services/GenomeAtlas/)

(35–40 bp), (ii) enterobacterial repetitive intergenic consensus (ERIC) sequences (124–127 bp), and (iii) BOX elements (154 bp) (Olive and Bean 1999). Depending on which sequences are targeted, these assays are referred to as REP-, ERIC-, or BOX-PCR, respectively. Collectively, these methods are referred to as rep-PCR. Targets most commonly used for the typing of *Burkholderia cepacia* complex organisms are the ERIC (Liu et al. 1995; Cimolai and Trombley 1996; Seo and Tsuchiya 2005) and BOX elements (Chen et al. 2001; LiPuma et al. 2002; Biddick et al. 2003; Coenye et al. 2004; Seo and Tsuchiya 2005). This approach has also been used to investigate *Burkholderia pseudomallei* (Currie et al. 2007) (BOX), *Ralstonia solanacearum* (Smith et al. 1995; Norman et al. 2009; Stevens and van Elsas 2010; Xue et al. 2011) (ERIC, REP, and BOX), *Ralstonia pickettii* and *Ralstonia insidiosa* (Ryan et al. 2011) (BOX), and *Pandoraea apista* (Atkinson et al. 2006) (ERIC, REP, and BOX). Finally, BOX-PCR was also used to compare root-nodule isolates with reference isolates of *Burkholderia phymatum*, *Burkholderia tuberum*, *Burkholderia mimosarum*, *Burkholderia nodosa*, *Burkholderia sabiae*, *Burkholderia caribensis*, and *Cupriavidus taiwanensis* (Liu et al. 2011).

Genome Comparison

Genome sequences are currently available for many species of this family, but clinically relevant species like *B. cenocepacia*, *B. mallei*, and *B. pseudomallei*,

phytopathogens like *R. solanacearum*, and strains from species with potential for specific applications like *C. necator* are overrepresented. A selection of genomes of representatives of the *Burkholderiaceae* and their key properties are shown in *Table 28.1*. More information can be found in reviews by Mahenthiralingam and Drevinek (2007) and Vandamme and Dawyndt (2011).

Many members of the *Burkholderiaceae* (most notably species from the genera *Burkholderia*, *Cupriavidus*, and *Ralstonia*) have large and unusual multireplicon genomes that lie at the basis of the remarkable phenotypic diversity demonstrated by these bacteria (Mahenthiralingam and Drevinek 2007). Early research carried out by Cheng and Lessie (1994) showed that *B. multivorans* ATCC 17616 contained three large circular replicons of 3.4, 2.5, and 0.9 Mb. Each of these replicons contained rRNA genes, so they could be considered as real chromosomes. Rodley et al. (1995) showed that the type strain of *B. cepacia* and strains belonging to *B. glumae* and *B. glathei* also contained multiple replicons, as did strains belonging to *R. pickettii*, *R. solanacearum*, and *R. eutropha*. Further research by Lessie et al. (1996) showed that representatives of all members of the *B. cepacia* complex contain two or three chromosomes, with the total genome size ranging from 4.7 to 8.1 Mb. Research from others also demonstrated the multiple replicon structure in *B. gladioli* (Wigley and Burton 2000). Interestingly, large genomes have been described as disproportionately enriched in regulation and secondary metabolism genes and depleted in protein duplication, DNA replication, cell division, and nucleotide metabolism genes in comparison to small-sized genomes (Konstantinidis and Tiedje 2004). This may explain why species with large genomes dominate in environments where resources are scarce but diverse, such as in soils (Konstantinidis and Tiedje 2004). Recent work demonstrated that the smallest chromosome in the *B. cepacia* complex (chromosome 3) is not essential, but should be considered as a large plasmid that encodes virulence, secondary metabolism, and other accessory functions in *B. cepacia* complex bacteria (Agnoli et al. 2012). Based on a bioinformatics approach, Juhas et al. (2012) recently claimed that the core genome of the order *Burkholderiales* consists of 649 genes. All but two of these identified genes were located on the largest chromosome (chromosome 1) of *B. cenocepacia*, including the known essential genes *infB*, *gyrB*, *ubiB*, and *valS*, as well as the so far uncharacterized genes BCAL1882, BCAL2769, BCAL3142, and BCAL3369.

There is a growing interest in using information derived from whole-genome sequencing projects for taxonomic purposes (Coenye and Vandamme 2003b; Coenye et al. 2005; Gevers et al. 2005). Several of the approaches were evaluated by Vanlaere et al. (2009; on 13 genomes) and by Vandamme and Dawyndt (2011; on 44 genomes) to determine their ability to contribute to our taxonomic understanding of the *Burkholderiaceae* (with a strong focus on the genus *Burkholderia*). Parameters that have been included in these studies are average nucleotide identity (ANI), average amino acid identity (AAI), and core gene identity (CGI) (Konstantinidis and Tiedje 2005a, b, 2007; Goris et al. 2007). ANI and CGI analysis of 44 genomes (43 *Burkholderia* genomes + *C. metallidurans* CH34) resulted in highly correlated similarity matrices for both methods ($r^2 = 0.95$) (Vandamme and Dawyndt 2011). Trees based on these similarity matrices showed a much better resolved picture of the phylogenetic relationships of more distantly related species. For example, the *B. cepacia* complex and the *B. mallei*/*B. pseudomallei* group were extremely well resolved with high bootstrap values and both formed distinct lines of descent (Vandamme and Dawyndt 2011).

Phenotypic Analyses

Burkholderia Yabuuchi et al. 1993 Emend. Gillis et al. 1995

Burk.hold.er'i.a. M.L. dim. ending *-ia;* M.L. fem. n. *Burkholderia*, named after W. H. Burkholder, the American bacteriologist who first discovered the etiological agent of sour skin of onions.

The following genus description was presented in 1995 by Gillis et al. and was based on the 11 species described at that time. *Burkholderia* cells are Gram-negative, nonfermentative, straight rods that have a single polar flagellum or a tuft of polar flagella. A single species, *B. mallei*, is atrichous and nonmotile. Catalase is produced, and oxidase activity varies between species. The cellular fatty acids are characterized by the presence of 3-hydroxy C16:0. The type strains of several species are characterized by the presence of two types of ornithine lipids. Most species grow at 40 °C. All species can grow with the following substrates as sole carbon sources: glucose, glycerol, inositol, galactose, sorbitol, and mannitol. Some species are pathogenic for humans, animals, or plants. They are isolated from plant material, soil, or clinical samples and can be recognized on the basis of 16S rRNA characteristics. Most strains accumulate polyhydroxybutyrate as carbon reserve material and are capable of *ortho* cleavage of protocatechuate. The G + C content is 59.0–69.5 mol%. The type species is *Burkholderia cepacia*.

Phenotypic characteristics distinguishing the closely related species *Burkholderia mallei*, *Burkholderia pseudomallei*, and *Burkholderia thailandensis* are shown in Table 28.2. Phenotypic characteristics distinguishing the members of the *Burkholderia cepacia* complex and *Burkholderia gladioli* from each other are shown in Table 28.3.

Chitinimonas Chang et al. 2004 Emend. Kim et al. 2006

Chi.ti.ni.mo'nas N.L. n. *chitinum* chitin; Gr. n. *monas* unit, monad; N.L. fem. n. *Chitinimonas*, a chitin-utilizing monad.

Cells are Gram-negative rods and motile by means of single polar flagella. Poly-β-hydroxybutyrate granules are stored as reserve material. Endospores are not formed. Grows well by using chitin as the exclusive carbon, nitrogen and energy source both under aerobic and anaerobic conditions. Growth occurs at 4–39 °C, pH 4 to 10, and 0–1 % NaCl salinity. Catalase and oxidase activity is present. Nitrate is reduced, no indole production or glucose fermentation. Esculin, gelatin, and urea may or may not be hydrolyzed. The major fatty acid components are 16:0, 18:1 ω7*c*, and summed feature 3 (16:1 ω7*c* or 15 iso 2-OH or both). The type species is *Chitinimonas taiwanensis*.

Cupriavidus Makkar and Casida 1987 Emend. Vandamme and Coenye 2004

Cup.ri.a.vi'dus. L. n. *cuprum* copper; L. adj. *avidus* eager for, loving; M.L. neut. N. *Cupriavidus* lover of copper.

Cells are Gram-negative, peritrichously flagellated rods, and chemoheterotrophic or chemolithotrophic. The metabolism is oxidative. Several amino acids are used as sole carbon and nitrogen sources. Catalase and oxidase activity is produced. Resistance to various metals is widespread. The respiratory quinone Q8 has been reported in [*Ralstonia*] *eutropha* (Yabuuchi et al. 1995). The DNA G + C content is between 63 and 69 mol%. Species occur in soil and human-clinical specimens, particularly in samples from debilitated patients. The type species is *Cupriavidus necator*. Characteristics to differentiate *Cupriavidus* and *Ralstonia* species are shown in Table 28.4.

Lautropia Gerner-Smidt et al. 1995

Lau.tro'pia, in honor of the late Hans Lautrop, Danish bacteriologist.

Gram-negative cocci occur in at least three forms: small encapsulated cocci (1–2 μm in diameter), often occurring in clusters of 10 to more than 100 cells; small unencapsulated cocci (1–2 μm in diameter), motile by the action of a tuft of three to nine flagella; and large (>5 μm in diameter) spheroplast-like cells. They are facultative aerobes but grow best under aerobic conditions with no requirement for CO_2. They are mesophilic, growing at temperatures between 30 °C and 44 °C; nonpigmented; grow on most enriched media, especially on chocolate and Levinthal, TGY, and Tween 80 agar; and grow slower with no hemolysis on horse-blood agar. Three colony morphologies can be observed, flat, dry, and circular colonies predominating in young cultures, becoming larger, wrinkled, crisp, and crateriform on prolonged incubation and smooth,

glistering, raised, round, mucoid colonies. The colony diameter varies between pinpoint size and more than 5 mm; all colony types may occur in all sizes, largest in older cultures; and colonies are usually adherent to the substrate. Growth in broth is granular with a coarse sediment and granules adherent to the side of the tube. Biochemically, strains are oxidase, catalase, and urease positive; reduce nitrate and nitrites; produce polysaccharide on sucrose agar; ferment glucose, fructose, maltose, sucrose, and mannitol; and do not ferment lactose, trehalose, raffinose, inulin, salicin, adonitol, dulcitol, sorbitol, inositol, xylose, rhamnose or arabinose, or hydrolyse starch. Most strains hydrolyse esculin. They may produce β-xylosidase, but not β-galactosidase or β-glucuronidase, do not decarboxylate lysine or ornithine, and do not produce arginine decarboxylase/dihydrolase or phenylalanine deaminase. They are VP, gelatinase, and H_2S negative, do not hydrolyze hippurate or Tween 80, and are sensitive to penicillin G, ampicillin, piperacillin, cefuroxime, gentamicin, and erythromycin. Mean mol% (G + C) is 65 (range 64.6–65.4). The habitat is the human oral cavity. The type species is *Lautropia mirabilis*.

Limnobacter Spring et al. 2001 Emend. Lu et al. 2011

Lim.no.bac'ter. Gr. n. *limnos* lake; M.L. n. *bacter* rod; M.L. masc. n. *Limnobacter* lake rod, referring to the isolation of the type species from lake sediment.

Cells are Gram-negative, slightly curved rods that are motile by single polar flagella. Polyhydroxybutyrate is stored as a reserve material. Endospores are not formed. *Limnobacter* are strictly aerobic and oxidase and catalase positive. Growth occurs between 4 °C and 44 °C. Carboxylic acids and amino acids are used as energy and carbon sources, but no carbohydrates or polyols are used. They are not able to grow autotrophically. Thiosulfate is oxidized to sulfate in the presence of an organic carbon source. Major fatty acids are 18:1ω7*c*, 16:1ω7*c*, 16:0, and 10:0 3-OH. The major ubiquinone is Q-8. The G + C content is between 55 % and 59 %. The type species is *Limnobacter thiooxidans*.

Pandoraea Coenye et al. 2000

Pan.do.rae'a. N.L. fem. n. *Pandoraea*, referring to Pandora's box in Greek mythology, which was the origin of diseases of mankind and thus to the surprisingly diverse members of this genus.

Pandoraea cells are Gram-negative, nonsporulating straight rods of 0.5–0.7 by 1.5–4.0 µm. They occur single and are motile by means of a single polar flagellum. Catalase activity is present. Growth is observed at 30 °C and 37 °C. Nitrite is not reduced. There are no denitrification, no β-galactosidase or DNAse activity, no liquefaction of gelatin, no esculin hydrolysis, no indole production, and no hydrolysis of Tween 80. Additional characteristics are listed in the Results section above. The following fatty acid components are present: 12:0, 12:0 2OH, 16:0, 17:0 cyclo, 16:0 2OH, 16:0 3OH, 19:0 cyclo ω8c, 18:1 2OH, summed feature 3, summed feature 4, and summed feature 7. The G + C content is between 61.2 and 64.3 mol%. Strains of this

genus are isolated from human clinical samples (mostly cystic fibrosis patients) and the environment and do not cause soft rot on onions. The clinical data that are presently available indicate that at least some of these organisms may cause chronic infection in and have been transmitted among cystic fibrosis patients. The type species is *Pandoraea apista*. Phenotypic characteristics allowing the differentiation of the different *Pandoraea* species are shown in Table 28.5.

Paucimonas Jendrossek 2001

Pau.ci.mo'nas. L., adj. *paucus* little, few; Gr. fem. *monas* unit, cell; *Paucimonas* bacterium with restricted (few) catabolic capacities.

Paucimonas cells are Gram-negative with chemoorganotrophic and strictly respiratory metabolism and are catalase and oxidase positive. Preferred carbon sources are organic acids. Most sugars (e.g., glucose, fructose, xylose), sugar acids (e.g., gluconate), polyalcohols (e.g., sorbitol, glycerol), alcohols (e.g., ethanol, butanediol, phenol), amino acids, polypeptides (e.g., nutrient broth, gelatin, Luria-Bertani broth), or polysaccharides (e.g., starch, cellulose) do not support growth. PHB and related homopolyesters and/or copolymers of hydroxyalkanoic acids can be accumulated intracellularly. Chemolithoautotrophic or phototrophic growth has not been observed. Type species of the genus is *Paucimonas lemoignei*.

Polynucleobacter Heckmann and Schmidt 1987 Emend. Hahn et al. 2009

Po.ly.nuc'le.o.bac.ter. Gr. adj. *polys* numerous; L. masc. n. *nucleus* nut, kernel; N.L. masc. n. *bacter* the equivalent of the Gr. neut. n. *bactron* a rod; N.L. masc. *Polynucleobacter* rod with many nucleoids.

It harbors endosymbiotic strains of several *Euplotes* species and free-living strains dwelling in the water column of freshwater lakes, ponds, and streams and is essential for their host species and nonmotile. Not all strains affiliated with the genus possess multiple nucleoid-like structures as indicated by the genus name. The type species is *Polynucleobacter necessarius*.

Ralstonia Yabuuchi et al. 1996

Ral.sto'n.ia. M.L. dim. *-ia* ending; M.L. fem. n. *Ralstonia* named after Ericka Ralston, the American bacteriologist who first described *Pseudomonas pickettii*.

Ralstonia cells are Gram-negative rods; have no formation of endospores; are nonmotile or motile by means of a single polar or peritrichous flagella; are aerobic, with a respiratory metabolism with oxygen as terminal electron acceptor; and are able to grow on ordinary peptone media. The colony color is beige for most species. They are oxidase and catalase positive and lysine and ornithine decarboxylase negative. The major ubiquinone is Q-8. Cellular lipids contain two kinds of phosphatidylethanolamine. Major fatty acids are C16:0, a mixture of C18:0 ω9t and C18:1 ω7c, and C14:0 3OH. The G + C content is between 64 and 68 mol%. The type species is *Ralstonia pickettii*. Characteristics to differentiate *Ralstonia* and *Cupriavidus* species are shown in Table 28.4.

Thermothrix Caldwell et al. 1981

Ther.mo'thrix. Gr. adj. *thermos*, hot; Gr. fem. n. *thrix*, hair; N.L. fem. n. *Thermothrix*, hot hair.

Thermothrix cells are Gram-negative rods, mobile with a single polar flagellum, and thermophiles with growth temperatures ranging from 63 °C to 86 °C. They are aerobic and are

facultative or obligate chemolithotrophs. Under unfavorable conditions (lack of oxygen, pH around 8.5, or temperature close to maximum growth temperature), cells will form filaments and are isolated from geothermal sources where the pH is close to neutral. The type species is *Thermothrix thiopara*.

Wautersia Vaneechoutte et al. 2004

Wau.ter′si.a. L. fem. n. *Wautersia* named in honor of the Belgian microbiologist Georges Wauters.

Wautersia cells are Gram-negative rods that are motile by means of peritrichous flagella. They are aerobic, form smooth colonies that reach 1–2 mm within 48 h at 30°C on blood agar, and are positive for catalase and oxidase. Glucose is neither acidified nor assimilated. They are susceptible to colistin. Cellular fatty acids are of the saturated and monounsaturated straight-chain types, mainly C16:1ω9*c*, C16:0, C18:1ω11*c*, and C14:0. The type species of the genus is *Wautersia eutropha*. As mentioned above, only *Wautersia numazuensis* still remains in this genus, with all other species (including the type species *Wautersia eutropha*) being reclassified as *Cupriavidus* species. It is clear that *Wautersia numazuensis* should also be reclassified as a *Cupriavidus* species and that the use of the name *Wautersia* should be discontinued.

Isolation, Enrichment, and Maintenance Procedures

Most members of the family *Burkholderiaceae* grow on a wide range of media, including (but not limited to) nutrient agar, tryptic soy agar, Mueller-Hinton agar, Columbia agar, and LB agar, with or without blood. However, the use of selective media can be required to recover relevant species (*Burkholderia pseudomallei*, *Burkholderia cepacia* complex) from clinical samples. Note that attempts to grow *Polynucleobacter necessarius* subsp. *necessarius* outside its eukaryotic host have so far been unsuccessful (Hahn et al. 2009). Similarly, several obligate endosymbionts of *Psychotria* plants (and other *Rubiaceae*) have been described, but since attempts to obtain these in pure culture were unsuccessful, they have been described as "Candidatus Burkholderia kirkii" (Van Oevelen et al. 2002), "Candidatus Burkholderia calva" and "Candidatus Burkholderia nigropunctata" (Van Oevelen et al. 2004), "Candidatus Burkholderia andongensis" and "Candidatus Burkholderia petitii" (Lemaire et al. 2011), "Candidatus Burkholderia harborii" and "Candidatus Burkholderia schumanniana" (Verstraete et al. 2011), and, finally, "Candidatus Burkholderia hispidae," "Candidatus Burkholderia rigidae," and "Candidatus Burkholderia schumannianae" (Lemaire et al. 2012).

Several different media have been developed for the selective isolation of *Burkholderia cepacia complex* isolates from sputum of cystic fibrosis, e.g., *Pseudomonas cepacia* (PC) medium (containing 300U polymyxin B per ml and 100 µg ticarcilline per ml) (Gilligan et al. 1985); oxidation-fermentation agar supplemented with lactose, 300U polymyxin B per ml, and 0.2U of bacitracin per ml (OFPBL agar) (Welch et al. 1987); and *B. cepacia* selective agar (BCSA) (containing 1 % lactose and 1 % sucrose in an enriched base of casein and yeast extract with 600U of polymyxin B per ml, 10 µg of gentamicin per ml, and 2.5 µg vancomycin per ml) (Henry et al. 1997). BCSA was reported superior compared to OFPBL and PCA for the rapidity and quality of recovery of *B. cepacia* complex organisms from cystic fibrosis respiratory specimens and was more inhibitory towards other organisms (Henry et al. 1999). A comparison of three commercially available "*Burkholderia cepacia*" media (MAST Diagnostics, Bootle, Merseyside, United Kingdom; LAB M Ltd., Bury, United Kingdom; and Oxoid Ltd., Basingstoke, United Kingdom), through the analysis of 142 clinical and environmental isolates, showed that BCSA and Mast *B. cepacia* medium supported the growth of *Burkholderia cepacia* complex isolates most efficiently (Vermis et al. 2003b). BCSA and MAST were also compared in terms of sensitivities and specificities for the isolation of *Burkholderia cepacia* complex species from sputum specimens from cystic fibrosis patients; in that study, BCSA was found to be as sensitive as MAST agar but more selective (Wright et al. 2001). It should be noted that several *Pandoraea*, *Ralstonia*, and *Cupriavidus* isolates will also grow on BCSA. The selectivity of the abovementioned media for the isolation of environmental *Burkholderia cepacia* complex isolates may be much lower (Carson et al. 1988), and therefore the use of other media, like PCAT medium (containing azelaic acid and tryptamine) (Burbage and Sasser 1982), may be recommended, although not all *Burkholderia cepacia* complex species grow on the latter medium (Vermis et al. 2003a). An enrichment medium, based on the ability of *Burkholderia cepacia* complex, isolates to use L-threonine and L-arabinose as carbon sources, and their insensitivity to polymyxin B and 9-chloro-9-(4-diethylaminophenyl)-10-phenylacridan (C-390), was developed by Vermis et al. (2003b) and successfully used to demonstrate the presence of *Burkholderia cepacia* complex in water and soil samples (Vermis et al. 2003b; Vanlaere et al. 2005). However, other bacteria were also recovered (including isolates belonging to the genera *Pandoraea, Chryseobacterium, Comamonas, Ralstonia, Herbaspirillum*, and *Pseudomonas*) following this enrichment procedure. Ashdown medium (containing crystal violet and gentamicin as selective agents) is typically used for the isolation of *Burkholderia pseudomallei* (LiPuma et al. 2011). If enrichment is required, an enrichment broth consisting of Ashdown medium supplemented with 50 mg of colistin was found to be superior to standard enrichment broth such as tryptic soy broth and increases recovery of *Burkholderia pseudomallei* (LiPuma et al. 2011).

For short-term preservation (several weeks up to months), stab cultures in semisolid medium or cultures on slants (with storage at 4 °C) are appropriate. For long-term storage, media containing glycerol (20 % v/v) and storage at −80 °C or in liquid nitrogen are recommended.

Ecology

For reviews of the ecology of *Burkholderia* species, see Coenye and Vandamme (2003) and Compant et al. (2008). Members of the genus *Burkholderia* occupy diverse ecological niches and can be found in the soil, in water, and in (close) association with plants, animals, and fungi. Several *Burkholderia* species (including *Burkholderia vietnamiensis*) are capable of nitrogen fixation and several *Burkholderia* species are capable of forming root nodules on several plants. Others, including *Burkholderia gladioli* and *Burkholderia glumae*, are notorious plant pathogens (Gonzalez et al. 2007), as is *Ralstonia solanacearum* (Genin and Boucher 2004; Mansfield et al. 2012). Much less is known about the ecology of other genera of this family.

Pathogenicity: Clinical Relevance

Burkholderia pseudomallei and *Burkholderia mallei*

The family *Burkholderiaceae* contains two highly pathogenic organisms, *Burkholderia pseudomallei* and *Burkholderia mallei* (LiPuma et al. 2011). *Burkholderia pseudomallei* causes melioidosis, an infection characterized by a wide range of clinical manifestations, ranging from asymptomatic colonization to fulminant sepsis. The most common presentations of melioidosis include pneumonia, soft-tissue infection, abscesses of liver and spleen, and septicemia (Dance 1991; LiPuma et al. 2011). *Burkholderia pseudomallei* is a saprophytic organism, broadly distributed in soil and water in Southeast Asia and northern Australia. The majority of infected people acquire the organism through percutaneous inoculation on exposure to contaminated soil or water, although the possibility of inhalation or ingestion as modes of infection requires further investigation (Dance et al. 2000; Haase et al. 1995; Currie et al. 2001). Sporadic cases have resulted from person-to-person or animal-to-person spread (Dance 2000). Exposure in endemic areas is quite frequent due to the organism's ubiquity, and latent infections are common. Thus, it is difficult to accurately determine what sort of environmental exposure poses the greatest risk of melioidosis. Sporadic cases of human melioidosis occur in regions outside the endemic area, such China, Korea, the Philippines, Indonesia, India, and West Africa. Most cases in Europe and North America are thought to be imported by immigrants or international travelers (Dorman et al. 1998; Dance et al. 1999). Several reports describe the occurrence of *B. pseudomallei* in European cystic fibrosis patients. In these cases, the organisms were most likely acquired during travel, although this could not always be confirmed (Visca et al. 2001; Schulin and Steinmetz 2001; O'Carroll et al. 2003; Engelthaler et al. 2011).

Burkholderia mallei is primarily a pathogen in horses, in which it causes glanders, a disease characterized by fever, inflammation of the nasal mucosa, necrosis, and obstruction of the oropharynx. In humans, infection can be limited to subcutaneous tissues or can disseminate to cause sepsis (LiPuma et al. 2011). If inhaled, *Burkholderia mallei* can cause pneumonia with necrosis of the tracheobronchial tree (Srinivasan et al. 2001). *Burkholderia mallei* can be spread via contact with infected animals or through exposure in research laboratories (Srinivasan et al. 2012; CDC 2000). Glanders has been virtually eliminated in the Western world due to stringent infection control measures, including the immediate slaughter of affected animals. However, research interest in this species due to recent concerns about biological warfare may result in an increasing risk of occupational exposure.

Respiratory Tract Infections in Cystic Fibrosis Patients

Members of the *Burkholderia cepacia* complex and phenotypically similar species (including *B. gladioli* and *Pandoraea, Cupriavidus*, and *Ralstonia* species) are notorious for causing respiratory tract infections in cystic fibrosis patients. The reader is referred to several detailed reviews on this topic for more information (LiPuma 2005, 2010, 2011; Coenye and LiPuma 2003).

Application

Burkholderia cepacia Complex Bacteria as Biocontrol, Bioremediation, and Plant-Growth-Promoting Agents

The biological control of plant diseases, insects, and nematodes by microorganisms (both bacteria and fungi) has been proposed as an alternative or a supplement to chemical pesticides, and the use of introduced biological control could have enormous ecological and economic benefits. The two traditional approaches used for biological control of soilborne plant pathogens in the field have been (1) crop rotations, to allow time for resident antagonists to "sanitize" the soil or for propagules of specialized pathogens to die, and (2) the addition of organic amendments to soil, to stimulate resident antagonists. However, the greatest progress towards biological control of soilborne plant pathogens has been made with antagonists introduced with the planting material, i.e., biological control with plant-associated microorganisms. It has often been shown that *Burkholderia cepacia* complex strains can be used to control seedling and root diseases in vitro and in field tests and could replace chemical alternatives like captan, thiram, PCNB, benlate, and thiabendazole (LiPuma and Mahenthiralingam 1999). Field tests have shown that *Burkholderia cepacia* complex can colonize the rhizosphere of several crops, including corn, maize, rice, pea, sunflower, and radish and thereby significantly can increase the crop yield, even in the absence of pathogens (see, e.g., McLoughlin et al. 1992; Parke et al. 1991; Bowers and Parke 1993; Hebbar et al. 1998; see Balandreau and Mavingui (2007) for a review on this topic).

In addition, the exceptional metabolic versatility of this organism can be used for bioremediation purposes. Constituents of crude oils (including polycyclic aromatic compounds), herbicides (including 2,4-dichlorophenoxyacetic acid and 2,4,5-trichlorophenoxyacetic acid, the principal component of "Agent Orange") TCE, and ether derivatives used as gasoline additives can be degraded by several *Burkholderia cepacia* complex isolates (Kilbane et al. 1982; Folsom et al. 1990; Krumme et al. 1993; Bhat et al. 1994). Well-characterized biodegradative strains belonging to the *Burkholderia cepacia* complex include G4 (Nelson et al. 1987; Folsom et al. 1990; Shields et al. 1991; Leahy et al. 1996; McClay et al. 1996; Massol-Deya et al. 1997) and CRE-7 (Mueller et al. 1996). Potentially useful strains have also been identified in other *Burkholderia* species, including the species *Burkholderia xenovorans* (strain LB400, degradation of biphenyl and polychlorinated biphenyls) (Haddock et al. 1993; Seeger et al. 1995; Billingsley et al. 1997; Master and Mohn 1998; Bopp 1985; Goris et al. 2004) and *Burkholderia kururiensis* (trichloroethylene) (Zhang et al. 2000). For more information, readers are referred to Denef (2007) for a review on this topic. Another extensively studied strain with demonstrated biodegradative capacities is *Cupriavidus necator* JMP134 (for a recent review, see Perez-Pantoja et al. 2008).

However, many strains used or under development for those purposes are taxonomically poorly characterized and their potential hazard to people with cystic fibrosis is unclear (Govan and Vandamme 1998; Holmes et al. 1998; Vidaver et al. 1999; Govan et al. 2000). Until more is known about the organisms currently used or under development for agricultural applications and the potential risks for cystic fibrosis patients, widespread use of these organisms has been forbidden by several national regulatory agencies, including the United States Environmental Protection Agency (EPA).

Heavy-Metal Resistance in the Genus *Cupriavidus*

Many members of the genus *Cupriavidus*, including *Cupriavidus metallidurans*, *Cupriavidus campinensis*, and *Cupriavidus basilensis*, are known for their metal resistance (Goris et al. 2001). The high resistance of certain *Cupriavidus* strains to cadmium, copper, zinc, cobalt, lead, and mercury has attracted considerable attention and opened the possibilities of developing bacterial biosensors for contamination and the development of novel approaches for the bioremediation of contaminated water and soils. For more information, the reader is directed to the reviews of Mergeay et al. (2003), Diels et al. (2009), and von Rozycki and Nies (2009) and the references therein.

29 The Family *Comamonadaceae*

Anne Willems
Laboratory of Microbiology, Department of Biochemistry and Microbiology, Faculty of Science, Ghent University, Ghent, Belgium

Abstract
The family *Comamonadaceae* is a large and diverse bacterial family belonging to the order *Burkholderiales*. It is regularly enlarged with new genera and species and currently comprises over 100 species in the following 29 genera: *Acidovorax*, *Albidiferax*, *Alicycliphilus*, *Brachymonas*, *Caenimonas*, *Comamonas*, *Curvibacter*, *Delftia*, *Diaphorobacter*, *Extensimonas*, *Giesbergeria*, *Hydrogenophaga*, *Hylemonella*, *Lampropedia*, *Limnohabitans*, *Macromonas*, *Malikia*, *Ottowia*, *Polaromonas*, *Pseudacidovorax*, *Pseudorhodoferax*, *Ramlibacter*, *Rhodoferax*, *Simplicispira*, *Tepidicella*, *Variovorax*, *Verminephrobacter*, *Xenophilus*, and *Xylophilus*. These genera form a phylogenetic cluster with a relative level of 16S rRNA gene sequence similarity of 93–97 %, yet harbor a remarkable phenotypic diversity that includes aerobic organotrophs, anaerobic denitrifiers and Fe^{3+}-reducing bacteria, hydrogen oxidizers, photoautotrophic and photoheterotrophic bacteria, and fermentative bacteria. Most are environmental bacteria from water and soil habitats; however, some *Comamonadaceae* are also pathogens, and others have been described from earthworms, rumen fluid, and human clinical samples. Most are mesophiles, although a few have been found in Antarctic habitats and some in hot springs.

Taxonomy, Historical and Current

Short Description of the Family

Co.ma.mo.na.da'ce.ae. N.L. fem. n. *Comamonas*, type genus of the family; suff. *-aceae*, suffix to denote a family; N.L. fem. pl. n. *Comamonadaceae*, the *Comamonas* family.

The family *Comamonadaceae* belongs to the *Burkholderiales* order in the *Betaproteobacteria* class of the phylum Proteobacteria. It was proposed in 1991 as a formal taxon for the so-called [*Pseudomonas*] *acidovorans* rRNA complex (Willems et al. 1991a), one of the five distinct clusters that had been recognized in the

E. Rosenberg et al. (eds.), *The Prokaryotes – Alphaproteobacteria and Betaproteobacteria*, DOI 10.1007/978-3-642-30197-1_238,

genus *Pseudomonas* on the basis of rRNA characteristics (Palleroni et al. 1973; De Vos and De Ley 1983). The *Pseudomonas acidovorans* rRNA group comprised at least 10 *Pseudomonas* species and also *Alcaligenes paradoxus*, *Xanthomonas ampelina*, *Comamonas terrigena*, and several *Aquaspirillum* species (De Vos and De Ley 1983; De Vos et al. 1985; Willems et al. 1987, 1991c). At the time of its description, the family comprised five genera. With the exception of *Comamonas* which is a revived genus (De Vos et al. 1985), most genera of the new family had been recently created for species that were originally placed in other genera based on phenotypic similarities: *Acidovorax* and *Hydrogenophaga* (both for several former *Pseudomonas* species), *Xylophilus* (formerly *Xanthomonas ampelina*), and *Variovorax* (formerly *Alcaligenes paradoxus*). The family also comprised several *Aquaspirillum* and phytopathogenic *Pseudomonas* species that had been phylogenetically misnamed at genus level (Willems et al. 1991a). These have since been transferred to the other genera *Simplicispira* (Grabovich et al. 2006), *Giesbergeria* (Grabovich et al. 2006), *Comamonas* (Wauters et al. 2003), *Curvibacter* (Ding and Yokota 2004), and *Acidovorax* (Willems et al. 1992). In addition many new genera and species have been described over the years so that the *Comamonadaceae* currently comprise 29 genera and 104 species.

The single most salient common feature of the members of this family is their membership of a phylogenetic cluster in the 16S rRNA gene phylogeny of the Betaproteobacteria. They occur in various natural or man-made habitats, pristine as well as polluted, ranging from soil, freshwater, groundwater, activated sludge, and industrial processing water (*Albidiferax*, *Alicycliphilus*, *Caenimonas*, *Curvibacter*, *Comamonas*, *Delftia*, *Diaphorobacter*, *Extensimonas*, *Giesbergeria*, *Simplicispira*, *Hydrogenophaga*, *Hylemonella*, *Lampropedia*, *Limnohabitans*, *Macromonas*, *Malikia*, *Ottowia*, *Polaromonas*, *Pseudacidovorax*, *Pseudorhodoferax*, *Rhodoferax*, *Variovorax*, *Xenophilus*). Some are plant associated (*Simplicispira psychrophila*) and several are plant pathogens (*Acidovorax*, *Xylophilus*). Others are found in clinical samples (*Acidovorax*, *Comamonas*, *Delftia acidovorans*), inside associated with chironomid egg masses (insects in freshwater habitats) (*Brachymonas*), in nephridia of earthworms (*Verminephrobacter*), or in the gut of termites (*Comamonas odontotermitis*). Other members have been found in sulfur or sulfide springs (*Comamonas thiooxidans*, *Giesbergeria kuznetsovii*), in hot springs (*Tepidicella*), in polar or other extremely cold habitats (*Polaromonas*, *Rhodoferax antarcticus*) including the Antarctic Ocean (*Polaromonas vacuolata*), and in desert soil (*Ramlibacter*).

From this wide range of habitats, it comes as no surprise that morphological and physiological features vary considerably between genera and species. The family includes oligotrophs living in freshwater as well as very versatile heterotrophs that can metabolize complex organic pollutants, psychrophiles, as well as mild thermophiles. Most are free-living environmental saprophytes, but others are plant or animal associated including plant pathogens. Most have an aerobic heterotrophic metabolism, yet some are able to denitrify and use nitrates (some *Comamonas*, *Hydrogenophaga*, *Simplicispira*, and *Acidovorax* species, *Albidiferax*, *Alicycliphilus*, *Brachymonas denitrificans*, *Diaphorobacter nitroreducens*, *Ottowia thiooxydans*, and *Variovorax ginsengisoli*) or Fe(III) (*Albidiferax*, *Comamonas guangdongensis*) as terminal electron acceptors and some are able to oxidize thiosulfate (some *Comamonas* species, *Ottowia*) and grow autotrophically on hydrogen (*Hydrogenophaga* and some environmental *Acidovorax* species, *Variovorax paradoxus*) or carbon monoxide (some *Hydrogenophaga pseudoflava* strains), photoauto- or photoheterotrophically (*Rhodoferax*).

There are some common chemotaxonomic features such as the presence of the straight chain fatty acids C16:0, C16:1ω7c, and C18:1ω17c and the hydroxy fatty acids C10:0 3-OH and/or C8:0 3-OH and Q-8 as the main respiratory quinone; however, these features are also present in many other Betaproteobacteria and are therefore not diagnostic.

Phylogenetic Structure of the Family and Its Genera

In the 16S rRNA gene phylogeny, the *Comamonadaceae* family forms a single large cluster in the phylum Betaproteobacteriaceae. Inside this large cluster, the species of each of the majority of the different genera group together per genus. However, *Acidovorax*, *Comamonas*, and *Hydrogenophaga* species each form large clusters that also comprise the species of one or two genera as separate subclusters or lineages (*Fig. 29.1*) as discussed below, and the taxonomy of these groups may therefore require further changes in the future.

The *Acidovorax* species make up two clusters, one comprising the environmental species *Acidovorax defluvii*, *Acidovorax radicis*, *Acidovorax facilis* (type species), *Acidovorax temperans*, *Acidovorax delafieldii*, *Acidovorax soli*, and *Acidovorax caeni* and the other uniting the plant-pathogenic species *Acidovorax avenae*, *Acidovorax cattleyae*, *Acidovorax oryzae*, *Acidovorax citrulli*, *Acidovorax anthurii*, and *Acidovorax valerianellae*. Both these clusters are each other's nearest neighbors; however, several phylogenetic algorithms place *Verminephrobacter eiseniae* and *Xylophilus ampelinus* with the environmental and the plant-pathogenic *Acidovorax* cluster, respectively (*Fig. 29.1*). *Xylophilus ampelinus* is a pathogen of grapevines and is yellow pigmented as are the plant-pathogenic *Acidovorax* species. In contrast to these plant pathogens, it is a very slow-growing organism that does not grow at temperatures above 30 °C (Willems et al. 1987, 1992). The placement of *Verminephrobacter* close to the environmental *Acidovorax* species was also reported by Pinel et al. (2008) who proposed this genus for symbiotic bacteria from the nephridia of lumbricid earthworms. In addition to 16S rRNA gene sequences, they also used partial *recA*, *gap*, and *rpoC* gene sequences to study the phylogenetic relationships. Their findings suggest that nephridial isolates, environmental and phytopathogenic *Acidovorax* species may form three sister clusters and indicate that with more data, further taxonomic rearrangements of the current genus *Acidovorax* may follow in the future (Pinel et al. 2008).

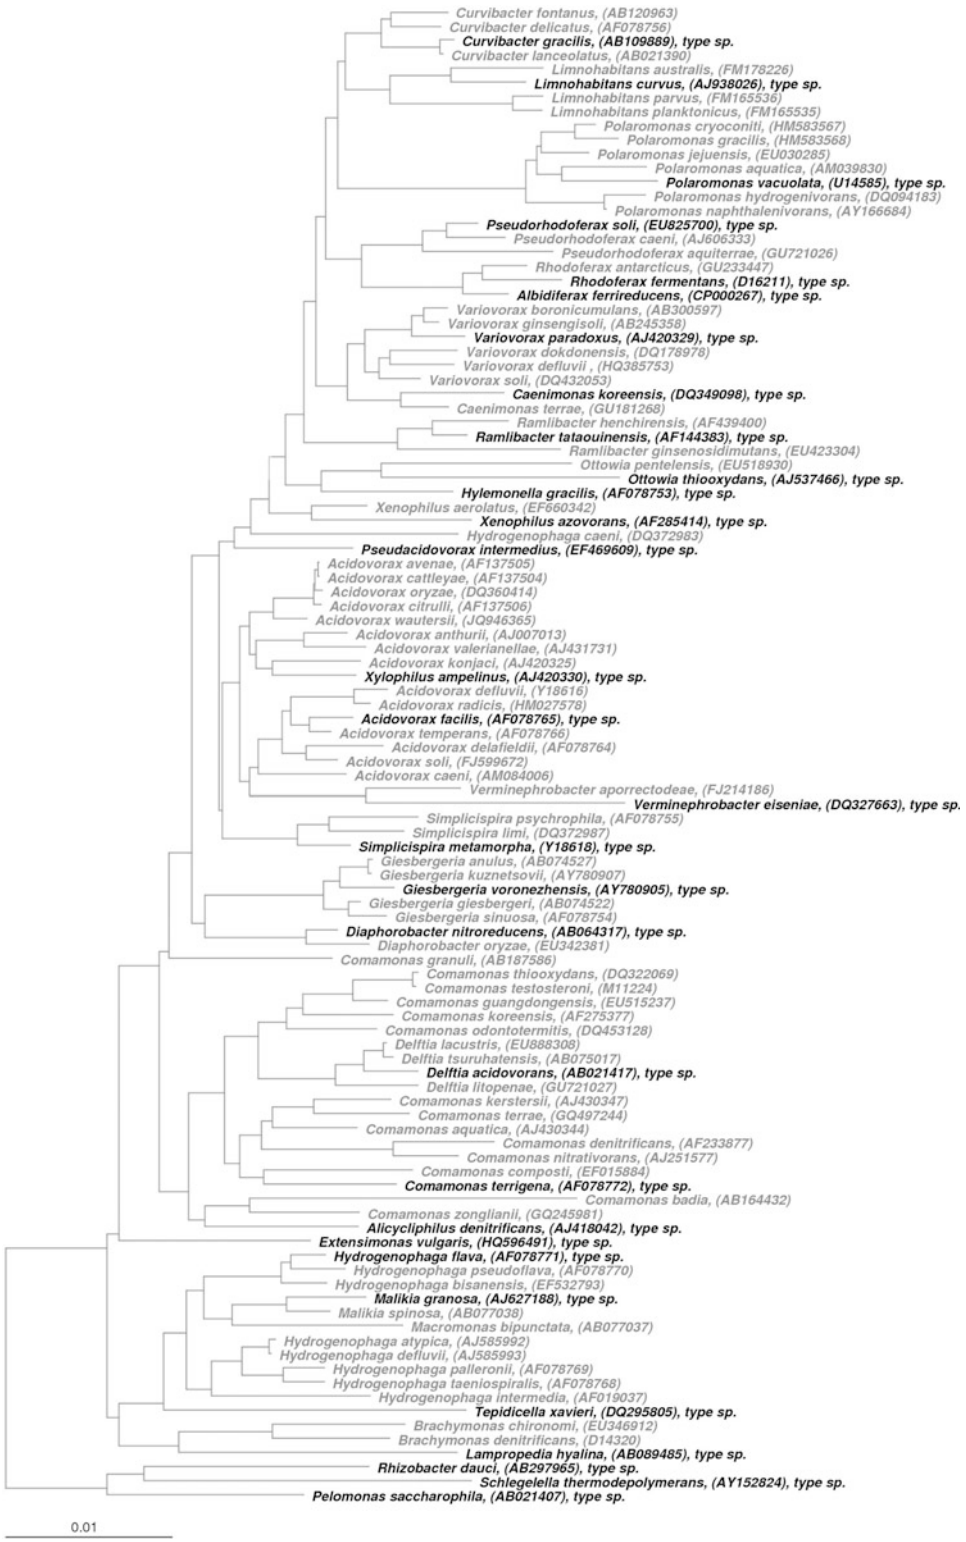

Fig. 29.1

Phylogenetic reconstruction of the family *Comamonadaceae* based on 16S rRNA and created using the neighbor-joining algorithm with the Jukes–Cantor correction. The sequence datasets and alignments were used according to the All-Species Living Tree Project (LTP) database (Yarza et al. 2010; http://www.arb-silva.de/projects/living-tree). The tree topology was stabilized with the use of a representative set of nearly 750 high-quality type strain sequences proportionally distributed among the different bacterial and archaeal phyla. In addition, a 40 % maximum frequency filter was applied in order to remove hypervariable positions and potentially misplaced bases from the alignment. Scale bar indicates estimated sequence divergence

The genus *Comamonas*, originally proposed by Davis and Park in 1962, was not included in the Approved Lists of Bacterial Names (Skerman et al. 1980). The genus was revived by De Vos et al. (1985) who studied the relationships of a series of *Comamonas*, *Vibrio*, and *Lophomonas* (also not on the Approved Lists) sp. strains with uncertain taxonomic affiliation. Initially only one species, *Comamonas terrigena*, was proposed (revived) for strains from a hay infusion, soil, and blood (De Vos et al. 1985). Tamaoka et al. (1987) then transferred *Pseudomonas acidovorans* and *Pseudomonas testosteroni* to *Comamonas* as separate species. Later three subgroups were described in *Comamonas terrigena*, one of them comprising the type strain of *Aquaspirillum aquaticum* (Willems et al. 1991c). These subgroups were since recognized as separate species with the proposal of *Comamonas aquatica* and *Comamonas kerstersii* (Wauters et al. 2003). *Comamonas acidovorans* was later placed in a separate genus, *Delftia* (Wen et al. 1999). At present the genus *Comamonas* comprises 14 species and two further species are proposed (Zhang et al. 2013a; Sun et al. 2013). The 16 *Comamonas* species make up three closely related clusters with *Comamonas granuli* at the periphery: the first cluster comprising *Comamonas terrigena* (type species), *Comamonas aquatica*, *Comamonas kerstersii*, *Comamonas denitrificans*, *Comamonas nitrativorans*, *Comamonas terrae*, and *Comamonas composti*; the second one *Comamonas badia* and *Comamonas zongliani;* and the third one *Comamonas odontotermitis*, *Comamonas koreensis*, *Comamonas thiooxydans*, *Comamonas testosteroni*, and *Comamonas guangdongensis* (Fig. 29.1). The second cluster has *Alicycliphilus denitrificans* as its nearest neighbor. The genus *Delftia*, which currently comprises four species, forms a separate cluster that is the nearest neighbor of this third *Comamonas* cluster (Fig. 29.1). The position of some species such as *Comamonas granuli*, *Comamonas badia*, and *Alicycliphilus denitrificans* varies with different phylogenetic algorithms and additional information (e.g., of other genes) may therefore in future lead to further taxonomic rearrangements.

The *Hydrogenophaga* species (four former *Pseudomonas* species and five more recently created species) form two related subclusters in the phylogenetic tree: one subcluster comprising *Hydrogenophaga flava* (type species), *Hydrogenophaga pseudoflava*, and *Hydrogenophaga bisanensis* and the other *Hydrogenophaga atypica, Hydrogenophaga defluvii, Hydrogenophaga palleronii*, *Hydrogenophaga taeniospiralis*, and *Hydrogenophaga intermedia*. These subclusters are separated by two *Malikia* species and *Macromonas bipunctata* (Fig. 29.1). The position of *Hydrogenophaga caeni* varies with the algorithm used: neighbor-joining analysis placed it outside the *Hydrogenophaga* main cluster whereas maximum likelihood placed it within this cluster. *Hydrogenophaga* species are found in aquatic or soil habitats and activated sludge, as are *Malikia* and *Macromonas* species (Spring et al. 2005; Dubinina et al. 2005). The phylogenetic position of these latter two genera also varies with the phylogenetic algorithm used, however: the *Malikia* cluster and the *Macromonas bipunctata* lineage group inside or at the periphery of the *Hydrogenophaga* cluster. Also here, additional new information may lead to taxonomic rearrangements in the future.

The genus *Macromonas* was created in 1924 (Utermöhl and Koppe 1924) and included on the Approved Lists of Bacterial Names (Skerman et al. 1980). However, strains of the type species of *Macromonas*, *Macromonas mobilis*, are not available, and its characteristics and phylogenetic position can thus not be verified. The position of the only other species, *Macromonas bipunctata*, which is morphologically and ecologically similar to the type species, has been established by 16S rRNA gene sequence analysis as close to the genus *Hydrogenophaga* and relatives (Dubinina et al. 2005) and is confirmed here in Fig. 29.1. Until strains of the type species are isolated for comparison, it therefore seems sensible to consider this genus as a member of the family *Comamonadaceae* for now (Dubinina et al. 2005).

The genus *Aquaspirillum* was proposed by Hylemon et al. (1973) for aerobic freshwater spirilla with a G+C range of 49–65 mol% in a large study which revised the taxonomy of the genus *Spirillum*. Several of the species were later shown to belong to the *Comamonadaceae* (Willems et al. 1991a) and were in recent years placed in separate genera that occupy separate positions in the family phylogeny. *Aquaspirillum delicatum* was accommodated in the genus *Curvibacter* as *Curvibacter delicatus* (Ding and Yokota 2004). *Hylemonella gracilis* was created to accommodate *Aquaspirillum gracile* (Spring et al. 2004). *Giesbergeria* was created in 2006 to accommodate two *Aquaspirillum* species that had previously been proposed but not validly published (Grabovich et al. 2006). In addition the authors transferred three valid but generically misnamed *Aquaspirillum* species (*Aquaspirillum anulus, Aquaspirillum giesbergeri*, and *Aquaspirillum sinuosum*) to the genus. The genus thus comprised five species: the type species *Giesbergeria voronezhensis*, *Giesbergeria kuznetsovii*, *Giesbergeria anulus*, *Giesbergeria giesbergeri*, and *Giesbergeria sinuosa* (Grabovich et al. 2006). In the same study, a second genus *Simplicispira* was created to host two further generically misnamed *Aquaspirillum* species as *Simplicispira metamorpha*, the type species, and *Simplicispira psychrophila* (Grabovich et al. 2006). Since then a third species, *Simplicispira limi*, has been described (Lu et al. 2007).

Albidiferax ferrireducens was originally proposed as a new species in the genus *Rhodoferax* because of its phylogenetic grouping with members of this genus (Finneran et al. 2003). However, the inability to perform anoxygenic photosynthesis and lack of photosynthetic pigments later led to its transfer to a new genus *Albidoferax* (Ramana and Sasikala 2009), corrected to *Albidiferax* on validation of the name. *Albidiferax* ferrireducens does form a single and tight cluster with the two *Rhodoferax* species in the 16S rRNA gene phylogeny (Fig. 29.1). Sequence similarity between the three species is 97.25–98.5 % (Ramana and Sasikala 2009; Madigan et al. 2000).

The above paragraphs illustrate that the family *Comamonadaceae* comprises many species that were previously assigned to other genera (or species). Some come from old genera that were created using mostly phenotypic

characterization. The introduction of the 16S rRNA sequence as an essential indication for the phylogenetic placement has led to many taxonomic transfers and the creation of new genera. An overview of name changes is given in *Table 29.1*. Furthermore, the correct placement of the old genus *Lampropedia* (Schroeter 1886) in the *Comamonadaceae* was deduced from studies of the rRNA genes (Lee et al. 2004). It was originally mainly recognized as a separate genus because of its conspicuous tablet-shaped arrangement of cells. It is found in water rich with organic material and in rumen fluid. Only one species has been described, *Lampropedia hyalina*, with several strains available in collections. Most of these strains in cultivation have lost the capacity to form tablets, and Lee et al. (2004) suggest this feature should therefore not be decisive for species description.

Brachymonas forms one of the deeper branching lineages of the family *Comamonadaceae* (Wen et al. 1999 and *Fig. 29.1*). In addition to the two valid species, *Brachymonas denitrificans* (Hiraishi et al. 1995) and *Brachymonas chironomi* (Halpern et al. 2009), an isolate enriched from an oil refinery wastewater sludge using cyclohexane as carbon source was described tentatively as a new species "*Brachymonas petroleovorans*," however, without a species description or type strain assignment (Rouvière and Chen 2003).

Comments on the Membership of the Family

Xylophilus is not listed as a member of the family in the List of Prokaryotic names with Standing in Nomenclature (www.bacterio.cict.fr). However, phylogenetically, it does belong to the *Comamonadaceae* cluster (*Fig. 29.1*), and it was assigned to the family in the original description (Willems et al. 1991a).

In the original description of the family, in a separate section at the end of the paper, the nearest neighbors of the *Comamonadaceae* were discussed (Willems et al. 1991a). These include the facultatively photolithotrophic organism

Rubrivivax gelatinosus, the hydrogen oxidizers *Pseudomonas saccharophila* (now *Pelomonas saccharophila*) and *Alcaligenes latus* (currently *Azohydromonas lata*), and the sheathed manganese-oxidizing bacteria belonging to the genera *Leptothrix* and *Sphaerotilus*. In the past these were reported to be closely related or to belong to the acidovorans rRNA complex (De Vos and De Ley 1983; Willems et al. 1991b). At the time of the description of the family, they were explicitly excluded because they appeared less related than the other family members according to DNA–rRNA hybridizations and rRNA oligonucleotide catalogues and because their inclusion would result in a very widely defined family (Willems et al. 1991a).

Meanwhile the family *Comamonadaceae* has become more diverse by the inclusion of many new genera; however, the phylogeny of 16S rRNA gene sequences which is now available places *Rubrivivax* and relatives in a separate cluster near the *Comamonadaceae* (Fig. 29.1). Several additional genera have been described that group in this part of the phylogenetic tree. Some, such as *Kinneretia asaccharophila* gen. nov., sp. nov., isolated from a freshwater lake, was described as a member of the *Rubrivivax* branch of the family *Comamonadaceae* (Gomila et al. 2010). *Caldimonas* was described as "related to the *Rubrivivax* subgroup and the family *Comamonadaceae*" (Takeda et al. 2002). Indeed, *Caldimonas*, *Kinneretia*, *Pelomonas*, *Roseateles*, and *Schlegelella* are listed as members of the family in the List of Prokaryotic names with Standing in Nomenclature (www.bacterio.cict.fr). However, phylogenetically, they are not part of the *Comamonadaceae* cluster (Fig. 29.1) and constitute neighboring clusters that include the genera *Kinneretia* (1 species), *Pelomonas* (3 sp.), *Mitsuaria* (1 sp.), *Roseateles* (3 sp.), *Paucibacter* (1 sp.), *Inhella* (2 sp.), *Leptothrix* (5 sp.), *Sphaerptilus* (3 sp.), *Vitreoscilla* (3 sp.), *Rubrivivax* (2 sp.), *Ideonella* (2 sp.), *Aquincola* (1 sp.), *Azohydromonas* (2 sp.), *Aquabacterium* (5 sp.), *Caldimonas* (2 sp.), Schlegelella (2 sp.), and *Tepidimonas* (4 sp.)

Comment on the genus *Caenibacterium*: The genus *Caenibacterium* was created for an organism isolated from a thermophilic aerobic digester of municipal sludge for which the name *Caenibacterium thermophilum* was proposed (Manaia et al. 2003). The species has since been shown to be a later synonym of *Schlegelella thermodepolymerans* (Lütke-Eversloh et al. 2004). *Caenibacterium* and *Schlegelella* are listed as members of the family in the List of Prokaryotic names with Standing in Nomenclature (www.bacterio.cict.fr). However, as pointed out above, *Schlegelella* does not belong to the phylogenetic cluster of the *Comamonadaceae* family.

Molecular Analyses

DNA–DNA Hybridization Studies

In nearly all multispecies genera of the family, DNA–DNA hybridizations with existing species have been performed to justify proposals of new species. In most cases the values obtained between species are low (less than 45 %). Recent examples include the genus *Acidovorax* where DNA–DNA hybridization values between *Acidovorax soli* strain BL21^T and other *Acidovorax* strains between 12 % and 28 % (Choi et al. 2010) and the genus *Acidovorax* where hybridizations between *Acidovorax radices* N35^T and eight other *Acidovorax* species were between 25 % and 56 %. With the closely related. *Simplicispira Metamorpha* DSM 1837^T, 39 % was Obtained (Li et al. 2011).

Occasionally higher values are reported between species, and in those cases the polyphasic approach provides additional information to help decide on species status. For example, in the genus *Delftia*, hybridization values between the type strains of *Delftia acidovorans* and *Delftia tsuruhatensis* were just below 69 %. Nevertheless, they were regarded as separate species because of phenotypic and chemotaxonomic differences (Shigematsu et al. 2003). *Delftia lacustris* 332^T showed 36–66 % DNA–DNA hybridization with the type strains of both other *Delftia* species (Jørgensen et al. 2009), and more recently, *Delftia litopenaei* wsw-7^T showed 40–50 % DNA–DNA relatedness with the type strains of the other species (Chen et al. 2012).

Other Sequence Analyses

Whereas in the 16S rRNA phylogeny the family constitutes a radiation of mostly equally related genera, studying more variable genes might shed some light on closer relationships that may exist between some genera but that are not strongly reflected in the phylogeny of conserved 16S rRNA genes. However, genes other than the 16S rRNA genes have rarely been used to study the members of the family *Comamonadaceae*. This may change as more complete genomes can be mined, but at present only a few studies have used other genes to study diversity of species.

Many members of the *Comamonadaceae* are capable of accumulating polyhydroxyalkanoates such as PHB in the cell. Chen et al. (2012) compared the polyhydroxyalkanoate synthase gene (phaC, partial sequence of 606 bp) in several of these organisms and found the phylogeny largely congruent with that of 16S rRNA genes with separate clusters for the genera *Acidovorax*, *Alicycliphilus*, *Variovorax*, *Delftia*, *Polaromonas*, and *Comamonas*.

For *Verminephrobacter* strains, the *recA*, *gap*, and *rpoC* sequences were determined and compared with those of environmental and plant-associated members of the genus *Acidovorax*. The phylogenies revealed that *Verminephrobacter* strains form a coherent cluster among strains and clusters of the *Acidovorax* species with uncertain branching orders, possibly indicating the heterogeneity of the current genus *Acidovorax* (Pinel et al. 2008).

Genome Comparisons

Over the last 5 years, 33 complete or draft genome sequences have been reported for representatives of 10 genera of the family (Table 29.2). These genomes mostly comprise 1 chromosome (although a *Variovorax paradoxus* strain has two chromosomes, Table 29.2), no plasmids or sometimes 1–8 plasmids; reported sizes range from 3.62 Mb for *Hylemonella gracilis* ATCC 19624^T to 7.01 Mb for *Acidovorax* sp. CF316 (Table 29.2). In most cases, a strain of some particular interest was sequenced; however, nine type strains are also included (Table 29.2). For many of these sequences, detailed analyses are still underway. Several have, however, already been explored in more detail, and the most striking observations published. Those that have been reported on carry one to three rRNA operons (see below).

Xie et al. (2011) reported the genome of *Acidovorax avenae* subsp. *avenae* RS-1, isolated from rice shoots and capable of causing bacterial strip of rice. This strain contains three rRNA operons; pathogenicity-related genes involved in hypersensitivity response, type III secretion, synthesis of fimbriae, and adhesion proteins are present. The genome comprises 301 ORFs that are not present in other *Acidovorax* genomes and that are clustered apparently forming several genomic islands in this strain (Xie et al. 2011). An isolate from soil and capable of degrading polychlorinated biphenyl, *Acidovorax* sp. KKS102, was reported to have a circular chromosome with three rRNA operons (Ohtsubo et al. 2012), whereas *Acidovorax* sp. NO1, from gold mine soil, had a single rRNA operon (Huang et al. 2012). This latter strain is a facultative anaerobic nitrate reducer that can oxidize arsenite aerobically as well as anaerobically. Its genome contains the *aio* operon for arsenite oxidation, three *ars* operons for arsenite resistance operons, and a denitrification pathway that lacks nitrite reductase (*nir*) (Huang et al. 2012). *Acidovorax* strain TPSY, an organism obtained from groundwater and capable of facultatively anaerobic mixotrophic nitrate-dependent Fe(II) oxidation, has been referred to as "*Acidovorax ebreus*," although no species description was published (Byrne-Bailey et al. 2010). Its genome was reported to be a single circular chromosome, carrying the expected metabolic genes and also genes for resistance against lead, arsenite, and mercury; genes involved in twitching motility, but no known pathogenicity; and genes such as type I and type III secretion systems (Byrne-Bailey et al. 2010).

The genomes of two strains of *Alicycliphilus denitrificans*, K601^T and BC, have been sequenced. Both have been isolated from different wastewater treatment plants and are able to degrade cyclic hydrocarbons using either oxygen or nitrate as terminal electron acceptors. Strain BC can also use chlorate as terminal electron acceptor. Both strains carry a circular chromosome; K601^T also hosts one plasmid (75 k), and BC hosts two plasmids (79 kbp and 120 kbp). Genes involved in benzene degradation are located on the chromosome in both strains, while in strain BC, the chlorate reductase and chlorite dismutase genes are located on the megaplasmid that is absent from strain K601 (Oosterkamp et al. 2011).

Comamonas testosteroni ATCC 11996^T grows aerobically on steroids and aromatic compounds. Its genome comprises a circular chromosome that carries one rRNA operon and degradation genes for these compounds; it has an incomplete pentose phosphate pathway that may account for the inability to metabolize most sugars (Gong et al. 2012). A second strain of this species, strain CNB-2 from activated sludge, carries – in addition to its circular chromosome – a large plasmid that contains the genes required for 4-chlorobenzene degradation (Ma et al. 2009). The genome encodes for enzymes that degrade short chain fatty acids and aromatic and cyclic hydrocarbons. Like the type strain, it carries an incomplete pentose phosphate pathway. Many genes are involved in transport functions (22 %). Four different terminal oxidase complexes were detected, functioning at different oxygen concentrations. Furthermore, nitrate can serve as an alternative electron acceptor at low oxygen concentrations. These genes are thought to contribute to the competitiveness of this organism in the soil and wastewater environment (Ma et al. 2009).

The genome of *Hydrogenophaga* sp. strain PBC, an organism from textile wastewater and capable of degrading 4-aminobenzene sulfonate, was reported to carry three rRNA operons and the necessary genes for the degradation of 4-aminobenzene sulfonate as well as other aromatic compounds (Gan et al. 2012).

Polaromonas naphthalenivorans CJ2^T was recovered from coal-tar waste contaminated sediments. Its genome consists of a circular chromosome (4.4 Mb, 63 mol% G+C) and eight plasmids with a lower mol% G+C and sizes ranging from 353 bp to 6.4 kbp (Yagi et al. 2009). The chromosome carries two rRNA operons, genes for several central pathways (Embden–Meyerhof–Parnas glucolytic pathway, Entner–Doudoroff pathway, citric acid cycle, Calvin cycle for CO_2 fixation using type II RuBisCO) and several pathways for metabolizing aromatic compounds. The plasmids encode 845 genes, and their function differs with three of the plasmids not carrying genes for metabolism or energy production; one plasmid harboring many unknown genes and one plasmid carrying mostly genes involved in conjugation and degradation. The genome carries 309 mobile genetic elements that indicate a mosaic nature for the genome. A comparison with other genomes revealed that about 60 % of the genes of this organism were homologous to genes in other Betaproteobacteria (max. E-value 10^{-5}, min. identity 30 %) (Yagi et al. 2009).

De Luca et al. (2011) report on the genome of *Ramlibacter tataouinensis* TTB310^T, an organism from a semiarid region with an unusual cell cycle that involves immobile cyst-like cells that can multiply and vegetative cells that are highly motile. Its genome is a circular chromosome with a high mol% G+C of 70; it carries one rRNA operon and a number of genes reflecting possible adaptations to desert life such as genes for carotenoid biosynthesis, exopolysaccharide synthesis and hydrolysis, trehalose synthesis, type IV pili involved in gliding, blue and red light sensors, and a complex network of two component systems that may be involved in the control of the cell cycle in relation to fast environmental changes (De Luca et al. 2011).

Table 29.2

Overview of genome sequences available for members of the *Comamonadaceae*

Organism	Genome structure	Size (Mb)	GC%	Genes	Proteins	GenBank	References

Data obtained from the NCBI genome pages http://www.ncbi.nlm.nih.gov/genome

The complete genomes of *Verminephrobacter aporrectodeae* and *Verminephrobacter eiseniae*, two species that live as extracellular endosymbionts in earthworms, have been compared with those of two closely related free-living strains, *Acidovorax avenae* subsp. *citrulli* strain AAC00-1 and *Acidovorax* sp. JS42. The comparison revealed that genome size was not reduced and showed no A-T bias in the symbionts. Positive selection was detected in genes involved in DNA metabolism, tRNA modification, and TonB-dependent iron uptake, indicating that these may be involved in functions important in symbiosis. The comparison revealed Average Nucleotide Identity (ANI) values of 82.2 ± 6.4 % between both *Verminephrobacter* strains and approximately 76 ± 8 % of these species with *Acidovorax* strains (Kjeldsen et al. 2012).

In a recent study comparing the genes encoding oxygenases involved in aromatics biodegradation in 80 Burkholderiales genomes, 16 *Comamonadaceae* were included (Pérez-Pantoja et al. 2012). The authors report in detail on the presence and organization of various central and peripheral degradative pathways. Within the family *Comamonadaceae*, *Comamonas*, *Variovorax*, *Delftia*, and *Polaromonas* strains have a quite distinguishable catabolic pattern involving the protocatechuate *meta*-cleavage pathway, whereas other genera of this family, such as *Acidovorax* and *Alicycliphilus*, have a restricted aromatic catabolic potential (Pérez-Pantoja et al. 2012).

Phenotypic Analyses

A comparison of some general features of the members of the *Comamonadaceae* is given in *Table 29.3*.

Acidovorax Willems et al. (1990), 394^{VP}

A.ci.do'vo.rax, N.L. neut. n. *acidum* (from L. adj. *acidus*, sour) an acid; L. adj. *vorax*, voracious; N.L. masc. n. *Acidovorax*, acid-devouring (bacteria).

Table 29.3

Morphological and chemotaxonomic characteristics of the genera of *Comamonadaceae*. Data taken from the original descriptions and references as given in the main text

Genus	Source	# Species	Morphology	Motility	Metabolism	Temperature preference	Major fatty acids	Major hydroxy fatty acids	G+C content
Acidovorax	Water, soil, plants, clinical samples	15	Straight to slightly curved rods	+, polar flagellum	Aerobic chemoorganotrophic (some strains fac. hydrogen oxidizers; some strains capable of nitrate respiration)	Mesophilic	C16:0, C18:1 ω7c, SF3 (iso-C15:0 2-OH/C16:1 ω7c)	C8:0 3-OH, C10:0 3-OH	62–70
Albidiferax	Coastal aquifer sediments	1	Rods	+, single polar flagellum	Facultatively anaerobic chemoorganotrophic; respiration using Fe(III)-nitrilotriacetic acid, Mn(IV) oxide, fumarate, nitrate and oxygen	Mesophilic, psychrotolerant	ND	ND	59.5
Alicycliphilus	Municipal sewage plant	1	Short rods	+	Oxidative using oxygen, nitrate or nitrite at TAE	Mesophilic	C16:1 ω7c, C16:0, C18:1 ω7c	C10:0 3-OH	66
Brachymonas	Activated sludge, chironomid egg mass	2	Cocci or short rods	−	Aerobic chemoorganotrophic, fac. Anaerobic using nitrate	Mesophilic, psychrotolerant	C16:1 ω7c, C16:0, C18:1 ω7c	C10:0 3-OH	60–65
Caenimonas	Activated sludge, paddy soil	2	Rods or curved rods	−	Aerobic chemoorganotrophic	Mesophilic	SF 3 (C16:1ω7c and/or iso-C15:0 2-OH), C16:0	C10:0 3-OH	62.7–68.7
Comamonas	Soil, water, clinical	16	Rods	− or +, polar flagella	Aerobic, non-fermentative, chemoorganotrophic	Mesophilic	C16:0, C18:1 ω7c, SF3 (C16:1 ω7c/C15:0 iso 2-OH)	C10:0 3-OH	61–70
Curvibacter	Well water or distilled water	4	Slightly curved rods	− or 1 to 6 polar flagella	Aerobic chemoorganotrophic	Mesophilic	C16:0, SF3 (iso-C15:0 2-OH/C16:1 ω7c), C18:1 ω7c	C8:0 3-OH, C10:0 3-OH (species dependent)	62–67
Delftia	Aquatic habitats, soil, clinical samples	4	Straight to slightly curved rods	+, polar or bipolar tufts of 1 to 5 flagella	Aerobic, non-fermentative, and chemoorganotrophic	Mesophilic, some psychrotolerant	C16:0, C17:0 cyclo, C18:1w7c, SF3 (C16:1ω7c and/or C16:1ω6c)	C10:0 3-OH	63–66
Diaphorobacter	Activated sludge, sediment from paddy field	2	Rods	+, polar flagellum	Aerobic, one species able to denitrify	Mesophilic	C16:1ω7c, C16:0, C18:1 ω7c	C10:0 3-OH	63–65
Extensimonas	Industrial wastewater	1	Short rods, elongating at higher temperature	+, polar flagellum	Aerobic, chemoorganotrophic	Moderately thermophilic	SF3 (C16:1 ω7c/C15:0 iso 2-OH), C17:0 cyclo	C10:0 3-OH	68.8

Giesbergeria	Pond water, sulfide spring, wastewater	5	Spirilla	+, bipolar tufts of flagella	Aerobic, chemoorganotrophic	Mesophilic	C16:1, C16:0	(C10:0 3-OH)	56.5–60
Hydrogenophaga	Water, soil	9	Rods	+, one or two polar to subpolar flagella	Aerobic, chemoorganotrophic	Mesophilic	C16:0, C18:1 ω7c, SF3 (C16:1 ω7c/C15:0 iso 2-OH)	C8:0 3-OH, C10:0 3-OH (species dependent)	64–69
Hylemonella	Pond water	1	Spirilla	+, bipolar tufts of flagella	Aerobic, chemoorganotrophic	Mesophilic	C16:0, C16:1 ω7c, C18:1 ω7c	C10-3OH, C12:0 2-OH (species dependent)	65
Lampropedia	Water rich in organic material, rumen fluid	1	Coccoid cells in tablet formation	−, Twitching may occur	Aerobic chemoorganotrophic	Mesophilic	C14:0, C16:0, C18:1 ω7c	C10:0 3-OH, C12:0 3-OH	63–67
Limnohabitans	Freshwater	4	Straight or curved rods	−	Aerobic chemoorganotrophic, facultative anaerobic	Mesophilic, some species psychrotolerant	C16:0, C16:1 ω7c/ω6c	C8:0 3-OH	55–60
Macromonas	Freshwater environments with low oxygen and hydrogen sulfide concentrations	2	Large irregular bean-shaped or cylindrical cells with inclusions	+, polar tuft of flagella	Aerobic chemoorganotrophic	Mesophilic	C16:1 ω7c, C17:1 ω6c, C18:1 ω7c, C16:0 (M. bipunctata)	-	67.6 (M. bipunctata)
Malikia	Activated sludge, river water	2	Straight to slightly curved rods	+, one or two polar flagella	Aerobic chemoorganotrophic	Mesophilic, psychrotolerant	C16:0, C16:1 ω7c, C18:1 ω7c	C8:0 3-OH	66–67
Ottowia	Activated sludge	2	Rods	−	Aerobic, chemoorganotrophic, mixotrophic with thiosulfate	Mesophilic, psychrotolerant	C16:0, C16:1 ω7c, C18:1 ω7c	C10-3OH, C12:0 2-OH (species dependent)	59–69
Polaromonas	Antarctic ocean, glacier cryoconite, sediment, soil, water	7	Coccoid to rod shaped	+ or −	Aerobic chemoorganotrophic	Psychrotrophic or mesophilic	C16:0, SF3 (C16:1 ω7c and/or iso-C15:0 2-OH), C18:1 ω7c	C8:0 3-OH, C10:0 3-OH	52–64
Pseudacidovorax	Soil	1	Short rods	+, polar flagellum	Facultative aerobic chemoorganotrophic	Mesophilic	C16:0, SF3 (C16:1 ω7c and/or iso-C15:0 2-OH), C18:1 ω7c	C8:0 3-OH, C10:0 3-OH, C16:1 2-OH, C18:1 2-OH	70.1
Pseudorhodoferax	Soil, activated sludge, groundwater	3	Short rods	+, polar Flagellum	Aerobic, Chemoorganotrophic	Mesophilic	C16:0, C18:1 ω7c, summed feature 3 (C16:1 ω7c and/or C15:0 iso 2-OH)	C10:0 3-OH	67.6–70.1

Table 29.3 (continued)

Genus	Source	# Species	Morphology	Motility	Metabolism	Temperature preference	Major fatty acids	Major hydroxy fatty acids	G+C content
Ramlibacter	Soil	2	Straight to curved rods and coccoid cells	− or +, peritrichous flagella	Aerobic, chemoorganotrophic	Mesophilic	C16:0, C17:0 cyclo, SF4 (C16:1 ω7c and/or C15:0 iso 2-OH), SF7 (C18:1 ω7c and/or ω9t and/or ω12t)	C10:0 3-OH, C12:0 3-OH	66.6–69.6
Rhodoferax	Ditch water, activated sludge, aquatic microbial mat	2	Curved to spiral-shaped rods	+, one or more polar flagella	Fac. anaerobic Photoheterotrophic or photoautotrophic, aerobic heterotrophs or anaerobic fermenters	Mesophilic, psychrotolerant (one species)	C16:0, C16:1	C8:0 3-OH	60–61.5
Simplicispira	Freshwater, wastewater, Antarctic mosses	3	Slightly curved rods to spirilla	+, bipolar tufts of flagella or a single polar flagellum	Aerobic, organotrophic, some facultative anaerobic with denitrification	Mesophilic	C16:1, C16:0, C18:1	C10:0 3-OH	63–65
Tepidicella	Hot spring runoff	1	Short rods	+, polar flagellum	Aerobic organotrophic	Moderately thermophilic	C16:0, C18:1 ω7c, C17:0 cyclo	C8:0 3-OH	64.9–65.5
Variovorax	Soil, sewage	6	Straight to slightly curved rods to oval-shaped cells	+, one to multiple Peritrichous flagella	Aerobic chemoorganotrophic (some *V. paradoxus* are fac. hydrogen oxidizers; *V. ginsengisoli* is capable of nitrate respiration)	Mesophilic	C16:0, C17:0 cyclo, SF4 (C16:1 ω7c and/or iso-C15:0 2-OH), SF7 (C18:1 ω7c and/or ω9t and/or ω12t)	C10:0 3-OH	65–71
Verminephrobacter	Nephridia of earthworm	2	Rods	− or +, polar flagellum	Aerobic chemoorganotrophic, prefers low oxygen tension	Mesophilic	C16:0, C16:1 ω7c, C18:1 ω7c, C17:0 cyclo	C10:0 3-OH	67
Xenophilus	Soil, air	2	Straight to curved rods	+, polar flagellum	Aerobic organotrophic	Mesophilic	C16:0, SF (C16:1 ω7c and/or iso-C15:0 2-OH), C18:1 ω7c, C17:0 cyclo	C8:0 3-OH, C10:0 3-OH, C16:1 2-OH, C16:0 2-OH, C18:1 2-OH	69–70.4
Xylophilus	Vitis vinifera, diseased	1	Straight to curved rods	+, a polar flagellum	Aerobic organotrophic	Mesophilic	C16:0, SF (C16:1 ω7c and/or iso-C15:0 2-OH), C18:1 ω7c, C17:0 cyclo	C8:0 3-OH	68–69

The genus *Acidovorax* contains 15 species that either originate from the environment (soil, water) (*Acidovorax caeni, Acidovorax defluvii, Acidovorax delafieldii, Acidovorax facilis, Acidovorax soli, Acidovorax temperans*) or are phytopathogenic (*Acidovorax anthurii, Acidovorax avenae, Acidovorax cattleyae, Acidovorax citrulli, Acidovorax konjaci, Acidovorax oryzae, Acidovorax valerianellae*) or plant-associated species (*Acidovorax radicis*). *Acidovorax temperans* and *Acidovorax wautersii* were also isolated from clinical samples. They can be regarded as versatile saprophytes, aerobic chemoorganotrophs, although *Acidovorax caeni* and some strains of *Acidovorax delafieldii* (not the type strain) and *Acidovorax temperans* (including the type strain) are able to grow anaerobically using nitrate as terminal electron acceptor (Willems et al. 1990; Heylen et al. 2008). *Acidovorax facilis* strains and some strains of *Acidovorax delafieldii* (though not the type strain) are capable of autotrophic growth using hydrogen as an energy source (Willems et al. 1990).

Additional features and differentiating characteristics of the species are shown in ❯ *Table 29.4*.

Albidiferax corrig. Ramana and Sasikala (2009), 2647[VL]

Al.bi.di.fe'rax, L. adj. *albidus*, whitish; L. adj. *ferax* fertile; N.L. masc. n. *Albidiferax*, whitish and fertile.

Albidiferax ferrireducens (originally described as *Rhodoferax ferrireducens*) was isolated from coastal aquifer sediments by anaerobic enrichment culturing in a mineral medium with acetate as electron donor and Fe(III) nitrilotriacetic acid (NTA) as electron acceptor (Finneran et al. 2003). Cells are rods, 3–5 µm by 1 µm, and are motile by means of a single polar flagellum. In addition to acetate, alternative electron donors with the same electron acceptor include lactate, propionate, pyruvate, and malate (all 20 mM) and succinate (10 mM) and benzoate (1 mM). However, formate, butyrate, ethanol, methanol, or glycerol (all 20 mM); caproate, isobutyrate, valerate, butanol, or propanol (all 10 mM); or hydrogen (160 kPa) could not be used. Electron acceptors that can be used with lactate or acetate as electron donor included Fe(III)–NTA and Mn(IV) oxide (both 10 mM), fumarate (20 mM), and atmospheric oxygen. Not utilized were poorly crystalline Fe(III) oxide (100 mM); Fe(III) citrate (50 mM); anthraquinone-2, 6-disulfonate (AQDS) or chromium(VI) (both 5 mM); cobalt-EDTA (0.05 mM); uranium(VI) (2.5 mM); elemental sulfur (1 g l^{-1}); nitrite, selenate, or selenite (all 10 mM); or sulfate, sulfite, or thiosulfate (all 20 mM); and 1 % oxygen. Nitrate (20 mM) can serve as an electron acceptor with lactate, but not with acetate (Finneran et al. 2003).

Cells produce polyhydroxyalkanoate inclusions when grown in carbon-rich medium. No growth on yeast extract (0.1 %) and no autotrophic growth by converting H_2 and CO_2 to acetate. No phototrophic growth and no fermentative growth (Finneran et al. 2003).

Temperature and pH range for growth are 4–30 °C and 6.7–7.1. Optimal growth occurs at a temperature of 25 °C and pH 7.0. Anaerobic growth with Fe(III) reduction is possible at 4 °C, indicating *Albidiferax ferrireducens* is psychrotolerant (Finneran et al. 2003).

Genomic G+C content is 59.5 mol% (Finneran et al. 2003). No fatty acid data have been reported.

Alicycliphilus Mechichi et al. (2003), 149[VP]

A.li.cyc.li'phi.lus. Gr. adj. *aliphos* fat; L. n. *cyclus*, circle or ring; N.L. pref. *alicycli* referring to circular fat-like organic compounds; N.L. adj. *philus* (from Gr. adj. *philos*), friend; N.L. masc. adj. *Alicycliphilus* alicyclic compound-liking, referring to the substrates used for the isolation of this organism.

Alicycliphilus was first isolated from a municipal sewage plant by anaerobic enrichment with cyclohexanol and nitrate. Only one species has been described. Cells are short rods (0.6 by 1–2 µm), motile, and catalase and oxidase positive. Oxidative metabolism using a wide range of organic substrates and oxygen, nitrate or nitrite but not sulfate, sulfite or fumarate as terminal electron acceptors. Best growth (aerobically or anaerobically) at 28–30 °C and at pH 7.2–7.4 (Mechichi et al. 2003).

Alicycliphilus denitrificans K601^T is able to use the following substrates under anoxic conditions: cyclohexanol, cyclohexanone, 1,3-cyclohexanedione, 2-cyclohexenone, 1,3-cyclohexanediol (cis and trans), monocarboxylic acids (C2–C7), adipate, pimelate, 5-oxocaproate, citrate, 2-oxoglutarate, succinate, L-malate, propionate, crotonate, L-lactate, pyruvate, and fumarate. It is unable to use the following substrates: aniline, phenol, benzoate, 2-aminobenzoate, 2-hydroxybenzoate, 3-hydroxybenzoate, 4-hydroxybenzoate, resorcinol, hydroxyquinol, *m*-cresol, *o*-cresol, *p*-cresol, vanillate, naphthoate, indole, 1,2-cyclohexanediol, 1,2-cyclohexanedione, 2-hydroxycyclohexanone, 1,4-cyclohexanedione, cyclohexane, formate, D-glucose, D-fructose, D-xylose, and aliphatic alcohols (C1–C8). Under aerobic conditions, the following compounds are used: propionate, L-malate, aniline, fumarate, indole, vanillic acid, acetate, 4-hydroxybenzoate, *m*-cresol, *o*-cresol, *p*-cresol, crotonate, D-glucose, L-lactate, and pyruvate. The following compounds are not used aerobically: 4-aminobenzoate, benzoate, resorcinol, 2-naphthoate, biphenyl 2-carboxylate, 2-aminobenzoate, 3-hydroxybenzoate, gentisate, protocatechuate, hydroxyquinol, 3-fluorobenzoate, and 3-chlorobenzoate (Mechichi et al. 2003). *Alicycliphilus denitrificans* strain BC is able to degrade benzene, toluene, phenol, *o*-cresol, *m*-cresol, *p*-cresol, catechol, and acetate using chlorate or oxygen as an electron acceptor but not using nitrate. It can use acetate, lactate, pyruvate, succinate, propionate, butyrate, malate, citrate, fumarate, glycerol, and yeast extract with nitrate as terminal electron acceptor. In contrast to the type strain, it cannot use cyclohexanol (Weelink et al. 2008). A further strain of *Alicycliphilus denitrificans*, KN Bun08, was recently described; it is capable of aerobic as well as anaerobic growth using nitrate with the following substrates: acetone, acetate, DL-lactate, pyruvate, succinate, propionate, butyrate, malate, citrate, fumarate, 3-hydroxybutyrate, ethanol, xylose, glucose, and fructose,

but not formate; in aerobic conditions, it can also use the aromatic compounds benzoate, phenol, aniline, resorcinol, and cresol and, more slowly, also alicyclic compounds including cyclohexanol, cyclohexanediols, and cyclohexanediones (Dullius et al. 2011).

The major fatty acids reported for the type strain are C16:1ω7c, C16:0, and C18:1 ω7c. Present in smaller amounts were C10:0 3-OH and C12:0, C15:0 and cyclo C17:0. Genomic G+C content is 66 mol% (Mechichi et al. 2003).

Brachymonas Hiraishi et al. (1995), 879[VL]

Bra.chy.mo'nas. Gr. adj. *brachus*, short; L. fem. n. *monas*, a monad, unit; N.L. fem. n. *Brachymonas*, a small short unit.

Brachymonas was created for small coccobacilli isolated from activated sludge that are aerobic chemoorganotrophs with the capacity to also grow anaerobically with the respiration of nitrate to nitrogen (Hiraishi et al. 1995). Originally one species, *Brachymonas denitrificans*, was proposed; however, a second species was proposed later, *Brachymonas chironomi*, isolated from chironomid egg masses. This latter species is unable to grow anaerobically with nitrate, although it does reduce nitrate to nitrite (Halpern et al. 2009).

Brachymonas species are nonmotile coccobacilli or rods, oxidase and catalase positive, urease negative, and negative for lysine and ornithine decarboxylase. Both reduce nitrate to nitrogen in the case of *Brachymonas denitrificans* and to nitrite in the case of *Brachymonas chironomi*. Neither species produces acid from carbohydrates (Hiraishi et al. 1995; Halpern et al. 2009).

Additional characters and differentiating features of both species are shown in ➲ *Table 29.5*.

Caenimonas Ryu et al. (2008), 1067[VP]

Cae'ni.mo.nas. L. n. *caenum* mud, sludge; L. fem. n. *monas*, a unit, monad; N.L. fem. n. *Caenimonas*, monad isolated from sludge.

Caenimonas koreensis has been described for strain KCTC 12616^T isolated from activated sludge (Ryu et al. 2008). Recently a second species, *Caenimonas terrae*, was proposed for a paddy soil isolate (Kim et al. 2012). These authors also proposed an emendation of the genus *Caenimonas* which is incorporated in the following description of the genus.

The organism is strictly aerobic. Cells are rods to curved rods. *Caenimonas koreensis* cells are nonmotile; motility is not reported for *Caenimonas terrae* (Kim et al. 2012). Colonies on R2A are circular and white. Chemoorganotrophic metabolism. *Caenimonas koreensis* is unable to use hydrogen as an energy source; for *Caenimonas terrae*, hydrogen oxidation was not reported (Kim et al. 2012). Catalase positive or negative and oxidase positive. Both species are positive for hydrolysis of gelatin, and *Caenimonas koreensis* also hydrolyzes Tween 20 (Ryu et al. 2008). Both species oxidize thiosulfate to sulfate but are negative for glucose fermentation, indole production, arginine dihydrolase, and hydrolysis of aesculin, casein, Tween 80, starch, xanthine, hypoxanthine, CM-cellulose, and chitin (Ryu et al. 2008; Kim et al. 2012).

Both are positive for the assimilation of saccharose, 3-hydroxybutyrate, and proline, but negative for assimilation of D-mannose, adipate, phenylacetic acid, rhamnose, inositol, itaconate, sodium malonate, lactate, potassium-5-ketogluconate, salicin, and fucose (Kim et al. 2012).

Both species produce in API test systems alkaline phosphatase, leucine arylamidase, esterase (C4), esterase lipase (C8), and naphthol-AS-BI-phosphohydrolase. Neither species produces lipase (C14), cystine arylamidase, trypsin, α-chymotrypsin, α-galactosidase, β-galactosidase, β-glucuronidase, α-glucosidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, and α-fucosidase (Ryu et al. 2008; Kim et al. 2012).

The major respiratory quinone is ubiquinone Q-8. Major fatty acids are summed feature 3 (C16:1ω7c and/or iso-C15:0 2-OH) and C16:0; hydroxy fatty acid is C10:0 3-OH.

The G+C content of genomic DNA is 62.7–68.7 mol% (Ryu et al. 2008; Kim et al. 2012).

Additional characters and differentiating features of *Caenimonas* species are shown in ➲ *Table 29.6*.

In addition, *Caenimonas koreensis* hydrolyzes urea and is negative for H_2S or acetoin production, lysine decarboxylase, ornithine decarboxylase, and assimilation of capric acid and weakly produces tryptophan deaminidase. It produces acid from raffinose, myo-inositol, D-lactose, L-arabinose, and D-fructose, however, not from D-glucose, sorbitol, sucrose, rhamnose, amygdalin, melibiose, D-galactose, D-mannose, D-mannitol, arbutin, or salicin (Ryu et al. 2008).

Caenimonas koreensis utilizes D-fructose, malonate, and maleate as sole carbon sources, but not glycerol, D-mannitol, or D- or L-tryptophan (Ryu et al. 2008). Sole carbon source utilizations are not reported for *Caenimonas terrae* (Kim et al. 2012).

Comamonas (ex Davis and Park **1962**) De Vos et al. (1985), 450[VP]

Co'ma.mo.nas. L. n. *coma*, hair (of the head), hair; L. fem. n. *monas*, a unit, monad; N.L. fem. n. *Comamonas*, cell with a polar tuft of flagella.

The genus *Comamonas* comprises 16 species originating from water, soil, activated sludge, and clinical samples. All are oxidase and catalase positive. Aerobic chemoorganotrophic metabolism.

Comamonas denitrificans is a facultative anaerobic organism capable of denitrification of nitrate to nitrogen. Five strains of this species possess a nitrite reductase containing hemes c and d (=NirS) (Gumaelius et al. 2001). *Comamonas nitrativorans* is also a facultative anaerobe capable of reducing nitrate to nitrogen (Etchebehere et al. 2001). *Comamonas guangdongensis* is able to use Fe(III) as an alternative terminal electron acceptor while using citrate, glycerol, glucose, or sucrose as the electron donor. It can transform 2,4-D to 4-chlorophenol, and under anaerobic conditions, Fe(III) reduction and 2,4-D degradation occur simultaneously (Wu et al. 2009).

[a]Data from Ryu et al. (2008)
[b]Data from Kim et al. (2012)

In liquid culture, *Comamonas badia* grows in a flocculated state with cells embedded in a polysaccharide matrix comprising glucosamine, glucose, mannose, galactose, and rhamnose (Tago and Yokota 2004).

Comamonas kerstersii is able to grow at temperatures up to 44 °C (Wauters et al. 2003).

Comamonas thiooxidans is an aerobic heterotroph and is also able to grow mixotrophically with the oxidation of thiosulfate in mineral salts–thiosulfate medium supplemented with arabinose, citrate, succinate, pyruvate, acetate, glucose, or galactose (Pandey et al. 2009).

Comamonas aquatica, *Comamonas kerstersii*, *Comamonas koreensis*, *Comamonas odontotermitis*, *Comamonas terrae*, *Comamonas terrigena*, and *Comamonas testosteroni* are negative for lysine and ornithine decarboxylase. *Comamonas* species generally use very few sugars and prefer to grow on organic or amino acids, although *Comamonas koreensis* is reported to utilize glucose, tagatose, and mannitol and oxidize several other sugars in Biolog GN tests (Chang et al. 2002) and *Comamonas thiooxidans* utilizes glucose, galactose, and lactose (Narayan et al. 2010).

Additional characters and differentiating features of *Comamonas* species are shown in ❯ *Table 29.7*.

Curvibacter Ding and Yokota (2004), 2228[VP]

Cur.vi.bac'ter. L. adj. *curvus*, curved or crooked; N.L. masc. n. *bacter*, rod; N.L. masc. n. *curvibacter*, curved rod.

The genus *Curvibacter* comprises four species that occur in freshwater wells. All are aerobic chemoorganotrophs. *Curvibacter fontanus* is reported to grow better in microaerophilic conditions (Ding and Yokota 2010). Published descriptions for the well-water isolates are relatively limited and are summarized in ❯ *Table 29.8*.

Delftia Wen et al. (1999), 573[VP]

Delf.'tia. N.L. fem. n. *Delftia* referring to the city of Delft, the site of isolation of the type species, and in recognition of the pioneering role of Delft research groups in the development of bacteriology.

Strains of the genus *Delftia*, which currently comprises four species, are particularly versatile organotrophs, and the utilization of many different carbon sources has been reported in a number of studies (Palleroni 1984; Tamaoka et al. 1987; Willems et al. 1991c; Wen et al. 1999; Jørgensen et al. 2009; Shigematsu et al. 2003; Chen et al. 2012), with corroborating results and also with some contrasting results, probably as a consequence of differences in procedures. In the most recent new species description, Chen et al. (2012) have ensured comparability by including the four type strains under identical conditions in all tests. Therefore, these data have been included here. All four type strains are able to accumulate poly-β-hydroxybutyrate and are positive for oxidase, catalase, DNase, alkaline phosphatase, C8 esterase lipase, leucine arylamidase, acid phosphatase, and naphthol-AS-BI-phosphohydrolase activities; hydrolysis of Tweens 20, 40, and 60; nitrate reduction; and assimilation of glucose, mannitol, gluconate, adipate, malate, and phenylacetate. All four type strains are negative for C14 lipase, cystine arylamidase, trypsin, α-chymotrypsin, α-galactosidase, β-galactosidase, β-glucuronidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, α-fucosidase, arginine dihydrolase, and urease activities; hydrolysis of aesculin, starch, urea, gelatin, chitin, CM-cellulose, corn oil, and Tween 80; indole production; and glucose fermentation. All strains are sensitive to sulfamethoxazole plus trimethoprim, chloramphenicol, tetracycline, novobiocin, and nalidixic acid. Additional differentiating features of the species are shown in ❯ *Table 29.9*.

The genus description dates from the time when the type species was the only *Delftia* species (Wen et al. 1999). It describes the positive hydrolysis of Tween 80 (lipase) and absence of growth on glucose as genus characteristics. However, the youngest species, *Delftia litopeniae* is negative for the former and positive for the latter (Chen et al. 2012). The genus description contains a number of features that have not been reported for most other species of the genus: hydrolysis of acetamide (positive for *Delftia acidovorans* and *Delftia tsuruhatensis*), absence of denitrification (negative except for *Delftia litopeniae* for which no data are available), absence of autotrophic growth with H_2 (negative for *Delftia acidovorans*), negative levan formation from sucrose (negative for *Delftia acidovorans*), meta-cleavage of protocatechuate (positive for *Delftia acidovorans* and *Delftia tsuruhatensis*), the presence of Q-8 as main quinone (only reported for *Delftia acidovorans* and *Delftia litopeniae*), the presence of Q-7 and Q-9 as minor quinones, the absence of menaquinone, and the presence of putrescine and 2-hydroxyputrescine as main polyamines (only reported for *Delftia acidovorans*). The genus description also describes the motility as driven by polar or bipolar tufts of 1–5 flagella. Again this feature has not been reported for other species, although all are motile.

Diaphorobacter Khan and Hiraishi (2003), 936[VL]

Di.a.pho.ro.bac'ter. Gr. adj. *diaphoros*, different, advantageous, profitable; N.L. masc. n. *bacter*, rod; N.L. masc. n. *Diaphorobacter*, distinguished and profitable rod, referring to usefulness in nitrogen removal.

Two *Diaphorobacter* species have been described, *Diaphorobacter nitroreducens* and *Diaphorobacter oryzae*, from activated sludge and paddy field sediments, respectively (Khan and Hiraishi 2002; Pham et al. 2009). Both species are aerobic rods and motile with one polar flagellum. Strains of *Diaphorobacter* are positive for oxidase, catalase, nitrate reduction, arginine dihydrolase, protease, and urease and utilization of acetate, propionate, 3-hydroxybutyrate, potassium gluconate, L-alanine, DL-lactate, valerate, L-proline, and malate. They do not produce acid from glucose and are negative for β-galactosidase and hydrolysis of starch, casein, and DNA and do not utilize citrate, malonate, and most sugars, although the type strain of *Diaphorobacter oryzae* is reported to use D-glucose (Pham et al. 2009). *Diaphorobacter nitroreducens* is able to degrade

poly-3-hydroxybutyrate and poly(3-hydroxybutyrate-co-hydroxyvalerate) under aerobic and anaerobic denitrifying conditions; it also breaks down 1-chloro-4-nitrobenzene (Khan and Hiraishi 2002). *Diaphorobacter oryzae* is reported to reduce nitrate, but it is not clear whether true anaerobic denitrification was tested (Pham et al. 2009). Major respiratory quinone is Q-8 (Khan and Hiraishi 2002; Pham et al. 2009).

Additional characters and differentiating features of the type strains of the two *Diaphorobacter* species are given in *Table 29.10*.

Extensimonas Zhang et al. (2013b). 2065^{VP}

Ex.ten.si.mo.'nas. L. part. *extensus*, extended; L. fem. n. *monas*, a unit, monad; N.L. fem. n. *Extensimonas*, extended unit.

Extensimonas with a single species, *Extensimonas vulgaris*, was created for a bacterium from industrial wastewater that grows at 15–50 °C (Zhang et al. 2013b).

Cells are short rods (0.8–0.9 × 1.3–1.9 μm) that elongate when grown at high temperatures, motile with a polar flagellum. Cells may contain polyphosphate granules. *Extensimonas vulgaris*

Aerobic assimilation of		
Adipate, suberate	+	−
2-Ketogluconate, caprate, histidine	−	+

grows at NaCl concentrations of 0–2 %, temperatures of 15–50 °C, and a pH range of 5.5–8.5. Optimal growth conditions were 0.5 % NaCl, 48 °C, and pH 7.0–7.5. Strictly aerobic; sodium thiosulfate, sodium sulfite, sodium sulfate, sodium nitrite, sodium nitrate, and $FeCl_3$ are not used as accessory electron acceptors. Heterotrophic metabolism. No growth factors required. The following substrates are used as sole carbon sources: alanine, glutamate, asparagine, succinate, citrate, malonate, fumarate, and salicylate; not used are formate, acetate, and DL-lactate. Sugars or alcohols are not used. The following complex substrates support growth: yeast extract, peptone, and casamino acids. Catalase, oxidase, and urease are positive. Using API ZYM test, the following enzymes were present: alkaline phosphatase, esterase C4, lipase C8, leucine arylamidase, valine arylamidase, cystine arylamidase, acid phosphohydrolase, and naphthol-AS-BI-phosphohydrolase. Nitrate is reduced to nitrite; nitrite is not reduced. Hydrolysis of starch, casein, and gelatin is negative.

The major quinone is Q-8. Major fatty acids are C16:0; SF3 (C16:1ω7c/iso-C15:0 2-OH), C17:0 cyclo, and C18:1ω7c; C10:0 3-OH is the main hydroxy fatty acid, although several 2-hydroxy fatty acids are also present at more than 1 %: C16:0 2-OH, C16:1 2-OH, and C18:1 2-OH. Polar lipids include phosphatidylethanolamine, phosphatidylglycerol, diphosphatidylglycerol, an unknown aminoglycolipid, an unknown glycolipid, and two unknown phospholipids. The G+C content of the genomic DNA is 68.8 mol% (Zhang et al. 2013b).

Giesbergeria Grabovich et al. (2006), 571[VP]

Gies.ber.ger'i.a. N.L. fem. n. *Giesbergeria* named after the researcher G. Giesberger, who made a great contribution to the study of the physiology of heterotrophic spirilla.

Cells of *Giesbergeria* are spiral shaped and motile by means of bipolar tufts of flagella. They can accumulate poly-3-hydroxybutyrate and some also accumulate polyphosphate and elemental sulfur. Cells are aerobic, catalase and oxidase positive, neutrophilic and mesophilic, and unable to grow with 3 % NaCl or to hydrolyze casein or starch. Aerobic chemoorganotrophs that do not reduce nitrate to nitrate. Not able to use nitrates, sulfates, thiosulfate or fumarate as electron acceptors. No indole production. Unable to use sugars such as glucose, fructose, maltose, arabinose, xylose, or galactose.

Giesbergeria kuznetsovii and *Giesbergeria voronezhensis* can use ammonium salts, casein hydrolysate, yeast extract, peptone, aspartate, glutamate, and cysteine as nitrogen sources. For the other species, this information was not reported (Grabovich et al. 2006; Hylemon et al. 1973).

The major quinone is Q-8 (Grabovich et al. 2006).

Additional characteristics of the *Giesbergeria* species are shown in ❯ *Table 29.11*.

Hydrogenophaga Willems et al. (1989), 329[VP]

Hy.dro.ge.no'pha.go. N.L. n. hydrogenum (from Gr. n. hydoor, water; Gr. n. gennao, to create), hydrogen, that which produces water; Gr. v. phagein, to eat; N.L. fem. n. Hydrogenophaga, eater of hydrogen.

Hydrogenophaga strains are all rod shaped with cell sizes of 0.3–0.6 by 0.6–5.5 µm. They are motile by means of one or two polar to subpolar flagella, although flagellation was not reported for all species. Chemoorganotrophic, aerobic metabolism; some species are able to grow anaerobically using nitrate as terminal electron acceptor (❯ *Table 29.12*); some species are able to grow autotrophically using hydrogen, and some can oxidize thiosulfate (❯ *Table 29.12*). Some *Hydrogenophaga pseudoflava* strains, but not the type strain, are capable of N2 fixation (Jenni et al. 1989). The strains previously classified as "*Pseudomonas carboxydoflava*" are capable using CO for mixotrophic growth on organic substrates or for autotrophic growth with CO_2. For CO-autotrophic growth, the presence of molybdopterin cytosine dinucleotide is required as a cofactor (Meyer and Schlegel 1983; Volk et al. 1994). All have Q-8 as major quinone. *Hydrogenophaga* strains can use various carbon sources; all species can use lactate and 3-hydroxybutyrate (although this data is unavailable for *H. caeni*); all species can use gluconate except for *Hydrogenophaga caeni*. Additional differentiating features for the different species are shown in ❯ *Table 29.12*.

Hylemonella Spring et al. (2004), 104[VP]

Hy.le.mo.nel'la. N.L. fem. dim. n. *Hylemonella*, named after Philip B. Hylemon, who made important contributions to the taxonomy of freshwater spirilla.

Hylemonella cells are slender spirilla (diameter 0.2–0.3 µm, wavelength 2.8–3.5 µm, helix diameter 0.5–2.1 µm, length 3.5–14 µm) and motile with bipolar tufts of flagella. No internal storage of polyhydroxyalkanoates. Colonies are pinpoint sized and unpigmented. No growth at temperatures below 15 °C or above 42 °C. Metabolism is aerobic and chemoorganotrophic. No anaerobic growth with nitrate. No chemolithoautotrophic growth with hydrogen. No oxidation of thiosulfate to sulfate. Growth factors are required. Oxidase, urease, and catalase positive. Negative for hydrolysis of hippurate, casein, and starch. Uses only carbohydrates as carbon sources. Strains of *Hylemonella gracilis* (formerly *Aquaspirillum gracile*), the only species, were found not to utilize any of the sole carbon and nitrogen sources that were tested by Hylemon et al. (1973) and therefore are thought to have complex nutritional requirements. Acid is produced from D-glucose, D-galactose, and L-arabinose. *Hylemonella gracilis* can reduce nitrate to nitrite. Major respiratory quinone is Q-8. Major fatty acids are C16:1, C16:0, C18:0, C10:1, and C17:0, and hydroxyl fatty acids are C10:0 3-OH and C12:0 3-OH. Polyamines are 2-hydroxyputrescine and putrescine, and G+C content of DNA is 65 mol% (Spring et al. 2004; Hylemon et al. 1973; Sakane and Yokota 1994; Hamana et al. 1994).

Lampropedia Schroeter (1886), 151[AL]

Lam.pro.pe.di.a. Gr. adj. *lampros*, bright; Gr. neut. n. *pedion*, a plain; N.L. fem. n. *Lampropedia*, a shining flat sheet (of cells).

Lampropedia cells grow as square sheets of 16, 32, or 64 coccoid cells (1–2 µm), arising through the synchronous division of the cells in two planes and surrounded by an envelope layer. Occasionally cells occur in pairs or tetrads. The ability to grow with conspicuous tablet morphology is often lost in laboratory cultures. Requires biotin and thiamine for growth. Cells are unpigmented and do not carry flagella but can display twitching motility. Tolerant to 1.5 % NaCl; pH range 6–9; temperature range 10–40 °C. Poly-3-hydroxybutyrate granules are accumulated in the cells and some strains accumulate polyphosphate under cyclic aerobic–anaerobic conditions. Strictly aerobic chemoorganotrophic metabolism. No nitrate reduction. Oxidase and catalase are positive. The only species, *Lampropedia hyalina*, uses only intermediates of the tricarboxylic acid cycle as energy sources and ammonium salts and some

Fatty acid data taken from Yoon et al. (2008), Kämpfer et al. (2005). Cells were grown on YPG agar (Contzen et al. 2000) at 28 °C for 48 h. For *H. caeni* data are for cells grown on R2A (no data on YPG were available) (Chung et al. 2007)

w, weak response; v, varies in different reports; ND, no data

amino acids as sole nitrogen source (Lee et al. 2004; Murray 2005). It is able to grow on Green Top Agar medium, LB medium, and R2A medium and is positive for assimilation of acetate, DL-3-hydroxybutyrate, and propionate (Lee et al. 2004).

DNA G+C content is 63–67 mol%, and major fatty acids are C14:0, C16:0, and C18:1ω7c, and important hydroxyl fatty acids are C10:0 3-OH and C12:0 3-OH (Lee et al. 2004).

Limnohabitans Hahn et al. (2010a), 1361[VP]

Lim.no.ha'bi.tans. Gr. n. *limne*, lake; L. part. adj. *habitans*, inhabiting; N.L. part. adj. used as a masc. n. *Limnohabitans*, lake dweller, referring to the type of ecosystem from which the type species was first isolated.

Limnohabitans are nonmotile, straight, or curved rods that are found in the water column in freshwater habitats where they can be very abundant. No gas vesicles have been reported. Aerobic, facultatively anaerobic on nutrient broth, soytone, and yeast extract (NSY) medium (Hahn et al. 2004). Chemoorganotrophic; no data available on nitrate reduction, denitrification, or accumulation of storage materials. Nonpigmented and oxidase and catalase positive or negative (species dependent). Not halotolerant. Metabolic capabilities of some members of the genus may be more diverse: two *Limnohabitans* strains not belonging to the current species (Kasalicky 2012) were recently shown to possess a photosynthesis gene cluster, RuBisCO, CO dehydrogenase, ammonia monooxygenase, and sulfur-oxidizing genes (Zeng et al. 2012).

Major quinone is Q-8. Major fatty acids are C16:0 and C16:1ω7c/ω6c; also present though in lower amounts are C12:0 and C18:1ω7c/ω6c; main hydroxy fatty acid is C8:0 3-OH. DNA G+C content is 55–50 mol% (Hahn et al. 2010a, b; Kasalicky et al. 2010).

Differentiating features of the four *Limnohabitans* species are given in ❯ *Table 29.13*. It should be noted that to overcome inefficient growth on media with a single carbon source, the utilization of substrates was tested in one-tenth strength NSY medium which contains nutrient broth, soy peptone, and yeast extract (Kasalicky et al. 2010; Hahn et al. 2004).

Macromonas Utermöhl and Koppe in Koppe (1924), 632[AL]

Ma.cro.mo'nas. Gr. adj. *makros*, large; Gr. fem. n. *monas*, a unit, monad; N.L. fem. n. *Macromonas*, a large monad.

Macromonas cells are large, irregular pear- or bean shaped, cylindrical, or slightly bent. They are characterized by large inclusions of calcium oxalate. In addition, sulfur granules may be present. Motile by means of a polar tuft of flagella. Two species have been described: *Macromonas mobilis*, the type species, and *Macromonas bipunctata*. No pure cultures are available of the type species, *Macromonas mobilis*, whereas axenic strains are available of the second species, *Macromonas bipunctata*.

Both species have similar cells that differ notably in size with the type species being the larger: cells of *Macromonas mobilis* are 6–14 × 10–30 µm and cells of *Macromonas bipunctata* are 2.2–4 × 3.3–6.5 µm. Cells carrying more inclusions move more slowly.

In *Macromonas bipunctata*, in addition to sulfur and calcium oxalate granules, also calcium polyphosphate and poly-3-hydroxybutyrate have been reported, the type and amount of inclusions depending on the growth conditions. *Macromonas bipunctata* was isolated from the sediment of an aeration tank in a sewage treatment plant. It is an aerobic chemoorganotroph that prefers moderate concentrations of growth substrates (5–10 mM). Carbon metabolism comprises the tricarboxylic acid cycle and glyoxylate cycle. Many organic acids are good substrates. They include acetate, benzoate, fumarate, malate, oxaloacetate, and succinate but not citrate, isocitrate, aconitate, malonate, and glycolate. Sugars, most alcohols, and amino acids are not utilized. Ammonium, peptone, casein hydrolysate, and glutamate, but not nitrate and nitrite, can be used as sole nitrogen sources. *Macromonas bipunctata* can oxidize sulfide to sulfur and thiosulfate to tetrathionate by means of hydrogen peroxide; however, these processes do not provide useful energy. Vitamins are required for growth and the addition of sulfides, thiosulfate, or catalase improves growth and survival of cultures. Optimal temperature is 28 °C and optimal pH range is 7.5–8.2. No anaerobic growth with nitrate, sulfate, thiosulfate, or fumarate as terminal electron acceptors (Dubinina et al. 2005).

Malikia Spring et al. (2005), 627[VP]

Ma.li'ki.a. N.L. fem. n. *Malikia*, named after Kuhrsheed A. Malik, for his contributions to our knowledge of the cultivation and taxonomy of hydrogen-oxidizing and polyhydroxyalkanoate-accumulating proteobacteria.

Malikia was proposed as a new genus for a strain isolated from activated sludge which was named the type species, *Malikia granosa*. In the same study, the *Pseudomonas spinosa* was shown to represent a second species in the same genus and was thus renamed as *Malikia spinosa* (Spring et al. 2005).

Straight to slightly curved rods and motile by means of one to three polar flagella. In nutrient-rich media, filamentous cells of up to 50 µm length may occur. Under nitrogen-limited conditions, cells grown on acetate (*Malikia granosa*) or maltose (*Malikia spinosa*) accumulate granules of polyhydroxyalkanoates (PHAs). Under carbon-limited conditions, PHA granules are degraded and polyphosphate granules accumulate. Nonpigmented. Strictly aerobic chemoorganotrophic. Unable to grow anaerobically or phototrophically. Oligotrophic. A variety of substrates (tested at concentrations of 0.1 %) can be used by *Malikia granosa*; *Malikia spinosa* is more restricted in its food sources. Both species can utilize D-glucose, but not D-fructose, D-mannitol, formate, or glycerol. Oligonitrophilic: able to

Ottowia cells are nonmotile straight to slightly curved rods that accumulate poly-3-hydroxybutyrate internally. They are aerobic chemoorganotrophs and can convert thiosulfate to sulfate to grow mixotrophically but not autotrophically. No autotrophic growth with hydrogen. *Ottowia thiooxydans*, but not *Ottowia pentelensis*, is able to denitrify reducing nitrate and nitrite to nitrous oxide. Growth factors are required for *Ottowia thiooxydans*, but this information is unavailable for *O. pentelensis*. Oxidase and catalase are positive. Substrate utilization is restricted to some organic acids including malic acid and phenyl acetic acid but not malonate; most sugars and sugar alcohols are not utilized. Major respiratory quinone is Q-8 (Spring et al. 2004; Felföldi et al. 2011). Additional and differentiating features of the two species are shown in *Table 29.15*.

Polaromonas Irgens et al. (1996), 825^{VP}

Po.lar.o.mo'nas. N.L. adj. *polaris* (from L. n. *polus*, the end of an axis, a pole; and L. suff. *-aris*, suffix denoting pertaining to), referring to the geographic poles; L. fem. n. *monas*, a monad, unit; N.L. fem. n. *Polaromonas*, polar bacterium.

Polaromonas was created by Irgens et al. (1996) for gas-vacuolated bacteria from Antarctic marine water samples, with initially just one species, *Polaromonas vacuolata*. Since 2004, a further six species have been described, most but not all capable of growing at 1 °C.

Polaromonas comprises coccoid to rod-shaped cells and nonmotile or motile cells. Many, though not all, species are psychrotrophic and can grow at 1 °C. Aerobic chemoorganotrophic metabolism. Anaerobic growth was not detected in tow of the species and was not tested in other species. Two of the species are able to grow autotrophically with hydrogen (Sizova and Panikov 2007), and one species is able to grow with naphthene as sole carbon and energy source (Jeon et al. 2004). Oxidase and catalase are positive. All species are able to utilize Tween 40 and Tween 80, except for the type species *Polaromonas vacuolata*, for which this information is not documented.

Additional features and differentiating characters of the species are shown in *Table 29.16*.

Major quinone is Q-8; major fatty acids are C16:0, SF3 (C16:1ω7c and/or iso-C15:0 2-OH), and C18:1ω7c, and important fatty acids are C8:0 3-OH and C10:0 3-OH, although one of both may be absent from some species. The G+C content of genomic DNA is 52–64 mol%.

Pseudacidovorax Kämpfer et al. (2008), 493[VP]

Pseu.da.ci.do.vo'rax. Gr. adj. *pseudes*, false; N.L. masc. n. *Acidovorax*, a bacterial genus name; N.L. masc. n. *Pseudacidovorax*, the false *Acidovorax*.

Cells are short rods and motile by means of a polar flagellum. Aerobic or facultatively anaerobic chemoorganotrophic metabolism. The type and only species, *Pseudacidovorax intermedius*, is able to grow at 15–36 °C, not at 10 or 45 °C, on several complex media such as nutrient agar, tryptic soy agar, and R2A where it forms beige-pigmented colonies. Oxidase and catalase are positive. Unable to denitrify, reduce nitrate, or grow autotrophically with hydrogen. Capable of fixing nitrogen; the *nif* H gene was most similar to that of *Burkholderia vietnamiensis* and *Pelomonas saccharophila* and thus grouped with other nitrogen-fixing Betaproteobacteria.

Pseudacidovorax intermedius is able to utilize several organic acids and few sugars including acetate, propionate, azelate, fumarate, glutarate, DL-3-hydroxybutyrate, DL-lactate, L-alanine, L-aspartate, L-proline, *cis*- or *trans*-aconitate (weak), 4-aminobutyrate (weak), citrate (weak), L-arabinose (weak), D-glucose (weak), and D-fructose (weak). It is unable to use *N*-acetyl-D-galactosamine, *N*-acetyl-D-glucosamine, *p*-arbutin, D-cellobiose, D-gluconate, maltose, D-mannose, melibiose, L-rhamnose, D-ribose, sucrose, salicin, trehalose, D-xylose, adonitol, *i*-inositol, maltitol, D-mannitol, sorbitol, putrescine, adipate, itaconate, mesaconate, 2-ketoglutarate, suberate, β-alanine, L-leucine, L-ornithine, L-phenylalanine, L-serine, L-tryptophan, 3-hydroxybenzoate, 4-hydroxybenzoate, and phenylacetate.

Major fatty acids (>10 %) are C16:0, SF3 (C16:1ω7c and/or iso-C15:0 2-OH), and C18:1ω7c; another important fatty acid (5–10 %) is C17:0 cyclo; main hydroxy fatty acids (> = 1 %) are C8:0 3-OH, C10:0 3-OH, C16:1 2-OH, and C18:1 2-OH. DNA G+C content is 70.1 mol% (Kämpfer et al. 2008).

Pseudorhodoferax Bruland et al. (2009), 2706[VP]

Pseu.do.rho.do.fer'ax. Gr. adj. *pseudes*, false; N.L. masc. n. *Rhodoferax*, a bacterial genus name; N.L. masc. n. *Pseudorhodoferax*, the false *Rhodoferax*.

At present the three species in this genus each consist of only a type strain. Colonies are circular and convex; those of *Pseudorhodoferax soli* TBEA3[T] are white, those of *Pseudorhodoferax caeni* SB1[T] are white to light yellow, and those of *Pseudorhodoferax aquiterrae* NAFc-7[T] are light yellow. All three strains are aerobic chemoorganotrophs that grow on complex media within 1–2 days. All species are able to accumulate polyhydroxybutyrate (Bruland et al. 2009; Chen et al. 2013).

Pseudorhodoferax strains are oxidase and catalase positive (Bruland et al. 2009; Chen et al. 2013). The data of Bruland et al. (2009) and Chen et al. (2013) are generally in good agreement. Positive for alkaline phosphatase, C4 esterase, C8 esterase lipase, C14 lipase, leucine arylamidase, valine arylamidase, acid phosphatase, and naphthol-AS-BI-phosphohydrolase activities and for hydrolysis of Tweens 20, 40, and 60 and assimilation of arabinose, mannitol, gluconate, D-fructose, propionate, and malate (Chen et al. 2013). All strains are negative for DNase, arginine dihydrolase, cysteine arylamidase, trypsin, alpha-chymotrypsin, alpha-galactosidase, beta-galactosidase, alpha-glucosidase, beta-glucosidase, *N*-acetyl-beta-glucosaminidase, alpha-mannosidase, and alpha-fucosidase activities, hydrolysis of aesculin, starch, gelatin, CM-cellulose, corn oil and indole production, glucose fermentation, assimilation of glucose, mannose, N-acetyl-glucosamine, and caprate (Chen et al. 2013). All strains are sensitive to chloramphenicol, kanamycin, tetracycline, novobiocin, and nalidixic acid and resistant to rifampicin, penicillin G, and ampicillin (Chen et al. 2013). In addition, *Pseudorhodoferax caeni* and *Pseudorhodoferax soli* strains were positive for growth with acetate, taurine, and succinate; both were negative for growth with maltose, D-mannose, inositol, sorbitol, rhamnose, sucrose, 3,3′-dithiodipropionic acid, L-cysteine, L-homocysteine, 3-mercaptopropionic acid, mercaptosuccinic acid, and thiolactic acid (Bruland et al., 2009). Both species are unable to ferment D-fructose and D-glucose in Hugh–Leifson oxidative/fermentative tests and are negative for protease (Bruland et al. 2009). Additional differentiating features of the three species are shown in ❯ *Table 29.17*.

Ramlibacter Heulin et al. (2003), 593[VP]

Ram.li.bac'ter. N.L. n. *ramlis* (from Arabic *raml*), sand; N.L. masc. n. *bacter*, rod; N.L. masc. n. *Ramlibacter*, rod isolated from sandy soil.

Cells are rod shaped and may form coccoid cyst-like cells that are resistant to desiccation and vacuum. Coccoid cells are able to divide. Both types of cells may contain polyhydroxyalkanoate granules. Cells are motile with polar flagella or unflagellated, however, are motile on solid media by gliding. Optimal pH is 7–7.5 and optimal temperature for growth 30 °C; weak growth at 37 °C. *Ramlibacter ginsenosidimutans* grows at 25–37 °C, but not at 18 or 42 °C. Growth factors are required by *Ramlibacter tataouinensis* and *Ramlibacter henchirensis*.

Aerobic chemoorganotrophic metabolism. Catalase, oxidase, and β-glucosidase positive. Arginine dihydrolase and urease negative. Unable to denitrify and no reduction of nitrate to nitrogen. The following substrates are not utilized: arabinose, mannose, mannitol, *N*-acetylglucosamine, gluconate, caprate, adipate, citrate, and phenylacetate (Heulin et al. 2003; Wang et al. 2012).

G+C content of genomic DNA is 66.6–69.7 mol% (Heulin et al. 2003). Major fatty acids are C16:0, C17:0 cyclo, summed feature 4 (C16:1 ω7c and/or C15:0 iso 2-OH), and summed feature 7 (C18:1 ω7c/ω7c/ω7c). The hydroxyl fatty acids C10:0 3-OH and/or C12:0 3-OH are present in some of the species (Wang et al. 2012).

Additional characteristics of *Ramlibacter* species are shown in ❯ *Table 29.18*.

[a]Data from Chen et al. (2013)

[b]Data from Bruland et al. (2009)

[c]SF, summed feature: several fatty acids that cannot be separated by the Microbial Identification System. In Chen et al. (2013), summed feature 2 consisted of C16:1 iso I and/or C14:0 3-OH, and summed feature 3 consisted of C16:1 ω7c and/or C16:1 ω6c

[d]In Bruland et al. (2009), summed feature 2 consisted of C12:0 aldehyde, C16:1 iso I, and/or C14:0 3-OH. Summed feature 3 consisted of C16:1 ω7c and/or C15:0 iso 2-OH

[e]Phosphatidylethanolamine (PEA), phosphatidylglycerol (PG), diphosphatidylglycerol (DPG), unidentified phospholipid (UPL)

Rhodoferax Hiraishi et al. (1992), 191^{VL}

Rho.do.fer'ax. Gr. n. *rhodon*, the rose; L. adj. *ferax*, fertile; N.L. masc. n. *Rhodoferax*, red and fertile. *Rhodoferax* was created to accommodate photoheterotrophic bacteria from ditch water and activated sludge that were previously referred to as the "*Rhodocyclus gelatinosus*-like" group, with initially just one species, *Rhodoferax fermentans* (Hiraishi et al. 1991). A second species was later described from an aquatic microbial mat sample from Antarctica (Madigan et al. 2000).

Rhodoferax cells are curved to spiral-shaped cells that are motile with one or more flagella. Both species are facultatively anaerobic photoheterotrophs using a variety of substrates including glucose, fructose, pyruvate, lactate, acetate, succinate, fumarate, malate, citrate, and aspartate. *Rhodoferax antarcticus* is also able to grow slowly photoautotrophically using hydrogen; this property is not documented for *Rhodoferax fermentans*. Both species can also grow aerobically heterotrophically in the dark, and *Rhodoferax fermentans* is able to grow anaerobically in the dark by fermenting pyruvate, glucose, or fructose.

Important hydroxy fatty acids (> = 1 %)	C10:0 3-OH		C12:0 3-OH
DNA G+C content (mol%)	69.6	66.6	68.1

Bacteriochlorophyll a and spheroidene-type carotenoids are present as phototrophic pigments although no obvious intracytoplasmic photosynthetic membranes have been observed.

Rhodoferax antarcticus is a psychrotrophic species with optimal growth 12–18 °C, whereas *Rhodoferax fermentans* is a mesophilic species that grows best at 25 °C and 30 °C. Both species do not grow at 37 °C and both require growth factors. Both species are capable of nitrogen fixation and can use ammonium and glutamate as sole nitrogen sources. Both are freshwater organisms that can grow without added NaCl; with 1 % NaCl, *Rhodoferax fermentans* is unable to grow and *Rhodoferax antarcticus* grows weakly. Additional and differentiating features of both species are shown in *Table 29.19*.

The G+C content of DNA is 60–61.5 mol% (Hiraishi et al. 1991; Madigan et al. 2000). Major fatty acids and hydroxy

fatty acids have only been reported for *Rhodoferax fermentans* and include C16:0, C16:1, C18:1, and C8:0 3-OH (Hiraishi et al. 1991; Hiraishi and Imhoff 2005). Major quinones have also only been reported for *Rhodoferax fermentans* and consist of ubiquinone Q-8 and rhodoquinone RQ-8 (Hiraishi et al. 1991).

Simplicispira Grabovich et al. (2006), 575^{VP}

Sim.pli.ci.spi'ra. L. adj. *simplex–icis*, simple; L. fem. n. *spira*, a spiral; N.L. fem. n. *Simplicispira*, a simple spiral. *Simplicispira* cells are polymorphic rods or weakly curved rods to spiral-shaped cells. They are motile by means of bipolar tufts of flagella or a single flagellum. Cells are catalase and oxidase positive. Aerobic chemoorganotrophic metabolism. Two species are also facultative anaerobic with reduction of nitrate to nitrogen for *Simplicispira psychrophila* (Terasaki 1979) and to nitrite for *Simplicispira limi* (Lu et al. 2007). Neutrophilic and mesophilic. The major quinone is Q-8. All species are catalase and oxidase positive. Sugars are generally not utilized, except for maltose which is utilized by *Simplicispira limi*. The following substrates are not utilized by any of the species: glycerol, leucine, ornithine, phenylalanine, and serine; casein and starch are not hydrolyzed and indole is not produced (Lu et al. 2007; Hylemon et al. 1973; Terasaki 1979). Differentiating substrate utilization patterns as well as other distinctive features for the three species are shown in *Table 29.20*.

Tepidicella França et al. (2006), 56[VP]

Te.pi.di.cel'la. L. adj. *tepidus*, warm; L. fem. n. *cella*, chamber, cell; N.L. fem. n. *Tepidicella*, a cell living in a warm environment.

Only one species, *Tepicella xavieri*, has been described for two isolates from a hot spring runoff (França et al. 2006). Cells are rod-shaped, 0.5–1 × 1–2 μm, and motile with one polar flagellum. Growth is possible in the temperature range of 25–55 °C, with an optimum of 45 °C; pH range is 6.5–10.5 with an optimum of 8.5–9.0. These organisms can thus be regarded as slightly thermophilic and moderately alkaliphilic. Grows in the presence of 0–2 % NaCl.

Aerobic chemoorganotrophic metabolism. Non-fermentative. No anaerobic growth with nitrate, nitrite, Fe(III)-nitrilotriacetic acid, fumarate, sulfate, or thiosulfate. L-cysteine, thiosulfate, and tetrathionate are oxidized to sulfate without an increase in cell biomass. Negative for reduction of nitrate to nitrite.

Oxidase, catalase, DNAse, acid phosphatase, urease, alkaline phosphatase, esterase (C4), lipase (C8), leucine arylamidase, valine arylamidase, and naphthol-AS-BI-phosphohydrolase are positive; amylase and xylanase negative; aesculin, hippurate, and Tween 20 are hydrolyzed. Negative for cystine arylamidase, trypsin, α-chymotrypsin, α-galactosidase, β-galactosidase, β-glucuronidase, α-glucosidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, and α-fucosidase. Utilizes mainly organic and amino acids including succinate, acetate, lactate, pyruvate, citrate, malate, 2-ketoglutarate, aspartate, L-phenylalanine, L-lysine, L-leucine, L-serine, L-histidine, L-tryptophan, L-tyrosine, L-ornithine, L-proline, L-alanine, L-asparagine, L-glutamate, and L-glutamine. Sugars and polyols are not utilized, nor benzoate, glycine, L-valine, L-methionine, or L-threonine.

Major fatty acids are C16:0, C18:1ω7c, and C17:0 cyclo; also important (5–10 %) were C16:1ω7c and C19:0 cyclo ω8c; main hydroxy fatty acid was C8:0 3-OH.

Polar lipids consist of phosphatidylethanolamine and phosphatidylglycerol and main respiratory quinone is Q-8. G+C content of genomic DNA was 64.9–65.5 mol% (França et al. 2006).

Variovorax Willems et al. (1991), 447[VP]

Va.ri.'vo.rax. L. adj. varius, *various*; L. masc. adj. *vorax*, voracious; N.L. masc. n. *Variovorax*, [bacteria] devouring a variety [of substrates].

Strains of *Variovorax* are versatile chemoorganotrophs capable of using a wide range of organic compounds for growth. All are aerobic and *Variovorax ginsengisoli* was also reported to be capable of anaerobic respiration of nitrate (Im et al. 2010). Some strains of *Variovorax paradoxus* (Biotype I) are able to grow lithoautotrophically using hydrogen (Willems and Gillis 2005). When grown in TSB containing 100 mM boric acid (2 days at 25 °C), *Variovorax boronicumulans* BAM-48^T accumulated boric acid to a larger extent than related species did, although *Variovorax paradoxus* NBRC 15149^T and *Variovorax dokdonensis* KCTC 12544^T also showed some accumulation (Miwa et al. 2008).

The following description contains those characteristics of the genus that were reported consistently as present or absent in the individual species descriptions (Willems and Gillis 2005; Yoon et al. 2006; Kim et al. 2006; Miwa et al. 2008; Im et al. 2010; Jin et al. 2012), unless otherwise indicated. All *Variovorax* strains can assimilate L-arabinose (negative for *Variovorax dokdonensis* according to Yoon et al. 2006), histidine, 4-hydroxybenzoate, 3-hydroxybutyrate, 2-ketogluconate, and suberate. None of the strains assimilates *N*-acetylglucosamine, caprate (except *Variovorax boronicumulans* according to Miwa et al. 2008), maltose, rhamnose, inositol, sucrose, glycogen, L-serine, melibiose, or salicin. All strains are positive for catalase, oxidase, esterase lipase (C8), and leucine arylamidase but negative for nitrite reduction, indole production, glucose fermentation, arginine dihydrolase, gelatin hydrolysis, *N*-acetyl-β-glucosaminidase, α-chymotrypsin, cystine arylamidase, α-fucosidase, α-galactosidase, β-galactosidase, β-glucosidase, β-glucuronidase, lipase (C14), α-mannosidase, and trypsin. Additional and differentiating features of the *Variovorax* species are shown in ❯ *Table 29.21*.

Verminephrobacter Pinel et al. (2012), 2551[VL]

Ver.mi.ne.phro'bac.ter. L. n. *vermis*, a worm; Gr. n. *nephros*, a kidney; N.L. masc. n. *bacter*, a rod; N.L. masc. n. *Verminephrobacter*, earthworm-kidney (associated) bacteria.

Cells are short, straight rods and are nonmotile (*Verminephrobacter aporrectodeae*) or possess a polar flagellum (*Verminephrobacter eiseniae*, although in cultivation motility is rarely observed). Cells contain PHB granules. Aerobic chemoorganotrophic metabolism with a preference for low oxygen tension. Fumarate and nitrate are not used as alternative electron acceptors. *Verminephrobacter aporrectodeae* is able to ferment glucose and pyruvate; this feature was not documented for *Verminephrobacter eiseniae*. Both species are oxidase and catalase positive; urease negative. Nitrate is not reduced. Temperature range for growth is 10–30 °C. Moderate growth on complex media containing pyruvate and amino acids. Ammonium salts, urea, and nitrate can be used as nitrogen sources in defined media. Biotin is required for growth on defined mineral medium in the absence of amino acids. Both species utilize a variety of substrates including D-fructose, D-fucose, L-fucose, D-galactose, D-glucose, D-mannose, L-rhamnose, D-xylose, acetate, fumarate, lactate, malate, propionate, pyruvate, succinate, glycerol, L-alanine, L-aspartate, L-asparagine, L-glutamate, and L-glutamine. Neither species utilizes benzoate, citrate, glutarate, maleate, L-histidine, L-isoleucine, L-serine, L-threonine, L-lysine, L-methionine, and L-valine (Pinel et al. 2008; Lund et al. 2012).

Additional features of both species are shown in ❯ *Table 29.22*.

Within *Verminephrobacter aporrectodeae*, two subspecies have been proposed – though not validly published. They differ in the species of *Aporrectodea* they were isolated from (*Aporrectodea tuberculata* and *Aporrectodea caliginosa*) and also show small differences in preferred growth conditions (Lund et al. 2012).

Table 29.21

Comparison of selected characters[a] of the species of *Variovorax*. Data taken from Willems and Gillis (2005), Yoon et al. (2006), Kim et al. (2006), Miwa et al. (2008), Im et al. (2010), and Jin et al. (2012) were generally in good agreement unless otherwise indicated

Fatty acids have only been reported for *Verminephrobacter eiseniae*: major fatty acids (>10 %) are C16:0, C16:1ω7c, C18:1ω7c, and C17:0 cyclo, and also present in important amounts is C14:0; the hydroxyl fatty acid present is C10:0 3-OH (Pinel et al. 2008). The G+C content of the genomic DNA was only reported for *Verminephrobacter eiseniae* and is 67 mol% (Pinel et al. 2008).

Xenophilus Blümel et al. (2001), 1835^{VP}

Xe.no'phi.lus. Gr. adj. *xenos*, foreign; Gr. masc. n. *philos*, friend; N.L. masc. n. *Xenophilus*, friend of foreign compounds, referring to the isolation of the type species by enrichment on azo dyes.

Cells are straight to slightly curved, motile rods. For *Xenophilus aerolatus*, a polar flagellum was reported. Yellow pigmented. Aerobic, chemoorganotrophic metabolism. Oxidase and oxidase positive. Nitrate reduction negative. The following substrates are utilized by *Xenophilus azovorans* and *Xenophilus aerolatus*: itaconate, suberate, acetate, lactic acid, propionate, 3-hydroxybutyrate, 3-hydroxybenzoate, 4-hydroxybenzoate, dextrin, L-histidine, and L-proline; the following substrates are not utilized: sucrose, L-rhamnose, D-ribose, inositol, casein, methanol, tartaric acid, citrate, glycine, and L-serine. The main respiratory quinone was Q-8 (Blümel et al. 2001; Kim et al. 2010).

Additional carbon sources and other features of both species are given in *Table 29.23*.

Xylophilus Willems et al. (1987), 428^{VP}

Xy.lo.phi'lus. Gr. n. *xylon*, wood; N.L. adj. *philus* (from Gr. adj. *philos*), friendly, loving; N.L. masc. adj. *Xylophilus*, friend of wood.

Cells are straight to slightly curved rods, 0.4–0.8 × 0.6–3.3 μm. Filamentous cells of more than 30 μm long may occur in older cultures. Motile with a polar flagellum. Colonies are yellow pigmented, circular, and slightly raised with an entire margin.

Strictly aerobic, chemoorganotrophic metabolism. Growth is generally very slow and poor, even at the optimal growth temperature of 24 °C. Temperature range for growth is 6–30 °C. Maximum NaCl concentration is 1 %. Requires L-glutamate (0.1 %) for growth in defined media.

Oxidase negative and catalase and urease positive. No reduction of nitrate. The following substrates are used for growth: acetate (0.2 % but not 0.5 %), citrate, DL-malate, succinate, DL-tartrate, mannitol, sucrose, and fumarate (Willems et al. 1987; Kim et al. 2010); the following substrates are not used: formate (weakly used according to Kim et al. [2012]), propionate, malonate, maleate, oxalate, benzoate, and calcium gluconate. Lipolysis of Tween 80, but no hydrolysis of gelatin, aesculin, starch, casein, arbutin, and sodium hippurate. Potato soft rot test negative. H_2S is formed from cysteine and weakly from thiosulfate. Negative for production of indole and ammonia, Voges–Proskauer test, arginine dihydrolase, lysine and ornithine decarboxylase, lecithinase, and acid production from glucose (Willems et al. 1987).

Major fatty acids include summed feature 3 (C16:1ω7c and/or iso-C15:0 2-OH), C16:0, C18:1ω7c, and C17:0 cyclo. Hydroxy fatty acid C8:0 3-OH is present in significant amounts (Kim et al. 2010). The G+C content of the DNA ranges from 68 to 69 mol% (Willems et al. 1987).

Isolation, Enrichment and Maintenance Procedures

The genera and species of the family are metabolically very diverse and originate from a wide range of habitats. No single isolation or enrichment procedure is available to obtain all or most members of the family. The genera will therefore be discussed separately below.

Acidovorax comprises some environmental species and also several plant-associated/plant-pathogenic species. No single specific isolation protocol or selective medium is available. The environmental species can be encountered in soil, water, and occasionally in clinical samples. They will grow on nutrient agar. *Acidovorax defluvii* was isolated on R2A by whole-cell hybridization with a DNA probe targeting the beta1 subgroup of the Proteobacteria. It was grown on nutrient agar (Schulze et al. 1999). *Acidovorax soli* BL21^T was isolated from soil by dilution plating on Luria–Bertani agar and incubation at 30 °C for 3 days (Choi et al. 2010).

The plant-associated and plant-pathogenic species of *Acidovorax* can be isolated from plant material and will also grow on complex media such as nutrient agar. For example, *Acidovorax radicis* strain N35^T was isolated from the roots of wheat plants grown in agricultural soil, Neumarkt, Germany. Washed roots were surface sterilized, crushed, and plated on nutrient broth agar (no. 4, Fluka) (Li et al. 2011). For this strain two different colony types were observed: one showing the rough colonies on NB agar plates and forming flocks in liquid NB medium and the other forming smooth colonies and not flocculating in liquid medium. About 5 % of the rough-type colonies switch to the smooth type on NB agar plates. Reversal to the rough colony type was not observed. Cells of the smooth colony type had lost their flagellum (Li et al. 2011). Another example, *Acidovorax valerianellae* can be isolated from plants of *Valerianella locusta* affected by bacterial leaf spot. The bacterium is cultivated on YBGA (0.7 % yeast extract, 0.7 % Bacto-peptone, 0.7 % glucose, and 1.5 % agar; pH 7.3) at 25 °C (Gardan et al. 2003).

Albidiferax ferrireducens (originally named *Rhodoferax ferrireducens*) was isolated from sediments collected at 18 ft depth in Oyster Bay, VA, USA, by enrichment culturing. The enrichment medium (Lovley et al. 1993) contained 10 mM lactate as the electron donor and 100 mmol l^{-1} poorly crystalline Fe(III) oxide as the sole electron acceptor. Anaerobic tubes were flushed with N_2/CO_2 (80:20, v/v) to eliminate dissolved oxygen. The final pH was 6–7. The enrichment cultures were incubated at 20 °C in the dark and were transferred (10 % inoculum) at least five times. Isolation of pure cultures was performed using a similar medium solidified with agar that contained Fe(III) chelated with nitrilotriacetic acid rather than poorly crystalline Fe(III) oxide. Colonies were glossy white, smooth, round, and convex (Finneran et al. 2003).

Alicycliphilus strains have been isolated by enrichment using several specific carbon sources. *Alicycliphilus denitrificans* strain K601^T was isolated from a wastewater treatment plant in Konstanz, Germany, under denitrifying conditions and using the alicyclic compound cyclohexanol as sole carbon source (Dangel et al. 1988). The enrichment medium (also used for isolation and routine cultivation) consisted of l^{-1} distilled water: 1.08 g KH_2PO_4, 5.6 g K_2HPO_4, 0.54 g NH_4Cl, 0.15 g $CaCl_2{\cdot}2H_2O$, 0.2 g $MgSO_4{\cdot}7H_2O$, 1.27 g $NaNO_3$, 1 ml trace element solution SL-10 (Widdel et al. 1983), 1 ml selenite/tungstate solution (Tschech and Pfennig 1984), 1 ml vitamin solution VL-7 (Pfennig 1978), and 1 mM cyclohexanol. The final pH was 7.2–7.4. Oxygen was removed by applying several cycles of vacuum and flushing with oxygen-free nitrogen gas at room temperature. For aerobic growth, the same medium composition was used without $NaNO_3$. Cultures were routinely grown at 30 °C, and aerobically grown cultures were shaken at 120 r.p.m. (Mechichi et al. 2003). A further strain, BC, showing 99.7 % 16S rRNA gene sequence similarity with the type strain, was obtained by dilution culturing from enrichment cultures using benzene as a carbon source and chlorate as an electron acceptor (Weelink et al. 2008). A third strain, KN Bun08, was assigned to *Alicycliphilus denitrificans* based on its high rRNA gene sequence similarity with the type strain (99 %). This strain was isolated from sediment from a small tarn close to the University of Konstanz, Konstanz, Germany, through an enrichment culture using butanone as carbon source and nitrate as electron acceptor. The small whitish colonies of the acetone-degrading, nitrate-reducing strain KN Bun08 were purified by dilution culturing on agar with acetone plus nitrate (Dullius et al. 2011).

As can be expected from their different habitats, there is not a single isolation procedure for *Brachymonas* species. *Brachymonas denitrificans* was isolated from various types of wastewater sludge, the type strain from soybean curd waste sludge, and other strains from sewage sludge or activated sludge (Hiraishi et al. 1995). Strains do not require growth factors and grow well on nutrient agar or a mineral medium with a suitable carbon and energy source. Best growth with organic acids or amino acids rather than sugars (Hiraishi et al. 1995). *Brachymonas chironomi* was isolated from egg mass of chironomids, freshwater insects (Diptera, Chironomidae), from a waste stabilization pond in northern Israel. Washed egg mass was homogenized and dilutions were plated onto *m-Aeromonas* medium (Himedia) which promotes the growth of members of the genus *Aeromonas*. After incubation at 30 °C for 48 h, isolations were made (Halpern et al. 2009).

Caenimonas koreensis KCTC 12616^T was isolated from a serial dilution of a sample from activated sludge from a lab-scale sequencing batch reactor performing enhanced biological phosphorous removal with sodium acetate as a sole carbon source. Dilution samples were plated on R2A agar (Difco) and incubated at 20 °C for 7 days for isolation. Routine cultivation can be done on R2A agar at 30 °C (Ryu et al. 2008). Recently

a second species was proposed, *Caenimonas terrae*, from soil by serial dilution on R2A medium and incubation at 28 °C for 5 days. The organism can be maintained on glycerol stocks in liquid nitrogen or can be freeze-dried (Kim et al. 2012).

Comamonas strains have been isolated from various environmental sources (natural water or soil samples [De Vos et al. 1985; Narayan et al. 2010], soils with contamination [Chitpirom et al. 2012; Yu et al. 2011]), compost (Young et al. 2008), and wastewater treatment plants (Gumaelius et al. 2001; Tago and Yokota 2004), including bioreactors (Etchebehere et al. 2001; Kim et al. 2008); various clinical samples (De Vos et al. 1985; Willems et al. 1991c); and termite gut samples (Chou et al. 2007). Without a common selective medium, standard procedures of isolation using complex media can be used. Because these organisms are quite versatile, enrichment steps to select for particular metabolic traits can be used.

Curvibacter species have all been isolated from water. However, no single isolation medium or procedure is available. *Curvibacter delicatus* (originally *Spirillum delicatum*) and *Curvibacter lanceolatus* (originally *Pseudomonas lanceolata*) were isolated from distilled water samples using a salt-free agar containing ($g.l^{-1}$) 3 g Casitone, 1 g yeast extract, 1 g K_2HPO_4, and 15 g agar (pH 7.1). After drying overnight at 37 °C, 0.1 ml of sample diluted with sterile distilled water was plated and incubated for 2–5 days at 20 °C (Leifson 1962c) from distilled water. The procedure is not selective as many different gram-negative, polarly flagellated non-fermentative straight rods were obtained (Leifson 1962b). *Curvibacter gracilis* strain 7-1^T was isolated from well water and maintained on B104 medium containing 10 g polypepton, 2 g yeast extract, and 1 g $MgSO_4.7H_2O$, pH 7,0 (Ding and Yokota 2004). *Curvibacter fontanus* strains were isolated from well water and grew poorly in aerobic conditions but better under microaerophilic conditions (Ding and Yokota 2010). The PYMB medium used (polypeptone 1 g, yeast extract 0.2 g, $MgSO_4{\cdot}7H_2O$ 1 g, brain heart infusions 2 g, agar 15 g, water 1 l, pH 7) was enriched with 10 % sterile supernatant of a late logarithmic phase culture of *Micrococcus luteus* (Ding and Yokota 2010).

Also for *Delftia*, not a single isolation strategy is available. *Delftia acidovorans* (originally *Pseudomonas acidovorans* and *Comamonas acidovorans*) has been isolated from soil, mud, wood chips, and water using mineral medium with various aromatic compounds, hydrocarbons, and higher dicarboxylic acids (e.g., phenol, *m*-cresol, acetamide, muconic acid, *p*-hydroxybenzoate, indole, nicotinate, tryptophan, maleate, mesaconate, kerosene, crude oil) as sole carbon source (Gray and Thornton 1928; den Dooren de Jong 1926; Robert-Gero et al. 1969; Stanier et al. 1966). *Delftia lacustris* strain 332^T was isolated, after enrichment for peptidoglycan degraders, from filtered water (0.8 mm pore size) collected from the mesotrophic Lake Sjælsø, northern Zealand, Denmark. Microcosms were supplemented with peptidoglycan (2 mg l^{-1}) from *Bacillus* sp. strain A6 (Frette et al. 2004) purified according to the method of Pelz et al. (1998) and incubated for 7 days at 20 °C. Bacteria were isolated from the microcosms on 1/10 LB agar (Eisenstadt et al. 1994) and transferred to 1/10 LB agar supplemented with peptidoglycan (or with heat-denatured cell-wall material) from *Bacillus* sp. strain A6; strain 332^T formed distinct but opaque clearing zones. Routine cultivation is possible in LB broth or TSB in shake flasks incubated overnight at 22 °C or on PG-enriched media [tryptic soy agar or dilute tryptic soy broth amended with 2 mg peptidoglycan l^{-1}] (Jørgensen et al. 2009). *Delftia tsuruhatensis* strain T7^T was isolated from activated sludge from a domestic wastewater treatment plant in Japan by enrichment with terephthalate as sole carbon source (Shigematsu et al. 2003). *Delftia lacustris* strain 332^T was isolated from the mesotrophic freshwater Lake Sjælsø, northern Zealand, Denmark, by selection for peptidoglycan degradation (Jørgensen et al. 2009). *Delftia litopenaei* wsw-7^T was isolated from a freshwater sample from a shrimp culture pond in Pingtung, Southern Taiwan, by plating on R2A medium (Chen et al. 2012).

Diaphorobacter nitroreducens was isolated from activated sludge with pellets and flakes of poly(3-hydoxybutyrate-*co*-3-hydroxyvalerate) (PHBV) as the sole added substrate under anaerobic denitrifying conditions. Strains can be maintained on medium PBY (0.5 % Bacto-peptone (Difco), 0.3 % beef extract (Difco), and 0.1 % yeast extract (Difco)) at 28–30 °C with aeration through shaking. For denitrification experiments, a supplement of 0.2 % KNO_3 can be added (Khan and Hiraishi 2002). *Diaphorobacter oryzae* strains were obtained from sediment samples from rice fields through aerobic thiosulfate-oxidizing enrichment culturing in basal freshwater medium (Taylor et al. 1981) plus 1 mM thiosulfate at 20 °C, although the strains themselves do not oxidize thiosulfate (Pham et al. 2009).

Extensimonas was isolated from filtered wastewater by dilution plating on CM agar (containing, per liter distilled water, 0.5 g NaCl, 0.5 g yeast extract, 0.5 g beef extract, 1 g peptone, and 1.0 g glucose, pH 7.0–7.2) and incubating at 28 °C. After 3 days, colorless colonies were purified and maintained on the same medium. Longer-term storage is possible on the same medium plus 25 % glycerol at −80 °C (Zhang et al. 2013b).

Giesbergeria comprises five species from pond water, sulfur spring, and wastewater. *Giesbergeria anulus* (originally *Spirillum anulus*) and *Giesbergeria sinuosa* (originally *Spirillum* sinuosum) were isolated by supplementing a 100 ml water sample from a stagnant small pond with 1 g peptone or yeast autolysate and incubating at room temperature for 3–7 days. Further enrichment could be achieved by dilution of the medium (Williams and Rittenberg 1957). They can be maintained on peptone-succinate-salts (PSS) medium (Hylemon et al. 1973) or modified PSS medium (Grabovich et al. 2006). Strains can be preserved in liquid nitrogen as a dense suspension in PSS broth with 15 % glycerol (Hylemon et al. 1973).

Chemolithotrophic hydrogen-oxidizing strains of *Hydrogenophaga* can be isolated from soil or water by enrichment in a mineral medium (Palleroni and Doudoroff 1972) with incubation in an atmosphere of H_2, O_2, and CO_2. Heterotrophic strains can be isolated from soil or water by selection with various carbon sources or can be isolated using dilution plating on general media: for example, *Hydrogenophaga bisanensis* was

isolated from wastewater of a textile dye factory by means of dilution plating on nutrient agar at 30 °C (Yoon et al. 2008). *Hydrogenophaga caeni* was isolated from activated sludge involved in phosphorous removal, by dilution plating on R2A and incubation at 20 °C; subculturing was done at 30 °C (Chung et al. 2007).

Hylemonella gracilis was originally isolated (as *Spirillum gracile*) from pond water using a medium composed of (per l) 5 g peptone, 0.5 g yeast extract, 20 mg Tween 80, 0.1 g K_2HPO_4, and 10 g agar (pH 7.2). The authors used the small cell size as a selective feature by placing sterile cellulose ester filter disks (average pore size 0.45 µm) on the plates, adding 0.05 ml of pond water in the center, and incubating at room temperature for 1.5–5 h before removing the filters. Further incubation of at least 3 days resulted in spreading, semitransparent areas of subsurface growth of the spirilla (Canale-Parola et al. 1966).

Lampropedia strains can be found in water rich with organic matter, wastewater, and rumen fluid. They will grow on rich media, however, may be hard to isolate because the source of samples for isolation usually contains large numbers of other bacteria. The tablet-like sheets can be picked out using a microscope. In liquid culture, they form a hydrophobic and rumpled pellicle on the surface of cultures left aerobically at room temperature (Murray 2005). On solid media, a strain is still able to be transparent; strains that had lost this ability produced round colonies that may be slimy and glossy or matt and fry (Lee et al. 2004). They can be maintained by regular subculturing, although this may select for mutants. Lyophilization is possible with a fair degree of survival (Murray 2005).

Limnohabitans represents a group of freshwater bacteria, referred to as the R-BT065 freshwater cluster (Simek et al. 2001) that can be quite abundant in many habitats (Kasalicky et al. 2010; Newton et al. 2011). Isolation of strains in culture and subsequent species description was possible thanks to the filter and dilution–acclimatization method which eliminates fast-growing competing bacteria by filtration and allows for the adjustment of bacteria to higher nutrient concentrations by using gradually more concentrated NSY (nutrient broth, soytone, yeast extract) medium (up to 3 g l^{-1}) in consecutive subcultures (Hahn et al. 2004). Purity can be verified by plating on NSY agar.

Macromonas bipunctata cultures can be obtained using a semisolid medium comprising, per l distilled water, 1 g sodium acetate, 0.1 g calcium chloride, 0.1 g casein hydrolysate, 0.1 g yeast extract, 1 g agar with vitamins, trace elements, and 200 mg of freshly precipitated iron(II) sulfide added after sterilization (Dubinina et al. 2005). Inoculations in 10 ml portions should be incubated at 28 °C for 2–3 days when growth appears as a white surface film that can be streaked onto the same medium solidified with 10 g of agar to purify strains (Dubinina et al. 2005). Lyophilization is unsuccessful; however, cultures can be maintained on semisolid agar medium (0.15 % agar) with 1 g l^{-1} thiosulfate instead of FeS (Dubinina et al. 2005).

Malikia granosa was isolated from activated sludge from a wastewater treatment plant by dilution plating on solid medium of Rouf and Stokes (1964) which was designed to select for bacteria of the *Sphaerotilus/Leptothrix* group. The strain was selected by whole-cell hybridization (Spring et al. 2004) with an oligonucleotide probe LDI23a for the same group (Wagner et al. 1994). A second species, *Malikia spinosa*, is the former *Pseudomonas spinosa* which originates from river water and was isolated by enrichment of water samples with low amounts (0.01–0.1 %) of nutrients such as acetate, ammonium salts, and yeast extract and purification on salt-free nutrient agar (Leifson 1962a). No data are published on preservation. However, strains are available from culture collections as lyophilized cultures.

The same approach as used for the isolation of *Malikia granosa* also led to the isolation of a second organism that was described as *Ottowia thiooxydans* (Spring et al. 2004). More recently, *Ottowia pentelensis* was isolated from a laboratory-scale activated sludge for coke plant effluent using plate dilution on TC medium containing potassium thiocyanate (500 mg l^{-1}) and later maintained on TSA (Felföldi et al. 2010).

Polaromonas species have been isolated from cold habitats including water from the Southern Ocean, glacier cryoconites, and forest soil from Alaska but also from less cold environments such as a coal-tar contaminated aquifer, tap water from a paper mill, and soil. No specific isolation procedure targets *Polaromonas* in general, and several different procedures have been used to obtain the described species. Gosink and Staley (1995) recovered *Polaromonas vacuolata* from Antarctic sea ice and water samples by plating on seawater-*Cytophaga* medium (oligotrophic medium containing beef extract, yeast extract, tryptone, and succinate in half-strength artificial seawater (Irgens et al. 1989)). Plates were incubated at 4–6 °C for 3–8 weeks, and gas-vacuolate colonies were selected visually for their white appearance. *Polaromonas jejuensis* was isolated from soil samples by plating serial dilutions on R2A plates and incubating at 28 °C for 5 days (Weon et al. 2008).

Other species were obtained by selecting for a particular metabolic property. *Polaromonas hydrogenivorans*, which is capable of autotrophic growth with hydrogen, was selectively enriched from forest soil by using this property. An enrichment in mineral medium with H_2 and CO_2 as energy and carbon source, respectively, was incubated at 0.1–1 °C (Sizova and Panikov 2007).

Polaromonas naphthalenivorans was selected from samples of surface freshwater sediment obtained from groundwater flowing through naphthalene-rich coal-tar waste contamination. Serially diluted samples were plated onto minimal salts base agar medium (Stanier et al. 1966) and incubated in the presence of naphthalene vapor as the sole carbon source at 10 °C for 1 month. *Polaromonas naphthalenivorans* formed large (0.5 cm) mucoid colonies (Jeon et al. 2004).

Pseudacidovorax was isolated from soil by serial dilution and plating on nutrient agar. It can be maintained on tryptic soy agar and grows well at 28 °C (Kämpfer et al. 2008).

Pseudorhodoferax soli strain TBEA3^T was isolated from a soil enrichment using the thioether 3,3′-thiodipropionic acid as a sole source of carbon and energy (Bruland et al. 2009). *Pseudorhodoferax caeni* strain SB1^T was isolated using aniline-containing enrichment cultures from activated sludge after conjugal transfer of the aniline-degradative plasmid pNB2 (Bathe 2004). Both strains grow on complex media within 1–2

days. They can be grown on mineral salts medium (MSM; Schlegel et al. 1961) supplemented with a suitable carbon source, 0.5 % (w/v) 3,3′-thiodipropionic acid for *Pseudorhodoferax soli* TBEA3^T, or 1 % (w/v) sodium gluconate for both *Pseudorhodoferax soli* TBEA3^T and *Pseudorhodoferax caeni* SB1^T. To enhance growth on MSM, the medium can be supplemented with yeast extract (0.1 % w/v) or with a vitamin solution containing (l^{-1}) 20 mg biotin, 20 mg folic acid, 60 mg lipoic acid, 50 mg thiamine, 50 mg riboflavin, 50 mg nicotinic acid, 100 mg pyridoxal hydrochloride, 50 mg pantothenic acid, 50 mg vitamin B12, and 50 mg *p*-aminobenzoic acid (Mohn 1995). *Pseudorhodoferax aquiterrae* NAFc-7^T isolated groundwater from Tainan countryside, Southern Taiwan, by incubation on R2A agar (BD Difco) at 25 °C for 3 days (Chen et al. 2013).

Ramlibacter species were also isolated from soil. Heulin et al. (2003) isolated *Ramlibacter tataouinensis* and *Ramlibacter henchirensis* from desert soil while studying alterations to meteorite fragments. Isolations were performed by diluting a crushed sample in tenfold-diluted tryptic soy broth (TSB/10; 3 g l^{-1}) supplemented with 100 mM $CaCO_3$ (TTB medium) to mimic natural selective pressure (carbonated sandy soil). After 2 days incubation at 30 °C, the resulting culture was filtered using a 0.45 µm filter to select the smallest bacterial forms. The filtrate was diluted tenfold in tubes of TSB/10 and incubated for 5 days at 30 °C. Tubes in which associations of rod-shaped and spherical bacteria were microscopically observed were plated on TTA agar medium (TSB, 3 g l^{-1}; granulated agar, 15 g l^{-1}; CaCO3 100 mM) and stored at 30 °C for 1 month. *Ramlibacter* appeared as small yellow-orange colonies (0.1–0.5 mm in diameter), embedded in a medium, and all purified colonies contained the two cell types (rods and coccoid cells) (Heulin et al. 2003). An unvalidated species, "*Ramlibacter ginsenosidimutans*," that phylogenetically groups with other *Ramlibacter* species was isolated from soil of a ginseng field in China using serial dilution on modified xylan-nutrient agar (per liter: 0.02 g tryptone, 0.02 g yeast extract, 0.02 g malt extract, 0.02 g beef extract, 0.02 g casamino acid, 0.02 g soytone, 1.0 g xylan, 0.1 g sodium pyruvate, 0.3 g K2HPO4, 0.05 g MgSO4, 0.05 g CaCl2, and 15 g agar, pH 7.0) and incubation at 30 °C for 1 month. Routine cultivation was on R2A agar (Difco) or 1/10 TSA (trypticase soy agar; Difco) at 25 °C. Preservation was done in a glycerol solution [20 % (w/v)] at −70 °C (Wang et al. 2012).

Freshwater phototrophic *Rhodoferax* have been isolated from different sources, relatively rich in organic matter, including ditch water, activated sludge, and microbial mats from Antarctic ponds. Isolation by enrichment for purple nonsulfur bacteria can be made more selective for *Rhodoferax fermentans* by the addition of 0.5 mM EDTA (Hiraishi and Imhoff 2005). Suitable anaerobic incubation is under illumination at 1,000–2,000 lx at 28 °C for *Rhodoferax fermentans* and at 12–18 °C for *Rhodoferax antarcticus*. MYCA medium (Hiraishi et al. 1991) containing 0.1 % DL-malate, 0.3 % yeast extract, 0.2 % casamino acids, and 0.05 % ammonium sulfate (pH 6.6–6.8) can be used as a simple medium for the purification of *Rhodoferax* (Hiraishi and Imhoff 2005). *Rhodoferax* can be lyophilized or stored frozen at −80 °C or in liquid nitrogen (Hiraishi and Imhoff 2005).

Simplicispira metamorpha (originally *Spirillum metamorphum*) was isolated from a putrid infusion of freshwater mussels (*Corbicula japonica* Prime) on a medium containing (per l) 5 g peptone, 3 g yeast extract, 1 g NaCl, and 200 ml shellfish extract (obtained by boiling 250 g of broken shellfish in 500 ml of water for 20 min followed by filtering) (pH 8.0–8.2). The inoculum consisted of broken putrid shellfish that had been incubated with a teaspoon of mud in 0.1 % NaCl solution at 27–28 °C in a Petri dish. Incubation temperature for isolation was 30 °C (Terasaki 1970). It is thought that the source of the bacteria may also have been mud that was incubated with the shellfish (Krieg 1976). *Simplicispira psychrophila* (originally *Spirillum psychrophilum*) was isolated from an infusion of a moss (*Ceratodon purpureus*) collected from Antarctica and can be maintained at 4° by 3-monthly transfers on a medium containing (per l) 5 g peptone, 3 g meat extract, and 15 g agar (Terasaki 1979). *Simplicispira limi* was isolated from activated sludge that performed enhanced biological phosphorus removal in a laboratory-scale sequencing batch reactor. A serially diluted sludge sample was plated on R2A agar plates and incubated at 20 °C for 5 days (Lu et al. 2007).

Tepidicella strains were isolated from a hot spring runoff (temperature 70 °C, pH 7.5). Water samples were passed over membrane filters, and filters were placed on agar-solidified *Thermus* medium (Williams and Da Costa 1992), wrapped in plastic bags, and incubated at 50 °C for up to 4 days for isolation. For cultivation, Degryse 162 medium (Degryse et al. 1978) results in higher growth yields (França et al. 2006).

Variovorax species have been isolated from soil using diverse procedures. *Variovorax paradoxus* can be isolated from soil, mud, and water by enrichment in mineral medium by selecting for typical properties. Facultatively chemolithotrophic hydrogen-oxidizing strains can be isolated incubated at 30 °C under an atmosphere of 50 % H_2, 4–20 % O_2, 5 % CO_2, and 25–41 % N_2 (Davis et al. 1970). Heterotrophic strains can be isolated from soil by enrichment with pantothenate (Davis et al. 1970), poly-3-hydroxybutyrate (Delafield et al. 1965), or various other chemicals given the large metabolic versatility of the species (Willems and Gillis 2005). *Variovorax soli* GH9-3^T was isolated from greenhouse soil cultivated with lettuce, Wanju, Korea. It was obtained from a serial dilution series on R2A (Reasoner and Geldreich 1985) after 3 days incubation at 30 °C. The isolate was maintained on R2A and stored at −80 °C with 15 % glycerol (v/v) (Kim et al. 2006). *Variovorax dokdonensis* DS-43^T was isolated from soil using standard dilution plating on nutrient agar and incubation at 25 °C. It can be routinely cultivated on tryptic soy agar at 30 °C (Yoon et al. 2006). *Variovorax boronicumulans* strain BAM-48^T was obtained from soil from an experimental field at the Yayoi campus of the University of Tokyo, Japan. Soil samples (5 g) were incubated in sterilized PBS (pH 7.0) at 30 °C for several days, after which the supernatant was streaked on tryptic soya agar (TSA; Difco) and incubated at 25 °C. The strain was purified and maintained on TSA and as glycerol (35 %, w/v) stocks at −80 °C (Miwa et al. 2008). *Variovorax ginsengisoli* strain Gsoil 3165^T was first isolated from soil from a ginseng field, Pocheon Province, South

Korea. A serial dilution of soil sample in 50 mM phosphate buffer (pH 7.0) was plated on one-fifth-strength modified R2A agar (per liter distilled water: 0.25 g tryptone, 0.25 g peptone, 0.25 g yeast extract, 0.125 g malt extract, 0.125 g beef extract, 0.25 g casamino acids, 0.25 g soytone, 0.5 g glucose, 0.3 g soluble starch, 0.2 g xylan, 0.3 g sodium pyruvate, 0.5 g KNO_3, 0.3 g K_2HPO_4, 0.05 g $MgSO_4$, 0.05 g $CaCl_2$, and 15 g agar). After anaerobic incubation ($N_2/CO_2/H_2$ at a ratio 80/15/5) at 25 °C, single colonies were purified and grown on modified R2A agar or half-strength modified R2A agar. Strain Gsoil 3165^T was routinely cultured under aerobic conditions on R2A agar (Difco) at 30 °C. Preservation was as a glycerol suspension (20 %, w/v) at −70 °C (Im et al. 2010). *Variovorax defluvii* strains 2C1-b^T and 2C1-21 were isolated from sewage, South Korea, during screening for 2-chlorophenol-degrading bacteria. Sewage samples were stimulated with 100 p.p.m. 2-chlorophenol, and stimulated cultures were serially diluted and plated on R2A agar. Yellow colonies were isolated after 7 days incubation at 25 °C (Jin et al. 2012).

Verminephrobacter can be isolated from nephridia of earthworms using *Acidovorax* complex medium (ACM) containing l^{-1}: 0.5 g yeast extract, 1.0 g casamino acids, 2.0 g pyruvic acid, 2.0 g L-glutamine, 0.3 g KH2PO4, 0.3 g MgSO4, and 2.0 g 3-(*N*-morpholino)propanesulfonic acid (MOPS), pH 7.2–7.3, adjusted with 5 M KOH before autoclaving (Pinel et al. 2008). For plates, 1.5 % Phytagel was added. Crushed and diluted nephridia are plated and incubated, sealed with parafilm, at about 25 °C. Pinel et al. (2008) used fluorescence in situ hybridization (FISH) with an *Acidovorax*-specific probe to identify and purify desired bacteria. Colonies of *Verminephrobacter* were circular and convex and had a diameter of 0.5–2 mm and an entire or lightly erose margin and a light bisque to peach color after 15–20 days incubation at room temperature (Pinel et al. 2008). Lund et al. (2012) used a similar procedure and FISH verification; however, they used modified R2A medium (DSMZ medium 830 containing in g l^{-1}: 0.5 proteose peptone, 0.5 yeast extract, 0.5 casamino acids, 0.5 glucose, 0.5 soluble starch, 0.3 sodium pyruvate, 0.3 K2HPO4, 0.3 MgSO4 · 7H2O, 0.3; pH adjusted to 7.0 with 1 M HCl). Gelling agent was 1 % Phytagel (Lund et al. 2012).

Xenophilus azovorans was isolated from a soil inoculum by selection for usage of the azo-dye carboxy-Orange II as the sole source of carbon and energy (Kulla et al. 1984). The species grows well on various nutrient-rich media (Luria ± Bertani or nutrient broth), at 30 °C, but rapidly loses the ability to degrade Orange II in these conditions (Blümel et al. 2001). *Xenophilus aerolatus* was isolated from air in an outdoor region of Suwon City, Republic of Korea, using a MAS-100 air sampler (Merck; single-stage multiple-hole impactor) containing Petri dishes with R2A agar with cycloheximide (200 μg ml^{-1}). Plates were incubated at 30 °C for 5 days before isolation (Kim et al. 2010).

Xylophilus ampelinus can be isolated from diseased tissue of *Vitis vinifera* on which this bacterium causes necrosis and canker. It can be grown on nutrient agar, but growth is generally very slow and poor with yellow colonies attaining a diameter of 0.2–0.3 (6 days) to 0.6–0.8 mm (15 days). Better growth is obtained on GYCA medium (in wt/vol, 1 % glucose, 0.5 % yeast extract, 3 % CaC03, 2 % agar), and the best growth is observed on a medium containing 1 % yeast extract, 2 % D-galactose, 2 % $CaC0_3$, and 2 % agar at 24 °C. On this medium, colonies are also yellow, and a brown diffusible pigment is produced. Some strains may produce two colony types of similar appearance but differing in size due to a difference in growth rate (Willems et al. 1987).

Ecology

From the preceding sections, it is clear that members of the family *Comamonadaceae* are very diverse. They inhabit a wide range of habitats. Three broad types of can be recognized: (1) bacteria that are free-living in the natural and man-made environment (various clean or polluted soils and waters, industrial settings, water purification, and bioremediation sites), (2) bacteria that are plant associated or plant pathogenic, and (3) bacteria that are associated with animals or clinical samples. An overview of the genera and species in these broad categories is given in *Table 29.24*. Environmental habitats are by far the most common (89 species), with plant-associated or plant-pathogenic species (10 species) and animal-associated species and species from clinical samples (11 species) restricted to the genera *Acidovorax*, *Simplicispira*, and *Xylophilus* and *Acidovorax*, *Brachymonas*, *Comamonas*, *Delftia*, *Simplicispira*, and *Verminephrobacter*, respectively.

Of the plant-associated species, *Acidovorax radicis* strain N35^T was isolated from the roots of wheat plants and found to be truly able to colonize roots endophytically. It is nonpathogenic and has plant growth-promoting properties (Li et al. 2012a). *Simplicispira psychrophila* was obtained from an infusion of mosses, but its possible association with these plants is undocumented (Terasaki 1979).

Pseudacidovorax intermedius is a nitrogen-fixing bacterium isolated from agricultural soil in Korea (Kämpfer et al. 2008). It has also been reported as an endophyte (Thomas and Soly 2009) and more recently also from surface sediments from the South China Sea (Zhang and Chen 2012).

Among the aquatic environmental species, many originate from activated sludge or various aquatic sediments (*Table 29.24*). However, quite a number of species inhabit at more oligotrophic freshwater habitats. For example, *Curvibacter* species are found in distilled water and well water; *Delftia lacustris* and *Delftia licopenaei* were described from freshwater, although the latter species came from a shrimp cultivation pond which may therefore be rather nutrient rich; also *Hylemonella gracilis* and several *Giesbergeria* species were isolated from pond water and one from a sulfide spring; *Malikia spinosa*, *Hydrogenophaga palleronii*, and *Hydrogenophaga pseudoflava* were found in river water, and *Polaromonas aquatica* was reported from tap water, *Polaromonas vacuolata* from the Antarctic ocean; *Pseudorhodoferax aquiterrae* was described from ground water (*Table 29.24*). The importance of these organisms in their ecosystem remains largely unknown. Most have been isolated

Table 29.24

Overview of habitats of species of the *Comamonadaceae*

Species	Environmental habitats	Plant associated or plant pathogenic	Animal associated or clinical	Remarks	References

through some selective or enrichment process indicating that there abundance is perhaps not very high (e.g., size selection for *Hylemonella gracilis* [Canale-Parola et al. 1966], enrichment through repeated dilution of cultures for *Giesbergeria* [Williams and Rittenberg 1957], enrichment for hydrogen oxidizers for *Hydrogenophaga* [Palleroni and Doudoroff 1972]).

Limnohabitans is an important planktonic representative of the Betaproteobacteria in many freshwater habitats. It belongs to the R-BT065 freshwater cluster that can be quite abundant as was shown through the application of a specific FISH probe for the group (Simek et al. 2001; Kasalicky et al. 2010; Newton et al. 2011). Despite its numerical importance, relatively little is known about the metabolic capacities of this taxon. Recent genome analyses reports hint at larger metabolic versatility with the presence of phototropic genes, genes for RuBisCO, CO dehydrogenase, ammonia monooxygenase, and sulfur-oxidizing genes (Zeng et al. 2012).

Macromonas is found in freshwater environments with low oxygen and hydrogen sulfide concentrations, for example, the surface sediment in aeration tanks of sewage treatment plants, the upper layers of mud in lakes and ponds, the hypolimnion, and the chemocline layers of freshwater lakes (Dubinina et al. 2005).

Studying the microbial community associated with hypoxic zones below a *Microcystis* bloom in Lake Taihu, *Comamonadaceae* were found to be a prominent group at all stages of the development of the hypoxia. One hypothesis for their role is that they may be involved in the decomposition of the *Microcystis* biomass (Li et al. 2012b).

Although a large majority of *Comamonas* species have been described from various environmental samples (*Table 29.24*), one species, *Comamonas odontotermitis*, has been isolated from the gut of the termite *Odontotermes formosanus* recovered from a decaying bamboo tree, although its role or persistence in the termite gut is not documented (Chou et al. 2007). More recently, an endosymbiont in the parasitic nematode *Spirocerca lupi* was found to be a novel (as yet undescribed) member of the genus *Comamonas* (Gottlieb et al. 2012).

Several *Polaromonas* species are psychrophilic, and this genus has been found as one of the dominant groups together with *Flavobacterium* and *Pseudomonas* in shallow freshwater lakes in northern Victoria Land, East Antarctica (Michaud et al. 2012). Analyses of all available long-read 16S rRNA gene sequences of *Polaromonas* phylotypes from glacial and periglacial environments worldwide revealed that *Polaromonas* phylotypes are globally distributed with weak isolation by distance patterns at global scales. Analyses of aerobiological and genomic data suggest that *Polaromonas* phylotypes may be globally distributed as dormant cells through high-elevation air currents. A glacial-ice metagenome and the two sequenced *Polaromonas* genomes contain the gene *hipA*, suggesting that *Polaromonas* can form dormant cells (Darcy et al. 2011).

Tepidicella is a moderately thermophilic and moderately alkaliphilic genus that was isolated from the runoff of a hot spring in the Furnas geothermal area on the Island of Sao Miguel in the Azores. The 16S rRNA genes of two strains were closely related to sequences of environmental clones from a deep terrestrial fracture system and a gold mine borehole. The ecological significance of these observations is at present unclear (França et al. 2006).

Malikia strains have been isolated from activated sludge. Depending on growth conditions (mainly C and N sources), reserve materials such as PHA or poly-P granules are accumulated in the cells in large numbers. This capacity for storage makes *Malikia* a potentially important player in the enhanced biological phosphorus removal (EBPR) process used in some wastewater treatment plants although this remains to be firmly proved (Spring et al. 2005).

Verminephrobacter strains were isolated from the nephridia of several lumbricid earthworm species and genera (*Oligochaeta*, *Lumbricidae*). They are aerobic, though with a preference for low oxygen concentrations, and can grow on a range of sugars, fatty acids, and amino acids, at temperatures of 10 °C to about 30 °C. These characteristics are in agreement with the conditions reported or inferred for the nephridial environment (Lund et al. 2012). These microorganisms are thought to be vertically transmitted to the next generation of worms (Davidson and Stahl 2006, 2008), and their 16S rRNA gene sequence type is rarely detected in surveys of soils or worm culture bedding (Pinel et al. 2008). This seems to suggest the bacteria do not survive in the soil and have a close symbiotic relation with the earthworms. Although it is clear that the bacteria can utilize many fatty acids, sugars, and amino acids that are to be present in the host, the potential benefit for the earthworm remains unclear (Lund et al. 2012).

Pathogenicity and Clinical Relevance

The family *Comamonadaceae* comprises two genera with plant-pathogenic species, *Xylophilus* and *Acidovorax*, although not all species of the latter genus are pathogens.

Xylophilus ampelinus is the causal agent of bacterial necrosis and canker on *Vitis vinifera*, mainly of the woody parts. It has been reported from many of the wine-producing areas of the world (Willems et al. 1987). A real-time PCR assay has been developed for the detection of this pathogen (Dreo et al. 2007).

The plant-pathogenic species of *Acidovorax* can cause considerable damage to their hosts that include some important food, feed, and ornamental species: *Acidovorax anthurii* (bacterial leaf spot of *Anthurium*), *Acidovorax avenae* (pathogenic for various *Poaceae* including oats, corn, wheat, barley, rye, sorghum, sugarcane (red stripe disease), rice seedlings (bacterial stripe disease), Italian millet, and proso millet), *Acidovorax cattleyae* (leaf spot and bud rot on *Cattleya*, *Dendrolobium*, and *Phalaenopsis* orchids and their hybrids), *Acidovorax citrulli* (pathogenic for various species of the *Cucurbitaceae*, including watermelon, cantaloupe, cucumber, and squash), *Acidovorax konjaci* (bacterial leaf blight on *Amorphophallus rivieri* cv. Konjac), *Acidovorax oryzae* (pathogenic on rice), and *Acidovorax valerianellae* (bacterial spot disease of the salad

vegetable *Valerianella locusta*) (Gardan et al. 2000, 2003; Willems et al. 1992; Schaad et al. 2008). Recently, *Acidovorax valerianellae* was also reported to infect watermelon in Korea and cause bacterial black spot disease (Han et al. 2012). An ELISA-based system was developed for the detection of *Acidovorax citrulli* in leaves and seed of Cucurbitaceae (Himananto et al. 2011). Also for *Acidovorax valerianellae*, an ELISA test for its detection in seeds was recently developed (Thiele et al. 2012).

Some species of the genera *Acidovorax*, *Comamonas*, and *Delftia* have been isolated from various clinical samples. Both *Acidovorax delafieldii* and *Acidovorax temperans* include strains that were first described as members of E. Falsen (EF) groups 13 and 16. These groups comprised clinical isolates that were received for identification at the Culture Collection of the University of Goteborg, Sweden, examined using immunological methods and provisionally placed in two unnamed groups, EF13 and EF 16 (Willems et al. 1990). No pathogenic effects are documented, and the close relationship with free-living environmental strains would suggest the presence of these strains in clinical samples is most probably opportunistic (Willems et al. 1990). Recently a further species from clinical and environmental samples, *Acidovorax wautersii*, was described (Vaneechoutte et al. 2013). These authors report that the clinical isolation of *Acidovorax* strains is fairly rare and provide a recent inventory of human *Acidovorax* isolates from urine, nasopharynx, wound secretion, tibia puncture, and foot, classified as *Acidovorax delafieldii*, *Acidovorax temperans*, or *Acidovorax avenae* without a clear description of the clinical context (Malkan et al. 2009; Willems et al. 1990; Shetty et al. 2005).

A similar observation of close relatedness of environmental and clinical strains can be made for several *Comamonas* species and *Delftia acidovorans*. *Comamonas terrigena*, *Comamonas testosterone*, *Comamonas aquatica*, and *Comamonas kerstersii* comprise strains that were first placed in the unnamed clinical group EF10. Clinical significance of these strains was undocumented (Willems et al. 1991c). However, in a recent study, Vaneechoutte et al. (2013) provide for a literature overview of case reports of *Comamonas acidovorans* and *Comamonas testosteroni* (and once *Comamonas terrigena*) involving bacteremia (Gul et al. 2007; Lair et al. 1996; Nseir et al. 2011; Siebor et al. 2007; Smith and Gradon 2003; Tsui et al. 2011), endocarditis (Cooper et al. 2005; Horowitz et al. 1990), pneumonia (Franzetti et al. 1992), catheter-related bloodstream infections (Castagnola et al. 1997; Ender et al. 1996; Le Moal et al. 2001), and ocular infections (Lee et al. 2008; Lema et al. 2001; Miño de Kaspar et al. 2000; Reddy et al. 2009; Stonecipher et al. 1991).

Application

Several species belonging to at least 12 different genera of the family *Comamonadaceae* have been isolated from activated sludge (*Table 29.24*), and several of these are able to denitrify (e.g., *Acidovorax caeni*, *Acidovorax temperans*, *Brachymonas denitrificans*, *Diaphorobacter nitroreducens*, *Hydrogenophaga caeni*, *Ottowia thiooxydans*, *Simplicispira limi*). For the removal of nutrients from wastewater, denitrification is an important process that requires sufficient organic material as electron donor. The use of polyhydroxyalkanoates (PHA) and related biodegradable polymers as substrates for a solid-phase denitrification process has been studied as an alternative to liquid carbon sources, and PHA-degrading, denitrifying bacteria were found to be predominantly members of the *Comamonadaceae* (Hiraishi and Kahn 2003). In a study of the solid-phase denitrification of poly(3-hydroxybutyrate-*co*-3-hydroxyvalerate), denitrifiers were isolated and identified by 16S rRNA gene sequencing as well as by characterization of *nirS* and *nosZ* genes. The results confirm that members of *Acidovorax*, *Brachymonas*, *Comamonas*, *Diaphorobacter*, and *Simplicispira* are important active denitrifiers in this system (Kahn et al. 2007). Similarly, in a denitrifying packed-bed bioreactor using another biodegradable polymer, poly-(butanediol succinate) (PBS), as a carbon source and biofilm support, pyrosequencing showed that most of the PBS-degrading bacteria belong to the *Comamonadaceae* (Wu et al. 2013).

Brachymonas denitrificans is an active denitrifier in activated sludge (Hiraishi et al. 1995) and tannery wastewater (Leta et al. 2004). It was found to be tolerant to relatively high concentrations of chromium(III) and sulfide (Leta et al. 2004). It is studied for use as part of denitrifying biofilms for wastewater treatment. Its activity was found to be influenced by interspecies interactions (Andersson et al. 2011). A PHB-accumulating isolate of *Brachymonas denitrificans* was shown to protect *Artemia* nauplii from pathogenic *Vibrio campbellii* (Halet et al. 2007).

Diaphorobacter strains are regularly reported to be present in bioremediation-related habitats. They have been reported to be able to perform nitrification and denitrification simultaneously in wastewater (Khardenavis et al. 2007). Some isolates are capable of nitrate-dependent arsenite (III) oxidation (Sun et al. 2009), others of pyrene degradation (Klankeo et al. 2009), degradation of several organophosphorus pesticides (Liang et al. 2011), and chloroaniline (Zhang et al. 2010).

Many other *Comamonadaceae* have been obtained from polluted soils or were obtained from soil or water by selecting for the degradation of particular pollutants. For example, *Alicycliphilus denitrificans* was isolated under denitrifying conditions using cyclohexanol as sole carbon source (Dangel et al. 1988), *Pseudorhodoferax caeni* was isolated using aniline-containing enrichment cultures (Bathe 2004), *Variovorax paradoxus* was obtained from soil by enrichment with pantothenate (Davis et al. 1970), and *Xenophilus azovorans* was isolated from soil using the azo-dye carboxy-Orange II as the sole carbon source (Kulla et al. 1984). The literature on the metabolic versatility and biochemical characterization of members of soil- and water-inhabiting genera, such as *Comamonas*, *Delftia*, *Acidovorax*, and *Variovorax*, is very extensive and too diverse to summarize in a short chapter. Some particular applications are listed below.

Pseudorhodoferax caeni has been used in bioaugmentation experiments. It was detected together with other bacteria in

2,4-dichlorophenoxyacetic acid (2,4-D) degrading aerobic granular sludge, obtained through plasmid pJP4 mediated bioaugmentation (Ma et al. 2012).

During studies using a pilot-scale bioreactor for the aerobic degradation of methyl tert-butyl ether (MtBE), a widely used fuel oxygenate and widespread environmental pollutant, *Hydrogenophaga* was found to be a member of the MtBE-degrading community (Zein et al. 2004). With a view to its application for bioaugmentation of contaminated aquifers, an adhesion-deficient variant of the MtBE-degrading wild-type strain *Hydrogenophaga flava* strain ENV735 was selected, which has improved mobility through sediments (Streger et al. 2002).

A novel strain of *Delftia tsuruhatensis*, isolated from the rhizoplane of rice, was found to have plant growth-promoting potential as a diazotroph and potential biocontrol agent against 14 fungal or bacterial plant pathogens of rice (Han et al. 2005).

30 The Family *Gallionellaceae*

Lotta Hallbeck[1] · *Karsten Pedersen*[1,2]
[1]Microbial Analytics Sweden AB (MICANS), Mölnlycke, Sweden
[2]Department of Civil and Environmental Engineering, Chalmers University of Technology, Göteborg, Sweden

Abstract
The family *Gallionellaceae* comprises the genus *Gallionella* with one established type species, *Gallionella ferruginea*. The phylogenetic position of *Gallionellaceae*, as determined by 16S-rDNA sequence comparisons, is among the *β-proteobacteria*. Its phylogenetic neighbors are *Methylophilaceae*, *Nitrosomonadaceae*, and *Spirillaceae*. The family contains gram-negative, chemolithoautotrophic, neutrophilic, and aerobic ferrous iron-oxidizing bacteria with the ability to secrete an extracellular twisted stalk composed of numerous fibers. *Gallionellaceae* can be found where anaerobic groundwater containing ferrous iron reaches an environment that contains oxygen. Large amounts of stalk material are usually produced; this material attracts iron hydroxides and many trace metals, giving it a brown, macroscopic appearance. The stalk and iron hydroxide masses formed may eventually cause severe clogging of ditches, drinking-water wells, and any other facilities utilizing iron-bearing, anaerobic groundwater. The family is relevant to biotechnological processes, as it can be used to remove ferrous iron when producing drinking water from groundwater.

Introduction

The family *Gallionellaceae*, with one established type species, *Gallionella ferruginea*, belongs to the microorganism group named "iron bacteria." Together with members of the sheath-forming genus *Leptothrix*, *Gallionella* is a signature organism for problems related to clogging by iron oxides and iron bacteria. *Gallionella* was first described in the early nineteenth century and is by that the earliest described bacterium, but nevertheless, its physiology and phylogeny are continuously discussed. The bacterium is easily recognized under the microscope by its twisted stalk, but it is a challenge to obtain, maintain, and study pure cultures of *Gallionella*. The carbon source for *Gallionella* is carbon dioxide, and the energy source is ferrous iron which is oxidized to ferric iron. The habitats of *Gallionella* are in gradients of ferrous iron and oxygen which can be iron seeps, drainage systems, drinking-water wells, i.e., when iron-rich groundwater comes in contact with air at neutral pH. In this environment, *Gallionella* produces a twisted stalk that can reach a length of 100 μm per cell. The analysis of environmental DNA libraries has revealed that iron bacteria, to which *Gallionella* belong, comprise a diverse group of unrelated species. Recent studies have shown that production of twisted stalks is not exclusively found in the family *Gallionellaceae* but also in another genus, i.e., the marine microorganism *Mariprofundus* (Emerson et al. 2007). In the future, DNA studies of pure cultures of iron-oxidizing and stalk-forming bacteria will give a better understanding how these characteristics are distributed in the microbial world.

Historical and Current Taxonomy

The family *Gallionellaceae* comprises the genus *Gallionella* with one established type species, *Gallionella ferruginea*. Historically, *Gallionella* has been described based on its production of a twisted stalk. The first report naming *Gallionella* was published in 1836 by Ehrenberg (1836), who examined ochre masses under the microscope. However, Ehrenberg described *G. ferruginea* as a fossil infusorian and called it "die Eisenochertierchen," i.e., the small iron ochre animal. In 1879, Zopf (1879) included *G. ferruginea* in Monera. For a long time, discussion of the morphology and physiology of *Gallionella* focused on the stalks (Van Iterson 1958). Winogradsky (1888, 1922) proposed that the so-called iron bacteria, including *G. ferruginea*, were lithotrophic. He suggested that these bacteria could grow using carbon dioxide as the sole carbon source and ferrous iron as the energy source and electron donor. Hanert (2006) proposed that the genus *Gallionella* could be differentiated into two species based on the stalk morphology, i.e., *G. ferruginea* (with stalks consisting of 40 or more filaments) and *G. filamenta* (with stalks consisting of 3–8 filaments).

The sequenced type strain of *G. ferruginea* (Hallbeck et al. 1993) was isolated from a drinking-water well drilled in granitic rock and was later denoted "Johan" (Hallbeck and Pedersen 2005). The phylogenetic position of *Gallionellaceae*, as determined by 16S-rDNA sequence comparisons for *G. ferruginea*, is

E. Rosenberg et al. (eds.), *The Prokaryotes – Alphaproteobacteria and Betaproteobacteria*, DOI 10.1007/978-3-642-30197-1_398,

Fig. 30.1

Maximum likelihood genealogy reconstruction based on the RAxML algorithm (Stamatakis 2006) of the sequence of the *Gallionellaceae* type strain, *Gallionella ferruginea* strain Johan (Hallbeck et al. 1993). The tree was reconstructed using a subset of sequences representative of close related genera to stabilize the tree topology. In addition, a 40 % conservation filter for the whole bacterial domain was used to remove hypervariable positions. The number in the triangle denotes number of taxa included. The bar indicates 5 % sequence divergence

among the *β-proteobacteria* (Fig. 30.1). Its phylogenetic neighbors are Methylophilaceae, Nitrosomonadaceae, and Spirillaceae. The sequence of strain Johan was obtained in 1993, and it is still the only available type strain sequence obtained from a pure culture of a *Gallionella* species. Recently, the full genome of a strain denoted ES-2 was obtained (Emerson et al. 2013), and the 16S rDNA gene of this strain indicates close relationship (98.6 %) to *G. ferruginea*.

Phenotypic Analyses

The cell of *G. ferruginea* has a curved rod shape, usually 1.6–2.5 × 0.5–0.8 μm. Cells of strain Johan were 2.3 (SD ± 0.2) × 0.7 (SD ±0.1) μm in the exponential growth phase culture and 1.7 (SD ± 0.1) × 0.6 (SD ± 0.07) μm in the stationary phase culture (Hallbeck and Pedersen 1990). The cells are gram-negative (Teichmann 1935) with an outer membrane and a thin peptidoglycan cell wall (Hallbeck and Pedersen 2005). The cell has one polar flagellum and contains carboxysome-like structures, polyhydroxybutyrate granules, and glycogen as carbon storage compounds (Lutters and Hanert 1989). The mol% G+C was reported to be 51–54.6 % for strain BD (Hanert 1989), which agrees well with the G+C content of 53 % reported for strain ES-2 with a full genome size of 3.0 Mb (Emerson et al. 2013). As indicated by its assimilation of carbon from hydrogen [^{14}C]carbonate under inorganic cultivation conditions (Hallbeck and Pedersen 1991), *G. ferruginea* is a chemolithotroph using ferrous iron as its energy source and electron donor and carbon dioxide as its sole carbon source. Mixotrophic organic carbon assimilation was found for glucose, fructose, and sucrose concomitant with carbon dioxide fixation. The autotrophic character was recently confirmed by the presence of the form II RubisCO gene cluster in strain ES-2 (Emerson et al. 2013). The ferrous iron requirement is compulsory, and growth does not occur with organic carbon as the sole electron donor. Both nitrate and ammonium are used as sources of nitrogen.

Table 30.1 compares strain Johan from a drinking-water well in Sweden, strain BD isolated from groundwater in Braunschweig, Germany (Hanert 1989), as previously presented (Hallbeck and Pedersen 2005), and strain ES-2 isolated from groundwater in Michigan, USA (Emerson and Moyer 1997), with distantly related stalk-forming bacteria denoted R-1 (Krepski et al. 2012) and *Mariprofundus ferrooxydans* (Emerson et al. 2007). Strains Johan and ES-2 grow in a defined ring on the walls of glass culture tubes with opposing gradients of oxygen and ferrous iron, while strains BD and R-1 grow in small dot-like colonies on the glass walls of the tubes. Strains Johan and ES-2 are closely related, judging from their respective 16S rRNA sequences, even though strain ES-2 reportedly lacks stalks. Hallbeck and Pedersen (1995) have demonstrated that the ability to form stalks can be lost in laboratory cultures. The absence of stalk production is the only characteristic that currently distinguishes ES-2 from *G. ferruginea*. The presence of large clusters of genes involved in the production of exopolymers in the genome of strain ES-2 (Emerson et al. 2013) therefore suggests that strain ES-2 represents a *G. ferruginea* strain that has lost its stalk-forming ability due to weak selective pressure for stalk formation during enrichment of this strain in agarose-stabilized tubes, as suggested by Krepski et al. (2012).

G. ferruginea strain Johan grows to 1–5 × 10^6 cells mL^{-1} in a generation time of approximately 8 h at the optimum temperature of 20 °C (Table 30.1). It grows in the temperature range of 5–25 °C and in the pH range of 5.0–6.5. Temperature and pH values for growth have previously been reported for *G. ferruginea*, but they have been correlated to stalk formation and not to cell growth (Kucera and Wolfe 1957; Hanert 1973). Stalk production is initiated when the pH rises above 6, which coincides with cultures' reaching the stationary growth phase. When the pH rises along with increasing oxygen tension in the tubes, ferrous iron oxidizes and precipitates as hydroxides. This chemical iron oxidation both reduces the availability of ferrous iron for growth and probably induces stalk formation.

Table 30.1

Diagnostic properties in which the three described strains differ from each other and two other stalk-forming bacteria

X = not reported

Cholodny (1924) conducted microscopic studies of cover slips submerged in habitats containing *G. ferruginea*. He sketched detailed images of cells attached to the ends of stalks and demonstrated that the stalk was excreted by the cell and was not a living part of it. Teichmann (1935) made cultures according to Lieske (1911) and found a great number of curved rods in the fluid. This observation prompted Pringsheim (1949) to suggest that "it is not impossible that motile cells are formed under certain conditions," a conclusion later confirmed with pure cultures of strain Johan (Hallbeck and Pedersen 1990). Detailed descriptions of stalk elongation rates were obtained using single cells and measurements of iron oxidation in both natural samples and lab cultures (Hanert 1968, 1970). Other early analyses suggested various functions of the stalk of *G. ferruginea* that were later found to be irrelevant. In 1953, Beger and Bringmann (1953) compared older drawings of the stalk of *G. ferruginea* with their own electron microscopy studies and proposed that the genus *Gallionella* consisted of five species. Excellent electron microscopy images of *G. ferruginea* were presented in a thesis by Van Iterson (1958), who suggested that the stalk was a living part of the organism with sporangia in the form of membrane sacs on the stalk. Balashova (1967a, b, 1968) and Balashova and Cherni (1970) concluded that the stalk might have zoogloeal forms and budding cells on the stalks, judging from electron microscopy observations.

In the laboratory, the cells produce a twisted stalk when the population enters the stationary phase, as demonstrated by simultaneous measurement of cell growth (using fluorescent staining of living cells) and of stalk length (Hallbeck and Pedersen 1990). The stalk consists of many definite, linear, electron-opaque strands, as first demonstrated by Vatter and Wolfe (1956) and later by van Iterson (1958). The cells produce an extracellular stalk 0.3–0.5 μm wide and up to 400 μm long, composed of numerous 2-nm-wide fibers protruding from the concave side of the cell, (*Table 30.1*). The chemical composition of the stalk is still unclear, but in vitro studies of the carbon/nitrogen (C:N) ratio found that a stalk-forming strain had a C:N ratio of 6.8, while a strain that lost its ability to produce stalks had a C:N ratio of 4.3, which suggests that the stalk is made of polysaccharides and contains significantly less nitrogen than does the cell (Hallbeck and Pedersen 1995). Studies of natural samples of extracellular *Gallionella*-like stalks have confirmed that the stalk is organic in character with numerous carboxylic groups (Martinez et al. 2003).

Enrichment, Isolation, and Maintenance

There are numerous reports of successful enrichment cultures of stalk-forming *Gallionella* strains, but few have been completed as pure cultures. Adler (1904) reported small amounts of

G. ferruginea in freshwater from the iron well of Karlspader, but when the water was left in bottles for several days, they "*ausserordentlich stark vermehrt*," i.e., they had grown or, more correctly, the stalks had become elongated. Lieske (1911) succeeded in cultivating *G. ferruginea* in carbonic water with metallic iron as the ferrous iron source. In 1957, Kucera and Wolfe (1957) introduced an excellent growth medium containing iron sulfide as a source of reduced iron and demonstrated that *G. ferruginea* can be cultivated in opposing ferrous iron and oxygen gradients using carbon dioxide as the sole carbon source. The source of ferrous iron was a solid phase such as ferrous sulfide, which was later demonstrated to be replaceable with ferrous carbonate (Hallbeck and Pedersen 1995).

Various media for the enrichment and cultivation of *Gallionella* strains have been reported. To create proper growth conditions, ferrous iron and carbon dioxide must be in the medium. Kucera and Wolfe's (1957) growth medium, which consists of a salt solution and iron sulfide, made it possible to obtain pure cultures of *Gallionella*. The salt solution was initially prepared with tap water, because the medium lacked a crucial component, later found to be calcium. The ferrous iron medium has since been widely used with some minor modifications. Kucera and Wolfe's modified medium is made as follows: Screw-capped tubes (180 × 16 mm) are filled with 10 mL of salt medium consisting of 1.0 g of NH_4Cl, 0.4 g of $MgSO_4 \times 7 H_2O$, 0.1 g of $CaCl_2 \times 2 H_2O$, 0.05 g of K_2HPO_4 and 1 L of double-distilled water. The salt medium is autoclaved, chilled to 5 °C and infused with sterile, and filtered CO_2 to pH 4.6–4.8. A ferrous sulfide or ferrous carbonate precipitate (0.5 mL) is added slowly to the bottom of the tubes using a Pasteur pipette, and the tubes are left for 4–6 h to allow gradient conditions to become established before inoculation. The ferrous sulfide and ferrous carbonate must be prepared in the laboratory. Ferrous sulfide is prepared by dissolving 7.8 g of $FeSO_4(NH_4)_2SO_4$ (Mohr's salt) and 4.8 g of sodium sulfide each in 200 mL of boiling, double-distilled water, and subsequently pouring the ferrous solution into the sulfide solution. Use two 500-mL beakers and stir with a glass rod. Fill the receiving beaker to the top and seal it with a rubber stopper to prevent oxidation of the ferrous iron. Let the iron sulfide settle for at least 4 h; decant and wash the iron sulfide with boiling double-distilled water five times. After centrifuging at high velocity, collect the iron sulfide in small bottles, fill the bottles with water, and seal them with airtight lids. Sterilize the bottles at 121 °C for 20 min. Store the bottles at a cool temperature in airtight vials. Ferrous carbonate is prepared by dissolving 3.9 g of $FeSO_4(NH_4)_2SO_4$ and 1.0 g of anhydrous Na_2CO_3 each in 100 mL of boiling double-distilled water and subsequently pouring the carbonate solution into the ferrous solution, preferably under a nitrogen atmosphere. The precipitated ferrous carbonate is then washed five times with boiling double-distilled water and sterilized in closed vials at 121 °C for 20 min. Store the precipitate at a cool temperature in airtight vials. It is recommended that all solutions used for preparing the medium and ferrous iron source be filter sterilized (0.2 μm) to remove any cells or particles that may give an elevated background during microscopic counts.

The best sources for *Gallionella* enrichment are places where groundwater containing ferrous iron meets the air. These could be natural springs, drainage systems, drinking-water wells, ditches, or drilled boreholes yielding groundwater. The closer to the anaerobic environment the sample is taken, the lower the oxygen concentration and the better the chance of obtaining *Gallionella* enrichment. It is not necessary to obtain stalk material with iron oxides for the successful enrichment of *Gallionella*; rather, the opposite is the case, because the bacteria are more active in their stalkless, exponential growth condition. Since most *Gallionella* strains are sensitive to temperatures above 20 °C, water samples should be kept cool, at approximately 5 °C, until inoculation.

The growth medium must be kept cool and inoculated culture tubes should be stored at temperatures below 22 °C. The optimum temperatures for strains BD and Johan were 17 °C and 20 °C, respectively (*Table 30.1*). The iron–oxygen gradient in culture tubes is easily disturbed by temperature-imposed convection, so tubes should be protected from temperature variation and air turbulence in culture chambers. *Gallionella* growth is normally visible after 4–7 days as a ring or as colonies of whitish material on the tube wall that, with time, turn brownish-orange due to the precipitation of oxidized iron on the stalks.

Pure cultures can be obtained by serial dilution of a successful enrichment culture. The medium, together with cells and stalk material, is withdrawn using a sterile Pasteur pipette to an empty tube and shaken. This material is serially diluted 10 times to a dilution of 10^{-8}. From each dilution, five growth tubes are inoculated and the tubes are incubated until growth is visible. The culture isolation is continued using one tube from the highest dilution series that displayed growth. The dilution step is repeated at least six times before a pure culture can be obtained. Purity is checked microscopically and by using a variety of heterotrophic and autotrophic media, i.e., yeast extract bouillon, nutrient agar, and media for species of *Nitrosomonas* and *Thiobacillus*. The retention of a pure culture requires subculturing with serial dilution transfers every 4–8 weeks.

Ecology

The environments where stalk-forming *Gallionella* can be found, commonly attached to surfaces, are in slow-flowing groundwater that is rich in ferrous iron but has low organic carbon content and low oxygen tension. Typical places to search for *Gallionella* are the insides of drainpipes, storage cisterns for groundwater from deep wells, as well as inside tunnels and on rock walls subject to groundwater seepage. A common feature of these environments is that cold (i.e., below 20 °C), reduced, anaerobic, and ferrous iron-bearing groundwater reaches an atmosphere that contains oxygen. Such environments are suitable for chemolithotrophic growth with ferrous iron as the energy source and electron donor and with oxygen as the electron acceptor. A flow appears to be an absolute prerequisite for

the growth of *Gallionella*, as it continuously supplies ferrous iron and possibly also carbon dioxide from the groundwater to the attached cells. Under such conditions, the stalk may act as a holdfast and prevent the cells from being washed out to a more oxidized environment that lacks ferrous iron.

Hallbeck and Pedersen (1995) have demonstrated an additional function of the stalk. The iron oxidation that occurs in a typical *Gallionella* environment can be divided into two processes: (a) respiratory iron oxidation performed by the cells in their energy metabolism and (b) non-metabolic iron oxidation induced by the increasing oxygen tension as the anoxic groundwater reaches the atmosphere. Ferrous iron reacting with oxygen participates in a chain of reactions yielding highly reactive oxygen species such as perhydroxyl (HO_2), hydrogen peroxide (H_2O_2), and the hydroxyl radical (HO). The survival of a stalk-forming (Sta^+) *Gallionella* variant of strain Johan in media with a low or high potential for oxygen radical formation was compared with that of a variant of strain Johan that had irreversibly lost its stalk-forming ability (Sta^-). *Gallionella* Sta^+ was found to survive longer (i.e., 9 weeks) than did Sta^- (i.e., 6 weeks) in cultures with a high potential for oxygen radical formation. It was therefore suggested that the stalk of *Gallionella* protects the cells against the toxic oxygen species discussed above by directing the oxidation of iron to the stalk. This phenomenon could be compared to the action of the protein ferritin, thought to perform iron oxidation in both prokaryotic and eukaryotic cells (Artymiuk et al. 1991). Whether the iron oxidation on the stalk is enzymatic or whether the stalk acts as a surface catalyst for the oxidation reaction is not known.

In conclusion, the stalk acts as a holdfast and gives *Gallionella* the unique ability to colonize and survive in an ecological niche with high contents of ferrous iron and with some oxygen, a niche inaccessible to bacteria without a defense system against the oxygen radicals formed during the inorganic oxidation of ferrous iron.

The stalks of *Gallionella* attract large amounts of iron hydroxides and other metals. Results from well-developed in situ biofilms suggest that *Gallionella* can concentrate metals at levels up to 1×10^3-fold higher than found in the host rock and more than 1×10^6 times the levels found in the groundwater (Anderson and Pedersen 2003). The processes governing the coating of the stalks with iron hydroxides and metals are not well established, although several intriguing theories exist. It is possible that the enzymatic ferrous iron oxidation occurring when *Gallionella* is extracting electrons for energy production takes part in the buildup of metal oxides on the stalks. In this process, oxidized, ferric iron from this metabolic process would be expelled and adsorbed on the stalk. In addition, as suggested above, the stalk may act as a protective agent against the creation of toxic levels of oxygen radicals. The stalk would in this case have a ferrous iron oxidation capability and a sorption capacity for ferric iron hydroxides and other metals. An interesting function of the stalk, in line with these assumptions, has been suggested by Banfield et al. (2000). This group discovered ferrihydrite nanocrystalline growth in samples containing *Gallionella* stalks and suggested that the stalks attract or flocculate 2–3-nm ferrihydrite particles formed by the cells' enzymatic oxidation of ferrous iron. The stalks then govern an aggregate-based growth of polycrystalline materials. Surfaces of nanocrystalline iron oxyhydroxides, such as goethite formed from ferrihydrite, are active adsorption sites for metals at neutral to alkaline pH levels. *Gallionella* may, consequently, exert an important influence on the fate of metals dissolved in natural groundwater.

Applications

Gallionella, together with other iron bacteria, are mostly known for the problems they cause by clogging filters and drainage systems. However, iron oxidation and biomass production can also have beneficial effects. This capability has been employed for the treatment of iron-rich groundwater to produce drinking water (de Vet et al. 2011a, b; Katsoyiannis and Zouboulis 2006). By the use of filters like sand or granulated carbon with biofilms of *Gallionella*, ferrous iron and trace metals are very efficiently removed from the water. The produced sludge is removed by back flushing and left to settle in sedimentation basins. The fact that the iron oxides adsorb anions like phosphate and arsenate very efficiently (Kappler and Straub 2005) makes it possible to remediate polluted groundwater by the use of iron-oxidating *Gallionella* biofilms (Katsoyiannis and Zouboulis 2006). Many metals coprecipitate with iron oxides and the bacterial structures, and thereby the metal concentration in the water phase is decreased (Ferris et al. 1999, 2000). One example presented by Ferris et al. (1999) shows how masses of iron oxides adsorbed metal ions as Co, Cu, Cr, and Zn.

31 The Family *Hydrogenophilaceae*

Johann Orlygsson[1] · *Jakob K. Kristjansson*[2]
[1]University of Akureyri, Akureyri, Iceland
[2]Prokazyme ehf, Reykjavik, Iceland

Abstract
Hydrogenophilaceae, a family within the order *Hydrogenophilales*, comprises the genera *Thiobacillus*, *Hydrogenophilus*, *Petrobacter*, *Tepidiphilus*, and *Sulfuricella*. Members of the family are all Gram negative, rod shaped, and non-sporulating; the reported biochemical characteristics of individual species are highly variable concerning various morphological and chemotaxonomic properties. Most members of the family are chemolithotrophic or mixotrophic using various inorganic electron donors such as reduced sulfuric compounds or hydrogen. Members of the family are either mesophilic or moderately thermophilic and have been isolated from various environments, e.g., freshwater, aerobic digesters on water treatment sludge, and hot springs. No strains have been reported as pathogens.

Taxonomy, Historical and Current

Short Description of the Family

Hy.dro.ge.no'phil.ce.ae. N.L. masc. n. *Hydrogenophilus*, type genus of the family; suff. *-aceae*, ending to denote family; N.L. fem. pl. n. *Hydrogenophilaceae*, the *Hydrogenophilus* family.

Hydrogenophilus is the type genus of the order *Hydrogenophilales* and of the family *Hydrogenophilaceae*, phylum Betaproteobacteria (Garrity et al. 2005). The family contains the type genus *Hydrogenophilus* (Hayashi et al. 1999), *Thiobacillus* (Bejerinck 1904), *Petrobacter* (Salinas et al. 2004), *Sulfuricella* (Kojima and Fukui 2010), and *Tepidiphilus* (Manaia et al. 2003). Species within all five genera are Gram negative and rod shaped and are motile by means of polar flagellum (*Table 31.1*). Most members of the family are chemolithotrophic using various reduced sulfur compounds or hydrogen as electron donors. Some species are mixotrophic, often using organic acids for growth. Members are typically aerobic but some are microaerophilic or facultative anaerobic using nitrate instead of oxygen as final electron acceptor. The predominant fatty acids, when analyzed, are straight chain C16, C18, and cyclo-C19. The dominant quinone is Q-8. Polar lipids, when analyzed, are typically phosphatidylethanolamine and phosphatidylglycerol, similar to other Betaproteobacteria. The G+C values of DNA range between 59 and 66 mol%. Mesophilic and psychrophilic species are found in anoxic lakes, sediments of sandy aquifers, soil, and industrial waste treatment lagoons. Moderately thermophilic species are found in aerobic water treatment digesters, terrestrial oil reservoirs or hot baths, and hot springs. No isolates have been demonstrated to be pathogenic.

Phylogenetic Structure of the Family and Its Genera

Figure 31.1 shows the position of the five genera within the family. The family is clearly not monophyletic, and *Thiobacillus* and *Sulfuricella* make up a subcluster together with bacteria that belong to other orders within the Betaproteobacteria, e.g., orders *Neisseriaceae*, *Methylophilaceae*, *Nitrosomonadaceae*, and *Spirillaceae*. The other three genera of the family make up another subcluster with the order *Rhodocyclaceae*.

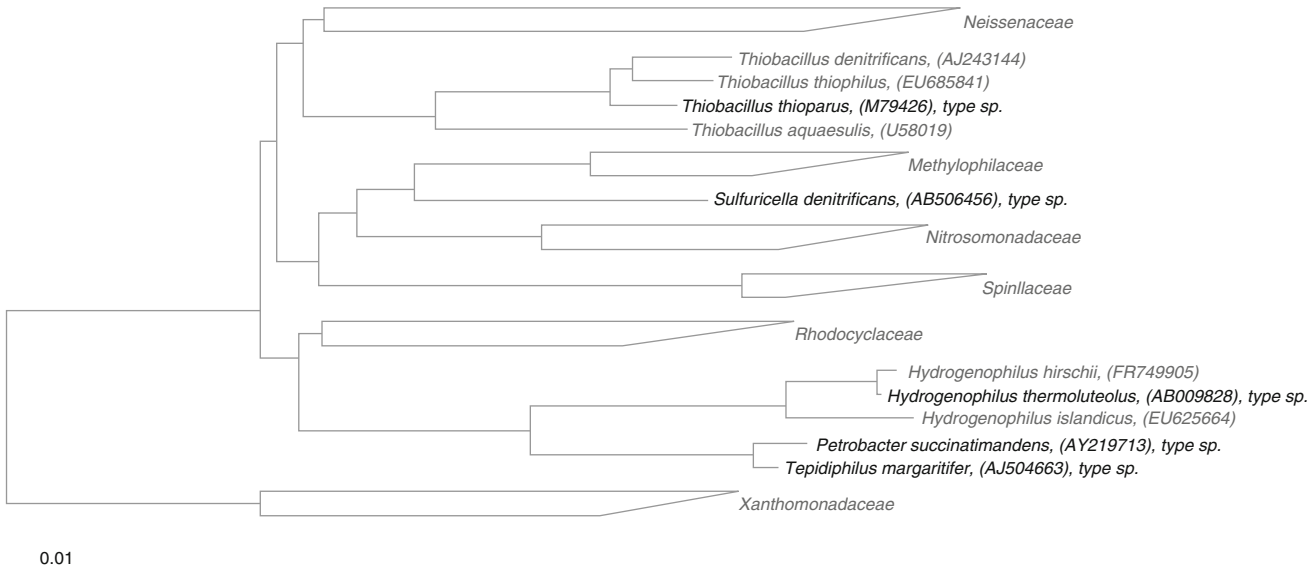

Fig. 31.1

Phylogenetic reconstruction of the family *Hydrogenophilaceae* based on 16S rRNA and created using the neighbor-joining algorithm with the Jukes-Cantor correction. The sequence dataset and alignment were used according to the All-Species Living Tree Project (LTP) database (Yarza et al. 2010). The tree topology was stabilized with the use of a representative set of nearly 750 high-quality type strain sequences proportionally distributed among the different bacterial and archaeal phyla. In addition, a 40 % maximum-frequency filter was applied in order to remove hypervariable positions and potentially misplaced bases from the alignment. Scale bar indicates estimated sequence divergence

The family *Hydrogenophilaceae* was established by Garrity et al. (2005) and consists of five genera: *Hydrogenophilus*, *Petrobacter*, *Tepidiphilus*, *Thiobacillus*, *and Sulfuricella*. *Hydrogenophilus* is the type genus of the family and consists of three validly described species: *H. thermoluteolus* (type species), *H. hirshii*, and *H. islandicus*. All known species are thermophilic and were isolated from hot springs. Goto and coworkers (Goto et al. 1977, 1978) originally isolated strains that were assigned to two different genera, *Pseudomonas* and *Flavobacterium*. These strains were later reassigned to the genus *Hydrogenophilus* (with *H. thermoluteolus* as the type strain), based on further phylogenetic studies (Hayashi et al. 1999). Later, two other species were included in the family: *H. hirshii* (Stöhr et al. 2001) and *H. islandicus* (Vesteinsdottir et al. 2011). Together with *Hydrogenophilus*, *Petrobacter*, and *Tepidiphilus* form a subcluster within the family (*Fig. 31.1*) all of thermophilic origin and do not use reduced sulfur compounds (except for *H. thermoluteolus*). *Hydrogenophilus* species can oxidize hydrogen, but *Petrobacter* and *Tepidiphilus* do not grow chemolithotrophically but can use nitrate instead of oxygen as electron acceptors.

Today, the *Thiobacillus* genus has only four species but has in earlier volumes of *The Prokaryotes* received special attention and been described separately together with other "thiobacilli" and "colorless sulfur bacteria" (Robertsson and Kuenen 2006). The main reason for this reduction is based on the large number of species that were originally described as *Thiobacillus* that have now been moved to other genera. The genus was first described by Bejerinck (1904) where it was described as bacteria that could use reduced sulfur compounds as a source of energy. At this time, the genus comprised of only *T. thioparus* (type species) and *T. denitrificans*. This property of using reduced sulfur compounds, in addition to being rod shaped, non-phototrophic, and Gram negative, was used for placing new isolates within the genus for a long time. Modern taxonomic methods (16S rRNA gene sequencing and other molecular methods) have dramatically changed a number of existing or new genera, e.g., *Acidithiobacillus*, *Acidiphilium*, *Halothiobacillus*, *Paracoccus*, *Starkeya*, *Thiomonas*, and *Thermithiobacillus* (Battaglia-Brunet et al. 2011; Hirashi and Imhoff 2005; Katayama et al. 2006; Kelly and Wood 1998, 2000a; Kelly et al. 2000, 2005, 2007). In the last edition of *The Prokaryotes*, the genus consisted of three species: *T. thioparus* (type species), *T. denitrificans*, and *T. aquaesulis*. Since then, one new species has been identified, *T. thiophilus* (Kellerman and Griebler 2009), but two other have been accepted based on their 16S rRNA gene sequences, "*T. plumbophilus*" (Drobner et al. 1992) and "*T. sajanensis*" (Dul'tseva et al. 2006) but await full acceptance. *Sulfuricella denitrificans* is most closely related to *Thiobacillus plumbophilus*, showing 93 % homology, and was thus proposed as a new genus. All four *Thiobacillus* species, together with *Sulfuricella denitrificans*, are strictly chemolithoautotrophic and use reduced sulfur compounds as an energy source; all are of mesophilic or psychrophilic origin (although *C. aquaesulis* has temperature optimum at 43 °C).

Of the four validated *Thiobacillus* species, only *T. thioparus* and *T. denitrificans* have been retained through all the editions of *Bergey's Manual*, but the original isolates of these two species were lost. The type strain of the type species of the genus, *T. thioparus*, was originally isolated by Starkey (1934). A recent phylogenetic assessment of various culture collection strains of *T. thioparus* together with *T. denitrificans* has been done by Boden et al. (2012). Sequences of four examples of the Starkey type strain were identical, confirming their sustained identity after passage through different laboratories. Comparison of the 16S rRNA gene sequences of *T. denitrificans* indicates the importance of using the sequence for the type strain (NCIMB 9548 T) as a reference.

Molecular Analyses

DNA-DNA Hybridization Studies

Very few reports are on DNA-DNA hybridization analysis on bacteria within the *Hydrogenophilaceae family*. This is not surprising since three of the five genera in the family include only one species, and 16S rRNA analysis of the three *Hydrogenophilus* species shows less than 97 % similarity (Vesteinsdottir et al. 2011). The newest *Thiobacillus* species *B. thiophilus* was, according to 16S rRNA analysis, with 97.6 % similarity with *T. denitrificans* (Kellerman and Griebler 2009). To determine the genomic relatedness between these two strains, DNA-DNA hybridization was performed and showed relatedness value of 24.8 % indicating a clear distinction between the two strains.

Genome Comparison

Of the ten species that are presently members within the family, only one, *T. denitrificans* (ATCC 25259), has been sequenced for its complete genome (Beller et al. 2006a). The genome is 2,9 Mbp long and contains 2,827 protein-encoding genes, and the mol% G+C of DNA is 66.1 %. The genome contains two identical copies of the 16S rRNA gene, but these show only 97.6 % sequence identity to the type strain (NCIMB 9548 T) which is comparable to the difference between two distinct species.

Genes encoding for c-type cytochrome represent 1–2 % of the genome, and two genes were found to encode for NiFe hydrogenases which is interesting since there is no information on hydrogenases for the bacterium. More than 50 genes associated for sulfur compound oxidation were detected, and a relatively large number of genes are associated with inorganic ion transport, and heavy metal resistance is present. Finally, genes encoding for transporters of organic compounds were detected, which is not surprising since the bacterium is a strict chemolithotroph. Further studies (Beller et al. 2006b) on the expression of genes are involved in major chemolithotrophic metabolism (e.g., oxidation of sulfur compounds and fixation of carbon dioxide) under both aerobic and denitrifying conditions by using the whole genome data obtained. This further increases our knowledge of the basic regulation of genes involved during these processes

Phenotypic Analyses

The main features of *Hydrogenophilus* and *Thiobacillus* are listed in ❯ *Tables 31.2* and *31.3*, respectively.

Hydrogenophilus

Hy.dro.ge.no'phi.lus. Gr. n. hydro water; Gr. v. *genein* to produce; M.L. neut. n. *hydrogenum* hydrogen (that which produces water); Gr. adj. *philo* loving, friendly to; M.L. masc. n. *Hydrogenophilus* hydrogen lover (Hayashi et al. 1999).

The type strain of the genus is *H. thermoluteolus* TH-1^T (Hayashi et al. 1999). Gram-negative cells are slender rods ranging between 0.4 and 0.8 µm in diameter. The rods vary considerably in length (*H. hirshii*, 1.5 µm; *H. thermoluteolus*, 3.0 µm) and occur singly. Little or no data is available on pleomorphic structure depending on culture age or conditions. *H. hirshii* has polar flagella and is motile as is *H. islandicus* (Stöhr et al. 2001; Vesteinsdottir et al. 2011); *H. thermoluteolus* is not motile (Hayashi et al. 1999) although it was originally reported to be so (Goto et al. 1978). Colonies of *H. islandicus* are grayish in color and are about 1 mm in diameter, but *H. thermoluteolus* produces a dull yellow pigment (Goto et al. 1978). Optimum growth occurs at moderate thermophilic range (50–65 °C). *H. thermoluteolus* can grow at 35 °C, and *H. hirshii* has a maximum temperature of 65 °C. No spores have been detected in any species. All strains grow chemolithotrophically on hydrogen and carbon dioxide under aerobic conditions, but only *H. thermoluteolus* can use thiosulfate as electron donor (Miykae et al. 2007). The strains are also heterotrophic and grow on various organic substrates, although the extent and substrate spectrum varies to a great extent (❯ *Table 31.2*). The strains use the Calvin-Benson-Bassham cycle for carbon fixation as shown for, e.g., *H. thermoluteolus* (Hayashi and Igarashi 2002). *H. islandicus* is mixotrophic as well and able to grow on both hydrogen and butyrate as energy source (Vesteinsdottir et al. 2011).

The major cellular fatty acids in all strains are C16:0 and C18:0, but species that can be distinguished as both *H. islandicus* and *H. hirshii* also have considerable amount of cyclo C17:0, whereas *H. thermoluteolus* has higher amounts of 2-OH C10. The major quinone in all three species is Q-8.

Thiobacillus

Thi.o.ba.cill.us. Gr. n. *theion* (Latin transliteration *thium*), sulfur; L. masc. n. *bacillus*, a small rod; N.L. masc. n. *Thiobacillus*, sulfur rodlet (Bejerinck 1904).

The type strain of the genus is *T. thioparus* ATCC 8158^T (Starkey type). Cells are Gram-negative, motile rods and vary in length from 0.9 to 3.0 µm with typical diameters from 0.3 to 0.8 µm (❯ *Table 31.3*). Anaerobically grown colonies of *T. thiophilus* are circular, smooth, shiny, convex, and yellow in color with a lighter-colored fringe after two weeks of incubation (Kellerman and Griebler 2009). Cells of *T. denitrificans* are clear or weakly opalescent during anaerobic growth on thiosulfate nitrate agar but may become white with time with sulfur (Kelly and Wood 2000b). Cells of *T. aquaesulis* are small (1–2 mm), circular, convex, and smooth, becoming white or yellow with the formation of precipitated sulfur (Wood and Kelly 1988). Species of the genus are oxidase and catalase positive. Three of the strains are mesophilic, growing optimally at 25–30 °C, whereas *T. aquaesulis* is a moderate thermophile, with a T_{opt} of 43 °C. All strains grow in the presence of oxygen and reduced sulfur compounds (thiosulfate, trithionate, and tetrathionate) and produce sulfur or sulfate during aerobic growth conditions. All strains are facultative anaerobes, capable of using nitrate as an electron acceptor instead of oxygen-producing nitrite or, in the case of *T. denitrificans*, molecular nitrogen.

The dominant quinone for all four species is Q-8, and no information has been reported on the most common fatty acids in *Thiobacillus*.

Sulfuricella

Sul.fu.ri.cel'la. L. neut. n. *sulfur* sulfur; L. fem. n. *cella* a small room and, in biology, a cell; N.L. fem. n. *Sulfuricella* sulfur (−oxidizing) cell (Kojima and Fukui 2010).

The type strain, *Sulfuricella denitrificans* skB26^T, was isolated from anoxic water of a freshwater lake in Japan (Kojima and Fukui 2010); it is oxidase positive and catalase negative. Cells are 0.8–2.0 µm long and 0.4–0.6 µm wide and motile, but does not produce spores. Growth occurs up to 28 °C (optimum at 22 °C) and pH 6.0–9.0 (optimum at pH 7.5–8.0). Optimum growth was observed in medium without NaCl, and no growth occurred in medium containing more than 1.28 % NaCl.

The bacterium is strictly chemolithotrophic and oxidizes thiosulfate and sulfur to sulfuric acid in the presence of oxygen; nitrate (but not nitrite) can be utilized under anaerobic conditions with nitrogen as the end product. *S. denitrificans* skB26^T is negative for chemolithotrophic growth on sulfide, sulfite, and tetrathionate and does not utilize hydrogen and $FeSO_4$. Growth under 20 % oxygen concentration is considerably slower compared to concentrations of 2 % and 10 %. Carbon fixation occurs using the Calvin cycle. Growth of the strain was inhibited by kanamycin and ampicillin.

Tepidiphilus

Te.pi.di'phi.lus. L. adj. *tepidus* lukewarm; Gr. adj. *philos* friendly to; N.L. masc. n. *Tepidiphilus* liker of lukewarm conditions (Manaia et al. 2003).

The type species of *Tepidiphilus margaritifer* N2-214^T was isolated from an enrichment culture, growing on caprolactone, obtained from water treatment sludge aerobic digester at 60 °C; it is oxidase and catalase positive (Manaia et al. 2003). Cells are rod shaped, 2.0 µm long and 0.7 µm wide, motile by means of polar flagellum, and non-sporulating. Colonies are nacre-like and 1–2 mm in diameter after 36–48 h of growth. Growth occurs

at above 25–61 °C (optimum at 50 °C) and pH 6.0–8.0. The strain produces polyhydroxybutyrate and can grow in the presence of 3 % NaCl.

The bacterium is aerobic, heterotrophic, and capable of growing on organic acids, some alcohols, and amino acids but is asaccharyolytic. The strain can grow anaerobically and reduce nitrate to compounds more reduced than nitrite. The strain could not grow autotrophically in medium supplemented with hydrogen carbonate on hydrogen, sulfur, or thiosulfate. However, it can reduce triphenyltetrazolium in the presence of hydrogen indicating a presence of hydrogenase activity.

According to API 50CH system, the strain shows positive growth on acetate, malate, caproate, benzoate, phenylacetate, ethanol, proline, L-asparagine, and L-glutamic acid. Strains do not utilize glycerol, erythritol, D-arabinose, L-arabinose, ribose, D-xylose, L-xylose, adonitol, methyl β-xyloside, galactose, D-glucose, D-fructose, D-mannose, L-sorbose, rhamnose, dulcitol, inositol, mannitol, sorbitol, methyl α-D-mannoside, methyl α-D-glucoside, *N*-acetylglucosamine, amygdalin, arbutin, salicin, cellobiose, maltose, lactose, melibiose, sucrose, trehalose, inulin, melezitose, D-raffinose, starch, glycogen, xylitol, β-gentiobiose, D-turanose, D-lyxose, D-tagatose, D-fucose, L-fucose, D-arabitol, L-arabitol, gluconate, 2-ketogluconate, 5-ketogluconate, hydroxyproline, L-alanine, L-serine, L-glycine, L-histidine, DL-methionine, L-arginine, toluene, and caprolactone.

According to API ZYM system, the strain is positive for the following enzymes: alkaline phosphatase, esterase (C_4), esterase lipase (C_8), lipase (C_{14}), leucine acrylamidase, valine acrylamidase, acid phosphatase, naphthol-AS-BI-phosphohydrolase, and β-glucosidase. The strain was negative for cystine acrylamidase, trypsin, α-chymotrypsin, α-galactosidase, β-galactosidase, β-glucuronidase, α-glucosidase, *N*-acetyl-β-glucosaminidase, α-fucosidase, α-mannosidase, tweenase (Tween 80), amylase, and gelatinase and did not grow in the presence of ampicillin (10 μg) and penicillin G (10 U).

Petrobacter

Pe.tro.bac'ter. Gr. fem. n. *petra* rock, stone; M.L. masc.n. *bacter* equivalent of Gr. neut. n. *bacterion* rod, staff; N.L. masc. n. *Petrobacter* the stone bacterium (Salinas et al. 2004).

The *Petrobacter succinatimandens*-type strain, 4BON^T, was isolated from a non-water-flooded Australian terrestrial oil reservoir; it is oxidase and catalase positive (Salinas et al. 2004).

Cells are 2 μm long but only 0.3–0.4 μm wide, motile by means of one polar flagellum, and non-sporulating. Colonies are round (1–2 mm) after 1-week incubation. Growth occurs at 35–60 °C (optimum at 55 °C) and between pH 5.5 and 8.0 (optimum at pH 6.9). The strain grows in the presence of 0–3 % NaCl (optimum at 0.5 %) concentrations.

The bacterium is aerobic and heterotrophic on organic acids and ethanol. Nitrate could be used instead of oxygen as electron acceptor, being reduced to nitrous oxide with nitrite as an intermediate. Elemental sulfur, sulfate, thiosulfate, and nitrite are not used as electron acceptors.

The strain is positive for growth on fumarate, pyruvate, formate, ethanol, succinate, and yeast extract, but growth was poor in the absence of yeast extract. The strain did not growth on acetate, propionate, butyrate, valerate, isovalerate, lactate, adipate, alanine, L-glutamate, L-proline, L-serine, L-valine, fructose, glucose, lactose, maltose, ribose, xylose, vanillate, benzoate, 4-hydroxygbenzoate, 3-methylbenzoate, phenylacetate, 4-aminobenzoate, and benzaldehyde.

Isolation, Enrichment, and Maintenance Procedures

Most members of the family *Hydrogenophilaceae* are chemolithotrophic, and most species have been isolated and enriched on simple mineral medium with reduced sulfur compounds or hydrogen as the electron donors in the presence of either oxygen or nitrate. The main problem in isolation of strictly chemolithotrophic bacteria is the persistence of heterotrophic contamination because, in most cases, no carbon source other than carbon dioxide is available and cell debris that arise in growing cultures will be used as a substrate for heterotrophic contaminants. Therefore, pure cultures have to be isolated on agar as colonies repeatedly and rechecked for contaminants by cultivating them under heterotrophic conditions.

As earlier mentioned, the genus *Thiobacillus* has been dramatically reclassified in recent years and now consists of only four species (*T. thioparus*, *T. denitrificans*, *T. aquaesulis*, and *T. thiophilus*) based on the analysis of the 16S rRNA gene. These colorless sulfur bacteria have, in most cases, been isolated on mineral medium with reduced sulfur compounds as the energy source and carbon dioxide as carbon source. Most isolations have been in the presence of oxygen and/or nitrogen; the isolates have been described as aerobic or facultative anaerobes. The type species, *T. thioparus*, can be isolated from freshwater, estuarine, and marine sediments (Vishniac and Santer 1957). *T. denitrificans* can be easily isolated from similar environments, and selection can be made by using anaerobic conditions with nitrate as the electron acceptor (Kelly and Wood 2000b; Robertsson and Kuenen 2006). *T. aquaesulis* is the only moderate thermophile within the genus and was isolated from thermal sulfur spring on thiosulfate as electron donor in simple mineral medium (Wood and Kelly 1988). Finally, *T. thiophilus* was isolated from sediment collected from a tar oil-contaminated aquifer at a former gaswork site in Germany (Kellerman and Griebler 2009). In that case, initial enrichments were made on "Widdel freshwater medium" with sodium thiosulfate as the electron donor and sodium nitrate as the electron acceptor. The isolation procedure was actually performed anaerobically, and the enrichment was allowed to grow at 16 °C for 3–4 months, wherefrom dilution series led to the isolation of the bacterium on agar.

Sulfuricella denitrificans was isolated from the hypolimnion of a meromictic freshwater lake in Japan (Kojima and Fukui 2010) by using a carbonate-buffered defined medium modified from the medium for sulfate-reducing bacteria (Widdel and Bak 1992), where sulfate was eliminated and thiosulfate was used instead of sulfide as an alternative reductant and sulfur source. Enrichment was performed under anaerobic conditions (N_2/CO_2; 80/20, v/v) at 22 °C. Repeated enrichments followed by the use of agar shake dilutions resulted in a pure culture of a facultative anaerobic chemolithotrophic bacterium.

The three *Hydrogenophilus* species have all been isolated in mineral medium with hydrogen as the electron donor, oxygen as the electron acceptor, and carbon dioxide as the carbon source (Goto et al. 1977; Stöhr et al. 2001; Vesteinsdottir et al. 2011). The three species are all of thermophilic origin (from soil or water around hot spring or hot spring liquid-mud samples). Pure cultures were obtained by reinoculating positive samples several times into fresh medium, and individual colonies were selected from agar plates following end point dilutions.

Tepidiphilus margaritifer was isolated from a caprolactone enrichment culture obtained from a thermophilic aerobic digester of a domestic wastewater treatment plant in Portugal (Manaia et al. 2003). The decanted sludge was subjected to a mesobiotic anaerobic digestion followed by a thermophilic aerobic digestion (maximum temperature was 60 °C). The sludge was enriched (in air) on mineral medium at 50 °C (Manaia and Moore 2002) supplemented with polycaprolactone diol. The original enrichment resulted in a mixed culture dominated by *Bacillus* species, but *T. margaritifer* was isolated through purification of cultivable organisms in the mixed culture by using Luria-Bertani agar medium. Surprisingly, the purified isolate could not use caprolactones, but acetate served as good carbon donor which may be explained by the presence of yeast extract (0.2 g/L) in the mineral medium, tryptone (10 g/L), and yeast extract (5 g/L) in the agar medium, indicating that the organisms was using other carbon sources than caprolactones both during enrichment and isolation.

Petrobacter succinatimandens was isolated from a non-waterflooded Australian oil reservoir on anaerobically prepared *mineral medium containing acetate* (10 mM) and yeast extract (1 g/L) under a hydrogen and carbon dioxide gas phase. After three enrichment series, strains were isolated by repeated use of the Hungate roll-tube technique (Hungate 1969). Oil reservoirs are mainly thought to be anaerobic ecosystems (Magot et al. 2000), but the occurrence of aerobic and microaerophilic bacteria may be explained due to water flooding during oil extraction (Gevertz et al. 2000; Voodouw et al. 1996). Despite the presence of hydrogen as energy source in the enrichment medium, the isolate, *P. succinatimandens*, is a heterotrophic bacterium, capable of using organic acids both aerobically and anaerobically, but

not hydrogen. This is most likely due to the presence of yeast extract in the enrichment medium.

For the short-term preservation of strict chemolithotrophic bacteria, large inoculum volumes (10 % v/v) *should be used and serial transfers*. Transfers should be done with a 4-week interval and cultures kept at 4 °C. The medium-term storage of cells should be done in appropriate medium containing glycerol (20 % w/v) at −20 °C or −80 °C. Long-term preservation methods include freeze-drying and maintenance in liquid nitrogen at −196 °C.

Ecology

Habitat

The common trait among most *Hydrogenophilaceae* bacteria is their chemolithotrophic capacity. The strict chemolithotrophs, *Thiobacillus* and *Sulfuricella*, have been found in aquifers, hot springs, soil or mud, and anoxic water. A crucial factor for presence and growth is the presence of sulfides as electron donor and either molecular oxygen or nitrogen oxides as electron acceptors. Many of the "colorless sulfur bacteria" grow in narrow zones and gradients where sulfide and oxygen coexist (Nelson and Jannasch 1983), often in stratified lakes and interfaces between aerobic and anaerobic environments, sediments, and wet soils. The thiobacilli, together with mixotrophic bacteria, have been viewed as very important organisms for transformation of sulfur compounds in soil and sediments. The other members of the family, the three *Hydrogenophilus* species, *Petrobacter succinatimandens*, and *Tepidiphilus margaritifer* are all of thermophilic origin, isolated from hot springs, thermophilic digesters, and terrestrial oil reservoir. Little data is available on other habitats although the presence of both *Petrobacter* and *Tepidiphilus* species has been documented in microbial consortium with the ability to degrade cellulose, cotton, and rice straw (Wang et al. 2011) as well as acetate in anaerobic chemostat with synthetic wastewater (Tang et al. 2008).

Pathogenicity, Clinical Relevance

No species within any of the five genera that belong to the family *Hydrogenophilaceae* are known to be pathogenic.

Application

Removal of H_2S from Wastewater and Gas

The members of the *Hydrogenophilaceae* have, in general, not been used in many biotechnological applications. However, based on their chemolithotrophic ability, especially the oxidation of sulfur compounds by the thiobacilli, some members have been used for removal of contaminating sulfides, both from industrial wastewater and gaseous systems (Syed et al. 2006). The highly acidophilic thiobacilli (not discussed here) have been used extensively in mineral leaching for a long time. Leaching of uranium, gold, nickel, and zinc is an example where the acidophilic thiobacilli have been used (Brandl 2008; Chen et al. 2008; Ehrlich and Brierley 1990; Kelly 1985; Rawlings 2002).

Thiobacillus denitrificans and *T. thioparus* are those members of the neutrophilic thiobacilli that have primarily been investigated for industrial uses (Syed et al. 2006; Sublette et al. 1998). *T. thioparus* has been used for removal of H_2S from gas streams by using immobilized cells in biofilters (Kim et al. 2002; Oyarzún et al. 2003; Sublette and Sylvester 1987; Ramirez et al. 2009). The breakdown and detoxification of organic thiol compounds, such as thiocyanate and methyl sulfide, from contaminated streams and gas by *Thiobacillus thioparus* has also been studied (Aroca et al. 2007; Kanagawa and Kelly 1986; Kanagawa and Mikami 1989; Katayama and Kuraishi 1978). *T. denitrificans* has been studied for use in oxidative removal of H_2S from gas and wastewater aerobically and anaerobically through the reduction of nitrate to nitrogen gas (Kleerebezem and Mendez 2002; Soreanu et al. 2005; Zhang et al. 2009).

Corrosion of Concrete

The oxidation of sulfides and sulfur by thiobacilli results in accumulation of sulfuric acid which is known to corrode concrete structures. This is a particular problem for concrete sewer pipes used in many cities. The biologically mediated corrosion of sewer pipes is therefore a considerable cost to many municipalities, especially if the sewer water contains high concentrations of sulfates (Zhang et al. 2008). High sulfate concentrations promote the growth of sulfate-reducing bacteria, followed by sulfide oxidation and sulfuric acid formation.

Other Uses and Applications

Some hydrogen-oxidizing bacteria, in particular *Wautersia eutropha*, have attracted interest for the purpose of producing microbial biomass from hydrogen and carbon dioxide. Studies have shown that high growth yields and density up to 60 g dry cell weight (DCW) per liter have been reached by growing hydrogen-oxidizing bacteria under chemolithotrophic conditions (Taga et al. 1997). Even more interesting has been the use of autotrophic bacteria such as *Wautersia eutropha* and the *Hydrogenophilus* members for the production of polyhydroxyalkanoate-based bioplastics (Loo and Sudesh 2007). None of the *Hydrogenophilus* species discussed here have, however, been investigated for such applications.

No members of the *Hydrogenophilaceae* discussed here are known to be used as sources of any industrial enzymes. However, the presence of important enzymes of the sulfur metabolism has been demonstrated in *Thiobacillus thioparus* (Matin and Rittenberg 1971), as well as enzymes of the CO_2 fixation pathway in *T. thiophilus* (Kellermann et al. 2012). A cytochrome c from

Hydrogenophilus thermoluteolus has been isolated and its thermostability compared to related proteins (Nakamura et al. 2006).

Bacteria with similarities to *Tepidiphilus margaritifer* and *Petrobacter succinatimandens* have been identified in a microbial consortium with the ability to degrade cellulose, cotton, and rice straw (Wang et al. 2011) as well as acetate in anaerobic chemostat with synthetic wastewater (Tang et al. 2008).

32 The Family *Methylophilaceae*

Nina Doronina · Elena Kaparullina · Yuri Trotsenko
G.K. Skryabin Institute of Biochemistry and Physiology of Microorganisms, Russian Academy of Sciences, Pushchino, Moscow Region, Russia

Abstract
Methylophilaceae, a family within the order *Methylophilales*, embraces the genera *Methylophilus* (type genus), *Methylobacillus*, *Methylovorus*, and *Methylotenera*. Betaproteobacterial obligate and restricted facultative methylotrophs capable of utilizing methanol or methylamine as a sole source of carbon and energy. Do not use methane (methylobacteria). Gram-negative rods, multiply by binary fission. Assimilate C_1 compounds via the ribulose monophosphate (Quayle) cycle. Major fatty acids are $C_{16:1\omega7c}$ and $C_{16:0}$. However, obligate methylobacteria possess similar morphology and metabolic organization. Thus, the main criteria used to clarify obligate methylobacteria into separate genera and species are their genomic and phylogenetic characteristics. On the other hand, members of the family are defined by some chemotaxonomic and biochemical properties, such as specific phospholipids and enzymes which are used for the delineation of genera. Members of the family are mainly found in activated sludge, mud, river, lake and pond waters, and plants.

Taxonomy: Historical and Current

Short Description of the Family

Me. thy. lo. phi. la' ce. ae. M.L. masc. n. *Methylophilus* type genus of the family, *-aceae* ending to denote family, M.L. fem. pl. n. *Methylophilaceae* the *Methylophilus* family.

Phylogenetically a member of the order *Methylophilales*, class *Betaproteobacteia* (Garrity et al. 2005). The family contains the type genus *Methylophilus* (Jenkins et al. 1987), *Methylobacillus* (Yordy and Weawer 1977: emended by Urakami and Komagata 1986), *Methylovorus* (Govorukhina and Trotsenko 1991: emended by Doronina et al. 2005a), *Methylotenera* (Kalyuzhnaya et al. 2006).

Members of the family are not halophilic obligate or restricted facultative methylotrophs, assimilate one-carbon compounds via the 2-keto-3-deoxy-6-phospogluconate (KDPG) variant of the ribulose monophosphate (RuMP) pathway. Gram-negative rods, multiply by binary fission. Motile by means of one or several polar or subpolar flagella or nonmotile. Do not form resting bodies. Do not grow in TGY, LB, and Nutrient media. Methane is not used. Aerobic, having a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor. Major cellular fatty acids are $C_{16:1\omega7c}$ and $C_{16:0}$. The major phospholipid is phosphatidylethanolamine. Ubiquinone Q-8 is the predominant isoprenoid quinone. The phylogenetic distance between the four genera is about 93–96 % 16S rRNA gene sequence similarity.

Phylogenetic Structure of the Family and Its Genera

Analysis of the nearly complete sequences of the 16S rRNA genes indicate that methylobacteria of the family *Methylophilaceae* are separated from sequences of species representing the genera *Methylophilus*, *Methylobacillus*, *Methylovorus*, and *Methylotenera* (Fig. 32.1).

E. Rosenberg et al. (eds.), *The Prokaryotes – Alphaproteobacteria and Betaproteobacteria*, DOI 10.1007/978-3-642-30197-1_243,

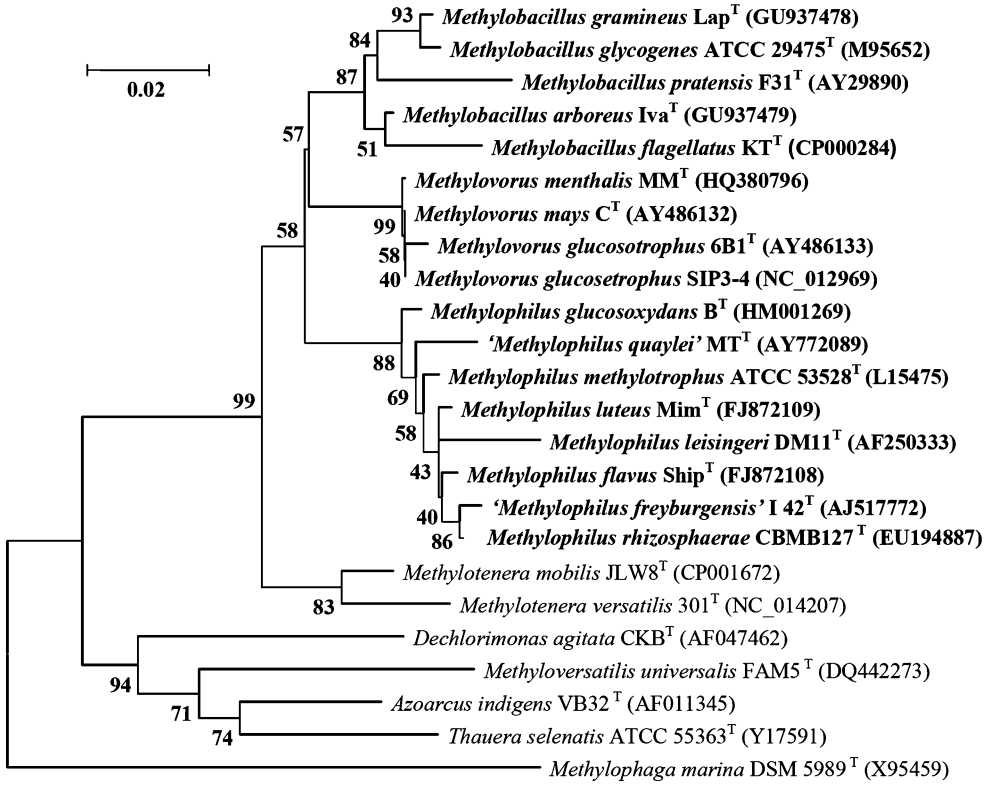

Fig. 32.1

***Maximum likelihood* phylogenetic tree showing the relationship of representatives of the *Methylophilaceae* based on 16S rRNA gene sequences. The evolutionary history was inferred by using the maximum likelihood method based on the Tamura-Nei model (Tamura and Nei 1993). The bootstrap consensus tree inferred from 1,000 replicates is taken to represent the evolutionary history of the taxa analyzed (Felsenstein 1985). Evolutionary analyses were conducted in MEGA5 (Tamura et al. 2011)**

Functional gene—the *mxaF* gene encodes the large subunit of the classical pyrroloquinoline quinone–linked methanol dehydrogenase which is found in majority of extant Gram-negative methylobacteria (Anthony and Williams 2003). Phylogenetic tree based on mxaF amino acid sequences show high levels of similarity between the members of the family *Methylophilaceae* (Fig. 32.2).

Molecular Analyses

DNA-DNA Hybridization Studies

Almost all descriptions of *Methylophilus*, *Methylobacillus*, and *Methylovorus* species include results of DNA-DNA hybridization (DDH) studies. Levels of DNA-DNA relatedness between *Methylophilus* strains—*M. methylotrophus* NCIMB 10515^T, *M. leisingeri* DSM 6813^T, *M. quaylei* VKM B-2338^T, *M. rhizosphaerae* CBMB127^T, *M. flavus* VKM B-2547^T, *M. luteus* VKM B-2548^T, and *M. glucosoxydans* VKM B-1607^T were 28–46 % (Madhaiyan et al. 2009; Doronina et al. 2012).

DNA-DNA relatedness between the reference strains of the genus *Methylobacillus* (*M. glycogens* ATCC 29475^T, *M. flagellatus* DSM 6875^T, *M. pratensis* NCIMB 13994^T, *M. gramineus* VKM B-2591^T, *M. arboreus* VKM B-2590^T) were in the range 38–45 % (Gogleva et al. 2011).

DDH relatedness between *Methylovorus glucosetrophus* VKM B-1745^T and *Methylovorus mays* VKM B-2221 was 56–58 % (Doronina et al. 2000). The levels of DNA-DNA homology between *Methylovorus menthalis* VKM B-2663^T and *M. glucosetrophus* VKM B-1745^T and *M. mays* VKM B-2221^T were 40 and 58 %, respectively (Doronina et al. 2011).

Moderate DDH relatedness of 12–18 % between type strains of the genera *Methylophilus*, *Methylobacillus*, and *Methylovorus* is a proof for intrageneric membership (Govorukhina and Trotsenko 1991; Doronina and Trotsenko 1994).

Genome Comparison

The complete genome sequence of five species branching within the 16S rRNA gene tree of *Methylophilaceae* have been released: the type strain of *Methylobacillus flagellatus* KT^T (Chistoserdova et al. 2007), *Methylotenera mobilis* JLW8^T, *Methylotenera versatilis* 301^T, and *Methylovorus glucosetrophus* SIP3-4 (Lapidus et al. 2011) and unclassified *Methylophilales* strain HTCC 2181^T

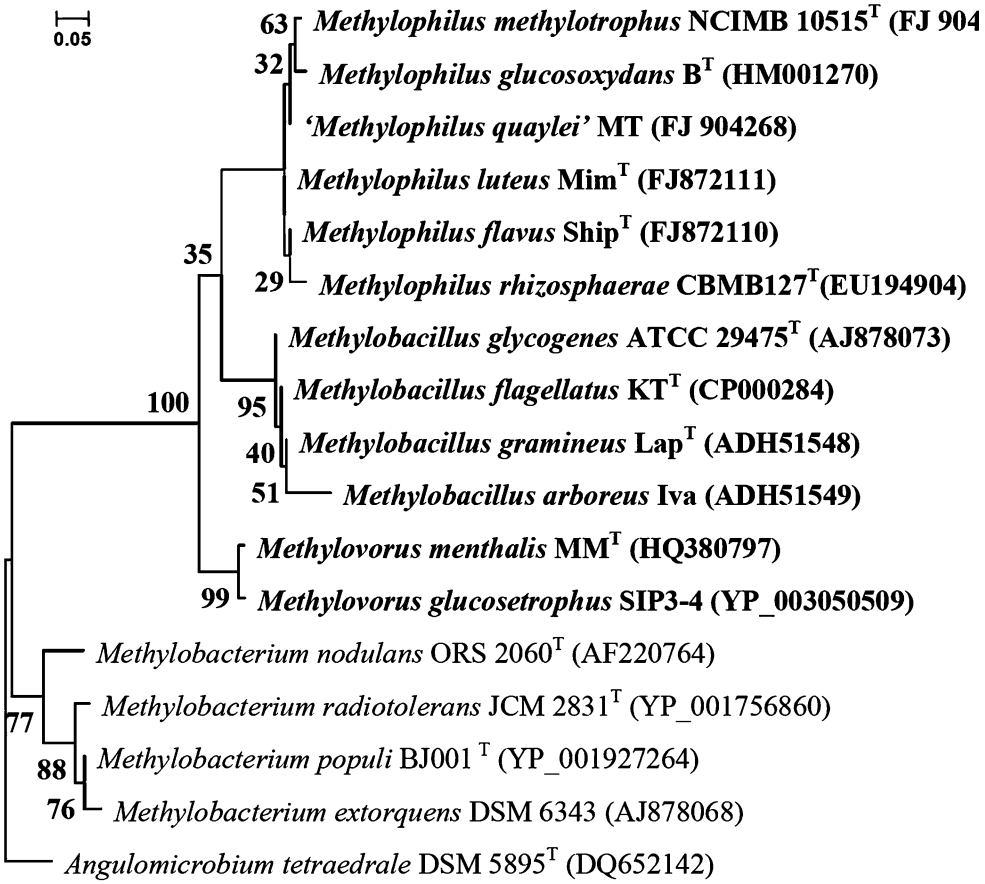

Fig. 32.2

Maximum likelihood tree based on *mxa*F amino acid sequences showing the phylogenetic position members of *Methylophilaceae* among methylotrophic bacteria. The numbers at the branch points are bootstrap values from 1,000 replicates. Bar, 5 % of evolutionary distance (5 amino acid substitutions per 100 amino acids). The evolutionary history was inferred by using the maximum likelihood method based on the Tamura-Nei model (see previous *Fig. 32.1*)

(Giovannoni et al. 2008) (*Tables 32.1–32.3*). The genome of *Methylobacillus flagellatus* KT^T represented by a single circular chromosome of approximately 3 Mbp, potentially enoding a total of 2,766 proteins.

Based on genome analysis as well as the results of mutational analyses, their methylotrophy is enabled by methanol and methylamine dehydrogenases and their specific electron transport chain components, the tetrahydromethanopterin (H_4MPT)-linked formaldehyde oxidation pathway and the assimilatory and dissimilatory RuMP cycles, and by a formate dehydrogenase. Some of the methylotrophy genes are present in more than one (identical or nonidentical copy). The obligate dependence on single-carbon compounds appears to be due to the incomplete tricarboxylic acid cycle (TCA), as no genes potentially encoding alpha-ketoglutarate, malate or succinate dehydrogenases are identifiable. The genome of *M. flagellatus* was compared in terms of methylotrophy functions to the previously sequenced genomes of three methylotrophs, *Methylobacterium extorquens* (an alphaproteobacterium, 7 Mbp) (Chistoserdova et al. 2003), *Methylibium petroleiphilum* (a betaproteobacterium, 4 Mbp) (Kane et al. 2007), and *Methylococcus capsulatus* Bath (a gammaproteobacterium, 3.3 Mbp) (Ward et al. 2004). Strikingly, metabolically and/or phylogenetically, the methylotrophy functions in *M. flagellatus* were more similar to those in *M. capsulatus* and *M. extorquens* than to the ones in the more closely related *Methylibium petroleiphilum* species, providing the first genomic evidence for the polyphyletic origin of methylotrophy in *Betaproteobacteria*.

Comprehensive proteomics to assess the expressed portion of the genome of *Methylobacillus flagellatus* was implemented (Chistoserdova et al. 2009; Chistoserdova 2011; Hendrickson et al. 2010). A total of 1,671 proteins (64 % of the inferred proteome) were detected, including all the predicted essential proteins. Nonrandom patterns observed with the nondetectable proteins appeared to the corresponding silent genomic islands, as inferred through the functional profiling and genome localization. The protein contents in methylamine- and methanol-grown cells showed a significant overlap, confirming the commonality of methylotrophic metabolism downstream of the primary oxidation reactions. The new insights into methylotrophy include detection of proteins for the *N*-methylglutamate pathway of methylamine

Table 32.1
Genome statistics and general features of *Methylophilaceae* species

Strain	Genome size (bp)	%GC DNA	No. of:				Mean coding sequence length (bp)	% Coding regions	Reference
			Proteins encoded	rRNA operons	$tRNA_s$	Replicons			
Methylotenera mobilis JLW8	2,547,570	45.51	2,348	2	46	1	975.63	89.96	Lapidus et al. (2011)

Methylophilales strain HTCC2181	1,304,428	37.93	1,338	1	36	1	923.45	95.00	Giovannoni et al. (2008)

Table 32.2
Relationships between the five *Methylophilaceae* strains compared on the basis of 16S rRNA gene identity and on percentage of common proteins (Lapidus et al. 2011)

Strain	Gene or protein identity[a] with:				
	Mt. mobilis JLW8	*Mt. versatilis* 301	*Mv. glucosetrophus* SIP3-4	*Mb. flagellatus* KT	*Methylophilales* strain HTCC2181
Mt. mobilis JLW8		96.6	94.3	93.8	94.6
Mt. versatilis 301	51.6		93.5	93.6	94.3
Mv. glucosetrophus SIP3-4	33.6	29.6		96.5	93.9
Mb. flagellatus KT	29.6	25.9	38.7		92.9
Methylophilales strain HTCC2181	17.0	16.9	15.7	15.2	

[a]16S rRNA identity is shown in the upper right and percentage of common proteins (at 70 % identity) in the lower left

oxidation that appears to be auxiliary. Two alternative enzymes for the 6-phosphogluconate dehydrogenase reaction (GndA and GndB) and the formate dehydrogenase reaction (FDH1 and FDH4) were detected. Mutant analysis revealed that GndA and FDH4 are crucial for the organism's fitness, while GndB and FDH1 are auxiliary.

Comparative analysis revealed that the core genome of *Methylophilaceae* may be as small as approximately 600 genes, while the pangenome may be as large as approximately 6,000 genes. Significant divergence between the genomes in terms both gene content and gene and protein conservation was uncovered, including the varied presence of certain genes involved in methylotrophy. Overall, data demonstrate that metabolic potentials can vary significantly between different species of *Methylophilaceae*, including organisms inhabiting the very same environment. These data suggest that genetic divergence among the members of the family may be responsible for their specialized and nonredundant functions in C1 cycling, which in turn suggests means for their successful coexistence in the specific ecological niches.

Phenotypic Analyses

The main features of members of *Methylophilaceae* are listed in *Tables 32.4–32.7*.

Methylophilus Jenkins et al. 1987, 447[VP]; Doronina et al. 2010, 2012

Me.thy.lo.phi'lus. Fr.n. *methyle* the methyl radical; Gr.adj. *philos* loving; M.L. masc.n. *Methylophilus* methyl radical loving.

Gram-negative, asporogenous, motile by polar flagella or nonmotile rods that are 0.2–0.6 × 1.0–2.5 μm in size. Some strains produce exopolysaccharide. Colonies on methanol—minimal salt

agar plates incubated for 2 days at 29 °C—are pigmented or nonpigmented, 1–4 mm in diameter, with entire edge, convex, translucent to opaque, smooth. No or extremely poor growth on nutrient or blood agar; no hemolysis. Optimal temperature 24–37 °C; no growth occurs at 4 °C and 45 °C. Optimal pH 6.5–7.8. Aerobic. Metabolism respiratory; very little or no acid is produced from glucose. Methanol is oxidized as the sole carbon and energy source by all the strains. In addition, a very limited range of other carbon compounds such as methylated amines, formate, glucose, and fructose may be utilized as sole carbon and energy sources. Methane is not used. No vitamins or other growth factors are required. Catalase- and oxidase positive. Nitrate and ammonium salts are used as nitrogen sources. Produce indole from tryptophan on medium with nitrate as nitrogen source. The predominant cellular fatty acids are $C_{16:0}$ and $C_{16:1}$. The major isoprenoid quinone component is ubiquinone with eight isoprene units (Q-8). The predominant phospholipids are phosphatidylethanolamine and phosphatidylglycerol; diphosphatidylglycerol (cardiolipin) is absent.

Formaldehyde is assimilated via the RuMP pathway. Assimilate NH_4^+ via the glutamate cycle. The tricarboxylic acid cycle is incomplete due to the absence of α-ketoglutarate dehydrogenase. Glyoxylate shunt enzymes are absent. The mol% G + C of DNA is 48–54.

The type species is *Methylophilus methylotrophus* Jenkins, Byron, and Jones 1987. The type strain is AS1 (ATCC 53528^T = DSM 46235^T = LMG 6787^T = NCIMB 10515^T = VKM B-1623^T).

Comparison of selected characteristics of members of the genus *Methylophilus* are listed in ❯ *Table 32.4*.

produce slime. Multiply by binary fission. No aggeregation or pigmentation in liquid medium. Colonies on methanol mineral salt agar incubated for 2 days at 30 °C are circular, 0.5–2.0 mm in diameter, with entire edges, convex and translucent to opaque, creamy or milky in color. No growth under an atmosphere of $CH_4 + O_2$ or $H_2 + CO_2 + O_2$. No growth in the presence of 3 % NaCl. Strictly aerobic with respiratory metabolism. Obligate or restricted facultative methylotrophs. Utilize methanol as the carbon and energy source. Some strains can grow poorly on glucose. Nitrates, ammonium salts, and glutamate serve as the nitrogen sources. Acetoine, H_2S, and NH_3 are not produced in test medium. Urease-, catalase-, and oxidase-positive. Peroxidase is variable. Do not degrade cellulose, gelatin, Tween 80. Indole is formed from L-tryptophan in mineral medium with methanol as the sole carbon and energy source with KNO_3 as a nitrogen source. Ammonium ions inhibit tryptophan

deamination. Assimilate C_1 compounds through the RuMP pathway (Entner-Doudoroff variant) and ammonia via the glutamate cycle (glutamate synthase and glutamine synthetase). Neither α-ketoglutarate dehydrogenase nor the glyoxylate shunt enzymes are present. 6-phosphogluconate dehydrogenase is specific for NAD^+ (not $NADP^+$). The prevailing cellular fatty acids are $C_{16:0}$ $C_{16:1\omega7}$. The major ubiquinone is Q-8. The predominant phospholipids are phosphatidylethanolamine, phosphatidylglycerol, and phosphatidylcholine. Cardiolipin is present.

The G + C content of DNA is 54–58 mol%. The type species is *Methylovorus glucosotrophus* Govorukhina and Trotsenko 1991. The type strain is 6B1 (VKM B-1745^T = ATCC 49758^T = DSM 6874^T = NCIMB 13222^T = UCM B-1745^T). *Table 32.5* lists characteristics of the type strains of the genus *Methylovorus*.

Methylotenera Kalyuzhnaya, Bowerman, Lara, Lidstrom, and Chistoserdova 2006, 289^{VP}, Emend. Kalyuzhnaya, Beck, Vorob'ev, Smalley, Kunkell, Lidstrom, Chistoserdova, 2012

Me.thy.lo.te'ner.a. N.L. *methylum* (from French *me´thyle*, back-formation from French *méthylène*, coined from Gr. n. *methu* wine and Gr. n. *hulê* wood) the methyl group radical; N.L. pref. *methylo-* pertaining to the methyl radical; L. fem. adj. *tenera* delicate; N.L. fem. n. *Methylotenera* a methyl group-oxidizing delicate bacterium.

Gram-negative rods. Some strains are motile. Do not form resting bodies and multiply by binary fission. Utilize methylamine. In addition, may utilize methanol, betaine, fructose, ethanol, and pyruvate as the sole sources of carbon and energy. Some strains are positive for urease and nitrate reduction. Oxidize methylamine by methylamine dehydrogenase or via *N*-methylglutamate pathway and assimilate C_1 compounds via the RuMP pathway. The major cellular fatty acids are $C_{16:1\omega7c}$ and $C_{16:0}$. The DNA G + C content is in the range 42.6–45.5 mol%.

The type species is *Methylotenera mobilis* Kalyuzhnaya et al. 2006. The type strain is JLW8 (= ATCC BAA-1282^T = DSM 17540^T).

Comparison of selected characteristics of the type strains of the genus *Methylotenera* are listed in *Tables 32.7* and *32.8*.

Colonies of *Methylotenera mobilis* JLW8^T (= ATCC BAA-1282^T = DSM 17540 ^{T}) were cream to light brown and 1–2 mm in diameter when grown at 30 °C for 4–7 days. No pigmentation was observed when cells were grown in liquid culture (Kalyuzhnaya et al. 2006).

Colonies of *Methylotenera versatilis* 301^T were white (slightly yellowish in old cultures), mucoid, undulate, circular, convex, viscous, and up to 5 mm in diameter. The isolate grew well on solid media but not in a liquid culture. Only cultures incubated without shaking showed some growth (Kalyuzhnaya et al. 2012).

Isolation, Enrichment, and Maintenance Procedures

Isolation, Enrichment

Strains of *Methylophilus methylotrophus* have been isolated from activated sludge, mud, river, and pond water (MacLenman et al., British patent 1370892). The type strain AS1^T was isolated from activated sludge.

Methylophilus leisingeri DM11^T was isolated in Switzerland from groundwater contaminated with dichloromethane (Gaelli and Leisinger 1985; Doronina and Trotsenko 1994). 20 ml groundwater was passed through a 0.2 µm pore diameter membrane filter, and the filter was incubated in 50 ml mineral medium containing 10 mM dichloromethane. The medium contained (g/l): $K_2HPO_4 \cdot 3H_2O$, 4.1; KH_2PO_4, 1.4; $(NH_4)_2SO_4$, 0.2; $MgSO_4 \cdot 7H_2O$, 0.2. Prior autoclaving, the pH of the medium was adjusted to 7.2. After sterilization dichloromethane was added, and 1 l of the medium was supplemented with 1 ml trace element solution (g/l): $FeSO_4 \cdot 7H_2O$, 1.0; $MnSO_4 \cdot H_2O$, 1.0; $(NH_4)_6Mo_7O_{24}$ $4H_2O$, 0.25; H_3BO_3, 1.0; $CuCl_2 \cdot 2H_2O$, 0.25; $ZnCl_2$, 0.25; NH_4VO_3, 0.1; $Co(NO_3)_2 \cdot 6H_2O$, 0.25; and $Ca(NO_3)_2$, 0.25. The bacteria were grown at 29 °C in 750-ml Erlenmeyer flasks containing 100 ml of the medium on a rotary shaker at 180 rpm. The flasks were tightly closed with rubber stoppers. Since the pH of the medium decreased when dichloromethane was used, dichloromethane was added in three portions to a final concentration of 10 mM (0.85 g/l) each after the pH of the medium had been adjusted to 7.2 by NaOH. Pure culture was isolated by the method of

exhausting plating of enrichment onto the same medium, containing 2.0 % purified agar Difco and 0.1 g/l of Bromothymol Blue. Petri plates were incubated in a 2.5 l desiccator, 0.2 ml portions of dichloromethane being added after 24 h. Colonies of bacteria that decompose dichloromethane are surrounded by yellow zones due to formation of HCl.

Methylophilus quaylei MT^T was isolated as an airborne contaminant during cultivation of methanotroph *Methylocystis methanolicus* on methanol (Doronina et al. 2005b). The sample of mixed liquid culture grown on medium "K" containing gl^{-1}: KH_2PO_4—2.0; $(NH_4)_2SO_4$—2.0; $MgSO_4 \cdot 7H_2O$—0.025; NaCl—0.5; $FeSO_4 \cdot 7H_2O$—0.002, pH 7.2 in Petri dish ($h = 5$ mm) was UV incubated for 10 min. After UV treatment, the culture was serially diluted and grown on "K" agar (Difco 2.0 % w/v) with 2 % (v/v) CH_3OH. A successive isolation of a single colonies resulted in the isolation of a pure culture of obligately methylotrophic strain MT^T, which could not grow on Difco nutrient agar or in atmosphere of methane: air (1:1).

Methylophilus rhizosphaerae $CBMB127^T$ was isolated from rhizosphere soils of rice cultivars (*Oryza sativa* L. cv O-dae and Nam-pyeoung, respectively) on selective ammonium mineral salt (AMS) medium (Whittenbury et al. 1970) with 0.5 % methanol. Cells were maintained on nutrient agar (NA, Difco) with 1 % (v/v) methanol or on AMS medium (Madhaiyan et al. 2009).

Strains *Methylophilus flavus* $Ship^T$ and *Methylophilus luteus* Mim^T were isolated from the phyllosphere of dog rose (*Rosa cinnamomea* L.) and coltsfoot (*Tussilago farfara* L.), respectively, sampled from the city park in Pushchino (Moscow region, Russia) (Gogleva et al. 2010). The strains were grown on medium "K." Solidified medium "K" was prepared by adding 2.0 % (w/v) Difco agar.

Methylophilus glucosoxydans B^T was isolated from rhizosphere rice (*Oryza sativa* L.) sampled from Vietnam on "K" agar with 2.0 % methanol (Doronina et al. 2012).

An enrichment culture of *Methylobacillus glycogenes* $T\text{-}11^T$ was prepared by adding a small amount of partially decayed tomato to a liquid mineral salt medium containing 2 % methanol (v/v) (Yordy and Weaver 1977). The bacterium was isolated from the enrichment culture by streaking for isolated colonies on a mineral salt agar medium containing 2 % methanol. A colony was picked and cultured at 30 °C with shaking (200 rpm) in a liquid mineral salt medium (pH 7.0), containing 2 % methanol. The procedure was repeated until a pure culture was obtained.

The strain *Methylobacillus flagellatus* KT^T was isolated by the same procedure from sewage (Govorukhina et al. 1987). *Methylobacillus pratensis* $F31^T$ was isolated on mineral salt medium, containing 0.5 % (v/v) methanol from meadow grass (*Poa trivialis* L.) sampled from the city park in Helsinki (Finland) (Doronina et al. 2004).

Stains *Methylobacillus arboreus* Iva^T and *Methylobacillus gramineus* Lap^T were isolated from willow buds (*Salix fragilis* L.) and phyllosphere of silverweed (*Potentilla anserina* L.), respectively, sampled from the city park in Pushchino (Moscow Region, Russia) (Gogleva et al. 2011).

Strain of the genus *Methylovorus* were isolated from activated sludge, mud, soil, pond water, and plants (Govorukhina and Trotsenko 1991; Seo and Kim 1993; Doronina et al. 2000, 2005a, 2011).

Methylovorus glucosotrophus $6B1^T$ was isolated from pond water (Govorukhina and Trotsenko 1991). *Methylovorus mays* C^T was isolated from maize phyllosphere (*Zea mays* L.) (Doronina et al. 2000). *Methylovorus menthalis* MM^T was isolated from the root of corn mint (*Mentha arvensis* L.) (Doronina et al. 2011).

The root was washed three times with sterile distilled water and placed into an Erlenmeyer flask (750 ml) with 200 ml of K medium and 0.5 % (v/v) methanol. After three transfers for 2 days on a rotary shaker (180 rpm) at 29 °C, the suspension of the methylobacterial enrichment culture was plated to obtaining

single colonies (exhaustive inoculation) onto agarized "K" medium with methanol. Isolated methylobacterial colonies were reinoculated on agar slants, transferred into liquid medium, and then again on solid medium for exhaustive inoculation. Reisolated methylobacterial colonies were reinoculated on slant agar. The purity of the isolated culture was controlled by light and electron microscopy, as well as by the uniformity of colonies on the agarized medium with methanol.

An obligate methylamine utilizer, *Methylotenera mobilis* JLW8^T, was isolated from Lake Washington sediment (Washington State, USA) after enrichment in a basal salt medium (Harder et al. 1973) diluted fivefold and supplemented with 0.1 % methylamine (Kalyuzhnaya et al. 2006). Also the restricted facultative methylotroph *Methylotenera versatilis* 301^T was isolated from this ecosystem by a dilution-plating approach (Kalyuzhnaya et al. 2012). To isolate strain 301^T, 1 ml aliquot of sediment samples was mixed with 9 ml filtered lake water, and serial dilutions were plated onto plates containing lake water-based medium solidified with agar (2 %; Difco) supplemented with 5 mM methylamine. After 2 weeks incubation at room temperature, individual colonies were restreaked onto fresh agar plates.

Maintenance Procedures

Generally, strains of the family *Methylophilaceae* are maintained on basal salts media as agar slants at 4 °C for 1 month. Some members of the genus *Methylophilus* must be subculturing every 10 days. For long-term storage at −20 °C or −80 °C, cells are suspended in the basal salts media and supplemented with 10 % DMSO or 20 % glycerol. Long-term preservation methods include freeze-drying in skim milk and maintenance in liquid nitrogen at −196 °C.

Ecology

Strains of the family *Methylophilaceae* are obligate or restricted facultative methylotrophs (methylobacteria) capable of growth on single-carbon compounds (methanol, methylamines, dichloromethane) and play an important role for the aerobic conversion of C1 compounds in different ecological niches. They have been isolated from activated sludge, mud, river, lake and pond waters, plant rhizosphere and phyllosphere. Association of aerobic methylobacteria with plants are permanent and results from the fact that methylobacteria consume methanol released by plant into the environment through leaf stomata (Nemecek-Marshall et al. 1995; Fedorov et al. 2011). Methanol is formed during demethylation of cell wall pectin under active growth of plant cells. Plants are therefore the main source of methanol in the biosphere (Galbally and Kirstine 2002). Association between plants and methylotrophs is mutually advantageous, because methylobacteria stimulate plant growth and development due to production of bioactive substances: phytohormones (auxins, cytokinins) and vitamins (Fedorov et al. 2011).

Methylophilus rhizosphaerae (Madhaiyan et al. 2009), *Methylophilus flavus* and *Methylophilus luteus* (Gogleva et al. 2010), *Methylophilus glucosoxydans* (Doronina et al. 2012), *Methylobacillus pratensis* (Doronina et al. 2004), *Methylobacillus arboreus* and *Methylobacillus gramineus* (Gogleva et al. 2011), *Methylovorus mays* (Doronina et al. 2000), and *Methylovorus menthalis* (Doronina et al. 2011) were isolated from plants.

Pathogenicity

No reports of the family *Methylophilaceae* causing overt or opportunistic infections in humans, animals, or insects have been published. The members of this family are obligate or restricted facultative methylotrophs and unable to grow on blood agar or other complicated media.

The type strain *Methylophilus methylotrophus* AS1 is resistant to penicillin, oleandomycin, and susceptible to nalidixic acid and streptomycin (Jenkins et al. 1987). *Methylophilus leisingeri* DM11^T (VKM B-2013^T = DSM 6813^T) is resistant to erythromycin and sensitive to nalidixic acid, novobiocin, and kanamycin (Doronina and Trotsenko 1994). *Methylophilus flavus* Ship^T (VKM B-2547^T = DSM 23073^T = CCUG 58411^T) is resistant to streptomycin and oxacillin and sensitive to ampicillin, novobiocin, nalidixic acid, gentamicin, neomycin, and lincomycin (Gogleva et al. 2010). *Methylobacillus flagellatus* KT^T (ATCC 51484 = DSM 6875 = VKM B-1610) is resistant to streptomycin, erythromycin, ampicillin, neomycin, and lincomycin and sensitive to novobiocin, nalidixic acid, kanamycin, and gentamicin (Govorukhina et al. 1987). *Methylobacillus arboreus* Iva^T (VKM B-2590^T = CCUG 59684^T = DSM 23628^T) is resistant to ampicillin, oxacillin, novobiocin, streptomycin, and neomycin and sensitive to nalidixic acid, gentamicin, kanamycin, and lincomycin (Gogleva et al. 2011). *Methylobacillus gramineus* Lap^T (=VKM B-2590^T= =CCUG 59683^T = DSM 23629^T) is resistant to novobiocin, nalidixic acid, and neomycin and sensitive to ampicillin, oxacillin, gentamicin, streptomycin, kanamycin, and lincomycin (Gogleva et al. 2011).

Mehylovorus glucosetrophus 6B1^T (=ATCC 49758^T = VKM B-1745^T = NCIMB 13222^T) is resistant to neomycin, lincomycin, erythromycin, and ampicillin, but sensitive to novobiocin, nalidixic acid, kanamycin, and streptomycin (Govorukhina and Trotsenko 1991).

Methylovorus mays C^T (=VKM B-2221^T = NCIMB 13922^T) is resistant to ampicillin and lincomycin and sensitive to gentamicin, kanamycin, nalidixic acid, neomycin, novobiocin, streptomycin, and erythromycin (Doronina et al. 2000).

Methylotenera mobilis JLW8^T (=ATCC BAA-1285^T = DSM17540^T) is sensitive to gramicidin, kanamycin, and tetracycline (Kalyuzhnaya et al. 2006). *Methylotenera versatilis* 301^T (=JCM 17579^T = VKM B-2679^T) is resistant to kanamycin, ampicillin, streptomycin, neomycin, and erythromycin (Kalyuzhnaya et al. 2012).

Application

Forage protein methylobacteria of the genera *Methylophilus* and *Methylobacillus* are characterized by higher values of specific growth rate, economic coefficient, protein and lysine content, and favorable composition of elements and fatty acids (MacLennan et al. 1974; Doronina and Trotsenko 1986; Large and Bamforth 1988; Trotsenko et al. 2005). For all the reasons above, they are preferable for large-scale cultivation and forage protein production.

Exopolysaccharides (EPSs)

Methylobacteria of the genera *Methylobacillus*, *Methylophilus*, and *Methylovorus* synthesize EPSs from methanol; of note, EPSs yield may be regulated by varying the composition of the medium and growth conditions (Doronina et al. 2005b; Gogleva et al. 2010).

Phytosymbiosis

Aerobic methylobacteria are ubiquitous in the phyllosphere and rhizosphere of plants and often colonize their seeds (Trotsenko et al. 2001; Fedorov et al. 2011). Biological testing (using *Amarantus caudatus* L. seedlings), TLC, HPLC, and solid-phase enzyme immunoassays established the presence of zeatin and zeatin riboside in the culture liquid of *Methylovorus mays* (Ivanova et al. 2000). It was also demonstrated that representatives of the genera *Methylophilus*, *Methylobacillus*, and *Methylovorus* synthesize indole compounds, particularly indoleacetic acid (IAA) when grown in media containing methanol or methylamine in the presence of 5 mM L-tryptophan (Doronina et al. 2002; Gogleva et al. 2010, 2011).

The synthesis of auxins in methylobacteria depended on the composition of the medium: when $(NH_4)_2SO_4$ was replaced by KNO_3, the amount of IAA synthesized increased three- to fivefold.

Methylovorus mays exerted a beneficial effect on the growth and morphogenesis of tobacco, potato, and fiber flax grown in vitro (Kalyaeva et al. 2001). This obligate methylobaterium stimulated morphogenesis and antifungal resistance of Chinese cabbage *Brassica chinensis* L. (Doronina et al. 2009). The ability of methylobacteria to stimulate the growth and morphogenesis of plants indicates their promise in experimental plant physiology and agrobiotechnology.

Enzymes

Enzymological studies demonstrated that a number of enzymes of methylobacteria exhibit very high activity. These results provided a basis for isolating pure preparations of various dehydrogenases and other enzymes, which have a potential as research reagent and analytical tools: glucose-6-phosphate dehydrogenase (EC 1.1.1.49; 250U/mg protein) (Sokolov et al. 1980); $NADP^+$ glutamate:dehydrogenase (EC 1.4.1.4; 180 U/mg protein) (Sokolov and Trotsenko 1987).

Biodegradation of Toxic Compounds

Methylobacteria of the family *Methylophilaceae* degrade a broad spectrum of highly toxic compounds: methanol, formaldehyde, methylated amines, and dichloromethane. The culture of *Methylobacillus* sp. is appropriate for elimination of methanol from industrial sewage (cellulose sulfate manufacturing facilities) (Trotsenko et al. 2005).

33 The Genus *Neisseria*

Julia S. Bennett · Holly B. Bratcher · Carina Brehony · Odile B. Harrison · Martin C. J. Maiden
Department of Zoology, University of Oxford, Oxford, UK

Abstract

The genus *Neisseria* comprises a number of closely related Gram-negative organisms isolated from humans and animals. Their interrelationships are poorly resolved by phenotypic approaches, and the classification of the species groups by molecular techniques has been confused by a combination of their genetic similarity and extensive shared sequence polymorphism as a consequence of shared ancestry, horizontal genetic exchange, or both. Whole genome sequence analysis, especially of large numbers of draft genome sequences, has enabled the comparison of core genes across the genus, and this has proved to be an effective means of defining species groups within the genus. This redefinition is largely consistent with previous species designations with relatively few adjustments necessary. Most members of the genus are not, or are very rarely, pathogenic, but the genus contains the globally significant pathogens *Neisseria meningitidis*, the meningococcus, and *Neisseria gonorrhoeae*, the gonococcus. The meningococcus is an "accidental pathogen": predominantly existing as a harmless commensal, with very few infections resulting in pathology. Pathology does not appear to play a role in the transmission of this organism, although some genotypes have a greater propensity to cause disease than others. The majority of work on the genus concentrates on the two pathogenic species, with attempts to develop a comprehensive vaccine against the meningococcus a major driver for research. The gonococcus is antigenically highly diverse but genetically quite uniform, and probably emerged from a single clone that changed its niche. Emerging antibiotic resistance of the gonococcus currently represents the most significant global health challenge presented by this genus.

Taxonomy: Historical and Current

Short Description of the Genus

The genus *Neisseria* is a group of Gram-negative, oxidase positive, aerobic β-Proteobacteria bacteria within the family *Neisseriaceae* (*Fig. 33.1*, *Table 33.1*) and are mostly diplococci (Tonjum 2005). The members of the genus are all very similar phenotypically and genetically and are poorly resolved from each other with 16S rDNA phylogenies (Harmsen et al. 2001; Bennett et al. 2012). They have conventionally been distinguished with a range of phenotypic tests, especially sugar utilization characteristics (Tonjum 2005), but genomic analyses have been required to fully characterize the members of the genus (Bennett et al. 2012).

The genus represents an excellent model system for studying the genetic traits of closely related organisms that exhibit very different phenotypes (Maiden 2008; Falush 2009; Bratcher et al. 2012), and members of the genus, especially the meningococcus and gonococcus, have been in the forefront of work on the population biology of bacteria in general and pathogens in particular (Spratt and Maiden 1999). The meningococcus was among the first organisms to be investigated by multilocus enzyme electrophoresis (MLEE) (Caugant et al. 1986) and the first to be studied with multilocus sequence typing (MLST) (Maiden et al. 1998). Population genetic studies indicate that most invasive disease cases are caused by a limited number of hyperinvasive lineages, whereas carriage isolates belong to many different lineages, many of which have never been associated with disease (Claus et al. 2005). In the context of its close relatives, comparative studies have provided valuable insights into meningococcal biology and understanding its pathogenicity (Maiden 2008). The gonococcus appears to be the descendant of a single clone of the ancestral population that gave rise to present-day meningococci and gonococci, that changed its primary niche from the oral cavity to the urogenital tract (Bennett et al. 2007).

E. Rosenberg et al. (eds.), *The Prokaryotes – Alphaproteobacteria and Betaproteobacteria*, DOI 10.1007/978-3-642-30197-1_241,

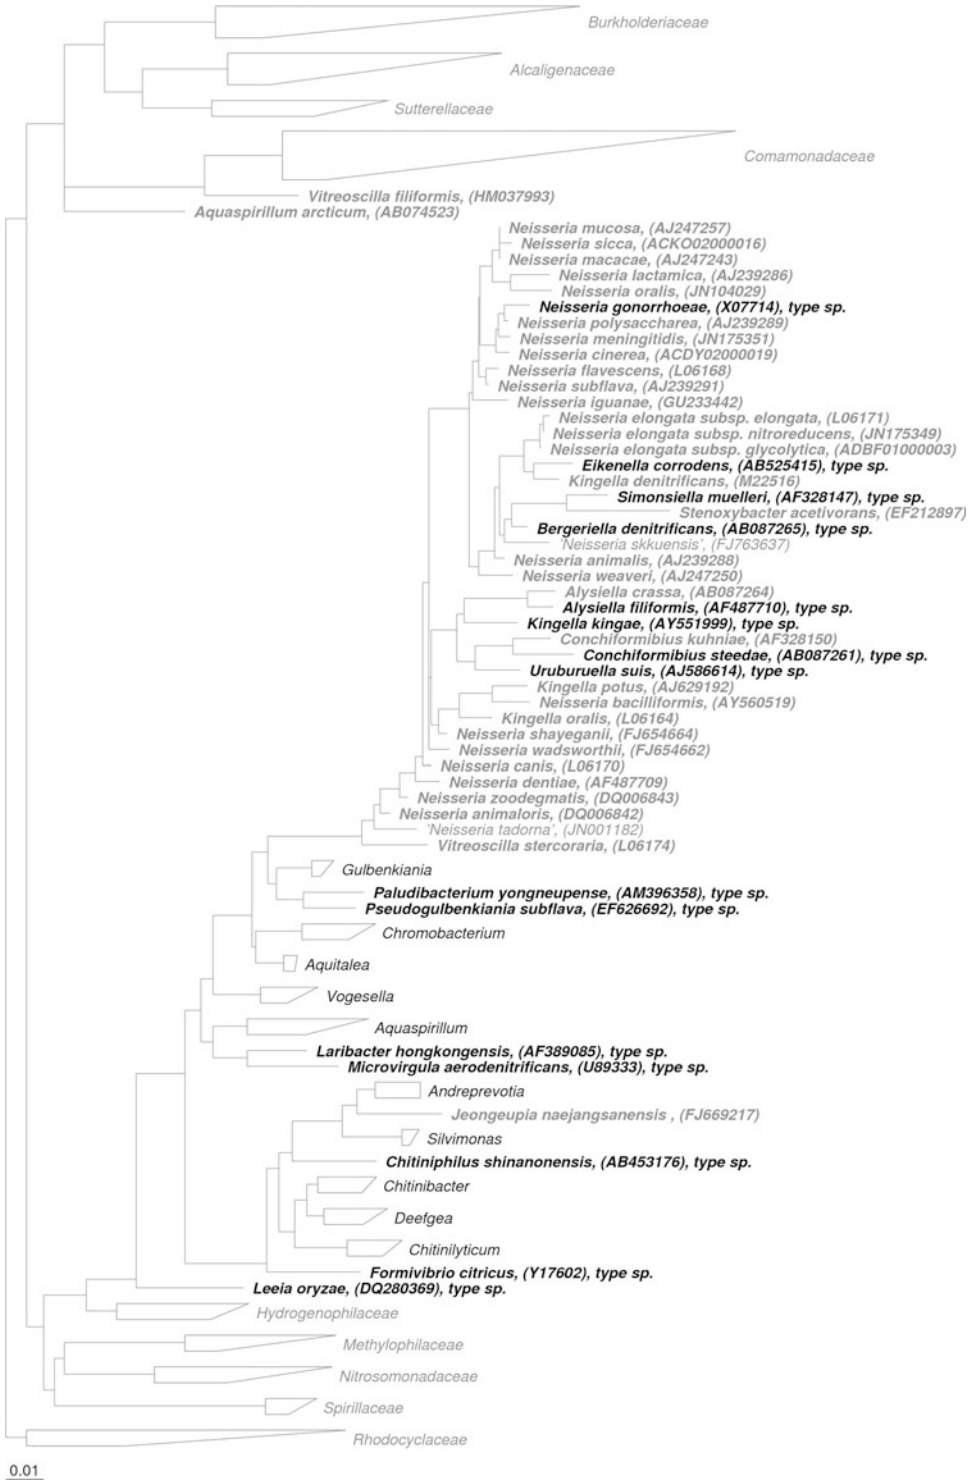

Fig. 33.1

Phylogenetic reconstruction of the position of the genus *Neisseria* within the family *Neisseriaceae* based on the maximum likelihood algorithm RAxML (Stamatakis 2006). Sequence dataset and alignments according to the All-Species Living Tree Project, release LTPs108 (Yarza et al. 2010). Representative sequences from close relative genera were used to stabilize the tree topology. In addition, a 40 % maximum frequency filter was applied to remove hypervariable positions from the alignment. Scale bar indicates estimated sequence divergence. The family *Neisseriaceae* comprises the genera *Alysiella*, *Amantichitinum*, *Andreprevotia*, *Aquaspirillum*, *Aquitalea*, *Bergeriella*, *Chitinibacter*, *Chitinilyticum*, *Chitiniphilus*, *Chromobacterium*, *Conchiformibius*, *Deefgea*, *Eikenella*, *Formivibrio*, *Gulbenkiania*, *Iodobacter*, *Jeongeupia*, *Kingella*, *Laribacter*, *Leeia*, *Microvirgula*, *Morococcus*, *Neisseria*, *Paludibacterium*, *Prolinoborus*, *Pseudogulbenkiania*, *Silvimonas*, *Simonsiella*, *Snodgrassella*, *Stenoxybacter*, *Uruburuella*, *Vitreoscilla*, and *Vogesella*

Molecular Analyses

Genome Structure

High-quality finished and annotated genome sequences for three meningococcal isolates, MC58 (Tettelin et al. 2000), Z2491 (Parkhill et al. 2000), and FAM18 (Bentley et al. 2007), and one *Neisseria lactamica* isolate (Bennett et al. 2010), demonstrate a genome size of about 2.2 Mbp, containing approximately 2,000 protein coding sequences, with an average G+C in the region of 51.5 %. These data are consistent with other published genomes, mostly from the meningococcus and, at the time of writing, high-quality draft genomes were available for over 100 *Neisseria* isolates, including at least one representative for type strains of each of the named species in *Table 33.1*, with the exception of *Neisseria zoodegmatis*, *Neisseria animaloris*, *Neisseria iguanae*, "*Neisseria skkuensis*," and "*Neisseria tadorna*" (Schoen et al. 2008; Marri et al. 2010; Budroni et al. 2011; Bennett et al. 2012). About 80 % of the genomes contain protein coding sequences and the finished genomes are largely co-linear; however, inversions around the origin of replication are seen in a number of these isolates (Bennett et al. 2010; Bratcher et al. 2012) and there is also extensive evidence for frequent inter- and intra-genomic genetic exchange (Bentley et al. 2007). Members of the genus have many associated non-chromosomal genetic elements, plasmids, prophages, and genetic islands (Snyder et al. 2009). At least one independent genetic element, thought to be a bacteriophage, has been associated with virulence in the meningococcus (Bille et al. 2005, 2008) and the gonococcus and some meningococci contain a 57 kb genomic island, also thought to be mobile among strains (Snyder et al. 2005; Dominguez et al. 2011). Plasmids are common in *N. gonorrhoeae* and have been observed in *N. lactamica*, but have been rarely reported in the meningococcus. Members of the genus are also characterized by large numbers of restriction and modification systems (Lau et al. 1994; Stein et al. 1995; Claus et al. 2000; Budroni et al. 2011). A large number of genes are phase variable (Jordan et al. 2005; Bentley et al. 2007).

Molecular Phylogeny

Genetic taxonomy in *Neisseria* was pioneered by Catlin and Cunningham in 1961 (Catlin and Cunningham 1961), who demonstrated close relationships between most *Neisseria* species. Members of the genus *Neisseria* are poorly resolved by techniques for bacterial speciation such as DNA-DNA hybridization (Guibourdenche et al. 1986) and *16S rRNA* sequencing (Harmsen et al. 2001; Bennett et al. 2012). Phylogenies produced from concatenated MLST fragments (MLSA) (Gevers et al. 2005) can be used to distinguish *N. meningitidis*, *N. gonorrhoeae*, and *N. lactamica* (Bennett et al. 2007), but are unsatisfactory for examination of the genus as a whole, as robust species-specific groups are not generated (Bennett et al. 2012) and some genes are absent from some species. Shared ancestry among conserved genes or horizontal genetic exchange among *Neisseria* contributes to difficulties in speciation (Bennett et al. 2012), but horizontal genetic exchange among species, at least in the core genome, is not as frequent as has been reported (Unemo and Dillon 2011). Ribosomal multilocus sequence typing (rMLST) (Jolley et al. 2012a) overcomes these problems, as it indexes variation in the 53 complete ribosomal protein subunit genes that encode the bacterial ribosomal proteins, which are present in all *Neisseria* (Bennett et al. 2012).

A phylogeny produced from the concatenated ribosomal protein subunit genes from 21 named species, generates distinct species groups, with *N. gonorrhoeae* most closely related to *N. meningitidis* (*Fig. 33.2*). The phylogeny supports previous deoxyribonucleic acid relatedness studies (Guibourdenche et al. 1986), which showed that *N. meningitidis*, *Neisseria*

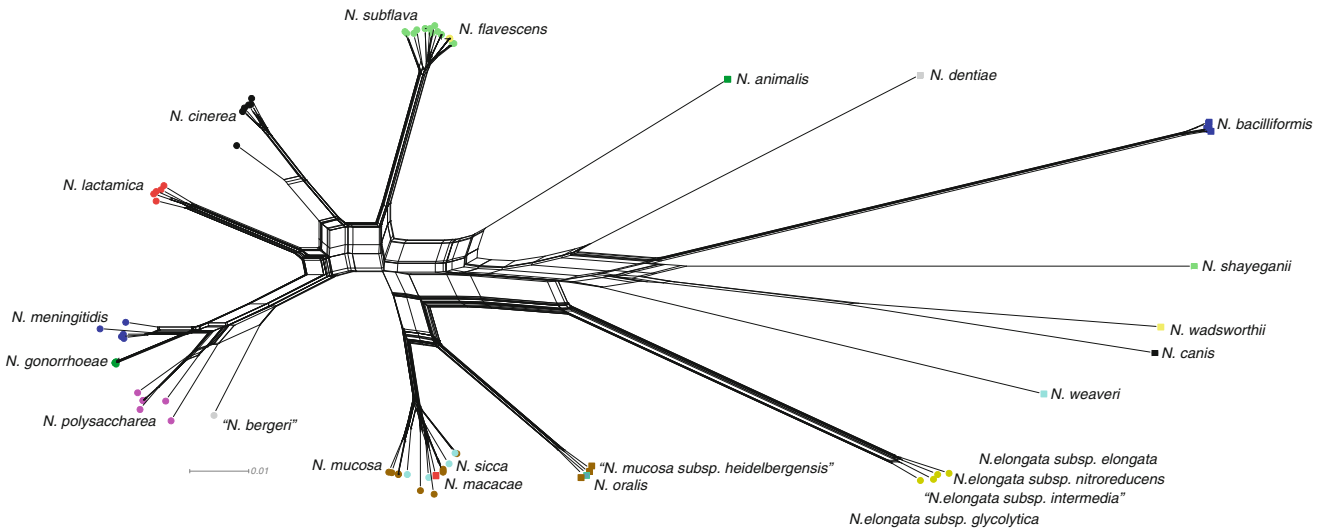

Fig. 33.2
Phylogeny of the genus *Neisseria* reconstructed with 53 concatenated *rps* genes (rMLST)

polysaccharea, *N. gonorrhoeae*, and *N. lactamica* were closely related. Another putative species is also very closely related genetically to *N. meningitidis* (Bennett et al. 2012). The proposed name for this species is "*Neisseria bergeri*," after the author who first described the strain as a phenotypically distinct strain of *N. polysaccharea* (Fig. 33.2; Berger 1985). This phylogeny is supported by one constructed from the concatenated sequences of 246 genes present in all members of the genus (Bennett et al. 2012).

The rMLST phylogeny refines the relationships among members of the genus, resolving a number of issues. Importantly, despite evidence for frequent recombination within and among currently recognized species groups in the genus (Spratt et al. 1991), the phylogenies reconstructed from the 53 ribosomal protein subunit genes, and indeed other "core" genes, demonstrate a coherent structure, with all isolates examined so far by this means being members of well-resolved clusters. These clusters are largely, but not entirely, congruent with species designations arrived at with more conventional techniques, and suggest that a number of reassignments of bacterial species names might be usefully made within the group (Bennett et al. 2012). This coherence is consistent with most interspecies recombination mostly involving the "accessory genome," those genes that are not universally present even within one species group (Hotopp et al. 2006; Bennett et al. 2010; Marri et al. 2010).

Within the rMLST phylogeny (Fig. 33.2), the *Neisseria cinerea* isolates form a species-specific group, although a subspecies may be present. *Neisseria subflava* and *Neisseria flavescens* isolates are present in a single cluster, and it has been suggested that *N. flavescens* should be reclassified as *N. subflava*, due to its genetic relatedness (Bennett et al. 2012). Three previously defined species, *Neisseria mucosa*, *Neisseria macacae*, and *Neisseria sicca*, cluster within a single distinct group, and these should be considered a single species (*N. mucosa*) based on their genetic relatedness (Bennett et al. 2012). Strains originally defined as "*Neisseria mucosa* subsp. *heidelbergensis*" (Berger 1971), a subspecies not officially validated, are very closely related to the recently defined species *Neisseria oralis* (Wolfgang et al. 2012): they also have up to 100 % *16S rRNA* and 99.5 % *23S rRNA* identity to this species (Harmsen et al. 2002). "*N. mucosa* subsp. *heidelbergensis*" strains should therefore be considered to be *N. oralis*. Eight other species were distantly related to *N. meningitidis*, including the *Neisseria elongata* variants: *Neisseria elongata* subsp. *elongata*, *Neisseria elongata* subsp. *glycolytica*, *Neisseria elongata* subsp. *nitroreducens*, *and* "*Neisseria elongata* subsp. *intermedia*." Two newly defined species: *Neisseria shayeganii* and *Neisseria wadsworthii* (Wolfgang et al. 2011) were more distantly related to *N. meningitidis* than many nonhuman strains.

Phenotypic Analyses

Cells of most *Neisseria* spp. are cocci except for *N. elongata*, *Neisseria weaveri*, *Neisseria bacilliformis*, and *N. shayeganii* which are rods (Table 33.1) normally occurring in pairs or quartets. They are Gram-negative and oxidase positive, with optimal growth at 35–37 °C in a 5–10 % CO_2 atmosphere. *Neisseria* can be differentiated from similar organisms using biochemical or other tests although definitive identification can prove difficult. Test results for carbohydrate utilization (Table 33.2), enzymatic activities, and cellular fatty acid composition may vary within a species (Wolfgang et al. 2012) and therefore cannot reliably be used alone to speciate *Neisseria*. Two enzyme substrate tests can be used to aid identification of *N. meningitidis* (gamma-glutamylaminopeptidase-positive) and *N. lactamica* (beta-galactosidase-positive), and gonococcal-specific antibodies can help to identify *N. gonorrhoeae*. As many species display similar phenotypic properties, it is recommended that at least two methods should be used to identify *Neisseria* in the laboratory, although the increasing availability of molecular techniques, especially sequencing approaches such as rMLST (Jolley et al. 2012a), suggests that these should form the basis of future isolate characterization and species definition (Bennett et al. 2012).

Isolation, Enrichment, and Maintenance Procedures

The pathogenic species may be grown on a selective medium, such as Thayer-Martin (Thayer and Martin 1966), which suppresses the growth of some commensal species. Species such as *N. mucosa*, *N. sicca*, *N. subflava*, *N. flavescens*, *N. meningitidis*, *N. cinerea* and *N. lactamica* can be grown on LBVT.SNR medium which is selective for commensal *Neisseria* (Knapp and Hook 1988). The meningococcus grows best on enriched media, such as blood agar (BAP) or chocolate agar (CAP), at 37 °C and in an atmosphere of 5 % carbon dioxide and fails to grow under strictly anaerobic conditions; however, under oxygen limitation, the bacterium expresses a denitrification pathway which does supplement growth (Rock et al. 2005). The gonococcus grows best on Thayer-Martin or Modified Thayer-Martin media (MTM) or chocolate agar (CAP) in a high carbon dioxide atmosphere (5–10 %) incubated at 35–37 °C. Colonies appear pinkish-brown and translucent, with smooth consistency and defined margins 0.5–1 mm in diameter. Fastidious strains may produce small, ~0.25 mm "pinpoint" colonies.

Ecology

Habitat

The majority of *Neisseria* have been isolated from the mucosal and dental surfaces of animals. Members of the genus have been shown to be consistent components of the commensal oral microbiota of humans (Dewhirst et al. 1993, 2010) and while many have only been isolated from humans, some species have been isolated from other sources including monkeys, dogs, cows, and even lizards (Vedros et al. 1983; Barrett et al. 1994; Sneath and Barrett 1996; Vandamme et al. 2006). The biology of many

of these species is poorly understood, but the genus plays an important part in the normal oral microbiome of humans (Zaura et al. 2009).

Although a number of different species have been involved in various pathologies, by far the most important diseases are caused by the meningococcus, which can be a cause of devastating meningitis and septicemia (Stephens 2007) and the gonococcus which causes one of the most important sexually transmitted diseases (Morse and Knapp 1992; Tapsall et al. 2009). The principal interest in this genus has been these two pathogens, which are both of global significance and many studies of other *Neisseria* species have been with reference to these two organisms, with the aim of identifying the genetic determinants of virulence. This has, however, proved to be complex as with a few exceptions, most of the genetic elements thought to confer increased virulence are also found in the essentially non-pathogenic species, most meningococcal infections cause no overt pathology and even many gonococcal infections are asymptomatic (Hotopp et al. 2006; Snyder and Saunders 2006).

Pathogenicity and Clinical Relevance

Meningococcal Disease

Historical evidence suggests that epidemic meningococcal disease emerged at the beginning of the nineteenth century, with the first definitive description made by the Swiss physician Gaspard Vieusseux in 1805 (Vieusseux 1806), of an outbreak in Geneva which lasted three months, affecting children and young people, resulting in 33 deaths. The second recorded description was reported a year later in Medfield, Massachusetts, in the United States: in March 1806, nine fatal cases occurred over a period of 23 days. The youngest patient was just 15 months old and the oldest 10 years of age (Danielson and Mann 1806). Many outbreaks followed with the first epidemics of meningococcal disease in Africa described in 1905, with major epidemics occurring in the sub-Saharan "meningitis belt" for much of the twentieth century (Greenwood 1999).

The meningococcus was isolated from human cerebrospinal fluid in 1887 (Weichselbaum 1887), and in 1890, it was acknowledged that the organism could be found in an asymptomatic carrier state, in addition to being isolated from cases of invasive disease (Kiefer 1896). Fulminant meningococcal septicemia, or Waterhouse–Friderichsen syndrome, was first described in an 8-month-old child in 1911 (Waterhouse 1911). Bacterial meningitis remains a major threat to global health, accounting for an estimated annual 500,000 cases worldwide with at least 50,000 deaths (WHO.org). It is believed that 5–20 % of the population may be asymptomatic carriers of *N. meningitidis* at any given time and the rate may be higher in epidemic situations, although in diseased individuals, as long as an appropriate antimicrobial is administered promptly, prognosis is extremely good (Cartwright et al. 1992).

Meningococcal disease occurs with a range of different epidemiologies (Schwartz et al. 1989): sporadic cases of disease occur globally, with increases in disease incidence occurring from time to time. These can take the form of: (i) small scale localized outbreaks focused on a single family or contact group such as a university campus or a military recruit camp, (ii) hyperendemics, where a particular geographic region experiences increased rates of disease over a prolonged period of time, often lasting many months or years, and (iii) large-scale epidemic or pandemic outbreaks (Rosenstein et al. 2001). It is now known that each of these increases in incidence is related to the spread in asymptomatic carriage of particular genotypes of the meningococcus which are associated with the ability to cause invasive disease (Caugant and Maiden 2009).

Meningococcal disease comprises two distinct syndromes which can occur either separately or together. Meningitis, the syndrome most frequently associated with *N. meningitidis*, is a consequence of invasion of the cerebrospinal fluid and meninges, the membranes that surround the brain. If untreated, this is frequently fatal and surviving patients can exhibit serious sequelae such as brain damage, loss of coordination, and hearing loss. Meningococcal septicemia is a consequence of the invasion and uncontrolled rapid growth of the meningococcus in the blood stream; in many ways, this is even more serious than the meningitis syndrome. The release of endotoxins causes extensive tissue damage and shock, as a consequence of capillary leak and overstimulation of the innate immune system due to the release of meningococcal lipooligosaccharide: one of the most potent endotoxins known (Brandtzaeg and van Deuren 2012). In addition to being frequently fatal, meningococcal septicemia frequently results in extensive tissue damage, often resulting in digit or limb loss (Pace and Pollard 2012).

Neisseria meningitidis

N. meningitidis was first described by Weichselbaum (1887) and the first studies of intra-species meningococcal variation employed serological analyses, focusing initially on the serogroups, which are defined by the capsular polysaccharide (Vedros 1987). Further serological studies identified additional antigenic variation in the outer membrane proteins and short-chain lipopolysaccharides, leading to the development of meningococcal serotypes, serosubtypes, and immunotypes (Frasch et al. 1985). Sequence-based typing has become the method of choice for characterizing the highly variable surface proteins of this organism (Jolley et al. 2007). The capsule is of particular significance as it is both a virulence determinant, as only encapsulated meningococci regularly cause disease (Brandtzaeg and van Deuren 2012), and it is a major component of meningococcal vaccines (Tan et al. 2010).

Neisseria meningitidis Serogroups

The serogroup is the single most important characteristic of the meningococcus from a clinical perspective as it relates to the expression of a capsular polysaccharide, which is a prerequisite

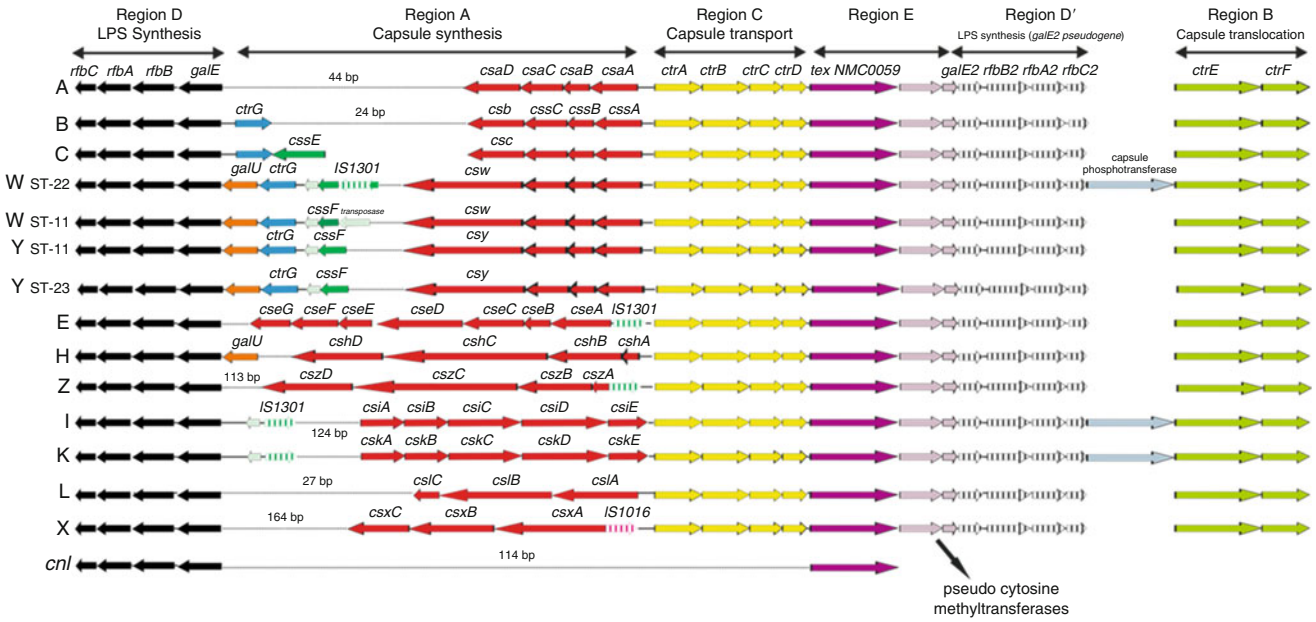

Fig. 33.3
Alternative genetic structures that occupy the *cps* region of the meningococcal genome

for meningococcal disease. Each meningococcus is genetically capable of expressing one type of capsule, known as a serogroup, although a significant proportion of meningococcal isolates from the oropharynx lack the genes required for capsule synthesis (Claus et al. 2002) and these can, very rarely, cause disease (Findlow et al. 2007). These meningococci have a short sequence known as the capsule null locus (*cnl*), which is also found in other *Neisseria* species. There are 12 serogroups, defined on the basis of biochemical properties and nucleotide sequences of the region of the genome encoding capsule synthesis (*cps*) (*Fig. 33.3*). Of these, six serogroups (A, B, C, W, X, and Y) cause the majority of meningococcal disease. Some *N. meningitidis* isolates express serogroup H, E, L, I, K, and Z polysaccharide capsules, but these are rarely associated with invasive disease and are more commonly found in asymptomatic carriage.

Within the genus, the expression of a polysaccharide capsule is unique to the meningococcus, with isolates from the related *N. lactamica* and *N. gonorrhoeae* species only containing regions D and E of the *cps* region, which are not implicated in capsule synthesis (*Fig. 33.3*; Petering et al. 1996). However, many meningococcal isolates recovered from carriage are unencapsulated either through the absence of capsule genes or through phase variation of the capsule biosynthesis genes (Hammerschmidt et al. 1996a, b; Claus et al. 2002). Since the pathogenicity of *N. meningitidis* is significantly dependent on the structure and expression of polysaccharide capsules, acquisition of the genes necessary for capsule expression may have been a critical step in the evolution of pathogenic *N. meningitidis* strains.

The capsule expressed by *N. meningitidis* is categorized as a group II capsule based on the similar chemical and physical properties of capsular polymers, with the genes encoding group II capsules from different bacterial species including *Haemophilus influenzae*, *Salmonella typhi Vi*, and *Escherichia coli* K5 containing a comparable genetic organization (Frosch et al. 1991; Roberts 1996; Frosch and Vogel 2006). The increasing number of bacterial genomes becoming available necessitates a more unified approach to the nomenclature of genes including those implicated in capsule biosynthesis. For example, there are in the annotated genomes belonging to FAM18, MC58 and Z2491, genes defined as *lipA* and *lipB* occurring twice, once in the capsule locus and then further on in the genome. Consequently, a nomenclature for the *N. meningitidis cps* locus has been proposed and accepted by the *Neisseria* community with the genes *lipA* and *lipB* renamed as *ctrE* and *ctrF* and a revised nomenclature for all of the remaining genes found in the *cps* locus. (*Table 33.3* and *33.4*; Harrison et al. 2013). The serogroup A capsule is composed of repeating units of *O*-acetylated (α1 → 6)-linked *N*-acetyl-D-mannosamine-1-phosphate (*Table 33.3*; Liu et al. 1971b). The capsule biosynthesis genes are contained within region A, the first gene *csaA*, encoding the UDP-*N*-acetyl-D-glucosamine (UDP-GlcNAc) 2-epimerase which converts UDP-GlcNAc into UDP-*N*-acetyl-D-mannosamine (UDP-ManNAc), *csaB* is the polymerase linking ManNAc-phosphate monomers together with *csaC* encoding an *O*-acetyltransferase transferring acetyl groups to ManNAc (Swartley et al. 1998; Gudlavalleti et al. 2004; Harrison et al. 2013). The fourth gene, *csaD*, is involved in either capsule transport or in cross-linking of the capsule to the meningococcal cell surface.

Capsular polysaccharides from serogroups B, C, W, and Y are composed of sialic acid derivatives with serogroups B and C expressing (α2 → 8)- and (α2 → 9)-linked sialic acid

Table adapted from Frosch and Vogel (2006)
ManNAc N-acetylmannosamine, *NeuNAc N*-acetylneuraminic acid (sialic acid), *OAc O*-acetylated, *Gro* glycerol, *GulNAc A* 2-acetamido-2-deoxy-L-guluronic acid, *Gal* galactose, *Glc* glucose, *P* phosphate, *GlcNAc N*-acetylglucosamine

homo-polymers respectively, while alternating sequences of D-galactose or D-glucose and sialic acid are expressed by serogroups W and Y (*Table 33.3*; Liu et al. 1971a; Bhattacharjee et al. 1975, 1976). All four serogroups contain the conserved *cssABC* genes for cytidine-5′-monophosphate-*N*-acetylneuraminic acid (CMP-NANA) synthesis (other designations include *siaABC*, *synABC* and *neuABC*). These are followed by *csb*, *csc*, *csw*, or *csy* genes (*siaD* or *synDEFG* respectively) which are the capsule polymerases and determine the functional and nucleotide specificity for the four serogroups. Serogroups C, W, and Y contain *O*-acetyltransferase genes termed *cssE* (*oatC*) or *cssF* (*oatWY*), respectively (Claus et al. 2004). The serogroup E capsule consists of alternating D-galactosamine and 2-keto-3-deoxyoctulosonate (KDO) residues (Bhattacharjee et al. 1978). Region A contains seven genes *cseA-G* (formerly 29eABCDEFGH) with genes including *cseE* encoding a putative 3-deoxy-phosphooctulonate synthase, *cseF* a putative 3-deoxy-D-manno-octulosonate cytidylyltransferase and *cseG* a D-arabinose 5-phosphate isomerase protein.

The biochemical structures of serogroups H and Z contain monosaccharide glycerol-3-phosphate repeat units and share similarities with teichoic acid polymers (Jennings et al. 1979; van der Kaaden et al. 1984). BLAST searches of region A genes encoding the capsule biosynthesis genes revealed that these were homologous to biosynthesis genes belonging to *Actinobacillus pleuropneumoniae* (Dubreuil et al. 2000) (Xu et al. 2010). These genes are predicted to encode a glycerol-3-phosphate cytidylyltransferase, and a hypothetical protein containing a LicD domain for a role in phosphorylcholine incorporation into teichoic acid polymers has been suggested. Serogroup L capsule polysaccharides contain 2-acetamido-2-deoxy-D-glucosyl residues and phosphate groups (Ding et al. 1981; Ashton et al. 1983), while the serogroup X capsular polysaccharide is composed of (α-1 → 4)-linked *N*-acetylglucosamine 1-phosphate (Bundle et al. 1974). Serogroup I capsules consist of *O*-acetylated alternating *N*-acetyl-guluronic acid and *N*-acetylmannosaminuronic acid (ManNAcA) units, while serogroup K capsules are composed of *O*-acetylated disaccharide repeat units containing *N*-acetylmannosaminuronic acid (Michon et al. 1985; Van der Kaaden et al. 1985).

Genes within the capsule locus are divided into six regions: A, B, C, D, D′, and E (*Fig. 33.3*), with genes in region A encoding enzymes for the biosynthesis of the capsular polysaccharide and regions B and C implicated in the translocation of the high molecular weight polysaccharides to the cell surface. Genes in regions D and D′ are involved in LPS biosynthesis, while genes in region E are not implicated in capsule biosynthesis or transport and are thought to encode a methyltransferase and a gene homologous to the *tex* gene belonging to *Bordetella pertussis* (Fuchs et al. 1996). All 12 serogroups have comparable *cps* loci with regions occurring in the following order D-A-C-E-D′-B, revealing a conserved gene synteny and a replication of the genomic rearrangements (*Fig. 33.3*). Genes in regions B, C, D, D′, and E are conserved, whereas genes in region A are diverse, in line with the distinct biochemical composition found within each serogroup.

Neisseria meningitidis Subcapsular Antigens

The meningococcal subcapsular antigens, which are components of the outer membrane of these Gram-negative organisms, have also been used for typing and as possible vaccine components. As with the capsule, the subcapsular antigens are also associated with particular clonal complexes. The major outer membrane proteins (OMPs) PorA and PorB are porins which have highly diverse surface regions (Urwin et al. 2004; Russell et al. 2008) and were first recognized as serotyping and serosubtyping antigens (Frasch et al. 1985). PorA in particular has also attracted interest as a vaccine component as it has been shown to elicit bactericidal immune responses in humans, although the diversity of this protein is a challenge in the formulation of vaccines which contain it (Granoff 2010).

The iron regulated surface protein FetA (also known as FrpB) (Thompson et al. 2003) has attracted similar interest and together with the serogroup, these antigens form the basis of the meningococcal strain typing nomenclature which is currently adopted by the European Centres for Disease Control (Jolley et al. 2007). It has the form: serogroup: PorA type: FetA

type: sequence type (clonal complex), thus: B: P1.19, 15: F5-1: ST-33 (cc32). Such typing schemes can be applied to surveillance, population biology, and epidemiological studies. For example, finetype data (serogroup: PorA: FetA) of invasive disease isolates collected in Germany over 42 months were used to retrospectively detect clusters of disease cases using automated scan statistics (Elias et al. 2006). This has been further extended to real-time GIS surveillance at the national level in Germany with EPIScanGIS which can potentially detect emerging clusters of disease using finetype data (Reinhardt et al. 2008). Unified and Web-accessible nomenclature schemes have greatly aided the study of the meningococcus. For example, a harmonized scheme was developed for the vaccine candidate fHbp which previously had two separate classification systems. The established database facilitates querying of sequences and submission of new allele sequences and cross-referencing with the other schemes, thereby enabling the monitoring of circulating variants (Brehony et al. 2007).

Examination of strain types from large collections of isolates has shown that the protein surface antigens occur in non-overlapping structure, such that strains that occur at high frequencies and persist do not share the same variants (Caugant 1998; Urwin et al. 2004; Russell et al. 2008; Watkins and Maiden 2012). This structuring is consistent with models that invoke immune selection as a driver of bacteria population structure and has important implications for the design of vaccines based on these proteins (Gupta et al. 1996; Buckee et al. 2008, 2010).

Neisseria meningitidis Population Structure

The meningococcus exhibits significant population structure, notwithstanding the fact that there is extensive evidence for horizontal genetic exchange within meningococcal populations. This structuring was first identified with MLEE (Caugant et al. 1987), and has since been confirmed with MLST (Maiden et al. 1998) and rMLST (Jolley et al. 2012b). MLST characterizes organisms by assigning each isolate an ST, a unique combination of alleles at the housekeeping loci (there are seven in the meningococcal scheme). Some of these STs are much more common in population samples than others, and these tend to be persistent over time and geographic spread. Analysis of these data with heuristic approaches, such as SPLITSTREE (Huson and Bryant 2006) and EBURST (Feil et al. 2004), shows that there are many variants of these abundant STs, which have up to three loci with different alleles (Maiden 2006). The central genotypes are used to define "clonal complexes" of related organisms, which have been shown to have a genealogical basis. The biological significance of these clonal complexes is that they are associated with particular phenotypes, particularly the expression of given serogroups or outer membrane protein repertoires (Urwin et al. 2004). Further, clonal complexes are associated with different epidemiologies and the likelihood of causing disease (Yazdankhah et al. 2004; Caugant and Maiden 2009).

Serogroup associations among hyper-virulent clonal complexes have been documented with, for instance, ST-1, ST-4, and ST-5 lineages almost exclusively possessing serogroup A capsules, while most invasive ST-32 meningococci express serogroup B capsules (Wang et al. 19921992; Scholten et al. 1994; Guibourdenche et al. 1996; Baker et al. 2001; Harrison et al. 2009). The majority of ST-11 clonal complex meningococcal disease has been caused by serogroup C isolates although there have been instances of invasive serogroup W, ST-11 isolates. The predominant clonal complex associated with serogroup Y meningococci is the ST-23 lineage. Serogroup X outbreaks have been reported in Niger and Ghana, Burkina Faso, and Togo (Gagneux et al. 2002; Boisier et al. 2007; Delrieu et al. 2011), with sporadic cases found in industrialized countries, a significant proportion of these isolates belonging to the ST-181 complex.

Gonococcal Disease

Gonococcal disease is one of the most important sexually transmitted infections (STIs) globally, causing both symptomatic and asymptomatic genital and extragenital tract infections. Disseminated infections do occur although they are less common, and rates vary greatly in both the developing and developed countries, with the highest rates in southern and southeast Asia, Sub-Saharan Africa, and Latin America, although reliable incidence data are often incomplete or inaccurate and are usually prevalence based rather than incidence based (Gerbase et al. 1998). In Western countries, gonorrhea is second only to chlamydia as the most common bacterial STI, with rates increasing in some countries since the mid-2000s presumably a result of emerging antimicrobial resistance.

Given the relatively recent history of meningococcal disease, it is interesting that gonococcal disease is one of the oldest syndromes known to man, with clinical descriptions dating from the earliest civilizations. The Ebers papyrus, for example, which dates from at least 1550 BCE, includes a reference to gonorrhea. However this compilation of therapeutic, diagnostic and theoretical considerations for the problems of everyday life, health and disease, when cross referenced with other papyri, suggests an origin closer to c. 3000 BCE. The name "gonorrhea" is believed to have been coined by the Greek physician Galen in the second century; it literally translates as "flow of seed" – one of the disease symptoms in males is urethral discharge.

N. gonorrhoeae is regarded as an obligate human pathogen with colonization which follows on from infection usually resulting in a localized inflammatory response. More rarely, this results in disseminated infection, which can lead to dermatitis, endocarditis, meningitis septic arthritis, and pelvic inflammatory disease (PID) (Morse and Knapp 1992). Symptoms of uncomplicated infection include discharge, dysuria, and inflammation of the urethral and cervical tissues. A serious complication of gonorrhea in women, particularly if left untreated, is PID. Once established, it is difficult to treat and can lead to chronic abdominal pain and infertility. Gonorrhea is usually contracted

from a sex partner who is either asymptomatic or only has minimal symptoms. While 85–90 % of men will develop symptoms within five days of infection, in women, the incubation period is longer, with 30–60 % of infected women remaining asymptomatic (van Duynhoven 1999). Women with asymptomatic infections are thus more at risk of developing PID and disseminated infection. Those with asymptomatic infections are important contributors to disease prevalence. Gonorrhea is unlike many other communicable diseases in that reinfection can occur as it does not appear to induce protective immunity. This means that incidence rates often do not account for reinfection and therefore, the true disease burden is distorted.

Neisseria gonorrhoeae

The German physician Albert Neisser first identified the gonococcus as the causative agent of gonorrhea in 1879, and the genus was thus named after him. Like the meningococcus, *N. gonorrhoeae* is naturally competent for DNA uptake and is therefore able to evade the immune system by frequent antigenic alteration. Unlike the meningococcus however, it does not possess a capsule. This along with highly diverse OMPs is a reason for the difficulty in developing a vaccine against the organism. Typing methods used to discriminate gonococcal isolates include phenotypic techniques such as auxotyping, serotyping, and antimicrobial susceptibility testing and genotypic methods such as restriction fragment length polymorphism (RFLP), ribotyping, pulsed field gel electrophoresis (PFGE), Opa-typing, PorB typing, *N. gonorrhoeae* multiantigen sequence typing (NG-MAST), and MLST (Unemo and Dillon 2011). DNA-based typing methods are now considered the "gold standard" due to their discriminatory power, reproducibility, and ease of use relative to phenotypic methods.

Virulence Factors, Iron Acquisition

For successful proliferation within the body or on mucosal surfaces, the natural habitat of the *Neisseria*, microorganisms must possess the ability to acquire iron from their hosts. The latter contain an iron-withholding defense system that, while allowing host cells access to iron, inhibits potential pathogens from acquiring it. A variety of mechanisms are employed to suppress free iron in the human body (Weinberg 1978, 2009). These include: transferrin, which sequesters iron found in plasma, lymph, and cerebrospinal fluids (Evans 1999); lactoferrin, which is found in most mucosal secretions (Levay and Viljoen 1995); and hemoglobin and haptohemoglobin complexes (Stojilijkovic et al. 1995; Lewis et al. 1997, 1998, 1999).

N. meningitidis and *N. gonorrhoeae* are able to acquire iron from human transferrin and lactoferrin via distinct but parallel pathways through the expression of high-affinity receptors specific for each glycoprotein. These receptors consist of two iron-repressible outer membrane proteins: the transferrin or lactoferrin binding proteins A (TbpA or LbpA) and B (TbpB or LbpB). In addition, iron may be acquired from hemoglobin using the hemoglobin receptor HmbR and from haptohemoglobin complexes using the bipartite receptor HpuAB (Stojilijkovic et al. 1995; Lewis et al. 1997). Both receptors are phase variable with isolates variably expressing these such that for example, meningococci may express: (i) HmbR only; (ii) HpuAB only; (iii) both receptors simultaneously or (iv) neither (Tauseef et al. 2011). Furthermore, there is a significantly higher prevalence of meningococci associated with disease containing the *hmbR* gene and an under-representation of a *hpuAB* only phenotype (Harrison et al. 2009; Tauseef et al. 2011). All of these receptors have elicited some interest in vaccine research as they possess attributes making them ideal vaccine candidates. For example, they are surface-exposed and they are expressed in vivo. However, phylogenetic analysis of, for example, the lactoferrin and transferrin binding proteins has revealed them to be highly diverse and indeed, studies have shown for the transferrin and lactoferrin binding proteins, that although these were able to induce bactericidal antibodies, the cross-reactivity was limited (Rokbi et al. 1995, 1997a, b; Pettersson et al. 1998, 1999). Congruence was observed among meningococci expressing the hemoglobin receptor, *hmbR*; however, as this receptor is not universally expressed by all meningococci and gonococci (the latter persistently containing nonfunctional *hmbR* genes), it is not a suitable vaccine candidate (Evans et al. 2010).

Applications

The major applications of the study of the *Neisseria* are the monitoring of infection and the development of effective treatments and vaccines against meningococcal and gonococcal disease. Despite many years of research and development, these remain very active areas with significant problems yet to be resolved: there is no vaccine against the gonococcus and, despite major successes, no comprehensive meningococcal vaccine, and antimicrobial resistance is emerging as a significant problem in the gonococcus.

Vaccine Development

There has been considerable interest in the development of vaccines against both the meningococcus and the gonococcus, with appreciably more success in the former. For many years, the main component of meningococcal vaccines has been the polysaccharide capsule. This is an ideal component as there are relatively few capsular serogroups associated with disease (six, with most disease caused by three, serogroups A, B, and C). As well as raising protective bactericidal responses (Gotschlich et al. 1969), the capsule is also the major virulence determinant and there have been major successes with using capsular polysaccharide vaccines, especially since the development of protein conjugate vaccines (Tan et al. 2010).

The first capsular polysaccharide vaccines were developed in the 1960s and were specifically designed to target the serogroups A and C which had been responsible for various epidemics worldwide since World War 2. The vaccines proved effective in prevention of serogroup A and C disease in US military recruits and in epidemic control in Africa (Makela et al. 1975; Greenwood and Wali 1980; Hassan-King et al. 1988). However, as polysaccharide vaccines are T-cell independent, they do not induce immunological memory; so, the period of protection is short (3–5 years) and as they do not prevent mucosal colonization, there is no protection provided through herd immunity. These limitations and the success of the *Haemophilus influenzae* type b vaccine (Heath and McVernon 2002) spurred on the development of conjugate polysaccharide vaccines.

Conjugate meningococcal vaccines have been introduced successfully in several countries. The meningococcal C conjugate (MCC) vaccine was introduced by the Department of Health in the UK in October 1999 in response to increasing levels of serogroup C disease in the country. It was the first country to include the meningococcal conjugate vaccine in a routine infant immunization program (Miller et al. 2001). Infants were immunized at 2, 3, and 4 months of age, and all children up to 18 years of age were targeted in a catch-up campaign from November 1999 to December 2000. The impact of the campaign has been a dramatic reduction in serogroup C disease of over 80 % within 18 months of onset of the program (Miller et al. 2001). There was also a reduction of 66 % in carriage of serogroup C in adolescents a year after the program began (Maiden et al. 2002). The effects of herd immunity, i.e., protection of the unvaccinated population, have been shown with a reduction of disease by 67 % in this group, thanks to the high vaccine coverage rate and the reduction in carriage (Ramsay et al. 2003). A quadrivalent vaccine targeting serogroups A, C, W and Y was licensed in the USA in 2005 for adolescents aged 11–12, those who have not been vaccinated before high-school entry at 15 years, college freshmen, and various individuals at risk (Bilukha and Rosenstein 2005). The Meningitis Vaccine Project (MVP), a collaboration with WHO, PATH (Program for Appropriate Technology in Health), and various worldwide parties was established with the aim to produce conjugate vaccines for Africa at an affordable price and eventually eliminate epidemic meningococcal disease in Africa (Jodar et al. 2003; LaForce et al. 2007). The mass vaccination campaign began in 2010 with 19.5 million people vaccinated in Burkina Faso, Mali, and Niger and then to be rolled out across meningitis belt countries.

Vaccines against serogroup B are, however, a problem, as this polysaccharide is poorly immunogenic in humans due to identity to host antigens (Finne et al. 1983). Consequently, there have been many efforts to develop subcapsular, mainly outer membrane protein based serogroup B substitute vaccines. A major problem is the extensive diversity of these antigens, although this is ameliorated somewhat by the antigenic structuring of these antigen variants by clonal complex (Urwin et al. 2004). Attempts to overcome this problem have included the development of vaccines against particular clonal complexes and their associated antigens (Bjune et al. 1991; Rodriguez et al. 1999; O'Hallahan et al. 2005), the use of cocktails of antigenic variants (Rouppe van der Voort et al. 2000), or by attempts to identify "conserved antigens" (Pizza et al. 2000; Bernfield et al. 2002). To date none of these have been entirely successful, although some novel vaccines are in clinical development at the time of writing (Tan et al. 2010; Scarselli et al. 2011).

Gonococcal vaccines face many of the challenges seen for the meningococcus, except that if anything the outer membrane antigens are more variable for this pathogen. There is also limited understanding of the gonococcal immune response in humans. Infection stimulates an inflammatory response and the appearance of polymorphonuclear neutrophils. Antibodies against the major surface antigens pili, lipooligosaccharide, Opa and Por are produced in the serum (IgG, IgM), and at the mucosal surface (IgA) (Zhu et al. 2011). IgA is present in mucosal secretions and is thought to prevent bacterial adherence. However, in spite of the presence of antibody response to infection, there is no evidence of a protective immune response to gonococcal antigens and, as a result, individuals may be reinfected with no evident reduction in disease severity or duration (Fox et al. 1999). Relative to the meningococcus, there has been little research into potential gonococcal vaccines, with only two making it to clinical trial (Zhu et al. 2011). Current research is focused on developing correlates of human protection including the mouse model (Gu et al. 2010) and DNA and recombinant vaccines based on OMPs such as PorB and TbpB (Zhu et al. 2004; Price et al. 2005).

Antimicrobial Resistance

Despite their genetic similarity, the situation with antibiotic resistance, as with vaccines, differs markedly between the meningococcus and the gonococcus. While antimicrobial resistance is very widespread among gonococci, leading to serious concerns as to the future treatment options against this important pathogen, reduced susceptibility to antimicrobial agents is yet to become a major concern for the treatment of meningococcal disease. Resistance to antimicrobials in the gonococcus includes target-mediated resistance, such as the recruitment of gene fragments of penicillin binding protein genes, efflux pumps, such as the Mtr efflux pump, and the possession of plasmids encoding resistance elements such as the *tetM* gene and β-lactamases (Unemo and Shafer 2011).

With the meningococcus, the major problem with antimicrobial resistance is a historic one arising from the use of sulphonamides as a prophylactic against carriage (Perez-Trallero et al. 1989; Kristiansen et al. 1990; Tzanakaki et al. 1992) as well as treatment during and after World War 2. This led to widespread resistance to these antimicrobials, as a consequence of both mutation or horizontal genetic exchange involving the *folP* (*dhps*) gene which encodes dihydropterate synthase. This resulted in treatment failure and large-scale outbreaks of meningococcal disease in the US military recruits training for the Vietnam War (Millar et al. 1963). By 1972, 6 % of UK strains

were resistant and by the 1990s ~30 % were resistant (Jones and Kaczmarski 1994), so they are no longer used to treat meningococcal infection or carriage (Oppenheim 1997).

The differences in the biology of antibiotic resistance in the meningococcus and gonococcus underline a major feature of the biology of the genus as a whole: despite their close genetic similarity, the organisms belonging to the different species within the genus exhibit dramatic differences in the phenotypes which they express, and to a large extent, this can be explained by their responses to the different selection pressures which they are exposed to.

34 The Family *Nitrosomonadaceae*

James I. Prosser[1] · *Ian M. Head*[2] · *Lisa Y. Stein*[3]
[1]Institute of Biological and Environmental Sciences, University of Aberdeen, Aberdeen, UK
[2]School of Civil Engineering and Geosciences, Newcastle University, Newcastle upon Tyne, UK
[3]Department of Biological Sciences, University of Alberta, Edmonton, AB, Canada

Abstract
The *Nitrosomonadaceae* comprise a monophyletic phylogenetic group within the betaproteobacteria, all of whose cultivated representatives are lithoautotrophic ammonia oxidizers. Ammonia oxidizers generally exert control over nitrification by oxidizing ammonia to nitrite, which is subsequently oxidized by bacterial nitrite oxidizers to nitrate. They therefore play major roles in control of the nitrogen cycle in terrestrial, freshwater, and marine environments and in wastewater treatment processes. They are also of significant economic and environmental importance, leading to loss of ammonium-based fertilizers, nitrous oxide production, and nitrate pollution. Ammonia oxidation is also carried out by thaumarchaea, gammaproteobacteria, and anammox organisms.

Phylogeny of the *Nitrosomonadaceae* is now based on analysis of 16S rRNA genes and *amoA* genes that encode subunit A of ammonia monooxygenase, which catalyzes the first step in ammonia oxidation. Sequences of cultivated strains and those obtained directly from environmental DNA and RNA suggest two genera, *Nitrosomonas* and *Nitrosospira*, each containing seven lineages, although support for these lineages in *Nitrosospira* is weaker. Two of these lineages are not represented by a laboratory isolate. Genomic analyses are providing insights into the evolution of the *Nitrosomonadaceae* and into metabolic processes of relevance to ecological studies.

Taxonomy, Historical and Current

Nitrification, the oxidation of ammonia to nitrite and its subsequent oxidation to nitrate, are performed by two functional groups, ammonia oxidizers and nitrite oxidizers. Their combined role in this important step in the global nitrogen cycle led to their initial grouping within the *Nitrobacteraceae* (Buchanan 1917, 1918), with subdivisions based solely on their source of energy, ammonia or nitrite. The family *Nitrobacteraceae* was substantially revised and rationalized by Watson (1971) with description of three genera of autotrophic ammonia-oxidizing bacteria (*Nitrosomonas*, *Nitrosococcus*, and *Nitrosospira*) and three genera of autotrophic nitrite-oxidizing bacteria (*Nitrobacter*, *Nitrococcus*, and *Nitrospina*) and type and neotype strains designated for each genus (*Nitrosomonas europaea* ATCC25978; *Nitrosococcus oceanus* ATCC 19707; *Nitrosospira briensis* ATCC 25961; *Nitrobacter winogradskyi* ATCC 25391; *Nitrococcus mobilis* ATCC25380; *Nitrospina gracilis* ATCC25379). The advent of 16S rRNA gene-based phylogeny (Woese et al. 1984a, b, 1985) demonstrated ammonia and nitrite-oxidizing bacteria to be phylogenetically distinct, with ammonia oxidizers falling within the betaproteobacteria and gammaproteobacteria. The latter contains only two validly named species, *Nitrosococcus nitrosus* and *Nitrosococcus oceani* (formerly *Nitrosocystis oceanus* and *Nitrosococcus oceanus*; Watson 1971). Two other species *Nitrosococcus halophilus* and *Nitrosococcus watsonii* have also been described, but these have not yet been validly named in an IJSEM validation list (Campbell et al. 2011).

E. Rosenberg et al. (eds.), *The Prokaryotes – Alphaproteobacteria and Betaproteobacteria*, DOI 10.1007/978-3-642-30197-1_372,

The majority of known bacterial ammonia oxidizers therefore belong to the Betaproteobacteria, where they form the *Nitrosomonadaceae*. The *Nitrosomonadaceae* contains two genera, *Nitrosomonas* and *Nitrosospira*, while the genus *Nitrosospira* includes organisms that were previously assigned to the genera *Nitrosospira, Nitrosolobus*, and *Nitrosovibrio* (Watson 1971; Watson et al. 1971; Harms et al. 1976; Head et al. 1993). The known genera of nitrite-oxidizing bacteria fall within a range of phylogenetic groups: *Nitrobacter* (Alphaproteobacteria), *Nitrococcus* (Gammaproteobacteria), *Nitrospira* (Nitrospirae), *Nitrospina* (Deltaproteobacteria), *Nitrolancetus* (Chloroflexi; Sorokin et al. 2012), and Candidatus "Nitrotoga" (Betaproteobacteria; Alawi et al. 2007). In addition ammonia-oxidizing archaea also exist and belong to the Thaumarchaeota (see Chap. 26, "The Phylum Thaumarchaeota", in Volume 11, *The Prokaryotes – Other Major Lineages of Bacteria and the Archaea*).

Early classification of genera and species within the *Nitrosomonadaceae* was based on a limited number of morphological and physiological characteristics: cell size and shape, presence and organization of intracellular membranes, motility, urease activity, ammonia affinity and sensitivity, and salt requirement and tolerance (Koops et al. 2006). Again, taxonomy has been revised following phylogenetic analysis of both 16S rRNA sequences and *amoA*, encoding subunit A of ammonia monooxygenase, which catalyzes the initial oxidation of ammonia to hydroxylamine. This analysis includes genes from cultivated ammonia oxidizers but also sequences obtained by amplification of nucleic acids extracted from a wide range of environments (Koops et al. 2006). This analysis generates seven well-supported lineages within the genus *Nitrosomonas* and a number of less well-supported lineages within the genus *Nitrosospira*, including the previously described genera *Nitrosolobus* and *Nitrosovibrio* (Stephen et al. 1996; Purkhold et al. 2000).

Molecular Phylogeny of Autotrophic Ammonia-Oxidizing Bacteria

The phylogenetic position of ammonia-oxidizing bacteria was initially determined on the basis of 16S rRNA cataloguing (Woese et al. 1984b, 1985; Fox and Stackebrandt 1988) and subsequently refined using near full-length, PCR-amplified 16S rRNA gene sequences (Head et al. 1993; Teske et al. 1994). Comparative analysis of genes encoding different components of ammonia monooxygenase largely confirmed and extended the relationships revealed on the basis of comparative 16S rRNA gene analysis (Purkhold et al. 2000; Aakra et al. 2001a, b; Calvó et al. 2005) as did analysis of intergenic transcribed spacer (ITS) sequences (Aakra et al. 2001a). However, the validity of the relationships inferred from ITS sequences has been questioned due to some incongruences between 16S rRNA-derived trees and ITS trees attributed to the high sequence variation of ITS and difficulties in reliable alignment of such variable sequences (Koops et al. 2006).

In broad terms these analyses have shown that cultivated ammonia-oxidizing bacteria fall within three main lineages; two distinct, but sister lineages, representing the genera *Nitrosomonas* and *Nitrosospira*, fall within the Betaproteobacteria and collectively form the *Nitrosomonadaceae*, while those from the genus *Nitrosococcus* fall within the *Chromatiaceae* in the Gammaproteobacteria.

Nitrosococcus

The genus *Nitrosococcus* does not belong in the *Nitrosomonadaceae* but for historical reasons and completeness is included here. There are two validly named species of *Nitrosococcus*: *N. nitrosus* and *N. oceani* (formerly *N. oceanus* and before that *Nitrosocystis oceanus*), but *Nitrosococcus halophilus*, a salt lake isolate, has been described and the marine isolate C-113 has been proposed as a new species, *N. watsonii* (Campbell et al. 2011). A further species *Nitrosococcus mobilis* has been described, but 16S rRNA and *amoA* sequence analysis revealed this to be a misnamed *Nitrosomonas* sp., and it has been suggested that this be renamed *Nitrosomonas mobilis* (Campbell et al. 2011).

Nitrosomonas

Stephen et al. (1996) and Kowalchuk et al. (1997) delineated three clusters within the *Nitrosomonas* lineage (clusters 5, 6, and 7; *Fig. 34.1*) by comparative analysis of 16S rRNA gene sequences from cultured lithoautotrophic ammonia-oxidizing bacteria. Increasing numbers of 16S rRNA and *amoA* sequences led to recognition of seven lineages within the genus *Nitrosomonas* (clusters 5, 6a, 6b, 7, 8, *N. cryotolerans*, and cluster 9/Nm143 lineage) with cluster 5 currently represented only by sequences recovered from environmental samples (Purkhold et al. 2000, 2003; Koops et al. 2006; *Fig. 34.1*—note that cluster 5 is not presented).

- *N. europaea*/*Nc. mobilis* lineage (cluster 7 of Kowalchuk et al. 1997)
- *N. communis* lineage including *N. nitrosa* (cluster 8)
- *N. marina* lineage including *N. aestuarii* (cluster 6b after Kowalchuk et al. 1997)
- *N. oligotropha* lineage including *N. ureae* (cluster 6a after Kowalchuk et al. 1997)
- *N. cryotolerans* lineage
- *Nitrosomonas* sp. Nm143 lineage (cluster 9)
- Cluster 5 of Stephen et al. (1996) and Kowalchuk et al. (1997)

These lineages contain nine validly named species of *Nitrosomonas*: *N. aestuarii, N. communis, N. europaea, N. eutropha, N. halophila, N. marina, N. nitrosa, N. oligotropha*, and *N. ureae* (*Fig. 34.1*). In addition several species have been described that are not validly named or are misnamed including *N. cryotolerans* and *Nitrosococcus mobilis*. The second of these is a misnamed *Nitrosomonas* sp. It has been suggested that cultivated *Nitrosomonas* spp. represent 19 genospecies on the basis of DNA-DNA similarity $\leq$60 % and/or 16S rRNA sequence identity less than 97.5 % (Koops et al. 2006).

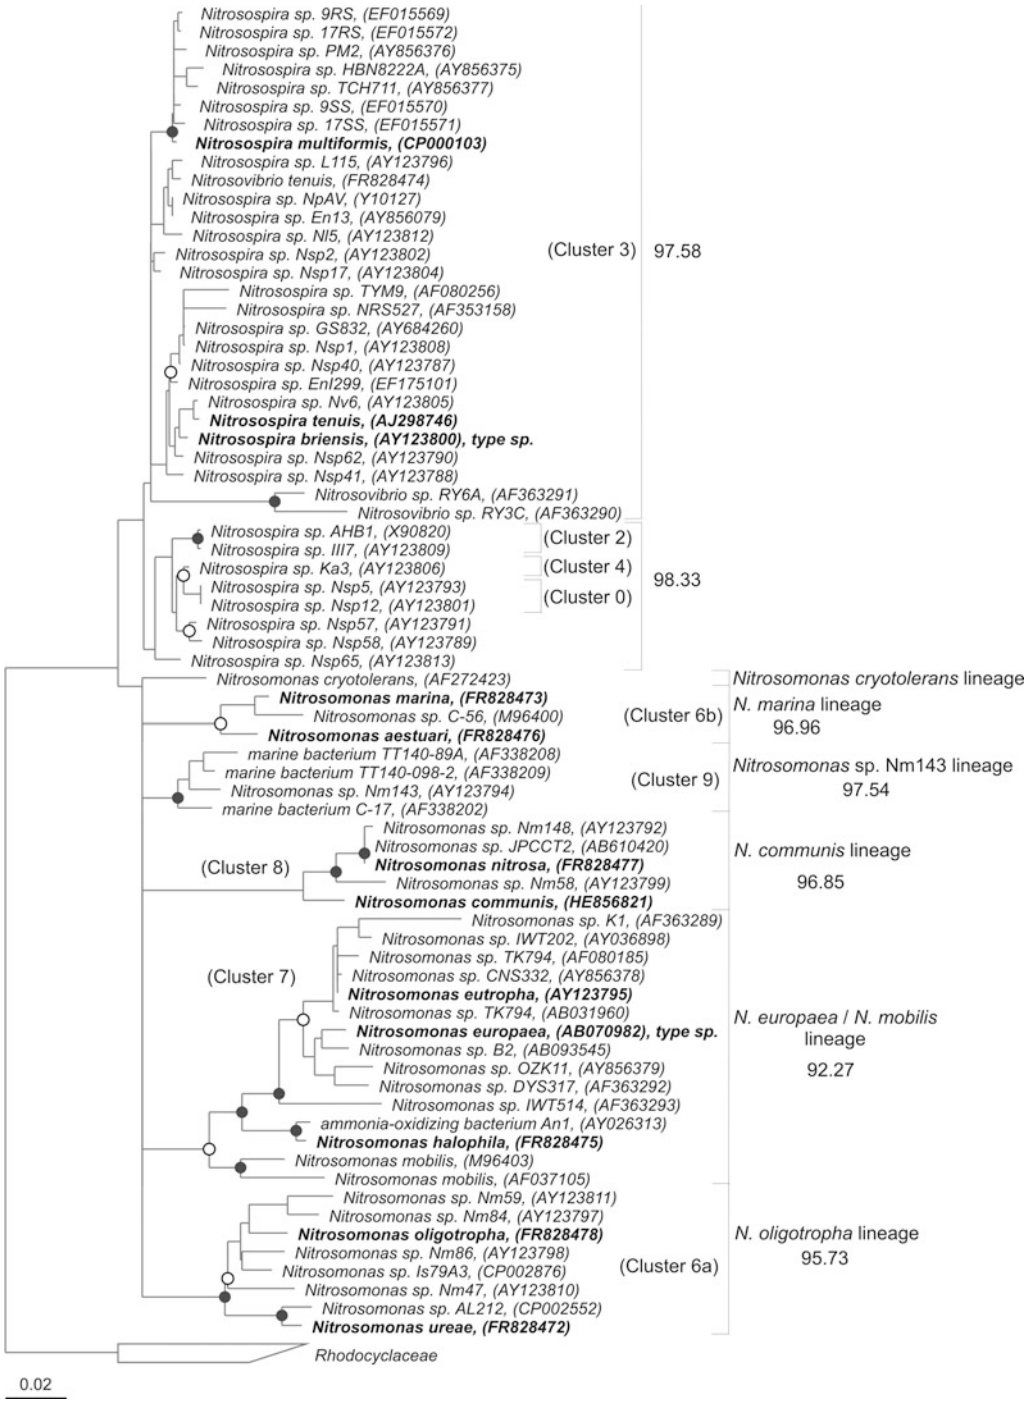

Fig. 34.1

Consensus phylogenetic tree of the family *Nitrosomonadaceae* based on the 16S rRNA gene. Final topology is based on a mix of reconstructions including maximum likelihood (RAxML, Stamatakis 2006), maximum parsimony (ARB, Ludwig 2004), and neighbor joining with the Jukes-Cantor correction. Initial trees were calculated using sequences longer than 1,300 nucleotides. Shorter sequences were added to the consensus tree using the ARB maximum parsimony tool. The sequence dataset and alignment were obtained from the All-Species Living Tree Project (LTP) database (Yarza et al. 2010; http://www.arb-silva.de/projects/living-tree) for validly published species (*bold* characters) and Silva SSU r114 database (http://www.arb-silva.de/search) for other sequences. Representative sequences from closely related taxa were used as out-groups. In addition, a bacterial homologues site filter was applied in order to remove hypervariable positions and potentially misplaced bases from the alignment. Unstable topologies are shown as multifurcations. Filled and empty round nodes indicate neighbor-joining bootstrap values (100 re-samplings) above 90 % and 70 %, respectively. Minimum 16S rRNA sequence similarity among members of each cluster is depicted. Scale bar indicates estimated sequence divergence

Nitrosospira

Stephen et al. (1996) and Kowalchuk et al. (1997) delineated four clusters (clusters 1–4) within the *Nitrosospira* lineage, and more comprehensive analysis including a wider range of sequences from both cultures and environmental samples led to the discovery of three more clusters (cluster 0, a second cluster represented by the isolate *Nitrosospira* sp. Nsp65 and a third comprising *Nitrosospira* sp. Nsp57 and Nsp58; ❯ *Fig. 34.1*). However, these clusters are not consistently recovered with different treeing methods using either 16S rRNA or *amoA* sequences to infer relationships (Koops et al. 2006). This contrasts with the clear and distinct lineages that are recovered consistently within the genus *Nitrosomonas*. Moreover, one of the clusters identified by Stephen et al. (1996; cluster 1) is represented only by sequences recovered from environmental samples, and as with *Nitrosomonas* cluster 5 is not shown on ❯ *Fig. 34.1*.

Organisms now accommodated in the genus *Nitrosospira* were previously assigned to three different genera (*Nitrosospira*, *Nitrosolobus*, and *Nitrosovibrio*), but their 16S rRNA sequences have high identity (Woese et al. 1984a; Head et al. 1993), and even the most dissimilar sequences within the lineage exhibit 96.1 % 16S rRNA sequence identity (Koops et al. 2006). This compares with minimum 16S rRNA sequence identity values for individual lineages within the genus *Nitrosomonas* that range from 92.4 % to 97.5 % (Koops et al. 2006). Moreover, the differences in phenotypic characteristics of *Nitrosospira*, *Nitrosolobus*, and *Nitrosovibrio* are minimal, and the primary distinguishing feature is their morphology, which is pleomorphic, as illustrated by the specific name of the only described *Nitrosolobus* sp., *Nitrosolobus multiformis* (Head et al. 1993). Consequently the three genera were combined with the generic epithet *Nitrosospira* having precedence (Head et al. 1993).

It was subsequently suggested that *Nitrosolobus* be reinstated as a separate genus (Teske et al. 1994; Aakra et al. 2001b), but a more comprehensive analysis has shown that different lineages within the *Nitrosospira* radiation may represent different species and the data currently available do not strongly support separation of different members of the *Nitrosospira* lineage into different genera (Koops et al. 2006). Currently there are three named *Nitrosospira* species: *N. briensis*, *N. multiformis*, and *N. tenuis* (❯ *Fig. 34.1*). However, based on DNA-DNA hybridization values of $\leq$60 % and/or 16S rRNA sequence identity $\leq$97.5 % for named *Nitrosospira* spp., cultivated *Nitrosospira* sp. may comprise 15 genospecies (Koops et al. 2006). It is clear that much is yet to be learned of the evolutionary relationships within the genus *Nitrosospira* from ongoing genome sequencing projects. The genome sequence of *Nitrosospira multiformis* ATCC 25196 is available (Norton et al. 2008), and sequencing of three further *Nitrosospira* genomes is currently underway (see section below on "❯ Genome Sequences").

Genome Sequences

At present, there are five published, closed, genome sequences of ammonia-oxidizing bacteria (AOB) within the *Nitrosomonadaceae*: *Nitrosomonas europaea* ATCC 19718 (Chain et al. 2003), *Nitrosomonas eutropha* C91^T (Stein et al. 2007), *Nitrosomonas* sp. AL212 (Suwa et al. 2011), *Nitrosomonas* sp. Is79 (Bollmann et al. 2013), and *Nitrosospira multiformis* ATCC 25196^T (Norton et al. 2008). As of this writing, known yet unpublished draft genome sequences of *Nitrosomonadaceae* isolates include *Nitrosomonas marina* C-113a, *Nitrosospira briensis* C128, *Nitrosospira tenuis* Nv1^T, *Nitrosospira* sp. B6 (cluster 2), *Nitrosomonas ureae* Nm10^T, *Nitrosomonas oligotropha* Nm45, *Nitrosomonas cryotolerans* Nm55^T, and *Nitrosomonas communis* Nm2^T. A published draft sequence of Nitrosospira sp. APG3, a cluster 0 isolate, is also available (Garcia et al. 2013). Genome sequences from four gammaproteobacterial ammonia-oxidizing bacteria have also been determined (*N. oceani* ATCC19707^T (CP000127; plasmid: CP000126), *Nitrosococcus* sp. strain C-113 (proposed as *N. watsonii*; one chromosome and two plasmids), *N. oceani* strain AFC-27(ABSG00000000.1), and *N. halophilus* strain Nc4; Campbell et al. 2011), but not all of these are closed. It is anticipated that many more isolates will be genome sequenced and publicly released within the next few years as genome sequencing costs continue to decline. Annotation and analysis of the five presently published AOB genomes reported information and statistics from the discontinued portal at the US Department of Energy Oak Ridge National Laboratories (ORNL); the information presented herein is reported from the Integrated Microbial Genomes (IMG) database, which is continuously maintained and updated by the US Department of Energy Joint Genome Institute (https://img.jgi.doe.gov/).

Each of the five closed AOB genome sequences contains a single circular chromosome and three contain plasmids of variable size (❯ *Table 34.1*). In addition, all of the genome sequences contain one complete ribosomal RNA operon and a full complement of tRNA genes. All of the *Nitrosomonadaceae* genomes encode multiple copies of the gene clusters encoding key genes of ammonia-oxidizing catabolism (❯ *Table 34.2*), a feature that is not shared by marine-dwelling gammaproteobacterial nitrosococci (Klotz et al. 2006). The presence of pseudogenes (❯ *Table 34.1*), numerous IS elements (Arp et al. 2007), large tandem repeats in the *N. europaea* ATCC 19716 genome (Chain et al. 2003), and a ca. 117 kb genomic island flanked by tRNA genes and phage-related integrase in the *N. eutropha* C91^T genome (Stein et al. 2007) indicate a high degree of recombinogenic activity among the AOB genomes. Comparison of highly conserved genes and neighborhoods in *N. europaea* ATCC 19718 and *N. eutropha* C91^T genome sequences (Stein et al. 2007) provides evidence of extensive replication and reshuffling. Prophage induction in *N. multiformis* ATCC 25196^T was stimulated by a variety of disturbances including changes in pH and exposure to chromium or cyanide (Choi et al. 2010).

Table 34.1

Properties of closed genome sequences of ammonia-oxidizing bacteria in the family *Nitrosomonadaceae* (Data were derived from the Integrated Microbial Genomes and Metagenomes annotation portal of the US Department of Energy Joint Genome Institute at: https://img.jgi.doe.gov/)

Numbers following gene inventory indicate the number of gene or operon copies present within the particular genome sequence. Inventory implicated in producing a functional enzyme or enzyme complex for ammonia monooxygenase, hydroxylamine oxidoreductase with electron transport partners, nitrite reductase, and cytochrome *c* nitric oxide reductase are listed as well as uncharacterized inventory encoded within the same operon. Because all of the strains encode a complete Calvin cycle for carbon fixation, only the type of RuBisCO is indicated. Details of these enzyme complexes and encoding gene inventory can be found in Sayavedra-Soto and Arp (2011) and references therein

Correlation coefficients from genome inventories based on four different gene-calling models (COG, Pfam, KEGG Orthology, and TIGRfam) show variable relationships between the genome sequences (*Table 34.3*). The most closely related genomes, as determined by the average correlation coefficient across the four models, are *Nitrosomonas* sp. AL212 and *Nitrosomonas* sp. Is79. Both of these are oligotrophic strains isolated from environments with low ammonium concentration, even though *Nitrosomonas* sp. AL212 was isolated from activated sludge and *Nitrosomonas* sp. Is79 was isolated from a freshwater lake. The most distantly related strains are *N. europaea* ATCC 19718, which is adapted to relatively high ammonium concentration and salinity, and *Nitrosomonas* sp. Is79. The moderate degree of similarity between the genome of *Nitrosospira multiformis* ATCC 25916^T, a soil isolate, to all of the *Nitrosomonas* strains is perhaps to be expected given that it falls within a different genus. Additional genome sequences of *Nitrosospira* isolates will allow for a much clearer evolutionary comparison between the two *Nitrosomonadaceae* genera. All five *Nitrosomonadaceae* genome sequences maintain multiple copies of operons encoding the central components of the ammonia oxidation pathway (*Table 34.2*): ammonia monooxygenase (AMO), hydroxylamine oxidoreductase (HAO), and the two cytochromes (c_{554} an c_{M552}) that relay electrons from hydroxylamine oxidation to the quinone pool for production of a proton motive force and continued oxidation of ammonia by the reductant-requiring AMO (Sayavedra-Soto and Arp 2011). The *haoAB*, *cycA*, and *cycB* genes encoding HAO and cytochrome c_{554} and c_{M552} form the hydroxylamine redox module (HURM) that enables lithotrophic growth of bacteria on ammonium (Klotz and Stein 2008). The numbers and component genes of *amo* operons are variable among the genomes and, except for *Nitrosomonas* sp. Is79, encode the copper resistance genes (*copCD*) immediately following the *amoCABED* operons (Arp et al. 2007). All five of the *Nitrosomonadaceae* genomes encode three copies of the HURM operon, although both *N. europaea* ATCC 19718 and *N. eutropha* C91^T lack the *cycB* gene in one of these operon copies (*Table 34.2*). One copy of the operons encoding AMO and HURM is near each other in the genomes of *N. europaea* ATCC 19718 and *N. eutropha* C91^T, while the *amoCAB* operon in the *N. multiformis* ATCC 25196^T genome forms a contiguous supercluster with one of the *haoAB-cycAB* operons (Arp et al. 2007).

The *N. multiformis* ATCC 25196^T genome encodes all of the inventory for functional urease and hydrogenase (Norton et al. 2008). Urease genes and function have been detected in a number of other *Nitrosomonadaceae* and *Nitrosococcus* (gammaproteobacterial ammonia oxidizer) isolates (Koper et al. 2004), including *Nitrosomonas* sp. AL212 (Suwa et al. 2011). Although *Nitrosomonas* sp. Is79 encodes the biotin-containing urea carboxylase and putative allophanate hydrolase, its growth on urea has not been detected (Bollmann et al. 2013).

Table 34.3

Pearson correlation coefficients below the yellow boxes are based on COG (top left), Pfam (top right), KEGG Orthology (bottom left), and TIGRfam (bottom right) categorizations of genome inventories from IMG annotation. Average correlation coefficients and standard deviations of the four models are presented above the yellow boxes. Higher values indicate closer relationships than lower values

	Nitrosomonas europaea ATCC 19718	*Nitrosomonas eutropha C91*	*Nitrosomonas* sp. AL212	*Nitrosomonas* sp. Is79	*Nitrosospira multiformis* ATCC 25916

In addition, all of the genes present in the genome of *N. multiformis* ATCC 25196^T, except for an ORF encoding a hypothetical protein for the NiFe hydrogenase, are also encoded in the *Nitrosomonas* sp. Is79 genome. However, the genes are not clustered together as in *N. multiformis* ATCC 25196^T, but are scattered throughout the genome (Bollmann et al. 2013). Neither hydrogenase activity nor its expression has yet been reported for any AOB isolate.

Sections of the nitrifier denitrification and nitrosative stress tolerance inventory, including copper-containing nitrite reductase (*nirK* with or without associated genes), cytochrome *c*- dependent nitric oxide reductase (*norCBQD* and *norSY-senC-orf1*), cytochrome P460 (*cytL*), and cytochrome c′-beta (*cytS*), are present in all *Nitrosomonadaceae* genomes, although some genes are apparently missing or have not yet been identified in the oligotrophic strains (*Table 34.2*). Both *Nitrosomonas* sp. AL212 and *Nitrosomonas* sp. Is79 lack the sNOR nitric oxide reductase *norSY-senC-orf* 1, and *Nitrosomonas* sp. Is79 also lacks the cNOR nitric oxide reductase (*norCBQD*). *Nitrosomonas* sp. Is79 is the first AOB examined that lacks both the *norCBQD* operon and the *ncyA* gene encoding the red copper protein, nitrosocyanin. Until now, nitrosocyanin was considered the only unique hallmark of the obligate chemolithotrophic AOB lifestyle and was hypothesized to be essential to ammonia lithotrophy (Arp et al. 2007). The physiological consequence of missing both cNOR and nitrosocyanin functions will be an important topic of research to define the core requirements for obligate ammonia chemolithotrophy and the correspondence of these genes and their translated products to the production of nitrogen oxide intermediates (Klotz and Stein 2008). All of the genomes encode the copper-containing nitrite reductase, *nirK*, which has been implicated in assisting hydroxylamine oxidation by *N. europaea* (Cantera and Stein 2007b) and in the nitrifier denitrification pathway for reduction of nitrite to nitric oxide (Stein 2011). Acquisition of *nirK* and *norCBQD* into AOB genomes was via lateral gene transfer from several origins (Cantera and Stein 2007a; Garbeva et al. 2007).

All the AOB examined to date use the Calvin cycle for fixation of carbon dioxide. Three of the five genomes encode a single variety of Type I RuBisCO, whereas *Nitrosomonas* sp. AL212 and *Nitrosomonas* sp. Is79 genomes encode both the "green" and "red" types, perhaps to retain flexibility in oligotrophic environments (*Table 34.2*). Only the *N. eutropha* C91^T genome encodes the full suite of genes for carboxysome biosynthesis, although carboxysomes have been observed microscopically in many other AOB strains whose genomes have yet to be sequenced (Koops et al. 1991).

Iron is an essential nutrient for AOB as they rely on several cytochromes and the iron-rich HAO enzyme for ammonia chemolithotrophy. The genomes of *N. multiformis* ATCC 25196^T, *N. eutropha* C91^T, and *N. europaea* ATCC 19718 have 29, 28, and 90 genes, respectively, with putative involvement in iron uptake. Only the genome of *N. europaea* ATCC 19718 has a remarkable diversity of putative iron siderophore uptake genes along with the absence of siderophore biosynthetic genes (Chain et al. 2003). The genome of *Nitrosomonas* sp. Is79 also encodes a low-affinity iron permease that may function under iron-replete conditions (Bollmann et al. 2013).

Other interesting, less central features of the five published genome sequences, including cell envelope, central carbon, biosynthetic, ion transport, and terminal oxidase inventories, can be found in the relevant reports for each genome sequence. In addition, several review articles comparing inventory and evolution of AOB and related genome sequences were published prior to publication of the two oligotrophic *Nitrosomonas* spp. genome sequences (Arp et al. 2007; Klotz and Stein 2008, 2011).

Phenotypic Analysis

By far the greatest knowledge of AOB and the process of chemolithotrophic ammonia oxidation derives from studies of the single model organism, *Nitrosomonas europaea* ATCC 19718. Several review articles have described in detail the enzymes and electron transport processes of ammonia oxidation based on studies of this strain (Whittaker et al. 2000; Arp and Stein 2003; Sayavedra-Soto and Arp 2011). Studies of other AOB isolates have revealed universally shared properties with *N. europaea* ATCC 19718, such as the apparent requirement for ammonia as the energy-deriving substrate. Other properties of AOB are not obligate, such as autotrophy and the requirement of O_2 by ammonia monooxygenase. Much focus has been placed on phenotypes that allow particular AOB phylotypes to occupy and sometimes dominate a niche, including ammonium and oxygen concentrations and tolerance to toxins. There has been extensive study of NO_x production by both the ammonia oxidation and nitrifier denitrification pathways among AOB phylotypes. The following descriptions focus on broad distinguishing phenotypic characteristics that inform niche preference of the seven phylogenetic lineages that contain cultivated members within the *Nitrosomonadaceae*.

Nitrosomonas europaea/Nitrosomonas (Nitrosococcus) mobilis Lineage

Members of this lineage include isolates with adaptation to relatively high concentrations of ammonium (tolerance to 400–600 mM; K_s for ammonia 30–61 μM) and salinity (maximum salt tolerance 400–900 mM NaCl). This lineage includes the cultured species *N. europaea*, *N. eutropha*, *N. halophila*, and *Nitrosomonas (Nitrosococcus) mobilis*. Molecular surveys have confirmed dominance of this lineage among AOB phylotypes in environments marked by high ammonium concentration, such as wastewater treatment plants and heavily fertilized soils (Koops and Pommerening-Röser 2001). *N. europaea* ATCC 19718 has been studied extensively as a model system to define the substrate range of ammonia monooxygenase for potential use of AOB in bioremediation strategies (Arp and Stein 2003). Members of this lineage also tend to be fairly tolerant to toxins including solvents and a variety of metals, yet their immediate stress responses have allowed process engineers to identify molecular markers indicative of early inhibition of ammonia oxidation (Radniecki and Lauchnor 2011).

Studies on the regulation of ammonia oxidation in *N. europaea* ATCC 19718 have shown that NH_3, the substrate of AMO, is a transcriptional activator of *amoA* and also enhances activity in whole cells by increasing expression of the AMO holoenzyme (Hyman and Arp 1995; Stein et al. 1997). In addition, nitrite is a specific inactivator of AMO activity in the absence of its substrates (Stein and Arp 1998), although nitrite can also enhance the recovery of *N. europaea* following starvation from ammonium (Laanbroek et al. 2002). Studies of anaerobic ammonia oxidation in both *N. europaea* ATCC 19718 (Schmidt et al. 2004) and *N. eutropha* N904 (Schmidt et al. 2001) revealed the use of NO_2 as an alternate oxidant for AMO while using nitrite as an electron acceptor. However, growth in continuous culture over several months showed that, while the presence of NO_2 can prevent loss of *N. eutropha* C91^T biomass, it does not allow sustainable anaerobic ammonia oxidation or cell growth (Kartal et al. 2012).

Nitrous oxide (N_2O)-producing pathways have been extensively characterized in *N. europaea* ATCC 19718 (Stein 2011). Two pathways produce N_2O: the oxidation of hydroxylamine produced during active ammonia oxidation and the reduction of nitrite and nitric oxide during nitrifier denitrification. The latter pathway is stimulated under low O_2 tension, while the former is more easily measured under high O_2 tension, but both processes can occur simultaneously. N_2O formed during ammonia oxidation is greatest under conditions of high ammonium and high oxygen, such as in certain wastewater treatment plants (Law et al. 2012) or during immediate recovery from anoxia (Yu and Chandran 2010). Nitrifier denitrification in *N. europaea* is positively regulated by nitrite. At high nitrite concentration, the NsrR transcriptional repressor releases the promoter of the nitrite reductase operon (*ncgABC-nirK*) and allows its expression (Beaumont et al. 2004). Mutagenized strains of *N. europaea* ATCC 19718 that do not express NirK show high levels of N_2O production from hydroxylamine under high oxygen, but low levels of N_2O production under hypoxia (Cantera and Stein 2007b). These results suggest that for *N. europaea* ATCC 19718, nitrite reduction by NirK under fully aerobic conditions is important to foster the complete conversion of hydroxylamine to nitrite. Under low oxygen, nitrifier denitrification may be important for siphoning electrons from the cytochrome pool

as re-oxidation by the terminal oxidase slows down and has the potential to create an electron flow bottleneck (Stein 2011). Under anoxic conditions, both NirK and the cytochrome *c* nitric oxide reductase, NorB, were necessary for the anaerobic oxidation of ammonium using NO_2 as an oxidant and nitrite as a terminal electron acceptor as described above (Schmidt et al. 2004).

N. europaea ATCC 19718 can use fructose or pyruvate as sole carbon sources, allowing it to grow chemolithoheterotrophically (Hommes et al. 2003). Under such growth conditions, ammonium was still required to support energy generation. Other members of this lineage have not been investigated for their ability to assimilate organic molecules. However, evidence from combined autoradiography and fluorescent in situ hybridization of ammonia-oxidizing bacterial populations in a wastewater treatment plant (Daims et al. 2001a) suggests that this ability may not be uncommon.

Nitrosomonas communis Lineage

Two named species are found in this lineage, *N. communis* (Nm2^T) and *N. nitrosa* (Nm90^T), and three further genospecies, represented by four isolates (*Nitrosomonas* sp. Nm33, Nm41 and Nm58, Nm148), are available in culture (Koops et al. 2006). Like the *N. europaea/Nc. mobilis* lineage, *N. communis* and *N. nitrosa* are adapted to relatively high ammonium concentration (up to 250 mM; K_s for ammonia 30–61 μM) and with the exception of *N. nitrosa* lack urease activity. It is rare to find sequences representative of this lineage in molecular diversity studies, perhaps due to poor recognition and hybridization to available primer sequences (Koops et al. 2006). The isolate *N. communis* YSNRA has significantly higher activity for HAO and lower activity for RuBisCO than *N. europaea* ATCC 25978^T or other AOB strains (Tokuyama et al. 2004), indicating physiological variation among species.

Nitrosomonas marina Lineage

Cultivated members of this lineage are all from marine environments, although related sequences have been detected in nonmarine ecosystems (Koops et al. 2006). They have a salt requirement, are urease positive, and are adapted to high concentrations of ammonium, 200–400 mM (Koops et al. 1991). This lineage is represented by two described species, *N. marina* (Nm22^T) and *N. aestuarii* (Nm36^T), and one undescribed genospecies (represented by isolatesNm51 and Nm63). *N. marina* C-113a produces nitrous oxide from both the ammonia oxidation and nitrifier denitrification pathways depending on cell density, nitrite concentration, and oxygen tension (Frame and Casciotti 2010). Members of this lineage may be important contributors of nitrous oxide to the atmosphere from marine ecosystems.

Nitrosomonas oligotropha Lineage

This lineage comprises two named species *N. oligotropha* (Nm45^T) and *N. ureae* (Nm10^T). A further four genospecies are represented in culture by seven isolates (Nm47, Nm59, Nm84, Nm86, AL212, Is79, and JL21), and culture-independent studies indicate that more species exist within this radiation (Speksnijder et al. 1998). Most isolates tested are urease positive. Molecular surveys indicate broad distribution of this phylotype from freshwater rivers and lakes to wastewater treatments plants to soils (Koops et al. 2006). *Nitrosomonas oligotropha* Nm45^T and *Nitrosomonas ureae* Nm10^T are the type strains of the two named species from this lineage, and their genomes are currently being sequenced. Several strains representing different species exist in current culture collections and two have published genome sequences (AL212 and Is79; see above). Strains in this lineage are adapted to moderate (*N. ureae*) to very low concentrations of ammonium (maximum tolerance 50–200 mM, but some grow in medium containing 1–5 mM ammonium) with the highest affinity to ammonium (K_s for ammonia 1.9–4.2 μM) of all AOB yet measured (Koops et al. 1991). The type strains of the two named species (Nm10^T and Nm45^T) and *Nitrosomonas* sp. AL212 are urease positive, but *Nitrosomonas* sp. Is79 is urease negative (Bollmann et al. 2013). It is surprising to find an oligotrophic AOB strain that lacks urease activity, as ammonium concentration is generally low in environments dominated by these strains. Along with adaptation to low ammonium, members of this phylotype tend to exist in biofilms and have been noted to produce ample amounts of EPS (Stehr et al. 1995).

Nitrosomonas cryotolerans Lineage

Only one isolate of this lineage, *N. cryotolerans* ATCC 49181^T (=Nm55^T) is in current culture collections. It is the only strain in the *Nitrosomonadaceae* that grows near 0 °C, although it is not a psychrophile (Jones et al. 1988). The lowest temperature for growth by other members of this family is around 5 °C (Koops et al. 1991). *N. cryotolerans* ATCC 49181^T was isolated from a marine environment; hence it has a requirement for salt. It is also urease positive and is adapted to relatively high ammonium concentrations (up to 400 mM; K_s for ammonia 42–59 μM). Nitrous oxide production by *N. cryotolerans* ATCC 49181^T is optimal during active ammonia oxidation at high cell density, high nitrite concentration, and low oxygen tension (Miteva et al. 2007) and continues in frozen cultures at temperatures as low as −32 °C.

Nitrosomonas sp. Nm143 Lineage

There is no named type species for this lineage but four representatives are available in culture (*Nitrosomonas* sp. Nm143, C-17, TT140-89A, TT140-098-2). Members of this lineage are associated with marine and estuarine environments and as such

are considered highly salt tolerant. Sequences related to *Nitrosomonas* sp. Nm143 and *Nitrosomonas cryotolerans* dominated active estuarine AOB, as assessed by stable isotope probing (Bernhard and Bollmann 2010). There have been no physiological studies on members of this lineage as the original isolates were lost from culture collections. Recently, further members of this lineage have been isolated and await further characterization.

Uncultured *Nitrosomonas* spp.

One lineage within the *Nitrosomonas* radiation is comprised solely of sequences recovered in culture-independent analyses. These have been termed environmental lineage or cluster 5, and members of this group have been detected in freshwater and marine systems and in coastal sand dunes (Koops et al. 2006).

Nitrosospira

Members of this lineage are considered to be the most dominant of the AOB in terrestrial environments based on frequency and abundance of their molecular markers in ecological surveys. Gene sequences related to *Nitrosospira* have been identified in other ecosystems including marine, wastewater, freshwater, and sand dunes (Koops et al. 2006). Interestingly, although *Nitrosospira* has been inferred to be prevalent in many marine systems (McCaig et al. 1994; Stephen et al. 1996; Phillips et al. 1999; Bano and Hollibaugh 2000; Horz et al. 2000; Hollibaugh et al. 2002; Nicolaisen and Ramsing 2002), no marine *Nitrosospira* isolates have yet been obtained. The *Nitrosospira* lineage was formed from the merging of three genera (*Nitrosospira*, *Nitrosolobus*, and *Nitrosovibrio*) and is more diverse phenotypically than the other lineages of the *Nitrosomonadaceae*, though they do not seem to form groups that are both phylogenetically and phenotypically consistent (Koops et al. 2006). *Nitrosospira* spp. are adapted to a wide range of ammonium concentrations (maximum tolerance 50–200 mM) and have a range of cellular morphologies, and only some are urease positive (Koops et al. 2006). Cultivated members from phylogenetic clusters 0, 2, 3, and 4 are maintained in current collections. *N. multiformis* ATCC 25196^T, currently the only member of this lineage with a published genome sequence, is from cluster 3. Although not yet publicly available, genome sequences of a cluster 2 isolate is undergoing completion, and a draft sequence from a cluster 0 isolate is publicly available (Garcia et al. 2013). Cultured isolates may be delineated into 15 genospecies, and interestingly it has been suggested, on the basis of DNA-DNA hybridization data, that *Nitrosospira* clusters 0, 2, and 4 might each represent single species (Koops et al. 2006) with cluster 3 being substantially more diverse. In addition to these main clusters, a fifth cluster (cluster 1) defined only from environmental sequences exists, as do two further lineages defined by isolates Nsp65, and Nsp58 and Nsp57 (Koops et al. 2006).

Nitrous oxide production in several *Nitrosospira* species results from both the ammonia oxidation and nitrifier denitrification pathways (Shaw et al. 2006; Sutka et al. 2006). However, for some *Nitrosospira* species, production of nitrous oxide is favored more during ammonia oxidation than under the low oxygen conditions that favor nitrifier denitrification (Dundee and Hopkins 2001). Expression of the *nirK* gene in *N. multiformis* ATCC 25196^T was constitutive and not influenced by the presence of nitrite as in *N. europaea* ATCC 19718 (Cua and Stein 2008). However, expression of *amoA* decreased in *N. multiformis* ATCC 25196^T in response to nitrite, indicating a different response to that of *N. europaea* ATCC 19718 or *N. eutropha* C91^T to the terminal product of ammonia oxidation.

Isolation, Enrichment, and Maintenance Procedures

Enrichment of members of the *Nitrosomonadaceae* from environments in which they have relatively high abundance is not difficult and is routinely achieved in selective inorganic media, which are also used for isolation of pure cultures. Media vary in composition (Koops et al. 2006), but all contain ammonium chloride or sulfate, mineral salts, and buffers of different strengths. Buffering is required because ammonia oxidation to nitrite produces acid equivalents. All cultivated AOB grow optimally at neutral or moderately alkaline pH and the majority cannot grow below pH 7, with the minimum for growth of 6.5 in liquid batch culture.

Isolation of pure cultures is difficult for two reasons. First, maximum specific growth rates of autotrophic ammonia oxidizers are low and much lower than many of the heterotrophs present in environmental samples that can grow on organic contaminants in solid media, glassware, volatile compounds entering liquid medium, and by-products of ammonia oxidizer growth. The second problem is low growth yield on ammonia and inhibition from acidity and nitrite. This prevents growth of readily visible colonies on solid medium, even when supplied with relatively high ammonium concentration, and reduces dominance over heterotrophs in liquid enrichment cultures. As a consequence, re-streaking of isolated colonies and inoculation of liquid media, as used to isolate typical heterotrophs, is difficult and continued subculture in liquid medium does not eliminate heterotrophs.

Despite these difficulties, pure cultures have been obtained using both approaches and many early attempts at purification involved isolation of colonies on solid medium (Kingma-Boltjes 1935; Meiklejohn 1950). Colonies were detected by binocular microscopy and were removed using micromanipulators and Pasteur pipettes, breaking the pipette tip into liquid medium. This is often necessary because colonies can be difficult to collect and disperse because of extensive EPS production. Colony detection can be increased by inclusion of neutral red, which stains acid-producing ammonia oxidizer colonies red (Macdonald and Spokes 1980), and heterotrophic growth can be reduced

by inclusion of antibiotics. Contamination of media with organic carbon can be reduced by use of gelatin, silica gel, or purified agar (Gould and Lees 1960; Soriano and Walker 1968). More recently, single colonies of variant *Nitrosomonas europaea* ATCC 19718 and *Nitrosospira multiformis* ATCC 25196^T were grown on nitrocellulose filters overlaying solidified mineral medium in order to cultivate cell lines containing introduced mutations (Sayavedra-Soto and Stein 2011).

Pure cultures are more frequently obtained by dilution of heterotrophs to extinction in liquid culture (e.g., Gibbs 1920; Lewis and Pramer 1958; Watson et al. 1971). This is possible if ammonia oxidizers are more abundant than heterotrophs and involves successive dilution to a level that eliminates heterotrophs but not ammonia oxidizers, followed by inoculation into many tubes of liquid medium. The approach was used to isolate the first ammonia oxidizer (Frankland and Frankland 1890), probably a *Nitrosomonas* sp. (Macdonald 1986). Contamination of liquid medium with organic carbon can be reduced by oven-heating of glassware and growth in sealed vessels, to reduce contamination with volatile compounds, although this requires sufficient headspace to avoid oxygen limitation (Aakra et al. 1999).

These methods are tedious and technically challenging but, like all cultivation-based methods, are selective and may not yield organisms that are representative of dominant or active organisms in the environment under study (Smith et al. 2001), which may be important for ecological studies. Traditionally this was addressed by inoculation of liquid medium from higher dilutions of probable number (MPN) tubes exhibiting growth (Belser and Schmidt 1978). This increases the diversity of cultures, including faster growing organisms dominating lower dilutions and those with high relative abundance, which are found in the higher dilutions (Watson et al. 1981). Enrichment and isolation are now accompanied by molecular analysis of source environments, to identify target phylotypes, and enrichment cultures, to identify cultures in which they are growing. This approach is, however, limited by current knowledge and will not detect organisms outside the range of current primer sets.

Growth conditions have also been modified to reflect source environments, e.g., through modification of salt concentration, pH, and incubation temperature. Traditional selective media contain ammonium at concentrations much greater than those in most natural environments. Reduction in initial ammonium concentration and continuous and semicontinuous culture have therefore been used to select strains that prefer low ammonia concentration, and continuous culture methods also increase selection of slower growing organisms (MacFarlane and Herbert 1984; Watson 1971; Bollmann and Laanbroek 2001; Bollmann et al. 2011). Ammonia oxidizers in many environments will be attached to particulate material, and biofilm growth is known to influence their ecophysiological characteristics (Armstrong and Prosser 1988; Powell and Prosser 1992; Allison and Prosser 1993). In fact, early ammonia oxidizer enrichment media contained insoluble carbonate, to which cells attached, and dispersed growth of cell suspensions was not considered possible. Enrichment and isolation in systems enabling growth on surfaces or as aggregates may increase the probability of enriching organisms of environmental relevance and increase the diversity of cultivated strains.

Although AOB were traditionally considered to be strict autotrophs, they are now known to contain organisms with the potential for mixotrophic and heterotrophic growth. Current enrichment methods, however, are designed to select for chemolithoautotrophs. Inclusion of organic carbon in media may increase selection for mixotrophic ammonia oxidizers, but will also increase growth of highly competitive heterotrophic non-ammonia oxidizers, and new approaches may therefore be required.

Ammonia oxidizers can be maintained by continued subculture, although this increases the probability of selection of strains that are specifically adapted to the cultivation conditions, potentially reducing their value for ecological studies. A further, practical disadvantage of this approach is the risk of contamination by heterotrophs and difficulty in subsequent re-isolation. Ammonia oxidizers may also be maintained at −80 °C in glycerol or by freeze-drying. The success of these methods varies between strains and resuscitation often requires 1–2 months. When successful, however, these approaches are more practical and avoid problems of strain selection. More recently, techniques have been developed for long-term freezer storage and resuscitation of AOB that, if adopted, may be extremely useful for safeguarding collections (Heylen et al. 2012).

Ecology

Soil

Both nitrosomonads and nitrosospiras have been isolated from soil and were considered to be the major contributors to soil ammonia oxidation before the discovery of abundant thaumarchaeal *amoA* genes in soil (Leininger et al. 2006). Reports of ratios of thaumarchaeal:bacterial *amoA* abundance >1 suggested greater contributions of thaumarchaea to soil nitrification in many soils. The limitations in relating functional gene (*amoA*) abundance to activity are discussed in Prosser and Nicol (2008, 2012), and the lower specific cell activity of cultivated thaumarchaea and other factors suggest reassessment of their relative contributions (Prosser and Nicol 2012). Other, more direct assessments of growth and activity (e.g., stable isotope probing, microcosm studies) provide evidence for dominance of thaumarchaea (Offre et al. 2009; Zhang et al. 2010) and bacterial ammonia oxidizers (Jia and Conrad 2009) in different soils, although the mechanisms determining their different contributions are currently not clear.

The apparent greater ease of isolation from soil of nitrosomonads, including *N. europaea*, suggested dominance over nitrosospiras in soil bacterial ammonia oxidizer communities. The first molecular analysis of soil demonstrated considerable diversity within both nitrosomonads and nitrosospiras and suggested dominance by the latter (Stephen et al. 1996). Subsequent studies, analyzing both 16S rRNA and *amoA* gene

sequences amplified from soil, provide further evidence for this (Norton 2011; Prosser 2011). A putative ammonia oxidizer group, *Nitrosomonas* cluster 5, has not yet been cultivated, and there is no reported evidence of gammaproteobacterial ammonia oxidizers in soil.

Nitrosomonadaceae can be detected using molecular techniques in virtually all soils, the exception being some acid soils (pH < 5.5), where current evidence suggests that thaumarchaea drive nitrification (Gubry-Rangin et al. 2011; Lehtovirta et al. 2011). Although some physiological characteristics of cultivated strains appear to be representative of particular lineages (see above) (Koops and Pommerening-Röser 2001), these relationships are based on relatively few strains and focus on nitrosomonads rather than nitrosospiras, which have been studied less. Physiological characteristics have also been implied from links between relative abundance of phylotypes and environmental characteristics or, more reliably, from experimental studies demonstrating differential growth of different phylotypes under different conditions (Webster et al. 2005). Generally, however, it is difficult to discern patterns between phylogeny and soil environmental characteristics (Norton 2011). The biogeography of soil ammonia oxidizers has been reviewed by Norton (2011), who presents evidence for spatial structure in nitrosospiras at fine-scale resolution of 16S rRNA gene sequences, and Prosser (2011), who considers the influence of soil characteristics and land management regimes on AOB community structure.

Marine

Nitrosomonas spp., *Nitrosospira* spp., and *Nitrosococcus* spp. have all been detected in marine environments, but only *Nitrosomonas* and *Nitrosococcus* spp. have been isolated in culture from marine systems (Koops et al. 2006). *Nitrosomonas* spp. from the *N. europaea*/*N. mobilis* lineage, *N. marina* lineage, and the *Nitrosomonas* sp. Nm143 lineage have all been detected and isolated from marine systems (Freitag et al. 2006). In addition the uncultured "cluster 5" *Nitrosomonas* spp. has been detected predominantly in marine systems. Members of the *N. marina* and *Nitrosomonas* sp. Nm143 lineages, however, seem to be the most prevalent of these (Koops et al. 2006). Members of the *N. oligotropha* and *N. communis* lineages do not appear to be major components of marine ammonia oxidizer communities.

It has been reported that *Nitrosomonas* spp. are primarily associated with marine particulates with higher ammonia concentration, while *Nitrosospira* spp. are apparently more prevalent in free-living planktonic state where ammonia concentration is likely to be lower (Phillips et al. 1999). Other studies suggest that salinity is the primary driver of AOB community composition (Freitag et al. 2006; Francis et al. 2003; Bollman and Laanbroek 2002; de Bie et al. 2001) with ammonium concentration being the second most significant factor (Francis et al. 2003; Ward et al. 2007) and oxygen levels also influencing AOB community composition (Ward et al. 2007; de Bie et al. 2001). Some studies have also demonstrated a shift in AOB communities in estuaries from terrestrial/freshwater communities dominated by *Nitrosomonas* spp. to marine communities dominated by *Nitrosospira* spp. (Freitag et al. 2006).

Although exclusively isolated from saline environments (marine waters and hypersaline lakes), detection of gammaproteobacterial AOB (*Nitrosococcus* spp.) in marine (or any other setting) using PCR-based approaches has rarely been successful (Nold et al. 2000; Ward and O'Mullan 2002). Despite their physiological adaptation to saline environments and detection using fluorescent antibody techniques (Ward 1982), it appears that they are not abundant or widespread in seawater (Ward et al. 2007).

Nitrosospira are the most frequently detected AOB in marine systems interrogated using betaproteobacterial AOB-specific 16S rRNA gene PCR or *amoA* PCR. Indeed these seem to be predominantly associated with cluster 1 *Nitrosospira*, which is currently known only from culture-independent AOB community inventories. The frequent detection of *Nitrosospira* spp. in marine environments and less frequently in marine nitrifying enrichments is in some ways paradoxical because none of the *Nitrosospira* spp. available in pure culture has an obligate salt requirement and their maximum salt tolerance is 100–250 mM NaCl (Koops et al. 2006), compared to typical seawater salt concentrations of approximately 600 mM.

Even though many studies based on PCR amplification of 16S rRNA or *amoA* genes and array-based analyses show *Nitrosospira* to be prevalent in marine environments (Phillips et al. 1999; Hollibaugh et al. 2002; O'Mullan and Ward 2005; Freitag et al. 2006; Ward et al. 2007), there is still no true consensus on the role of uncultured *Nitrosospira* in marine systems (Koops et al. 2006). In the absence of any cultured members of *Nitrosospira* cluster 1, evidence for their activity in the marine environment has come from stable isotope probing using ^{13}C-labelled bicarbonate (Freitag et al. 2006). Interestingly, in SIP experiments only DNA from AOB related to *Nitrosomonas* sp. Nm143 and *Nitrosomonas cryotolerans* and the nitrite oxidizer *Nitrospira marina* was labelled, and no *Nitrosospira* cluster 1 sequence was recovered, even when it was shown to be dominant in standard analysis of the same samples. The role of organisms from marine *Nitrosospira* cluster 1 therefore remains unclear, and conflicting data may result from the incubation conditions used for SIP analysis (high ammonia and high temperature), or *Nitrosospira* cluster 1 may be lithoheterotrophic ammonia oxidizers or indeed may not be ammonia oxidizers at all. The second of these possibilities is perhaps less likely given that *amoA* sequences from uncultured *Nitrosospira* have high sequence identity with genuine ammonia monooxygenase genes.

In addition to ammonia-oxidizing bacteria, members of the Thaumarchaeota have also been implicated in ammonia oxidation in marine environments (Francis et al. 2005; Könneke et al. 2005) and may even be the major ammonia oxidizers in some situations (Wuchter et al. 2006) with ammonia-oxidizing Thaumarchaeota predominating in oxygen minimum zones and in higher salinity reaches of estuaries. There was also a strong quantitative relationship between archaeal and bacterial ammonia oxidizer relative abundance with archaea

predominating at lower ammonia concentration (Bouskill et al. 2012). Anaerobic ammonia-oxidizing planctomycetes (anammox bacteria; see Chap. ?) may also be important players in the transformation of ammonia and nitrite in oxygen minimum zones and some anoxic sediments (Kuenen 2008).

Freshwater

Based on culture-independent analyses, members of the *Nitrosomonas oligotropha* lineage are typically dominant AOB in freshwater systems (Whitby et al. 2001; Speksnijder et al. 1998; Bollmann and Laanbroek 2001; Chen et al. 2009). This is supported by frequent isolation of organisms from this lineage from the highest positive dilutions of MPN cultures (Koops and Harms 1985; Stehr et al. 1995; Koops and Pommerening-Röser 2001) and in enrichment cultures (French et al. 2012). This group is also found in the upper (freshwater) reaches of estuaries (Freitag et al. 2006; de Bie et al. 2001). In addition, 16S rRNA sequences of *Nitrosospira* clusters 0, 2, 3, and 4 have been identified in freshwater habitats (Speksnijder et al. 1998; Whitby et al. 2001) and in a freshwater aquarium (Burrell et al. 2001). *N. europaea*, *N. eutropha*, and *N. nitrosa* strains have also been isolated from eutrophic freshwater environments (Koops and Pommerening-Röser 2001). Furthermore, 16S rRNA sequences from the *N. europaea/Nc. mobilis lineage*, *Nitrosomonas* environmental cluster 5, and the *N. marina* lineage have been detected in freshwater system (Speksnijder et al. 1998; Bollmann and Laanbroek 2001; Burrell et al. 2001).

As with marine and soil systems, AOB often share their environment with Thaumarchaeota that carry ammonia monooxygenase genes, and in a number of cases, these have been shown to be lithotrophic ammonia oxidizers (French et al. 2012; Hatzenpichler 2012). However, considerably less is known about freshwater ammonia-oxidizing archaea than those from marine and soil systems. One study has however shown that cultures of freshwater ammonia-oxidizing archaea are better adapted than AOB to low oxygen and low ammonia concentrations, and their growth rate was also less affected by changes in pH. Ammonia-oxidizing archaea are also more sensitive to continuous light and light cycles and recover from light exposure less well than AOB (Merbt et al. 2012; French et al. 2012). These factors may well dictate the relative significance of ammonia oxidizing bacteria and archaea in freshwater environments, though more systematic in situ studies will be required to test this fully (French et al. 2012). These factors may well dictate the relative significance of ammonia-oxidizing bacteria and archaea in freshwater environments, though more systematic in situ studies will be required to test this fully (French et al. 2012).

Wastewater Treatment Systems

Ammonia oxidation is a critical process for nitrogen removal in wastewater treatment plants, and the close physical and metabolic association of ammonia oxidizers and nitrite oxidizers is critical to its reliable operation (Mobarry et al. 1996; Schramm et al. 1996; Okabe et al. 1999; Graham et al. 2007). Nitrite produced from oxidized ammonia may, depending on prevailing conditions, be used as an electron acceptor by anaerobic ammonia-oxidizing planctomycetes leading to direct removal of nitrogen as nitrogen gas (Kuenen 2008) or as an electron donor for nitrite oxidizers forming nitrate that may be removed by classical denitrification. AOB are commonly considered to be strictly chemolithoautotrophic aerobic microbes that grow slowly, are rate limiting for nitrification, and are poor competitors for oxygen and ammonia compared to co-occurring heterotrophs (Verhagen and Laanbroek 1991; van Nielm et al. 1993; Laanbroek and Gerards 1993). Consequently, nitrifying systems are usually operated at solids retention time (SRT) of greater than 5 days and dissolved oxygen (DO) concentration above 2 mgl^{-1} to satisfy both carbon and nitrogen removal requirements and to overcome diffusional resistance to oxygen transfer to ammonia oxidizers in flocs. By virtue of urease production by many ammonia oxidizers, they are also central in conversion of urea to ammonia, an important process in wastewater treatment plants where urea is an important nitrogen species.

Nitrosomonas spp. appear to be the predominant AOB in wastewater treatment systems such as activated sludge plants (Mobarry et al. 1996; Schramm et al. 1996, 2000; Juretschko et al. 1998; Okabe et al. 1999; Daims et al. 2001a; Gieseke et al. 2001; Rowan et al. 2003a). This is typically recorded in analysis of activated sludge communities using FISH- or PCR-based analysis of AOB 16S rRNA genes or *amoA* to detect AOB (Koops et al. 2006). Nevertheless, *Nitrosospira* spp. have also been detected in wastewater treatment reactors though they are rarely found in full-scale plants (Schramm et al. 1998).

The most commonly identified ammonia oxidizers in municipal wastewater treatment plants come from the *Nitrosomonas europaea/Nitrosomonas (Nitrosococcus) mobilis* lineage (Juretschko et al. 1998; Koops and Pommerening-Röser 2001; Rowan et al. 2003a). *N. eutropha* appears to be the most commonly encountered isolate (Watson and Mandel 1971; Koops and Harms 1985). *Nitrosomonas (Nitrosococcus) mobilis* was once thought to be exclusively marine in origin, but it is the dominant ammonia oxidizer in some wastewater treatment plants, especially those treating industrial wastewaters, which often have higher salinity than domestic wastewater (Juretschko et al. 1998; Rowan et al. 2003a).

Almost all lineages in the *Nitrosomonas* radiation have been detected in wastewater treatment plants, and only organisms related to *Nitrosomonas cryotolerans* have not been detected. 16S rRNA gene sequences most closely related to the *Nitrosomonas halophila* lineage have been detected in lab-scale reactors treating industrial wastewater (Rowan et al. 2003b), and relatives of *Nitrosomonas* sp. Nm143 were detected in a full-scale reactor treating saline industrial wastewater (Rowan et al. 2003a). Interestingly, when this reactor ceased to be fed industrial wastewater and was instead fed domestic wastewater, the community composition altered and was dominated by *N. oligotropha*-like organisms (Head et al. unpublished data). Some nitrifying wastewater treatment plants are dominated by

a single AOB species (Juretschko et al. 1998; Rowan et al. 2003a), while other plants harbor a higher diversity of AOB (Rowan et al. 2003b; Purkhold et al. 2000; Daims et al. 2001b; Gieseke et al. 2001), and this in part relates to reactor configuration, with a full-scale biologically aerated filter exhibiting lower AOB diversity than a conventional trickling filter treating identical wastewater (Rowan et al. 2003a).

AOB in wastewater treatment reactors are typically found in large multicellular aggregates that have a close physical association with nitrite-oxidizing bacteria (Mobarry et al. 1996; Schramm et al. 1996, 1998; Juretschko et al. 1998; Okabe et al. 1999). Combining FISH or qPCR counts of AOB with measurements of ammonia oxidation in wastewater treatment plants has allowed estimation of cell-specific ammonia oxidation rates (CSAOR). These show a remarkable variation of over three orders of magnitude (from 43 to 0.03 fmol cell^{-1} h^{-1}) (Coskuner et al. 2005), and it appears that plants where AOB have higher CSAOR are more prone to failure (Coskuner et al. 2005).

As with other environments ammonia-oxidizing archaea may in some instances compete with AOB, though ammonia-oxidizing archaea are generally considered to be adapted to low ammonia concentration (French et al. 2012; Bouskill et al. 2012) not usually considered typical of wastewater. A number of studies have detected ammonia-oxidizing archaea in wastewater treatment plants (Park et al. 2006; Wells et al. 2009; Zhang et al. 2009, 2011; Jin et al. 2010; Sonthiphand and Limpiyakorn 2011; Kayee et al. 2011; Limpiyakorna et al. 2011; Bai et al. 2012), though in many, but not all cases, they are less abundant than co-occurring AOB. Mussman et al. (2011) surveyed 52 wastewater treatment plants from across Europe with only 6 giving positive detection by end-point PCR. Quantitative analysis however revealed that only two of these had high numbers of ammonia-oxidizing archaea (ca. 10^8 cells ml^{-1}; Mussman et al. 2011). Process modeling indicated that these population sizes were too great to be sustained from the levels of ammonia oxidation observed in the treatment plant. Subsequent analysis of inorganic carbon fixation by combined microautoradiography and FISH demonstrated that the AOB but not the archaea were capable of fixing inorganic carbon under the incubation conditions used. This coupled with no change in the expression of archaeal *amoA* in response to ammonia suggested that the archaea were not autotrophic ammonia oxidizers in this system. The debate therefore remains open regarding the relative importance of AOB and Thaumarchaeota in ammonia oxidation in wastewater treatment plants, though their low frequency of occurrence in these systems indicates that they are not commonly key players in nitrification in wastewater treatment plants.

Application

Nitrification is responsible for major losses of ammonium-based fertilizers. In some agricultural systems, as little as 30 % of fertilizer nitrogen is used by crops, the remainder being oxidized to nitrate or converted to nitrogen or the greenhouse gas nitrous oxide. Leaching of nitrate can lead to pollution of groundwaters, particularly in areas of intensive agriculture, while denitrification converts it to gaseous forms, nitrogen or nitrous oxide. Gruber and Galloway (2008) and Schlesinger (2009) estimated global nitrogen fertilizer input to soil at 100–150 Tg y^{-1}. Nitrogen fertilizer application will continue to increase with expanding global populations, and the economic and environmental significance of ammonia oxidizers will therefore increase. Strategies to reduce fertilizer loss include better informed management of fertilizer addition, application of inhibitors of ammonia oxidizers, and development of crops that produce natural inhibitors of ammonia oxidation. Persistent nitrification, through long-term fertilization, also acidifies soil and increases mobilization of toxic metals.

Ammonia-oxidizing bacteria also play a major role in cycling nitrogen in aquatic environments. Nitrogen budgets in soil and freshwater are closely coupled with most of the nitrogen in freshwater systems resulting from nitrogen run-off from land (Gruber and Galloway 2008). Of the estimated 295 Tg N y^{-1} input of fixed nitrogen to terrestrial environments from all sources (natural and driven by human activity), around 110 Tg N y^{-1} is lost to the atmosphere by denitrification (Schlesinger 2009), and close to 50 % of this budget is accounted for by denitrification in freshwater systems (Gruber and Galloway 2008). Although the contribution of ammonia conversion to nitrite and, indirectly, nitrate by ammonia-oxidizing bacteria and archaea relative to direct run-off of nitrate from other sources is poorly constrained, it is clear that AOB and AOA play an important role in this component of the global nitrogen cycle.

In marine settings AOB also play a crucial role in oxidizing the reduced nitrogen entering the world's oceans. The bulk of the nitrogen entering from rivers and atmospheric deposition (ca. 130 Tg y^{-1}) is in the form of nitrate, though atmospheric deposition of ammonia to the oceans does occur (Gruber and Galloway 2008). However, the 140 Tg N y^{-1} entering the ocean from nitrogen fixation (Gruber and Galloway 2008) must first be mineralized and oxidized by AOB and AOA before it can be removed by denitrification, which approximately balances marine nitrogen input (Gruber and Galloway 2008). Anaerobic ammonia-oxidizing planctomycetes also play an important role in driving nitrogen loss in some marine settings, and the interactions of anaerobic ammonia oxidation, ammonia oxidation, and denitrification and dissimilatory reduction of nitrate to ammonia and in marine settings are a hotly debated topic (Voss and Montoya 2009).

In engineered environments too, AOB play a vital role in nitrogen removal. In aerobic wastewater treatment systems such as trickling filters and activated sludge, it seems that AOB, rather than archaea, may be the principal drivers of ammonia oxidation (Mussman et al. 2011). A conservative underestimate (data are not available from all countries) indicates that around 250 billion m^3 of municipal wastewater is generated annually, of which 130 billion m^3 is treated (Mateo-Sagasta and Salian 2012). Municipal wastewater contains 20–85 mg Nl^{-1} (UN Food and Agriculture Organization; http://www.fao.org/docrep/t0551e/t0551e03.htm) equating to a total amount of

2.6–11.2 Tg of N in the municipal wastewater that is treated annually, worldwide. It should however be noted that only a proportion of treatment plants are operated for active nitrification but it is clear that AOB have a vital and large-scale role in nitrogen removal in wastewater treatment globally.

In all of the environments where the activity of ammonia-oxidizing bacteria has important practical consequences, their role in generation of the greenhouse gas nitrous oxide through ammonia oxidation or nitrifier denitrification must also be considered, and as discussed above, this can be a significant source of nitrogen oxide emissions under certain circumstances.

Abstract
Oxalobacteraceae is a family within the order *Burkholderiales* in the subclass of *Betaproteobacteria* which contains the 13 genera: *Collimonas*, *Duganella*, *Glaciimonas*, *Herbaspirillum*, *Herminiimonas*, *Janthinobacterium*, *Massilia*, *Noviherbaspirillum*, *Oxalicibacterium*, *Oxalobacter*, *Pseudoduganella*, *Telluria* and *Undibacterium*. According to the 16S rRNA gene sequence similarities of the type species, the genera *Herbaspirillum*, *Noviherbaspirillum*, *Collimonas*, *Glaciimonas*, *Oxalobacter*, and *Oxalicibacterium* as well as the genera *Telluria*, *Massilia*, *Duganella*, *Pseudoduganella*, *Janthinobacterium*, *Undibacterium*, and *Herminiimonas* appear more closely related within the family *Oxalobacteraceae*. The members of the family are heterotrophic and nonspore-forming gram-negative bacteria; they are mesophilic with the exception of some psychrophilic species.

E. Rosenberg et al. (eds.), *The Prokaryotes – Alphaproteobacteria and Betaproteobacteria*, DOI 10.1007/ 978-3-642-30197-1_291,

Their morphologies are rod, curved rod, vibrio- or spirillum-like. They represent a wide range of phenotypic and ecological properties. The general metabolism is mostly aerobic/microaerobic to facultative anaerobic in some species; only members of the genus *Oxalobacter* have a strictly anaerobic lifestyle. Members of the family *Oxalobacteraceae* are found in diverse environmental habitats like water, soil, and plant associated; some species/strains are mild plant pathogens or are claimed to be opportunistic human pathogens. Members of some genera (like *Collimonas* or *Glaciimonas*) are adapted to oligotrophic conditions, while, e.g., the genus *Herbaspirillum* harbors species of root-associated or even endophytic nitrogen-fixing bacteria, which are applied as plant growth-promoting bacterial inoculants in agriculture.

Taxonomy, Historical, and Current

Short Description of the Family

Oxalobacteraceae (Ox.al.o.bac.ter.a'ce.ae. M.L. masc. n. *Oxalobacter* type genus of the family; *-aceae* ending to denote family; M.L. fem. Pl. n. *Oxalobacteraceae* the *Oxalobacter* family; Garrity et al. 2005).

Phylogenetically, the family of *Oxalobacteraceae* is a member of the order *Burkholderiales* and class *Betaproteobacteria* in the phylum Proteobacteria (Stackebrandt et al. 1988; Garrity et al. 2005). According to the 16S ribosomal ribonucleic acid (rRNA) gene sequence comparison of the type species, the next related family within the *Burkholderiales* is the *Alcaligenaceae* (De Ley et al. 1986). The family *Oxalobacteraceae* contains the genera *Oxalobacter* (type genus) (Allison et al. 1985), *Herbaspirillum* (Baldani et al. 1986), *Noviherbaspirillum* (Lin et al. 2013), *Collimonas* (De Boer et al. 2004), *Glaciimonas* (Zhang et al. 2011), *Janthinobacterium* (De Ley et al. 1978; Lincoln et al. 1999), *Undibacterium* (Kämpfer et al. 2007), *Herminiimonas* (Fernandes et al. 2005), *Oxalicibacterium* (Tamer et al. 2002), *Duganella* (Hiraishi et al. 1997), *Pseudoduganella* (Kämpfer et al. 2012a), *Massilia* (La Scola et al. 1998), and *Telluria* (Bowman et al. 1993). The family is metabolically diverse and includes strict anaerobes, aerobes, and nitrogen-fixing organisms. The Gram staining of these bacteria is negative. The morphological forms vary from rods to curved rods, vibroid, or spirillum shapes. Most of the bacteria are motile by means of one or several polar or peritrichous flagella; some species are nonmotile.

The genus name *Oxalobacter* was first proposed by Allison and collaborators (1985). The description of the type species *Oxalobacter formigenes* was based on an anaerobic oxalate-degrading isolate (OxB^T) from sheep rumen (Dawson et al. 1980a). The type strain $WoOx3^T$ of the second species, *Oxalobacter vibrioformis*, was isolated from anoxic freshwater sediments (Dehning and Schink 1989).

First isolates of the genus *Herbaspirillum* were initially thought to be a new *Azospirillum* species due to its cell form, growth behavior, and habitat within grass roots (Baldani et al. 1984). However, RNA/RNA hybridization experiments showed no close relatedness with *Azospirillum* spp. or *Aquaspirillum itersonii* (Falk et al. 1986), and therefore the genus *Herbaspirillum* was defined with nitrogen-fixing endophytic bacterial isolates as the genus species *Herbaspirillum seropedicae* (Baldani et al. 1986). The genus was then expanded to embrace strains from the species [*Pseudomonas*] *rubrisubalbicans*, a mild pathogen causing mottled stripe disease in some susceptible sugarcane plants (Pimentel et al. 1991). Due to the high degree of DNA–DNA hybridization similarity (Gillis et al. 1990) and additional phenotypic characteristics to the genus *Herbaspirillum*, including the ability to fix nitrogen, it was reclassified as *H. rubrisubalbicans* (Baldani et al. 1996). A group of clinical isolates (EF group 1), non-nitrogen-fixing strains, had to be included into the genus *Herbaspirillum* as species 3 because of its molecular and overall physiological relatedness. However, the taxonomic position of the *Herbaspirillum* species 3 is uncertain and will not be treated here. New species were later described (DDH, 16S rRNA, and physiological characteristics), but few of them were found associated with plants (*H. frisingense*, *H. lusitanum*, *H. hiltneri*, and *H. rhizosphaerae*) and showed the ability to fix nitrogen (*H. frisingense*). The species *H. lusitanum* was described as nitrogen fixer, but this characteristic was not confirmed by genome sequencing of the type species (Weiss et al. 2012). The other species (*H. aquaticum*, *H. autotrophicum*, *H. huttiense* subsp. *huttiense*, *H. huttiense* subsp. *putei*) were isolated from water and lakes, while *H. chlorophenolicum* was originated from soil sediments. The species *H. canariense*, *H. aurantiacum*, *H. soli*, and *H. psychrotolerans*, isolated from soil, were reclassified based on polyphasic analysis and transferred to the genus *Noviherbaspirillum* that includes the type species *N. malthae* (Lin et al. 2013).

Bacteria belonging to the genus *Collimonas* were originally isolated from sandy dune soil in the Netherlands and were characterized by their mycophagous activity as *C. fungivorans* (De Boer et al. 2004). Different species (*C. arenae* and *C. pratensis*) were isolated from low-carbon sandy soil further on (Höppener-Ogawa et al. 2008a, b). An 18 bp stretch of the 16S rRNA gene of *Collimonas* spp. was found absent in a survey of the entire data set of 16S rRNA gene sequences. A fluorescence-labeled 18 bp probe (5′-CTCTTCGGGATTCTGTAC-3′) complementary to this region (998–1015) proofed to provide a quick discriminative test between *Collimonas* isolates and members of other species and genera (De Boer et al. 2004).

Glaciimonas immobilis was isolated from alpine glacier cryonite in Tyrol, Austria, by Zhang et al. (2011). It is nonmotile and metabolically adapted to oligotrophic conditions. Recently, phylogenetically related bacterium was obtained from water collected in a uranium mine in Portugal and named *G. singularis* (Chung et al. 2013).

Based on studies involving rRNA similarities of the *Chromobacterium* genus, De Ley et al. (1978) proposed a new genus named *Janthinobacterium* for the strains formerly classified as *Chromobacterium lividum*. The genus *Janthinobacterium* belong to the class *Betaproteobacteria*, order *Burkholderiales*, and *Oxalobacteraceae* family. The genus is composed by two validly published species. The G+C content range of the DNA for the

genus *Janthinobacterium* is 61–67 mol %. By quantitative comparison of rRNA cistron similarities studies with *Chromobacterium violaceum*, *Chromobacterium lividum*, and great variety of gram-negative bacteria with uncertain taxon position, De Ley et al. (1978) proposed a new genus named *Janthinobacterium* with one species *Janthinobacterium lividum* (syn. *C. lividum*) with *C. violaceum* nomenclature maintained. The previous *Chromobacterium* cluster with two species was constructed based on results from numerical analysis of phenotypic traits, and many authors pointed that the species of *Chromobacterium* were very different and should be separated at genus level (Leifson 1956). rRNA similarity maps clearly indicated separated clusters with all C. *lividum* strains and all *C. violaceum* strains tested forming tight separate clusters around their respective neotype strains (De Ley et al. 1978). More recently, Kämpfer et al. (2008b) using 16S rRNA gene sequence comparisons, chemotaxonomic approaches, and several biochemical characteristics reclassified *Pseudomonas mephitica* CCUG 2513^T as a later heterotypic synonym of *Janthinobacterium lividum*. Lincoln et al. (1999) isolated bacteria that caused a soft rot disease of *Agaricus bisporus* and based on nutritional, physiological, chemical, and molecular techniques had shown similarities with *Janthinobacterium* (*J. lividum*). These authors described a high degree of genotypic similarity between members of the genus *Janthinobacterium* and *Herbaspirillum* (DNA–RNA hybridization) and high degree of 16S rRNA sequence similarity between members of the genera *Janthinobacterium*, *Herbaspirillum*, *Oxalobacter*, and *Duganella*. However, members of the genus *Janthinobacterium* could be easily distinguished from these taxa by the use of whole-cell fatty acid analysis. Polyphasic data obtained for the mushroom pathogenic strains indicate a novel species within the genus *Janthinobacterium* named *Janthinobacterium agaricidamnosum* (Lincoln et al. 1999).

The genus *Undibacterium* was described based on two strains (CCUG 49009^T and CCUG 49012) that was isolated from drinking water (Kämpfer et al. 2007). Chemotaxonomic data (major ubiquinone, polyamines, and polar lipids plus fatty acids) coupled with 16S rRNA gene sequence similarities studies involving closely related genera allowed to propose a new genus named *Undibacterium* gen. nov., with one species, Undibacterium *pigrum* sp. nov., within the family *Oxalobacteraceae*. The type strain of *Undibacterium pigrum* is strain CCUG 49009^T (= CIP 109318^T). Four years later, Eder et al. (2011) described a new species, *Undibacterium oligocarboniphilum* sp. nov. (an isolate from purified water), as well as reclassified *Undibacterium pigrum* strain CCUG 49012 as the type strain of *Undibacterium parvum* sp. nov. and proposed an emended descriptions of the genus *Undibacterium* and the species *Undibacterium pigrum*. *Undibacterium oligocarboniphilum* sp. nov. was proposed based on similar chemotaxonomic profiles obtained for members of the family *Oxalobacteraceae*. The fourth species of the genus, *Undibacterium terreum*, was proposed based in one strain C3^T, isolated from permafrost soil in China. 16S rRNA gene sequences analysis revealed close relationship with *Undibacterium* genus and biochemical and physiological distinguishable characteristics allowed indicate this isolate as a new species from the genus. Quite recently, two new species emerged, *Undibacterium jejuense* and *Undibacterium seohonense*, based on two bacterial strains (JS4-4^T and SHS5-24^T) isolated from soil and freshwater, respectively (Kim et al. 2014).

The genus *Herminiimonas* was created to accommodate new bacterial isolates from water samples within the family *Oxalobacteraceae* (Fernandes et al. 2005). Currently, the genus comprises six validly published names species.

The genus *Oxalicibacterium* harbors as type strain a yellow-pigmented bacterial strain (TA17^T) which was isolated from litter of oxalate-rich plants in Turkey (Tamer et al. 2002). The strain was similar to the genus *Pseudomonas*, but differed from it with respect to 16S rRNA sequence and physiological and biochemical data, which led to the description of the genus *Oxalicibacterium*, with type species and strain *Oxalicibacterium flavum* (Tamer et al. 2002, 2003). Two additional species, *Oxalicibacterium horti* and *Oxalicibacterium faecigallinarum* (Sahin et al. 2009a, b) and a fourth species (*Oxalicibacterium solurbis*) were described later (Sahin et al. 2010a, b).

Duganella zoogloeoides was originally described as an isolate within the genus *Zoogloea* because of the formation of cell clumping and the formation of a zoogloeal matrix. Therefore, it was presented in the second edition of the Prokaryotes within the genus *Zoogloea* (Dugan et al. 1992). Due to its floc-forming ability, it was reasoned to have an important role in wastewater treatment. *Duganella violaceinigra* was recently renamed to *Pseudoduganella violaceinigra* by Kämpfer et al. (2012b). *Duganella* and *Pseudoduganella* are related to *Massilia*.

To date, the genus *Massilia* is the most species-rich genus of the family *Oxalobacteraceae*, currently composed of 22 described species with validly published names. The genus has a relatively recent history, being created in 1998 to harbor an isolate from human origin as a new species *Massilia timonae*, the type species, with UR/MT95^T as the type strain (La Scola et al. 1998, 2000). New species were incorporated to the genus only from 2006 to 2011. The genus was proposed based on a single fastidious, strictly aerobic, gram-negative isolate from a culture of blood of an immunocompromised patient with cerebellar lesions (La Scola et al. 1998), mainly based on sequence analysis of 16S rRNA gene that demonstrated its closer proximity to *Duganella zoogloeoides* and *Telluria mixta* and polyphasic characterization (La Scola et al. 1998, 2000). Three more strains were added to the species based on its 16S rRNA sequence and phenotypic similarities, and an emended description of the species was proposed (Lindquist et al. 2003). These new strains were also isolated from human patients' blood, cerebrospinal fluid, and bone samples (Lindquist et al. 2003). However, as La Scola et al. (1998) pointed out, although some evidences for the Timone isolate being the causal agent of the patient syndrome were observed, its close proximity to environmental species may also be a naturally niche for Timone isolate. Accordingly, new species added later confirmed this hypothesis, being isolated from environmental samples, such as water, air, and soil. The genus *Naxibacter* was proposed by Xu and collaborators (2005)

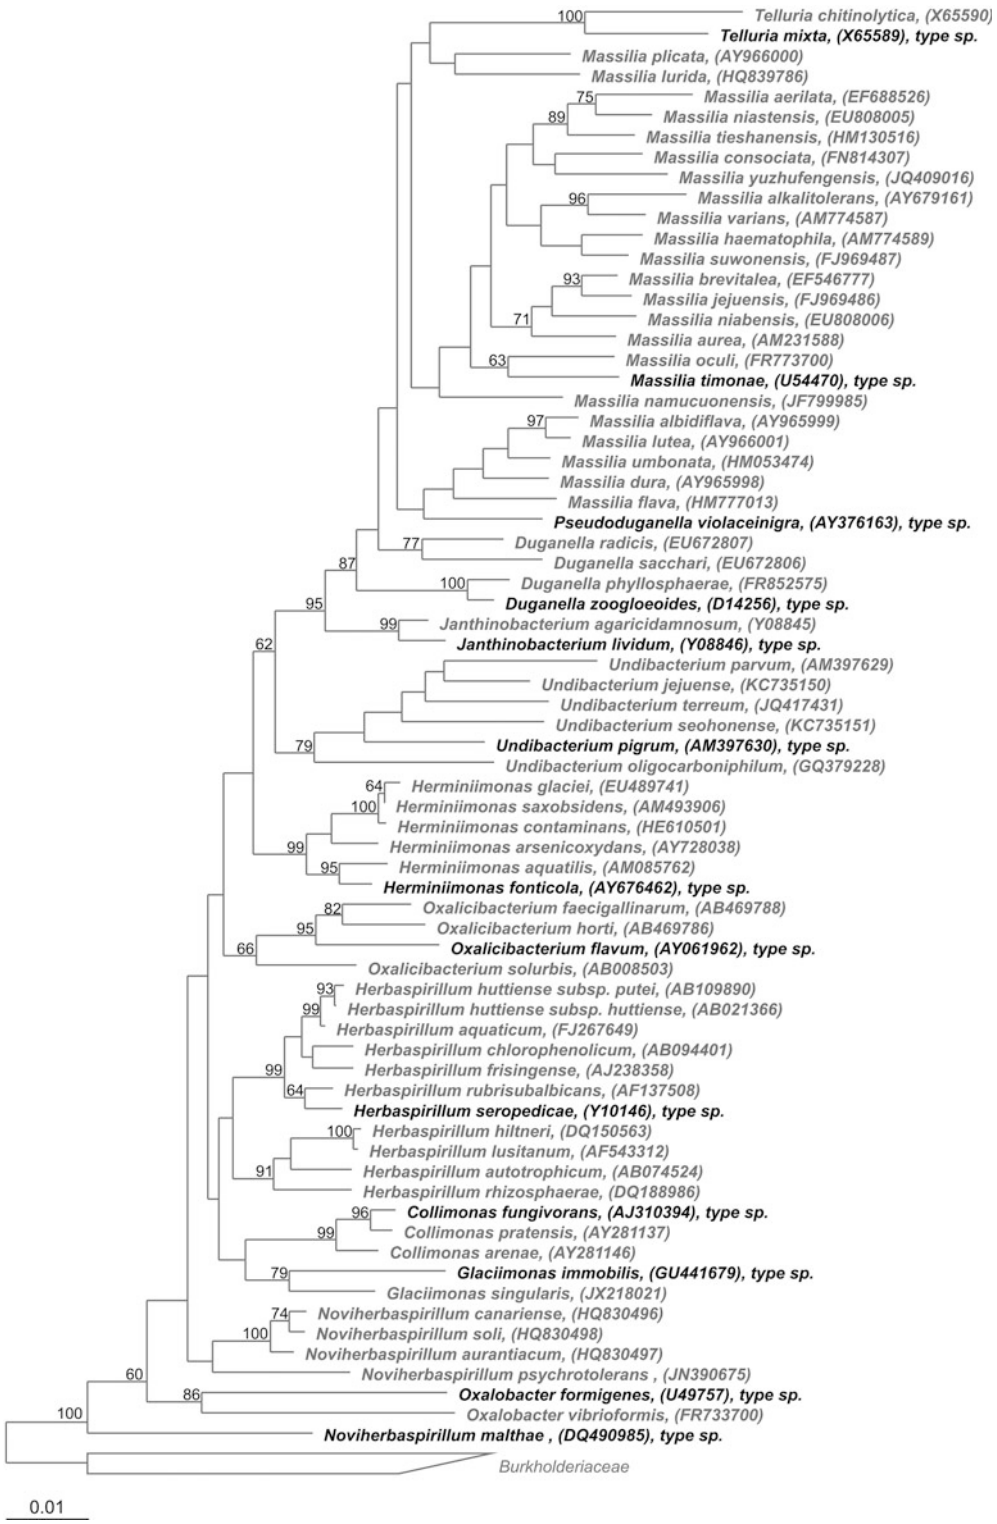

Fig. 35.1

Phylogenetic reconstruction of the family *Oxalobacteraceae* based on 16S rRNA and created using the neighbor-joining algorithm with the Jukes-Cantor correction. The sequence datasets and alignments were used according to the All-Species Living Tree Project (LTP) database (Yarza et al. 2010; http://www.arb-silva.de/projects/living-tree). 1000 resampling boostrap values over 50 % shown. Scale bar indicates estimated sequence divergence

with the type species *Naxibacter alkalitolerans*. Phylogenetically, it was placed in the vicinity of *Massilia*, *Telluria*, *Duganella*, and *Janthinobacterium*. Later, two additional species, *Naxibacter varians* and *Naxibacter haematophilus*, were published together with an emended description of the genus *Naxibacter* (Kämpfer et al. 2008a). In the same year, the fourth species of the genus, *Naxibacter suwonensis*, was described (Weon et al. 2010). However, 16S rRNA sequence analyses and chemotaxonomic data justified the transfer of all *Naxibacter* species to the genus *Massilia*, as *Massilia alkalitolerans*, *Massilia varians*, *Massilia haematophilus*, and *Massilia suwonensis* (Kämpfer et al. 2011).

The history of the genus *Telluria* started with the characterization of a novel species of polysaccharide-degrading bacteria, which was named *Pseudomonas mixta* in 1988 (Bowman et al. 1988). Phenotypic, genotypic, and phylogenetic evidence showed that *Pseudomonas mixta* was highly similar to the chitin-degrading bacterium *Pseudomonas chitinolytica* and that both species differed from other Pseudomonads, leading to the description of the new genus *Telluria* (Bowman et al. 1993). The type species is *Telluria mixta*, and the second known species is *Telluria chitinolytica* (Bowman et al. 1993).

Phylogenetic Structure of the Family and Its Genera

According to the phylogenetic relationship based on 16S rRNA gene sequence analyses within the order *Burkholderiales*, the family *Oxalobacteraceae* is moderately affiliated to the family *Alcaligenaceae* (Garrity et al. 2005). Extensive 16S rRNA gene sequence analyses of type species and strains constitute the phylogenetic structure within the family *Oxalobacteraceae* (*Fig. 35.1*).

Herbaspirillum: The phylogenetic analysis based on the 16S rRNA sequences (performed using maximum-likelihood and maximum-parsimony methods) showed that the genus *Herbaspirillum* did not constitute a monophyletic group. The species *Herbaspirillum hiltneri*, *H. lusitanum*, *H. rhizosphaerae*, *and H. autotrophicum* formed a separated cluster (Carro et al. 2012). Similarly, the species *H. canariense*, *H. aurantiacum*, *H. soli*, and *H. psychrotolerans*, previously included in the genus *Herbaspirillum*, form a separate group and therefore were reclassified and transferred to the genus *Noviherbaspirillum* containing also the species *N. malthae* (genus species). Members of the genus *Herbaspirillum* have 94.1–95.2 % 16S rRNA gene sequence similarity to members of the genus *Noviherbaspirillum* (Lin et al. 2013) and 95.9–96.7 to the genus *Collimonas* (De Boer et al. 2004). Furthermore, members of *Herbaspirillum* have 96 % to genus *Herminiimonas*, 96.3–97.0 % to genus *Glaciimonas*, and lower than 96.2 % 16S rRNA gene sequence similarities to members of the genus *Oxalicibacterium* (Chung et al. 2013). Interestingly, the ten *Herbaspirillum* species exhibit very high degree of 16S rRNA gene sequence similarities with each other (97.0–99.9 %). Based on these 16S rRNA gene similarities, new species cannot be described. However, Rothballer et al. (2006) found only 14–32 % similarity in DNA–DNA hybridization experiments between the members of the new species *H. hiltneri* and *H. lusitanum*, although the 16S rRNA gene similarity was 98.9–99.0 % between the two species. A similar situation was found for *H. frisingense* (Kirchhof et al. 2001). On the other hand, the high level of the 16S and 23S rRNA gene sequence similarities between the type strains of *H. putei* and *H. huttiense* (99.9 % and 99.7 %) and DDH of 96 % with the *H. huttiense* DSM 10281T used as a probe excluded the possibility of both strains as representatives of different species (Dobritsa et al. 2010). However, the genome of *H. huttiense* type strain is 0.9 MB lower than that of *H. putei* type strain so that this difference reduced the DNA–DNA relatedness to 72 % which is very close to the threshold for delineating new bacterial species so two subspecies were described (*H. huttiense subsp. putei* and *H. huttiense subsp. huttiense*).

Noviherbaspirillum: Members of the genus *Noviherbaspirillum* have shown 94.1–95.2 % 16S rRNA gene sequence similarities to members of the genus *Herbaspirillum* but slightly lower for the closest genera within the family: *Oxalicibacterium* (93.4–94.4 %), *Duganella* (93.1–94.4 %), *Undibacterium* (93.2–94.3 %), *Herminiimonas* (93.5–94.2 %), *Collimonas* (93.8–94.0 %), *Janthinobacterium* (93.7 %), *Massilia* (92.5–93.2 %), *Oxalobacter* (93.1 %) and *Telluria* (91.1 %) (Lin et al. 2013). The type species *Noviherbaspirillum malthae* showed a high degree of similarity to *N. soli* (96.5 %), *N. aurantiacum* (96.3 %), *N. canariense* (96.0 %), and *N. psychrotolerans* (95.4 %) (Lin et al. 2013). However, these values were lower than that observed for the species *N. psychrotolerans* when compared to *N. canariense* (97.3 %), *N. aurantiacum* (97.2 %), and *N. soli* (97.2 %) (Bajerski et al. 2013). Higher degree of 16S rRNA gene sequence similarities (99.2–99.6) were observed during the phylogenetic tree construction involving the three species *N. canariense*, *N. aurantiacum*, and *N. soli* (Carro et al. 2012). However, all these species formed a cluster clearly divergent from the species of the genus *Herbaspirillum*.

Collimonas–Glaciimonas: *Collimonas* and *Glaciimonas* are closely related species; their nearest neighbors are *Herbaspirillum* and *Oxalicibacterium*. In all cases, full or almost full length 16S rRNA gene sequences are available which allowed calculating phylogenetic trees and 16S rRNA gene sequence similarities. Members of the genus *Glaciimonas* have 96.1–97.0 % 16S rRNA gene sequence similarity to members of the genera *Collimonas* and *Herbaspirillum* (Zhang et al. 2011; Chung et al. 2013). Furthermore, members of *Collimonas* have 95.9–96.7 % and 94.3–95.6 % 16S rRNA gene sequence similarities to members of the genera *Herbaspirillum* and *Janthinobacterium*, respectively (De Boer et al. 2004). *Pseudoduganella* has 96.8 % 16S rRNA gene sequence similarity to *Duganella* and also 96.5–97.1 % 16S rDNA gene sequence similarity to members of the genera *Duganella* and *Massilia*, respectively (Kämpfer et al. 2012b).

Janthinobacterium: Reference strains of species from *Janthinobacterium lividum* had shown values ranging from

99.0 % to 99.8 %. 16S rRNA gene sequence similarities of *Janthinobacterium* and closely related type species *Herbaspirillum seropedicae*, *Duganella zoogloeoides*, *Oxalobacter formigenes*, *Telluria mixta*, and *Telluria chitinolytica* were 90.6–96.4 %.

Undibacterium: The genus *Undibacterium* was described based on 16S rRNA sequence analysis of two strains (CCUG 49009^T and CCUG 49012) and emerged as a new member of *Oxalobacteraceae* family, not related to any other known most closely related genus (*Herminiimonas*, *Massilia*, *Duganella*, *Telluria*, *Herbaspirillum*, *Janthinobacterium*, *Naxibacter*, and *Paucimonas*) showing less than 96.5 % 16S rRNA gene sequence similarities (Kämpfer et al. 2007). Related to genospecies of *Undibacterium*, 16S rRNA gene sequence similarities were higher than 95.6 % with maximum value of 97.6 %, indicating that all species belong to the genus *Undibacterium*. In addition, genomic DNA–DNA hybridization showed low levels of relatedness (below 70 %), which support the proposition of six separated species.

Herminiimonas: Phylogenetic analysis of the 16S rRNA gene sequence between all the six reference strains of the genus *Herminiimonas* obtained similarity levels ranging from 97.7 % to 99.6 % which suggest their affiliation to the genus *Herminiimonas*. The separation into six separate species is supported by the low levels of genomic DNA–DNA hybridization (below 57 %). The genus *Herminiimonas* was described based on 16S rRNA sequence and RAPD analysis of four strains (S-94^T, S-97, S-99, and S-92) and emerged as clone of a new betaproteobacterium member of *Oxalobacteraceae* family, not closely related to any other known species (Fernandes et al. 2005). 16S rRNA gene sequence similarities of new isolates of *Herminiimonas* to the type species of nearest related genera from *Oxalobacteraceae* family such as *Herbaspirillum*, *Paucimonas*, *Janthinobacterium*, and *Duganella* are in the range 93.0–96.5 %. For species belonging to the *Herminiimonas* genus, 16S rRNA gene similarities were higher than 97.9–100 %.

Oxalicibacterium: Analysis of the 16S rRNA sequence of *Oxalicibacterium flavum* strain TA 17^T showed sequence similarity between 88 % and 93 % with the genera *Janthinobacterium*, *Duganella*, *Herbaspirillum*, and *Burkholderia* (Tamer et al. 2002, 2003). 16S rRNA gene sequences of *Oxalicibacterium horti* OD1^T and *Oxalicibacterium faecigallinarum* YOx^T showed 97.1 % and 97.44 % resp. sequence similarities with strain TA 17^T. In contrast, sequence similarities were lower than 96.2 % with all other established genera of the *Oxalobacteraceae* family (Sahin et al. 2009a, b). The 96.8 % 16S rRNA sequence similarity of strain MY14^T with *Oxalicibacterium flavum* was consistent with its phylogenetic characterization as *Oxalicibacterium solurbis*.

Duganella–Pseudoduganella: In a phylogenetic analysis, *Pseudoduganella violaceinigra* YIM 31327^T was clustered with the *Massilia* species using the neighbor-joining and maximum-likelihood methods, but it was grouped in another cluster containing *Duganella zoogloeoides* IAM 12670^T in the maximum-parsimony tree (Du et al. 2012). However, another phylogenetic tree based on the neighbor-joining method supported the reclassification of *D. violaceinigra* (Shen et al. 2013).

Massilia–Telluria: Phylogenetic 16S rRNA gene sequence analyses of *Massilia* and former *Naxibacter* species often grouped together and were found intermixed depending on the mode of sequence comparison (Kämpfer et al. 2008a; Weon et al. 2009, 2010). Even with the inclusion of *Naxibacter* species, phylogeny of the genus *Massilia* based on 16S rRNA gene sequences continues to be not well resolved. Kämpfer et al. (2011) observed that *Telluria* spp. fell together with a cluster of four *Massilia* spp. and suggests a detailed investigation of *Telluria* spp. However, topology and clusters in phylogenetic trees are very sensitive to the set of organisms used, choice of models of evolution and phylogenetic methods, alignment reliability, and sequence lengths/quality, to cite a few. Further, many of the clusters within *Massilia* genus are not well supported by bootstrap analysis in the phylogenetic trees reported so far. Accordingly, species from other genera of the family can also be seen clustering with *Massilia* (i.e., *Duganella* spp., *Pseudoduganella* spp., *Janthinobacterium* spp., and *Telluria* spp.) based on 16S rRNA gene sequence phylogeny (Monteiro et al. 2014). For example, *Telluria* species fell together with *M. albidiflava*, *M. dura*, *M. lutea*, and *M. plicata*. [*Duganella*] *violaceinigra* was reclassified within a novel genus as *Pseudoduganella violaceinigra* (Kämpfer et al. 2012b). Kämpfer et al. (2011) suggested that the fatty acid $C_{14:0}$ 2-OH, found in the species *M. albidiflava*, *M. dura*, *M. lutea*, and *M. plicata*, which grouped together with the species of the genus *Telluria* in 16S rRNA gene sequence phylogenetic tree, may represent a separate line of variation. Although these species consistently clusterize in different phylogenetic trees, this fatty acid is also observed in *M. aerilata*, *M. aurea*, *M. flava*, and *M. lurida*, in proportional amounts, and in *M. umbonata* in less than 1 %. However, these species fell outside the cluster of *Massilia* species containing $C_{14:0}$ 2-OH (Monteiro et al. 2014; Rodríguez-Díaz et al. 2013). Although the distinct phylogenetic positions and differences in chemotaxonomic markers such as polar lipids and fatty acids are usually used to distinguish bacteria at the genus level, assigning any novel isolate to Massilia–Duganella–Telluria species needs particular care because of the absence of clear phylogenetic boundaries and genus-specific chemotaxonomic markers (Shen et al. 2013).

Molecular Analyses

DNA–DNA Hybridization Studies

DNA–DNA hybridization analyses support the phylogenetic structure of the family *Oxalobacteraceae* and the genera within this family.

Herbaspirillum: The DNA–DNA hybridization values between the type strains of the ten *Herbaspirillum* species, and the type species *H. seropedicae* are in the range of 1–34 %. Higher values were observed for the species *H. huttiense* subsp. *putei* and *H. huttiense* subsp. *huttiense* hybridized against *H. aquaticum* (59 %) (Dobritsa et al. 2010) and *H. huttiense* subsp. *huttiense* toward *H. rhizosphaerae* (56 %) (Jung et al. 2007).

Noviherbaspirillum: The genus *Noviherbaspirillum* with five species was created based on polyphasic analysis including the 16S rRNA gene sequence similarities. Concerning the reclassification of *Noviherbaspirillum* and *Herbaspirillum*, the determination of DNA–DNA hybridization values of the different type strains with the type species of *Herbaspirillum* was decisive. The species *N. canariense*, *N. aurantiacum*, and *N. soli* presented DNA–DNA hybridization values of 25 %, 12 %, and 11 %, respectively, with *H. seropedicae* Z67. These DNA relatedness values were below 60 % when the three species type strains of *Noviherbaspirillum* were compared (Carro et al. 2012). In the case of *N. psychrotolerans*, the DNA–DNA relatedness values were below 30 % for the type strain hybridized against the other three *Noviherbaspirillum* species (Bajerski et al. 2013).

Collimonas: Within the genus *Collimonas*, the DNA–DNA hybridization values are in the range of 31–64 %, while they are between 70–75 % and 75–87 % within the species *C. fungivorans* and *C. pratensis*, respectively (Höppener-Ogawa et al. 2008b).

Janthinobacterium: The *Janthinobacterium* genus was proposed by De Ley et al. (1978) based on comparisons of DNA–rRNA cistron similarities of hybrids between the ^{14}C-labeled 23S rRNA fraction of *Janthinobacterium* (*Chromobacterium*) *lividum* against DNA from a variety of bacteria and DNA–DNA hybridization assays. The rRNA cistron of both *Chromobacterium* species were quite distinct in nucleotide ($Tm_{(e)}$) and percent rRNA binding, and the low degree of DNA hybridization conducted the authors to conclude that the species of *Chromobacterium* were not species of the same genus. Genotypic data coming from DNA–RNA hybridization analysis had shown a close relationship among members of the genus *Janthinobacterium* and *Oxalobacter*, *Duganella*, and *Herbaspirillum*. DNA–DNA hybridization between *J. lividum* DSM 1522T and the *J. agaricidamnosum* strain Wlr3T gave a very low value (35 %) to consider them as the same species.

Undibacterium: Few results of DNA–DNA hybridization related to *Undibacterium* were reported. In one study, two strains (CCUG 49009^T and CCUG 49012) were shown to represent separate species (sharing only 20 % DNA–DNA relatedness) being positioned as different species (Kämpfer et al. 2007; Eder et al. 2011) value. Values of DNA–DNA relationship for new proposed species of *Undibacterium* against reference strains of *Undibacterium* ranged in 29 % ± 4 % and 39 % ± 5 %, confirming the six proposed genomic species in the genus *Undibacterium*.

Herminiimonas: Despite the high 16S rRNA gene sequence similarities, DNA–DNA hybridization values among proposed species of the genus *Herminiimonas* showed levels ranging from 3.0 % to 25.7 %. Higher DNA–DNA hybridization values (52–57 %) were obtained among three species of the genus (*H. saxobsidens*, *H. glacier*, and *H. arsenicoxydans*), but the values were below the cutoff (<70 %) to proposed species level affiliation. These low hybridization values confirm the affiliation of six genospecies within *Herminiimonas*. In only one case, strain ND5^T previously classified as *H. glaciei* based on a DNA–DNA hybridization value of 78 % was reclassified as the second strain of *H. contaminans* (Kämpfer et al. 2013).

Oxalicibacterium: DNA–DNA homology experiments with three phenotypically similar strains (TA17^T, TA23, and TA24) of *Oxalicibacterium flavum* showed between 90 % and 100 % similarity values. These values clearly separated these strains from other strains tested such as oxalate-oxidizing strain TA25 (43 % similarity) and *Ralstonia eutropha* (41 % similarity) (Tamer et al. 2002). The DNA relatedness of *Oxalicibacterium horti* strain OD1^T and *Oxalicibacterium faecigallinarum* strain YOx^T was investigated by measuring the divergence between the thermal denaturation midpoint of homoduplex DNA and heteroduplex DNA (ΔT_m) (González and Sáiz-Jiménez 2005). When comparing DNA from different strains, the DNA reassociation values of pairs of strains TA17^T–OD1^T, TA17^T–YOx^T, andYOx^T–OD1^T were 9.7 °C, 6 °C, and 8 °C, respectively, thus above the threshold value (5 °C) for species delineation (Sahin et al. 2010a, b). *Oxalicibacterium solurbis* strain MY14^T showed a DNA reassociation value of 5.2 °C when compared to strain *Oxalicibacterium flavum* TA17^T, which was most similar to MY14^T with respect to 16S rRNA and *cpn60* gene sequence similarity, thus confirming that it belongs to a different species.

Massilia: Results for DNA–DNA hybridization (DDH) were obtained for all type strains of the described species of the genus *Massilia* and showed a maximum of 60.6 %, a minimum of 13.0 %, and with a mean of 34.1 % in cross-species hybridization. The highest value (60.6 %) was observed between *M. oculi* CCUG 43427A^T versus *M. timonae* CCUG 45783^T (Kämpfer et al. 2012a). Elevated values (>50.0 %) were observed among *M. varians/M. consociata* and *M. oculi/M. timonae/M. aurea* (Kämpfer et al. 2011, 2012a). The lowest value (13.0 %) was observed for the hybridization between type strains of *M. aurea*, AP13^T, and *M. timonae*, DSM 16850^T (Gallego et al. 2006). An intergenus DDH of 20.0 % was observed between *M. flava* Y9^T and *Pseudoduganella violaceinigra* KCTC 12193^T (Wang et al. 2012). Interestingly, 62.0 % hybridization was observed between *M. alkalitolerans* CCUG 50882^T versus *M. varians*, non-type strain CCUG 48018. However, cross-hybridization between type strains of *M. alkalitolerans*, CCUG 50882^T, and *M. varians*, CCUG 35299^T, showed value of 43.0 %. Similar results (48.0 %) were obtained for DDH against two other non-type strains of *M. varians* CCUG 49054 and CCUG48700A (Kämpfer et al. 2008a). Intraspecific DDH experiments among five different *M. varians* strains (CCUG 35299^T, CCUG 48700A, CCUG 48018, CCUG 49054, CCUG 24677A) were performed by Kämpfer et al. (2008a). A maximum of 100 % were obtained, and most of comparisons reached values more than 84.0 %, except for strain CCUG 48700A, with values between 64.0 % and 76.0 %.

Telluria: DNA–DNA hybridization experiments conducted by Bowman and collaborators (1993) revealed 14 % DNA homology between the two known *Telluria* species (*T. mixta* strain ACM 1762^T and *T. chitinolytica* strain ACM 3522^T), confirming that they represent distinct species. *T. mixta* ACM

1762^T was also distinct from *Burkholderia* (former *Pseudomonas*) *gladioli* pv. *gladioli* ACM 1770^T (13 %), *Burkholderia* (former *Pseudomonas*) *cepacia* ACM 1771^T (13 %), and *Stenotrophomonas* (former *Xanthomonas* and *Pseudomonas*) *maltophilia* ACM 497^T (22 %) (Bowman et al. 1993).

MALDI-TOF Analysis

Collimonas spp. isolates were examined by MALDI-TOF analysis as well as Box-PCR-fingerprinting (Höppener-Ogawa et al. 2008b). They obtained consistent grouping of four clusters, which confirmed exactly the 16S rRNA gene similarity as well as phenotypic analyses.

Herbaspirillum lusitanum strains presented identical patterns when RFLP-16S rDNA fragments were digested with *Dde*I and *Cfo*I, while a different TP-RAPD profile was observed for each *Herbaspirillum* species (Valverde et al. 2003). A MALDI-TOF analysis has been applied to identify successfully different bacteria, including *Herbaspirillum* species, colonizing the human gut (Lagier et al. 2012a).

Ribotyping

Ribotype (*Eco*RI) patterns of *Oxalicibacterium flavum* strains TA 17^T and NS13 were highly similar, whereas *Oxalicibacterium horti* strain OD1^T and *Oxalicibacterium faecigallinarum* strain YOx^T differed from the two *O. flavum* strains and from each other, confirming the species delineation (Sahin et al. 2009a, b).

Genome Analysis

Despite the fact that many genomes have been sequenced, either completed or draft, the majority of the sequenced genomes within the *Oxalobacteraceae* family is from the genus *Herbaspirillum*. At least seven strains of different species and origin are reported.

Herbaspirillum and Noviherbaspirillum: The first complete *Herbaspirillum* genome sequenced was *H. seropedicae* strain SmR1/Z78 (Pedrosa et al. 2011), isolated from surface-sterilized roots of sorghum grown in Brazil (Baldani et al. 1986). The genome is composed of a circular chromosome of approximately 5.5 Mbp and a total of 4,804 genes. The genome sequence revealed that strain Z78 has the capacity to metabolize a wide range of carbon and nitrogen sources using four distinct terminal oxidases for energy production. It contains the *nif* genes involved in the nitrogen fixation process, NO_3^- and NO_2^- assimilation, and NO oxidation, but no denitrification genes were detected. The type I, type II, type III, type V, and type VI secretion systems and type IV *pili* were present suggesting a high potential to interact with host plants. In addition, genes coding for auxins and siderophore production, ACC deaminase activity and for hemagglutinins/hemolysins/adhesins were found which were proposed to play a role in plant growth promotion. The strain also contains genes coding for degradation of benzoate, benzamide, benzonitrile, hydroxybenzoate, and vanillate aromatic compounds that may confer both metabolic flexibility and defense against plant-derived toxic chemicals (Pedrosa et al. 2011).

Draft genome sequences from other *Herbaspirillum* species have been published recently. For example, a draft genome from *H. lusitanum* strain P6-16, isolated from common bean nodule, has an estimated size of 4.9 Mb (37 scaffolds) with 5,240 open reading frames covering 84 % of the chromosome, 38 tRNAs, and a single 16S-23S-5S rRNA operon (Weiss et al. 2012). The authors identified many genes similar to the *H. seropedicae* strain Z67 but the type III secretion system and the nitrogen fixation (*nif*) genes were absent, although the ability to fix nitrogen in nitrogen-free semisolid medium was mentioned in the species description (Valverde et al. 2003). An interesting finding was the presence of a gene coding for the ribulose-1,5-biphosphate carboxylase/oxygenase (RUBISCO), although the exactly gene function in this strain remains unknown.

Another draft genome was recently published for *H. frisingense* GSF30 by Straub et al. (2013a), a diazotrophic endophyte isolated from the energy plant *Miscanthus sinensis*, grown in Freising, Germany (Kirchhof et al. 2001). 93 contigs were assembled with a total length of 5.4 Mb, which is in the lower range for an endophyte genome. The *H. frisingense* GSF30 genome encodes, for example, the type I, type II, type IV, type VI, Sec-SRP, and the Tat-secretion system, similar as in, e.g., in *H. seropedicae* SmR1. Like many other beneficial endophytic bacteria, but in contrast to other sequenced *Herbaspirillum* genomes, it lacks the type III secretion system.

A report related to one-scaffold draft genome from the *H. huttiense* subsp. *putei* strain 7-2T (IAM 15032), isolated from well water, was published recently (Souza et al. 2013). The estimated genome size is 5.7 Mb with 5,317 open reading frames (covering 86 % chromosome), 49tRNAs, and 2 16S-23S-5S operons. No nitrogen fixation genes were found although genes for nitrate/nitrite metabolism were observed. Genes coding for the Embden–Meyerhof–Parnas, Entner–Doudoroff, and TCA pathways were present. Only one potential pathway for trehalose biosynthesis (*otsA* and *otsB*) was detected. No type III secretion system was observed in contrast to the presence of type I, II, and IV secretion systems. Similar to *H. rubrisubalbicans*, a gene cluster for cellulose biosynthesis and degradation was detected in this strain. Two strains (Os34 and Os45) belonging to *H. seropedicae* and considered pathogenic due to their ability to inhibit growth of rice seedlings and induce a hypersensitive response in tobacco leaves had their draft genome announced (Ye et al. 2012; Zhu et al. 2012). The strain Os34 contains 6.15 Mb and a total of 5,309 coding sequences, while the genome of the strain Os45 was estimated to 5.63 Mb with a total of 4,978 CDs. Both strains have 3 rRNA operons and 73 and 75 tRNAs, respectively. Similar to *H. seropedicae* strain Z78 both strains present genes involved in nitrogen fixation, IAA and siderophore production, and ACC deaminase activity. In addition, they also contain genes for the type III, type VI, and type IV pili. A draft

genome from a *Herbaspirillum* sp. strain GW103, isolated from the rhizosphere soil of the reed *Phragmites australis*, was also announced in 2012 (Lee et al. 2012). It contains approximately 5.04 Mb size and a total of 4,665 CDs, 56 tRNAs, and 6 rRNAs (two 5S, two 16S, and two 23S). No plasmids were detected. The strain also presents genes coding for the IAA and siderophore production and cellulolytic enzymes as well as hemagglutinins and hemolysins like those found for the *H. seropedicae* Z78. Other two draft genomes of *Herbaspirillum* sp. strains (CF444 and YR522), isolated from the endosphere of *Populus deltoids*, were announced and presents 5.59 Mbs (5,004 CDs) and 5.13 Mbs (4,949 CDs), respectively (Brown et al. 2012). A draft genome sequence of a *Herbaspirillum massiliense* (species validated after preparing the chapter and therefore was not included in the Table) strain isolated from a fecal flora of a healthy Senegalese patient contains approximately 4.18 Mb chromosome size and a total of 3,847 protein-coding sequences and 54 RNA genes including 3 rRNA genes (Lagier et al. 2012b). No sequenced genomes for the *Noviherbaspirillum* species are available at present.

Collimonas: The genome of *Collimonas fungivorans* Ter331 is fully sequenced and annotated (http://www.ncbi.nlm.nih.gov/genome/1392). The genome size is 5.19 Mb, and coding sequences for 4,432 proteins and 91 RNA genes were identified. There is also evidence for one plasmid. The genome contents of four *Collimonas* strains (Ter14, Ter6, Ter91, and Ter10) from three *Collimonas* species, *C. fungivorans*, *C. pratensis*, and *C. arenae*, were analyzed by hybridization to an microarray based on the reference genome of *C. fungivorans* Ter331 (Mela et al. 2012). The unique genes of strain Ter331 were in part on the plasmid. In addition, 136 genes could be identified as common in all tested *Collimonas* strains, but absent from the genomes of other members of the family *Oxalobacteraceae*. Predicted products of these "*Collimonas* core" genes include lytic, secreted enzymes such as chitinases, peptidases, nucleases, and phosphatases with a putative role in mycophagy and weathering (Mela et al. 2012).

Duganella–Pseudoduganella: There are two draft genome sequences available for *Duganella zoogloeoides* and *Pseudoduganella violaceinigra*. The draft assembly of the whole genome shotgun sequences and automatic prokaryotic genome annotation of *Duganella zoogloeoides* ATCC25935 by NCBI was released in 2013 (http://www.ncbi.nlm.nih.gov/genome/15561). The draft genome assembly of the *Pseudoduganella violaceinigra* DSM 15887 by the DOE Joint Genome Institute has after the primary assembly at present 41 scaffolds and 48 contigs (http://www.ncbi.nlm.nih.gov/assembly/60191).

Janthinobacterium: Four *Janthinobacterium* genome projects are available (under assembly and as complete genome). Antimicrobial effects related with water-insoluble pigment violacein, water-living gene, UV stress survival environments, and cold-adaptive properties are among the phenotypic trait of great interest in these genome projects. The general features of the genomes are *Janthinobacterium* sp. Marseille (4.11 Mb size, 3,697 predicted genes, 2,510 assigned functions, 6 rRNA operons, 46 tRNA.), *Janthinobacterium* sp. strain CG3 (6.26 Mb size, 5,352 predicted genes, 4,356 assigned functions, 15 rRNA operons, 81 tRNA), *Janthinobacterium lividum* strain PAMC 25724 (4.98 Mb, a total of 4,332 predicted genes, 3,538 assigned functions, 80 tRNA, 21 rRNA), and *Janthinobacterium* sp. strain HH01 (7.11 Mb size, a total of 5,098 predicted genes, 4,877 assigned functions, 84 tRNA, 20 rRNA). For more details, see (Audic et al. 2007; Smith et al. 2013; Kim et al. 2012; Hornung et al. 2013).

Herminiimonas: The only species of the genus *Herminiimonas* with whole genome sequenced is *H. saxobsidens* strain ASM2612v1 that is able to perform detoxification reaction, converting arsenite (As^{III}) in less toxic and less mobile form arsenate (As^{V}). The strain ASM2612v1 contains 3,424,307 bp, a total of 3,333 predicted genes, 6 rRNA operons, and 45 tRNA. As expected, the genome had shown biochemical machinery to arsenic-related stress adaptation involved in coupled redox reactions, efflux, chemotaxis, oxidative stress, DNA recombination, and repair and motility toward arsenic, biofilm expression, and metalloid scavenging by EPS (Muller et al. 2007).

Massilia: Only four genomes of the genus *Massilia* are available with draft status, three of them are genome sequences from strains of well-characterized species (*M. timonae*, *M. alkalitolerans*, and *M. niastensis*), while the fourth draft genome sequence is of *Massilia* sp. strain B08, an *Arabidopsis thaliana* rhizosphere/endosphere isolate. For *M. timonae*, a draft genome sequence is available for an isolate of the Human Microbiome Project. Interestingly, two other projects are included in NCBI BioProject: one for a plant-associated isolate (BioProject accession PRJNA187940) and other for an isolate from an immunocompromised patient with cerebellar lesions (BioProject accessions PRJNA187940); in both projects, no sequence data are available yet. The genome sequences for *M. alkalitolerans* (PRJNA163031) and *M. niastensis* (PRJNA200436) are part of the Genomic Encyclopedia of Bacteria and Archaea (GEBA), an initiative to fill phylogenetic gaps, generating reference genomes for every major and minor group of bacteria and archaea (www.jgi.doe.gov/programs/GEBA), reinforcing the need for an effort to fill the gap in this field for *Massilia* genus.

Oxalobacter: *Oxalobacter formigenes* strains can be divided into two main groups (Allison et al. 1985). Almost complete genome sequences of one strain of each group, OXCC13 and HOxBLS for groups 1 and 2, respectively, have been determined as part of the Human Microbiome Project (http://www.hmpdacc.org). Both strains have relatively small genomes containing between 2.4 and 2.5 Mb and 2,121 (for OXCC13) and 2,329 (for HOxBLS) genes. The functional comparison of the two genomes revealed few differences between strains OXCC13 and HOxBLS, both carrying genes involved in several signaling pathways, stress response, and phages (Knight et al. 2013). Nevertheless, the OXCC13 genome contains an apparent operon for the production of type 1 pili, which might be involved in adhesion to surfaces or to other cells. These genes are absent in the HOxBLS genome (Knight et al. 2013). Strain OXCC13 harbors a 5-nitroimidazole antibiotic resistance gene and is resistant to nitrofurantoin, whereas strain HOxBLS is sensitive to this antibiotic and lacks this gene (Knight et al. 2013).

Phenotypic Analyses

The main features of members of *Oxalobacteraceae* are listed in Table 35.1. The morphological and physiological characteristics within some genera present only very small differences making molecular analysis absolutely required to identify the species, while in other cases, only few aspects are sufficient to identify the species.

Herbaspirillum, Baldani et al. 1986. Baldani et al. 1996 Emend. Carro et al. 2012 Emend. Lin et al. 2013

Herbaspirillum (Her.ba.spi'ri.llum. L. fem. n. *herba*, an herb, grass, seed-bearing plant that does not produce persistent woody tissue; N.L. dim. neut. n. *spirillum* (from L. n. *spira*, a coil, spiral), small spiral; N.L. neut. n. *Herbaspirillum*, small, spiral-shaped bacteria from herbaceous, seed-bearing plants).

Cells are gram-negative; they are aerobic, curved, or slightly curved rods, sometimes spiral with a diameter varying from 0.3 to 0.8 μm. Cells lengths vary with the species and culture medium from 1.4 to 5.0 μm. They are motile, using one to five flagella at one or both poles. Oxidase and catalase activity is present. Nitrate is reduced by some species but no denitrification was detected. The species have a strictly respiratory type of metabolism; however, one species possesses a facultative hydrogen autotrophic system. Sugars are oxidized but not fermented. Optimal growth temperature is between 20 °C and 37 °C, although 40 °C is tolerated by some species. Optimum pH for growth is between 5 and 8. Nitrogenase activity occurs only in three species (*H. seropedicae*, *H. rubrisubalbicans*, and *H. frisingense*) only under microaerobic conditions, although the nifH/nifD genes, required for nitrogen fixation, have been detected in two non-nitrogen-fixing species (*H. lusitanum* and *H. huttiense subsp. putei*). The favored carbon sources are organic salts such as malate and succinate. Other carbon sources like glycerol, mannitol, D-glucose, and D-fructose are used by the majority of the species, except for *H. autotrophicum* and *H. chlorophenolicum*. *H. chlorophenolicum* is the only species able to grow in phenol and 4-chlorophenol, while *H. hiltneri* uses L-phenylalanine as a carbon source. Sucrose cannot be used as a carbon source by any of the species. Other carbon sources summarized in Table 35.2 have been used to separate species; but with few exceptions, the identification based only on phenotypic characteristics may not be sufficient and requires additional molecular methods. The use of the nitrogen-free JNFb semisolid medium allows the enrichment and isolation of the nitrogen-fixing species. Major cellular fatty acids are C16:0, C16:1 ω7c, and C18:1 ω7c. Ubiquinone 8 is the sole respiratory quinone. DNA G+C content varied from 57.9 to 65 mol%. This genus is most closely related to the genera *Glaciimonas*, *Collimonas*, *Herminiimonas*, and *Oxalicibacterium* of the family *Oxalobacteraceae*, order *Burkholderiales*, subclass *Betaproteobacteria*. The type species is *H. seropedicae*, and the type strain is Z67^T (=ATCC 35892 = CCUG 24564 = DSM 6445 = JCM 21448 = LMG 6513 = NBRC 102524). The genus contains 10 other species: *H. rubrisubalbicans* (red-whitish, referring to the symptoms of mottled stripe disease), *H. frisingense* (pertaining to Frisinga, now known as Freising, Germany, town where the species was first isolated), *H. lusitanum* (Lusitania, the Roman name of Portugal, where the strains reported in this study were isolated), *H. chlorophenolicum* (relating to chlorophenols), *H. autotrophicum* (self-nursing), *H. hiltneri* (*in honor of Professor Hiltner, who coined the rhizosphere concept in 1904*), *H. rhizosphaerae* (of the rhizosphere), *H. aquaticum* (living in water, aquatic.), *H. huttiense subsp. huttiense* (pertaining to Lower Hutt, New Zealand), and *H. huttiense subsp. putei* (of a well). The type strains and additional characteristics for these species are listed in Table 35.2.

Noviherbaspirillum, Lin et al. 2013

Noviherbaspirillum (No.vi.her.ba.spi'ril.lum. L. adj. novus, new; N.L. neut. n. *Herbaspirillum*, a bacterial genus name; N.L. neut. n. *Noviherbaspirillum*, new genus separated from *Herbaspirillum*).

Cells are gram-negative, slightly or short curved rods, 1.0–1.3 μm in width and 1.4–4.5 μm in length. They are motile using one polar flagellum. Catalase activity is positive although oxidase is variable. Nitrate is reduced to nitrogen but not to nitrite. The species have a respiratory type of metabolism; however, one species shows a facultative anaerobic system. Optimal growth temperature is between 14 °C and 30 °C, although few species tolerate the temperature of −5 °C to 40 °C. Optimum pH for growth is between 6 and 8. The species tolerate between 1.5 % and 2.5 % NaCl. Cells are unable to fix atmospheric N_2 under microaerobic conditions. The use of carbon sources is variable. Most of the species use malate, citrate, adipate, and gluconate. Glucose, L-arabinose, mannitol, mannose, *N*-acetylglucosamine, maltose, caprate, and phenylacetate are not used for growth. The species *N. malthae* uses Tween 80, β-hydroxybutyric acid, and L-proline (API 20NE system), while the *N. psychrotolerans* uses glycerol, DL-arabinose, D-xylose, D-galactose, D-fructose, D-lyxose, and D-fucose as sole carbon sources. Other carbon sources are summarized in Table 35.1 and have been used to separate species. With few exceptions, the identification based only on phenotypic characteristics may not be sufficient and requires additional chemotaxonomic and molecular methods. The polyamines putrescine (Put) and 2-hydroxylputrescine were predominant in the species. Major cellular fatty acids are C16:0, C16:1ω7c/C16:ω6c, and C18:1ω7c/C18:1ω6c. The polar lipid profile constitutes diphosphatidylglycerol (DPG), phosphatidylethanolamine (PE), phosphatidylglycerol (PG), phosphatidylcholine (PC), one unidentified glycolipid (GL), one unidentified aminophospholipid (APL), and five unidentified lipids (L1–L5). The predominant quinone is ubiquinone (Q-8). DNA G+C content varied from 60.4 to 63.4 mol%. This genus is most closely related to the genera *Herbaspirillum*, *Oxalicibacterium*,

Nd not determined, positive (+), negative (–)

Duganella, *Undibacterium*, *and Collimonas* of the family *Oxalobacteraceae*, order *Burkholderiales*, and subclass *Betaproteobacteria*. The type species is *Noviherbaspirillum malthae* (mal.tha'e. L. fem. n. maltha, a kind of thick petroleum; L. gen. n. malthae, of petroleum because the type strain was isolated from an oil-contaminated site). The type strain of the *N. malthae* is CC-AFH3^T (=BCRC 80516^T = JCM 18414^T) isolated from the oil-contaminated site at Kaohsiung city in Taiwan. The genus contains four other species reclassified from the genus *Herbaspirillum*: *N. canariense* (isolated from Canary Islands), *N. aurantiacum* (orange-colored), *N. soli* (from soil), and *N. psychrotolerans* (cold-tolerating strain). The type strains and additional characteristics for these species are listed in Table 35.3.

Collimonas, De Boer et al. 2004

Collimonas (Col.li.mo'nas. L. masc. n. *collis* hill; Gr. n. *monas* a unit, monad; N.L. fem. n. *Collimonas* cell from the hill).

Cells are gram-negative; they are strictly aerobic, straight, or slightly curved 0.3–0.5 × 1.0–2.0 μm in size. They occur singly and possess flagella (mostly one to three polar, but in some cases several lateral ones). When cultured in liquid media, they harbor pili. Oxidase reaction is positive, and the catalase activity is negative to weakly positive. Major cellular fatty acids are $C_{16:0}$ and $C_{16:1}$ ω7c. DNA G + C content is 57–62 mol%. This genus is most closely related to the genera *Glaciimonas*, *Herbaspirillum*, and *Janthinobacterium* in the family *Oxalobacteraceae*, order *Burkholderiales*, and subclass *Betaproteobacteria*. Collimonads are characterized by their special feature of mycophagous activity (De Boer et al. 2001). The mycophagous phenotype of collimonads was explained as an adaptation to life under conditions of limited nutrient availability (Leveau et al. 2010). Optimal growth temperature is between 20 °C and 30 °C; 35 °C are tolerated. Optimum pH for growth is 6.5. Cells are able to hydrolyze colloidal chitin and milk proteins, but not lichenan or cellulose. Halo formation of colloidal chitin is completely inhibited in agar containing glucose or TSB. The *nif* genes required for nitrogen fixation are not present. After 3 days incubation at 20 °C on tenfold diluted TSB agar, the type strain forms flat, glossy, turbid, and whitish colonies of 3–7 mm diameter with a layered structure (colony type I; De Boer et al. 2004). In purified sand, cells proliferate upon introduction of living fungal hyphae of various species of soil fungi. A wide range of sugars, alcohols, organic acids, and amino acids can be metabolized. DNA G + C content is 57–59 mol%. The type species is *Collimonas fungivorans* (fun.gi.vo'rans. L. n. *fungus* mold, mushroom, fungus; L. part. adj. *vorans* devouring, eating; N.L. part adj. *fungivorans* fungus-eating). The type strain is Ter6^T (=NCCB 100033^T = LMG 21973^T). Further reference strains are Ter166, Ter300, and Ter330. *Collimonas arenae* (isolated from sandy soil) and *Collimonas pratensis* (isolated from grassland) are described as further species in this genus (Höppener-Ogawa et al. 2008b). Details of the described species are given in Table 35.4.

Glaciimonas, Zhang et al. 2011

Glaciimonas (Gla.ci.i.mo'nas. L. fem. n. *glacies* ice: L. n. *monas* a unit, monad; N.L. fem. n. *Glaciimonas* a cell from the glacier).

The cells are staining gram-negative; they are rod-shaped and nonmotile. They are able to grow under aerobic and microaerobic conditions and unable to grow under anaerobic conditions. The cells are oxidase- and catalase-positive and negative for nitrate reduction. The predominant cellular fatty acids are $C_{16:0}$ and $C_{18:1}$ ω7c and summed feature 3 ($C_{16:1}$ ω7c and/or iso-$C_{15:0}$ 2-OH). The lipid profile showed the presence of phosphatidylethanolamine (PE), diphosphatidylglycerol (DPG), and phosphatidylglycerol (PG). The major respiratory quinone is ubiquinone 8 (UQ-8). The most closely related genus phylogenetically is *Collimonas*. The type species is *Glaciimonas immobilis* (im.mo'bi.lis. L. fem. adj. *immobilis* motionless). The type strain is Cr9-30^T (=DSM 23240^T = LMG 25547^T), isolated from alpine glacier cryonite collected from the Tiefenbachferner glacier in the Oetztaler Alps, Tyrol, Austria (Zhang et al. 2011). The DNA G+C content of the strain Cr9-30^T is 51.0 mol%. Strain Cr9-12 (=DSM 22814^T), isolated from the same source, is a second isolate. The following properties are observed. Cells are 0.9–1.0 × 1.1–1.9 μm in size. Flagella or pili are absent. Colonies on R2A agar are white, round, convex, and smooth with entire margins; in addition, slime is produced. Growth is good in R2A medium and on R2A agar plates at 1–20 °C. There is no growth at 25 °C on agar plates and weak in liquid culture. Growth on R2A agar plates is optimal in the presence of 0–1 % (w/v) NaCl and at pH 6–8. Cells are negative for indole and H_2S production, hydrolysis of urease, aesculin, gelatin milk proteins, and starch. Cells are also negative for arginine dihydrolase, lysine dihydrolase, and ornithine dihydrolase. The other species of the genus is *G. singularis* (*sin.gu.la'ris. L. fem. adj. singularis* alone of this kind, singular, referring to the different characteristics of this organism in relation to those of *G. immobilis*). It was isolated from water collected in uranium mine of Poco das Cobras (Urgeirica mine), central Portugal (Chung et al. 2013). For phenotypic details, see Table 35.5.

Janthinobacterium, De Ley et al. 1978

Janthinobacterium (*Jan.thin.o.bac.te'ri.um.* L. adj. *janthinus*, violet–blue, violet; L. neut. n. *bacterium*, rod or staff; N.L. neut. n. *Janthinobacterium*, a violet-colored rod).

Bacteria of the genus are rod-shaped, gram-negative motile bacteria measuring 0.8–1.5 μm (width) and to 1.8–6 μm (length). Colonies produce violet color by the presence of violacein pigment. Non-pigmented colonies on PAF medium

are 3–4 mm in diameter, translucent buff color, and circular, slightly convex, smooth, and slightly mucoid. The bacteria grow strictly aerobic, chemoorganotrophic, with optimum growth temperature at 25–30 °C; they do not grow at 2 or 37 °C. No growth occurs below pH 5 or in media containing 2–9 % NaCl. Negative for production of gas from nitrate, production of indole from tryptophan, fermentation of glucose, presence of arginine dihydrolase, presence of urease, β-galactosidase activity, assimilation of glucose, gelatin hydrolysis and assimilation of gluconate, and positive for assimilation of glucose, malate, mannose, and mannitol. Related to carbon use, the genus was positive for glycerol, ribose, D-glucose, D-fructose, D-mannose, inositol, mannitol, saccharose, and D-arabitol and negative for erythritol, L-xylose, adonitol, methyl P-xyloside, L-sorbose, dulcitol, methyl α-D-mannoside, methyl α-D-glucoside, amygdalin, aesculin, lactose, melibiose, melezitose, amidon, glycogen, D-turanose, D-tagatose, D-fucose, L-arabitol, gluconate, and 5-ketogluconate. *Janthinobacterium* major phospholipids are phosphatidylethanolamine, phosphatidylglycerol, and diphosphatidylglycerol, as well as Q-8 as respiratory lipoquinone. Characteristic fatty acid profile consists of $C_{10:0}$ 3-OH, $C_{12:0}$, $C_{12:0}$ 2-OH, $C_{14:0}$, $C_{16:0}$, $C_{16:1}$ω7c, $C_{17:0}$ cyclo, and $C_{18:1}$ω7c. The polyamine major compounds are 2-hydroxyputrescine and putrescine. The G+C range (mol %) is 64.2–66.1. The type species of the genus is *Janthinobacterium lividum*, and type strain is ATCC 12473^T (= CCUG 2344 = CIP 103349 = DSM 1522 = HAMBI 1919 = JCM 9043 = LMG 2892 = NCTC 9796 = VKM B-1223) (De Ley et al. 1978). The second species of the genus is *J. agaricidamnosum*, the causal agent of *A. bisporus* disease, type strain W1r3 (= CCUG 43140 = CIP 106332 = DSM 9628 = JCM 21444 = NBRC 102515 = NCPPB 3945) (Lincoln et al. 1999). The type strains and additional characteristics for these species are listed in *Table 35.6*.

Undibacterium, Kämpfer et al. 2007 Emend. Eder et al. 2011

Undibacterium (Un'di.bac.te'ri.um. L. n. *unda*, water; L. neut. n. *bacterium*, rod; N.L. neut. n. *Undibacterium*, a rod of water).

Common phenotypic traits shared by members of the genus are nonspore-forming, gram-negative, aerobic metabolism, and mesophilic growth. Cells are motile by one or more polar flagella, and they have pili. Temperature for growth ranged mainly between 10 °C and 30 °C, with few species growing at 4 °C and 37 °C. The bacteria of the genus are predominantly isolated from aquatic environments; they produce circular, entire, convex, and creamy- to yellow-colored colonies which can reach the size of 2.0 mm on R_2A agar. The bacteria are positive for oxidase, leucine arylamidase, acid phosphatase, alkaline phosphatase, and naphthol-AS-BI-phosphohydrolase, but negative for indole production, glucose fermentation, arginine dihydrolase, β-galactosidase (PNG), lipase, α-chymotrypsin, α-galactosidase, β-galactosidase, β-glucuronidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, and α-fucosidase. None of the strains assimilated L-arabinose, D-mannitol, capric acid, adipic acid, malic acid, trisodium citrate, phenylacetic acid, L-rhamnose, inositol, itaconic acid, sodium malonate, potassium 5-ketogluconate, glycogen, 3-hydroxybenzoic acid,

L-serine, salicin, melibiose, L-fucose, D-sorbitol, potassium 2-ketogluconate, or 4-hydroxybenzoic acid. Chemotaxonomic common data include putrescine and 2-hydroxyputrescine as major polyamines and ubiquinone Q-8 as the major quinone. The polar lipid profile consists of the predominant compound phosphatidylethanolamine with moderate amounts of diphosphatidylglycerol and phosphatidylglycerol. The major fatty acids are $C_{16:0}$, summed feature 3 ($C_{16:1}\omega7c/C_{15:0}$ iso 2-OH), and $C_{18:1}\omega7c$. $C_{10:0}$ 3-OH is the only hydroxylated fatty acid detected; $C_{17:0}$ cyclo is absent. Bacterial from the genus *Undibacterium* are sensitive to standard laboratory salt concentration being nonreactive in API or Biolog tests. Reduction of the salt or substrate concentration allows positive reaction and phenotypic pattern analysis. The G+C content for the genus ranges from 50.6 to 57.4 mol%. The type species of the genus is *Undibacterium pigrum*, type strain CCUG 49009 (= CIP 109318 = DSM 19792) (Kämpfer et al. 2007). The genus comprises other five species: *U. oligocarboniphilum* (Eder et al. 2011), *U. parvum* (Eder et al. 2011), *U. terreum* (Liu et al. 2013), *U. seohonense* (Kim et al. 2014), and *U. jejuense* (Kim et al. 2014). The type strains and additional characteristics for these species are listed in *Table 35.7*.

a unit, monad; N. L. fem. n. *Herminiimonas*, a monad isolated from mineral water coming from the Portuguese mountain *Mons Herminius* that is now known as the Serra da Estrela).

Bacteria of this genus form translucent or pale white, cream, or yellowish punctiformes to 3 mm diameter colonies. Common phenotypic traits shared by members of the genus are the rod shape, negative gram staining, motile, and nonspore-forming. The bacteria have an aerobic metabolism, mesophylic growth, and are oxidase and catalase-positive. They utilize short-chain organic acids and a few amino acids as carbon and energy sources and have a low ability to utilize carbohydrates. The optimum growth temperature ranged from 25 °C to 30 °C and optimum growth pH ranged from 7.0 to 8.5 among the species. *Herminiimonas* chemotaxonomic features include putrescine and 2-hydroxyputrescine as major polyamines; fatty acids straight-chained with major phospholipids as phosphatidylethanolamine, phosphatidylglycerol, and diphosphatidylglycerol; and ubiquinone Q-8 as the major respiratory quinone. All type strains of the genus *Herminiimonas* harbor fatty acid profiles composed of $C_{17:0}$ cyclo, summed feature 3 ($C_{16:1}$ω7c and/or iso-$C_{15:0}$ 2-OH), and $C_{16:0}$ as the major components. They are characterized by the absence of dodecanoic fatty acids that differ notably from those of other members of the *Oxalobacteraceae* family. The G+C content of the DNA is 52.2. Currently, the genus comprises six validly published species. The type species of the genus is *Herminiimonas fonticola*, and the type strain is S-94^T (= CCUG 52513 = CIP 108398 = LMG 22527) which was isolated from mineral water. The other species are *H. aquatilis* (Kämpfer et al. 2006), *H. arsenicoxydans* (Muller et al. 2006), *H. saxobsidens* (Lang et al. 2007), *H. glaciei* (Loveland-Curtze et al. 2009), and *H. contaminans* (Kämpfer et al. 2013). Most of these isolates were obtained directly from aquatic habitat, exception for lichen–rock interface (*H. saxobsidens*). Details for these species are presented in *Table 35.8*.

Oxalicibacterium, Tamer et al. 2002

Oxalicibacterium (*O*.xa.li.ci.bac.te'ri.um. N.L. *acidum* oxalicum, oxalic acid; gr. N. Bakterion, a small rod; N.L. neut. N. *Oxalicibacterium*, oxalic acid utilizing rod).

Bacteria from the genus *Oxalicibacterium* are small gram-negative, non-sporulating chemoorganoheterotrophic rods, which are motile by 1–3 polar flagella. They have a strictly

aerobic metabolism and use a limited number of organic acids. No autotrophic growth occurs with either H_2 or formate as an electron donor. The bacteria are catalase- and oxidase-positive. Poly-β-hydroxybutyrate is accumulated. No growth occurs on phenol, sugars, alcohols, and C_1 compounds. The main fatty acids are $C_{16:0}$ (14–24 %), summed feature 3 ($C_{16:1}\omega7c/C_{15:0}$ iso 2OH; 11.9–37.3 %), and moderate amounts of $C_{18:0}\omega7c$ (4.2–17 %). $C_{10:0}$ 3OH was the only hydroxylated fatty acid detected (Sahin et al. 2009a, b). The G+C content of the DNA varied from 55.6 to 64 mol%. The type species of the genus is *Oxalicibacterium flavum* (strain TA17^T = NEU98^T = LMG 21571^T), isolated by enrichment in synthetic medium (Aragno and Schlegel 1981) containing potassium oxalate as sole carbon and energy source, inoculated with litter of oxalate-producing plants from the genus *Mesembryanthemum* in the region of Izmir in Turkey. Two additional species, *Oxalicibacterium horti* and *O. faecigallinarum* were described based on two isolates, obtained by enrichment in oxalate-containing minimal medium, respectively, from garden soil (strain OD1^T = DSM

21640^T = NBRC 13594^T) and from chicken dung (YOx^T = DSM 21641^T = CCM 2767^T) (Sahin et al. 2009a, b). A fourth species of the genus named *Oxalicibacterium solurbis* (MY14^T = NBRC 102665^T = CCM 7664^T) was isolated from urban soil using a membrane-filter enrichment technique (Sahin et al. 2010a, b). *O. horti* can be distinguished from other *Oxalicibacterium* species by the presence of $C_{13:0}$ (0.5 %), *O. faecigallinarum* by the presence of $C_{18:0}\omega6c$ (11.1 %), and *O. solurbis* (MY14^T) by the lack of $C_{14:0}$ and summed feature 7 ($C_{18:1}\omega7c$, 12t/9t) from the fatty acid profiles. The type strains and additional characteristics for these species are listed in *Table 35.9*.

Oxalobacter, Allison et al. 1985

Oxalobacter (Ox.al.o.bac'ter. Gr. N. *oxal*-pertaining to oxalate; M.L.n. *bacter* the masculine form of the Gr. neut. n. *bactrum* a rod).

Oxalobacter spp. are anaerobic bacteria that have been isolated from the gastrointestinal tract of man and animals and from anoxic freshwater sediments. *Oxalobacter* cells are rod-shaped, gram-negative bacteria (0.4–0.6 × 1.2–2.5 μm) with rounded ends, occurring as single cells, in pairs or in chains. Often, the cells are curved. No endospores are formed. The motility is variable with 0–2 polar flagella. G+C content of DNA is 48.0–51.6 mol%. The bacteria are strictly anaerobic, chemoorganotrophic growth. Oxalate is decarboxylated to formate and used as major carbon and energy source. A small amount of acetate (0.5–2 mM) is also required for growth (Cornick and Allison 1996; Dehning and Schink 1989). Anaerobic growth occurs under a gas phase of CO_2 in a defined carbonate–bicarbonate-buffered medium that contains minerals, oxalate, and acetate. Growth is improved by the addition of yeast extract to the medium. Growth of some, and possibly all, intestinal and sediment strains requires acetate. Growth occurs at temperatures in the range of 14–45 °C. None of a wide variety of substances can replace oxalate as growth substrate. The type species is *Oxalobacter formigenes*. The type strain DSM 4420^T (= ATCC 35274^T, = BA-2^T, = CCUG 52237^T, = CIP 106513^T, = DSM 4420^T, = OxB^T) was isolated from sheep rumen by enrichment culture techniques (Dawson et al. 1980a, b; Allison et al. 1985). *O. formigenes* has an optimal growth temperature of 37 °C. Cells are rod-shaped and often curved, and occasionally chains are observed as spiral filaments. No flagella were observed (Allison et al. 1985). *O. formigenes* plays a role in the destruction of oxalate in the gastrointestinal tract, where it decarboxylates oxalate, generating formate and CO_2 (Anantharam et al. 1989). An oxalate^{2-}/formate$^-$ antiporter mediates simultaneous substrate import and product export accompanied by the net-extrusion of a proton (Anantharam et al. 1989). A lack of colonization by this species is believed to be a risk factor for the development of calcium oxalate disease (Knight et al. 2013). Based on cellular fatty acid composition, *O. formigenes* strains can be divided in two main groups. Group 1 strains are characterized by a predominant cyclic 17 carbon fatty acid, while in group 2 strains, a cyclic 19 carbon fatty acid is predominant (Allison et al. 1985). The second species of this genus is *Oxalobacter vibrioformis*, and the type strain (DSM 5502^T = WoOx3^T) was isolated from anoxic freshwater sediments. It is able to use oxamate as a carbon and energy source after deamination (Dehning and Schink 1989, 1990). The type strains and additional characteristics for these species are listed in *Table 35.10*.

Duganella, Hiraishi et al. 1997

Duganella (Du.ga.nel'la. M.L. dim. ending *-ella*; M.L. fem. n. *Duganella*, named after P. R. Dugan, an American microbiologist, who isolated the organism).

Cells are gram-negative, nonspore-forming, motile rods. The cells are aerobic chemoorganotrophs having a strictly respiratory type of metabolism with oxygen as the terminal electron acceptor. No chemolithotrophic growth occurs with molecular hydrogen. Amorphous or fingerlike flocculent growth occurs in liquid media. The organism is mesophilic and prefers neutral pH. Growth is good on ordinary nutrient media and also occurs in mineral media supplemented with simple organic compounds as carbon and energy sources. Catalase and oxidase are present. Acid from glucose and other carbohydrates is produced oxidatively. The cells harbor amylase, gelatinase, and urease. Major components of the cellular fatty acids are $C_{16:0}$ and 3-OH-$C_{10:0}$, and 3-OH-$C_{10:0}$ is the major hydroxyl-fatty acid. The predominant polar lipids are phosphatidylglycerol (PG) and phosphatidylethanolamine (PE). Ubiquinone 8 is the sole respiratory quinone. Putrescine and hydroxyputrescine are intracellular polyamines. The G+C content of the genomic DNA is 54.9–64 mol%. Members of the genera *Massilia* and *Telluria* are the closest phylogenetic neighbors. The type species is *Duganella zoogloeoides* (zo.o.gloe.o'i.des. M.L. bacterial genus name *Zoogloea*; Gr. suf. *-oides*, similar to; M.L. adj. *zoogloeoides*, similar to *Zoogloea*). The characters are the same as described for the genus. Cells are straight or slightly curved rods, 0.6–0.8 um wide, and 1.8–3.0 um long and motile by means of single polar flagella. The type strain is IAM 12670^T (=ATCC 25935^T = P. R. Dugan 115) (Hiraishi et al. 1997). The genus is constituted by three other species detailed in *Table 35.11*: *Duganella phyllosphaerae* (of the phyllosphere), *D. sacchari* (isolated from sugarcane), and *D. radicis* (of a root, isolated from sugarcane) (Kämpfer et al. 2012b; Madhaiyan et al. 2013). The type strains and additional characteristics for these species are listed in *Table 35.11*.

Pseudoduganella, Kämpfer et al. 2012

Pseudoduganella (Pseu.do.du.ga.nel'la. Gr. adj. *pseudes* false; N. L. fem. n. *Duganella* a bacterial genus name; N.L. fem. n. *Pseudoduganella* false *Duganella*).

Cells are gram-negative, obligate aerobic, and nonspore-forming. They are rod-shaped with flagella, about 0.4–0.6 × 0.8–1.0 μm in size, and occur singly. Violet-pigmented colonies are formed on agar media, like on R_2A agar or TSA. The major ubiquinone is Q-8, and the predominant polar lipids are phosphatidylglycerol and phosphatidylethanolamine. In addition, minor amounts of phosphatidylserine, an unidentified aminolipid and diphosphatidylglycerol are found. Major cellular fatty acids are $C_{16:0}$, $C_{16:1}$ ω7c, and $C_{15:0}$ iso 2OH (detected as summed feature). Hydroxylated fatty acids are $C_{12:0}$ 3-OH, $C_{10:0}$ 3-OH, and $C_{12:0}$ 2-OH. The optimum growth temperature is 28–30 °C, and the optimum pH for growth is 7.2. The DNA G + C content is 62.8 mol%. The type species is *Pseudoduganella violaceinigra* (vio.la.ce.i.ni'gra. L. adj. *violaceus* violet; L. adj. *niger-gra-grum*, black; N. L. fem. adj. *violaceinigra* violet-black, after the color of the colonies). Basonym: *Duganella violaceinigra* Li et al. (2004). The type strain is YIM 31327^T (=CIP 108077^T = KCTC 12193^T = CCUG 50881^T = DSM 15887^T) (Kämpfer et al. 2012b). For further details of phenotypic features, see *Table 35.12*.

Massilia, La Scola et al. 2000 Emend. Kämpfer et al. 2011

Massilia (*Mas.sil' i.a.* L. fem. n. *Massilia*, Latin name of Marseille, France. According to Kämpfer et al. 2011, *Massilia* La Scola et al. 2000 is an earlier heterotypic synonym of *Naxibacter* Xu et al. 2005).

The members of this genus are aerobic, gram-negative, motile, nonspore-forming rods, and are catalase-positive. Chemotaxonomically, ubiquinone Q-8 is the predominant isoprenoid quinone. The major compounds in the polar lipid profile are phosphatidylethanolamine, phosphatidylglycerol, and diphosphatidylglycerol. Oxidase reaction may be variable. Acid production occurs during utilization of carbohydrates. Arginine dihydrolase, urease, and aesculin reactions as well as gelatin hydrolysis may be variable. The G+C content of the DNA ranges from 62.4 to 68.9 mol% with an average of 66.2 mol%. The bacteria of the genus contain fatty acid profiles composed of summed features 3 (*iso*-$C_{15:0}$ 2-OH and/or $C_{16:1}$ ω7c) and $C_{16:0}$ as the major components, as well as $C_{18:1}$ ω7c, $C_{10:0}$ 3-OH, and

gram-negative, rod-shaped, nonspore-forming, and variably motile with one or more polar flagella. The predominant respiratory quinone is Q-8, although minor amounts of Q-7 are also detected. The G+C content of the DNA of is 62–63 mol %. The predominant fatty acids are $C_{16:1}\omega7c$ and $C_{16:0}$ (Xu et al. 2005; Kämpfer et al. 2008a). The first representant of the genus was isolated in a screening program for new antibiotics. This strain,YIM31775^T, which was found to contain genes for type I and type II polyketide biosynthesis, led to the description of the novel genus *Naxibacter* and species *N. alkalitolerans* (Xu et al. 2005). As by Xu and colleagues (2005), *N. alkalitolerans* are gram-negative nonspore-forming rods with rounded ends and which are motile with one or more polar flagella. The cells are oxidase-negative, catalase-positive, aerobic, and chemoorganotrophic. Colonies of strain YIM 31775^T are 1.1–1.4 mm in diameter, circular, entire, convex, glistening, butyraceous, and opaque with a pale white-yellow color on nutrient agar plates (Xu et al. 2005). Later, the description of the genus *Naxibacter* was emended by Kämpfer and colleagues (2008a), who described two additional species of the genus: *N. varians* and *N. haematophilus*. The description of *N. varians* is based on five isolates from water samples and from clinical samples in Scandinavia. The type strain CCUG 35299^T was isolated from the eye of a 90-year-old man in Norway. The same study describes a second new species, based on a single isolate from the blood of a 23-year-old man with multiple health problems (type strain CCUG 38318^T), which was named *N. haematophilus* (Kämpfer et al. 2008a). Both species presented nonmotile, nonspore-forming rods, gram-negative, and oxidase-positive with an oxidative metabolism. Both species produce the polyamines putrescine, 2-hydroxyputrescine, spermidine, and spermine. Good growth at 25–30 °C. After 24 h, colonies have a diameter of approximately 2 mm and are beige, translucent, and shiny with entire edges. Although the strains CCUG 35299^T and CCUG 38318^T showed 99 % 16S rRNA gene sequence similarity, DNA–DNA hybridization experiments led the authors to the description of these two novel species (Kämpfer et al. 2008a). These authors affirmed that Xu and colleagues (2005) had erroneously detected the glycolipid phosphatidylinositol mannoside in the polar lipid profile of strain YIM 31775^T. This absence of phosphatidylinositol mannoside was later also confirmed by Weon and colleagues (2010) when these authors described the fourth species of the genus, *N. suwonensis*. According to the emended description of the genus, its species share phosphatidylethanolamine, phosphatidylglycerol, and diphosphatidylglycerol as the major polar lipids. Also, the presence of 2-hydroxyputrescine and putrescine in the polyamine pattern was added as a common trait (Kämpfer et al. 2008a). One determining trait that justified the description of the novel genus *Naxibacter* was the erroneous detection of the glycolipid phosphatidylinositol mannoside by Xu and colleagues (2005). Also, 16S rRNA gene phylogenetic analyses and phenotypic traits do not permit a clear separation between the closely related genera *Naxibacter* and *Massilia* (Kämpfer et al. 2011; La Scola et al. 1998). Therefore, Kämpfer and colleagues (2011)

revised the description of the genus *Massilia*, by the reclassification of the species *N. alkalitolerans*, *N. varians*, *N. haematophilus*, and *N. suwonensis* as *Massilia alkalitolerans*, *M. varians*, *M. haematophila*, and *M. suwonensis*. No detailed table showing the differential characteristics among the Naxibacter species are provided considering that the genus was eliminated, and the species were transferred to the genus *Massilia*.

Telluria, Bowman et al. 1993

Telluria (Tel.lu'.ri.a. L. fem. N. *Tellus*, a Roman goddess of the earth, also the ground or earth; M. L. fem. N. *Telluria*, from the earth).

Bacteria from the genus *Telluria* – former [*Pseudomonas*] – are gram-negative rods of 0.5–1.0 × 2.0–3.0 μm, which occur singly, in pairs, or in short chains. In liquid media, single polar flagella are formed, while on solid media, lateral flagella are also observed. They accumulate β-hydroxybutyrate, have a strictly aerobic chemoheterotrophic metabolism, and are unable to chemolithotrophically derive energy from H_2. Denitrification does not occur. They are sensitive to NaCl. Good growth occurs on media containing carbohydrates and a combined nitrogen source; in media lacking carbohydrates and on nutrient agar, growth is poor. Complex carbohydrates, including starch and xylan, are used; cellulose is not hydrolyzed. The bacteria are able to hydrolyze gelatin, esculin, casein, DNA, Tween 40, Tween 60, and Tween 80. Optimal growth occurs between 30 °C-35 °C and at pH 7.0. The major ubiquinone is Q-8. The G+C content of DNA is between 67 and 72 mol%. The only known habitat is (rhizosphere) soil. The description of the type species *Telluria mixta* (former [*Pseudomonas*] *mixta*, Bowman et al. 1988) is based on dextranolytic strains, isolated from soil and from the rhizosphere of sugarcane plants in Queensland, Australia, in the 1970s. The type strain is ACM 1762 (= UQM 1762 = ATCC 49108). The G+C content of the DNA is determined as 69 mol%. The major fatty acids are $C_{16:0}$, $C_{16:1}\omega7c$, and/or $C_{15:0}$ iso 2-OH, $C_{17:0}$ cyclo, and $C_{18:1}\omega7c$ (Kämpfer et al. 2007). The second known species of the genus is *Telluria chitinolytica* (former *Pseudomonas chitinolytica*), which was described based on a single strain. The type strain (ACM 3522^T = CNCM I-804^T = $20M^T$) was isolated from a loamy soil from Israel amended with crustacean shell (Spiegel et al. 1991). The G + C content of the DNA is 72 mol%. The type strains and additional characteristics for these species are listed in *Table 35.14*.

Isolation, Enrichment, and Maintenance Procedures

Member of the family *Oxalobacteraceae* grow in a wide range of media, although specific media such as the nitrogen-free semisolid or specifically enriched media have been used successfully to isolate bacteria of some genera.

Herbaspirillum

H. aquaticum – isolated from deionized water in USA (Dobritsa et al. 2010) and can be cultivated in tryptic soy agar at 28 °C. Although it was not mentioned, it can be maintained in the same conditions applied to *H. huttiense* subspecies.

H. autotrophicum – isolated from a small eutrophic lake in Switzerland and the procedure was that essentially described by Aragno and Schlegel (1978). Water samples were filtered on membrane filters, and the filters were deposited on mineral agar medium: incubation was under an atmosphere of 60 % H_2–30 % air–10 % CO_2 at 30 °C. Pure cultures were obtained by repeated subculturing on mineral agar plates incubated under a hydrogen–air–carbon dioxide mixture. Stock cultures are maintained autotrophically on mineral agar slants and transferred to fresh medium every 2 months.

H. chlorophenolicum – isolated from soil sediment collected in an industrial stream sites using liquid MSM (minimal salt medium) containing 4-chlorophenol (50 mg/l) as described by Bae et al. (1996). Flasks are incubated up to 7 days at 30 °C until an increase in turbidity is observed. Single colonies are obtained by plating 0.1 ml suspension on 4-CP agar plates.

H. frisingense – isolated from washed roots or aerial part (stems and leaves) of *Miscanthus* and *Pennisetum* plants grown in Germany and in Brazil, respectively (Kirchhof et al. 2001). The N-free JNFb semisolid medium described for isolation of other nitrogen-fixing *Herbaspirillum* species (Döbereiner 1995) was applied to count and obtain single colonies. After 4 ± 6 days of incubation at 30 °C, characteristic subsurface pellicle-forming bacteria were subjected to further purification steps by streaking on JNFb agar plates containing an additional 20–50 mg yeast extract, and single colonies were again transferred for cultivation in fresh vials containing the same semisolid nitrogen-free medium. Pure isolates are obtained by streaking the veil-like pellicles on potato agar or BSA medium (Baldani et al. 1986). Stock cultures are maintained on JNFb supplemented with yeast extract or on potato agar slants under mineral oil, lyophilized, or cryopreserved at −70 °C.

H. hiltneri – isolated from surface-sterilized (chloramine T-1 %) wheat roots (4- to 8-week-old) grown in agricultural soil in Germany after roots were crushed in 1xPBS, diluted, and plated on NB solidified (16 g) agar. Single colonies were picked and streaked onto new NB agar plates. Cultures are maintained on NB slants under mineral oil or lyophilized according to the culture collection procedures.

H. huttiense subsp. huttiense – isolated from distilled water samples from New Zealand using simple peptone or yeast extract media as described by Leifson (1962). Medium B1 composed of 0.5 % polypeptone (Difco), 0.3 % yeast extract (Difco), 3 % NaCl, and 1.5 % agar are used to cultivate the species (Ding and Yokota 2004). The organism also grows readily on the strains were maintained in the laboratory for 3 years without changes (Leifson 1962), but no information about the maintenance method was indicated.

Habitat	Isolated from soils in Australia	Isolated from loamy soil in Israel

Reference: (1) Kämpfer et al. (2007)
nd not determined, positive (+), negative (–)

H. huttiense subsp. putei – isolated from well water in Japan. Cultivation and maintenance (stab) are carried out in medium B104 (IAM 1998) containing (per liter distilled water): 10.0 g polypeptone, 2.0 g yeast extract, and 1.0 g MgSO4.7H2O, pH 7.0.

H. lusitanum – isolated from young root nodules of common bean plants grown in soil in Portugal according to Vincent (1970) and using YMA medium (Bergersen 1961). Single colonies appeared after growth in YMA plates for 10 days at 28 °C. All strains were able to grow and form a pellicle in N-free JNFb semisolid medium (Döbereiner 1995). However, this characteristic was not confirmed during the genome sequencing study carried out with the *H. lusitanum* type strain P6-12 (Weiss et al. 2012).

H. rhizosphaerae – isolated from the rhizosphere soil sample of *Allium victorialis* var. *platyphyllum* using the standard dilution plating technique at 30 °C on nutrient agar (NA, beef extract 3.0 g, peptone 5.0 g, agar 15.0 g, and distilled water added to 1.0 L). Strains are routinely cultivated at 30 °C on NA. No maintenance procedure was provided.

H. rubrisubalbicans – initially, the bacteria were isolated from diseased leaves of the sugarcane variety D-74 grown in Louisiana, USA, using the methodology described for *Phytomonas rubrisubalbicans*, causing the mottled stripe disease (Christopher and Edgerton 1930), later renamed as *Pseudomonas rubrisubalbicans*. For that, the authors used small sections of stripe tissue sterilized in 1–1,000 mercuric chloride solution for 30 s, washed three times in sterile water, and then macerated in a small amount of Bacto-dextrose broth. Dilution cultures were then made with Bacto-dextrose agar and pure culture isolations obtained. Later on, during the identification of nitrogen-fixing strains among these *Pseudomonas rubrisubalbicans* strains (Pimentel et al. 1991), a new N-free semisolid medium (named JNFb) was developed (Baldani et al. 1992) and applied to isolate either *H. rubrisubalbicans* or *H. seropedicae* from different plants, including sugarcane, grown in Brazil (Baldani et al. 1996). The recipe and procedures to count, isolate, and maintain *H. rubrisubalbicans* are exactly the same as described below for *H. seropedicae*, the first species described for the genus *Herbaspirillum* (Baldani et al. 1986).

H. seropedicae – the species was initially isolated from roots of sorghum, maize, and rice plants using the semisolid NFb medium (used for isolation of *Azospirillum lipoferum* and *A. brasilense-Rhodospirillaceae*). As mentioned above, during the identification of the *H. rubrisubalbicans* species, the semisolid JNFb medium was established and becomes used in routine to count and isolate *H. seropedicae* in association with graminaceous plants. The JNFb medium contains (g L^{-1}) malic acid, 5.0; K_2HPO_4, 0.6; KH_2PO_4, 1.8; $MgSO_4.7H_2O$, 0.2; NaCl, 0.1; $CaCl_2.2H_2O$, 0.02; micronutrient solution ($CuSO4.5H_2O$, 0.04; $ZnSO4.7H_2O$, 0.12; H_3BO_3, 1.40; $Na_2MoO4.2H_2O$, 1.0; $MnSO4.H_2O$, 1.175. Complete volume to 1,000 mL with distilled water), 2 mL; Bromothymol blue (5 g L^{-1} in 0.2 N KOH), 2 mL; FeEDTA (16.4 g L^{-1}), 4 mL; vitamin solution (biotin, 10 mg; pyridoxal-HCl, 20 mg; dissolve in hot water bath; and complete to 100 mL adding distilled water), 1 mL; and KOH, pH 4.5. Add distilled water to bring total solution to 1 l. Adjust the pH to 5.8 with KOH. To semisolid and solid medium, add 1.8 and 17 g agar L^{-1}, respectively. The isolation procedure is essentially as described by

Baldani et al. (1986) and consists on the inoculation of the JNFb semisolid medium (10 ml vials containing 5 ml medium) with aliquot (0.1 ml) from serial dilutions of smashed soil, root, stem, and leaf samples and incubation for 1 week at 32 °C. Fine white pellicles, very similar to *Azospirillum* spp. are observed. Cells from these white pellicles move rapidly close to air bubbles when examined under the microscope. These pellicles are transferred to fresh JNFb semisolid medium, incubated for 24–48 h, and streaked out on solid NFb medium containing yeast extract (20–50 mg/L) and 3× the Bromothymol blue concentration of the medium. The grown colonies are small, moist with blue centers which are again transferred to fresh JNFb semisolid medium and further purified on potato agar medium or BSA. The cultures are maintained at −80 °C in Dygs medium (Rodrigues Neto et al. 1986 – composition (g L-1): glucose, 2.0; malic acid 2.0; peptone, 1.5; yeast extract, 2.0; K_2HPO_4, 0.5; $MgSO_4.7H_2O$), 0.5; glutamic acid, 1.5; and complete with distilled water up to 1,000 mL, containing 10 % (v/v) glycerol. Alternative preservation is by lyophilization after growth of the culture on slant tubes containing solid Dygs medium followed by resuspension on peptone – sucrose (10 %) preservative solution.

Noviherbaspirillum

N. canariense, *N. aurantiacum*, and *Noviherbaspirillum soli* – the TSA medium (Difco) containing 1 % soil extract was used for isolation of the three species. The soil extract is prepared by suspending 10 g of the original soil in 90 ml sterile water that is maintained under shaking conditions for 2 h. Ten ml of this suspension is added to 90 ml water to which the corresponding amount of TSA powder is added. The medium is then sterilized by autoclaving at 121 °C for 20 min and dispensed into Petri dishes. Decimal dilutions of the native soil extract are obtained, and 1 ml from each dilution is spread on these plates. Individual colonies are transferred to Petri dishes containing M9-CAS agar (Alexander and Zuberer 1991) and colonies surrounded by an orange halo indicative of siderophore production were transferred to TSA plates for identification.

N. psychrotolerans – the R_2A medium [0.05 % proteose peptone, 0.05 % casamino acids, 0.05 % yeast extract, 0.05 % glucose, 0.05 % soluble starch, 0.03 % dipotassium phosphate, 0.005 % magnesium sulfate heptahydrate, 0.03 % sodium pyruvate, 1.5 % agar for solid media (w/v), Reasoner and Geldreich 1985] is inoculated with a soil suspension diluted in sterile saline solution (0.9 % NaCl) and incubated at 10 °C for 3 weeks. The isolated bacteria are cultivated at 18 °C on R_2A and nutrient medium (w/v: 0.5 % tryptone, 0.3 % meat extract, for solid media 1.5 % agar, pH 7.2).

N. malthae – the M457 mineral basal medium (Meyer et al. 1999) containing heavily crude oil is inoculated with oil-contaminated soil samples for enrichment and incubated at 30 °C under darkness. After 1 week, samples are serially diluted with sterile saline solution (0.85 % NaCl) and plated on nutrient agar (NA, Hi-Media). Individual colonies are isolated and maintained on the nutrient agar after incubating at 32 °C for 3 days. The colonies are straw-colored, circular, and smooth. The species is preserved in glycerol suspension at −80 °C.

Collimonas

C. fungivorans was originally isolated on chitin agar plates of samples of slightly acidic dune soils located on the Wadden island Terschelling as described by De Boer et al. (1998). *C. arenae* and *C. pratensis* were also isolated from chitin agar plates of soil samples of (semi-) natural grasslands and a heathland in the Netherlands as described by Höppener-Ogawa et al. (2007). The ability of bacterial colonies to produce chitinases is indicated by the formation of clear zones (halos) on the colloidal chitin-containing agar plates. *Collimonas* spp. bacteria form translucent colonies of little biomass on minimal chitin agar. All isolates are stored at −80 °C and maintained on 10-fold diluted tryptone soy broth (TSB) agar for routine culturing.

Glaciimonas

G. immobilis was isolated from alpine glacier cryonite from an alpine glacier at an altitude of 2.900 m above sea level at 10 °C on R_2A-agar plates (Zhang et al. 2011). The cryonite sample had been shaken with 9 ml sterile 1 % sodium pyrophosphate for 20 min at 150 r.p.m. to desorb the bacteria. The other member of this genus, *G. singularis*, was recovered from a water sample from Poco das Cobras in the uranium mining area of Urgeirica, Portugal, on R_2A-agar after incubation at 30 °C for 7 days. The cultures are maintained at −80 °C in nutrient broth containing 15 % (v/v) glycerol.

Janthinobacterium

J. lividum and *J. agaricidamnosum* – *Janthinobacterium lividum* grows on PYE medium (0.3 % peptone from casein, 0.3 % yeast extract, pH 7.2) at optimum temperature of 25 °C. The procedure for isolation of *J. agaricidamnosum* was described by Lincoln et al. (1999) as followed: samples of diseased mushroom tissue were transferred aseptically to sterile quarter-strength Ringer's solution, and a tenfold dilution series was inoculated onto *Pseudomonas* agar F (PAF; Merck) and nutrient agar (Oxoid) and incubated at 25 °C for 24 h. All the strains can grow on nutrient agar for 24 h at 28 °C shaken at 100 r.p.m. on an orbital shaker. There are reports indicating the need for culturing *J. agaricidamnosum* every 10 d when maintained on agar.

Undibacterium

U. pigrum – the type strain, *U. pigrum* strain CCUG 49009^T, was isolated from a drinking water in Göteborg (Sweden) on R_2A agar. It forms beige-colored colonies after incubation at 25 °C for 7 days. The bacteria can also be cultivated on tryptone soy agar (TSA), nutrient agar, and MacConkey agar (Kämpfer et al. 2007).

U. oligocarboniphilum – strain EM 1^T (CCUG 57265^T) was isolated from purified water system at Roche, Penzberg (Germany) on R_2A agar (Oxoid) plates incubated for 7 days at 30 °C. Colonies on R_2A agar were tiny, cream-colored, and translucent. Strain EM 1^T was not able to grow on tryptone soy agar and was unable to grow at 8 g.L^{-1} NaCl (Eder et al. 2011). Such sensibility to salt concentration could explain the absence of reactivity of strain EM 1 on API 20NE or API 20E strips (BioMérieux).

U. parvum – strain CCUG 49012^T was isolated from drinking water forming yellowish and translucent, shiny, and convex colonies, 0.5 mm in diameter, with a narrow and delicate lacerated rim after 3 days. The bacteria were not able to grow on TSA, PYE, and grew only slowly on nutrient agar. A typical phenotypic trait of the species was the narrow temperature range for growth (optimum at 21 °C). A new medium to cultivate the strain CCUG 49012^T was proposed by Kämpfer et al. (2007), which consisted of the carbon sources of PYE medium and the salts of R_2A (designated R2-PYE) (l^{-1}: 0.75 g peptone from casein, 0.75 g yeast extract, 0.3 g K_2HPO_4, 0.024 g$MgSO_4$, pH 7.2), in which the bacteria presented flocculent growth.

U. terreum – strain C3^T (CGMCC 1.10998^T) was isolated from permafrost soil in Beijicun (Liu et al. 2013). The isolation procedure was described by Liu et al. (2013) as followed: soil samples from surface collected at a depth of 20–30 cm (not frozen at the time of sampling). Strain C3^T was isolated from dilution after plating on R_2A agar plates and incubation at 15 °C for 1 week. Colonies on R_2A agar appear after 3 days at 25 °C. They are circular, entire, and creamy colored with 2.2 mm diameter. Modified R_2A medium was used to grow strain C3^T as follows (g.l^{-1}): 0.5 protease peptone, 0.5 calamine acids, 0.5 yeast extract, 1.0 glucose, 1.0 soluble starch, 0.5 K_2HPO_4. $3H_2O$, 0.5 KH_2PO_4, 0.3 sodium pyruvate, 0.2 $MgSO_4$. $7H_2O$, and modified R_2A agar contains 15 g agar l^{-1}. The pH was adjusted to 7.0.

Herminiimonas

H. fonticola – the type species of the genus, *H. fonticola* strains S-94T, S-97, S-99, and S-92 were isolated occasionally from a borehole used as source for a mineral water bottling plant located in the Serra da Estrela in Eastern Portugal (Fernandes et al. 2005). Briefly, the isolation procedure involves water samples filtration through membrane filters (pore size 0.2 µm) and filters placement on R_2A agar (Difco) plates followed by incubation at 22 °C for 15 days. Purification steps were performed on R_3A agar, and maintenance procedures involve storage at 70 °C in nutrient broth (Difco) with 15 % (w/v) glycerol. Fernandes et al. (2005) stated that the bacterial growth was improved in the heterotrophic medium H3P (= DSMZ medium 428).

H. aquatilis – the strain CCUG 36956T was obtained from a municipal drinking water from Uppsala (Sweden) at routinely industrial hygiene control (Kämpfer et al. 2006). Cultivation and maintenance of the bacteria are on nutrient agar (Oxoid) at 25 °C. The strain grows slowly on nutrient-rich media, like TSA (Oxoid), R_2A agar (Oxoid), and nutrient agar at 30 °C.

H. arsenicoxydans – the strain ULPAs1T was isolated by Muller et al. (2006) from activated sludge of an industrial treatment plant contaminated with heavy metals after aerobic enrichment on chemically defined medium (CDM) supplemented with 1.33 µM As[III]. The medium is prepared as follows: 100 ml solution A [81.2 mM $MgSO_4.7H_2O$ (Sigma), 187 mM NH_4Cl (99.8 % purity; Merck), 70 mM Na_2SO_4 (99 %; Prolabo), 0.574 mM K_2HPO_4 (97 %; Prolabo), 4.57 mM $CaCl_2.2H_2O$ (99.5 %; Merck), 446 mM sodium lactate (98 %; Sigma)], 2.5 ml solution B [4.8 mM $Fe_2SO_4.7H_2O$ (99 %; Prolabo)], and 10 ml solution C [950 mM $NaHCO_3$ (99.5 %; Prolabo)] were mixed and made up to 1 l with water. The final pH of the medium was about 7.2 (Weeger et al. 1999).

H. saxobsidens – the strain NS11T was isolated from the lichen–rock interface of a limestone bedrock colonized by lichen at Mugla (Turkey), from enrichment cultures with potassium oxalate as the sole source of carbon and energy by Sahin et al. (2002). The bacterium grows routinely on nutrient agar (per liter: 5 g peptone, 3 g beef extract, 15 g agar; Difco) and R_2A medium (Difco; Reasoner and Geldreich 1985) at 28 °C. Culture enrichments can be achieved with addition of 4 g potassium oxalate per liter as the sole source of carbon and energy in mineral medium designed by Aragno and Schlegel (1992).

H. glaciei – strain UMB49T was isolated from 3,042 m deep Greenland ice core by a selective filtration enrichment procedure and long-term incubations at low temperatures according to Miteva and Brenchley (2005). The isolation was performed under anaerobic liquid culture in R_2B (Reasoner and Geldreich 1985), started from a 0.2 µm filtrate of a melted ice core sample and incubated for 7 months at 2 °C. Subsequently, the culture was plated on tryptic soy agar without glucose in a presence of oxyrase additive (Oxyrase) and incubated at 5 °C for 4.5 months, where two small brown-purplish colonies appeared. After that, under aerobic recultivation on TSA and R_2A (Becton Dickinson) at 18 °C, strain UMB49T formed small, convex, translucent colonies (Loveland-Curtze et al. 2009). Resuscitated strain UMB49T formed colonies on TSA and R2A within 3–4 days at 25 °C and grown in M9 mineral salts medium (Miller 1992) with a suitable carbon source, without supplementation with vitamins or other growth factors.

H. contaminans – the strain CCUG 53591T was isolated in Sweden as a contaminant of a biopharmaceutical production process (Kämpfer et al. 2013). Ordinary cultivation is performed on tryptone soy agar (TSA; Oxoid) at 28 °C for 48 h. Peptone yeast extract (PYE) broth (0.3 % peptone from casein, 0.3 % yeast extract, pH 7.2) at 28 °C is recommended for biomass cell production.

Oxalobacter

O. formigenes – strain OxB^T was obtained from sheep rumen contents using previously described enrichment procedures (Dawson et al. 1980a, b), based on previously described methods developed by Hungate and modified as described by Bryant (1972) and Holdeman and colleagues (1977). The primary enrichment occurred in a fermentor culture established with

sheep rumen contents which was maintained by feeding of ground alfalfa. Anaerobic conditions were maintained by flushing with CO_2. Tenfold dilutions from this system were inoculated into rumen fluid-oxalate (RFO) enrichment medium containing Na_2SO_4 (0.2 g), KH_2PO_4 (0.09 g), NaCl (0.09 g), $(NH_4)_2SO_4$ (0.09 g), $MnSO_4.H_20$ (0.001 g), $CaSO_4$ $7H_20$ (0.0001 g), $MgSO_4$. $7H_20$ (0.0005 g), yeast extract (0.1 g), clarified rumen fluid (10.0 ml), resazurin (0.0001 g), L-cysteine-$HCl.H_20$ (0.025 g), Na_2CO_3 (0.4 g), and sodium oxalate (0.6 g) completed to 100 ml with distilled water. The final pH of the medium was 6.8. After enrichment in RFO medium, a mixed population of oxalate-degrading bacteria and coliform non-oxalate-degrading bacteria appeared. To further enrich the oxalate degraders, a nutrient-depleted medium was developed by the cultivation of coliform contaminants in RFO medium and the resultant coliform-depleted (CD) medium (Dawson et al. 1980a). All cultures were kept under anaerobiosis by incubating under a CO_2 gas phase. Ten and 100× dilutions of the enrichment cultures were inoculated in roll tube cultures with RFO medium containing 2 % agar in 7 ml volumes, and single colonies were isolated (Dawson et al. 1980b). Later, another culture medium, medium A (Allison et al. 1985), was developed to facilitate the isolation of other oxalate-degrading anaerobes. Manipulation of the medium occurs under a CO_2 atmosphere to guarantee anaerobic conditions. This somewhat opaque medium contains calcium oxalate on which colonies of oxalate-degrading bacteria are detected by the formation of cleared zones. Another medium, designated as "medium B" was used for studies with DNA, lipids, and antigens by Allison and colleagues (1985). Manipulation of "medium A" and "medium B" should be under a CO_2 atmosphere to guarantee anaerobic conditions (Allison et al. 1985).

O. vibrioformis – strain WoOx3^T was isolated from anoxic freshwater sediments from polluted creeks by enrichment using a carbon-buffered, sulfide-reduced mineral medium described by Widdel and Pfennig (1981) and which contained a 7-vitamin solution (Widdel and Pfennig 1981), selenite–tungstate solution, and the trace element solution SL10 (Widdel et al. 1983). The pH was between 6.8 and 7.0, and the growth temperature was 30 °C. Enrichment cultures were inoculated with 50 mL freshwater and contained 20 mM diammonium oxalate and 3 mM acetate. The headspace of the enrichment cultures was composed of an N_2/CO_2 (90 %/10 %) gas mixture (Dehning and Schink 1989). Pure cultures were obtained by repeated application of the agar shake culture technique (Pfennig and Trüper 1981).

Oxalicibacterium

O. flavum – was isolated using a mineral medium described by Aragno and Schlegel (1981). Liquid enrichment cultures with this medium were amended with 0.4 % (w/v) potassium oxalate, inoculated with samples of 1 g, and incubated under air at 28 °C on a shaker for 5 days; the enrichment procedure was repeated three times by transferring 1 mL portions to new medium. Single colonies were obtained by spreading this enrichment culture on the same medium solidified with 1.2 % agar (Tamer et al. 2002).

Duganella

D. zoogloeoides was originally isolated by P. R. Dugan from a zoogloeal matrix from wastewater bacteria and misnamed as *Zoogloea ramigera*. The bacteria form characteristic cell aggregates surrounded by gelatinous matrices – the so-called zoogloeal matrix. The strain IAM12670 was later reclassified according the chemotaxonomic markers and 16S rDNA similarity as *D. zoogloeoides* (Hiraishi et al. 1997). Colonies on nutrient agar are glistening, convex with entire margins, viscous, and pale yellow to straw-colored. *D. phyllosphaerae* was isolated on tryptone soy (TS) agar from a leaf (phyllosphere) of *Trifolium repens* collected in the Hainich-Dün region, Germany (Kämpfer et al. 2012b). On TS agar, the colonies have a yellow color, and the morphology is circular, low convex with an entire margin and a smooth appearance. *Duganella sacchari* and *Duganella radicis* were isolated from rhizosphere soil and rhizoplane of sugarcane (*Saccharum officinarum* L., clone Co86032) on selective ammonium mineral salts (AMS) medium (Whittenbury et al. 1970). The rhizosphere sample was collected 90 days after planting from an experimental sugarcane field at the Sugarcane Breeding Institute, Coimbatore, Tamil Nadu, India. The colonies on AMS/R2A agar are white, tough, dry, viscous, and convex with entire margins and a smooth appearance.

Pseudoduganella

Duganella violaceinigra was recovered on HV agar medium (Hayakawa and Nonomura 1987) from a forest soil sample in Yunnan, China (Li et al. 2004). The strain is maintained on YM (yeast extract/malt extract) agar at 4 °C and as 20 % (w/v) glycerol suspension at −20 °C. This isolate is now reclassified based on striking phenotypic differences and refined 16S rDNA similarity to P*seudoduganella violaceinigra* (Kämpfer et al. 2012b).

Massilia

M. timonae – the type strain was isolated from blood of a 25-year-old male whose diagnosis was common variable immunodeficiency and meningoencephalitis in 2000 from a hospital in Marseille, France. Other strains were isolated from femur of a 25-year-old male patient diagnosed with osteomyelitis in 1985, cerebrospinal fluid (CSF) of a 49-year-old female patient diagnosed with pseudotumor in 1996, blood of a 41-year-old male in end stage renal disease in 1997, blood of a 39-year-old female with sepsis in 1999, and surgical wound infection in an immunocompetent 36-year-old male who had undergone orthopedic surgery. Cell shape is straight rods, and, occasionally, filamentous cells are formed in old cultures and are especially formed at 37 °C; no growth is observed at 4 °C. Cell size of 1.0 µm wide and 3.0 µm long with monotrichous or

polytrichous flagellation. Grow well in MacConkey agar and tend to form flocs and films in liquid medium without fingerlike projections. Growth does not occur at 42 °C, on SS agar, or in nutrient broth with 6 % NaCl. The species is sensitive to polymyxin B. A straw-colored growth pigment is produced on HI agar (Zhang et al. 2006; Lindquist et al. 2003, 2005; Sintchenko et al. 2000; La Scola et al. 1998).

M. umbonata – includes a single isolate from a lab-scale microcosm packed with a mixture of soil collected nearby Guadalimar (Jaén, Spain) and sewage sludge compost from Granada (Spain), designed to study the evolution of microbial biodiversity through the time. The rod-shaped cell is 0.6–0.8 μm wide and 2.0–2.5 μm long harboring a single polar flagellum. They form intracytoplasmic granules when grown on ISP2 medium amended with soluble starch. Colonies grown on TSG for 3 days are yellowish pigmented and glossy, with an umbo surrounded by bosses, and round, entire edges that grow outwardly in decreasing waves (Rodríguez-Díaz et al. 2013).

M. yuzhufengensis – includes a single isolate from 119.6 m deep ice core section from Yuzhufeng Glacier, Tibetan Plateau, China. Cell shape is rodlike with 0.7–1.0 μm width and 2.3–2.7 μm length containing a polar flagellum. Colonies produced on R_2A agar after incubation at 28 °C for 2–3 days are yellow, round, smooth, convex, and opaque (Shen et al. 2013).

M. tieshanensis – includes a single isolate from subsurface soil of a metal mine located at Tienshan, China. The rod-shaped cells are 0.3–0.6 μm wide and 1.2–2.0 μm long with monotrichous and polytrichous flagella present. Colonies are circular, convex, viscous, translucent, straw yellow, and 1.0–2.0 mm in diameter with entire edges on nutrient agar plates after 36 h of incubation. Some differences are observed using R_2A medium, on which colonies are opaque, yellowish, and rough. Growth occurs on nutrient agar, R_2A- and trypticase soy agar, but does not occur on MacConkey agar.

M. varians – former [*Naxibacter*] *varians* includes many isolates. The type strain was isolated from an eye of a male patient of 90-year-old in 1996 at Tromsö (Norway). Other strains were isolated from water in Sweden and from a human blood in 1989 in Stockholm (Sweden). Cell shape is rod with 1.0 μm wide and 2.0 μm long. Beige, translucent, and shiny colonies with entire edges and with a diameter of approximately 2 mm are formed within 24 h. Good growth occurs on R_2A agar, TSA, PYE agar, nutrient agar, and MacConkey agar at 25–30 °C.

M. haematophila – former [*Naxibacter*] *haematophilus* includes one isolate from blood of a 23-year-old man with multiple health problems. Good growth occurs on R_2A agar, TSA agar, PYE agar, and nutrient agar at 25–30 °C. The cells are rod-shaped and are 1.0 μm wide and 2.0 μm long colonies formed within 24 h are beige, translucent, and shiny with entire edges and a diameter of approximately 2 mm. Moderate amounts of an unknown aminolipid and an unknown aminophospholipid and minor trace amounts of one unknown aminolipid and three unknown phospholipids are present.

M. aerilata – includes one isolate from an air sample collected at Suwon, Republic of Korea. The cell shape is rodlike with 0.7–1.0 μm width and 1.5–3.0 μm lengths containing a single polar flagellum. Colonies are light yellow, round, and convex with clear margins. Grows well on R_2A agar, nutrient agar, and trypticase soy agar, but does not grow on MacConkey agar (Weon et al. 2008).

M. albidiflava – includes one isolate from heavy-metal-polluted farm soil in Nanjing, Jiangsu province, China. The strain was isolated by means of dilution plating method using yeast extract/malt extract agar medium (ISP 2 medium – 4.0 % yeast extract, 10.0 % malt extract, 4.0 % glucose, 2.0 % agar). After incubation at 28 °C on nutrient agar plates for 2 weeks, the colonies are 1.0–1.5 mm in diameter, circular, entire, convex, desiccated, opaque, and pale white to yellow on nutrient agar plates. The cells are short rods with 1.8–2.0 μm width and 3.0–3.5 μm length having peritrichous flagella. It cannot tolerate NaCl concentration higher than 1 % (Zhang et al. 2006).

M. plicata – includes one isolate from heavy-metal-polluted farm soil in Nanjing, Jiangsu province, China. The strain was isolated by means of dilution plating method using ISP 2 medium; incubation was at 28 °C for 2 weeks. Colonies on nutrient agar plates are 2.0–3.0 mm in diameter, circular, entire, convex, viscous, opaque, and yellow to pale brown. Cell shape is straight rod with 0.6–0.7 μm width and 1.8–2.5 μm length and contains one or more flagella. Soluble pigment is produced on ISP2 medium and some other tested media. It cannot tolerate > 1 % NaCl (Zhang et al. 2006).

M. dura – includes one isolate from heavy-metal-polluted farm soil in Nanjing, Jiangsu province, China. The strain was isolated by means of dilution plating method using ISP 2 medium; incubation was at 28 °C for 2 weeks. Colonies on nutrient agar plates are 0.9–1.2 mm in diameter, circular, entire, convex, opaque, hard, compact, and pale white to yellow. Cells shape is straight rod with 0.6–0.8 μm width and 1.8–2.5 μm length and one or more flagella. It cannot tolerate > 1 % NaCl (Zhang et al. 2006).

M. lutea – includes one isolate from heavy-metal-polluted farm soil in Nanjing, Jiangsu province, China. The strain was isolated by means of dilution plating method using ISP2 medium; incubation was at 28 °C for 2 weeks. Colonies are 2.0–3.0 mm in diameter, circular, entire, convex, viscous, opaque, and yellow on nutrient agar plates. Cell shape is short rods which are 1.8–2.0 μm wide and 3.0–3.5 μm long and shows peritrichous flagella. It cannot tolerate > 1 % NaCl (Zhang et al. 2006).

M. alkalitolerans – former [*Naxibacter*] *alkalitolerans* – includes one isolate from soil, collected at Lijiang, Yunnan Province, China, after incubation for 2 weeks at 28 °C on water proline agar (1 % proline/tap water). Colonies developing on nutrient agar plates are 1.1–1.4 mm in diameter, circular, entire, convex, glistening, butyraceous, opaque, and with pale white-yellow to straw color. The cell shape is rodlike with 0.45–0.8 μm width and 1.35–2.0 μm length and one or more flagella. The bacteria cannot grow in the presence of 3 % sodium chloride. The type strain, YIM 3175^T, is a soil bacterium with no apparent pathogenic or symbiotic relationship with mushrooms; it contains genes encoding both type I and type II polyketide biosynthesis pathways (Xu et al. 2005).

M. aurea – includes one isolate from drinking water distribution system of Seville, Spain. Samples (25 l) of drinking

water were concentrated by using a tangential flow filtration system, plated on plate count agar, and incubated at 28 °C for 7 days. Colonies on PCA agar plates after 2 days incubation are circular, translucent, yellow-pigmented, and 0.6–1.0 mm in diameter. Good growth occurs on TSA, R_2A, and nutrient agar medium. No growth occurs on MacConkey agar. Cells have a tendency to form pellicles on the surface of static liquid cultures, and they do not grow in the presence of 2 % NaCl. Cell shape is straight rod with 1.0 µm width and 1.6–3.0 µm length and occurs singly or in pairs on PCA medium at 28 °C after 48 h.

M. brevitalea – includes one isolate from lysimeter soil in association with higher plants from the Botanical Garden at the University of Bayreuth, Germany. The high-throughput MicroDrop technique was employed to inoculate bacterial cells into microtiter plates containing soil solution equivalent, buffered at pH of 7.0, and supplemented with artificial root exudates, yeast extract (0.01 %, w/v), and inducers. Cultures were incubated at 15 °C for 6 weeks. Bacterial strains were isolated by streaking liquid cultures onto the medium described above, solidified with gellan gum (8 g l^{-1}; Sigma-Aldrich Chemie). Colonies are circular, entire, convex, opaque, and pale white to yellow. Cell shape is short rod with 0.7–1.0 µm width and 1.5–2.0 µm length harboring a single polar flagellum. Occasionally, cells with two or three polar or lateral flagella are observed. Cells occur singly or in pairs (on 1:10-diluted HD medium at 15 °C after 36 h). A striking feature of the cells was the presence of numerous protuberances of various sizes, formed by the outer membrane, over the entire cell surface.

M. consociata – includes one isolate from blood of a 48-year-old man at Göteborg, Sweden. Beige, translucent, and shiny colonies with entire edges are formed within 24 h, with a diameter of approximately 2 mm. Cell shape is rod with 1.0 µm width and 2.0 µm length. Good growth occurs on R_2A agar, TSA, PYE agar, nutrient agar, and MacConkey agar at 25–30 °C. Growth occurs on TSA at temperature ranging from 15 °C to 37 °C and at pH values between 5.5 and 10.5. No growth occurs below 10 °C and above 45 °C. Moderate amounts of three unknown phospholipids and of one unknown aminolipid are present (Kämpfer et al. 2011).

M. flava – includes one isolate from a soil sample collected from Ningxia Province, China. For isolation, 1 g of soil was suspended in 100 ml of distilled water and spread on plates of ISP2 (containing 4 g yeast extract, 10 g malt extract, 4 g glucose, and 20 g agar; pH 7.5) medium after serial dilution. Plates were incubated at 28 °C for 3 days. Colonies are circular to irregular, convex, yellow, and 1–3 mm in diameter after 3 days cultivation at 28 °C on ISP2 medium. Cells are rods with 0.6–0.8 µm width and 1.5–2.5 µm length (Wang et al. 2012).

M. jejuensis – includes one isolate from an air sample from the Suwon region, Republic of Korea. The air samples were collected by using a MAS-100 air sampler that contained Petri dishes with R_2A medium (BBL) supplemented with cycloheximide at 200 mg/ml. Colonies are light orange, round, and convex with clear margins. Cells are rods with 1.1–1.5 µm width and 1.3–3.0 µm length and a single polar flagellum. Grow on R_2A and nutrient agar, but not on tryptic soy agar or MacConkey agar (Weon et al. 2010).

M. suwonensis – former [*Naxibacter*] *suwonensis* – includes one isolate from an air sample from the Suwon region, Republic of Korea. The air samples were collected by using a MAS-100 air sampler that contained Petri dishes with R_2A medium (BBL) supplemented with cycloheximide at 200 mg/ml. Colonies are ivory-colored, round, and convex with clear margins. Cells are rod-shaped with 0.6–0.8 µm width and 1.2–3.0 µm length and have a single flagellum (Weon et al. 2010).

M. lurida – includes one isolate from a soil sample collected from an experimental sunflower field in Wuyuan County, Inner Mongolia Autonomous Region, China. The soil sample (1.0 g) was suspended in 100 ml of sterilized water, and diluted solutions were spread on ISP2 medium at 28 °C and incubated for 3 days. Colonies are circular to irregular, convex, yellow, and 1–3 mm in diameter after 72 h cultivation at 28 °C on ISP2 medium. Cells shape is rodlike which are 0.6–0.9 µm wide and 1.4–2.8 µm long; cells are motile by means of flagella (Luo et al. 2013).

M. namucuonensis – includes one isolate from a soil sample collected from Namucuo in Tibet Autonomous Region, China. Soil samples were collected from sites located 25 m from the Namucuo Saltwater Lake (30° 46′ 27″ N, 90° 52′ 00″ E and 4,598 m in altitude). For isolation, 1 g soil sample was suspended in 50 ml distilled water and spread on plates of R_2A medium after serial dilution. After 3 days cultivation at 28 °C on R_2A-agar, colonies are circular to irregular, convex, opaque, and white to yellow in color having a diameter of 1.0–3.0 mm. No growth was observed on TSA and MacConkey agar. Cells are rod-shaped and 0.3–0.5 µm wide and 0.5–1.5 µm long.

M. niabensis – includes one isolate from an air sample collected from Suwon, Republic of Korea. Air samples were collected in the Suwon region of Korea (37° 16′ 46″ N 126° 59′ 10″ E) by using a MAS-100 air sampler that contained Petri dishes with R2A medium supplemented with cycloheximide at 200 µg/ml. Bacteria were isolated after incubation at 28 °C for 5 days. Colonies are yellowish white, round, and convex with clear margins. Grows well on R_2A and nutrient agar, but does not grow on trypticase soy agar or MacConkey agar. Cell shape is rodlike with 0.6–0.9 µm width and 1.4–4.0 µm length; cells are motile by means of a single polar flagellum (Weon et al. 2009).

M. niastensis – includes one isolate from an air sample collected from Suwon, Republic of Korea. Air samples were collected in the Suwon region of Korea (37° 16′ 46″ N 126° 59′ 10″ E) by using a MAS-100 air sampler that contained Petri dishes with R_2A medium supplemented with cycloheximide at 200 µg/ml. Bacteria were isolated after incubation at 28 °C for 5 days. Colonies are ivory-colored, round, and convex with clear margins. Grows well on R_2A and nutrient agar, but does not grow on trypticase soy agar or MacConkey agar. The cells are rods with a width of 0.6–0.8 µm and a length of 1.5–5.0 µm. They are motile by means of single polar flagella (Weon et al. 2009).

M. oculi – includes one isolate from the eye of a patient suffering from endophthalmitis at Linköping, Sweden. Within 24 h of incubation, colonies have a diameter of approximately 2 mm and are beige, translucent, and shiny. Cell shape is rodlike with 1.0 μm width and 2.0 μm length. Good growth occurs on R_2A agar, TSA, peptone yeast extract agar, nutrient agar, and MacConkey agar at 25–30 °C (Kämpfer et al. 2012a).

Telluria

T. mixta – former [*Pseudomonas*] *mixta* – the type species of the genus *Telluria* was isolated from the rhizosphere of sugarcane plants in Australia (Bowman et al. 1988), via enrichment using the method described by Blackall et al. (1985). The isolates formed semiopaque halos on dextran-containing mineral media, indicative of dextran hydrolysis.

T. *chitinolytica* – former *Pseudomonas chitinolytica* – the type species (strain ACM 3522^T) was isolated from a natural sandy loam soil from Bet Dagan in Israel, which was mixed with 1 % (wt/wt) crustacean shells (rich in chitin) and incubated up to 45 days in a glass house. Aliquots of this soil were suspended in sterile water, and this water was diluted and spread on agar plates containing 0.2 % (wt/vol) colloidal chitin as the sole carbon source and minerals. Colonies producing a cleared zone were isolated (Bowman et al. 1993).

Ecology

Habitat

The species belonging to the family *Oxalobacteraceae* present a very wide range of habitats. For example, members of the genus *Herbaspirillum* were first described as endophytic bacteria colonizing plant tissues, but more recently has been reported in a broad range of niches, such as contaminated soil, water, antarctic soil, and clinical samples. Species from the other genera such as *Massilia* have soil and water (rivers and lakes) as common habitats, although isolations from the phyllosphere and rhizosphere of plants and from clinical specimen have also been reported. Anaerobic environments are common habitats for species of the genus *Oxalobacter*, while members of other genera, e.g., feed on living fungal hyphae (*Collimonas*) or colonize environments with extremely low levels of available carbon, such as the alpine glacier cryoconite or groundwater.

Herbaspirillum: The genus *Herbaspirillum* was created in 1986 and included exclusively nitrogen-fixing strains belonging to *H. seropedicae* species isolated from *Poaceae* plants (Baldani et al. 1986). These characteristics were confirmed for the *H. rubrisubalbicans* and *H. frisingense* species but not for the other *Herbaspirillum* species despite an original report indicating the nitrogen fixation ability for *H. lusitanum*, bacteria isolated from nodules of common bean plants (Valverde et al. 2003). With the exception of *H. hiltneri* and *H. rhizosphaerae* that were also found associated with plants, the other species (*H. aquaticum*, *H. autotrophicum*, *H. huttiense subsp. putei*, and subsp. huttiense) were detected in water samples. On the other hand, H. *chlorophenolicum*, previously classified as *Comamonas testosteroni*, was the only species isolated from soil sediment. The ecological distribution of *H. seropedicae* has been more deeply investigated, and besides the colonizing roots of maize, sorghum, and rice plants grown in Seropédica, RJ, Brazil, it was later detected associated with poaceae plants grown in other regions of Brazil: roots, stems, and leaves of sugarcane varieties (Reis Junior et al. 2000), roots and stems of rice (Rodrigues et al. 2006), roots of forage grasses (Brasil et al. 2005), roots of wheat (Sala et al. 2005), and roots of sorghum (Bergamaschi et al. 2007). More recently, the species was detected colonizing rice plants grown in China (Zhu et al. 2012). The species are also associated with dicotyledonous plants such as pineapple and banana cropped in Brazil (Weber et al. 1999; Cruz et al. 2001). In addition, *Herbaspirillum* spp. were isolated from the endosphere of *Populus deltoids* grown along the Caney Fork River in central Tennessee and at the Yadkin River in North Carolina, USA (Brown et al. 2012). The species *H. rubrisubalbicans*, originally isolated as mild-pathogenic bacteria from leaves of sensitive sugarcane varieties grown in different countries (the USA, Mauritius, Jamaica, etc.), was later found colonizing resistant sugarcane (roots and stems) and weed (roots) plants grown in Brazil (Baldani et al. 1992) and sugarcane variety NIF-8 grown in Japan (Asis et al. 2000). More recently, it was isolated from a sensitive sugarcane variety grown in China (Tan et al. 2010). *H. frisingense* was found colonizing the C4-energy plants *Miscanthus sinensis* and *Pennisetum purpureum* grown in Germany and Brazil (Kirchhof et al. 2001). *H. lusitanum* was found cohabiting young nodules of common bean plants (*Phaseolus vulgaris*) grown in the northeast of Portugal (Valverde et al. 2003), while the species *H. hiltneri* was associated with wheat plants grown in Germany (Rothballer et al. 2006). *H. rhizosphaerae* was detected in the rhizosphere of *Allium victorialis* var. *platyphyllum* plants grown in South Korea (Jung et al. 2007). The species H. *aquaticum*, H. *autotrophicum*, *H. huttiense* subsp. *putei*, and subsp. *huttiense* were isolated from water samples collected in the USA, Switzerland, New Zealand, and Japan, respectively. As mentioned before, *H. chlorophenolicum* was isolated from soil sediment collected in a stream near the industrial region of Cheongju, Korea (Im et al. 2004). Other unclassified *Herbaspirillum* species have been isolated from rhizosphere soil of the reed *Phragmites australis* cultivated on reclaimed land (South Korea) (Lee et al. 2012) and wild and traditional rice plants grown in Japan (Elbeltagy et al. 2000).

An interesting characteristic related to the nitrogen-fixing *Herbaspirillum* spp. associated with plants is the ability of the bacteria to colonize plant tissues endophytically (Döbereiner 1992). Many studies have shown the endophytic colonization of the xylem of sugarcane roots by *H. seropedicae* and *H. rubrisubalbicans* strains (Olivares et al. 1997; James and Olivares 1998) as well as the intercellular spaces of root and stem tissues of two Japanese micropropagated sugarcane varieties (Njoloma et al. 2006). Infection and colonization of the rice root intercellular spaces were also demonstrated by

James et al. (2002). The colonization process seems to involve bacterial envelope structures such as LPS, EPS, adhesins, and the T3SS secretion system (Monteiro et al. 2012). Even for *H. rubrisubalbicans*, no pathogenic symptoms are observed during the colonization process of commercial-resistant sugarcane varieties cultivated in Brazil (Olivares et al. 1997). Similarly, the *H. frisingense* species are localized in intercellular spaces of the root cortex and the root vascular tissues of *Miscanthus sinensis* as well as in the central cylinder and xylem vessels of barley root tissues (Rothballer et al. 2008). Endophytic colonization of common bean plants has also been observed after inoculation with *H. seropedicae*, but no pathogenic symptoms or nodule formation was observed (Schmidt et al. 2011). The low number of strains available for most of the described *Herbaspirillum* species suggests that, with the exception of the nitrogen-fixing species, the other species are limited to their specific environmental local of isolation. The use of culture-independent method to search for the presence of *Herbaspirillum* associated with sugarcane and *Pennisetum* cultivated in Seropédica, Brazil, did not detect the presence of *Herbaspirillum* species (Fischer et al. 2012; Videira et al. 2013). On the other hand, assessment of the diazotrophic bacterial community within the rhizosphere, roots, and stems of maize grown in the South Brazil region showed the presence of bacteria from the genus *Herbaspirillum* dominating the interior of the plants but not the soil (Roesch et al. 2008). It is already known that *H. seropedicae* does not survive in soils and requires the seed germination for recovering the bacteria that may stay in viable but not culturable conditions in soil (Olivares et al. 1996).

Noviherbaspirillum: The genus *Noviherbaspirillum* was created quite recently (Lin et al. 2013) and includes species isolated from very specific niches. The three species *N. aurantiacum*, *N. canariense*, *and N. soli* occurred in an old volcanic mountain soil in northeast of Tenerife, Canary Islands (Carro et al. 2012). The vegetation at this site is dominated by herbaceous nitrophilous communities with species such as *Galactites tomentosa*, *Calendula arvensis*, *Oxalis pes-caprae*, *Sinapis arvensis*, and *Brachypodium distachyon* and also plantations of *Eucalyptus globulus*. The species *N. psychrotolerans* was detected in a soil sample of the Larsemann Hills, East Antarctica (69° 24′ S 76° 20′E) (Bajerski et al. 2013), while the type species of the genus, *N. malthae*, occurred in oil-contaminated soils in the vicinity of a refinery located at Kaohsiung city, Taiwan (Lin et al. 2013). No additional occurrence study has been reported up to date.

Collimonas and ***Glaciimonas***: *Collimonas* strains have the remarkable ability to grow on living fungal hyphae based on their chitinolytic activity (De Boer et al. 2001, 2004). This mycophagy was demonstrated in a gnotobiotic sand system, where bacterial numbers increased after invasion of common soil fungi like *Mucor hiemalis* and *Chaetomium globosum* (De Boer et al. 2001). It was shown that mycophagy also occurred under natural carbohydrate poor conditions in soil (Höppener-Ogawa et al. 2009). *Glaciimonas* seems also to specialize on very nutrient poor environments because its members colonize obviously also nutrient poor environments such as the alpine glacier cryoconite or from wastewater samples from a uranium mine (Zhang et al. 2011; Chung et al. 2013).

Janthinobacterium: The type species, *Janthinobacterium lividum*, have been predominantly isolated in temperate regions from soils and water bodies such as rivers, lakes, and springs (Johnson et al. 1990). There are reports for isolations associated with spoilage of pasteurized milk (Eneroth et al. 2000), and *J. lividum* syn. *P. mephitica* was isolated from butter (Claydon and Hammer 1939). *Janthinobacterium agaricidamnosum*, the causal organism of soft rot disease of *Agaricus bisporus*, was isolated on a farm in southern England. Lincoln et al. (1999) showed that the disease is most active under very moist conditions and thus may have been introduced to mushroom farms through the water supply or casing peat as *J. lividum* have been found in soil and water.

Undibacterium: The predominant habitat of the *Undibacterium* genus is the water and soil. The genus contains six validly published species, originally isolated from drinking water in Göteborg (Sweden), from purified water system at Roche, Penzberg (Germany), from a permafrost soil sample (China) and two new reports from soil and freshwater from South Korea (Kämpfer et al. 2007; Eder et al. 2011; Liu et al. 2013; Kim et al. 2014). Most of the species of *Undibacterium* are sensitive to elevated salt concentrations. This is the case for *Undibacterium oligocarboniphilum* strain EM 1^T isolated from pure water that is adapted to low NaCl concentration. Its notable predominance of environmental clones closely related to the 16S rRNA genes of *Undibacterium* was retrieved from aquatic environments in different studies – for example, in an ecological survey of a bacterial population recovered from arsenic-contaminated groundwater of North East India (Assam) reported by Ghosh and Sar (2013) as *Undibacterium* sp. VA1-17 16S ribosomal RNA gene and *Undibacterium* sp. A1-2 16S ribosomal RNA gene (both partial sequences). Other studies about the bacterial diversity in groundwaters and bottled natural mineral waters (*Undibacterium* sp. B6.09-36 16S rRNA gene, complete sequence), in subglacial Himalayan lakes (*Undibacterium* sp. NBGD29 16S ribosomal RNA gene, partial sequence), in the water of Powai Lake (uncultured *Undibacterium* sp. isolate DGGE gel band PW-14 16S ribosomal RNA gene, partial sequence), in biofilms formed on glass surfaces exposed to continuously flowing drinking water, and in bottled mineral water (*Undibacterium pigrum* strain A2RO6 16S ribosomal RNA gene, partial sequence), all demonstrate sequences resembling *Undibacterium* spp. Other habitats include cultivable isolates from soils, deep argillite geological formation (uncultured *Undibacterium* sp. clone 19186_CC1M241_B03 16S ribosomal RNA gene, partial sequence), excavation areas in Korea (*Undibacterium* sp. CMFN9 16S ribosomal RNA gene, partial sequence), and plant rhizosphere and roots of *Stellera chamaejasme* L. (uncultured *Undibacterium* sp. clone OTUrs17 16S ribosomal RNA gene, partial sequence) (Liu et al. 2013; Ghosh and Sar 2013; Sahay et al. 2013; Kim et al. 2014).

Herminiimonas: The predominant habitat of the quite recent described *Herminiimonas* genus (Fernandes et al. 2005) seems to be water bodies. The genus contains at present six validly published species. Members of these species were

originally isolated from bottled mineral water, drinking water (Sweden), arsenic-contaminated industrial wastewater sludge (East Germany), high depth Greenland ice (Antarctica), contaminant of a biopharmaceutical production process (Sweden and Japan), and from lichen-colonized rock (Fernandes et al. 2005; Kämpfer et al. 2006, 2013; Muller et al. 2006; Lang et al. 2007; Loveland-Curtze et al. 2009). More recently, *H. contaminans* (Kämpfer et al. 2013) was isolated from urban soil in Japan (Iizuka et al. 1998); this means that it can be isolated from environments other than water bodies. Reasonable evidences for a wide ecological occurrence of *Herminiimonas* would come from environmental clones obtained using culturable and non-culturable microbiological methods. Presumably, new habitats colonized by phylogenetically related *Herminiimonas* sp. could be detected through environmental sequences with 16S rRNA gene sequence similarities to cultured *Herminiimonas* spp. A 16S rRNA gene sequence closely related to *Herminiimonas* sequences was reported as uncultured *Herminiimonas* sp. (clone NJGS-34) and obtained from a Tibetan ice core. *Herminiimonas* sp. (clone ATA91) retrieved from postglacial soils of Ecology Glacier, King George Island, Antarctica, and *Herminiimonas* sp. (SP-B) from permanently cold arctic fjord sediments, resulted from studies conducted by Xiong et al. (2012), Zdanowski et al. (2013), and Canion et al. (2013), respectively. These psychrophilic sites resemble in part the habitat for the original description of *H. glaciei* that by a very elegant recovery, isolation procedure was resuscitated from deep Greenland ice core with an estimated age of 120,000 year (Loveland-Curtze et al. 2009). The authors highlighted that the conditions at this environment may be similar to other planets and open up opportunities to understand key life-forms outside the earth. Interestingly, the bacterium is 10–50 times smaller than *Escherichia coli*, and its size would help more efficient nutrient exchange and protection from predators and survival in the liquid veins that exist between crystals of ice in over 3 km deep. Such extremely cold environments, like in the depth of the Greenland ice, best analogies may exist for certain extraterrestrial habitats. Besides the aquatic habitat, rocks, soils, and sediments and its interfaces seem to be proper habitats to *Herminiimonas* related species. In ecological studies with bacterial communities in soils and the associated Fe–Mn nodules, an uncultured *Herminiimonas* sp. (clone SDn1-56) was retrieved. A combination of water–soil dynamics under psychrophilic to mesophilic conditions that cover the most predominant habitats for the genus was investigated in a study related to diversity of culturable bacteria from freshly deglaciated granite sand in the Central Alps, from where *Herminiimonas* sp. related clones were recovered. *H. arsenicoxydans* closely related clones (acr 26, 27, and 28) represent part of the microbial community of heterotrophic bacteria on marble surfaces of Acropolis monuments. *H. arsenicoxydans* is a heterotrophic bacterium capable of reducing and oxidizing arsenic with the objective of detoxification. Arsenic is both a product from natural sources and of human activities and is widely distributed in the environment (Kämpfer et al. 2006). The association of *H. saxobsidens* in the lichen–rock interface zone is remarkable, where bacteria biomineralization activities are promoted by oxalic acid produced by the lichen communities, which accelerate weathering of the rock by solubilizing the cement between the rock grains (Johnston and Vestal 1993). A clone closely related to uncultured *Herminiimonas* sp. (8,204) have been retrieved from mice skin under laboratory conditions (Chehoud et al. 2013), being part of the microbial ecosystem of the skin that is colonized by a diversity of microbiota. Sequences closely related to *H. saxobsidens* have been recovered from (AV109) human oral microbiome (Dewhirst et al. 2010) demonstrating possible association with human being.

Oxalobacter: *Oxalobacter* spp. occur in anaerobic environments, such as the rumen of man and mammals and in freshwater sediments (Allison et al. 1985; Dehning and Schink 1989), where they play a role in the degradation of oxalate, which readily occurs in such environments (Morris and Garcia-Rivera 1955; Allison et al. 1977, 2005).

Oxalicibacterium: Species from the genus *Oxalicibacterium* are aerobic oxalate degraders that have been isolated from soil (*O. horti* and *O. solurbis*), from oxalate-rich plant litter in Turkey (*O. flavum*) and from chicken dung (*O. faecigallinarum*) (Tamer et al. 2002; Sahin et al. 2009b, 2010b). Apart from their description, little information is available on the ecology of these bacteria.

Duganella and ***Pseudoduganella***: These bacteria thrive in quite diverse ecological niches, in wastewater sewage systems, and soils, but also in plant habitats, like roots or leaves (Aranda et al. 2011) and leaves (Kämpfer et al. 2012b). Some members of the genus *Duganella* are characterized by their extracellular polysaccharide production (Hiraishi et al. 1997). *D. sacchari* and *D. radicis* isolates from the rhizosphere/rhizoplane of sugarcane are claimed to have plant growth-promoting abilities (Madhaiyan et al. 2013).

Massilia: *Massilia*, as well as other members of *Oxalobacteraceae*, has been described in a broad range of niches in recent years (Ofek et al. 2012). It was initially characterized as clinical isolates, but subsequently isolated and detected in many environments, such as air, aerosols, dust, freshwater, soil, phyllosphere, and more recently as an important component of the rhizosphere (Ofek et al. 2012). This ability to explore different niches seems to be a characteristic for the family *Oxalobacteraceae* with more and more genera and species being isolated and characterized in diverse ecological niches. Recently, the number of bacterial species and genera classified as root-associated bacteria increases due to technical advances enabling comprehensive cultivation-independent studies. *Massilia* is such a group of organisms, and it was detected inside the roots and in the rhizosphere of many plant species as one of major groups, and it seems to play an important role (Ofek et al. 2012). In another study, *Duganella* and *Massilia*, among other groups, were found at higher frequencies associated to the rhizosphere of diseased wheat plants affected by *Rhizoctonia* bare patch, related to non-affected plants (Yin et al. 2013). The first evidence of a plant-associated *Massilia* sp. was in stems of soybean or of sweet pepper (Grönemeyer et al. 2012; Ikeda et al. 2009; Rasche et al. 2006). Many other studies have reported plant-associated *Massilia* sp. with increasing importance of the

Table 35.15
Rhizosphere-associated *Massilia*

Niche	Plant	Observation	Reference
Stem	Soybean (*Glycine max*)	Bacterial cell enrichment method to minimize interference of plant DNA	Ikeda et al. 2009
Stem	Sweet pepper (*Capsicum annuum*)	Climate chamber experiment testing the effect of low temperature on bacteria diversity	Rasche et al. 2006
Rhizosphere	Sugarcane (*Saccharum* sp.)	Crop field	Pisa et al. 2011
Rhizosphere	Wheat (*Triticum aestivum*)	*Rhizoctonia solani* bare patch diseased plants	Yin et al. 2013
Rhizosphere	*Alyssum murale*	Metal hyperaccumulator plants	Abou-Shanab et al. 2003, 2007
Rhizosphere	*Alyssum murale*	Ni-resistant bacteria in metal hyperaccumulator plants	Abou-Shanab et al. 2010
Rhizosphere	*Sonchus asper*	Germinated and raised from seeds under ozone exposure (65 days)	Dohrmann and Tebbe 2005
Rhizosphere	Willows (*Salix viminalis*)		Hrynkiewicz et al. 2010
Rhizosphere	Potato (*Ipomoea batatas*)	Crop field	Weinert et al. 2010
Surface-sterilized leaves/green branch segments	*Salix caprea*	Heavy-metal-accumulating plant	Kuffner et al. 2010
Surface-sterilized roots	Maize (*Zea mays*)		Grönemeyer et al. 2012
Root	Cucumber (*Cucumis sativus*)	Sown in three peat-based potting mixes amended with composts	Green et al. 2007

rhizosphere environment (Table 35.15). The successful recovery of *Massilia* isolates from soil under hyphae-exclusion bags (i.e., bags of 0.5 μm mesh which excludes hyphae of ectomycorrhizal fungi incubated in a forest soil) is also worth to mention (Brooks et al. 2011). Strain Y1243-1^T of *M. yuzhufengensis* is able to grow at 2 °C, whereas other species of this genus cannot and had a relatively higher proportion of $C_{18:0}$ (6.95 %) compared with recognized species of the genus *Massilia* (Shen et al. 2013).

Telluria: *Telluria mixta* and *T. chitinolytica* were isolated from soil in Australia and Israel, respectively. *T. chitinolytica* demonstrated to have nematicidal activity and potential for the control of the root-knot nematode *Meloidogyne javanica* (Spiegel et al. 1991). *T. chitinolytica* is able to degrade chitin, but not dextran or pectate that is performed by *T. mixta* (Sly and Fegan 2005).

Pathogenicity, Clinical Relevance

Analysis of the species belonging to the family *Oxalobacteraceae* indicates the presence of mild phytopathogenic species and opportunistic human pathogenic species/strains. Despite the large spectrum of antibiotic resistance among the species, the majority of them are not pathogenic to plants or human. No information is available so far for the genera *Collimonas*, *Glaciimonas*, *Duganella/Pseudoduganella*, *Herminiimonas*, and *Undibacterium*.

Plant-Related Pathogenicity

Herbaspirillum: The reclassification of few strains of *[Pseudomonas] rubrisubalbicans*, causative agent of the mottled strip disease in some older susceptible sugarcane varieties, to *Herbaspirillum rubrisubalbicans* (Gillis et al. 1990; Baldani et al. 1996) raised the question about the phytopathogenicity of *Herbaspirillum* strains colonizing plants. Olivares et al. (1997) showed that neither *H. rubrisubalbicans* nor *H. seropedicae* strains produced any characteristic symptoms when artificially inoculated into leaves of commercial-resistant varieties of sugarcane grown in Brazil. However, these species caused a red stripe disease in *Pennisetum* and *Sorghum bicolor* although the symptoms were very mild in *Sorghum* leaves inoculated artificially (Pimentel et al. 1991). It was also shown that a particular *H. rubrisubalbicans* strain caused a mottled stripe disease in a sugarcane cv Taiwan cultivated in China (Tan et al. 2010). More recently, it was claimed that the *H. seropedicae* strains Os45 and Os34, isolated from roots of the rice cultivar C2 grown in China, are pathogenic since they inhibited growth of rice seedlings

and induced a hypersensitive response in tobacco leaves (Zhu et al. 2012; Ye et al. 2012). On the other hand, no phytopathogenic symptoms have been observed for endophytic *H. frisingense* strains inoculated into barley and *Miscanthus* plants (Rothballer et al. 2008). There are also no reports showing the pathogenicity caused by the other *Herbaspirillum* species in plants.

Janthinobacterium: *Janthinobacterium agaricidamnosum* was reported to be pathogenic to mushroom crops, especially brown Agaricus strains. Reduction of relative humidity in crop house below 85 % can reduce the disease progress.

Telluria: *Telluria chitinolytica* demonstrated nematicidal activity and potential for control of the root-knot nematode *Meloidogyne javanica* (Spiegel et al. 1991).

Clinical Relevance

Herbaspirillum: Few reports associating the presence of *Herbaspirillum* species with opportunistic pathogenicity in human comes mainly from patients with cystic fibrosis, published in the last decade. For example, two *Herbaspirillum* strains (AU2210A and AU2339) showing high 16S rRNA sequence similarity to *Herbaspirillum huttiense* (99.5 %) and *H. frisingense* (99.6 %), respectively were identified among 51 bacterial isolates recovered from respiratory secretions of cystic fibrosis patients (Coenye et al. 2002). A report suggested that a bacteremia and cellulitis detected in a homeless man patient with cirrhosis was due to *H. seropedicae* (Tan and Oehler 2005). Another study involving the 16S rRNA sequence analysis of 28 bacteria isolated from persons with cystic fibrosis indicated that all strains belonged to the *Herbaspirillum* genus (Spilker et al. 2008). Three strains were identified (>99.5 % identity) as *H. huttiense subsp. huttiense*, three as *H. frisingense*, two as *H. seropedicae* and two as *H. huttiense subsp. putei*. The rest of the strains could not be assigned to any described species, but 14 of these strains shared 99 % similarity to *H. huttiense* subsp. *huttiense* and subsp. *putei*, while the other strains may constitute novel *Herbaspirillum* species. Despite the recovery of *Herbaspirillum* species from persons with cystic fibrosis, the authors argued that the frequency of occurrence was low, since *Herbaspirillum* sp. was recovered from only 3 % of all patients analyzed (1,100); it was speculated that isolation of *Herbaspirillum* sp. may be influenced by other species present in the samples which might overgrow *Herbaspirillum* during the isolation procedure. According to Morovic et al. (2010), the majority of the reported patients presenting chronic respiratory infection and bacteremia had only transient respiratory colonization by *Herbaspirillum*.

Janthinobacterium: The genus *Janthinobacterium* is probably not pathogenic. However, according to Patjanasoontorn et al. (1992), the species *Janthinobacterium lividum* caused opportunistic infections in hospital environment and fatal septicemia.

Massilia: *Massilia timonae* was first described by La Scola et al. in 1998 based on a single isolate from the blood of an immune-compromised patient with meningoencephalitis (La Scola et al. 1998). Since then, other isolates have been identified infecting humans as *M. timonae*, mainly based on 16S rRNA sequence comparison. The diagnosis for the patients from whom the bacteria were isolated varies: meningoencephalitis, wound infection following elective orthopedic surgery, osteomyelitis, cerebral pseudotumor, sepsis, lymphadenopathy, and otitis (Park and Shin 2013; Van Craenenbroeck et al. 2011; Lindquist et al. 2003; Sintchenko et al. 2000; La Scola et al. 1998). In one case, the isolate was derived from the lymph node of a patient with generalized lymphadenopathy and was reported as a coinfection with malaria (Van Craenenbroeck et al. 2011). These reports show the wide range of clinical presentation of *M. timonae* infections, but the source of infection appears to be unclear in all cases. In one patient, abscessed teeth were suspected to be the source, suggesting that *M. timonae* may occur as part of the transient normal oral flora. In another case, the contamination with this organism occurred possibly in a lake (Van Craenenbroeck et al. 2011). Furthermore, an isolate from otitis media was identified as *Massilia* sp., although the authors pointed out some possibility of contamination (Park and Shin 2013). Bacteria associated to otitis media commonly are *Streptococcus pneumonia*, *Moraxella catarrhalis*, and *Haemophilus influenza*. The identification of an isolate belonging to the genus *Massilia* possibly constitutes to a novel genus (Park and Shin 2013).

Oxalobacter: *Oxalobacter formigenes* is found in the gastrointestinal tract of man and animals. It relies on the presence of oxalate as energy and carbon source and aids in the destruction of dietary oxalate, a toxic substance which absorption contributes to increases of urinary oxalate and the formation of renal stones. This also limits the absorption of calcium and other minerals in the gastrointestinal tract (Holmes and Assimos 2004). At birth, the human intestine is free of *O. formigenes*, but newborn children are quickly colonized by these bacteria. There is clinical evidence that their absence in the gastrointestinal tract is a risk factor in the development of renal stone formation (Mittal and Kumar 2004). The oral application of Oxalobacter formigenes as a probiotic agent was tested in a clinical study with 43 human subjects. The application had no significant effect on urinary oxalate of treated subjects as compared to placebo-treated sub-jects (Hoppe et al. 2011).

Antibiotic Sensitivity

The antibiotic sensitivity is variable among members of the *Oxalobacteraceae* family and is dependent on the method used to test the minimal inhibitory concentration (MIC). Details about the levels of sensitivity/resistance are found in the description of the species, when available, or in the bibliography listed here.

Herbaspirillum: The antibiotic sensitivity varied among the *Herbaspirillum* species, and most of the available information are related to the wild type strains. *H. seropedicae* is susceptible to chloramphenicol, tetracycline, gentamicin, kanamycin, erythromycin, and streptomycin and is resistant to penicillin. *H. rhizosphaerae* is susceptible to chloramphenicol, gentamicin, kanamycin, neomycin, oleandomycin, streptomycin, and tetracycline but not to ampicillin, carbenicillin, cephalothin,

lincomycin, novobiocin, penicillin G, or polymyxin B. *H. lusitanum* is susceptible to gentamicin, tobramycin, netilmicin, and amikacin and resistant to cefotaxime and ceftazidime. *H. aquaticum* is resistant to polymyxin B. A *Herbaspirillum* sp. isolate from a patient was found to be susceptible to the majority of antimicrobial agents tested (amikacin, aztreonam, colistin, doxycycline, cefepime, tigecycline, ciprofloxacin, meropenem, piperacillin–tazobactam, ticarcillin–clavulanate, tobramycin, and ceftazidime).

Noviherbaspirillum: The species of the genus *Noviherbaspirillum* (*N. canariense*, *N. aurantiacum*, *and N. soli*) are sensitive to the antibiotics cefuroxim, ciprofloxacin, erythromycin, gentamicin, neomycin, polymyxin B, and tetracycline. However, *N. canariense* is resistant to ampicillin, penicillin, and cloxacillin. *N. aurantiacum* is resistant to cloxacillin and N. soil to penicillin (Carro et al. 2012). *N. psychrotolerans* carries resistance against the antibiotics ampicillin, cephalosporin, erythromycin, metronidazole, novobiocin, penicillin, fosfomycin, and troleandomycin and is sensitive to gentamicin, kanamycin sulfate, oxytetracycline, and rifampicin (Bajerski et al. 2013). No antibiotic studies were presented for the *N. malthae*.

Glaciimonas: *Glaciimonas immobilis* Cr9-30^T are resistant to ampicillin, fusidinic acid, and erythromycin and sensitive to streptomycin, chloramphenicol, tetracycline, kanamycin, gentamicin, amikacin, rifampicin, and nalidixic acid (Zhang et al. 2011).

Janthinobacterium: *Janthinobacterium* strains (W1r3^T, Clb4, H5, NCIMB 9230, NCIMB 9414, and DSM 1522^T) are resistant to penicillin G and vancomycin, but sensitive to erythromycin, streptomycin, tetracycline, or nalidixic acid. Interestingly, *J. lividum* has active metallo-beta-lactamase, which is responsible for resistance to several beta-lactam antibiotics (Rossolini et al. 2001).

Herminiimonas: *Herminiimonas arsenicoxydans* is resistant to tetracycline or ampicillin, but inhibited by kanamycin, chloramphenicol, streptomycin, and trimethoprim–sulfamethoxazole (Kämpfer et al. 2006). This species is able to resist to multiple toxic elements, especially arsenic. *Herminiimonas glaciei* strain UMB49^T is resistant to ampicillin, bacitracin, chloramphenicol, ciprofloxacin, penicillin, nalidixic acid, rifampicin, streptomycin, and vancomycin. Inhibition was detected for gentamicin, neomycin, and tetracycline.

Massilia: *Massilia aurea* is resistant to penicillin, bacitracin, and cephalothin. It is sensitive to the following antibiotics: tetracycline, rifampicin, streptomycin, neomycin, erythromycin, kanamycin, vancomycin, nalidixic acid, novobiocin, and chloramphenicol (Gallego et al. 2006), while *Massilia brevitalea* is resistant to bacitracin, carbenicillin, chloramphenicol, erythromycin, gentamicin, novobiocin, and penicillin G but sensitive to amikacin, ampicillin, kanamycin monosulfate, rifampicin, streptomycin sulfate, trimethoprim–sulfamethoxazole, tetracycline, tobramycin, and vancomycin (Zul et al. 2008). *Massilia haematophila and Massilia varians* are sensitive toward polymyxin B, penicillin G, amoxicillin, amoxicillin/clovalanat, gentamicin, trimethoprim, ciprofloxacin, rifampicin, and colistin (Kämpfer et al. 2008a). *Massilia tieshanensis* is sensitive to amoxicillin, ampicillin, cefotaxime, cefoxitin, chloramphenicol, erythromycin, kanamycin, nalidixic acid, neomycin, nitrofurantoin, novobiocin, polymyxin B, streptomycin, penicillin, tobramycin, and trimethoprim (Du et al. 2012). *Massilia namucuonensis* is susceptible to azithromycin, kanamycin, ofloxacin, tetracycline, rifampicin, cefotaxime, and streptomycin; it shows intermediate susceptibility to chloramphenicol and is resistant to amphotericin B (Kong et al. 2013). No information is available for the other *Massilia* species.

Oxalobacter: Four *Oxalobacter formigenes* strains HC1, Va3, CC13, and OxK, which are found in humans, have been tested for antibiotic sensitivity (Lange et al. 2012). All strains were sensitive to azithromycin, ciprofloxacin, clarithromycin, clindamycin, doxycycline, gentamicin, levofloxacin, metronidazole, and tetracycline. All strains were resistant to amoxicillin, clavulanate, ceftriaxone, cephalexin, and vancomycin. Only strain CC13 was resistant to nitrofurantoin (Lange et al. 2012).

Oxalicibacterium: *O. flavum* strain TA17^T was found to be sensitive to erythromycin, streptomycin, and gentamicin, whereas it was resistant to bacitracin and ampicillin (Tamer et al. 2002). Although Tamer et al. (2002) reported sensitivity of strain TA17^T to chloramphenicol, the strain is found resistant to this antibiotic in another study (Sahin et al. 2009b). *Oxalicibacterium faecigallinarum* strain YOx^T was found sensitive to the following antibiotics: chloramphenicol, erythromycin, streptomycin, penicillin, and colistin, whereas *Oxalicibacterium horti* strain OD1^T was resistant to chloramphenicol and penicillin (Sahin et al. 2009b).

Application

The *Oxalobacteraceae* family is formed by bacterial species with very diversified metabolic functions, but so far only *Herbaspirillum* and *Collimonas* species have already been applied as biofertilizer or biocontrol agents in agriculture, while other genera have been exploited for industrial application. Many species have shown biotechnological potential as suggested by the genome sequencing analyses, while others have not been exploited yet, such as *Noviherbaspirillum* spp., *Glaciimonas* spp., and *Telluria* spp.

Agricultural Application

Herbaspirillum: Among the species of the genus *Herbaspirillum*, only the species *H. seropedicae*, *H. rubrisubalbicans*, and *H. frisingense* have shown both the ability to fix nitrogen and to associate with plants of agricultural importance as plant growth-promoting agents (Monteiro et al. 2012). In addition to fix nitrogen, strains from these species produce phytohormones such as gibberellin and auxin (Bastián et al. 1998; Lambrecht et al. 2000; Bottini et al. 2004) and siderophores (Rosconi et al. 2013). In addition, they have abilities to solubilize inorganic P (Estrada et al. 2013) to present ACC deaminase to lower inhibitory ethylene levels in stressed plant roots (Rothballer et al. 2008) and to exert biological control activities

(Weber et al. 2007; Ting et al. 2011). All these features have been suggested to contribute to plant growth promotion (Baldani and Baldani 2005), but most of these effects have been observed under axenic conditions such as rice inoculated with *H. seropedicae* strains (Baldani et al. 2000), micropropagated sugarcane plants inoculated with both *H. seropedicae* and *H. rubrisubalbicans* strains (Canuto et al. 2003), and micropropagated *Miscanthus giganteus* seedlings inoculated with *H. frisingense* strain Mb11 (Rothballer et al. 2008). For *H. frisingense*, it could further be shown in a soil system that root ethylene signaling is involved in growth promotion of young plants of *Miscanthus sinensis* inoculated with endophytic strain *H. frisingense* GSF30^T (Straub et al. 2013b). Pot and field inoculation studies have been intensified in the last decade, although already in 1988, a successful field study had demonstrated a significant sorghum yield increase upon inoculation with *H. seropedicae* (Pereira et al. 1988). Yield responses due to inoculation with strain *H. seropedicae* ZAE94 was observed for different rice varieties (commercial and traditional ones) grown at different locations in Brazil (Ferreira et al. 2010; Araújo et al. 2013). Also, certain aluminum-tolerant rice varieties were stimulated in growth and nitrogen accumulation due to inoculation with *Herbaspirillum seropedicae* (Gyaneshwar et al. 2002). Additional studies showed that inoculation of maize varieties (hybrids and varieties) with strain ZAE94 resulted in significantly increased yields and in addition indicated that about 30 % of the nitrogen accumulated in the plant was derived from the BNF (Alves 2007). Furthermore, the *H. seropedicae* strain ZAE94 was recommended as a biofertilizer for inoculation of maize (Reis et al. 2009). Another study showed that the application of *H. seropedicae* strain Z67 together with humic substances via foliar application, produced 65 % higher grain yield than uninoculated maize plants grown under field conditions (Canellas et al. 2013). The strains *H. seropedicae* HRC54 and *H. rubrisubalbicans* HCC 103 are being used as components of a consortium inoculant recommended by the Brazilian Agricultural Research Enterprise (Embrapa) for sugarcane (Oliveira et al. 2006). A significant yield response to inoculation with a mixture of these bacteria was demonstrated for many commercial sugarcane varieties grown in different regions of Brazil (Schultz et al. 2012).

Collimonas: The species *Collimonas fungivorans* was demonstrated to have efficient biocontrol activity in vivo to suppress tomato foot and root rot in greenhouse experiments (Kamilova et al. 2007). *C. fungivorans* has a strong ability to colonize roots and is competing successfully against the excellent root colonizer *Pseudomonas fluorescens* WCS365. Direct competition for colonization and efficient in situ chitinolytic attack of *Fusarium oxysporum f. sp. radicis-lycopersici* is discussed as mechanisms of efficient biocontrol (Kamilova et al. 2007). Therefore, a potential for practical application is present for *Collimonas* similar as to chitinolytic *Serratia plymuthic*a (Berg 2000). In addition, some *Duganella* isolates from roots are claimed to have biotechnological potential (Aranda et al. 2011; Madhaiyan et al. 2013).

Janthinobacterium: Recently, it was demonstrated that *Janthinobacterium lividum* also produces indole-3-carboxaldehyde and that this plays a role in a possible mutualistic relationship with the red-backed salamander *Plethodon cinereus*, acting as a chemical defense mechanism against the chytrid fungus *Batrachochytrium dendrobatidis*, causal agent of the chytridiomycosis disease (Brucker et al. 2008). Such biological properties of *J. lividum* could be potentially explored to provide antifungal biocontrol. In addition to its antifungal product, three antibiotics produced by *J. lividum* act against both gram-negative and gram-positive bacteria (under patent process).

Industrial Application

Janthinobacterium: Some strains of *Janthinobacterium*, especially *J. lividum* strains, produce the pigment violacein that is preferentially produced when glycerol is the carbon source. Pantanella et al. (2007) showed a relationship between violacein production, biofilm formation, and improved survival, suggesting that it may play a role in response to environmental stress. Although the role of this pigment in bacterial life and metabolism is at present not fully understood, different functions have been attributed to violacein such as regulation of tryptophan production, environmental competition with other microorganisms, an antiprotozoal, antibacterial, anti-candida, antiviral, and antitumoral activity (Momen and Hoshino 2000; Matz et al. 2004; Leon et al. 2001). An industrial application involves its use as dye for natural or synthetic fibers (Shirata et al. 2000).

Massilia: Six bacteria of the genus *Massilia*, isolated from plants at Mallorca Island, Spain, and phylogenetically related to *M. aurea*, *M. plicata*, *M. niabensis*, and weakly to *M. niastensis* and *M. aerilata* (two potentially new species) were found to produce poly-3-hydroxybutyrate (PHB) when cultured with glucose or glycerol as carbon source. Polyhydroxyalkanoate (PHA) yields varied considerably among strains, but reach up to 50 wt% of cell mass as polyhydroxybutyrate (PHB) when grown on glycerol (Bassas-Galia et al. 2012). Type strains of many nonpathogenic *Massilia* species (*M. plicata*, *M. dura*, *M. aurea*, *M. albidiflava*, *M. brevitalea*, *M. lutea*, *M. aerilata*, and *M. umbonata*) were also shown to produce PHB when grown on different carbon sources (Rodríguez-Díaz et al. 2013; Bassas-Galia et al. 2012; Cerrone et al. 2011). An isolate of *Massilia* sp., designated BS-1, was shown to produce violacein, a compound produced by various bacteria and presenting important biological activities, including broad-spectrum antibacterial activity against gram-positive bacteria and antifungal, antiprotozoan, antimalarial, antitumor, antiviral, antioxidant, and antidiarrheal activities (Agematu et al. 2011). Although the 16S rRNA gene sequence of BS-1 isolate was reported to be closer to *Massilia* sp. strains (Agematu et al. 2011), a more recently search using MegaBLAST (Zheng et al. 2000) against NCBI 16S ribosomal RNA sequences (Bacteria and Archaea) database showed the best hit with *Massilia brevitalea* byr23-80 with 98 % identity.

Environmental Application

Herbaspirillum: In addition to a plant growth-promoting effect, it was shown that *Herbaspirillum chlorophenolicum* strain FA1 was able to use fluoranthene as sole carbon and energy source. It was therefore suggested as potential bioremediation technology for treatment of fluoranthene-polluted soil (Xu et al. 2011). A Brazilian *H. seropedicae* isolate was able to degrade Trifluralin (α,α,α-trifluoro-2,6-dinitro-*N,N*-dipropyl-*p*-toluidine) to an extent comparable to the only TFL degrader found in a commercial culture collection (Bellinaso et al. 2003).

Herminiimonas: Based on the predominant habitat and phenotypic traits, some potential applications of *Herminiimonas* genus can be raised. For example, the well-demonstrated ability of *H. arsenicoxydans* to perform the oxidation of As[III] to arsenate As[V] represents potential biotechnological relevance for detoxification, converting As[III] into the less toxic and less mobile form As[V] (Muller et al. 2006). With improved technological approaches and backed up by whole genome sequence information of this species (Muller et al. 2007), more efficient bioremediation process may be generated. The type strain of *H. arsenicoxydans* is resistant to numerous heavy metals such as Se [IV], Mn[II], Cr[III], Cd[II], Sb[III], and Ni[II], increasing its potential as a bioremediation resource. Delivering methods for microbial release to contaminated environments have been attempted using bacteria immobilized in a calcium alginate gel (Simeonova et al. 2005). As a common genus associated to water bodies, its potential for water reclamation should be tested. Other possible applications are related to the biomineralization abilities of *Herminiimonas saxobsidens*, which could be tested in agriculture systems to increase the nutrient availability of, for example, P, Zn, and K elements for plant production.

Massilia: Some species of the genus *Massilia* were reported to metabolize glucose (Padmanabhan et al. 2003) and to have the ability to degrade phenanthrene (Bodour et al. 2003) or other aromatic compounds (Khammar et al. 2005). Additional yet unidentified members of the genus *Massilia* have shown their capacity to degrade aromatic compounds (Bodour et al. 2003; Khammar et al. 2005). *M. tieshanensis* TS3^T was isolated from a mining soil as an arsenic-resistant bacterium. Test have shown its high tolerance to Cu^{2+} (4.0 mM), which is about 10 times more than in other *Massilia* species (*M. niastensis*, *M. aerilata*, *M. varians*, and *M. consociata*) (Du et al. 2012).

Undibacterium: There are no reports available yet about possible biotechnological application of *Undibacterium spp.* Its intimate relationship with water environment, including low resistance to salts, could raise interesting aspects about its dynamic role on water quality.

Acknowledgements

The support of INCT-FBN, CNPq, FAPERJ, as well as EMBRAPA Agrobiologia and Helmholtz Zentrum München is greatly acknowledged. The chapter was prepared with contributions from all of the authors, and they contributed equally.

36 The Family *Rhodocyclaceae*

Aharon Oren
Department of Plant and Environmental Sciences, The Institute of Life Sciences, The Hebrew University of Jerusalem, Jerusalem, Israel

E. Rosenberg et al. (eds.), *The Prokaryotes – Alphaproteobacteria and Betaproteobacteria*, DOI 10.1007/978-3-642-30197-1_292,

Abstract

The order *Rhodocyclales*, phylogenetically affiliated with the *Betaproteobacteria*, currently (April, 2012) consists of a single family, the *Rhodocyclaceae*, with 18 genera (*Rhodocyclus* [type genus], *Azoarcus*, *Azonexus*, *Azospira*, *Azovibrio*, *Dechloromonas*, *Dechlorobacter*, *Denitratisoma*, *Ferribacterium*, *Georgfuchsia*, *Methyloversatilis*, *Propionivibrio*, *Quatrionicoccus*, *Sterolibacterium*, *Sulfuritalea*, *Thauera*, *Uliginosibacterium*, and *Zoogloea*), and a total of 45 species. Members of the order display many different modes of living: There are anoxygenic photoheterotrophs; plant-associated nitrogen-fixing aerobes, species that degrade a wide range of carbon sources including many aromatic compounds, using oxygen, nitrate, chlorate, perchlorate, selenate, and other electron acceptors; and sulfur-oxidizing chemoautotrophs, methylotrophs, and anaerobes that perform propionic acid fermentation. These highly disparate organisms are classified within a single family solely on the basis of 16S rRNA phylogeny. Representatives have been isolated from diverse environments: soil; sewage treatment plants; polluted and unpolluted waters of ponds, rivers, and aquifers; and plant roots. Some aromatic compound-degrading members have considerable potential for biodegradation of organic waste material and bioremediation of polluted environments.

Taxonomy, Historical and Current

Order *Rhodocyclales* Garrity, Bell, and Lilburn 2006, 3^{VP} (Effective Publication: Garrity, Bell, and Lilburn 2005a, 887)

Rho.do.cy.cla'les. N.L. masc. n. *Rhodocyclus*, type genus of the order; suff. *–ales*, ending denoting an order; N.L. fem. pl. n. *Rhodocyclales*, the *Rhodocyclus* order.

The mol% G + C of the DNA varies between 59 and 71.

Type genus: *Rhodocyclus*.

The order *Rhodocyclales* was created in 2005, based on 16S rRNA sequence comparisons. Currently (April 2012) the order consists of a single family, the *Rhodocyclaceae*. Physiologically the group is very disparate. Some members are anoxygenic photoheterotrophs; others are plant-associated nitrogen-fixing bacteria; there are species that degrade a wide range of carbon sources, including many aromatic compounds, using oxygen, nitrate, nitrite, chlorate, perchlorate, or selenate as electron acceptors; one genus contains anaerobes that perform propionic acid fermentation, one species is a sulfur-oxidizing chemolithoautotroph, and one species is a versatile facultative methylotroph that grows on a wide range of one-carbon compounds and on larger organic compounds as well.

At the time of writing (April 2012), the family *Rhodocyclaceae* consisted of 18 genera (*Table 36.1*) with 45 species (*Tables 36.2–36.10*): *Rhodocyclus* (type genus) (2 species), *Azoarcus* (8 species) *Azonexus* (3 species), *Azospira* (2 species), *Azovibrio* (1 species), *Dechloromonas* (3 species), *Dechlorobacter* (1 species, thus far only effectively published), *Denitratisoma* (1 species), *Ferribacterium* (1 species), *Georgfuchsia* (1 species), *Methyloversatilis* (1 species), *Propionivibrio* (4 species, one of which was only effectively published), *Quatrionicoccus* (1 species), *Sterolibacterium* (1 species), *Sulfuritalea* (1 species), *Thauera* (9 species), *Uliginosibacterium* (1 species), and *Zoogloea* (4 species). All these genera were described in the last two decades, with two exceptions: *Zoogloea* and *Rhodocyclus*.

Zoogloea ramigera was first published as a taxon in 1868 (Itzigsohn 1868). The name *Zoogloea* was used earlier by Cohn (1854), who used it to describe a growth form and not as a nomenclatural genus (Zvirbulis and Hatt 1967). Strain ATCC 19544 was proposed as neotype of *Z. ramigera* by Unz (1971), and as such it appeared in the Approved Lists of Bacterial Names published in 1980. A taxonomic reevaluation of strains classified in the genus *Zoogloea* in the 1990s based on analysis of fatty acids, isoprenoid quinones, and DNA-DNA hybridization showed that the genus contained members that were unrelated (Hiraishi et al. 1992; Shin et al. 1993). Comparative analysis of 16S rRNA sequence data (Rosselló-Mora et al. 1993) led to the reclassification of a number of strains affiliated with the *Alphaproteobacteria* and containing ubiquinone-10 in the newly created genus *Shinella*, while the ubiquinone-8 and rhodoquinone-8 containing strains affiliated with the *Betaproteobacteria* remain classified in the genus *Zoogloea* (An et al. 2006).

The genus *Rhodocyclus* was created by Pfennig (1978) with the description of the red anoxygenic phototrophic *Rhodocyclus purpureus* showing unusual ring-shaped cells. It uses acetate, butyrate, caproate, pyruvate, malate, fumarate, benzoate, cyclohexane carboxylate, and H_2 + CO_2 anaerobically in the light when supplied with small amounts of yeast extract. Its photosynthetic pigments are bacteriochlorophyll *a* and carotenoids of the rhodopinal series. Originally it was classified within the family *Rhodospirillaceae*. The second red anoxygenic phototroph currently classified in the genus *Rhodocyclus* as *Rhodocyclus tenuis* was originally described as *Rhodospirillum tenue* (Pfennig 1969). The two isolates share a similar type of lipopolysaccharide in their outer membrane (Weckesser et al. 1983). A taxonomic rearrangement of the anoxygenic purple nonsulfur bacteria placed the two in the genus *Rhodocyclus*, while the former *Rhodocyclus gelatinosus* (Molisch 1907; Imhoff et al. 1984) comb. nov. was renamed *Rubrivivax gelatinosus* and classified within the family *Comamonadaceae* (*Betaproteobacteria*) (Imhoff 2005; Imhoff et al. 1984).

Further taxonomic rearrangements made within the family *Rhodocyclaceae* are the splitting of the genus *Azoarcus*, established by Reinhold-Hurek et al. (1993), into four genera: *Azoarcus*, *Azovibrio*, *Azospira*, and *Azonexus*. This rearrangement was necessary, as the genus *Azoarcus sensu lato* was not monophyletic, and was supported by analyses of electrophoresis patterns of proteins, genomic fingerprints, and morphological and nutritional features (Reinhold-Hurek and Hurek 2000). The organism previously described as *Dechlorosoma suillum* (Achenbach et al. 2001; Brenner et al. 2005e) was transferred to the genus *Azospira* as a later heterotypic synonym of *Azospira oryzae* (Tan and Reinhold-Hurek 2003).

The fermentative propionic acid producing isolate previously described as *Propionibacter dicarboxylicus*

Table 36.1

The genera classified within the order *Rhodocyclales*, family *Rhodocyclaceae*, as of April 2012

Genus	Number of species[a]	Type species	General properties
Rhodocyclus (type genus)	2	*Rhodocyclus purpureus*	Anoxygenic phototrophs containing bacteriochlorophyll *a* and carotenoids. Preferably grow photoheterotrophically under anoxic conditions in the light with different organic substrates as carbon and electron sources. Chemotrophic growth is also possible under microoxic to oxic conditions in the dark. Reduced sulfur compounds are not used as photosynthetic electron donors
Azoarcus	8	*Azoarcus indigens*	Chemoorganoheterotrophs, having a strictly respiratory metabolism with O_2 as the terminal electron acceptor (except for *A. anaerobius*). Under anaerobic conditions, nitrate can be used as an electron acceptor. Some species fix nitrogen under microaerobic conditions. Most species grow on salts of organic acids but not on mono- or disaccharides. Some soilborne species use aromatic substrates as sole carbon sources under denitrifying conditions
Azonexus	3	*Azonexus fungiphilus*	Chemoorganoheterotrophs, aerobic or microaerophilic when fixing nitrogen. O_2 is the only electron acceptor. Grow on salts of organic acids but not on mono- or disaccharides
Azospira	2	*Azospira oryzae*	Chemoorganoheterotrophs, aerobic or microaerophilic when fixing nitrogen. Some species use nitrate and perchlorate as electron acceptors. Growth does not occur on most amino acids or on mono- or disaccharides
Azovibrio	1	*Azovibrio restrictus*	Chemoorganoheterotrophs, aerobic or microaerophilic when fixing nitrogen. Some species use nitrate as electron acceptor. Grow on acetate, ethanol, fumarate, L-glutamate, DL-lactate, L-malate, propionate, and succinate. No growth occurs on most other organic acids or on any mono- or disaccharides
Dechloromonas	3	*Dechloromonas agitata*	Chemoorganoheterotrophs with a strictly respiratory metabolism. Oxidize acetate with O_2, chlorate, perchlorate, or nitrate
Dechlorobacter	1	*Dechlorobacter hydrogenophilus*	Chemoorganoheterotrophs with a strictly respiratory metabolism. Oxidize acetate with O_2, chlorate, perchlorate, Mn(IV), or nitrate as electron acceptors
Denitratisoma	1	*Denitratisoma oestradiolicum*	Chemoorganoheterotrophs with a strictly respiratory metabolism, using O_2, nitrate, nitrite, chlorate, or perchlorate as electron acceptors. Can grow anaerobically on 17β-oestradiol with nitrate as electron acceptor
Ferribacterium	1	*Ferribacterium limneticum*	Chemoorganoheterotrophs that oxidize acetate, benzoate, formate, and lactate using Fe(III) as the electron acceptor. Acetate is oxidized using fumarate or nitrate as electron acceptors
Georgfuchsia	1	*Georgfuchsia toluolica*	Chemoorganoheterotrophs with a strictly respiratory type of metabolism, capable of degrading aromatic compounds
Methyloversatilis	1	*Methyloversatilis universalis*	Versatile methylotrophs, able to use a variety of C_1 and multicarbon compounds. Assimilate C1 units via the serine pathway
Propionivibrio	4	*Propionivibrio dicarboxylicus*	Strictly anaerobe or aerotolerant chemoorganoheterotrophs that produce propionate and acetate as end products of fermentation of sugars, dicarboxylic acids, sugar alcohols, and aspartate. Succinate is decarboxylated to propionate. *Propionivibrio militaris* (a name not yet validated) cannot be considered to be a member of the genus as its metabolism is respiratory and not fermentative
Quatrionicoccus	1	*Quatrionicoccus australiensis*	Chemoorganoheterotrophic large aerobic cocci, occurring in tetrads
Sterolibacterium	1	*Sterolibacterium denitrificans*	Chemoorganoheterotrophs with a strictly respiratory type of metabolism with oxygen or nitrate as terminal electron acceptor. Does not grow on complex media. Cholesterol is completely oxidized to CO_2, coupled with nitrate reduction
Sulfuritalea	1	*Sulfuritalea hydrogenivorans*	Chemolithoautotroph growing under anoxic conditions by the oxidation of reduced sulfur compounds and hydrogen. Heterotrophic growth occurs on organic acids
Thauera	9	*Thauera selenatis*	Chemoorganoheterotrophs with a strictly respiratory metabolism. Molecular oxygen, nitrate, nitrite, and nitrous oxide are used as terminal electron acceptors. Selenate is used as the electron acceptor by some strains. Various organic acids, amino acids, and aromatic and aliphatic compounds are used as sole substrates. Only a few carbohydrates are utilized

Table 36.1 (continued)

Genus	Number of species[a]	Type species	General properties
Uliginosibacterium	1	*Uliginosibacter gangwonense*	Chemoorganoheterotrophs, strictly aerobic, that oxidize a range of simple sugars and organic acids
Zoogloea	4	*Zoogloea ramigera*	Chemoorganoheterotrophs. Aerobic, having a strictly respiratory type of metabolism with oxygen or nitrate as the terminal electron acceptor. Major carbon sources include salts of several organic acids, dicarboxylic amino acids, alcohols, and salts of certain aromatic acids. Form flocs and films in liquid media at late growth stages, when the cells become embedded in gelatinous matrices

[a]Including species whose names have been effectively but not yet validly published

+ positive in most strains, − negative in most strains, +/− variable among strains

(Tanaka et al. 1991) was found to be phylogenetically affiliated with *Rhodocyclus* (Hippe et al. 1999). *Propionibacter pelophilus*, another Gram-negative propionigenic bacterium (Meijer et al. 1999), was reclassified in the genus *Propionivibrio* as *Propionivibrio pelophilus* comb. nov. (Brune et al. 2002). A further rearrangement within the genus *Propionivibrio* may be necessary in the future when the name *Propionivibrio miltaris*, which currently is only effectively published (Thrash et al. 2010), will be validated. The genus description circumscribes the members of *Propionivibrio* as strictly anaerobic or aerotolerant fermentative organisms that produce propionate and acetate. The organism described as *Propionivibrio miltaris* is not fermentative but lives as a facultative anaerobe, oxidizing acetate or propionate using O_2, perchlorate, chlorate, nitrate, or nitrite as electron acceptors.

Phylogenetic Structure of the Family and Its Genera

Figure 36.1 shows a neighbor-joining tree of the type strains of the 45 species of the order *Rhodocyclales*. The family is associated with the *Betaproteobacteria*, the closest relatives being the families *Nitrosomonadaceae* and *Methylophilaceae*.

Generally, the 18 genera currently recognized within the family are well separated in the tree. One notable exception is the position of *Propionivibrio militaris* (a name not yet validly published) which does not cluster closely with the type strains of the two other genera of *Propionivibrio*: *P. decarboxylicus* and *P. pelophilus*. As stated above, also the mode of life of *P. militaris* (respiration using a range of electron acceptors) differs greatly from that of the other two species (fermentation). The monospecific genera *Ferribacterium* and *Quatrionicoccus* form a cluster within the genus *Dechloromonas*, separating the type species *D. agitata* from *D. hortensis* and *D. denitrificans*. This topology is supported by at least one other tree reconstruction algorithm (RAxML).

Genome Analysis

In view of the possible application of some representatives of the *Rhodocyclales* in biodegradation and bioremediation operations,

NR not reported, *d* different reactions in different isolates of the species

Data taken from: [a]Brenner et al. (2005a), [b]Reinhold-Hurek and Hurek (2006, [c]2000), [d]Quan et al. (2006), [e]Chou et al. (2008), [f]Bae et al. (2007)

[g]A nitrogenase gene was detected, but growth on N_2 as sole nitrogen source could not be demonstrated

it is not surprising that a number of genome sequencing projects have targeted isolates belonging to the group. ❯ *Table 36.11* summarizes the data available at the time of writing (April 2012). The seven investigated genomes are 3.8–5.1 Mbp in length. Only one of the sequencing projects dealt with a type strain (*Methyloversatilis universalis*) (Kittichotirat et al. 2011). Further, there is genomic information for three *Azoarcus* strains (BH72, EBnI, and KH32C) (Krause et al. 2006; Nishizawa et al. 2012; Rabus et al. 2005), the strain earlier known as *Dechlorosoma suillum* PS and now reclassified as a strain of *Azospira oryzae*, a strain known as "Dechloromonas aromatica RCB" that still awaits taxonomic evaluation and description (Coates et al. 2001; Kellaris Salinero et al. 2009), and *Thauera* strain MZ1T.

The ~4.2 Mbp genome of *Methyloversatilis universalis* FAM5^T, the only methylotrophic member of the family, is as yet not completely closed, and is available as three scaffolds (Kittichotirat et al. 2011). Publication of the genome of the mutualistic, N_2-fixing grass endophyte *Azoarcus* strain BH72 (Krause et al. 2006) was preceded by the publication of a physical map based on a bacterial artificial chromosome library as a platform for genome sequencing and functional analysis (Battistoni et al. 2005). The genome of the denitrifying and N_2O-reducing bacterium *Azoarcus* sp. strain KH32C contains genes for plant-microbe interactions and gene clusters for aromatic compound degradation, and consists of a circular chromosome (5.1 Mbp) and a megaplasmid (0.74 Mbp) (Nishizawa et al. 2012).

Additional data on growth substrates are given by Heider and Fuchs (2005) and are given in the original species descriptions
NR not reported
Data taken from: [a]Heider and Fuchs (2005), [b]Macy et al. (1993), [c]Mechichi et al. (2002), [d]Tschech and Fuchs 1987, Evans et al. 1991, Anders et al. (1995), [e]Dubbels et al. (2009), [f]Song et al. (2001), [g]Takahashi et al. 1980, [h]Foss and Harder (1998), [i]Scholten et al. (1999)

Analysis of the genome of the soil microbe "*Dechloromonas aromatica* RCB" gives indications for a surprisingly complex lifestyle and cryptic anaerobic pathways for degradation of aromatic compounds such as chlorobenzoate, toluene, and xylene, using perchlorate as electron acceptor. Classic pathways such as the benzylsuccinate synthase genes (responsible for fumarate addition to toluene) and the central benzyl-CoA pathway for degradation of monoaromatic compounds appear to be missing. Unexpectedly, genes coding for enzymes of the Calvin cycle enzymes and sulfur oxidation are present as well (Kellaris Salinero et al. 2009).

Phages

No phages active on strains of *Rhodocyclales* have yet been described.

Phenotypic Analyses

The Properties of the Genera and Species of *Rhodocyclaceae*

As the genera and species of the order *Rhodocyclales*, family *Rhodocyclaceae* are physiologically so diverse, there are very few common properties beyond the fact that all show a Gram-negative type of cell wall, as expected on the basis of their affiliation with the *Proteobacteria*. Information on the phenotypic properties of the genera and species as is summarized below and in *Tables 36.2–36.10*.

Family *Rhodocyclaceae* Garrity, Bell, and Lilburn 2006, 3[VP] (Effective Publication: Garrity, Bell, and Lilburn 2005b, 887)

Rho.do.cy.cla'ce.ae. N.L. masc. n. *Rhodocyclus*, type genus of the family; suff. *–aceae*, ending to denote a family; N.L. fem. pl. n. *Rhodocyclaceae*, the *Rhodocyclus* family.

The family *Rhodocyclaceae* was circumscribed on the basis of phylogenetic analysis of 16S rRNA sequences. The family is phenotypically, metabolically, and ecologically diverse. It includes photoheterotrophs, aerobes, anaerobes, and facultative anaerobes utilizing a number of electron acceptors, fermentative organisms, and nitrogen-fixing organisms.

Type genus: *Rhodocyclus*.

The representatives of the family are further discussed in the following order: (1) the anoxygenic photoheterotrophs of the type genus *Rhodocyclus*; (2) the nitrogen fixers *Azoarcus*, *Azonexus*, *Azospira*, and *Azovibrio*; (3) the genus *Thauera* consisting of facultatively anaerobic degraders of aromatic compounds; (4) the floc-forming aerobes of the genus *Zoogloea*; (5) the chlorate reducers of the genera *Dechloromonas* and *Dechlorobacter*; (6) the sterol degraders of the monospecific

Table 36.6

genera *Sterolibacterium* and *Denitratisoma*; (7) the disparate monospecific aerobic genera *Methyloversatilis*, *Quatrionicoccus*, *Uliginosibacterium*, and *Sulfuritalea*; (8) the genera *Propionivibrio*, *Ferribacterium*, and *Georgfuchsia*, showing different types of anaerobic metabolism.

The Anoxygenic Photoheterotrophs of the Type Genus *Rhodocyclus*

Genus *Rhodocyclus* Pfennig 1978 (Approved Lists 1980)

Rho.do.cy'clus Gr. n. *rhodon*, the rose; L. masc. n. *cyclus*, a circle; N.L. masc. n. *Rhodocyclus*, red circle.

Cells are slender, curved, or straight thin rods. Motile by means of polar flagella or nonmotile. Multiply by binary fission. Gram negative. Internal photosynthetic membranes may appear as small, single, finger-like intrusions of the cytoplasmic membrane, or may be absent. Photosynthetic pigments are bacteriochlorophyll *a* and carotenoids. Respiratory quinones are ubiquinone-8 and menaquinone-8. The major cellular fatty acids are $C_{16:1}$ and $C_{16:0}$; $C_{10:0\ 3\text{-OH}}$ is present. The major phospholipids are cardiolipin, phosphatidylethanolamine, and phosphatidylglycerol. Preferably grow photoheterotrophically under anoxic conditions in the light with different organic substrates as carbon and electron sources. Benzoate and cyclohexane are both used. Photoautotrophic growth with molecular hydrogen may be possible if growth factors are supplied. Chemotrophic growth is also possible under microoxic to oxic conditions in the dark. Reduced sulfur compounds are not used as photosynthetic electron donors. Assimilatory sulfate reduction is possible. Growth factors may be required. Mesophilic and neutrophilic freshwater bacteria. Habitat: freshwater ponds, sewage ditches, swine waste lagoons.

The mol% G + C of the DNA is 64.1–65.1.

Type species: *Rhodocyclus purpureus*.

The genus currently contains two species: *R. purpureus* and *R. tenuis* (Table 36.2). *Rhodocyclus gelatinosus* (Molisch 1907; Imhoff et al. 1984), comb. nov. has been transferred to the genus *Rubrivivax* (*Comamonadaceae*, *Betaproteobacteria*) (Imhoff 2005; Imhoff et al. 1984).

The type species *R. purpureus* was isolated only once and was never observed in nature again. Some strains of *R. tenuis*, including the type strain, are colored brownish-red, as they transform rhodopin further to spirilloxanthin. Other strains are purple-violet and do not form anhydrorhodovibrin and spirilloxanthin, but accumulate major amounts of rhodopinal, rhodopinol, and lycopenal (Imhoff 2005).

[e]Name yet to be validly published

The Nitrogen Fixers *Azoarcus*, *Azonexus*, *Azospira*, and *Azovibrio*

Genus *Azoarcus* Reinhold-Hurek, Hurek, Gillis, Hoste, Vancanneyt, Kersters, and De Ley 1993, 582[VP]

A.zo.ar'cus. N.L. n. *azotum* (from Fr. n. *azote* [from Gr. prep. *a*, not; Gr. n. *zôê*, life; N.Gr. *azôê*, not sustaining life]), nitrogen; N.L. pref. *azo-*, pertaining to nitrogen; L. masc. n. *arcus*, arch, bow; N.L. masc. n. *Azoarcus*, nitrogen (–fixing) bow.

Straight to slightly curved rods, 0.4–1.5 × 1.1–4.0 μm. Cell pairs often appear slightly S shaped. In most species, some elongated cells (8–12 μm) occur in late-exponential or stationary-phase cultures. Highly motile by means of one polar flagellum; rarely there are two flagella. Accumulate poly-β-hydroxybutyrate granules. Gram negative. Some species are nitrogen fixers; these require microaerobic conditions for growth on N_2. On semisolid nitrogen-free media, microaerophilic growth can be observed as veil-like pellicles developing several millimeters below the surface and moving to the medium surface during growth. In most species, colonies on VM agar (Reinhold-Hurek et al. 2005) supplemented with ethanol develop a nondiffusible yellowish pigment. Optimal temperature for growth 30–40 °C; no growth occurs at 45 °C. Chemoorganoheterotrophic. Bacteria have a strictly respiratory metabolism with O_2 as the terminal electron acceptor (except for *A. anaerobius*). Alternatively, under anaerobic conditions nitrate can be used for dissimilatory nitrate reduction. Oxidase positive. Grow well on salts of organic acids such as L-malate, succinate, fumarate, DL-lactate; also grow well on ethanol, on L-glutamate, but not on mono- or disaccharides except for species that are not plant associated. These soilborne species utilize a variety of aromatic substrates as sole carbon sources under denitrifying conditions. Nitrate can be used as a nitrogen source (assimilatory nitrate reduction). Growth factor requirements vary: Some strains depend on *p*-aminobenzoic acid or on cobalamin. All investigated species have $C_{16:1}$ as major cellular fatty acid; all species except one have $C_{16:1\ \omega7c}$ and $C_{18:1}$ as the major cellular fatty acids.

The mol% G + C of the DNA is 62–68.

Type species: *Azoarcus indigens*.

The genus currently contains eight species: the plant-associated *A. indigens* and *A. communis* (Reinhold-Hurek and Hurek 1998) and the species *A. evansii*, *A. anaerobius*, *A. buckelii*,

Data taken from: [a]Tarlera and Denner (2003), [b]Fahrbach et al. (2006)
Additional data on growth substrates are given in the original species descriptions

A. toluclasticus, *A. tolulyticus*, and *A. toluvorans*, isolated from soils, aquifers, or wastewater (Reinhold-Hurek et al. 2005) (*Table 36.3*). All *Azoarcus* spp. are strictly respiratory and fermentative metabolism was never demonstrated. All species except *A. anaerobius* can use oxygen as electron acceptor. Carbohydrates are poorly metabolized if at all; none of the plant-associated species is able to utilize any out of 50 mono- and disaccharides tested (Reinhold-Hurek et al. 1993). Nitrogen fixation is widespread, but the property can no longer be considered universal in the genus. Attempts to amplify a *nifH* gene fragment from *A. evansii* failed and no hybridization with a *nifH* probe was obtained (Hurek et al. 1997); however, recently the species was reported to fix nitrogen (Mechichi et al. 2002). *Azoarcus* sp. strain BH72, an endophyte isolated from Kallar grass, produces stacks of intracellular membranes ("diazozomes") when grown on N_2 as sole nitrogen source (Hurek et al. 1995).

Genus *Azonexus* Reinhold-Hurek and Hurek 2000, 658[VP]

A.zo.nex.us N.L. n. *azotum* (from Fr. n. *azote* [from Gr. prep. *a*, not; Gr. n. *zôê*, life; N.Gr. *azôê*, not sustaining life]), nitrogen; N.L. pref. *azo-*, pertaining to nitrogen; L. masc. n. *nexus*, coil; N.L. masc. n. *Azonexus*, nitrogen-fixing coil.

Gram-negative, non-sporeforming, slightly curved motile rods, 0.6–0.8 × 1.5–4.0 μm. Elongated straight to coiled cells of up to 50 μm occur in stationary phase, alkalinized, nitrogen-fixing cultures. Motile by means of a single polar flagellum. Microaerophilic growth occurs as veil-like pellicles which move up to the surface in semisolid N-free media. Chemoorganoheterotrophic and aerobic; microaerophilic when fixing nitrogen. Strictly respiratory, O_2 being the only electron acceptor. Oxidase and catalase positive. Fix N_2. Require cobalamin. Grow on acetate, ethanol, fumarate, DL-lactate, L-malate, 2-oxoglutarate, L-proline, and succinate. None of the tested mono- or disaccharides serves as sole carbon source. Grow well at 37 °C, can grow at 40 °C. Neutral pH optimal for growth.

The mol% G + C of the DNA is 64–66 (but no information is available on the G + C content of the DNA of the type species).

Type species: *Azonexus fungiphilus*.

Currently, the genus contains three species: *A. fungiphilus*, *A. caeni*, and *A. hydrophilus* (*Table 36.4*).

Genus *Azospira* Reinhold-Hurek and Hurek 2000, 658[VP], Emend. Bae, Rash, Rainey, Nobre, Tiago, da Costa, and Moe 2007, 1525

A.zo.spi'ra N.L. n. *azotum* (from Fr. n. *azote* [from Gr. prep. *a*, not; Gr. n. *zôê*, life; N.Gr. *azôê*, not sustaining life]), nitrogen; N.L. pref. *azo-*, pertaining to nitrogen; L. fem. n. *spira*, coil, spire; N.L. fem. n. *Azospira*, nitrogen-fixing spiral.

Gram-negative, non-sporeforming curved rods, 0.4–0.6 × 1.1–2.5 μm. Elongated cells with one to several spiral windings of up to 8 μm cell length occur rarely in late-stationary-phase, alkalinized, nitrogen-fixing cultures. Motile by means of one polar flagellum. Microaerophilic growth as veil-like pellicles which move up to the surface in semisolid N-free media. Chemoorganoheterotrophic and aerobic; microaerophilic when fixing N_2. Strictly respiratory; variable with respect to use of nitrate and perchlorate as electron acceptors. Oxidase and catalase positive. Fix N_2. Growth does not occur on most amino acids or on mono- or disaccharides. Grow on acetate, *n*-caproate, ethanol, fumarate, L-glutamate, DL-lactate, L-malate, 2-oxoglutarate, propionate, and succinate. Growth factor requirement varies. Grows well at 37 °C. Produces poly-β-hydroxybutyrate storage granules. Neutral pH optimal for growth. Major cellular fatty acids are $C_{16:1\ \omega7c}$, $C_{16:0}$, and $C_{18:1\omega7c}$.

The mol% G + C of the DNA is 65–68.

Type species: *Azospira oryzae*.

The genus *Azospira* currently consists of two species: *A. oryzae* and *A. restricta* (Brenner et al. 2005b) (*Table 36.4*). It includes

Additional data on growth substrates are given in the original species descriptions

Dechlorosoma suillum Achenbach et al. 2001, considered a later heterotypic synonym of *Azospira oryzae* Reinhold-Hurek and Hurek 2000 emend. Tan and Reinhold-Hurek 2003. *Dechlorosoma suillum* was reported to oxidize Fe(II) aerobically using oxygen as electron acceptor or anaerobically in the presence of nitrate, generating orange ferric oxyhydroxide or ferrihydrite (Lack et al. 2002).

Genus *Azovibrio* Reinhold-Hurek and Hurek 2000, 657[VP]

A.zo.vi'bri.o N.L. n. *azotum* (from Fr. n. *azote* [from Gr. prep. *a*, not; Gr. n. *zôê*, life; N.Gr. *azôê*, not sustaining life]), nitrogen; N.L. pref. *azo-*, pertaining to nitrogen; L. v. *vibrio*, to set in tremulous motion, move to and fro, vibrate; N.L. masc. n. *vibrio*, that which vibrates, and also a bacterial genus name of bacteria possessing a curved rod shape (*Vibrio*); N.L. masc. n. *Azovibrio*, nitrogen-fixing organism that vibrates.

Gram-negative, non-sporeforming slightly curved motile rods, 0.6–0.8 × 1.5–3.6 μm. Elongated cells occur very rarely in stationary, alkalinized cultures. One polar flagellum. Microaerophilic growth as veil-like pellicles which move up to the surface in semisolid N-free media. Chemoorganoheterotrophic and microaerophilic. Strictly respiratory; O_2 and nitrate are electron acceptors. Oxidase positive. Catalase weak. Fix N_2. Grow on acetate, ethanol, fumarate, L-glutamate, DL-lactate, L-malate, propionate, and succinate. No growth occurs on most other organic acids or on any mono- or disaccharides. Grow well at 37 °C. Neutral pH optimal for growth. Major cellular fatty acids are $C_{16:1\ cis\text{-}9}$, $C_{16:0}$, $C_{18:1}$, $C_{14:0}$, and $C_{10:1\ 3\text{-}OH}$.

The mol% G + C of the DNA is 64–65.

Type species: *Azovibrio restrictus*.

Currently the genus *Azovibrio* is represented by a single species, *A. restrictus* (Brenner et al. 2005c) (*Table 36.4*).

The Genus *Thauera* Consisting of Facultatively Anaerobic Degraders of Aromatic Compounds

Genus *Thauera* Macy, Rech, Auling, Dorsch, Stackebrandt, and Sly 1993, 139[VP] (Emend. Anders, Kaetzke, Kämpfer, Ludwig, and Fuchs 1995, 331; Emend. Song, Young, and Palleroni 1998, 893)

Thau'e.ra. N.L. fem. n. *Thauera*, named after R.K. Thauer, a German microbiologist.

Table 36.10

Additional data on growth substrates are given in the original species descriptions

Data taken from: [a]Tanaka et al. (1990), [b]Brenner et al. (2005g), [c]Brune et al. (2002), [d]Brune and Schink (1992), Hansen (2005), Hansen et al. (1990), Meijer et al. (1999), [e]Thrash et al. (2010), [f]Cummings et al. (2000), Brenner et al. (2005f), [g]Weelink et al. (2011)

[h]Name yet to be validly published

Rods, 0.5–1.4 × 1.4–3.7 μm, usually occurring singly. Some species exhibit great variability of cell form, from rods to coccoid forms of different sizes. Gram negative. Most species are motile by a single polar flagellum. No resting stages known. Oxidase and catalase positive. Colonies on minimal medium are nonpigmented. Aerobic, having a strictly respiratory metabolism; never fermentative. Molecular oxygen, nitrate, nitrite, and nitrous oxide are used as terminal electron acceptors, and the nitrogen oxides are reduced to N_2O or N_2; selenate is used as the electron acceptor by some strains and reduced to elemental selenium. Contains the lipoquinone Q-8. Optimal temperature 28–40 °C. All species grow at pH 7.5; pH optima of individual species range from 7.2 to 8.4. Chemoorganotrophic, using various organic acids, amino acids, and aromatic and aliphatic compounds as sole substrates. Only a few carbohydrates are utilized. Ammonium and nitrate salts can be used as sole nitrogen sources. No N_2 fixation known. Vitamins are required for growth by some strains. Not proteolytic on casein or gelatin. Starch, cellulose, chitin, and agar are not hydrolyzed. The major polyamines are putrescine and 2-hydroxyputrescine. Occur in polluted freshwater and wet soil environments and wastewater treatment plants.

The mol% G + C of the DNA is 64–71.

Type species: *Thauera selenatis*.

Data taken from: [a]Kittichotirat et al. (2011), [b]Krause et al. (2006), [c]Rabus et al. (2005), [d]Nishizawa et al. (2012), [e]Kellaris Salinero et al. (2009)

[f]Also known as "Aromatoleum aromaticum"

The genus *Thauera* currently contains nine species: *T. selenatis*, *T. aminoaromatica*, *T. aromatica*, *T. butanivorans*, *T. chlorobenzoica*, *T. linaloolentis*, *T. mechernichensis*, *T. phenylacetica*, and *T. terpenica* (Table 36.5).

The Floc-Forming Aerobes of the Genus *Zoogloea*

Genus *Zoogloea* Itzigsohn 1868, 39 (Approved Lists 1980); Emend. Shin, Hiraishi, and Sugiyama 1993, 830

Zo.o.gloe'a. Gr. adj. *zôos*, alive, living; Gr. fem. n. *gloia*, glue; N.L. fem. n. *Zoogloea*, living glue.

The following description is representative of the genus based on well-characterized isolates recovered directly from naturally occurring, typical, fingered zoogloeae: Straight to slightly curved, plump rods, 1.0–1.3 × 2.1–3.6 μm, with rounded ends; sometimes tapered to a blunt point at one or both poles. Non-sporeforming and non-cystforming. Cells in older cultures are demonstrably encapsulated. Gram negative. Actively motile, especially in young cultures, by means of a single polar flagellum. Intracellular granules of poly-β-hydroxybutyrate are formed on media containing the salts of organic acids. Cultures enter into formation of flocs and films in liquid media at late growth stages; the cells become embedded in gelatinous matrices to form zoogloeae, which may be distinguished by a "tree-like" or "finger-like" morphology. Young colonies on solid media under a normal air atmosphere are translucent and punctiform, but may increase to 1–2 mm in diameter and exhibit opaque centers. Nonpigmented. Aerobic, having a strictly respiratory type of metabolism with oxygen or nitrate as the terminal electron acceptor. Denitrification occurs with formation of N_2. Optimal temperature for growth, 28–37 °C. Optimal pH 7.0–7.5. Oxidase positive. Weakly catalase positive. Chemoorganotrophic. Acid is not formed from carbohydrates except from xylose, glycerol, and ethanol, which are attacked oxidatively by a few strains. Proteolytic on gelatin. Most strains are urease positive. Litmus milk is unchanged. Hydrogen sulfide is usually not produced from cysteine. Major carbon sources include salts of several organic acids (e.g., lactate, pyruvate, and fumarate), dicarboxylic amino acids (e.g., aspartate, glutamate, and asparagine), alcohols, and

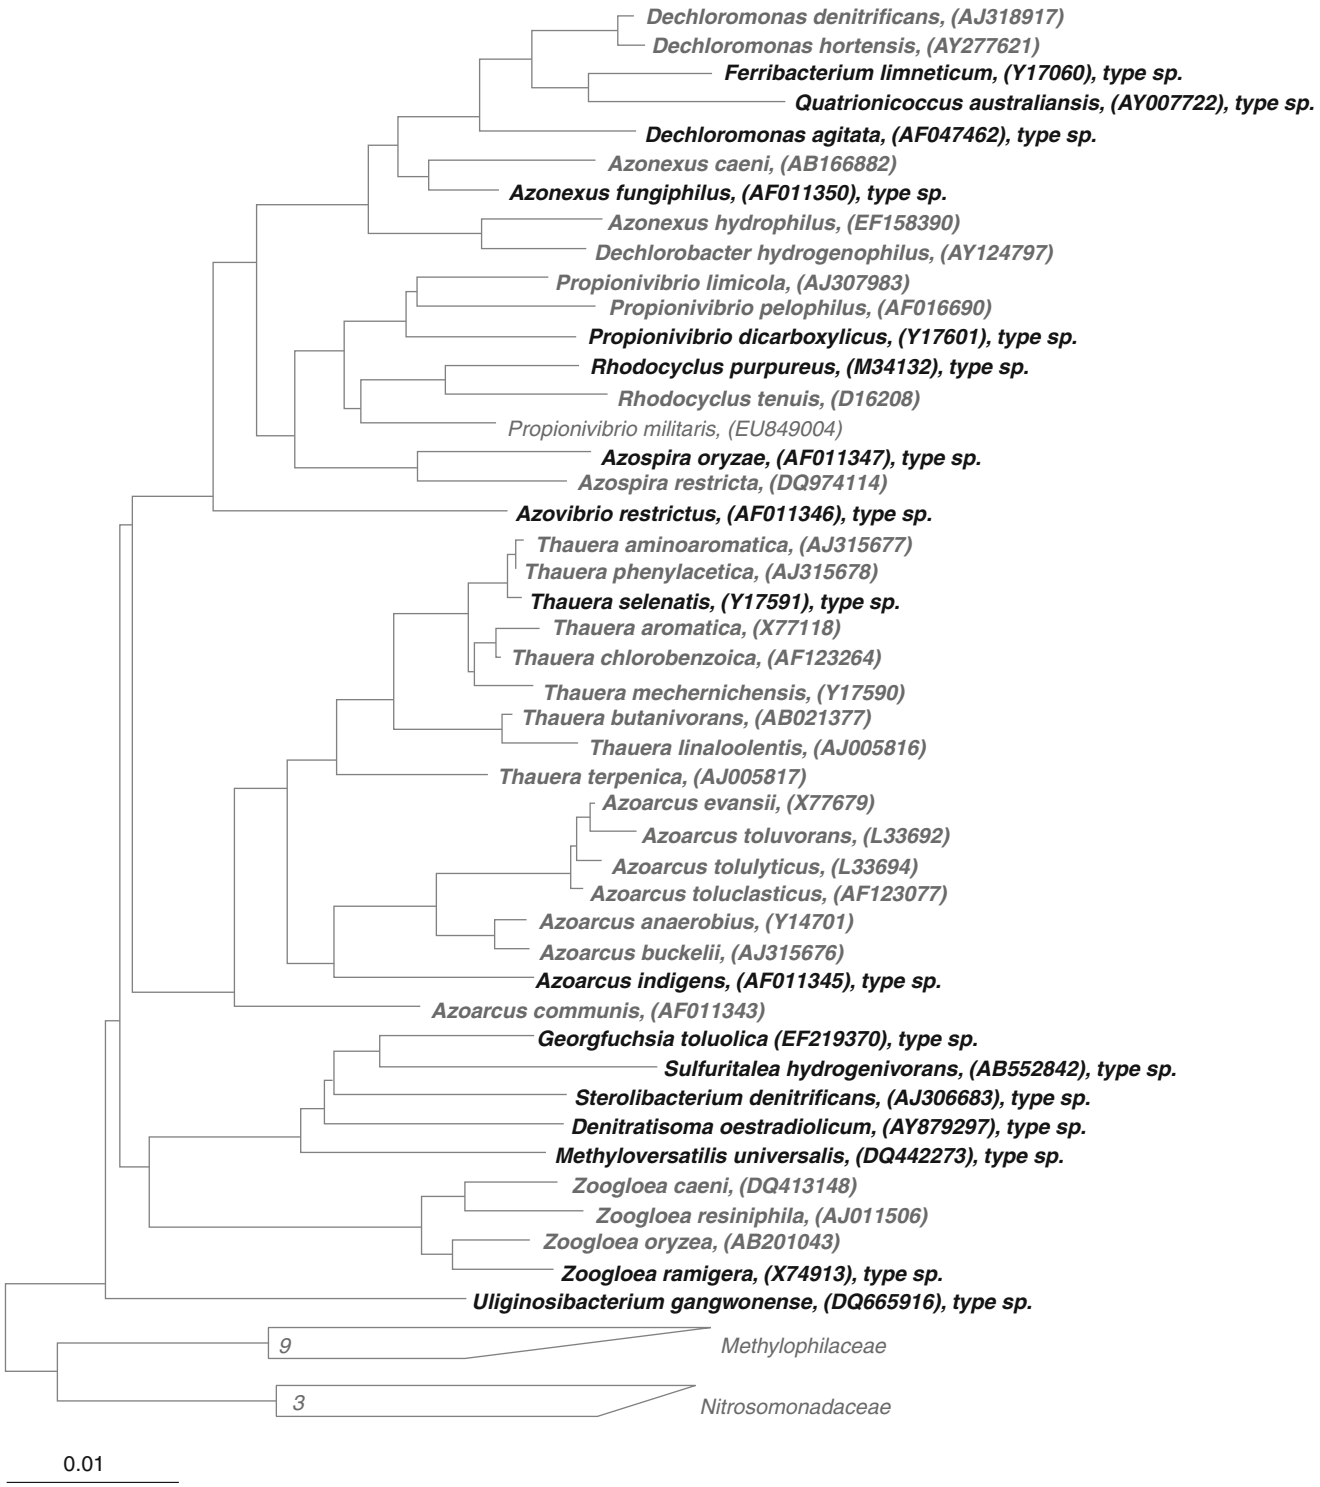

Fig. 36.1

Neighbor-joining genealogy reconstruction of the 45 species of the order *Rhodocyclales* present in the LTP_106 (Yarza et al. 2010). The tree was reconstructed by using a subset of sequences 767 type strains of Bacteria and Archaea to stabilize the tree topology. In addition, a 40 % conservational filter for the whole bacterial domain was used to remove hypervariable positions. Numbers in triangles denote number of taxa included. The bar indicates 1 % sequence divergence

salts of certain aromatic acids (e.g., benzoate and *m*-toluate). Benzene derivatives are attacked by *meta*-cleavage of the ring structure. Organic nitrogen compounds (e.g., dicarboxylic amino acids) and ammonia serve as nitrogen sources; nitrate is unsuitable. Specific growth factor requirements, if any, are unknown. Major cellular fatty acids are $C_{16:1}$ and $C_{10:0\ 3\text{-OH}}$ with smaller amounts of $C_{12:0\ 3\text{-OH}}$. Major respiratory quinones are Q-8 and RQ-8. The major polyamine is 2-hydroxyputrescine. Occur free-living in organically polluted waters and in wastewaters at all stages of treatment.

The mol% G + C of the DNA is 65.1–69.0.

Type species: *Zoogloea ramigera*.

Four species are currently recognized within the genus: *Z. ramigera*, *Z.caeni*, *Z. oryzae*, and *Z. resiniphila* (Table 36.6).

The Chlorate Reducers of the Genera *Dechloromonas* and *Dechlorobacter*

Genus *Dechloromonas* Achenbach, Michaelidou, Bruce, Fryman, and Coates 2001, 531[VP]

De.chlo.ro.mo'nas L. pref. *de*, from; N.L. n. *chlorinum* (from Gr. adj. *chlorôs*, green) chlorine; N.L. pref. *chloro-* pertaining to chlorine; L. fem. n. *monas*, unit, monad; N.L. fem. n. *Dechloromonas*, a dechlorinating monad.

Gram-negative, non-sporeforming, facultatively anaerobic, rods, 0.5 × 2 μm, motile by a single polar flagellum. Occur singly or in chains of two or three cells. Strictly respiratory metabolism. Oxidizes acetate with O_2, chlorate, perchlorate, or nitrate. Chlorate and perchlorate are reduced to chloride; O_2 also serves as an electron acceptor; some strains use nitrate as an electron acceptor.

The mol% G + C of the DNA is 61.2–63.5.

Type species: *Dechloromonas agitata*.

Currently the genus contains three species: *D. agitata*, *D. denitrificans*, and *D. hortensis* (Table 36.7).

Genus *Dechlorobacter* (Effective Publication: Thrash, Pollock, Torok, and Coates, 2010, 340)

De.chlo.ro.bac'ter. L. pref. *de*, from; N.L. n. *chlorinum* (from Gr. adj. *chlorôs*, green) chlorine; N.L. pref. *chloro-* pertaining to chlorine; masc. n. *bacter* a short rod; N.L. masc. n. *Dechlorobacter*, a dechlorinating rod.

Rod-shaped cells, 0.3 × 0.8–1.6 μm, non-sporeforming, non-fermentative, facultative anaerobe. Cells are motile and occur singly or in chains. Gram negative. Strictly respiring, complete oxidizer that oxidizes acetate with O_2, perchlorate, chlorate, Mn(IV), or nitrate as electron acceptors. Perchlorate and chlorate are completely reduced to chloride.

The mol% G + C of the DNA of the type strain of the type species was not reported.

Type species: *Dechlorobacter hydrogenophilus*.

At the time of writing (April 2012), the names *Dechlorobacter* and *Dechlorobacter hydrogenophilus*, the only species yet assigned to the genus, were not yet validly published. Further information about its properties is given in Table 36.7.

The Sterol Degraders of the Monospecific Genera *Sterolibacterium* and *Denitratisoma*

Genus *Sterolibacterium* Tarlera and Denner 2003, 1089[VP]

Ste.ro.li.bac.te'ri.um. N.L. neut. n. *sterolum*, sterol; L. neut. n. *bacterium*, small rod; N.L. neut. n. *Sterolibacterium*, sterol-utilizing small rod.

Straight or slightly curved, small, rod-shaped, Gram-negative cells. Mesophilic. Strictly respiratory type of metabolism with oxygen or nitrate as terminal electron acceptor. Nitrate is reduced to N_2. Oxidase- and catalase positive. Chemoorganoheterotrophic. Does not grow on complex media. Cholesterol is completely oxidized to CO_2; this reaction is coupled to nitrate reduction. Q-8 is the sole lipoquinone. Phosphatidylethanolamine is the predominant polar lipid. Major fatty acids are $C_{16:0}$, summed feature 4 ($C_{16:1\ \omega7c}$ and/or iso-$C_{15:0\ 2\text{-OH}}$), $C_{18:1\ \omega7c}$ and $C_{10:0\ 3\text{-OH}}$; minor amounts of $C_{8:0\ 3\text{-OH}}$ and $C_{16:0\ 3\text{-OH}}$ are present.

The mol% G + C of the DNA of the type species, thus far the sole species of the genus, is 65.3.

Type species: *Sterolibacterium denitrificans*.

Genus *Denitratisoma* Fahrbach, Kuever, Meinke, Kämpfer, and Hollender 2006, 1549

De.ni.tra.ti.so'ma L. pref. *de-*, away, from; N.L. n. *nitras –atis*, nitrate; Gr. neut. n. *soma* body; N.L. neut. n. *Denitratisoma*, a body that reduces nitrate.

Cells are Gram negative, non-sporeforming, motile, curved rods (0.4–0.8 × 0.8–2.0 μm in size) with rounded ends, and occur singly or in pairs. In cultures grown on sodium acetate and nitrate, more elongated cells with light-refracting inclusions predominate (length up to 2.0 μm). Metabolism is strictly oxidative. Nitrate is reduced to a mixture of N_2O and N_2; nitrite accumulates intermediately. Oxidase positive and catalase negative. Anaerobic oxidation of 17β-oestradiol to CO_2 with nitrate as electron acceptor, but no growth with cholesterol or C19 steroids such as testosterone or 4-androstene-3,17-dione. Electron acceptors nitrate, nitrite, or (per)chlorate are used; sulfate or sulfite is not reduced. Optimal growth occurs at 28–30 °C and pH 7.0–7.2. Salinity range for growth is 0–1.0 % NaCl. Ubiquinone-8 is the only quinone. Major fatty acids are $C_{16:1\omega7c}$/iso-$C_{15:0\ 2\text{-OH}}$ and $C_{16:0}$. Minor components are $C_{18:1\ \omega7c}$ and $C_{8:0\ 3\text{-OH}}$ (as the only hydroxylated fatty acid).

The mol% G + C of the DNA of the type strain is 61.4.

Type species: *Denitratisoma oestradiolicum*.

The properties of *Sterolibacterium denitrificans* and *Denitratisoma oestradiolicum* are summarized in Table 36.8.

The Disparate Monospecific Aerobic Genera *Methyloversatilis*, *Quatrionicoccus*, *Uliginosibacterium*, and *Sulfuritalea*

Genus *Methyloversatilis* Kalyuzhnaya, De Marco, Bowerman, Pacheco, Lara, Lidstrom, and Chistoserdova 2006, 2521[VP]

Me.thy.lo.ver.sa'ti.ils N.Gr. n. *methyl* (from Gr. n. *methu*, wine and Gr. n. *hulê*, wood), methyl radical; L. adj. *versatilis*, versatile; N.L. fem. n. *Methyloversatilis*, versatile methyl (utilizer), reflecting the versatile trophic abilities of the first isolates.

Cells are Gram negative, nonmotile rods that multiply by binary fission. Able to utilize a variety of C_1 and multicarbon compounds. Assimilate C1 units via the serine pathway. The major fatty acids are $C_{16:1\ \omega7c}$ and $C_{16:0}$. The major quinone is Q8.

The mol% G + C of the DNA is 64–65.

Type species: *Methyloversatilis universalis*.

Genus *Quatrionicoccus* Tindall and Euzéby 2006, 2712[VP]

Qua.tri.o.ni.coc'cus. L. masc. n. *quatrio -onis*, the number four; N.L. masc. n. *coccus* (from Gr. masc. n. *kokkos*, grain, seed), coccus; N.L. masc. n. *Quatrionicoccus*, four spherical cells.

Large Gram-negative, non-sporeforming cocci, 2.2–4.5 μm in diameter, occurring in tetrads. Cells are aerobic, nonmotile, and no flagella are observed. Both polyphosphate and poly-β-hydroxyalkanoate granules are synthesized. Oxidase negative. Catalase positive.

The mol% G + C of the DNA of the type species, thus far the sole species of the genus, is 67.

Type species: *Quatrionicoccus australiensis*.

Note: The name *Quatrionicoccus* (Tindall and Euzéby 2006) was proposed to replace the name *Quadricoccus* (Maszenan et al. 2002) which was illegitimate as it was earlier used to name an algal genus.

Genus *Sulfuritalea* Kojima and Fukui 2011, 1654[VP]

Sul.fu.ri.ta'le.a L. n. *sulfur*, sulfur; L. fem. n. *talea*, a rod; N.L. fem. n. *Sulfuritalea*, sulfur-oxidizing rod.

Grows chemolithoautotrophically under anoxic conditions by the oxidation of reduced sulfur compounds and hydrogen. Heterotrophic growth occurs on organic acids. Major fatty acids are $C_{16:0}$ and summed feature 3 ($C_{16:1\ \omega7c}$ and/or iso-$C_{15:0\ 2\text{-}OH}$).

The mol% G + C of the DNA of the type species, thus far the sole species of the genus, is 67.

Type species: *Sulfuritalea hydrogenivorans*.

Genus *Uliginosibacterium* Weon, Kim, Yoo, Kwon, Go, and Stackebrandt 2008, 134[VP]

U.li.gi.no.si.bac.te'ri.um. L. adj. *uliginosus*, wet, moist, marshy; L. neut. n. *bacterium*, a rod; N.L. neut. n. *Uliginosibacterium*, a rod isolated from peat.

Gram-negative, strictly aerobic rods. Motile by means of a single polar flagellum. The major isoprenoid quinone is Q-8. The major fatty acids are $C_{16:0}$ and summed feature 3 ($C_{16:1\ \omega7c}$ and/or iso-$C_{15:0\ 2\text{-}OH}$). $C_{18:1\ \omega7c}$, $C_{17:0\ cyclo}$, $C_{14:0}$, and $C_{12:0\ 3\text{-}OH}$ are present as minor components.

The mol% G + C of the DNA of the type strain of the single species is 59.3.

Type species: *Uliginosibacterium gangwonense*.

Table 36.9 summarizes the properties of *Methyloversatilis universalis*, *Quatrionicoccus australiensis*, *Sulfuritalea hydrogenivorans*, and *Uliginosibacterium gangwonense*.

The Genera *Propionivibrio*, *Ferribacterium*, and *Georgfuchsia* Showing Different Types of Anaerobic Metabolism

Genus *Propionivibrio* Tanaka, Nakamura, and Mikami 1991, 331[VP], Emend. Brune, Ludwig, and Schink 2002, 443 (Effective Publication: Tanaka, Nakamura, and Mikami 1990, 327)

Pro.pi.o.ni.vi'bri.o. N.L. n. *acidum propionicum*, propionic acid; L. v. *vibrio*, to set in tremulous motion, move to and fro, vibrate; N.L. masc. n. *vibrio*, that which vibrates, and also a bacterial genus name of bacteria possessing a curved rod shape (*Vibrio*); N.L. masc. n. *Propionivibrio*, the propionic acid vibrio.

Gram-negative, curved or straight rods, may be motile by means of a single polar flagellum. Does not form spores. Strict anaerobe or aerotolerant. Chemoorganoheterotrophic. Propionate and acetate formed as end products of fermentation. Some species grow on sugars, dicarboxylic acids, sugar alcohols, and aspartate. Succinate is decarboxylated to propionate. Some species may reduce nitrate to nitrite. Mesophilic.

The mol% G + C of the DNA is 60.8–61.6.

Type species: *Propionivibrio dicarboxylicus*.

Currently the genus contains four species: *P. dicarboxylicus*, *P. limicola*, *P. pelophilus*, and *P. militaris*. The name of the last species was not yet validly published. The species was classified within the genus *Propionivibrio* only on account of its 16S rRNA gene sequence, without taking its further properties into account. The mode of life of this species (respiratory rather than fermentative) is very different from those given in the genus protologue, and therefore the organism cannot be considered to belong to the genus *Propionivibrio*. *P. militaris* completely oxidizes acetate using O_2, perchlorate, chlorate, nitrate, or nitrite as electron acceptors. It can also grow on propionate (Thrash et al. 2010).

Propionibacter pelophilus (Meijer et al. 1999) has been reclassified as *Propionivibrio pelophilus* comb. nov. (Brune et al. 2002).

Genus *Ferribacterium* Cummings, Caccavo, Spring, and Rosenzweig 2000, 953T (Validation List no. 77); Effective Publication Cummings, Caccavo, Spring, and Rosenzweig 1999, 187

Fer.ri.bac.te'ri.um. L. n. *ferrum*, iron; L. neut. n. *bacterium*, a small rod; N.L. neut. n. *Ferribacterium*, rod-shaped iron bacterium.

Strictly anaerobic straight or curved motile rods, 0.3–0.5 × 1.4–2.0 μm. Contain poly-β-hydroxybutyrate granules. Non-sporeforming. Oxidize acetate, benzoate, formate, and lactate using Fe(III) as the electron acceptor; also oxidize acetate using fumarate or nitrate as electron acceptors. Hydrogen and alcohols are not used as electron donors.

The mol% G + C of the DNA of the type species and only species described thus far has not been reported.

Type species: *Ferribacterium limneticum*.

Genus *Georgfuchsia* Weelink, van Doesburg, Saia, Rijpstra, Röling, Smidt, and Stams 2011, 1011^{VP} (Validation List no. 139); (Effective Publication: Weelink, van Doesburg, Saia, Rijpstra, Röling, Smidt, and Stams 2009, 583)

Ge.org.fuch'si.a N.L. fem. n. *Georgfuchsia*, named after Georg Fuchs, for his contribution to our present understanding of anaerobic microbial growth on aromatic hydrocarbons.

Straight or slightly curved, small, rod-shaped Gram-negative cells. Mesophilic. Strictly respiratory type of metabolism. Chemoorganoheterotrophic. Capable of degrading aromatic compounds.

The mol% G + C of the DNA of the type species and only species described thus far has not been reported.

Type species: *Georgfuchsia toluolica*.

The main features of the members of the genus *Propionivibrio*, *Ferribacterium*, and *Georgfuchsia* are summarized in Table 36.10.

Isolation, Enrichment, and Maintenance Procedures

There are relatively few procedures for the selective enrichment and isolation of members of the different genera and species of the *Rhodocyclaceae*. The type species of the type genus, *Rhodocyclus purpureus*, has been isolated only once. Theoretically, a suitable enrichment procedure could be based on incubation in the light using media with benzoate and vitamin B_{12} and without added reduced sulfur compounds. Benzoate is not a common substrate for purple nonsulfur bacteria, but is used by *R. purpureus* (Imhoff 2005).

The growth potentials of the different species within the family, as defined in the species descriptions and highlighted in Tables 36.2–36.10, provide strategies for the isolation of novel types belonging to the group. Especially the ability of some genera and species to metabolize aromatic compounds, sterols, and other organic substrates that are degraded by a few types of organisms only under anaerobic conditions, using nitrate, chlorate, or perchlorate as electron acceptors, may be exploited for the enrichment and isolation of novel members of *Azoarcus*, *Thauera*, *Georgfuchsia*, and other genera. *Ferribacterium limneticum* can be enriched using media containing acetate and Fe(III)-oxyhydroxide (Cummings et al. 1999). Maleate was suggested to be a substrate for the selective enrichment of *Propionivibrio dicarboxylicus* (Tanaka et al. 1990). The ability of some species to fix nitrogen can also be exploited when designing specific enrichment and isolation protocols for selected members of the family.

Maintenance

Long-term preservation is by lyophilization, or by freezing cell suspensions in liquid nitrogen or at −80 °C in the presence of a cryoprotectant (Heider and Fuchs 2005; Reinhold-Hurek et al. 2005; Unz 2005). For *Azoarcus* and for *Thauera*, 5 % DMSO was recommended as cryoprotectant (Heider and Fuchs 2005; Reinhold-Hurek and Hurek 2006; Reinhold-Hurek et al. 2005). Preservation in liquid nitrogen with 8 % glycerol was suggested for *Propionivibrio pelophilus* (Hansen 2005). For the anaerobes within the family, anaerobic conditions must be maintained during the preparation of cell suspensions for lyophilization or cryopreservation.

Physiological and Biochemical Features

A feature of special interest shown by many representatives of the *Rhodocyclales* is their ability to degrade a wide range of aromatic and other difficult-to-metabolize organic compounds under anaerobic conditions, and sometimes under aerobic conditions as well. Compounds degraded by representatives of the genera *Azoarcus*, *Azospira*, *Dechloromonas*, *Thauera*, *Sterolibacterium*, *Denitratisoma*, and *Georgfuchsia* include benzene; toluene; catechol (1,2-dihydroxybenzene); ethylbenzene; *o*-, *m*-, and *p*-xylene *m*- and *p*-cresol; benzoate; 3-chlorobenzoate; 3-bromobenzoate; 2-fluorobenzoate; 4-fluorobenzoate; 3-hydroxybenzoate; 4-hydroxybenzoate; 2-aminobenzoate (anthranilic acid) 3-aminobenzoate; protocatechuate; and pyridine; monoterpenes such as linalool, menthol, and eucalyptol, cholesterol, testosterone, and 4-androstene-3,17-dione (Beller and Spormann 1997; Braun and Gibson 1984; Chakraborty et al. 2005; Chiang et al. 2007, 2008; Ding et al. 2008; Fahrbach et al. 2006; Heider and Fuchs 2005; Kniemeyer and Heider 2001; Rhee et al. 1997; Song et al. 2000). The herbicide benazolin-ethyl (4-chloro-2-oxobenzothiazolin-3-yl-acetic acid) was found to be degraded by a strain of *Methyloversatilis* isolated from activated sludge from a wastewater treatment pool (Cai et al. 2011).

The biochemical pathways used in the anaerobic breakdown (and sometimes in the aerobic degradation as well) of aromatic compounds are often highly unusual. Therefore, the biochemistry of some of these pathways has been investigated in depth in recent years. One well-established anaerobic pathway of activation of aromatic rings (toluene, xylenes) operative in some members of the family is by the addition of fumarate to form benzylsuccinate (Beller and Spormann 1997), catalyzed by benzylsuccinate synthase via a glycyl radical (Krieger et al. 2001). This pathway was characterized in *Thauera* sp. strain DNT-1 (Shinoda et al. 2004). An isolate related to *Denitratisoma oestradiolicum* obtained from a mixed inoculum of freshwater pond sediment and wastewater treatment plant sludge completely oxidized *p*-xylene to CO_2 with nitrate as electron acceptor. 4-Methylbenzene(succinate) and (4-methylphenyl) itaconate were identified as metabolites, suggesting addition of fumarate as an initial activation reaction (Rotaru et al. 2010).

Anaerobic degradation of catechol (1,2-dihydroxybenzene) by *Thauera aromatica* with CO_2 as cosubstrate and nitrate as electron acceptor proceeds via catechol-phosphate followed by carboxylation in the *para* position by phenylphosphate carboxylase. The product protocatechuate (3,4-dihydroxybenzoate) is converted to protocatechuyl-CoA which is then reductively dehydroxylated to 3-hydroxybenzoyl-CoA, followed by reduction of the aromatic ring (Ding et al. 2008).

Hydroxyhydroquinone (1,2,4-trihydroxybenzene) was identified as intermediate in the degradation of resorcinol (1,3-dihydroxybenzene) by *Azoarcus anaerobius* (Philipp and Schink 2000). Denitrifying degradation of ethylbenzene by *Azoarcus* sp. strain EbN1 proceed via two sequential dehydrogenation reactions forming (*S*)-1-phenylethanol and then acetophenone (Kniemeyer and Heider 2001).

Degradation of cholesterol under denitrifying conditions by *Sterolibacterium denitrificans* starts with the oxidation of ring A to form cholest-4-en-3-one, followed by an oxygen-independent hydroxylation of the terminal C-25 of the side chain by a cholest-4-en-3-one-Δ^1-dehydrogenase. The anaerobic hydroxylation of this tertiary carbon using water as oxygen donor is unprecedented and may be catalyzed by a novel molybdenum-containing enzyme (Chiang et al. 2007, 2008).

Aerobic degradation of aromatic ring compounds by *Thauera aromatica* and other *Thauera* strains uses common oxygenases (Heider and Fuchs 2005; Shinoda et al. 2004). An unusual mode of aerobic metabolism of benzoate was found in *Azoarcus evansii*, an organism that metabolizes benzoate and 3-hydroxybenzoate both under aerobic and anaerobic conditions. None of the previously known aerobic pathways, including the conversion of benzoate to catechol or protocatechuate, is operative in this organism. The first step is the activation of benzoate to benzoyl-CoA by a benzoate-CoA ligase. It was first assumed that the following hydroxylation of benzoyl-CoA is catalyzed by a benzoyl-CoA oxygenase (Mohamed et al. 2001); however, it was recently shown that the reaction proceeds via formation of the 2,3-epoxide (Rather et al. 2010).

Metabolism of methylamine by *Methyloversatilis universalis* involves an unusual glutamate-mediated pathway in which *N*-methylglutamate and γ-glutamylmethylamide are intermediates. Cells grown on methylamine displayed high activities of *N*-methylglutamate synthetase, *N*-methylglutamate dehydrogenase, and γ-glutamylmethylamide synthetase (Latypova et al. 2010).

Ecology

The range of habitats inhabited by members of the *Rhodocyclales* is as diverse as the metabolic properties displayed by the genera and the species of the order.

Anoxygenic phototrophs of the genus *Rhodocyclus* have been isolated both from polluted environments (*R. purpureus* was obtained from a swine wastewater lagoon) and from unpolluted freshwater ponds (*R. tenuis*). They have not been frequently encountered, and little is known about their distribution worldwide (Imhoff 2005; Pfennig 1969, 1978).

The genera *Azoarcus*, *Azonexus*, and *Azospira* consist of two types of organisms: those that grow epi- or endophyically on grass roots (rice, Kallar grass), and soilborne strains. The soilborne organisms that can degrade aromatic hydrocarbons under denitrifying conditions have been isolated from a wide range of environments, polluted as well as uncontaminated soils, aquifers, activated sludge, and oil refinery sludge. Most soilborne species grow on aromatic compounds such as toluene or phenol, benzoate or resorcinol (Anders et al. 1995; Bae et al. 2007; Braun and Gibson 1984; Chou et al. 2008; Fries et al. 1994, 1997; Quan et al. 2006; Reinhold-Hurek and Hurek 2006; Song et al. 1999; Springer et al. 1998; Zhou et al. 1995). The recent discovery of *Azoarcus* strains that oxidize As(III) using nitrate, nitrite, chlorate, and oxygen as electron acceptors in sediments or sludge from pristine environments (Rodríguez-Freire et al. 2012; Sun et al. 2009) shows that the group may be more diverse than assumed thus far.

Thauera strains appear to be common saprophytic inhabitants of polluted freshwater and soil environments. The type species *T. selenatis* was encountered in agricultural drainage water in California (Macy et al. 1989, 1993). *Thauera* strains occur in wastewater treatment plants, aquifers, and contaminated lake and pond sediment compounds where they may be involved in mineralization and detoxification of toxic aromatic compounds (Foss and Harder 1998; Heider and Fuchs 2005; Liu et al. 2006; Scholten et al. 1999).

Zoogloea, with its typical extracellular polysaccharide slime and floc formation displayed by most species, is known for a century and a half as a characteristic inhabitant of polluted waters and aerobic wastewater purification plants (Itzigsohn 1868; Mohn et al. 1999; Shao et al. 2009; Unz 2005), but representatives have also been isolated from rice paddy soils (Xie and Yokota 2006).

Chlorate- and perchlorate-reducing bacteria of the genera *Dechloromonas* and *Dechlorobacter* have been isolated both from pristine sites such as garden soil and from chlorate-polluted sites such as paper mill waste and soil from an army ammunition plant (Achenbach et al. 2001;

Bruce et al. 1999; Thrash et al. 2010; Wolterink et al. 2005) and even from the gut of an earthworm (Horn et al. 2005).

The sterol-degrading *Sterolibacterium denitrificans* and *Denitratisoma oestradiolicum* were both isolated from water treatment plants. Little information is available about their geographic distribution (Fahrbach et al. 2006; Tarlera and Denner 2003), but 16S rRNA gene sequences similar to that of *D. oestradiolicum* were found in anaerobic enrichment cultures with *p*-xylene and nitrate using a mixed inoculum of freshwater pond sediment and wastewater treatment plant sludge (Rotaru et al. 2010).

Methyloversatilis strains were recovered from different environments: Lake Washington, USA, and contaminated soil in Portugal (Kalyuzhnaya et al. 2006). Strain *Methyloversatilis* cd-1, which uses the herbicide benazolin-ethyl (4-chloro-2-oxobenzothiazolin-3-yl-acetic acid) as sole carbon source, was isolated from a wastewater treatment pool (Cai et al. 2011).

Little is known about the distribution of the genera *Quatrionicoccus* (isolated once from activated sludge biomass in Australia) (Maszenan et al. 2002), the facultative autotroph *Sulfuritalea* (obtained once from a freshwater lake in Japan) (Kojima and Fukui 2011), and *Uliginosibacterium*, reported once from a Korean wetland (Weon et al. 2008).

The obligatory anaerobic representatives of the genus *Propionibacter* were isolated from a marine estuary (Hansen et al. 1990; Meijer et al. 1999) or from freshwater ponds in Germany and Japan (Brune and Schink 1992; Tanaka et al. 1990). The iron-reducing *Ferribacterium limneticum* was recovered from the sediments of a lake in Idaho contaminated with tailings of mining activities (Cummings et al. 1999). The strictly anaerobic *Georgfuchsia toluolica*, degrading aromatic compounds with Fe(III), Mn(IV), or nitrate as an electron acceptor, was obtained from a polluted aquifer in the Netherlands (Weelink et al. 2009). No further information is available about the geographic distribution of these genera.

For molecular, culture-independent ecological studies of the *Rhodocyclales*, a 16S rRNA gene-based oligonucleotide microarray (RHC-PhyloChip) was developed. This PhyloChip, designed for environmental monitoring, consists of 79 probes based on sequences of cultured and as yet uncultured species. It was successfully applied to analyze the microbial diversity of activated sludge of an industrial wastewater (Loy et al. 2005). Use of stable isotope probing has shed some light on the presence of *Methyloversatilis* in a denitrifying sequencing batch reactor fed with ^{13}C-methanol. Analysis of 16S rRNA clone libraries prepared from the ^{13}C-enriched DNA fraction showed the dominant methylotrophs to be affiliated with the genera *Methyloversatilis* and *Hyphomicrobium* (Baytshtok et al. 2008). A study of activated sludge of a wastewater treatment plant in Denmark was performed using an isotope array approach, allowing for parallel functional probing of different phylogenetic groups. The PhyloChip microarray identified 27 operational taxonomic units that grouped in at least seven main *Rhodocyclales* lineages. The substrate utilization patterns of probe-defined populations were determined by radioactive isotope array analysis and microautoradiography—fluorescence in situ hybridization of samples that were briefly exposed to different radiolabeled substrates under oxic and anoxic nitrate-reducing conditions. Most detected *Rhodocyclales* groups were actively involved in nitrogen transformation, but varied in their consumption of propionate, butyrate, or toluene (Hesselsoe et al. 2009).

Pathogenicity, Clinical Relevance

No pathogenic bacteria are known within the *Rhodocyclales*. The plant-associated species of the genus *Azoarcus* that colonize rice roots and stems mainly live intracellularly within the cortex and they rarely enter xylem cells. No symptoms of plant disease were ever attributed to *Azoarcus* and related organisms. These plant-associated bacteria may contribute fixed nitrogen to the plant, but the existence of a truly mutualistic relationship was never proven (Reinhold-Hurek et al. 2005).

Sensitivity to antibiotics and other antibacterial compounds was reported only for a very few members of the order. *Azoarcus indigens*, *Azoarcus communis*, *Azoarcus* strain BH72, *Azonexus hydrophilus*, *Azonexus caeni*, and *Azonexus fungiphilus* and are all sensitive to ampicillin, kanamycin, streptomycin, and tetracycline. *Azonexus hydrophilus*, *Azonexus caeni*, and *Azonexus fungiphilus* are in addition sensitive to chloramphenicol, erythromycin, gentamycin, nalidixic acid, novobiocin, and penicillin (Chou et al. 2008; Reinhold-Hurek and Hurek 2006; Reinhold-Hurek et al. 2005). *Methyloversatilis universalis* proved resistant to ampicillin, erythromycin, chloramphenicol, trimethoprim/sulfamethoxazole, vancomycin, and penicillin, but sensitive to amoxicillin, cephalothin, kanamycin, nalidixic acid, tetracycline, streptomycin, neomycin, and gentamycin (Kalyuzhnaya et al. 2006).

Application

The floc-forming *Zoogloea* is always associated with activated sludge water purification plants and probably contributes much to the oxidation of organic matter.

Many representatives of the *Rhodocyclales* degrade aromatic compounds aerobically and/or anaerobically. Many of the aromatic compound-degrading species were isolated from wastewater treatment plants (*Tables 36.3–36.5*, *36.7*, *36.8*, and *36.11*), and they can be assumed to contribute there to the breakdown of aromatic compounds. Because of the versatile nature of species of, e.g., *Thauera*, *Dechloromonas*, and *Azoarcus* spp. able to degrade a wide range of aromatic compounds under different conditions, they have been suggested as suitable candidates for bioremediation operations for the removal of aromatic chemicals (Chakraborty et al. 2005; Mao et al. 2010; Reinhold-Hurek et al. 2005).

Thauera selenatis was isolated from selenium-rich agricultural drainage water in California, and its possible use for selenium bioremediation has been proposed (Macy et al. 1993).

A second anaerobic/microaerophilic isolate that reduces selenate and selenite to elemental red selenium is an *Azospira oryzae* (*Dechlorosoma suillum*) strain that developed in a laboratory reactor setup to remove selenate from groundwater (Hunter 2007). Another suggested way to remediate selenium-contaminated agricultural drainage with relatively high nitrate levels is by using a combination of a selenate-reducing isolate known as *Bacillus* sp. RS1 and *Dechloromonas* sp. strain HZ. In model experiments, the *Bacillus* reduced part of the Se(VI) to Se(IV). Addition of the *Dechloromonas* enhanced the Se reduction while simultaneously removing nitrate (Zhang and Frankenberger 2007).

The finding of perchlorate-reducing organisms such as *Dechlorobacter hydrogenophilus* in soil collected at an army ammunition plant (Thrash et al. 2010) shows that perchlorate reducers (*Dechloromonas*, *Dechlorobacter*, *Propionivibrio militaris*) may find applications in the bioremediation of soil and groundwater near ammunition factories and other perchlorate-polluted industrial areas.

Abstract

Spirillaceae, a family with the order *Nitrosomonadales*, class of *Betaproteobacteria*, is monogeneric and contains only one genus *Spirillum*. Phylogenetic neighbors are the families *Nitrosomonadaceae*, *Methylophilaceae*, and species *Sulfuricella denitrificans*, which belong to the family *Hydrogenophilaceae*. Members of the family *Spirillaceae* (genus *Spirillum*) are a monophyletic branch of closely related organisms with similar phenotypic and genotypic characteristics. The genus is represented by three species (*S. volutans, S. winogradskyi*, and *S. kriegii*). All three species are morphologically close to each other and present themselves as large spiral cells. They are facultative microaerophiles with low level G + C (38–38.9 mol %) content and characterized by similar habitat environments. Preferably, they develop in stagnated water such as ponds, and industrial and domestic liquid-waste drains with microaerobic conditions and a high concentration of organic substrates.

Taxonomy: Historic and Current

Short Description of the Family and the Genus

Spirillaceae Migula 1894, 237[AL], Garritty, Bell and Lilburn, 2005

Spi.ril.la'ce.ae. ML.dim. neut.n. *Spirillum* type genus of the family; *aceae* ending to denote family; ML fem. pl.n. *Spirillaceae* – the *Spirillum* family.

The description is modified and an emended version of previous family description given on *Bergey's Manual*, 2nd edition (Garrity et al. 2005; Podkopaeva et al. 2006, 2005, 2009).

Based on phylogenetic analysis of the set of 16S rRNA gene sequence, the family *Spirillaceae* was placed in the phylum Betaproteobacteria of the order *Nitrosomonadales* (Garrity et al. 2005). The family *Spirillaceae* Migula 1894 comprises only genus *Spirillum* Ehrenberg 1832 (Krieg 2005) (type genus).

The genus *Spirillum* Ehrenberg 1832, 38[AL] is one of the oldest established bacterial genera. Prior to 1973, the genus *Spirillum* included several aerobic/microaerophilic chemoheterotrophic spirilla. Hylemon et al. (1973a) divided the genus into the three genera: *Spirillum*, *Aquaspirillum*, and *Oceanospirillum* on the basis of their DNA base composition and certain physiological characteristics. Currently, the genus *Spirillum* is reserved for large, microaerophilic, freshwater spirilla having DNA base composition of 38–38.9 mol % G + C (tm).

The 16SrRNA gene signature of the family *Spirillaceae* consists of: 121(C), 126–235 (A–U), 131–231 (U:A), 241–285 (C–G), 407–435 (G:C), 443–491 (G–C), 598–640 (C–G), 658–748 (U–A), 870 (A), 990 (U), 1124-1149 (G–C), 1131 (C).

Genus *Spirillum* Ehrenberg 1832 includes three species: *S. volutans*, *S. winogradskyi*, and *S. kriegii*.

Phylogenetic Structure of the Family and the Genus

According to the phylogenetic branching of proteobacterial type strains in the 16S rRNA gene tree of the Living Tree Project (Yarza et al. 2010), the family *Spirillaceae* is moderately related to the families *Nitrosomonadaceae*, *Methylophilaceae*, and *the* recently described type strain of *Sulfuricella denitrificans* (Kojima and Fukui 2010) from the family *Hydrogenophilaceae* (◗ *Figs. 37.1*, ◗ *37.2*). At present, the family *Spirillaceae* comprises a very narrow group of organisms. Only with the availability of sequences of newly described type strains within the family *Spirillaceae* will the phylogenetic boundary with close generic and suprageneric taxa be clarified.

After a loss of vital strains of type species of genus *Spirillum*, *S. volutans*, in international collections in 2009, it was recommended to place the name *Spirillum volutans* on the list of obsolete names, and to approve *S. winogradskyi* (Podkopaeva et al. 2009) as a neotype species of the genus. The vital type strain of the species *S. kriegii* was also lost, and is no longer maintained in any international collections.

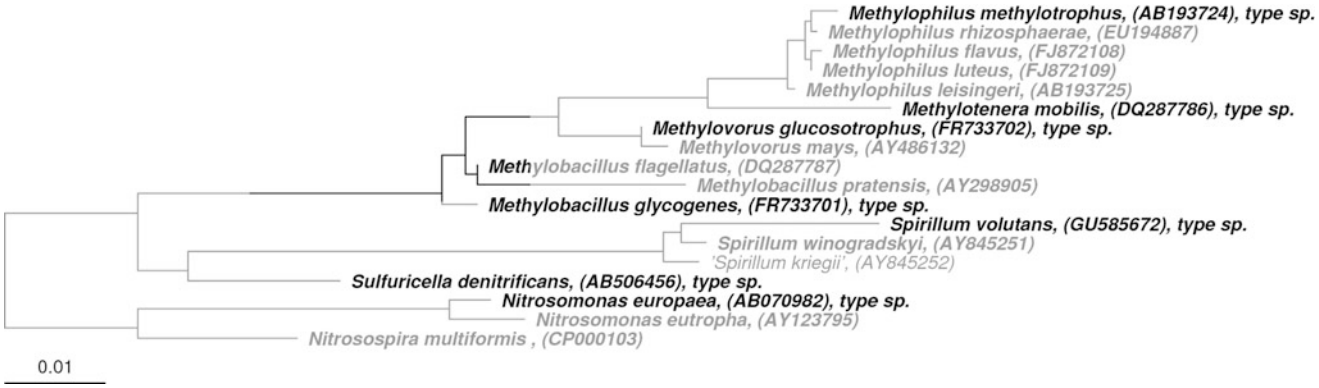

Fig. 37.2
Dendrogram of the type and the closest species of the genera *Spirillaceae* and related families

Phylogenetic reconstruction of the family *Spirillaceae* based on 16S rRNA and created using the maximum likelihood algorithm RAxML (Stamatakis 2006). The sequence dataset and alignment were used according to the All-Species Living Tree Project (LTP) database (Yarza et al. 2010; http://www.arb-silva.de/projects/living-tree). Representative sequences from closely related taxa were used as outgroups. In addition, a 40% maximum frequency filter was applied in order to remove hypervariable positions and potentially misplaced bases from the alignment. Scale bar indicates estimated sequence divergence.

Phenotypical Analyses

Main phenotypic features of the members of genus *Spirillum* (Family *Spirillaceae*) are given in *Table 37.1*.

Rigid helical cells, 1.4–2.1 * 10.5–60 μm motile by bipolar tufts of large flagella which are composed of 60–75 flagella and are visible in phase contrast microscope like one thick flagellum. Both cells and flagella of *S. winogradskyi* and *S. kriegii* are covered with sheath of polysaccharides (Podkopaeva et al. 2006).

Coccoid bodies with diameters up to 7–10 μm appear in *S. winogradskyi* and *S. kriegii* at the phase of stationary growth. In electron microscopy of ultrathin section reveals of the coccoid cells, with destruction of peptidoglycan layer of the cell wall and retention of the cytoplasmic membrane was evident. After passage in fresh medium under microaerobic conditions, coccoid cells revert to helical, allowing them to be considered as spheroplasts.

Intracellular poly-ß-hydroxybutyrate and polyphosphate granules are formed.

Some species (*S. winogradskyi* and *S. kriegii*) are capable of abundant accumulation of elemental sulfur inside the cells when cultured in the medium with sulfide.

Colonies of *S. volutans* are able to grow in a bilayer agar medium using Alban and Krieg's method (1996) which calls for pouring semisolid agar medium onto the surface of a Petri dish, and introducing 0.1–ml of inoculum added to 10 ml of semi-solid medium at 45 °C, poured onto the plates as an overlay, and incubated at 30 °C in the atmosphere of 6 % O_2 and 94 % N_2 for 3–4 days. Very small colonies with irregular form and uneven edges were grown in the upper agar strata. In contrast to *S. volutans, S. winogradskyi* and *S. kriegii* do not need bilayer agar for Petri dish cultivation, and they create small flat irregular form colonies with uneven edges 0.5–1 μm in diameter in the mass of agar medium. Their viability is about 3–5 days. *S. winogradskyi* is also able to grow on the surface of agar medium in the presence of reduced sulfur compound. Development of *S. kriegii* takes place within agar medium without reduced sulfur compound while exposing Petri dishes to air. This indicates a higher degree of microaerophily of *S. kriegii* in comparison with *S. winogradskyi*.

They have a strictly respiratory type of metabolism with oxygen as a terminal electron acceptor. They are facultative

microaerophils. Growth does not occur anaerobically with nitrate, sulfate, thiosulfate, elemental sulfur, or fumarate as electron acceptors. They also have weak catalase activity, and are oxidase-positive. Optimal temperature ranges from 27 °C to 33 °C for different species.

All three species use a limited number of organic substrates, mainly intermediate substances of the tricarboxylic acid cycle, such as succinate, fumarate, malate, oxaloacetate, and pyruvate. Additionally, in the presence of yeast extract, *S. winogradskyi*

uses citrate, aconitate, and isocitrate, and *S. kriegii* uses lactate. While *S. volutans* is able to grow on lactate, *S. winogradskyi* and *S. kriegii* can grow on acetate and 2-oxoglutarate in the absence of yeast extract. Representatives of the genus *Spirillum* do not use as a source of carbon: aminoacids (histidine, tyrosine, phenylalanine, alanine, glutamate, serine, aspartate, asparagine, glutamine, proline, valine, hydroxyproline, glycine, ornithine, arginine, lysine, methionine, cystine, cysteine, leucine, threonine, and tryptophan); alcohols (propanol, mannite, glycerol, ethanol, and butanol); carbohydrates (glucose, fructose, maltose, arabinose, galactose, and saccharose); and polymer compounds (peptone, starch, and casein hydrolysate).

As a source of nitrogen, the bacteria use ammonium salts, peptone, and casein hydrolysate. They are unable to utilize nitrate, nitrite, and individual amino acids. The nitrates are not reduced to nitrites, and the bacteria do not grow in a presence of NaCI higher than 0.5 % concentration.

In the presence of organic growth substrate, *S. winogradskyi* and *S. κriegii* are capable of oxidizing sulfide and polysulfide to elemental sulfur with its accumulation in the cells, and of quantitatively oxidizing thiosulfate to tetrathionate, which accumulates in the medium (Podkopaeva et al. 2005). Enzymes of sulfur oxidative metabolism were not found in these bacteria, and oxidation of inorganic sulfur compounds is not associated with energetic metabolism, but takes place as a result of a chemical interaction of reduced sulfur with reactive oxygen species (ROS) (Podkopaeva et al. 2003, 2005).

Analysis of the composition of fatty acids in cells was done for *S. winogradskyi* only. Major cellular fatty acids were 16:0, 16:1, and 18:1. The detailed fatty acid profile of *S. winogradskyi* D-427^T is shown in *Table 37.2*.

Several physiological and biochemical tests were carried out for *S. volutans* only. *S. volutans* is relatively inert biochemically in most routine characterization tests, but is phosphatase-positive (Hylemon et al. 1973b). It is negative for: enzymes DNase, RNase, urease, and arylsulfatase; gelatin liquefaction; hydrolysis of casein, starch, and esculin; indole production; reduction of selenite; and growth in the presence of 1 % bile or 1 % glycine. The response of *S. volutans* ATCC 19554 to 44 antibiotics and other chemotherapeutic agents was determined by Friedman (1987). The organism was inhibited by each of the agents tested except clindamycin, cloxacillin, lincomycin, and oxacillin. It is interesting that, although *S. volutans* respires with oxygen, its growth is completely inhibited by as little as 0.05 mkg/ml of metronidazole, a compound that is selectively toxic toward anaerobes. As indicated by Padgett and Krieg (1986), this provides circumstantial evidence for the occurrence of ferredoxins or flavodoxins in *S. volutans*, because metronidazole reduction is preferentially linked to these electron carriers.

The nucleotide DNA composition of all species of the genus *Spirillum* is close to each other: Content of G + C in DNA is 38–38.9 mol % (tm). DNA-DNA hybridization between *S. winogradskyi* and *S. volutans* has a degree of homology 12 %, and 28 % – with *S. kriegii* (Podkopaeva et al. 2006, 2009).

Influence of the Oxygen Regime of Cultivation on Growth and Metabolism

Though the known species of genus *Spirillum* prefer microaerobic growth conditions and traditionally belong to microaerophils, stationary growth is possible under specific conditions and on exposure to atmospheric air, particularly with the introduction of components which block toxic impact of H_2O_2 and other ROS to the medium: catalase (1–230 U/ml), SOD (4–30 U/ml), peptone (2 g/l), casein hydrolysate (2 g/l), pyruvate (1 g/l), norepinephrine (0.002 %), potassium metabisulfite (0.002–0.005 %), thiosulfate (1 g/l) correspond to these components (Bowdre et al. 1976; Padgett et al. 1982; Podkopaeva et al. 2003). The introduction of thiosulfate to the medium under aerobic conditions as a result of removing ROS by chemical interaction prevents cell lysis, doubles the cell harvest, and stabilizes the cultures (Podkopaeva et al. 2005).

Besides preventing cell lysis, augmentation of the cell harvest by thiosulfate oxidation is associated with decreasing expenditures on biosynthesis of exopolysaccharides as a way of protecting from abundance oxygen on the medium. Oxidation of thiosulfate in *S. winogradskyi* and *S. kriegii* takes place only during consumption of organic substrates and plays no part in energetic metabolism as inorganic donors of electrons.

Isolation, Enrichment, and Maintenance Procedures

Cultures of *S. volutans* occurring in hay infusions or other natural media can be enriched by inoculating Pringsheim's soil medium (Rittenberg and Rittenberg 1962). To date, the only

successful method for isolating *S. volutans* is the capillary method first described by Giesberger (1936) and used successfully with *S. volutans* by Rittenberg and Rittenberg (1962). Transfers from the capillary should be made directly to the test tubes of a suitable medium such as semisolid modified peptone-succinate-salts (MPSS) or casein hydrolysate-succinate-salts (CHSS). Media for *S. volutans*: MPSS broth (Caraway and Krieg 1972): Succinic acid (free acid) 1.0 g, $MgSO_4 \cdot 7H_2O$ 1.0 g, Bacto Peptone (Difco) 5.0 g, $(NH_4)_2SO_4$ 1.0 g, $FeCl_3 \cdot 6H_2O$ (0.2 % aqueous solution) 1.0 ml, $MnSO_4 \cdot H_2O$ (0.2 % aqueous solution) 1.0 ml.

The first four ingredients are dissolved in 1 l of distilled water and the pH is adjusted to 7.0 with 2 N KOH. The $FeCl_3$ and $MnSO_4$ solutions are added and the medium is sterilized by autoclaving. The medium is stored in the dark to avoid photochemical production of hydrogen peroxide. Semisolid MPSS medium is prepared by adding 0.15 % agar to the liquid medium. MPSS agar is prepared by adding 1.5 % agar to the liquid medium.

CHSS Broth (Padgett and Krieg 1986): Succinic acid (free acid) 1.0 g, $MgSO_4 \cdot 7H_2O$ 1.0 g, acid-hydrolyzed casein, "vitamin-free, salt-free" 2.5 g, $(NH_4)_2SO_4$ 1.0 g, NaCl 0.1 g, KH_2PO_4 0.14 g, $FeCl_3 \cdot 6H_2O$ (0.2 % aqueous solution) 1.0 ml, $MnSO_4 \cdot H_2O$ (0.2 % aqueous solution) 1.0 ml, potassium metabisulfite 0.05 g.

The first eight ingredients are dissolved in 1 l of distilled water and the pH is adjusted to 7.0 with 2 N KOH. The potassium metabisulfite is added, and the pH readjusted to 7.0. The medium is sterilized by autoclaving and stored in the dark.

Semisolid CHSS medium is prepared by adding 0.15 % agar to the medium after addition of the potassium metabisulfite, boiling to dissolve the agar, and then autoclaving. CHSS agar is prepared by adding 1.5 % agar to the liquid medium. Due to the difficulty of cultivating *S. volutans*, a detailed description of the method of medium preparation is given below. Goatcher et al. (1984) reported that Bactocasitone (Difco) could be substituted for the indicated casein hydrolysate, and that $MnSO_4$ could be omitted under these conditions. Bowdre and Krieg (1974) did not include NaCl in their original formulation of CHSS broth. However, Padgett et al. (1982) found that the casein hydrolysate used by Bowdre and Krieg was not completely salt-free. When salt-free batches of casein hydrolysate were used, a low level of NaCl was required for growth. Levels of NaCl greater than 0.02 % inhibited growth. Bowdre and Krieg (1974) did not include KH_2PO_4 in their original formulation of CHSS broth. However, its addition to the medium has since been found to increase the growth response of *S. volutans* (Friedman 1987). For *S. volutans*, optimal growth occurs between 30 °C and 36 °C and at pH values of 7.0–8.2 (Moore 1984). Although the organism is a microaerophile, cultures in semisolid media can be incubated in an air atmosphere due to stratification of the medium. Growth begins as a thin disk some distance below the surface at a point where the respiratory rate of the cells matches the rate of diffusion of oxygen to the cells. As the cell numbers increase, the disk becomes denser and migrates toward the surface. After 48 h, dense growth occurs just beneath the surface. Cultures grown in MPSS broth (no agar added) or on solid media for colony development should be incubated under an atmosphere of 6 % O_2 and 94 % N_2.

To isolate microaerophilic spirilla *S. winogradskyi* and *S. kriegii* from the sludge of municipal purification plants, samples were taken from aeration tanks of a wastewater treatment plant containing domestic wastewater, large spirilla, H_2S at a range between 1 and 2 mgl-1 and oxygen at 2–3.5 mgl-1 were used as passage material for the inoculation. A modified semisolid MPSS medium (Caraway and Krieg 1974) was used with a freshly prepared FeS suspension (Kucera and Wolfe 1957) with the following composition (l-1): 1 g $(NH_4)_2SO_4$; 1 g $MgSO_4$; 0.03 g $CaCl_2 \cdot 2H_2O$; 0.002 g $FeCl_3$ $6H_2O$; 0.002 g $MnSO_4$; 1 g sodium succinate; 1 g casein hydrolysate; 1 g agar (Difco). The pH of the medium was adjusted to 7.5. Vitamins and trace elements (Pfennig and Lippert 1966) were added before inoculation. Test tubes filled with medium at 2/3 volume were incubated at 28 °C after the passage, corresponding to the temperature in aeration tanks. After 3 days of incubation, thin white bands consisting of large motile spirilla with intracellular inclusions of elemental sulfur appeared in the medium at about 0.5–1.0 cm below the surface. These cells were collected with a capillary tube and transferred to a test tube. Enrichment cultures were obtained by using a serial 10-fold dilution technique in test tubes. The last positive tube was used for isolation on the same medium solidified with 1.5 % agar (Difco) in Petri dishes. After 5 days of incubation at 28 °C, small semitransparent colonies of large spiral cells appeared only below the agar surface. A single colony was transferred into liquid MPSS medium without FeS. Routine cultivation was carried out in liquid MPSS medium without FeS, casein hydrolysate being replaced by peptone at a concentration of 5 gl-1.

The members of the genus *Spirillum* may be maintained in semisolid MPSS of CHSS medium in test tubes exposed to air atmosphere at 28–30 °C, with transfer every 4–5 days for *S. volutans* and *S. kriegii*, and 14 days for *S. winogradskyi*.

Preservation

Preservation by lyophilization has not yet been possible for known species of the genus *Spirillum*, as well as preservation under −80 °C. Long-term preservation is possible in liquid nitrogen (Pauley and Krieg 1974) with 10 % dimethyl sulfoxide (DMSO) as cryoprotectant.

Ecology

Habitat

Representatives of the genus *Spirillum* are widespread in many stagnant fresh water reservoirs (Wells and Krieg 1965), polluted with organic substances, waste waters of treatment facilities, the cooling water of sugar refinery (Rittenberg and Rittenberg), and

aeration tanks of municipal sewage water treatment plants (Podkopaeva et al. 2006, 2009). As a rule, development of spirilla takes place in the water layer at a lower margin of oxygen distribution in microaerobic conditions. Species *S. winogradskyi* and *S. kriegii* were picked out from domestic waste water contained up to 1–2 mg/l of sulfide and 2.0–3.5 mg/l of oxygen.

38 The Family *Sutterellaceae*

Masami Morotomi
Yakult Central Institute for Microbiological Research, Tokyo, Japan

Abstract

Sutterellaceae, a family within the order *Burkholderiales* in the lineage of phylum Proteobacteria (class *Betaproteobacteria*), includes the genera *Sutterella* and *Parasutterella*. The genus *Sutterella* contains three validly described species: *Sutterella wadsworthensis* (the type species), *Sutterella parvirubra*, and *Sutterella stercoricanis*. In contrast, the genus *Parasutterella* comprises the species *Parasutterella excrementihominis* (the type species) and *Parasutterella secunda*. Members of the family are mainly found in the intestinal tract of humans and some animals as members of the indigenous intestinal microbiota, and can be isolated from both the intestinal tract and from infections of gastrointestinal origin (*S. wadsworthensis*). The cells are Gram-negative rods or coccobacilli, and grow under anaerobic conditions or in a microaerophilic atmosphere. They are asaccharolytic and negative for oxidase and catalase activities. The main isoprenoid quinone is methylmenaquinone-5 (MMK-5) or MMK-6. The type genus is *Sutterella* (Wexler et al. Int J Syst Bacteriol 46:252–258, 1996).

Taxonomy, Historical and Current

Sutterellaceae (Sut.te.rel.la'ce.ae. N.L. fem. n. *Sutterella* type genus of the family; *-aceae* ending to denote a family; N.L. fem. pl. n. *Sutterellaceae*, the *Sutterella* family).

The genus *Sutterella* was first described by Wexler et al. (1996) and was placed within the family *Alcaligenaceae* in the second edition of *Bergey's Manual of Systematic Bacteriology* (Wexler 2005). The genus *Parasutterella* was described by Nagai et al. (2009) as the closest neighbor of genus *Sutterella*. Morotomi et al. (2011) proposed the new family *Sutterellaceae* to accommodate these two genera after finding that the genera *Sutterella* and *Parasutterella* formed a separate line of descent within the order *Burkholderiales*. In their research, this lineage could not be associated with any of the four known families (*Alcaligenaceae*, *Burkholderiaceae*, *Comamonadaceae*, and *Oxalobacteraceae*) in the order *Burkholderiales* (◗ *Fig. 38.1*). The rationale for the new family was based both on the distinct phylogenetic positions and on the biological and biochemical differences of the genera *Sutterella* and *Parasutterella* from known genera in the family *Alcaligenaceae*, which is phylogenetically the nearest neighboring family of the *Sutterellaceae*. All known members of the genera *Sutterella* and *Parasutterella* are oxidase- and catalase negative, and no aerobic growth has been observed, although some species may grow in a microaerophilic atmosphere. In contrast, species in the *Alcaligenaceae* are oxidase- and catalase positive, and can generally grow aerobically (◗ *Table 38.1*). All type strains of the *Sutterellaceae* contain $C_{18:1}\omega9c$ (32–68 % of the total) and $C_{16:0}$ (9–23 %) as the predominant fatty acids (◗ *Tables 38.1* and ◗ *38.2*). However, $C_{18:1}\omega9c$ has not been reported to be a major component in any species of the family *Alcaligenaceae* (◗ *Table 38.1*). The major respiratory quinone of the members of the *Sutterellaceae* is methylmenaquinone-5 (MMK-5) or MMK-6, whereas ubiqinones have not been detected (◗ *Tables 38.1* and ◗ *38.3*). In contrast, species of the family *Alcaligenaceae* have, in general, been characterized by the presence of ubiquinone-8 (Q-8) as the major isoprenoid quinone (◗ *Table 38.1*; Fletcher et al. 1987; Oyaizu-Masuchi and Komagata 1988).

Molecular Analyses

Phylogeny

On the basis of 16S rRNA gene sequence similarities, members of the family *Sutterellaceae* are members of the order *Burkholderiales*, with the nearest neighboring family being the *Alcaligenaceae* (◗ *Fig. 38.1*). The phylogenetic distance between type species of the family is relatively high. The 16S rRNA gene sequence of the type strain of *Sutterella wadsworthensis* shares 94.6 % similarities with the sequences of *Sutterella parvirubra* and *Sutterella stercoricanis*. The type strains of *S. parvirubra* and

E. Rosenberg et al. (eds.), *The Prokaryotes – Alphaproteobacteria and Betaproteobacteria*, DOI 10.1007/978-3-642-30197-1_240,

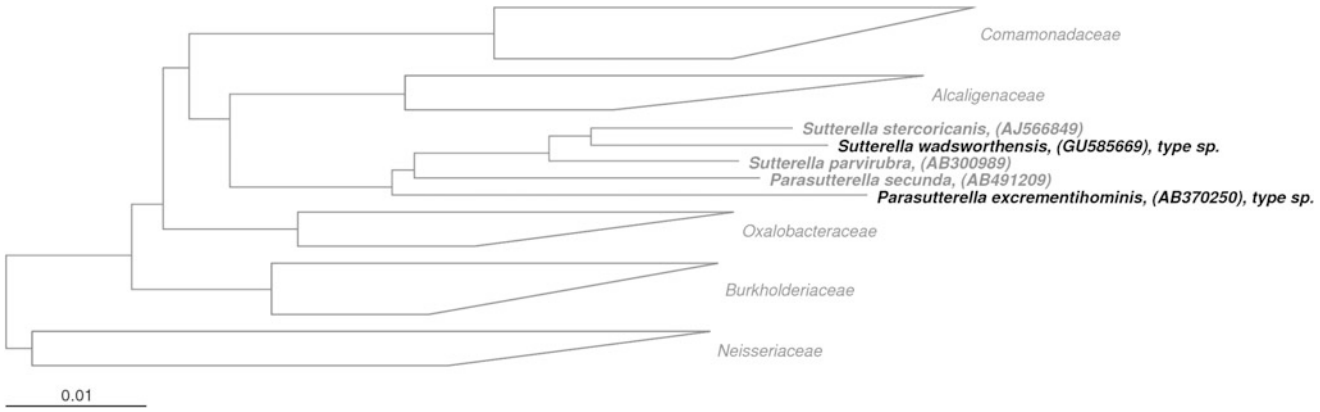

Fig. 38.1

Phylogenetic reconstruction of the family *Sutterellaceae* based on 16S rRNA and created using the neighbor-joining algorithm with the Jukes-Cantor correction. The sequence datasets and alignments were used according to the All-Species Living Tree Project (LTP) database (Yarza et al., 2010; http://www.arb-silva.de/projects/living-tree). The tree topology was stabilized with the use of a representative set of nearly 750 high-quality type-strain sequences proportionally distributed among the different bacterial and archaeal phyla. In addition, a 40% maximum-frequency filter was applied in order to remove hyper variable positions and potentially misplaced bases from the alignment. Scale bar indicates estimated sequence divergence. This tree was provided by Dr. Raul Muñoz of the Instituto Mediterráneo de Estudios Avanzados

S. stercoricanis share 94.7 % similarity. The type strains of the two *Parasutterella* species, *Parasutterella excrementihominis* and *Parasutterella secunda*, share 90.0 % similarity. In contrast, similarities between members of the *Sutterellaceae* and type species of the neighboring family *Alcaligenaceae* range between 88.3 % and 90.9 %. Thus, all species described so far can be unambiguously identified by their 16S rRNA gene sequence (Morotomi et al. 2011).

Genome

Sutterella parvirubra YIT 11816^T, *P. excrementihominis* YIT 11859^T, and four strains of *S. wadsworthensis* (HGA0223, HGP1, 3_1_45B, and 2_1_59BFAA) were selected for inclusion in the catalog of reference genomes by the Human Microbiome Project (http://commonfund.nih.gov/hmp/) and, at the time of writing, the assembled and annotated genomic sequences of three strains (*S. parvirubra* YIT 11816^T, *P. excrementihominis* YIT 11859^T, and *S. wadsworthensis* 3_1_45B) have been submitted to the GenBank/EMBL/DDBJ databases. The genome size, G+C content, number of predicted protein-encoding genes, and number of predicted rRNA and tRNA genes of these strains are listed in *Table 38.4*. Details are available from the National Center for Biotechnology Information database (http://www.ncbi.nlm.nih.gov/).

DNA–DNA Hybridization

Sutterella wadsworthensis WAL 9799^T did not undergo DNA–DNA hybridization with DNA from either *Campylobacter gracilis* or other *Campylobacter* species (*Campylobacter rectus*, *Campylobacter curvus*, *Campylobacter consisus*, *Campylobacter sputorum*, and *Campylobacter showae*), which cannot be differentiated phenotypically (Wexler et al. 1996). The degree of the hybridization between *S. wadsworthensis* CCUG 42229^T (= WAL 9799^T) and *S. stercoricanis* 5BAC4^T was 35 %, which is low enough to be consistent with separate species status (Greetham et al. 2004). No hybridization studies have been done for the *Parasutterella* species, as the 16S rRNA gene sequence similarity between the type strains of the respective species was only 90.0 % that indicates separate genospecies (Morotomi et al. 2011).

Matrix-associated laser desorption/ionization—time of flight mass spectrometry (MALDI-TOF MS).

Eleven strains of *S. wadsworthensis*, including the type strain, were analyzed by MALDI-TOF MS, and the results included a dominant peak at approximately 9,400 Da that was common to all *S. wadsworthensis* strains (Mukhopadhya et al. 2011). No mass spectrometry data is available for any other species in the *Sutterellaceae*.

Neither riboprinting nor ribotyping analyses are available for any member of the *Sutterellaceae*.

Phenotypic Analyses

Members of the *Sutterellaceae* are strictly anaerobic or microaerophilic, non-motile, non-spore-forming, Gram-negative rods or coccobacilli. Biochemically, they are largely unreactive and asaccharolytic.

Differential characteristics of members of the family *Sutterellaceae* and those of the phylogenetically nearest family, the *Alcaligenaceae*, are listed in *Table 38.1*. All type strains of the genera *Sutterella* and *Parasutterella* cannot grow under aerobic conditions, and are oxidase- and catalase-negative

Table 38.1

Differential characteristics of members of the family *Sutterellaceae* and those of the phylogenetically nearest (Fig. 38.1) family, the *Alcaligenaceae*

Taxa: 1 *Sutterella parvirubra* YIT 11816^T, 2 *Sutterella stercoricanis* DSM 17807^T, 3 *Sutterella wadsworthensis* DSM 14016^T, 4 *Parasutterella excrementihominis* YIT 11859^T, 5 *Parasutterella secunda* YIT 12071^T, 6 *Achromobacter xylosoxidans* (*n* = 10 strains), 7 *Advenella incenata* (*n* = 8), 8 *Alcaligenes faecalis* DSM 30033^T, 9 *Bordetella pertussis* (*n* = 12), 10 *Brackiella oedipodis* LMG 19451^T, 11 *Castellaniella defragrans* DSM 12141^T, 12 *Derxia gummosa* IAM 13946^T (=ATCC 15594^T), 13 *Kerstersia gyiorum* (*n* = 6), 14 *Oligella urethralis* (*n* = 8), 15 *Pelistega europaea* (*n* = 13), 16 *Pigmentiphaga kullae* K24^T, 17 *Pusillimonas noertemannii* BN9^T, 18 *Taylorella equigenitalis* LMG 6222^T, 19 *Tetrathiobacter kashmirensis* WT001^T

Symbols: + positive, – negative, *ND* no data available, *Q* ubiquinone

[a]Includes fatty acids that account for >10 % of the total, listed in descending order. Summed feature 2 (SF2) comprises 14:0 3-OH, 16:1 iso I, an unidentified fatty acid with an equivalent chain length (ECL) of 10.928 or 12:0 aldehyde. SF3 comprises 16:1$\omega7c$ or 15:0 iso 2-OH. SF7 comprises $C_{17:1}\omega9c$ or an unknown fatty acid of ECL 16.760. SF10 comprises $C_{18:1}\omega7c$ or an unknown fatty acid of ECL 17.834. SF12 contains iso-$C_{19:0}$ or an unknown fatty acid of ECL 18.622.

[b]Referred to as SF3 by Vandamme et al. (1998)

(Table 38.1). In addition, they are negative for urease and indole production and for hydrolysis of gelatin and aesculin (Greetham et al. 2004; Sakon et al. 2008; Nagai et al. 2009; Morotomi et al. 2011 and unpublished). In contrast, species of the family *Alcaligenaceae* have, in general, the opposite characteristics (Table 38.1). All type strains of the *Sutterellaceae* contain $C_{18:1}\omega9c$ (32–68 %) and $C_{16:0}$ (9–23 %) as the predominant fatty acids, and MMK-5 or MMK-6 as the major respiratory quinone (Tables 38.1 and 38.2). The typical fragmentation of a ubiquinone ring nucleus at mole peak of $m/z = 197$ was not detected in these strains, indicating that ubiquinones are not present in the known strains of the genera *Sutterella* and *Parasutterella* (Morotomi et al. 2011). In contrast, species of the family *Alcaligenaceae* are characterized by the presence of ubiquinone-8 (Q-8) as the major isoprenoid quinone, and fatty acids other than $C_{18:1}\omega9c$ are the major cellular fatty acids (Table 38.1).

All type strains of the genera *Sutterella* and *Parasutterella* do not utilize the following API 20A substrates: L-arabinose, D-cellobiose, glucose, glycerol, lactose, maltose, D-mannitol, D-mannose, D-melezitose, D-raffinose, L-rhamnose, salicin, D-sorbitol, sucrose, D-trehalose, and D-xylose (Greetham et al. 2004;

Sakon et al. 2008; Nagai et al. 2009; Morotomi et al. 2011 and unpublished). They are negative for the following API ZYM and API rapid ID 32 A reactions: N-acetyl-β-glucosaminidase, α-arabinosidase, chymotrypsin, cystine arylamidase, fermentation of mannose, fermentation of raffinose, α-fucosidase, α-galactosidase, β-galactosidase, α-glucosidase, β-glucosidase, β-glucuronidase, glutamyl glutamic acid arylamidase, histidine arylamidase, indole production, lipase (C14), α-mannosidase, 6-phosphate β-galactosidase, proline arylamidase, pyroglutamic acid arylamidase, trypsin, urease, and valine arylamidase (Greetham et al. 2004; Sakon et al. 2008; Nagai et al. 2009; Morotomi et al. 2011 and unpublished). Diagnostic phenotypic differences for the fatty acid compositions of the type strains of the genera *Sutterella* and *Parasutterella* are listed in *Table 38.2*.

The fatty acid and isoprenoid quinone compositions of the type strains of the genera *Sutterella* and *Parasutterella* are listed in *Tables 38.2* and *38.3*, respectively. *Table 38.5* provides additional phenotypic details.

Table 38.2

Taxa: 1 *Sutterella parvirubra* YIT 11816^T, 2 *Sutterella stercoricanis* DSM 17807^T, 3 *Sutterella wadsworthensis* DSM 14016^T, 4 *Parasutterella excrementihominis* YIT 11859^T, 5 *Parasutterella secunda* YIT 12071^T. Values are percentages of total fatty acids; only those fatty acids that make up more than 1 % of the total are shown. Data are from Morotomi et al. (2011)

[a]Data for *Sutterella stercoricanis* DSM 17807^T are slightly different from those of Greetham et al. (2004); the difference may have resulted from the different culture conditions

[b]Summed feature 1 (SF1) contained $C_{13:1}\omega12c$ or $C_{14:0}$ aldehyde. SF2 contained $C_{12:0}$ 3-OH or $C_{13:0}$ DMA. SF5 contained $C_{15:0}$ DMA or $C_{14:0}$ 3-OH. SF7 contained $C_{17:1}\omega9c$ or an unknown fatty acid of equivalent chain length (ECL) 16.760. SF10 contained $C_{18:1}\omega7c$ or an unknown fatty acid of ECL 17.834. SF12 contained iso-$C_{19:0}$ or an unknown fatty acid of ECL 18.622

Sutterella Wexler, Reeves, Summanen, Molitoris, Mcteague, Duncan, Wilson, and Finegold 1996a, 257[VP]

Sut.ter.el'la. M.L. dim. Fem. n. *Sutterella* named in memory of Vera Sutter, respected colleague and director of the Wadsworth Anaerobe Laboratory for 20 years.

The data described for *Sutterella* species in this section are from Sakon et al. (2008), Greetham et al. (2004), Wexler et al. (1996), Wexler (2005).

Cells of *Sutterella* species are straight rods (*S. wadsworthensis* and *S. stercoricanis*), 0.5–1.0 μm × 1.0–3.0 μm, or are coccoid to coccobacillary (*S. parvirubra*), approximately 0.4–1.0 μm × 0.4–2.0 μm. They grow under anaerobic conditions or in a microaerophilic atmosphere. Colonies of *S. wadsworthensis* on *Brucella* blood agar with 5 % lysed sheep blood, 1 μg/mL Vitamin K1, 1 μg/mL hemin, and 1 % w/w formate/fumarate after 48 h at 37 °C in anaerobic chamber are circular, entire, convex, yellow to brown, translucent to opaque, 1–1.5 mm in diameter. Colonies of *S. parvirubra* on GAM agar after 48 h anaerobic incubation are 0.2–1.1 mm in diameter, circular, flat, and translucent. No culture data has been reported for *S. stercoricanis* in the literature. *Sutterella wadsworthensis* and *S. stercoricanis* are resistant to 20 % (v/v) bile; no data are available for *S. parvirubra*. Other biological and biochemical characteristics of the type strains of the genus *Sutterella* are listed in *Tables 38.1–38.3* and *38.5*.

The G + C values for DNA of the species determined by HPLC for *S. parvirubra* YIT 11816^T and *S. stercoricanis* 5BAC4^T are 64.4 and 60.0 mol%, respectively. This value for *S. parvirubra* YIT 11816^T (64.4 mol%) is slightly lower than that determined by the genome analysis (65.3 mol%, *Table 38.4*). The value for *S. wadsworthensis* 3_1_45B determined by genome analysis is 55.1 mol% (*Table 38.4*), and that for the type strain has not been reported.

The type species is *S. wadsworthensis*.

The type strains are *S. parvirubra* YIT 11816^T (= DSM 19354^T = JCM 14724^T); *S. stercoricanis* 5BAC4^T (= CCUG 47620^T = CIP 108024^T); *S. wadsworthensis* WAL 9799^T (= ATCC 51579^T = CCUG 42229^T = CIP 104799^T = DSM 14016^T).

Parasutterella Nagai, Morotomi, Sakon, and Tanaka 2009, 1795[VP]

Pa.ra.sut.te.rel'la. Gr. prep. *para* besides, next to; N.L. fem. n. *Sutterella* name of a bacterial genus; N.L. fem. n. *Parasutterella* a genus similar to *Sutterella*.

Table 38.3
Isoprenoid quinone compositions of the type strains of the genera *Sutterella* and *Parasutterella*

	% of total isoprenoid quinones				
Isoprenoid quinone	**1**	**2**	**3**	**4**	**5**
		–	–	–	–
MK-4	–	–	–	1.58	–
MK-5	–	10.19	5.59	4.35	9.01
MK-6	–	–	–	13.40	–
MMK-5	100	89.75	94.41	3.16	90.99
MMK-6	–	–	–	77.51	–

Taxa: 1 *Sutterella parvirubra* YIT 11816^T, 2 *Sutterella stercoricanis* DSM 17807^T, 3 *Sutterella wadsworthensis* DSM 14016^T, 4 *Parasutterella excrementihominis* YIT 11859^T, 5 *Parasutterella secunda* YIT 12071^T. Values are percentages of total isoprenoid quinones; only those isoprenoid quinones that make up more than 1 % of the total are shown. MK-4, MK-5, and MK-6 are menaquinones with four, five, or six isoprene units, respectively; MMK-5 and MMK-6 are methylmenaquinones with five or six isoprene units, respectively. Data are from Morotomi et al. (2011)

The data described for *Parasutterella* species in this section are from Nagai et al. (2009) and Morotomi et al. (2011).

Cells of *Parasutterella* species are cocci to coccobacilli, 0.4–1.3 μm × 0.6–2.6 μm. Colonies on modified GAM agar after 4 days of anaerobic incubation at 37 °C are translucent to beige, circular, convex, and pinpoint in size. Growth in peptone-yeast extract broth (Holdeman et al. 1977) is weak, producing no visible turbidity, and no short-chain fatty acids are detected as an end product of metabolism. Addition of glucose, lactate, or succinate does not enhance growth or result in the production of short-chain fatty acids. Other biological and biochemical characteristics of the type strains of the genus *Parasutterella* are listed in *Tables 38.1–38.3* and *38.5*.

The G+C of DNA of the species determined by HPLC for *P. excrementihominis* YIT 11859^T and *P. secunda* YIT 12071^T are 49.8 and 48.2 mol%, respectively. The value for *P. excrementihominis* YIT 11859^T (49.8 mol%) is slightly higher than that determined by genome analysis (48.1 mol%, *Table 38.4*).

The type species is *P. excrementihominis*.

The type strains are *P. excrementihominis* YIT 11859^T (= DSM 21040^T = JCM 15078^T) and *P. secunda* YIT 12071^T (= DSM 22575^T = JCM 16078^T).

Isolation, Enrichment, and Maintenance Procedures

Sutterella wadsworthensis grows under anaerobic conditions or in a microaerophilic atmosphere of 2 % or 6 % oxygen. The type strain of *S. stercoricanis* grows in a microaerophilic atmosphere of 2 % oxygen but not at 6 % oxygen, or under anaerobic conditions. Growth of the type strains of *S. parvirubra*, *P. excrementihominis*, and *P. secunda* was only observed under strict anaerobic conditions (Wexler et al. 1996; Wexler 2005; Greetham et al. 2004; Sakon et al. 2008; Nagai et al. 2009; Morotomi et al. 2011).

Members of the family *Sutterellaceae* are asaccharolytic and their colonies on agar plates are very small, ranging from pinpoint in size to 1.5 mm in diameter. Therefore, the main problem in isolating these organisms from samples of feces or intestinal contents is the exclusion of the dominant intestinal microbiota, which cover large areas of the isolation plates.

Sutterella wadsworthensis is isolated on *Brucella* blood agar with 5 % lysed sheep blood, 1 μg/mL Vitamin K1, 1 μg/mL hemin, and 1 % w/w formate/fumarate, and is mainly obtained from the intestinal tract and from infections of gastrointestinal origin (Wexler 2005).

Sutterella parvirubra YIT 11816^T was isolated from the feces of a healthy human adult on a medium 10 (Caldwell and Bryant 1966) agar plate supplemented with 40 mM succinic acid as the sole carbon source, from which the other basal carbon sources (a mixture of glucose, cellobiose, soluble starch, and volatile fatty acids) had been excluded (Sakon et al. 2008).

Sutterella stercoricanis 5BAC4^T was isolated from the feces of a healthy male Labrador Retriever dog on bacteroides agar (Holdeman et al. 1977) by Greetham et al. (2004).

Parasutterella excrementihominis YIT 11859^T was isolated from the feces of a healthy human adult on anaerobe basal agar (Oxoid), pH 6.0 (Nagai et al. 2009).

Parasutterella secunda YIT 12071^T was isolated from the feces of a healthy human adult on modified Gifu anaerobic agar (GAM; Nissui Pharmaceutical) supplemented with oxacillin (4 μg/mL; Sigma) (Morotomi et al. 2011).

Some growth media suitable for cultivation of strains of the family *Sutterellaceae* and their compositions are shown in the websites of Leibniz-Institut DSMZ—Deutsche Sammlung von Mikroorganismen und Zellkulturen GmbH (http://www.dsmz.de/) and Japan Collection of Microorganisms (http://www.jcm.riken.jp/JCM/JCM_Home_J.shtm).

The strains are generally maintained in anaerobic medium as broths or agar slants at 4 °C for a few days. Medium-term maintenance is as suspensions in 20 % v/v glycerol, 20 % w/v skim milk, or 10 % w/v skim milk supplemented with 1 % w/v sodium glutamate at −70 °C. Long-term preservation is by lyophilization.

Ecology

Sutterella wadsworthensis was first reported when performing biochemical characterization and susceptibility testing of *Campylobacter gracilis*–like clinical isolates from patients with diverse infections of the gastrointestinal tract (Wexler et al. 1996). Although a potential role of *S. wadsworthensis* in human gastrointestinal diseases has been documented in the past (Wexler et al. 1996; Molitoris et al. 1997), recent evaluation of the colonic mucosal isolates of this species from patients with inflammatory bowel disease has led to the conclusion that this species is probably a commensal; *S. wadsworthensis* was detected in

Table 38.4

Basic genome statistics for strains of the family *Sutterellaceae*

	Genome size (bp)	G+C content (mol%)	Number of predicted genes		
			protein	rRNA	tRNA
Sutterella parvirubra YIT 11816^T	2,374,505	65.3	2,483	2	63
Sutterella wadsworthensis 3_1_45B	2,965,437	55.1	2,373	7	64
Parasutterella excrementihominis YIT 11859^T	2,831,696	48.1	2,751	1	54

Data are from the GenBank/EMBL/DDBJ databases

Taxa: 1 *Sutterella parvirubra* YIT 11816^T (Data from Sakon et al. 2008), 2 *Sutterella stercoricanis* DSM 17807^T (Greetham et al. 2004), 3 *Sutterella wadsworthensis* DSM 14016^T (Morotomi et al. 2011), 4 *Parasutterella excrementihominis* YIT 11859^T (Nagai et al. 2009), 5 *Parasutterella secunda* YIT 12071^T (Morotomi et al. 2011)

+positive, – negative, *w* weakly positive

[a]Data from Wexler et al. (1996)

83.8 % of adult patients with ulcerative colitis as opposed to 86.1 % of the control subjects (Mukhopadhya et al. 2011). This study also indicated that *S. wadsworthensis* adheres closely to the mucosal lining and is thus more likely to be detected in biopsy samples than in feces.

Recently improved sequencing technology has led to the deposition of a large number of uncultured bacterial clones in the GenBank/EMBL/DDBJ public databases. There is evidence that *S. wadsworthensis* occurs in human feces as a common member of the human indigenous microflora, because many uncultured bacteria with highly similar 16S rRNA gene sequences (>98.7 % identity, the threshold proposed for distinguishing species by Stackebrandt and Ebers (2006) have been reported in these databases. These uncultured bacteria have been identified in fecal samples and intestinal biopsy samples from apparently healthy subjects from different countries, suggesting that *S. wadsworthensis* is a normal inhabitant of the human intestinal microbiota.

As described above, *S. wadsworthensis* is not associated with inflammatory bowel disease, but its presence has been reported in ileal mucosal biopsy samples from children with autism and gastrointestinal dysfunction (AUT-GI) by Williams et al. (2012). They reported that the 16S rRNA gene sequences of either *S. wadsworthensis* or *S. stercoricanis* were found in 12 of 23 AUT-GI children but in none of 9 control children with GI but not autism. Further investigations of the microbiome are needed in larger cohorts of patients with AUT-GI compared to the control GI groups, as well as in patients with AUT but without GI manifestations and in normally developing children with no GI disturbances.

The two other *Sutterella* species, *S. parvirubra* and *S. stercoricanis*, were isolated as novel species of the genus from healthy human feces (Sakon et al. 2008) and from the feces of a healthy Labrador Retriever dog (Greetham et al. 2004), respectively. Although there are no subsequent reports of the isolation of these species, a number of uncultured bacteria with highly similar 16S rRNA gene sequences have been deposited in the GenBank/EMBL/DDBJ databases. For example, the most similar 16S rRNA gene sequences (99.8–99.9 % similarity) to the type strain of *S. parvirubra* were derived from studies of uncultured bacteria from human intestinal mucosal biopsies (accession nos. FJ507106, FJ507078, and FJ506786; Walker et al. 2011). In contrast, the most similar 16S rRNA gene sequence for *S. stercoricanis* (99.2 % similarity) was detected in the feces of dhole (*Cuon alpinus*, a species of canid native to southern and southeastern Asia). This sequence (accession no. JN559525) is a direct submission by Zhang et al. (Unpublished). Williams et al. (2012) reported detecting *S. stercoricanis* 16S rRNA gene sequences in ileal mucosal biopsy specimens from patients diagnosed with AUT-GI symptoms, although it remains unclear whether this species contributes to the disease or is simply a normal component of the human intestinal microbiota.

The genus *Parasutterella* contains two species, *P. excrementihominis* (Nagai et al. 2009) and *P. secunda* (Morotomi et al. 2011). These species were isolated from the feces of healthy human subjects and each was described based on a single strain. There are no subsequent reports of isolation of these species, but a number of uncultured bacteria with highly similar 16S rRNA gene sequences have been deposited in the GenBank/EMBL/DDBJ databases. For *P. excrementihominis*, 200 clones (as of August 2012) with similar 16S rRNA gene sequence (>98.7 % similarity) have been derived from feces, intestinal contents, and mucosal biopsies of healthy human subjects and of patients with gastrointestinal diseases (e.g., ulcerative colitis, Crohn's disease, and *Clostridium difficile*–associated diarrhea); from feces of the black lemur (*Eulemur macaco*), the brown rat (*Rattus norvegicus*), the wolf (*Canis lupus*), and cattle (*Bos taurus*); and from human skin samples and mattress dust. Based on these similar sources of isolation and the similar 16S rRNA gene sequences, *P. excrementihominis* is presumably common in the intestines of humans and other animals. For *P. secunda*, nine clones with a similar 16S rRNA gene sequence (>98.7 %) have been derived from human feces and the intestinal contents of turkeys and cattle.

Overall, all these data suggest that members of the family *Sutterellaceae* are common inhabitants of the intestines of humans and various animals.

Pathogenicity, Clinical Relevance

In addition to the details presented in the Ecology section, there is limited information on the antibiotic sensitivity of this family. Most strains of *S. wadsworthensis* (>95 %) are susceptible to amoxicillin/clavulanate, ticarcillin/clavulanate, cefoxitin, ceftriaxone, and clindamycin, and 85–95 % of the strains are susceptible to piperacillin, piperacillin/tazobactam, ceftizoxime, ciprofloxacin, trovafloxacin, azithromycin, clarithromycin, erythromycin, and roxithromycin (Wexler 2005). Strains of *S. wadsworthensis* (8 strains) were susceptible to kanamycin and colistin, but were resistant to vancomycin (Warren et al. 2005).

No information on antibiotic sensitivity and resistance is available for other species of the genera *Sutterella* and *Parasutterella*.

Acknowledgments

I gratefully acknowledge Dr. Raul Muñoz of the Instituto Mediterráneo de Estudios Avanzados for providing the phylogenetic tree in *Fig. 38.1*. I also thank my colleagues Fumiko Nagai, Hiroshi Sakon, and Yohei Watanabe of the Yakult Central Institute for Microbiological Research for their support.
