The diversity also increased among the large browser perissodactyls such as rhinos and tapirs. From the rhino side, the most common form at that time was *Aceratherium*. This hornless aceratherine, close to the Middle Miocene *Hoploaceratherium*, was one of the most long-lasting genera of the Late Miocene, surviving until the Miocene-Pliocene boundary about 5 Ma. It was a medium-sized rhino with long limbs and a still functional fifth metacarpal. The cheek teeth were brachydont, indicating a browsing diet based on leaves and soft vegetation. Its limb proportions, close to those of the living tapirs, suggest a similar lifestyle (Heissig 1989). The males of *Aceratherium incisivum* bore a pair of strong tusks which enabled them to browse the dense vegetation of the Early Vallesian laurophyllous woodlands. As in other aceratherines, these tusks were much smaller in the females. In the Greek-Iranian province, other advanced rhinos of probable African origin joined *Chilotherium* in the Late Miocene. This was the case of *Ceratotherium*, the genus that includes the living white rhino. The early representatives of *Ceratotherium* (*C. neumayri*) were only partly grass eaters, but a trend is observed in this group throughout the Miocene and the Pliocene to develop more open-country adaptations such as large body dimensions and slightly hypsodont cheek teeth.

Another group of perissodactyls that flourished at this time were the tapirs (*Tapirus priscus*), which reappeared in western Europe after their disappearance in the very Early Miocene. The anchitherine horses were represented by larger, more advanced species of *Anchitherium* which developed longer limbs and higher-crowned dentitions. These anchitherine horses persisted in central Europe until the latest Vallesian, although in some regions (Spain) they disappeared shortly after the entry of the first hipparionine horses. Among the smaller browsers, peculiar elements in Europe were the hyraxes, which are found at a number of Vallesian localities such as Can Llobateres (Vallès-Penedès, Spain), Melambes (Crete, Greece), and Eşme-Akçaköy (Turkey). Despite its small size and rabbitlike appearance, the hyraxes are archaic ungulates that today inhabit the rocky and steppe environments of central and southern Africa (although its range extends up to Lebanon). Their molars are brachydont and selenolophodont, strongly resembling those of some archaic perissodactyls. Although the living hyraxes are hare sized (about 50 cm in length), the Late Miocene European forms such as *Pliohyrax* reached large body dimensions, comparable to those of a tapir. The first hyraxes that settled in Europe in the Early Vallesian certainly had an African origin. Therefore, a limited exchange with northern Africa still existed in the Early Vallesian, although the possibility that hyraxes entered with the dryopithecids at the end of the Middle Miocene cannot be excluded.

Among the carnivores, the large amphicyonids of the species *Amphicyon major* persisted. The hypercarnivorous and cursorial amphicyonids *Thaumastocyon dirus* and *Agnotherium antiquus* persisted also in the Early Vallesian. *Agnotherium antiquus* is a poorly known species present in several localities from western and central Europe (Pedregueras, Eppelsheim, Rudabanya) and known also from northern Africa (Bled Douarah). It was similar to the better known Middle Miocene *Agnotherium grivensis* but smaller in size (160 kg). Among the bears, the small omnivorous ursids of the genus *Ursavus* diversified into the species *U. brevirhinus* and *U. primaevus*, while the mesocarnivore *Hemicyon* was represented by *H. goeriachensis* (of about 120 kg). But the most significant event in this group was the appearance of the first large ursids of the genus *Indarctos*. *Indarctos vireti*, of about 175 kg, was the first member of a lineage of large mesocarnivore ursids, which were characteristic elements of the Late Miocene carnivore community.

In the Early Vallesian, the true hyenids were still represented by the civetlike *Protictitherium*, the mongoose-like *Plioviverrops*, and the wolflike *Thalassictis*. At this time, *Protictitherium* also colonized northern Africa, being present in the Early Vallesian of Tunisia (*P. punicum*). The cursorial canidlike hyenid guild was enriched with new forms close to *Thalassictis* such as *Ictitherium* and *Hyaenictitherium*. Both may have been originated in the Greek-Iranian province or elsewhere in Asia and spread later into Europe. This time also records a high diversity of old viverrids (such as *Semigenetta ripolli* from Can Llobateres) and mustelids, which inherited the variety of forms present at the Middle Miocene: badgers (*Sabadellictis*), skunks (*Promephitis*, *Mesomephitis*), otters (*Sivaonyx*, *Limnonyx*, *Lutra*), wolverines, and glutton-related forms (*Trochictis*, *Circamustela*, *Marcetia*, *Plesiogulo*). Some of these glutton-related forms were relatively large sized for a mustelid, reaching 50 kg in the case of *Hadrictis* and *Eomellivora*.

Therefore, despite its significant zoogeographic importance, the spread of the hipparionine horses and their cohort of Asian immigrants was a quite limited event which did not result in a significant change in the structure of the previously existing western Old World mammalian communities. Newcomers like *Machairodus*, *Alilepus*, *Hipparion*, or *Decennatherium* joined the already highly diversified western European faunas without a clear and immediate replacement of the potential competitors which were there occupying similar guilds. The same situation is observed in the Potwar Plateau, where no significant mammal turnover is associated with the entry of *Hipparion*. Only the extinction of older species, notably suids and cricetids, is recorded at the base of chron C5N (ca. 10.8–10.9 Ma), shortly before the first occurrence of this equid in the Siwaliks sequence (Barry et al. 1985; Pilbeam et al. 1996). The Early Vallesian faunas in Europe are thus characterized by the "peaceful" coexistence of a number of species which seem to have filled similar ecological guilds. This led to a sort of "climax" situation in the western European ecosystems, which reached levels of mammalian diversity unknown in any other Late Cenozoic epoch. With more than 60 mammal species, localities such as Can Ponsic and Can Llobateres 1 in Spain or Rudabanya in Hungary are good examples of these Early Vallesian "inflated" faunas. Despite the presence of new immigrants like *Hipparion*, *Decennatherium*, or *Machairodus*, the western European Vallesian ecosystems were composed of almost the same elements that populated the Middle Miocene subtropical forests, retaining a similar community structure. In this environmental context, the Eurasian hominoids reached an extraordinary diversity, which included the forest-adapted, suspensor *Dryopithecus* and *Sivapithecus*; the dry-adapted *Ankarapithecus*; and the robust, gorilla-like *Graecopithecus*.

The Vallesian Crisis

After the high diversity levels attained in the Early Vallesian, an abrupt decline in the Vallesian mammalian faunas took place at about 9.6 Ma in what is known as the Vallesian Crisis (Agustí and Moyà- Solà 1990; Agustí et al. 2013). The Vallesian Crisis was first recognized in the Vallès-Penedès Basin of Spain and involved the sudden disappearance of most of the humid elements that characterized the Middle Miocene and Early Vallesian faunas from western Europe. Among the large mammals, this crisis particularly affected several groups of perissodactyls such as the rhinoceroses *Lartetotherium sansaniense* and "*Dicerorhinus*" *steinheimensis* and the tapirs (only the small tapirs of the badly known *Tapiriscus pannonicus* persisted until the Early Turolian in central Europe; Franzen and Storch 1999). These losses were only partly compensated by the entry just before the onset of the Vallesian Crisis of *Dihoplus schleiermacheri*, a large species of browsing rhino which bore a pair of massive horns and was the largest rhino of its time. Among the artiodactyls, the high diversity attained by the suids in the Early Vallesian times suddenly dropped and several characteristic elements vanished. This was the case for the browsers *Listriodon* and *Schizochoerus* (which made a short-lived incursion in western Europe at the beginning of the Late Vallesian), as well as for the tetraconodontines *Conohyus* and *Parachleuastochoerus*. In contrast, the "modern" suinae, such as *Propotamochoerus*, persisted and even enlarged their diversity with a new eastern immigrant *Microstonyx*. *Microstonyx* was a giant pig (about 300 kg), with a skull more than half a meter long. The Vallesian Crisis also involved the final decline of the Middle Miocene forest community of cervoids (the cervid *Amphiprox* and the moschid *Hispanomeryx*) and the spread of the boselaphine bovids like *Tragoportax*, which replaced their semiaquatic relatives of the genus *Protragocerus*. *Tragoportax* was a medium-sized bovid of about 80 kg with relatively long limbs, which suggests that it was a fast runner and a good jumper which lived in the open woodland. It possessed a short-faced skull with a long neurocranium and large backwardly curved horns. The teeth were high crowned and with cementum, resembling those of the living *Boselaphus* (Köhler 1993).

Among the rodents, the Vallesian Crisis involved the disappearance of most of the cricetids and glirids of Early or Middle Miocene origin (*Megacricetodon*, *Eumyarion*, *Bransatoglis*, *Myoglis*, *Paraglirulus*, *Eomuscardinus*), flying squirrels (*Albanensia*, *Miopetaurista*), and beavers (*Chalicomys*, *Euroxenomys*). However, other less diversified small mammal groups, such as lagomorphs and insectivores, remained almost unaffected by this crisis. In western and central Europe, this event coincided with the first dispersal of the murid rodents, the family that includes the living mice and rats. After their entry into Europe, this group became the dominant rodents in the Late Miocene communities and diversified into a number of genera: *Progonomys*, *Occitanomys*, *Huerzelerimys*, and *Parapodemus*.

Another group which was severely affected by the Vallesian Crisis was the large carnivores of the families Nimravidae and Amphicyonidae. Among the amphicyonids, all the genera and species still existing in the Early Vallesian disappeared: *Pseudarctos bavaricus*, *Amphicyon major*, and *Thaumastocyon dirus*. Only some poorly known *Amphicyon* representatives persisted in the Late Vallesian and Early Turolian in some parts of central Europe. Among the ursids, the Vallesian Crisis had an ambivalent effect. While the slender cursorial forms of Early Miocene origin like *Hemicyon* vanished, the robust ursids of “modern” aspect persisted, represented by larger species. This was the case with *Indarctos*, represented by the species *I. vireti* and *I. arctoides*, as well as *Ursavus* represented by *U. depereti*, the largest species of the genus. In turn, the mustelids were severely affected by the Vallesian Crisis, which involved a significant decrease in the once highly diversified Vallesian fauna.

At the same time, a number of eastern immigrants appeared for the first time such as the large hyenids of the genus *Adcrocuta* and *Hyaenictis*. These genera represent two opposite trends in the evolution of Late Miocene hyenids. *Hyaenictis* was a cursorial meat and bone eater, which prolonged the trend initiated by *Thalassictis* toward increasing cursoriality. They show also a trend toward the reduction of the bone-crushing portion of their dentition, developing and extending at the same time the sectorial part, so that the posterior molars were reduced or lost. At the other end of the scale, *Adcrocuta*, at about 70 kg, was the first representative of the modern bone-cracker hyenids leading to the living *Crocuta* and *Parahyaena*. They were characterized by advanced adaptation to bone crushing, with enlarged bone-cracking premolars. *Adcrocuta* had short stocky limbs, indicating that it was not a cursorial form. Like *Hyaenictis*, it was of probable Asian origin.

Among the large predator guild, the nimravids finally came to an end with the Vallesian Crisis, after representing the "large cat" guild for millions of years. Their extinction was compensated with the entry of *Promegantereon*, a new genus of machairodontine cats. *Promegantereon ogygia*, the oldest species of this genus, was smaller and more slender than *Machairodus aphanistus* (about 44 kg), retaining the archaic anatomy inherited from its ancestor *Pseudaelurus quadridentatus*. With their robust forelimbs and slender hind limbs, the members of this species were probably able to climb trees, carrying large prey as do living leopards. Their long muzzled skull was also superficially leopard-like, although, as a true machairodont, their upper canines were characteristically long and laterally flattened (Turner and Antón 1997).

Last but not least, the Vallesian Crisis led to an abrupt end of the hominoid experiment in Europe. Hominoids like *Dryopithecus*, *Ankarapithecus*, or *Graecopithecus* disappeared entirely from the fossil record, and only *Oreopithecus* in its island refuge and *Sivapithecus* in southwestern Asia survived this extinction event (see the next sections). *Dryopithecus* is still found in some early Late Vallesian localities dated at about 9.6 Ma (Can Llobateres 2, Viladecavalls) but disappeared from the fossil record shortly after. In the Greek-Iranian province, the robust *Graecopithecus* also disappeared at the beginning of the Late Vallesian. A similar case was that of the Turkish *Ankarapithecus*, its record ending again in the Late Vallesian. The extinction of these robust hominoids in this province coincides with the spread of the colobine monkeys of the genus *Mesopithecus*. This was not the case in western Europe, where the extinction of the slender dryopithecines did not involve its replacement by any other kind of primate species. Only the persistence until the latest Vallesian of the advanced folivorous pliopithecids of the genus *Anapithecus* can be quoted in this area, some hundred thousand years after the last *Dryopithecus*. In China, the pliopithecids survived even longer, until the latest Miocene, being represented by a large-sized form (*Laccopithecus*).

Causes of the Vallesian Crisis

What could have caused the set of extinctions and deep faunal restructuring which took place at 9.6 Ma during the Vallesian Crisis? Some evidence, such as the exit of several forest forms and the development of sigmodont teeth by some groups of rodents, would support the replacement at that time of the laurophyllous forests by grasslands. However, the spread of grasses over large extensions of Eurasia has been dated by Cerling and coworkers to between 8.3 and 7 Ma, and geochemical analyses carried out on teeth and soil nodules older than that timespan do not detect any sign of such an environmental change. Nevertheless, the fact that this major ecological restructuring of the western European mammal assemblages affected especially those taxa with tropical forest affinities, and the latitudinal character of these extinctions (a number of forest-adapted taxa survived until the Early Turolian in central Europe), strongly suggests its climatic forcing. This is supported by the Late Miocene oceanic evolution, which was a continuation of the processes started at the Middle-Late Miocene transition. Enhancement of the latitudinal thermal gradient resulted in the generation of new erosive oceanic surfaces (NH5) by intensification of the deep circulation. Further cooling resulted in new δ^{18}O-positive shifts (i.e., Mi6 and Mi7; Miller et al. 1987, 1991). Changes in benthic and planktonic assemblages also indicate colder climatic conditions and increasing isolation between low and middle latitudes. All these oceanic changes were nearly synchronous with some significant changes in low-latitude Old World terrestrial domains. In particular, there is a noticeable synchronism between the Mi7 isotopic shift at 9.3–9.6 Ma and the age of 9.6 Ma obtained for the Vallesian Crisis in the Vallès-Penedès stratigraphic sections. The Vallesian Crisis is also close to the beginning of the NH5 hiatus, one of the most important sets of deep oceanic discontinuities recognized in the Late Miocene (Keller and Barron 1983), which is dated between 9.0 and 9.5 Ma. NH5 has been also related to a period of cooling and major restructuring of the deep oceanic circulation and to the growth of ice sheets in western Antarctica (Keller and Barron 1983).

But how did these changes affect the composition of the terrestrial vegetation? A change to more open environments did not start until 8 Ma, the extension of grasslands taking place almost 2 Myr after the Vallesian Crisis. The pre-Vallesian floras in the region indicated the persistence of humid subtropical conditions, with abundance of broad-leaved mega-mesotherm elements such as *Ailanthus*, *Caesalpinia*, *Cassia*, *Cinnamomum*, *Ficus*, *Sapindus*, etc. (Sanz de Siria 1994). Indeed, the very rich mammal locality of Can Llobateres 1 yielded remains of some of these subtropical elements such as *Sabal*, *Ficus*, and others. However, we know that the laurophyllous subtropical woodland prevailing until the beginning of the Late Miocene in Europe was profoundly affected in some way. The answer arrived in 1994, when for the first time a well-calibrated Late Vallesian flora was discovered in a section close to the city of Terrassa in the Vallès-Penedès Basin (Sanz de Siria 1997). This flora has been dated by paleomagnetism at somewhat more than 9 Ma and therefore records the kind of vegetation that was dominant just after the Vallesian Crisis (Agustí et al. 2003).

The flora from the Terrassa section includes 36 different taxa from the families Lauraceae, Ulmaceae, Hamamelidaceae, Juglandaceae, Myricaceae, Fagaceae, Betulaceae, Tiliaceae, Salicaceae, Ericaceae, Sapotaceae, Myrsinaceae, Celastraceae, Aquifoliaceae, Rhamnaceae, Sapindaceae, Aceraceae, Oleaceae, Poaceae, and Typhaceae. Close to 45 % of this flora is composed of deciduous trees such as *Acer*, *Alnus*, *Fraxinus*, *Carya*, *Juglans*, *Populus*, *Parrotia*, *Zelkova*, *Ulmus*, or *Tilia*, that is, the elements that are now dominant in the temperate forests of the middle latitudes. In contrast, warm evergreen elements, represented by *Myrsine*, *Sapindus*, *Sapotacites*, etc., decreased to 7 %. Supporting the argument that this change was not related to the extension of grasslands was the persistence of a "hard core" of subtropical elements, represented by 33 % of evergreen trees, able to endure a certain level of seasonality, and which persisted in Europe until the Early Pliocene (*Laurophyllum*, *Laurus*, *Rhamnus*, *Daphnogene*, and others). The existence at that time of a dry season (summer drought) is confirmed by the presence at Terrassa of a 15 % of Mediterranean or pre-Mediterranean taxa

(*Quercus* cf. *ilex*, *Q. praecursor*). From a physiognomic point of view, 56.4 % of the species display leaves with entire margins, while the remainder present dentate or serrated margins. Regarding leaf size, most of the taxa are microphyllous (83.3 %) or nanophyllous (10 %).

According to these data, the Terrassa association is comparable to floras that are found today in parts of central-east China, south Japan, eastern North America, and North Africa, where a similar mixture of evergreen broad-leaved, warm-temperature, and deciduous elements is present (Wang 1961; Barbero et al. 1982; Richardson 1990; Barbour and Chistensen 1993). In these regions, similar mega-mesotherm taxa (*Lauraceae*, *Myrsine*, *Sapotacites*, *Sapindus*, and others) are concentrated in the lower levels of vegetation, with mean annual temperatures between 16 °C and 19 °C and mean annual precipitation levels above 1,000 mm. A clear winter season is already present at this stage. In some areas, drier, sclerophyllous elements (*Q. ilex*, *Rhamnus*, *Rhus*) coexist with the former ones. An evergreen broad-leaved forest is present at a medium stage because of the concentration of humidity due to the marine influence (*Cinnamomum*, *Persea*, *Laurus*, etc.). At higher altitudes a deciduous broad-leaved forest (including most of the temperate, deciduous elements like *Acer*, *Fraxinus*, *Juglans*, *Populus*, *Quercus*, *Tilia*, *Zelkova*, and others) is dominant. Mean annual temperatures at this stage decreased to around 12 °C. Therefore, a similar zonation probably developed in the transition from the Early to the Late Vallesian, causing a significant decrease of Middle Miocene evergreen elements (33 %) and the expansion of a deciduous broad-leaved forest at a medium stage (45 % of deciduous elements), where intake of fruit during the winter season must have been much more difficult.

The flora from Terrassa suggests that the deep faunal change at 9.6 Ma was not the consequence of the replacement of the subtropical Miocene forest by grasslands but rather the substitution of one kind of woodland by another. The intensification of the thermal gradients between the middle and low latitudes, probably enhanced by the Himalayan and Tibetan uplifts, led to an abrupt change in the previously existing evergreen subtropical woodlands of western Europe. These were probably replaced by an association in which more seasonally adapted, deciduous trees were dominant. Rather than the moderate cooling associated with the Mi7 isotopic shift, it was this change in the structure of the vegetation which determined the set of extinctions that took place during the Vallesian Crisis.

Most members of this fauna, including *Dryopithecus* and other European hominoids, were mainly frugivorous, with a diet based on fruits and the soft vegetables common in the evergreen broad-leaved forests of the Early and Middle Miocene. Therefore, although the decrease in temperature and increasing latitudinal gradient had little direct effect on the Vallesian mammals, the replacement of most of the evergreen trees by deciduous ones, well adapted to the new conditions of seasonality with colder winters and dryer summers, had much more dramatic effects. In this way, a number of elements, such as certain pigs, rodents, and primates, had to subsist during several months without fruit, a basic and highly nutritional component of their diet. This dietary factor, and not the extension of grasslands or the shift of temperature, was probably the direct agent that caused the abrupt drop of the rich Early Vallesian faunas.

In turn, the sudden disappearance of most of the medium-sized herbivores that had lived in Europe for millions of years probably led to a critical situation for the old predators of Middle Miocene origin, such as the nimravids and the amphicyonids, which until the Early Vallesian had successfully endured the competition from the machairodont cats and the large ursids. These carnivores were also indirect victims of the vegetation change that took place 9.6 Ma. An interesting element is that, contrary to *Dryopithecus*, the crouzeline pliopithecid *Egarapithecus* survived the Vallesian Crisis, a fact that is probably related to a folivorous rather than frugivorous diet.

Asian Survivors

The general absence of long sections of Vallesian age makes difficult the recognition of the Vallesian Crisis in other Old World regions, although there exist significant exceptions. In the well-calibrated succession of the Potwar Plateau in central Asia, a significant decay in the relative abundance of tragulids (from 45 % to 10 % of ruminant artiodactyls; Barry et al. 1991) is observed between 9.8 and 9.3 Ma, while the bovids became the dominant artiodactyls in the area (from 45 % to 80 %; Barry et al. 1991). However, the changes operating at 9.6 Ma in the region of the Siwaliks can hardly be compared with the dramatic effects of the Vallesian Crisis in western Europe. In contrast with Europe, the mammal faunal association linked to the existence of warm tropical-subtropical forested zones persisted in Siwaliks until chron 4r, at 8.3 Ma. It still included archaic carnivores and rhinoceroses (*Brachypotherium*), proboscideans (*Deinotherium*), dormice, shrews, and hominoids with climbing adaptations (*Sivapithecus*). As we have seen, the persistence of this kind of fauna in the Late Miocene of the Siwaliks can probably be explained by the settling of monsoon atmospheric dynamics in the latter region, which could have maintained the forested subtropical conditions there until 8.3 Ma.

However, between 8.3 and 7.8 Ma, a set of extinctions similar to those of the earlier Vallesian Crisis took place (Pilbeam et al. 1996). Several cricetid, bovid, and tragulid species disappeared, and the hominoid *Sivapithecus* was replaced by colobine monkeys. These faunal changes coincide in the southwestern central Asian region with a shift in the $\delta^{13}C$ isotopic composition of the paleosoil and dental carbonates, indicating a climatically forced change from a forest and woodland vegetation in which C_3 plants (trees and bushes) were dominant to grasslands dominated by grasses and other C_4 plants (Quade et al. 1989; Morgan et al. 1994; Cerling et al. 1997). They were also largely coeval to further oceanic cooling (White et al. 1997), development of extensive oceanic erosive surfaces (NH6) and development of ice sheets in the Arctic (Eyles 1996). Therefore, the change from C_3- to C_4-dominant vegetation had dramatic effects to the south of the Himalayas and led to the development of an open woodland also in southwestern Asia.

However, *Dryopithecus* may have subsisted for more time in some refuges of western Eurasia. One of these refuges seems to have been the southern Caucasus, where the presence of a slender dryopithecine (*Udabnopithecus garedziensis*, actually a small form of *Dryopithecus*) was reported a long time ago in the Early Turolian beds of Udabno (Georgia; Gabunia et al. 2001). According to its mammalian association, the age of the Udabno levels is close to 8.5 Ma. It means that *Dryopithecus* or another genus of thin-enameled hominoids persisted in the Black Sea region when this kind of primates went extinct elsewhere in Europe. The persistence of the evergreen subtropical forests to the south of the Caucasus, linked to the retention of special climatic conditions, probably enabled *Udabnopithecus* to survive in this region.

In Asia, the dryopithecines may have survived for longer in the Late Miocene, as suggested by the presence of *Lufengpithecus* in the Late Miocene of Chiang Muang, in Thailand (Chaimanee et al. 2003; Pickford et al. 2004), and Keiyuan and Lufeng in China (Zhang Xingyong 1987; Harrison et al. 2002). Chiang Muang presents a typical pre-*Hipparion* fauna with gomphotherids (*Tetralophodon* cf. *xiaolongtanensis*), rhinos (*Chirotherium intermedium*), peccaries (*Pecarichoerus sminthos*), large suids (*Hippopotamodon* cf. *hyotherioides*), tetraconodontine suids (*Conohyus sindiensis*, *Parachleuastochoerus sinensis*), and tragulids (*Dorcatherium* sp.) in a wooded context that resembles that of the late Middle Miocene of western Europe and Siwaliks. Similar in age and environment is the locality of Keiyuan, in China, which presents the same kind of hominoid (*Lufengpithecus keiyuanensis*). *Lufengpithecus* is still present in type locality of the genus, Lufeng, a site dated in 8 Ma (equivalent, therefore, to the Early Turolian levels of Europe).

The *Oreopithecus* Fauna: Survivors in an Island Environment

Even more significant was the case of *Oreopithecus*, an enigmatic hominoid which lived in the Tuscany area (northern Italy) from 9 to 7 Ma. At the time when *Oreopithecus* occupied the Tuscany region, Italy had a very different aspect from today. The territories which form the present Italian peninsula were in the Early Turolian an arch of isolated islands which extended from central Europe to northern Africa. One of these islands, close to the European mainland, was formed by Tuscany and the Corso-Sardinian block. A number of European immigrants settled in this area at some time between the Vallesian and the Turolian and persisted there until the end of the Miocene. The *Oreopithecus* faunas appear in several localities from Tuscany, like Casteani, Montebamboli, Ribolla, Montemassi, and also Fiume Santo in Sardinia. However, the best sequence is recorded in the Bacinello Basin, again in Tuscany, where a succession of fossiliferous levels has been recorded (Rook et al. 1999).

The lowermost ones, called V 0 and V 1, are Early Turolian in age and still include some “common,” nonendemic elements like the cricetid *Kowalskia* and the murids *Huerzelerimys* and *Parapodemus*. However, most of the *Oreopithecus* faunas of the Baccinello levels V 1 and V 2 are basically composed of endemic elements.

These faunas appear as a sort of impoverished, "miniaturized" Vallesian ecosystem. Thus, although already modified by the new insular conditions, most of the large mammalian components of this Late Miocene immigration wave can be referred to common elements of the Late Vallesian or Early Turolian European ecosystems, such as hypsodont bovids (*Thyrrenotragus*, *Maremmia*), giraffids (*Umbrotherium*), *Microstonyx*-like suinae (*Eumaiochoerus*), dryopithecids (*Oreopithecus*), or *Indarctos*-like ursids. *Umbrotherium* is a poorly known giraffid, probably related to a sivatherine stock. *Thyrrenotragus* and *Maremmia* were small bovids with very hypsodont dentitions. Both forms were once interpreted as African immigrants in the area: *Tyrrhenotragus* as a neotragine (the tribe that includes dwarf antelopes and gazelles) and *Maremmia* as a precocious alcelaphine (the tribe that includes the African gnus, hartebeests, and impalas). However, some of the features that relate them to these African groups, like the short metapodials of *Thyrrenotragus* and the probably ever-growing incisors of *Maremmia*, could have developed independently as specializations linked to an island environment. A small suid, *Eumaiochoerus*, is also present in the lignites of Bacinello (V 2) and in Montebamboli. It bore a short snout, elongated spatulate upper incisors and small-sized, chisel-shaped lower tusks. Despite these dental specializations and its small size, other features closely relate this endemic suid to the large *Microstonyx major*.

However, other elements in the Baccinello succession suggest that a previous Middle Miocene faunal background already existed on the Tusco-Sardinian Island before the Late Miocene settlement of *Oreopithecus* and its allies. This is the case, for instance, of *Anthracoglis*, a dormouse close to the Middle Miocene *Microdyromys* and *Bransatoglis* but significantly larger. A second unnamed giant dormouse is scarcely present in the level V 1 of Baccinello. Besides these endemic dormice, a third small mammal, the lagomorph *Paludotona*, is present in the V 1 level. *Paludotona* was an ochotonid whose body dimensions were again larger than those of its coeval relatives in Europe. The most striking feature of *Paludotona* is its archaic dental morphology, which relates it to some Early to Middle Miocene ochotonids like *Lagopsis*. But the last *Lagopsis* disappeared from Europe in the Middle Miocene, some million years before the deposition of the Bacinello lignites! It seems therefore that at the time of deposition of the V 1 level, there was a long history of isolation on the Tusco-Sardinian Island. The existence of a previous Early to Middle Miocene settlement of the Tusco-Sardinian Archipelago is also supported by the presence in Casteani (equivalent to level V 1 of Bacinello) of an anthracothere. The Tuscan anthracothere is a very archaic one which clearly differs from the advanced Late Miocene anthracotherids of northern Africa. Since the last anthracotheres disappeared from Europe in the Early Miocene, its presence in this area can only be explained as a result of an immigration event from Africa or by assuming its persistence as an Early Miocene relict as in the case of *Anthracoglis* and *Paludotona*.

The environment in which the *Oreopithecus* fauna developed was a mixed mesophytic forest, similar to those that today are found in east central China along the Yangtze River. Thus, tropical-subtropical trees, like *Engelhardia*, and warm-temperate trees and shrubs, like *Taxodium*, *Myrica*, etc., are well represented in the pollen analysis of the levels V 0 and V 1 of Bacinello, while more temperate and Mediterranean elements, such as *Quercus*, *Carpinus*, *Tilia*, *Carya*, *Pterocarya*, etc., are rare (Harrison and Harrison 1989; Benvenuti et al. 1994). The pollen analysis developed in the level V 2 shows an increase in temperate, cold-temperate, and mountain elements such as *Picea* and *Abies* (Benvenuti et al. 1994). However, a cold phase cannot clearly be recognized due to the scarcity of grains of elements such as *Tsuga* or *Cedrus*. The increase of temperate and cold-temperate trees in the level V 2 of Baccinello may be the result of a change in the climatic conditions (as in the case of the Late Vallesian floras) but could also be associated with the uplift of the Tuscan area.

The Tusco-Sardinian experiment came finally to an abrupt end when a connection to the continent was established at about 6.5 Ma. New herds of European immigrants entered the Tusco-Sardinian area, including such large predators as *Machairodus* and *Metailurus*. Not surprisingly, *Oreopithecus* and the other endemic elements of the Tuscan fauna underwent a rapid extinction, unable to resist the competition of the continental newcomers. This change in the faunal composition is also paralleled by a vegetation change. Therefore, the pollen analysis developed in the V 3 unit of Bacinello shows an increase in herbs (Chenopodiaceae, Compositae, Dipsacaceae, etc.) and sclerophyllous trees (*Pinus* t. *haploxylon*, *Cathaya*; Benvenuti et al. 1994). The *Oreopithecus* experiment came to an end, and the Tusco-Sardinian biome finally followed the general trend toward more open and dry environments that was dominant in the whole of Eurasia.

The Late Miocene African Record

As in other parts of the Old World, the beginning of the Late Miocene in Africa is characterized by the dispersal of the first hipparionine horses on this continent. As happened in Europe, the entry of these hipparionine horses at the beginning of the Sugutan (an African equivalent of the Eurasian Vallesian) did not involve a significant restructuring of the existing terrestrial ecosystems. Most of the elements which composed these ecosystems at the beginning of the Late Miocene in Africa were close relatives of similar taxa in western Eurasia. Faunas of this age, such as those of the Ngorora Formation (Tugen Hills, Kenya; Hill et al. 1985), Narumungule Formation (Samburu Hills, Kenya; Nakaya 1994), or Chorora Formation (Ethiopia; Geraads et al. 2002), are based on a mixture of Middle Miocene African survivors associated with several elements that are common to the Siwaliks and Greek-Iranian provinces. Large browsers include proboscideans (*Choerolophodon*, *Tetralophodon*, *Deinotherium* cf. *bozasi*), rhinos (*Chilotheridium*, *Paradiceros*, *Brachypotherium*), chalicotheres (*Ancylotherium*), hipparionine horses (*Hippotherium primigenium*), and a variety of ruminants of western Eurasian affinities (*Palaeotragus*, *Samotherium*, *Protagocerus*, *Miotragocerus*, *Palaeoreas*/*Sivoreas*, *Homiodorcas*, *Ouzoceros*, *Pseudotragus*, *Pachytragus*, *Gazella*). The persistence of forest conditions is indicated by the presence of tragulids (*Dorcatherium pigotti*) and gliding rodents (*Paranomalurus*). However, the presence of an iranotherine rhino (*Kenyatherium*) at Narumungule suggests the existence of more open conditions close to the woodlands. Typical African components of these faunas are the climacoceratid giraffoids (*Climacoceras*), listriodontine, and tetraconodontine suids (*Lopholistriodon* and *Nyanzachoerus*), and archaic hippos (*Kenyapotamus coryndoni*). As happened at the beginning of the Vallesian in Europe, the dispersal of the hipparionine horses involved other Asian elements, such as the saber-toothed machairodontine cats and the "false hyenas" of the genus *Percrocuta*. These elements joined other persisting Middle Miocene carnivores of Eurasian origin, such as the hypercarnivore amphicyonid *Agnotherium* and the ratel-like mustelid *Eomellivora*.

The persistence of forest conditions in this part of Africa is probably explained on the same basis as in southwestern Asia, that is, as a consequence of the monsoonal dynamics in this region. However, as happened in Siwaliks, a dramatic change is observed between 8 and 7 Ma in the mammalian communities of East Africa. At this time, there is a significant faunal turnover, involving the replacement of close to 75 % of the mammal species. Most of the old Middle Miocene holdovers are replaced by close relatives of the elements found today on the modern savannas. Therefore, this time records the first occurrence in Africa of leporids, hominids, new and extant viverrids, extant hienids, new felids, extant and diverse elephantids, new hippopotamids, extant giraffids, and several extant bovids. The former small- to medium-sized browser-based faunas are replaced by a new assemblage in which medium- to large-sized grazers, large browsers, and pursuit carnivores are dominant (Harris 1993).

This change parallels in many ways the one observed at the same time in the Siwaliks, when the former woodland biome opened and C_4 grasslands expanded over large parts of western Eurasia. Similarly, the period between 8 and 7 Ma records the expansion of the true savannas in the African continent, leading to the kind of open woodland and grasslands that are present in most of eastern and southern Africa. This is best exemplified by such latest Miocene faunas (Kerian) as Lothagam and Lukeino in Kenya or those of the Adu-Asa and the Sagantole Formations in Ethiopia. At Lothagam, recovery of more than 2,000 identifiable remains has produced a faunal list of more than 30 mammalian species (Leakey and Harris 2003). A number of new browsers replaced the medium-sized community of Middle Miocene origin, largely based on climacoceratid giraffoids and tragulids. Among them we find modern suids of the genera *Potamochoerus* and *Phacochoerus*, the peccary-like *Cainochoerus*, the tragelaphine antelope *Tragelaphus*, the black rhino *Diceros*, and the gomphotheres of the genus *Anancus*. These medium to large browsers joined a number of persisting elements that root in the former Sugutan faunas, such as the suids *Kubanochoerus* and *Nyanzachoerus*, the giraffid *Palaeotragus*, the bovids *Tragoportax* and *Sivatherium*, and the rhino *Brachypotherium*.

However, the most distinctive feature of the new fauna was the sharp increase in medium to large grazers, such as the large sivatherine giraffids of the genus *Sivatherium*; the first giraffines of the genus *Giraffa*; the elephantids *Stegotetrabelodon*, *Primelephas*, and *Elephas*; the modern hippos of the genus

Hexaprotodon; and the white rhino *Ceratotherium*. A new form of slender, grazer hipparionine horse, *Eurygnathohippus*, replaced the former mix-feeder *Hippotherium primigenium*. But the change to a grazer-dominated community is best exemplified by the bovids. Therefore, the new faunas include the first and abundant record of antelopes of the tribes Alcelaphini (*Damalacra*), Hippotragini (*Hippotragus*), Reduncini (*Kobus*, *Menelikia*), Aepycerotini (*Aepyceros*), and Antilopini (*Gazella*), which inhabit the present-day savannas.

The increase in diversity of large browsers and grazers led also to a change in the predator community. While the bear dog amphicyonids persisted, the number of pursuit carnivores suddenly increased. Thus, at Lothagam are represented several species of cursorial, wolflike hyenas (*Ictitherium*, *Hyaenictitherium*, *Hyaenictis*, *Ikelohyaena*), two species of machairodontine cats (*Lokotunjailurus*, *Dinofelis*), hunting viverrids (*Genetta*), and mustelids (*Ekoromellivora*, *Ekorus*).

Therefore, the change operated between 8 and 7 Ma from predominantly closed to predominantly open savanna environments led to a significant change in the mammalian communities, characterized by a dramatic increase in the number of medium to very large grazers, an increase in guild depth of large and very large browsers, and the presence of abundant and diverse pursuit carnivores (Harris 1993).

As evidenced by the Lothagam association, this is the environment where the first hominids succeeded. Besides a number of baboons (*Parapapio*, *Theropithecus*) and colobine monkeys (*Cercopithecoides*), Lothagam records the presence of an unidentified hominid, represented by some isolated teeth and a fragmented mandible. The site of Lukeino, dated between 6.2 and 5.6 Ma, also delivered remains of a hominid, *Orrorin tugenensis*, in a context that resembles that of Lothagam, with elephants (*Primelephas*, *Stegotetrabelodon*, *Loxodonta*), gomphotherids (*Anancus*), deinotheres (*Deinotherium*), rhinos (*Ceratotherium*, *Diceros*), chalicotheres (*Ancylotherium*), hipparions (*Eurygnathohippus*), hippos (*Hippopotamus*, *Hexaprotodon*), suids (*Nyanzachoerus*), giraffids (*Giraffa*), and a variety of antelopes: Cephalophini (*Cephalophus*), Reduncini (*Kobus*), Aepycerotini (*Aepyceros*), Tragelaphini (*Tragelaphus*), and Neotragini (Pickford and Senut 2001). The first hominids of the genus *Ardipithecus*, from the latest Miocene (5.7–5.5 Ma) of the Adu-Asa and Sagantole Formations in the Middle Awash, lived in a somewhat different environment (Wolde Gabriel et al. 2001). Although, as in Lothagam and Lukeino, large grazers are present (the elephants *Primelephas* and *Stegotetrabelodon*, the giraffid *Sivatherium*, the reduncine antelope *Kobus*, as well as hipparions), the dominance of browsing forms such as gomphotherids (*Anancus*), deinotheres (*Deinotherium*), rhinos (*Diceros*), hippos (*Hexaprotodon*), suids (*Nyanzachoerus*), and boselaphine and tragelaphine bovids (*Miotragocerus*, *Tragelaphus*) points to more wooded conditions.

Different again was the association found at Toros-Menalla 266, in Chad, dated between 7.4 and 5.2 Ma, where another early hominid species, *Sahelanthropus tchadensis*, was described (Vignaud et al. 2002). The faunal assemblage of Toros-Menalla shares with Lothagam and Lukeino the presence of a variety of large grazers: antelopes (*Kobus*, Hippotragini, Antilopini), elephants (*Loxodonta*), giraffids (*Sivatherium*), and hipparions (*Eurygnathohippus* cf. *abudhabiense*). However, the remaining association is based on medium to large browsers or mix feeders: *Anancus*, *Nyanzachoerus*, *Hexaprotodon*, and aff. *Palaeoryx*. Particularly surprising is the presence of the large, advanced anthracothere *Libycosaurus petrocchii* (also referred as *Merycopotamus petrocchii*), an element which is absent from the faunal associations of the same age in the eastern African basins. In fact, the Toros-Menalla 266 faunal assemblage fits better with the association found at the site of Sahabi (Libya), south of Benghazi.

The fauna from the Sahabi Formation (Boaz et al. 1987) shares a number of elements in common with the eastern basins, such as monkeys (*Macaca*, *Libypithecus*), archaic elephants (*Stegotetrabelodon*), rhinos (*Diceros*), hipparions (*Eurygnathohippus*), hippos (*Hexaprotodon*), tetraconodontine suids (*Nyanzachoerus*), giraffids (*Samotherium*), and a variety of antelopes: Reduncini (*Redunca*), Alcelaphini (*Damalacra*), Hippotragini (*Hippotragus*), and Antilopini (*Gazella*). However, a significant part of the association is composed of taxa that were common to the Greek-Iranian province and the Siwaliks region. This is the case, for instance, with the abovementioned anthracotherid *Libycosaurus* (related to *Merycopotamus*); the bovids *Miotragocerus*, *Prostrepsiceros*, and *Leptobos*; the amebelodontid gomphothere *Amebelodon*; and the whole carnivore taxocoenosis (*Machairodus*, *Chasmaporthetes*, *Hyaenictitherium*, *Adcrocuta*, *Indarctos*, *Agriotherium*; Howell 1987). In Sahabi, the botanical evidence provided by well-preserved fossil wood indicates an environment dominated by wooded savanna and semidesert grassland, with dominance of *Acacia* (64 %) and Mimosaceae (Dechamps and Maes 1987). The existence of periodic fires (a usual phenomenon in a savanna environment) is recorded as traumatic rings in fossil wood. The estuarine context of this site is reflected by the relative high proportion (13.5 %) of Salicaceae (*Populus euphratica*).

The western Asian character of the Sahabi fauna, which partly extends south to the Chad Basin (Toros-Menalla 266), opens the question of the origin of the Late Miocene African faunas, after the crisis at 7 Ma. It has been suggested that much of the current savanna fauna did not evolve in situ from the Early and Middle Miocene African mammals but migrated from more northern latitudes in the Late Miocene, replacing the previous forest endemic dwellers (Maglio and Cooke 1978). More specifically, with the drying out of Africa between 8 and 7 Ma, large mammals from the Greek-Iranian province may have colonized the lower latitudes, their adaptations to a sclerophyllous woodland (hypsodont teeth, cursorial skeletons) having acted as exaptations (sensu Gould and Vrba 1982) to a savanna biome (Solounias et al. 1999). This was probably the case for bovids, giraffids, equids, hyenas, rhinos, and hominids. The faunal composition of sites like Toros-Menalla and Sahabi strongly supports this scenario.

Conclusions

1. The Middle Miocene terrestrial ecosystems of western and central Europe were characterized by increasing levels of mammalian diversity of taxa associated with a woodland biome: proboscideans, chalicotherids, rhinoceroses, suids, cervids, tragulids, moschids, and hominoids; many of them were fruit eaters

and browsers. This high diversity of forest dwellers is also confirmed by the small mammal association, which includes eomyids, flying squirrels, dormice, and beavers. These high levels of diversity were probably a consequence of prevailing subtropical conditions.

2. In eastern Europe, however, we observe during the Middle Miocene a trend toward drier conditions, reflected in the abundance of hypsodont, grazing ruminants, mainly bovids and giraffids. This is the so-called Greek-Iranian Province, which extended from Greece to central Asia.
3. At the beginning of the Late Miocene (during the Vallesian Mammal Stage), diversity increased in Western Europe with the entry of new elements, like the hipparionine horses, giraffids, machairodont cats, ursids, and other eastern immigrants.
4. About 9.6 Ma, increasing seasonality and extension of deciduous forest led to the extinction of most of the browser taxa that had populated the Middle Miocene woodlands, such as suids, cervids, rhinoceroses, and hominoids (the so-called Vallesian Crisis). This loss of diversity is not clearly recognized in the Greek-Iranian Province, nor it is in western Asia, where a highly diversified mammalian fauna including hominoids is still present in the Siwaliks sequence.
5. However, worldwide extension of grasses at 7–8 Ma led to the final extinction of most of these elements in Eurasia, with the exception of eastern and southeastern Asia.
6. At this point, an extension to the south of the Greek-Iranian Province can be recognized. This led to the Plio-Pleistocene savanna biome, characterized by a high diversity of hypsodont bovids, large grazers like rhinoceroses and giraffids, and most probably the hominoids that led to the first hominins in Africa.

Postcranial and Locomotor Adaptations of Hominoids

Carol V. Ward

Contents

Abstract

Extant apes are adapted to various forms of below-branch forelimb-dominated arboreal locomotion and share morphologies associated with the shared aspects of their locomotor behaviors. With the expanding record of Miocene hominoid fossils, paleoanthropologists are coming to realize that although some shared characters may indeed be homologous, at least some almost certainly represent homoplasies. The apparently more primitive body plan of *Sivapithecus* than seen in Asian and African great apes indicates that at least some homoplasy has

occurred within these clades. Furthermore, the expanding fossil record may be indicating a greater diversity of positional behaviors within the Hominoidea than previously appreciated; for example, *Pierolapithecus* has been argued to indicate the evolution of suspensory locomotion in combination with arboreal quadrupedalism, and *Nacholapithecus* is unique with its enlarged forelimb but otherwise primitive body plan. These new fossils reveal that variation is prevalent and critical to appreciate for reconstructing hominoid evolutionary history. Furthermore, it seems increasingly likely that many postcranial and locomotor specializations of great apes may have evolved from ancestors that were more generalized than are living hominoids. This realization is critical for interpreting the ancestral morphology from which hominins were derived.

Introduction

One of the most distinctive shared characteristics of modern apes is their specialization for below-branch forelimb-dominated arboreal locomotion, many adaptations for which are still seen in humans today (Huxley 1863; Keith 1923). Extant apes all exhibit an overlapping set of adaptations to suspension and orthograde climbing in their torsos, limbs, hands, and feet. They have elongated forearms and hands; high-intermembral indices; laterally oriented shoulder joints; limb joints adapted to loading in a variety of postures; short, broad torsos; and absence of a tail. Given this suite of apomorphies, parsimony would seem to dictate that ancestral apes should have been suspensory as well (Gregory 1916). If not, extant hominoids must have developed these adaptations independently, which would, on the face of it, seem to involve an unlikely amount of homoplasy.

However, while below-branch forelimb-dominated arboreality distinguishes all modern ape taxa from other catarrhines (Schultz 1930, 1969a, b), it is not a monolithic adaptation (Larson 1988). Young (2003) has suggested that great ape postcranial adaptations are homologous (see also Pilbeam 2002) and that hylobatids may be autapomorphic, due to their small size and exclusively arboreal specialization for brachiation that involves moving rapidly through the trees in ricochetal fashion. Yet arboreal adaptations actually vary among extant ape genera more than is often emphasized in considerations of the evolution of hominoid locomotion, reflecting specialization on different types and amounts of climbing and suspensory behavior. Orangutans almost never use the ground, yet, given their large body size, they move cautiously through the upper levels of the canopy with quadrumanous climbing and arm hanging. Their forelimbs are astonishingly long and all joints are flexible and employed in diverse postures (MacKinnon 1974; Cant 1987).

Chimpanzees, arboreal when foraging, hunting, and sleeping, spend much of their time as terrestrial knuckle walkers (Goodall 1965; Hunt 1990), as do bonobos, although the locomotor behavior of the latter is less well studied (Doran 1993). Gorillas are extremely large and are even more terrestrial than chimpanzees or bonobos, yet particularly in certain habitats they habitually climb trees frequently for feeding and sleeping (Tuttle and Watts 1985; Remis 1995). Hominins, of course, modified their locomotor skeletons to specialize in the most distinctive of all primate locomotor behaviors, habitual terrestrial bipedality, although they likely evolved from ancestors that were at least somewhat adapted to climbing or suspensory arboreal locomotion. Given this variation among taxa, a certain level of independence in the acquisition of some suspensory traits should perhaps not be considered entirely unlikely.

The burgeoning fossil record is strengthening the hypothesis that climbing and suspensory adaptations developed in mosaic fashion over evolutionary time and occurred in different ways and even multiple times in separate hominoid lineages (Sarmiento 1987; Pilbeam et al. 1990; Moyà-Solà and Köhler 1995; Begun et al. 1997; Finarelli and Clyde 2004; Moyà-Solà et al. 2004; Crompton et al. 2008; Lovejoy et al 2009; Almécija et al. 2013; Hammond et al. 2013). Timing of wrist bone development differs among chimpanzees and gorillas, also suggesting some homoplasy even between these taxa (Kivell and Schmitt 2009). The hominoid fossil record now includes over 28 genera known from as early as 20 Ma, and many taxa are known from postcranial elements (see Hartwig 2002; Begun et al. 2012). Among these fossil taxa, there is much wider range of known locomotor modes than among extant ones. Adaptations seen in some, and even all, extant apes do not occur as a block. For example, *Nacholapithecus* has elongated forelimbs but a long, narrow torso and apparently pronograde quadrupedal posture (Rose et al. 1996; Senut et al. 2004; Ishida et al. 2004). *Pierolapithecus* has what appears to be a hylobatid-like torso structure, yet does not seem to have particularly long digits (Moyà-Solà et al. 2004; Hammond et al. 2013). Considering variation within living and fossil hominoids may lead us away from dichotomous views on whether the euhominoid ancestor was "great apelike" or "basal hominoid-like" (Pilbeam et al. 1990; Young 2003; Crompton et al. 2008) and may lead us to a more nuanced and more accurate understanding of how hominoids evolved.

The positional behavior variation among extant and fossil hominoids provides an important set of information about hominoid phylogeny and evolution. This chapter will summarize the postcranial adaptations of extant and the best-known fossil hominoid genera and put these taxa into phylogenetic context in order to explore evolutionary patterns in hominoid postcranial and locomotor adaptations.

Extant Hominoids

Living apes all share a suite of adaptations to below-branch, forelimb-dominated arboreality, although they do not exploit this locomotor niche identically and are distinguishable postcranially, although particularly among great apes differences are poorly characterized (Young 2003; but see Larson 1988; Inouye and Shea 1997; Drapeau 2001). All, though, have evolved to negotiate terminal branches of arboreal substrates by hanging below branches and distributing their weight among multiple supports. Their relatively large body sizes and long forelimbs allow them to bridge gaps in the canopy rather than leaping. They lack tails, which are no longer necessary for balance within this type of locomotor regime. As a consequence, the musculature usually associated with tails in nonhominoid primates has become restructured to form a muscular pelvic floor, providing support for the viscera during the orthograde postures common in all ape species today (Elftman 1929).

Apes have high-intermembral indices (Schultz 1930; Aiello 1981; Jungers 1985). When climbing, their long forelimbs and relatively short hindlimbs improve their ability to negotiate large-diameter vertical supports. The long arms also assist in increasing their reach for bridging gaps and grasping branches. Limb proportions vary however (Aiello 1981; Jungers 1984, 1985). Orangutans and hylobatids have proportionally longer forearms and hands than do chimpanzees, and chimpanzees and bonobos alone have differentially elongated metacarpals more than other extant apes (Drapeau 2001).

Ape torsos are broad, with the scapulae positioned dorsally and glenoid fossae oriented laterally (Keith 1923; Schultz 1930, 1961, 1969a; Benton 1965, 1976; Sarmiento 1987; Ward 1993). Their ribs have higher costal angles, sterna are broad, scapulae have a cranially oriented glenoid fossa, and their clavicles are long (Schultz 1937; Cartmill and Milton 1977; Larson 1993). The broad torso and wide pectoral girdle results in a shoulder position that places the scapulothoracic musculature more in the coronal plane, facilitating adduction of the upper limb (Erickson 1963; Benton 1965, 1976; Ward 1993). Adduction is accomplished primarily by the *latissimus dorsi* muscle along with others that are important in hoisting the body up from an arm-hanging position and in pulling the body among supports in the trees (Swartz et al. 1989; Hunt 1991). Extant hominoid pectoral girdle form also increases the reach of the forelimbs and circumduction at the shoulder (Cartmill and Milton 1977).

Extant hominoid lumbar spines are reduced in length, with only 5–6 lumbar vertebrae in lesser apes, compared with the typical primate number of 7, and great apes have only 3–4, so that the lower ribs approximate the iliac crest (Schultz and Straus 1945; Erickson 1963; Ankel 1967, 1972; review in Ward 1993). African apes differ from humans, orangutans, and hylobatids in having 13 rather than 12 thoracic vertebrae and ribs (Schultz 1930, 1969a, b). This variation in thoracic vertebral count among extant hominoids is noteworthy and may be yet another small line of evidence supporting hypotheses of postcranial homoplasy among extant apes. All great ape lumbar spines are almost completely inflexible (Slijper 1946; Schultz 1969a, b; Benton 1976). Their iliac blades are craniocaudally elongated, expanding the distance between hip and sacroiliac joints (Waterman 1929; Ward 1993). Part of *latissimus dorsi* inserts directly upon the iliac crest (Sonntag 1923, 1924; Waterman 1929; Gregory 1950). The reduced lumbar spine provides a stiffer platform for these muscles to act upon the upper limb and protects the vulnerable lumbar spine from excessive lateral bending moments during latissimus dorsi contractions (Cartmill and Milton 1977; Jungers 1984; Sarmiento 1985; Ward 1993).

Reaching overhead during climbing requires the ability to adduct the wrist, which apes can do due to a reduced ulnar styloid that has lost contact with the carpus (Lewis 1971, 1972, 1989; Sarmiento 1988; Whitehead 1993). The pisiform is more distally situated, facilitating extensive adduction at the wrist up to 90° (Sarmiento 1988). Apes rely on a hook grip during suspensory behaviors and have relatively long fingers with strong flexor musculature and reduced thumbs (Schultz 1930; Rose 1988). They also have strong grasping *pollices* and *halluces*, along with well-developed musculature for adduction. The fibula, site of attachment of the long hallucal flexor muscles, is well developed (Schultz 1930; Sonntag 1923, 1924; Gregory 1950; Swindler and Wood 1973). Manual and pedal phalanges have well-developed attachment sites for digital flexors (review in Begun 1994a). The curved forearm bones of apes have been linked to the presence of strong hand and finger flexors (Miller 1932; Knussmann 1967).

These adaptations are better developed in great apes than in lesser apes (review in Young 2003). Mechanical constraints on mechanical function, and stresses on the musculoskeletal system, increase exponentially with increasing body size; thus some differences between lesser and great apes may represent allometric issues (Aiello 1981; Jungers 1984). The small body size of hylobatids may be secondarily derived, as is their unique adaptation for ricochetal brachiation (Cartmill 1985). Their fore-limbs and hands are particularly elongate (Jungers 1984), their thumbs particularly short, and their body mass relatively low. Their lumbar vertebral columns are 5–6 segments long and their thoracic columns 12 (Schultz and Straus 1945).

Differences between African apes and orangutans have also been noted, including a smaller supraspinous region of the scapula, smaller acromion processes, and shorter scapulae in orangutans (Oxnard 1984; Larson 1988; Young 2003). Orangutans have higher intermembral indices (Aiello 1981), a nonuniformly curved iliac crest, and an anterior longitudinal ligament ridge on the anterior surfaces of the vertebral bodies. They also lack a ligamentum teres of the femoral head, along with particularly mobile knee and midtarsal joints. Orangutans alone among large hominoids retain separate centrale and scaphoid bones rather than the fused os centrale seen in extant African apes. These differences are presumably related to the highly developed and nearly exclusively quadrumanous arboreal locomotor behavior of orangutans on one hand compared with the partly terrestrial knuckle-walking habits of African apes on the other. It is worth noting, however, that little work has been done to explore the extent of morphological variation among great apes and their functional significance.

So, although apes do share a distinctive suite of morphologies, they are not identical in their behavior nor anatomy. Therefore, although a subset of shared morphologies undoubtedly was present in their common ancestor and represents synapomorphies of the hominoid clade, such differences indicate a combination either of locomotor specialization within each lineage or independent acquisition within lineages undergoing broadly similar selective pressures. Only careful examination of the currently known fossil record, and discovery of new hominoid fossils, will allow us to determine which scenarios led to the diversity of known hominoid locomotor adaptations.

Fossil Non-hominin Hominoids

Hominoids can essentially be grouped into temporal and adaptive grades, basal hominoids, and euhominoids (Begun et al. 1997, 2012; Begun 2010; Begun 2001) (Fig. 1). Basal hominoids are stem taxa known from the Early and Middle Miocene

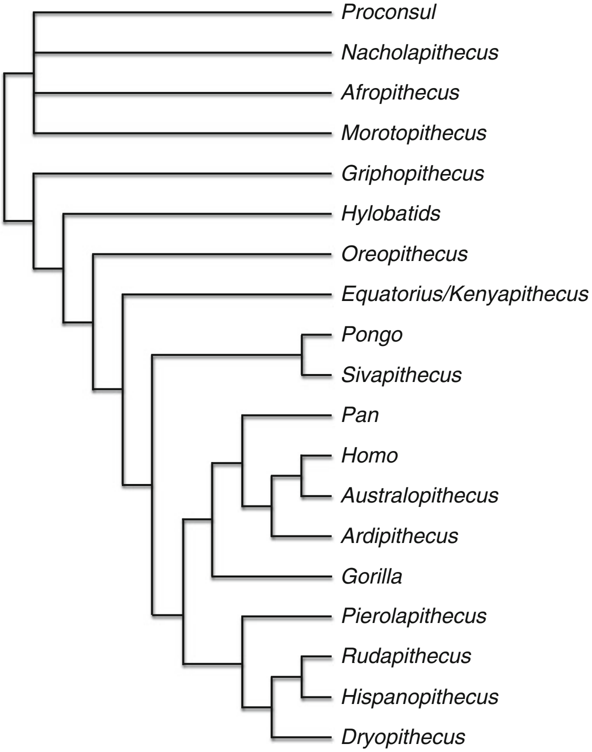

Fig. 1 Hypothesized phylogeny of hominoid relationships (based on Begun et al. 2012) followed in this chapter

and comprise taxa that are not crown hominoids and that lack postcranial specializations for extant apelike below-branch arboreality. Euhominoids are members of a crown hominoid clade, and so demonstrate extant hominoid synapomorphies, of which the postcranial anatomy is significant to this discussion. In an analysis of relatively well-known taxa (Begun et al. 1997), basal hominoid taxa include *Proconsul* and *Afropithecus* from the Early Miocene and *Kenyapithecus*, which in the analysis includes *Equatorius* (Ward et al. 1999), *Griphopithecus* (Begun 2000) from the Middle Miocene, and to which should now be added *Nacholapithecus* from the Middle Miocene (Ishida et al. 1984, 2004; Rose et al. 1996; Nakatsukasa et al. 1998). Euhominoids include *Sivapithecus*, *Oreopithecus*, *Pierolapithecus*, *Rudapithecus*, *Hispanopithecus*, and *Dryopithecus*

Proconsul and *Afropithecus*

Postcranially the best-known genus of Early Miocene hominoid is *Proconsul*, although *Afropithecus* is also represented by several postcranial elements. While these taxa differed craniodentally, *Afropithecus* is strikingly similar in preserved postcranial bones to *Proconsul nyanzae* (Ward CV1998). These taxa, among others less well known postcranially, represent a stem group referred to as basal hominoids

(Begun et al. 1997). Comprehensive reviews of these taxa can be found in Walker (1997) and Leakey and Walker (1997), and possibly *Nakalipithecus* (Kunimatsu et al. 2007), *Ouranopithecus* (Andrews et al. 1996; Moyà-Solà and Köhler 1995; de Bonis and Koufos 2001) and *Chororapithecus* (Suwa et al. 1997), but without good postcranial representation, these latter taxa are not discussed further here.

Proconsul was a genus composed of at least four species of pronograde, quadrupedal, arboreal frugivores that ranged in size from that of colobus monkeys to that of female gorillas. *Proconsul* individuals were very generalized animals. They were certainly above-branch arboreal quadrupeds that would have been capable, as most primates are, of limited below-branch postures and movement but that show no specialization for below-branch arboreality. *Proconsul* had a roughly even intermembral index and retained ulnar contact with the wrist (Beard et al. 1986). It also had a relatively long torso with six lumbar vertebrae, lacking the stiffening of the lumbar spine seen in extant apes (Ward 1993; Ward et al. 1993). The vertebrae have transverse processes arising from the vertebral body as in most monkeys, distinct accessory processes that suggest large *erector spinae* musculature, reflecting a narrow rib cage, and narrow and laterally facing iliac blades (Ward 1993). The pelvis was narrow, as, presumably, was the thoracic cage. The humerus is retroflexed with little torsion, reflecting ventrally oriented glenohumeral joints (Napier and Davis 1959; Larson 1988). The sternebrae are wider than those of cercopithecids, instead resembling atelines, but were not as broad as those of apes.

Proconsul is distinguished postcranially from earlier generalized catarrhines such as *Aegyptopithecus* (Rose 1997; Walker 1997) by a shoulder adapted to a wider range of loading, an elbow joint emphasizing joint loading in a variety of flexion-extension and pronation-supination postures, longer distal limb segments, a foot that may have been better adapted to inversion-eversion (Walker 1997, Table 1 p. 221), and the lack of a tail (Ward et al. 1991; Nakatsukasa et al. 2004). It is also true that *Proconsul* had a hip joint with a high neck-shaft angle, a femoral head set high on the neck, a centrally placed fovea capitis, and a greater trochanter that was shorter than that of many monkeys, indicating a hip joint adapted to loading in at least somewhat abducted postures (Ward 1992; Ward C 1997), although not necessarily with a greater range of possible abduction than found in most monkeys (Hammond 2013). The knee joint was broad, with a broad, flat patella, also indicating a very generalized and adaptable use of the lower limb. Most monkeys and earlier, generalized catarrhines have joints designed for fairly stereotypical loading environments principally comprising of quadrupedal postures in which the limbs are relatively adducted and the hands are pronated and palmigrade. Thus in comparison to *Aegyptopithecus*, *Proconsul* and other known Early Miocene basal hominoids were adapted for using their limbs in more abducted postures, with hands and feet grasping arboreal supports in a variety of positions.

The hands and feet of *Proconsul* have relatively well-developed first rays and supporting bones such as the large fibula. The phalanges are fairly long, with clear ridges for attachment of the finger and toe flexors (Begun 1993). The hallux and pollex were long relative to the other digits, suggesting that actual grasping was used rather than emphasizing the hook grips characteristic of extant apes.

Before the discovery of taillessness in *Proconsul*, reduction of a tail and commensurate restructuring of the pelvic floor musculature had been equated with the evolution of orthograde posture, which requires muscular support of pelvic viscera. However, the lack of a tail in *Proconsul*, and also in *Nacholapithecus* (Ward et al. 1991; Nakatsukasa et al. 2004), reveals that tail loss in hominoids was not associated with orthogrady, but rather with a decreased reliance on running and leaping behaviors and an emphasis on more deliberate arboreality, emphasizing manual and pedal grasping with weight distributed over multiple supports (Kelley 1995). Taillessness was likely a characteristic of all basal hominoids and one of the defining features of this superfamily.

In summary, a reasonable locomotor reconstruction of early hominoids is possible. The positional repertoire of the earliest known hominoids likely was distinguished from that of primitive catarrhines such as *Aegyptopithecus* by a specialization for deliberate arboreal climbing and clambering, using strong manual and pedal grasping to maintain balance and to move about in the arboreal environment. The emphasis on grasping meant that tails were no longer needed for balance, and thus an external tail became lost. A grasping adaptation enabled many hominoids to attain larger body sizes than seen in extant monkeys, yet still remain arboreal. This emphasis on cautious climbing and clambering enabled basal hominoids to reach fruit on the terminal branches and cross gaps in the canopy by giving them the ability to distribute their weight over multiple supports. They almost certainly also practiced vertical climbing and limited suspension but had not yet evolved selection for specialized adaptations to these behaviors; instead they spent most of their time above the branches. Their limb joints were adapted to loading in a wider variety of postures than is typical for most nonhominoids, including those involving an abducted hip and supinated elbow. They were certainly capable of orthograde postures and probably employed them often. Yet their narrow torso structure with ventrally oriented shoulder joints and ulnocarpal contact that limited ulnar deviation of the wrist indicate locomotion primarily with the limbs positioned mainly underneath the body or slightly abducted.

This generalized arboreal locomotor habitus permitted this early radiation of basal hominoids to exploit a variety of body sizes, as well as a breadth of ecological niches. *Proconsul* was likely a ripe-fruit frugivore and *Afropithecus* a seed predator (Leakey and Walker 1997). *Rangwapithecus*, less known postcranially, seemed to be at least partly folivorous (Kay and Ungar 1997). Thus, except for *Morotopithecus* (below), Early Miocene apes seem to be an adaptive radiation that shared a broadly similar set of locomotor adaptations.

Morotopithecus

Morotopithecus bishopi is the earliest Miocene ape known from eastern Uganda and dated at over 20.6 Ma (Gebo et al. 1997). The palate of this taxon resembles those of other basal hominoids and has been compared to both *Proconsul* (*P. major*) and *Afropithecus* (review in Leakey and Walker 1997). As such, this species is placed phylogenetically as a basal hominoid rather than as a euhominoid. Postcranially, however, it differs from other Early Miocene apes in displaying a more derived, modern apelike postcranial skeleton in some respects. The only postcranial elements known from *Morotopithecus* include a glenoid fossa, a lumbar vertebra and associated fragments of other lower vertebrae (Walker and Rose 1968), and partial femora.

The *Morotopithecus* glenoid fragment is similar to its counterpart in extant great apes, being ovoid and shallow and lacking a narrow, laterally concave cranial portion (MacLatchy et al. 2000). This suggests a shoulder joint adapted to loading in a variety of postures and may be associated with a broader upper torso morphology. A more extant apelike torso in *Morotopithecus* compared with *Proconsul* is also suggested by the lumbar vertebrae (Ward 1993; Sanders and Bodenbender 1994; Nakatsukasa 2008), which are morphologically similar to those of hylobatids in having short bodies relative to endplate dimensions (Nakatsukasa 2008) and have lumbar vertebral transverse processes which arise from the junction of the vertebral body and pedicle (Walker and Rose 1968) rather than from the body as in *Proconsul* (Ward 1993; Ward et al. 1993) or *Nacholapithecus* (Nakatsukasa et al. 1998; Nakatsukasa 2008). This is correlated with the lack of accessory processes (Ward 1993). The body is also not hollowed out laterally, although a rounded median keel or bulge (Nakatsukasa 2008) is present. The *Morotopithecus* femur is robust, with a small head, but displays the typical hominoid pattern of having a high neck-shaft angle and centrally placed fovea capitis. The distal femur is very broad mediolaterally, with condyles asymmetric in size, and there is a large popliteus groove as in extant apes, suggesting adaptation to habitual loading in a variety of postures, and a high degree of rotation of the knee joint. Still, *Morotopithecus* may have had more lumbar vertebrae than typical great apes based on additional vertebral fragments from the site showing more ventral wedging of the vertebral bodies than typical for great apes, variable placement of the transverse processes relative to the vertebral body and pedicle (Nakatsukasa 2008), and mediolaterally narrow laminae. This suggests that the overall vertebral column was not as derived as seen in extant apes.

Altogether *Morotopithecus* shares several key features with extant apes, suggesting adaptation for more below-branch arboreal activities. The shoulder, hip, and knee appear to suggest adaptation to a variety of postures, and the vertebrae suggest a certain amount of broadening and stiffening of the torso, but not perhaps as much as in extant great apes at least. There is also nothing in the *Morotopithecus* skeleton that is substantially more derived than that of hylobatids except for a broader knee joint and the presence of a gluteal ridge and perhaps also transverse process inclination (Young and MacLatchy 2004). The femoral characters may be related to body size variation, and the transverse process inclination is actually somewhat intermediate between that of gibbons and great apes (Shapiro 1993). Still, the hominoid similarities have led MacLatchy (2004), MacLatchy et al. (2000), and Young and MacLatchy (2004) to hypothesize that *Morotopithecus* is a basal member of the euhominoid clade and that other basal hominoids, like *Proconsul*, *Afropithecus*, *Nacholapithecus*, and *Equatorius*/*Kenyapithecus* at least, are more distantly related to extant apes. This hypothesis assumes that the postcranial adaptations shared by extant hominoids in torso restructuring, below-branch locomotion, and knee mobility are synapomorphies.

Given its primitive craniodental and perhaps some vertebral characters, the phylogenetic placement and thus the evolutionary implications of *Morotopithecus* are difficult to assess. But considering the homoplastic similarities between ateline monkeys, *Pliopithecus*, and extant hominoids, and the variation among extant hominoids, it certainly seems plausible that shared features of *Morotopithecus* and great apes represent homoplasies. Regardless of its phylogenetic affinities, it seems apparent that *Morotopithecus* was a more forelimb-dominated below-branch arboreal animal with a greater emphasis on orthograde postures than is typical for other basal hominoids.

Nacholapithecus

Nacholapithecus kerioi is a Middle Miocene ape from northern Kenya (Ishida et al. 1984, 2004; Pickford et al. 1987; Rose et al. 1996; Nakatsukasa et al. 1998; Nakatsukasa 2003a, b). It displays an unusual suite of morphologies in a very different combination than known for other hominoids. Its overall body plan is similar to that of *Proconsul*. It has a long vertebral column with six lumbar vertebrae shaped like those of *Proconsul* (Nakatsukasa et al. 1998). It appears to have had a narrow torso shape and no tail, yet its feet were long, its shoulder joints mobile, and its upper limbs very large (Nakatsukasa et al. 1998; Senut 2003; Ishida et al. 2004). The hands and feet reflect palmigrade, plantigrade quadrupedalism.

The body proportions of *Nacholapithecus* are striking, having very large forelimb and relatively small hindlimb elements, outside the observed ranges for even extant apes (Ishida et al. 2004). The lower limb is comparatively small, but there is a high neck-shaft angle of the femur and a short neck. Otherwise, the tibia, fibula, and tarsal bones are similar to those of *Proconsul*. What is different are the very long pedal digits found in *Nacholapithecus*, which are similar in size to those of chimpanzees despite the fact that it is thought to have weighed about half of what chimpanzees weigh (22 kg; Ishida et al. 2004). The ribs are relatively large, and it has a long clavicle and scapular spine (Ishida et al. 2004; Senut et al. 2004; Nakatsukasa et al 2007). The distal humerus is derived relative to that seen in *Proconsul*, with a better-developed ball-and-socket morphology of the humeroradial joint and a more symmetrical humeroulnar joint. It had a relatively long clavicle with ligament markings, suggesting that protraction of the humerus into overhead postures would have been emphasized rather than abduction (Senut et al. 2004). The morphological similarity between the shoulder bone morphologies and those of colobine monkeys underscores this interpretation. This difference in inferred upper limb use in climbing between *Nacholapithecus* and euhominoids is likely related to its lack of torso restructuring from the primitive condition. *Nacholapithecus* retained six or seven lumbar vertebrae with ventral median keels and hollowed sides, transverse processes arising from the body-pedicle junction, and small accessory processes are present as in *Proconsul*

(Nakatsukasa et al. 2007). This restructuring to make the torso shorter, stiffer, and broader is seen in apes emphasizing abduction-adduction movements of the upper limb (Ward 1993). This is consistent with the caudal orientation of the spinous processes in the lower thoracic and lumbar vertebrae as well (Nakatsukasa et al. 2007). Thus, *Nacholapithecus* does seem to have been adapted for more extensive forelimb-dominated climbing locomotion than were earlier basal hominoids, with enlarged forelimbs and small hindlimbs and long pedal phalanges, but in a fundamentally different way from what is seen in later euhominoids.

Equatorius/Kenyapithecus

The Middle Miocene African fossil sample originally attributed to *Kenyapithecus* has now been partly divided by some researchers and placed into *Equatorius* (Ward et al. 1999) or *Griphopithecus* (Begun 2000), with the result that there is now only one humerus known for *Kenyapithecus wickeri* (summary by Ward and Duren 2002). Given the taxonomic debate, here all samples are treated together.

Equatorius resembles other basal hominoids in several respects (Sherwood et al. 2002). It has a monkey-like scapula and a retroflexed humeral shaft, indicating a pronograde posture at the shoulder. The ulna still contacts the carpus, and the os centrale is unfused to the scaphoid. *Equatorius* has the mobile hip and knee joint morphology characteristic of all hominoids and slightly broader sternebrae than typical for monkeys, although it is reconstructed to lack the laterally expanded torso of extant apes. *Equatorius* (= *Kenyapithecus*) from Maboko Island has been interpreted as semiterrestrial based on its retroflexed humeral shaft, medial humeral epicondyle, and olecranon process, along with long radial head, short phalanges, and morphology of the metacarpal heads (McCrossin and Benefit 1997). However, it has also been described as resembling extant apes in having a straight humeral shaft and strong grasping capabilities (McCrossin 1997). It is difficult to reconcile these divergent descriptions at present. *Equatorius* does not display evidence of thoracic reorganization typical of *Morotopithecus* or extant apes, but instead was a more generalized pronograde quadruped that may have spent some time on the ground. If indeed *Equatorius/Kenyapithecus* is more closely related to euhominoids than is *Proconsul* (Ward and Duren 2002), it reinforces the hypothesis that the ancestral euhominoid was generalized postcranially.

Griphopithecus

Griphopithecus is known from the early Middle Miocene of central and eastern Europe and Turkey. Postcranially, phalanges from the site of Paşalar, Turkey, are fairly short and straight, lacking evidence of climbing adaptations (Ersoy et al 2008). A partial ulna and humerus from Kleinhadersdorf, Austria, also appear to be those of a generalized quadruped (Begun 2002; Alba et al. 2010).

Sivapithecus

Sivapithecus is known from more than one species from the Middle and Late Miocene of Pakistan. It shares an extensive suite of craniodental characters with orangutans, suggesting that they are sister taxa. Postcranially, however, these taxa are not similar. The discovery of humeral shafts attributed to *Sivapithecus* (Pilbeam et al. 1990) led to a startling revelation about the evolution of hominoid locomotion, referred to as the "*Sivapithecus* dilemma" by Pilbeam and Young (2001). The hand and foot remains known for *Sivapithecus* up to that time all exhibited a more derived modern apelike morphology than earlier hominoids such as *Proconsul*. It had longer, stronger phalanges, a better-developed hallux, and a more mobile elbow, and these morphologies were presumed to indicate at least a somewhat extant great-apelike overall postcranial gestalt (Rose 1986). To most researchers the marked craniofacial similarities between *Sivapithecus* and *Pongo* indicate a close phylogenetic relationship (Ward and Brown 1986; Ward SC 1997; Kelley 2002; Begun 2010; Alba et al. 2012), so the apparently modern apelike postcranial fossils fit a phylogenetic position of *Sivapithecus* well within the hominid clade.

The humeri, however, appear to paint a different picture. Although missing their proximal ends, both specimens appear to be inclined posteriorly and medially, the morphology seen in primates like most monkeys, *Proconsul*, and *Nacholapithecus* that have posteriorly directed humeral heads, ventrally facing scapular glenoid fossae, and narrow torso structures (Pilbeam et al. 1990; Richmond and Whalen 2001; Madar et al. 2002; Almécija et al. 2007; Desilva 2010).

If *Sivapithecus* had a narrow torso, and yet was a member of the pongine clade, this means that many of the postcranial apomorphies shared among *Pongo*, *Pan*, and *Gorilla* must represent homoplasies rather than homologies as previously interpreted. *Pongo* must have evolved a similar torso structure, limb proportions, and other below-branch specializations independently from African apes. This presented paleoanthropologists with the initially uncomfortable realization that the unique locomotor mode essentially shared by extant apes evolved independently, at least twice.

Pierolapithecus

The hypothesis that postcranial homoplasy has occurred among extant hominoids is bolstered by the recent discovery of *Pierolapithecus catalaunicus* from the Middle Miocene of Spain (Moyà-Solà et al. 2004). *Pierolapithecus* was originally interpreted as a basal hominid (Moyà-Solà et al. 2004; 2009; Casanovas-Vilar et al. 2008, 2011) but has also been considered a member of the hominine (African ape and human) clade (Begun and Ward 2005; Begun 2009; Begun et al 2012). The vertebrae of *Pierolapithecus* resemble those of *Morotopithecus* and, among extant apes, are most like those of hylobatids. It had a high costal angle, revealing that its torso shape was also hominoid-like. It lacked ulnar contact with the carpus, indicating the ability for substantial ulnar deviation. All of these features are also seen in extant hominoids and suggest an orthograde locomotor adaptation involving some climbing at least.

However, *Pierolapithecus* is more primitive than are extant apes in some ways. It lacks some shared specializations of extant great apes, such as dorsally positioned vertebral transverse processes, elongated curved phalanges, some reorganization of the carpus, or a flaring iliac blade as seen in large hominoids (Almécija et al. 2009; Moyà-Solà et al. 2004; Alba et al. 2010; Hammond et al. 2013). Still, the vertebrae and pelvic fragment appear to resemble those of hylobatids, which are highly suspensory, and the phalanges are similarly curved to those of chimpanzees, so some features in which the morphology does not resemble all great apes may not mean lack of orthograde or even suspensory behaviors. Too few elements are known from both *Sivapithecus* and *Pierolapithecus* to make extensive direct comparisons, so it is hard to say if they represent an ancestral morphology from which all extant apes evolved. But, because it lacks some of the shared specializations of extant great apes, *Pierolapithecus* provides more evidence that *Pongo* is convergent upon African apes in its specialized below-branch arboreal locomotor skeleton.

Oreopithecus

Oreopithecus bambolii is a Late Miocene ape from Italy represented by a deformed but nearly complete skeleton, as well as other isolated postcranial elements. It is known from most skeletal elements and has been the subject of intense debate regarding its locomotor behavior (Schultz 1960; Harrison 1986; Sarmiento 1987; Harrison and Rook 1997; Pilbeam 2004; Moyà-Solà et al. 1999; Rook et al. 1999). It has even been considered to be bipedal (Straus 1963; Köhler and Moyà-Solà 1997; Moyà-Solà et al. 1999, 2005; Rook et al. 1999; Macchiarelli et al. 2001), although its vertebral anatomy does not support this hypothesis as the lumbar vertebrae lack dorsal wedging and a caudal increase in interfacet distances (Russo and Shapiro 2013). Furthermore, many of the features argued to suggest bipedality are also found in suspensory mammals (Wunderlich et al. 1999).

Oreopithecus has extremely high-intermembral and brachial indices, resembling only those of orangutans. It has five lumbar vertebrae, as do humans and hylobatids, but without a lumbar lordosis (Russo and Shapiro 2013). It had a pelvis that is broader than those of hylobatids with enlarged anterior inferior iliac spines. Its upper thoracic and pectoral girdle morphology is more difficult to assess due to the crushing experienced by the published fossil bones. *Oreopithecus* also has a relatively large femoral head relative to neck size, associated with extensive hip joint mobility (Ruff 1988). It was clearly adapted for below-branch arboreality, although its metacarpals and phalanges are not particularly long (Moyà-Solà et al. 1999; Rook et al. 1999), perhaps suggesting that manual grasping was done between the pollex and medial digits rather than with the hook grip typical of extant apes. This would be yet another example of variations on the below-branch forelimb-dominated theme. *Oreopithecus* also demonstrates that hominoids can specialize in this type of locomotor behavior without having every specialization seen within any given extant ape taxon. Because of its apomorphic craniodental morphology, the phylogenetic position of *Oreopithecus* is debated (Harrison and Rook 1997; Begun et al. 2007; Begun 2009, 2010; Casanovas-Vilar et al. 2011), but it is considered to be a crown hominoid and probably a basal one (Begun et al. 2007; Begun 2009, 2010; Casanovas-Vilar et al. 2011). Thus, its clear adaptation to orthogrady supports the hypothesis that euhominoids were orthograde at least by the Middle Miocene in Europe, although its unusual morphology and unusual environment suggests that some of its extreme suspensory adaptations may represent homoplasies with extant large hominoids.

Dryopithecus

Miocene ape fossils from Spain, France, and Hungary until recently were all referred to the genus *Dryopithecus* but now are recognized as belonging to the distinct genera *Dryopithecus*, *Hispanopithecus*, and *Rudapithecus* (recent review in Begun et al. 2012). *Dryopithecus fontani* from the Middle Miocene of Spain and France is known postcranially only from some phalanges (Almécija et al. 2011), a proximal femur (Moyà-Solà et al. 2009; Alba et al. 2010; Pina et al. 2011), and two humeri (Lartet 1856; Alba et al. 2010; Alba et al. 2012). *Dryopithecus* does not appear to have been well adapted for suspensory behaviors, differing from extant apes in having a lower femoral neck-shaft angle and higher trochanter and somewhat curved humeri resembling those of quadrupedal catarrhines.

Hispanopithecus

Hispanopithecus catalaunicus is a Late Miocene euhominoid from Spain that appears to have among the most derived postcranial skeleton of any Miocene ape (Begun 1993, 1994b; Moyà-Solà and Köhler 1996; Almécija et al. 2007, 2009; Alba et al. 2012).

Hispanopithecus has dorsally positioned lumbar transverse processes that arise from the neural arch and are inclined posteriorly, although not as far as in extant great apes (Moyà-Solà and Köhler 1996). Its robust femur has a high neck-shaft angle and low trochanter, suggesting adaptation to using the hip in a variety of postures and in many respects is similar to that of orangutans (Köhler and Moyà-Solà 1997), and an extant apelike distribution of bone in its femoral neck (Pina et al. 2012). It is not possible to determine how many were originally present. It has long, powerful manual phalanges coupled with short, robust metacarpals and limb proportions similar to those of modern chimpanzees and bonobos (Moyà-Solà and Köhler 1996; Almécija et al. 2007, 2009; Alba et al. 2012; Pina et al. 2012). The ulna did not contact the wrist (Begun 1994b; Moyà-Solà and Köhler 1996), and the forelimb bones are elongate. Altogether, *Hispanopithecus* appears to have been orthograde and more highly suspensory than earlier Miocene apes.

Rudapithecus

Rudapithecus hungaricus is a Late Miocene ape from Hungary that also is a member of the crown hominid clade. Like *Hispanopithecus*, *Rudapithecus* appears to have had numerous adaptations to suspensory behavior. It has long, curved manual phalanges, although these are less robust than seen in *Hispanopithecus* (Begun 1992, 1993; Kivell and Begun 2009; Begun et al. 2012). The elbow shows signs of considerable mobility, and the femur is short with a large head, as in extant great apes (Begun et al. 2012). The wrist has no contact with the ulna, and there was a deep carpal tunnel suggesting powerful forearm flexors. *The Rudapithecus* scaphoid and capitate anatomy is similar to those of *Hispanopithecus* (Kivell and Begun 2009). The pelvis also appears to be quite flaring, as in great apes, although not elongate (Ward et al. 2008). All of this suggests an orthograde, suspensory adaptation, even though its morphology is not identical to any of the other living or fossil apes.

Conclusion

Putting the fossil evidence of locomotor evolution in hominoids together, it appears that an emphasis on deliberate arboreal quadrupedalism with weight support over multiple branches, hereafter referred to as clambering, probably served as a preadaptation for the below-branch specializations of later hominoids, as well as for *Morotopithecus*. Once the tail was lost, the tail musculature was in a position to become a strong pelvic floor, facilitating more extensive orthogrady. The strong manual and pedal grasping of multiple supports, and relatively mobile limb joints, provided a platform for more frequent hanging below branches, and this in turn would have selected for longer forearms, fingers, and toes, increased capacity for wrist adduction, and reorganization of the torso to enhance forelimb adduction. Knees and elbows would also have been selected to become even more mobile and support loading in a wider variety of postures.

All of these morphologies do not come as a thoroughly integrated package, as illustrated by *Nacholapithecus*. On the other hand, *Pierolapithecus* and perhaps *Morotopithecus* show a different suite of adaptations, with a broader rib cage and pelvis and more widely set pectoral girdle yet with a hand and foot that displays shorter phalanges. This pattern is reminiscent of that seen in extant great apes and to a lesser extent *Oreopithecus* and *Dryopithecus*. These variations underscore the growing realization that hominoids evolved below-branch arboreal adaptations more than once. Combining fossil data with data from extant apes, it seems increasingly likely that many of the postcranial and locomotor specializations of great apes may have evolved from ancestors that were more generalized, although not, perhaps, as generalized as basal hominoids like *Proconsul*.

The hypothesis that such homoplasy has possibly occurred multiple times within the Hominoidea is becoming more and more well supported by increased evidence.

All hominoids likely evolved from similar ancestors with a deliberate clambering mode of positional behavior. With similar selective pressures to exploit terminal branch arboreal settings, selection favored similar adaptations. Ateline monkeys resemble hominoids in having a slightly reduced lumbar region, broader thoracic cage, longer clavicle, mobile limb joints, and other adaptations to frequent suspension. *Epipliopithecus* also resembled lesser apes in its semisuspensory adaptations (Zapfe 1960) yet bears no close phylogenetic relation to apes.

The *Sivapithecus* dilemma initially appeared to suggest that perhaps postcranial anatomy could not be used to make phylogenetic inferences among hominoids. However, more recent discoveries of partial skeletons of *Equatorius*, *Nacholapithecus*, *Pierolapithecus*, and *Hispanopithecus*, as well as multiple postcranial elements known for *Rudapithecus*, show that, while there indeed may be postcranial homoplasy, the variation among these taxa is greater than supposed. Patterns of similarities and differences can, in fact, inform phylogenetic understanding, and so the understanding of the patterns of selection that led to the evolution of various hominoid taxa. Once paleoanthropologists can accurately interpret the phylogenetic relations among these taxa, they can reconstruct vectors of morphological change within clades. These vectors, in turn, will provide a record of the directional selection that shaped the various lineages. This provides us the opportunity to interpret the pressures that led to the observed morphological change and thus why different hominoid taxa evolved, which is what paleoanthropologists want to know above all.

The current picture of hominoid postcranial evolution is, therefore, one of recurring homoplasy. Different taxa represent different experiments in exploiting terminal branch arboreal habitats at relatively large body sizes, which requires the distribution of weight among different supports. Extant apes have all done this in somewhat different ways as did fossil ones. So rather than thinking about progressive stages evolving from an ancestral taxon like *Proconsul* to one like a modern great ape, researchers need to refocus their efforts and to explore the detailed similarities and differences among this growing collection of fossil ape skeletons to explore the diversity of locomotor adaptations within hominoids. The presence of homoplasy in hominoid evolution must not be looked at as an all-or-none phenomenon.

This approach to considering morphology is perhaps most visible to anthropologists in the origin of hominins. At present, there is no reason to assume that the most recent chimpanzee-human ancestor had such a dramatically stiffened torso, narrow cranial thorax with cranially oriented glenoid fossae and narrow scapula, or long metacarpals, and it may or may not have been a knuckle walker when terrestrial. Instead, a slightly less derived ancestor, perhaps something like *Pierolapithecus* or *Oreopithecus* in torso morphology and perhaps other characters, might be a more reasonable guess. Only more careful morphological analysis of known fossils, comparative anatomical study of extant apes, and of course discoveries of new fossils will lead to a better resolution of the ancestral condition.

Australopithecus differs from later hominins in retaining morphologies that evolved as adaptations to arboreal locomotion yet shows unequivocal strong selection for habitual terrestrial bipedality. The adaptive significance of these primitive morphologies is inherently unknowable. The extent to which *Australopithecus* and even earlier hominins, such as *Ardipithecus*, *Orrorin*, and *Sahelanthropus*, differed from the last common ancestor reveals the vector of selection that shaped hominin origins. All of these fossils indicate that the last common ancestor of them all was likely largely orthograde and adapted for some amount of vertical climbing and perhaps suspension. That *Australopithecus* evolved from a highly derived African apelike ancestor adapted to knuckle walking appears less and less likely. Rather, mounting evidence from the Miocene suggests that the australopith ancestor was orthograde, not a terrestrial quadruped (also see recent review in Crompton et al. 2008). If so, anthropologists may need to revisit the perennial question about australopith origins: the idea that hominins were selected to stand up on two legs from all fours. Rather, considering the evidence from the Miocene, including the Late Miocene hominin *Ardipithecus* (Lovejoy et al. 2009), the question that perhaps should be asked is, “why did early hominins remain orthograde when they began exploiting terrestrial niches?”

To understand why our own lineage diverged from that of other apes, it is necessary first to understand the ancestral morphology from which hominins evolved. Only then can paleoanthropologists determine, for example, whether australopith forearms reduced from the primitive condition or not. The expanding hominoid fossil record affords us ever more opportunities to appreciate the diversity, past and present. What may seem at first like an increasingly confusing picture of homoplasy must be viewed as an opportunity to obtain a more accurate and nuanced understanding of the adaptive diversity present throughout the hominoid radiation.

Abstract

The hominoid cranium represents a tightly constrained, functionally and developmentally integrated structure subject to multiple selective influences. Modern apes are the remnant of a much more diverse radiation, raising issues about their suitability as models for earlier hominoids. Among gibbons the folivorous siamang is cranially distinctive. The markedly airorynchous *Pongo* is cranially highly variable and lacks the anterior digastric muscle, thereby contrasting with other hominoids (except *Khoratpithecus*). African apes share a common cranial pattern differentiated by varying growth rates, not duration. Airorhynchy is common among fossil hominoids and differentiates hominoids from non-hominoids, suggesting that African ape klinorhynchy is derived. Bonobos are cranially smaller, lighter, and less dimorphic than chimpanzees. These are comparatively uniform, with extensive overlap between subspecies, whereas gorillas display considerable contrasts, especially between east and west populations. Early Miocene hominoids are already cranially diverse, with most species probably soft- or hard-fruit feeders. Middle and Late Miocene forms from Africa, Europe, and Western Asia are thicker enameled with more strongly constructed crania suggesting harder diets, although *Dryopithecus* (soft frugivory) and *Oreopithecus* (folivory) are exceptions. South and East Asian fossil hominoid diets ranged from soft fruits through harder items to bulky, fibrous vegetation. All extant ape crania are relatively lightly constructed compared with fossil forms, again prompting questions about their suitability as adaptive models of earlier hominoids.

Introduction

The hominoid fossil record has expanded markedly over the last two decades, sufficiently to indicate marked morphological diversity. This in turn reflects a major radiation or, more likely, series of radiations. The great bulk of the material is from Miocene contexts – apart from hominins there is still comparatively little from Plio-Pleistocene deposits – so that fossil and living hominoids are largely detached from one another. Whatever the details of this array, it is clear that the extant nonhuman apes represent but the surviving fragment of a significantly more numerous, geographically more extensive, and ecologically more diverse group of catarrhine primates. The extremely restricted modern comparative base and its (at best) tenuous links with the earlier material pose real challenges for adaptive and phylogenetic interpretations of the fossil hominoid record.

An outcome of this is that detailed phylogenies often differ appreciably from author to author, depending on the significance accorded to particular apomorphies and on the extent to which other similarities are deemed homoplasies. The upshot is a whole series of individual phylogenies and widespread disagreement about the status of particular groups which usually translate through into the taxonomies preferred by individual researchers. Since the thrust of this chapter is primarily adaptational, we do not concern ourselves with taxonomic or phylogenetic details; in what follows suprageneric categories are used informally and generally follow majority consensus usage. For those requiring more detailed information on phylogenetic issues concerning the Miocene hominoid record, the chapters "▶ Fossil Record of Miocene Hominoids" and "▶ Postcranial and Locomotor Adaptations of Hominoids," Vol. 2, and the papers by Harrison (2002), and contributors in Hartwig (2002) are excellent recent surveys.

Cranial form is influenced by multiple factors. Functionally, the head houses the visual, olfactory, and auditory organs and those of vocalization, taste, and balance; it contains the openings for the respiratory and alimentary tracts; and it houses and protects the brain. It incorporates structures for food acquisition and processing, while postural and respiratory factors influence basicranial morphology. Its superficial tissues may be patterned and convey information to conspecifics about sex and ontogenetic status. The interplay of these features, and especially the size and configuration of those concerned with food processing relative to neurocranial proportions, may lead to the development of external structures such as crests and tori on the skull. There are clearly intense selection pressures determining effective developmental and functional integration of these varied aspects of cranial function throughout the individual life cycle.

Fleagle et al. (2010) undertook a 3D geometric morphometric study (Procrustes and Principal Components Analysis) of primate crania to quantify broad aspects of cranial diversity. Their first PC differentiated on cranial flexion, orbit size and orientation, and relative brain size, while PC 2 reflected differences in cranial height and snout length. *Eulemur*, *Mandrillus*, *Pongo*, and *Homo* represent the limits in cranial shape. Overall, hominoids display the greatest diversity in cranial shape among extant primate clades, although much of this is driven by the atypical and highly distinctive cranium of *H. sapiens*.

Adult African apes including humans, known as hominids, share a broadly common pattern of covariation in cranial traits, with the oral and zygomatic regions primary integrative influences and with a lesser contribution from the nasal region, i.e., those craniofacial components primarily associated with mastication (Ackermann 2002, 2005). This differs from the pattern in both Old and New World monkeys, in which the oral region is the exclusive primary contributor to facial integration. Ackermann suggests that this contrast may reflect innovatory functional or developmental shifts after the differentiation of hominoids from other Anthropoidea or be an allometric consequence of increased body size. Orangutans and gibbons were not represented in the analyses, but the extent to which they share the primary oral/zygomatic integrative pattern should help decide between these possibilities and assist in determining whether the pattern is a hominoid or hominid synapomorphy.

There are similar allometric patterns in the midface and common opposite relationships between lower and upper face in the adults. Whereas visual inspection and morphological distance place adult *Pan troglodytes* and *Gorilla gorilla* close together and *Homo sapiens* distant, craniofacial covariation patterns accord with molecular data in indicating closer affinity between *P. troglodytes* and *H. sapiens*, with *G. gorilla* distant (Ackermann 2002). Such concordance, however, does not hold throughout ontogeny, with differing patterns of affinity between juveniles and subadults of the above taxa on the one hand and infants and “adolescents” on the other (Ackermann 2005).

Nonetheless, some general patterns emerge: in particular, across the species earlier and later (subadult and adult) integration appears to reflect different drivers. Oral integration is especially influential in the earlier stages, as well as thereafter, but there are specific differences in the onset of zygomatic integration. In *P. paniscus* and *P. troglodytes*, it appears during the juvenile/adolescent periods, whereas in *Gorilla* it occurs from infancy, perhaps a correlate of its rapid growth. In all species, zygomatic integration intensifies in later ontogeny. Where evident, nasal integration occurs in mid-/late ontogeny, its intensity varying inversely with oral integration, suggesting that separate developmental modularities underlie these regions. While the most highly integrated species as adults, humans are more developmentally labile than the other African apes prior to maturity. While differing in detail, however, all species show a common pattern of intensified integration throughout development, with a particular shift toward more constrained variation around sexual maturity or just after. The extent to which these similarities reflect shared, genetically determined, developmental pathways, or common selection pressures associated with vital functional requirements – the need for effective food processing mechanisms, for instance – remains to be determined. In the latter case, some proportion of the resemblance could be homoplastic.

A recent study by Singh et al. (2012) based on covariation in 56 morphometric landmarks representing the functional modules of the face, vault, and basicranium (Moss and Young 1960; Moss 1973) extends the analysis of cranial integration to include *Pongo* as well as the African apes. The results point to complex integrated shape changes, but despite marked contrasts in adult cranial morphology, all species display close similarities in covariation patterns between the face, basicranium, and vault. The implication is that the pattern of hominoid cranial integration has been conserved at least since the separation of the Asian ape and hominid clades, presumably due to strong stabilizing selection constraining developmental processes.

While some cranial features are relatively invariant in catarrhines (e.g., positioning of orbits; structure of the auditory region), others (e.g., orbital size and shape) are highly variable within genera, species, and even subspecies (Seiffert and Kappelman 2001). Some features seem to be determined less by their "primary" function than by influences reflecting the interactions of other functional systems; e.g., the size and proportions of the orbits appear to be determined more by the growth trajectories of the mid- and upper face and by requirements to resist the biomechanical forces generated by food processing as they affect those regions than by the dimensions of the visual organs housed within them (Schultz 1940). Other traits (e.g., the structure of the nasal floor and premaxilla/palatal relationships; Ward and Kimbel 1983; Ward and Pilbeam 1983) exhibit contrasts, the functional basis of which is poorly understood, but which serve as useful phylogenetic indicators (see below).

The compilation of long lists of character states as the raw data for computer-based cladistic analyses has been criticized by some (Rak 1983; Suwa et al. 1997; Asfaw et al. 1999, 2002) as resulting in the fragmentation or "atomization" of morphology as multiple discrete traits, rather than an integrated whole. It is therefore worth noting here the recent accounts that stress the importance of broader functional and developmental perspectives in analyzing morphology and its evolutionary/phylogenetic and adaptive contexts (Lovejoy et al. 1999, 2003; Lieberman et al. 2000a, b; McCollum and Sharpe 2001; Rae and Koppe 2000; Ackermann 2002, 2005; Singh et al. 2012). These build upon earlier studies such as those of Moss and Young (1960), Moss (1973), Enlow (1968, 1990), and Cheverud (1982, 1996); and biomechanical analyses such as that of Endo (1966); see also Rak (1983).

An example of this approach is McCollum's analysis of *Paranthropus* cranial morphology (McCollum 1997, 1999; McCollum and Sharpe 2001), which concludes that limited changes in the relative growth rates of jaws and teeth on the one hand and of the orbit and upper face on the other would be sufficient to produce in mature individuals the distinctive set of features that characterize the robust australopithecine cranium/face. Such growth rate changes are doubtless under simple, limited genetic control and, as such, are readily elicited in appropriate selective contexts. It is not difficult to envisage comparable pressures operating on Miocene hominoids, and so a variety of cranial forms thereby rapidly resulting from relatively limited genetic changes. So, for example, the contrasting morphologies of *Proconsul* and *Afropithecus* might both be derived relatively simply from an Oligocene precursor such as *Aegyptopithecus*, and purely phenetic measures of affinity between these forms could be seriously awry as indicators of phylogenetic relationship.

One outcome of cladistic studies has been the general recognition of the pervasiveness of homoplasy in the fossil record. From an adaptive perspective, instances of homoplasy can provide important clues as to the contexts of, and likely selective forces impacting on, hominoid communities. In such cases, the influence of phylogenetic constraint and contingency may be considerable. Minor initial differences between spatially distributed populations of a single species (or of closely related species), when further influenced by bottlenecking or other stochastic factors – easily occurring in small, localized arboreal groups, where gaps in tree cover impede gene flow – may result in significantly different morphological outcomes as responses to common selection pressures associated with similar niches. The evolution from the nasal/palatal structure seen in *Proconsul* and other Early Miocene forms of distinct anatomical configurations for that region in Middle/Late Miocene Afro-European and Asian hominoids may be an example of such a process and its outcomes.

A fundamental division of extant hominoids is that between gibbons (hylobatids) and large-bodied apes – the Asian orangutan (*Pongo*) and the African chimpanzee and bonobo (*Pan*), gorilla (*Gorilla*), and human (*Homo*), although the last taxon will be discussed elsewhere. *Pongo* and *Pan* are both largely frugivorous, with common dental adaptations (large anterior teeth and relatively small check teeth with enamel wrinkling) but differing in cranial features, whereas the more herbivorous *Gorilla* closely resembles *Pan* cranially despite its contrasting dietary niche (see below). These differing patterns of affinity illustrate the importance of developmental constraints and phylogenetic inertia in determining morphology and thus the lack of any necessary one-to-one correspondence between morphology and adaptation (for further discussion of this, see below).

It is possible in principle to extend the limited insights provided by the few extant great apes into the earlier radiation by supplementing them with modeling based on early hominins, which can be thought of as phenetically and adaptively "apes" in some respects. Apart from the dangers of circular reasoning (using modern ape data as inputs into constructing early hominin models that are then used to "extend" the ape comparator base) and the appropriateness of such models (what form and degree of terrestrial orthogrady, if any, is compatible with using hominins as analogues for non-hominins?), however, there are major issues of contextual relevance.

All extant apes (here and throughout meaning non-hominin hominoids) and early hominins are essentially from tropical contexts (forest, woodland, and savannah) with none present in higher latitudes, reflecting a comparatively narrow environmental range compared with earlier ape habitats. Even incorporating early hominins within the comparator base provides a time depth of little more than 4+ Myr, characterized by broadly modern faunas that include groups rare or absent in the earlier record. In contrast, Miocene hominoids are components of markedly distinct and diverse faunas, often including entire mammalian families now extinct. So community relationships within earlier faunas will have differed from contemporary ecological webs, and the place(s) of earlier hominoids in their ecological communities are unlikely to correspond closely to those of modern ape analogues.

An obvious primate example of this is the expansion and radiation of cercopithecoids over the last 10 Myr or thereabouts, so forming a major dimension of the community ecology of all recent hominoids, unlike that of earlier taxa. Floral communities also fluctuated as climatic conditions changed, with notable contrasts between Early to Middle Miocene habitats and those of the Late Miocene and Pliocene.

Against these differentiating features are some factors that make for modeling continuity: the range of potential (plant) food items is limited, and their physical properties even more so, limiting the nature and magnitude of the masticatory forces influencing hominoid cranial morphology. Metabolic and biomechanical constraints on body size and on locomotor form and activity, allometric influences on growth, and the functional and developmental interdependences of cranial form noted above all allow for a more comparative approach to hominid cranial variation. Below we review the probable ancestral condition for Hominoidea, then examine some aspects of cranial form in extant nonhuman hominoids before summarizing craniodental information on the more complete fossil forms.

Ancestral Hominoid Cranial Morphology

The combination of outgroup analysis of extant forms and the morphology of stem catarrhines provides an indication of the ancestral hominoid cranial morphotype. The Fayum fossil primates represent an early diversification of basal catarrhines, presumably reflecting dietary specialization. For example, the small and dentally and gnathically primitive *Catopithecus* (35.5–36 Ma) combines the characteristic 2.1.2.3 dental formula, postorbital closure (primarily formed from the zygomatic), fused frontals, and C^1/P_3 honing facet with triangular upper molars with only limited hypocone development and lower molars with high trigonids and sharp crests. *Catopithecus* had a deep and projecting face, with an especially broad premaxilla; small, widely separated orbits; and a small neurocranium with anteriorly prominent temporal lines merging to form a sagittal crest along the rear half of the vault and well-developed nuchal crests. The tympanic region is like that of platyrrhines, not catarrhines, and the mandibular symphysis is unfused. The anterior dentition displays broad, spatulate incisors and projecting, dimorphic canines, suggesting a predominantly frugivorous niche.

Many of these features, including the contribution of the premaxilla to facial proportions, small neurocranium with marked muscle attachments and pronounced ectocranial cresting, and ceboid-like tympanic region, are also seen in the younger (33.1–33.4 Mya) and dentally more derived propliopithecid *Aegyptopithecus*. The zygomatic is again deep and the face in general strongly constructed, with a characteristic angled profile, and the mandibular symphysis is fused. The gonial region is strongly constructed and the ramus broad and high. The interorbital distance is again broad, with bony septa separating the high, narrow orbits and the interorbital region projects anteriorly from the medial orbital margins. Semicircular supraorbital tori extend over each orbit and, meeting medially, anteriorly bound a diamond-shaped frontal planum, whose posterior limits are defined by the anterior temporal lines. The anterior teeth are small compared to the postcanine dentition, making a narrow anterior palate. The molars are inflated and highly bunodont, especially the second, and the elongated lower third molar has a centrally placed hypoconulid; the trigonid is reduced in occlusal area and height and lacks the paraconid, while the talonid is expanded with a large distal fovea. The upper molars are quadritubercular, with a well-developed hypocone. There is marked canine dimorphism, with upper canine honing capabilities increased by a lengthening of the anterior surface of P_3. Overall morphology points to the generation of greater occlusal pressures than in *Catopithecus* and a craniofacial form better able to withstand the resulting forces.

When the details of stem catarrhine facial morphology are considered with the evidence from extant outgroups of the Catarrhini (e.g., Platyrrhini), it is possible to infer the major changes that underlie the ancestral hominoid craniofacial skeleton. Unlike stem catarrhines or platyrrhines, hominoids are characterized by a palate that is wide at the level of the canines, nasals that are nonprojecting and lie near the medial orbital margin in transverse section, and a premaxillomaxillary suture that contacts the nasals inferiorly near the nasal aperture (Rae 1999). Unlike previous interpretations, it is also evident that the overall shape of the ancestral hominoid morphotype is more cercopithecine-like (Benefit and McCrossin 1991), with tall zygoma and a deep face. This suggests that the shared craniofacial configuration of gibbons and colobine monkeys (short face, sloping zygoma) is convergent.

Extant Hominoids

Hylobates

Gibbons represent a radiation of small-bodied, brachiating suspensory hominoid species with attendant postcranial specializations, distinguished from each other primarily by pelage color and patterning and by vocalization. Four main groups are usually recognized, sometimes accorded subgeneric or generic rank, depending on the author. Three groups – *Hylobates hoolock*, *H. concolor*, and *H. syndactylus* – are comparatively well defined; the *H. lar* group is more problematic. Valuable reviews of extant gibbon characteristics and diversity include Groves (1972), Marshall and Sugardjito (1986), and Groves (2001); see also Geissmann (2002) and Mootnick and Groves (2005) for recent findings on gibbon diversity that support generic distinction, although the traditional use of the single genus *Hylobates* is maintained here.

Gibbons are craniodentally primitive in some characteristics (see above), compared with other extant hominoids, whether by plesiomorphy (McNulty 2004) or reversal (Rae 2004); appreciation of this led to the realization that similarities with Miocene taxa, such as *Limnopithecus* and *Pliopithecus*, previously taken as grounds for regarding these as likely gibbon ancestors, do not betoken any especially close phylogenetic relationship. The upshot is that, in the absence of a fossil record other

Fig. 1 (*Upper*) Frontal and profile views of *H. hoolock* skull (Photograph © The Grant Museum of Zoology, University College London). (*Lower*) Frontal and profile views of *H. symphylangus* skull (Photograph courtesy C.P. Groves)

than dental remains from Quaternary deposits of China and Indonesia referable to the modern genus, the early evolutionary history of gibbons is wholly obscure.

Overall, the *Hylobates* skull is rather lightly constructed (Fig. 1). The neurocranium is thin walled and the vault low and ovoid in profile, with a capacity of about 80–125 cm^3. The frontal extends rearward between the parietals, and in most individuals the sphenoid sutures with the parietal on the vault wall. The orbits are rectangular and relatively large, with strongly developed lateral margins; a torus also develops laterally above the orbits but is not continuous, fading out medially. The lacrimal fossa extends beyond the orbital rim onto the maxilla, and the interorbital breadth is large; the short, broad nasals are usually fused above the ovoid nasal aperture. Overall the face is short, broad, and fairly projecting. Within the nasal cavity, the premaxilla and maxillary palatine process are separated by broad palatine fenestra linking the nasal and oral cavities (Fig. 2 upper left); the vomer extends only as far as the fenestra, and the bony nasal septum is continued anteriorly by the premaxillary prevomer, which fuses to the vomer and forms a small bony crest in the incisive region in all gibbon species except the smallest, *H. klossi* (McCollum and Ward 1997). The palate and mandible are long; both corpus and symphysis are comparatively lightly built, although external thickening of the latter may be evident in some individuals, as well as the usual internal reinforcement by a superior transverse torus. The ramus is short, broad, and vertical, with some expansion of the gonial region.

Reflecting gibbons' predominantly frugivorous niche, the anterior dental arcade is relatively broad compared with the rear. The upper incisors are markedly heterodont – I^1 broad and spatulate and I^2 narrow and pointed – the lowers more similar, vertically implanted, and subequal in size. The canines are long, curving, transversely slightly narrowed, and sharply pointed, with minimal sexual

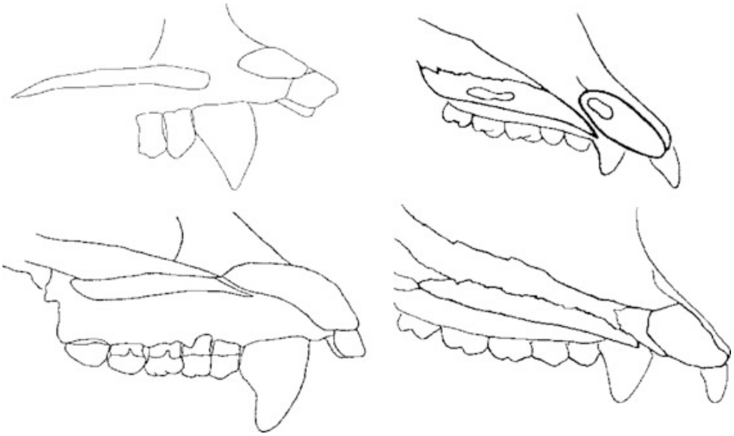

Fig. 2 Subnasal morphology of hominoids seen in sagittal section. *Upper left*: *Morotopithecus*, showing no overlap of the premaxilla on the maxilla (the primitive condition seen in extant *Hylobates* and most fossil hominoids). *Lower left*: *Pongo*, showing the smooth overlapped subnasal condition also seen in *Sivapithecus*. *Right*: *Pan* (*upper*) and *Gorilla* (*lower*) showing the stepped overlapped condition usual in extant African apes (Modified after Ward and Kimbel (1983))

dimorphism. There is well-developed honing of the upper canine against the long, highly compressed anterior face of the sectorial P_3, which is orientated in line with the molars. Cheek teeth exhibit considerable metric and morphological variation, but the rear molars are usually reduced compared with the first and especially the second molars except in *H.* (*Symphalangus*) *syndactylus* (see below).

The basicranium is long, with the foramen magnum and occipital condyles well behind the auditory meatus; there is no distinct mastoid process. The nuchal area is quite extensive, rising well up the occipital, with a distinct crest laterally that usually fades medially, although it may be continuous in some individuals. A sagittal crest is usually absent but may occur in small-brained individuals.

Detailed accounts of intra- and interspecific variation in *Hylobates* are given in Groves (1972, 2001) and Marshall and Sugardjito (1986) as above. Albrecht and Miller (1993) summarize their reanalysis, with caveats, of Creel and Preuschoft's (1976) craniometric data: canonical variate analysis (CVA) reveals *H. hoolock*, *H. concolor*, and *H. syndactylus* as cranially distinct from each other and from the *H. lar* group. This consists of a primary cluster including *H. lar*, *H. agilis*, *H. moloch*, and *H. muelleri* subspecies, with *H. pileatus* as an outlier and *H. l. vestitus* and *H. klossi* grouped together as a second, distinct, outlier. A subsequent analysis (Creel and Preuschoft 1984) produced patterns of resemblance that generally accord with geographical distribution but not always with the usually recognized species limits. A recent study by Leslie (2010) extends analysis to the relative orientation of internal cranial features and their variation across the recognized hylobatid groupings; the findings generally accord with those of the earlier studies based on external cranial features.

Fig. 3 Frontal and profile views of *Pongo pygmaeus* skull (Specimen courtesy of the Oxford University Museum of Natural History)

The only distinctive form noted here is the siamang *H.* (*S.*) *syndactylus* (Fig. 1, lower). This large, heavily built gibbon is more folivorous than other taxa and has a larger cranial capacity, a long, broad palate, and an inflatable air sac in the throat to aid calling. Postorbital constriction is more marked, and, despite the larger cranial capacity, sagittal cresting is both more frequent and larger than in other gibbons, an allometric correlate of greater body size (see below).

In the dentition, the canines are less lingually curved than in other gibbons, the protocone on P^3 and P^4 larger; and on the upper molars, crowns are elongated, the hypocone variable in size, and lingual cingula almost always absent. Third molar reduction occurs in only a minority of cases, and some individuals possess supernumerary molars. Again consistent with its more folivorous niche, relative shearing-crest development is greater than in other gibbon species (Kay and Ungar 1997, 2000). *H.* (*S.*) *syndactylus* has a larger, more airorhynchous (i.e., more dorsally flexed) face than other gibbons (Shea 1988) – see below.

Pongo

The Asian great ape, the orangutan, exhibits a distinctive overall cranial form (Fig. 3). In profile the large face is markedly prognathic subnasally, with a projecting, convex alveolar clivus. The comparatively small neurocranium is set above the facial skeleton, so that both frontal and occipital contours are relatively vertical. The orbits are elliptical, with their major axis vertical, and are surmounted by separate semicircular supraorbital costae rather than a continuous torus. The interorbital distance is very small, the ethmoid correspondingly constricted and set at a lower level than in the African apes (Shea 1988). There is no frontoethmoid sinus (Fig. 4), and the floor of the anterior cranial fossa forms a large part of the orbital roof (Winkler et al. 1988). In the fossa, the two wings of the frontal bone fail to meet behind the ethmoid, which retains contact with the sphenoid. The nasal bones are small, typically fused at an early age, and continue beyond the frontomaxillary suture, extending as a narrow wedge into the glabellar region of the frontal. On the medial orbital wall the lacrimal sutures with the ethmoid.

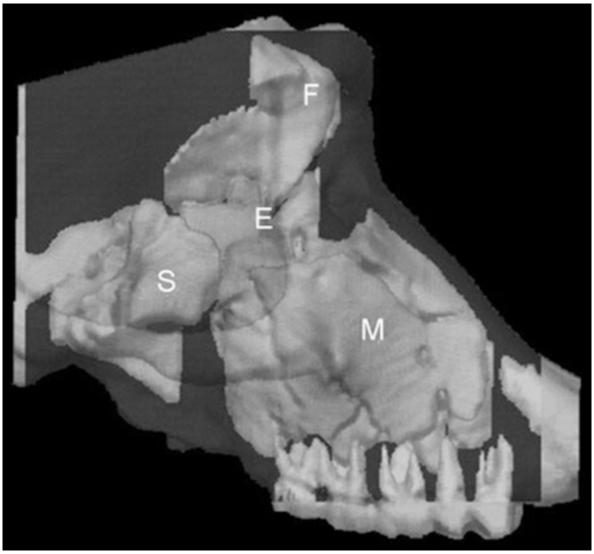

Fig. 4 Virtual three-dimensional reconstruction of *Pan* cranium from serial CT scans. The bone has been made transparent to show the paranasal sinuses and tooth roots. *F* frontal sinus, *E* ethmoidal sinus, *S* sphenoidal sinus, *M* maxillary sinus (Image courtesy of T. Koppe)

The midface region is short, the zygomatics are wide, deep, and flared, and there is usually a pronounced notch on the zygomatic process of the maxilla. The nasal cavity is tall and broad, the maxillary sinuses invade the interorbital pillar (sometimes as far superior as the frontal), and the lateral maxillary walls are obliquely inclined. The convex nasoalveolar clivus passes smoothly into the nasal cavity, extensively overlapping the anteriorly thin maxillary palatine process without a stepped incisive fossa; the fossa and canal are narrow, the latter long and orientated almost horizontally (Fig. 2 lower left). The vomer usually extends to the rear of the incisive canal but occasionally does not, in which case a small prevomer may be present (Ward and Kimbel 1983; Ward and Pilbeam 1983; McCollum and Ward 1997). Overall the palate is orientated anterosuperiorly.

The mandible is massive, the symphysis reinforced by a robust superior transverse torus and an especially pronounced inferior transverse torus extending back as far as P_4 or M_1 (Brown 1997). The corpus is deep and comparatively short. As in the African apes, there is a strongly developed platysma muscle extending laterally over much of the facial musculature and strongly attached to the swollen base of the mandibular corpus from the symphysis to the area of masseter insertion. Brown and Ward (1988) speculate that the massive platysma is associated with the orangutan's extensive laryngeal air sac system – greater than in other apes – aiding the regulation of air pressure and volume within the sac during vocalization. A distinctive feature of *Pongo* is the absence of the anterior digastric muscle (and so of the digastric fossae on the base of the symphysis) and associated separation of the posterior digastric from the hyoid and stylohyoid muscle (Dean 1984; Brown and Ward 1988). Instead the large posterior digastric, originating on the cranial base adjacent to *rectus capitis lateralis*, inserts onto the gonial region between the medial pterygoid and masseter muscles, acting to depress the mandible.

The orangutan's mylohyoid muscle is especially well developed, as are the geniohyoids. *Rectus capitis lateralis*, originating from a narrow area on the front of the atlas and inserting on the basioccipital anterior to the foramen magnum, is a more fan-shaped muscle than its homologue in the chimpanzee.

The cranial base is wider than in the African apes (Dean and Wood 1981, 1984), but the eustachian process is much smaller, providing the origin for only *tensor palati*, with *levator palati* originating from the apex of the petrous temporal (Dean 1985). The mastoid processes are poorly developed. In the articular region, there is a long preglenoid plane, an indistinct articular eminence, and a prominent postglenoid tubercle. The roof of the glenoid fossa is coronally oblique, slightly sloping inferomedially, so that the entoglenoid is less prominent than in the African apes. The temporomandibular ligament is well developed laterally but lacking the deeper horizontal band, suggesting closer approximation of the rear of the working condyle and the postglenoid tubercle during chewing (Aiello and Dean 1990).

The foramen magnum and occipital condyles are set well back on the skull base. A nuchal crest is present in all mature individuals, and a prominent sagittal crest develops posteriorly in most males, uniting with the nuchal crest but, reflecting the orangutan's greater airorhynchy, typically not extending as far beyond the rear of the vault proper as in *Gorilla* (see below). Anteriorly the temporal muscles diverge as lines or simple crests bounding a triangular area of the frontal. As in the African apes, the bulk of the *temporalis* muscle is orientated obliquely, with an emphasis on the posterior fibers.

The dentition reflects the orangutan's predominantly frugivorous niche. The upper incisors are the most heteromorphic of any extant hominoid: I^1 is very broad and spatulate, but I^2 is smaller, more pointed, and more convex in curvature. Well-developed median and marginal ridges reinforce the incisor crowns in biting. Lower incisors, high crowned and narrower than the uppers, are also reinforced by lingual ridging. Canines are conical, markedly dimorphic, and especially robust in males; females display more pronounced lingual cingula. Upper premolars are bicuspid; P_3 is sectorial with a narrow, elongate protoconid as the honing face; P_4 is bicuspid. Upper molars are more oval in occlusal outline than in other apes (Swarts 1988; Swindler and Olshan 1988; Uchida 1998b). Cheek teeth are relatively large compared to body size, low crowned, and with extensive, deep secondary wrinkling that further increases occlusal area. Molar shearing crests are rather well developed considering the emphasis on fruit (although significant quantities of bark and leaves are also ingested), exceeding those of chimpanzee species but considerably less than gorillas (Kay and Ungar 1997). They perhaps provide an instance of phylogenetic inertia, suggesting a more folivorous ancestor.

Orangutans are remarkably variable in cranial morphology (Wood Jones 1929; Röhrer-Ertl 1988a, b; Winkler 1988). Röhrer-Ertl (1988b) has shown that the most stable region is the midface, other cranial areas varying according to age, sex, dental eruption and masticatory development, hormonal status, dietary composition, and tooth use. Both the neurocranium and face exhibit greater growth in breadth than in length or height, a differential that is more marked in males than in females. While there is much individual and intrapopulational diversity, at least some variation reflects geographic factors: Groves (1971, 1986, 2001) and

Röhrer-Ertl (1988a, b) review cranial patterning and Brown (1997) mandibular form, while Uchida (1998b) summarizes dental differences. Within a context of admittedly high variability, Sumatran orangutans are characterized by an oblique but straight (not concave) facial profile with highly protuberant anterior teeth, a convex cheek region lacking a suborbital fossa, relatively short nasals, a shorter neurocranium but with a longer nuchal region, and a longer foramen magnum. The mandibular symphysis tends to be long and narrow, with an extensive inferior transverse torus. Dentally they exhibit relatively small paracones on P^3 and M^1 compared with their Bornean counterparts, M^1 larger than M^2 rather than subequal, and a broader M_3.

Bornean orangutans have a generally more prognathous and concave facial profile, display a distinct suborbital fossa on the cheek, and have more labially positioned incisors, a “trumpet-shaped” nasal aperture that becomes triangular in cross section at the level of the nasal tubercle (Röhrer-Ertl 1988a), and a more prominent interorbital pillar (Groves 2001). Their mandibles are deeper and broader anteriorly, and the symphysis is usually larger, thicker, and more bulbous than that of Sumatran orangutans. Taylor (2006) explored the relationships between feeding behavior, diet, and mandible morphology, specifically the greater exploitation of bark and relatively tough vegetation during low fruit periods by some Bornean orangutan populations compared with Sumatran ones. She found that the Bornean mandibles display a relatively deeper corpus, deeper and wider symphysis, and relatively greater condylar area, arguing that these features enable greater load resistance to masticatory and incisal forces, reflecting ingestion of harder food items. There is a gradient within Borneo, with populations in NE Kalimantan and Sabah *(P. p. morio)* displaying fullest expression of these traits, those in SW Kalimantan *(P. p. wurmbii)* rather less, and with those in NW Kalimantan (*P. p. pygmaeus*) generally intermediate between *P. p. morio* and the Sumatran mandibles, thus implying a spectrum of hard food exploitation in Bornean orangutans.

There is other craniodental differentiation within Borneo between populations from Sabah, NW and SW Kalimantan separated by the Kapuas River (Groves 1986, 2001; Courtney et al. 1988; Groves et al. 1992), often of comparable magnitude to that between Bornean and Sumatran orangutans. For example, Taylor and Schaik (2007) document variability in absolute and relative brain size in orangutan populations, finding significantly smaller brains among the north east Kalimantan/Sabah group (*P. p. morio*) compared with those from elsewhere in Borneo and from Sumatra. They relate these findings to differences in resource quality and life history: *P. p. morio* has the least productive habitat, lowest energy intake during extended periods of scarcity, and the shortest interbirth intervals, arguing that brain size and prolonged food scarcity may be inversely correlated. Uchida (1998b) was unable to identify any consistent pattern of dental differences between *Pongo* populations from W Borneo, SW Borneo, and Sumatra, with the Bornean groups often as distinct from each other as either was from the Sumatran sample. Bornean orangutans were significantly different from each other (but not from Sumatra) in P_4 and M_1 shape, but virtually identical in their narrow M_3 shape, with Sumatran orangutans having broader rear molars. Differences in molar cusp proportions showed similarly inconsistent patterning between the three groups. There were no obvious links to dietary differences, and Uchida concluded that on dental evidence, river and mountain systems within Borneo were as significant biogeographic barriers and so promoters of differentiation, as flooding of the Sunda shelf.

Bornean and Sumatran orangutans have generally been accorded subspecific status as *Pongo pygmaeus pygmaeus* and *P. p. abelii*, respectively (Schwartz 1988). In his latest revision, however, Groves (2001) distinguishes them as separate species (*P. pygmaeus* and *P. abelii*) on the basis of the more comprehensive morphological information now available and molecular differences well above levels usually associated with subspecies, which indicate a long period (c. 1.5 Ma) of isolation between the two forms. He also formalizes the intra-Bornean diversity noted above as subspecies of *P. pygmaeus*. This taxonomic framework, which is also followed, for example, by Taylor (2006), is reinforced by a study of multiple genetic loci which extends Sumatran and Bornean orangutan divergence back to 2.7–5.0 Mya, with isolation thereafter (Steiper 2006). The data also point to contrasting population histories, with Bornean orangutans having undergone recent population expansion beginning 39–64 Kya, while Sumatran populations remained stable.

The Sumatran and Bornean orangutans also exhibit developmental contrasts. Uniquely, male Sumatran orangutans may delay for many years full expression of secondary sexual characters, including their characteristic cheek flanges, whereas such long delays are much less common among Bornean males. Pradhan et al. (2012) relate such flexible developmental arrest to sociobiological factors and in particular to the potential for high-ranking males (flanged or unflanged) to monopolize sexual access to females. When the potential is low, no developmental arrest is the prevailing pattern, whereas at high monopolization potential the flexible, arrested development pattern is the stable one. Their model accords with field data indicating different monopolization potentials between Bornean and Sumatran flanged males and a lower proportion of these in the Sumatran orangutan population. Harrison and Chivers (2007) relate the evolution of developmental arrest to the onset of longer, more severe periods of low food availability reflecting climate change 3–5 Mya, with females dispersing more widely in search of food and adult flanged males less able to effectively guard a female harem, so providing an opening for the unflanged male as a quiet, quick, opportunistic "sexual predator."

Hominoids exhibit more dorsal flexing of the face relative to the cranial base (airorhynchy) than non-hominoids; their orbital axes and palates are both shifted more dorsally relative to their degree of basicranial flexion than those of other primates (Ross and Ravosa 1993; Ross and Henneberg 1995). While the functional basis for this is disputed (Ross and Ravosa 1993) and may well have multiple causes, within this context many of the orangutan's distinctive features can be plausibly related to its extreme airorhynchy (Delattre and Fenart 1956, 1960; Biegert 1964; Shea 1985, 1988; Brown and Ward 1988). Biegert (1964) argued that the hypertrophied laryngeal sac in *Pongo* is a prime determinant of its skull form, comparing it with the enlarged hyoid and associated throat organs of *Alouatta*. Shea (1985, 1988) and Brown and Ward (1988) have criticized this interpretation. Shea considers laryngeal specialization as just one potential determinant of airorhynchy, interacting with other factors, largely unknown. Brown and

Ward consider the *Pongo-Alouatta* analogy invalid in view of contrasts in the submandibular anatomy of these two genera, and it has also been rejected by Hershkovitz (1970) and Zingeser (1973).

Shea argues that pronounced dorsal flexion of the face links *Sivapithecus* and *Pongo* and that a degree of airorhynchy (although not to the extent seen in these two genera) is primitive for catarrhines and hominoids generally. On this view, the more ventral positioning of the face relative to the neurocranium seen in African apes and hominids is synapomorphous and, as such, a significant phylogenetic indicator (see also Ross and Ravosa 1993; Ross and Henneberg 1995; and below). The distinctiveness of *Pongo* is emphasized by its pattern of ectocranial suture closure (Cray et al. 2010). Vault suture synostosis is similar to *Gorilla* (but contrasts with that of *Pan* and *Homo* – see below), but the lateral-anterior pattern of fusion, with its strong superior to inferior gradient, is unique to *Pongo*, reflecting its relative phylogenetic isolation among hominoids.

The African Apes

As is well known, the African apes (hereinafter meaning gorillas, chimpanzees, and bonobos, i.e., non-hominin hominines) share a basic similarity of cranial form and in many respects are scaled variants of a common bauplan (Figs. 5 and 6). Many of the craniodental differences between them have been related, with varying degrees of success, to differences in dietary niche (see Chaps. "▶ The Paleoclimatic Record and Plio-Pleistocene Paleoenvironments," Vol. 1, "▶ Geological Background of

Fig. 5 (*Upper*) Frontal and profile views of *Pan paniscus* skull (Specimen courtesy of the Oxford University Museum of Natural History). (*Lower*) Frontal and profile views of *Pan troglodytes* skull (Specimen courtesy of the Oxford University Museum of Natural History)

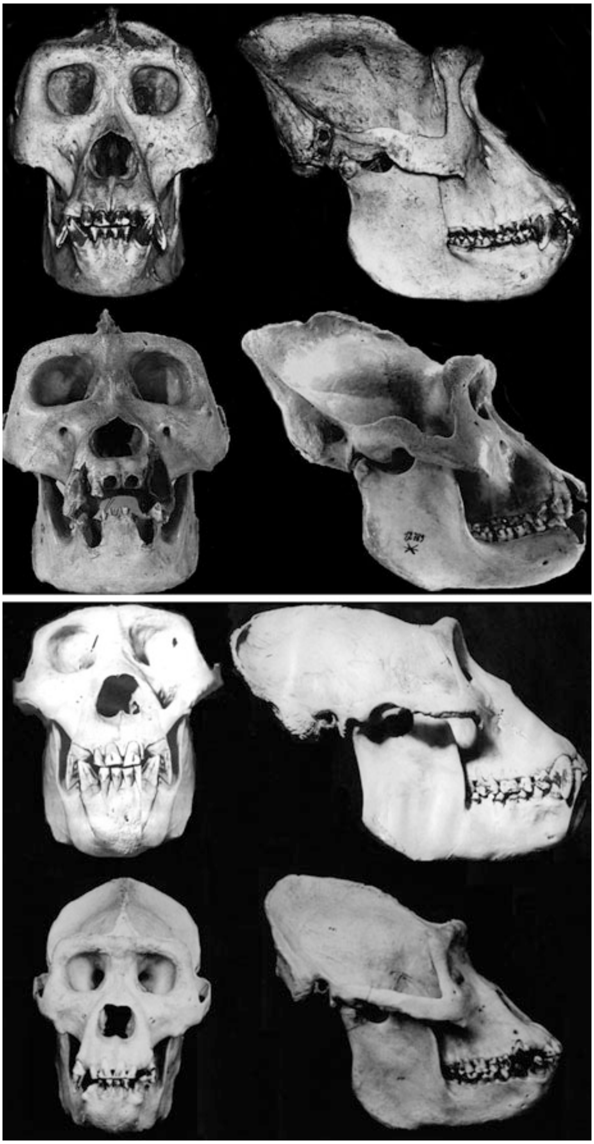

Fig. 6 *Top* (*Upper*) Frontal and profile views of *Gorilla gorilla gorilla* skull (Photograph courtesy of C.P. Groves). Groves). (*Lower*) Frontal and profile views of *G. g. beringei* skull (Photograph courtesy of C.P. Groves)

Early Hominid Sites in Africa," Vol. 1, "▶ Paleosols," Vol. 1, "▶ Quaternary Geology and Paleoenvironments," Vol. 1, "▶ Zoogeography: Primate and Early Hominin Distribution and Migration Patterns," Vol. 1, and ▶ Modeling the Past: Archaeology, Vol. 1). Taylor (2002) also provides a useful recent summary of African ape diets. Within a highly variable context of local preferences and seasonal fluctuations and with considerable overlap in the fruits exploited, gorillas are, broadly speaking, more folivorous than chimpanzees. Gorillas consume less fruit than chimpanzees and exploit leaves, pith, bark, bamboo, and terrestrial herbaceous items. The eastern mountain gorilla (*G. g. beringei*) is the most exclusively folivorous form; the western lowland gorilla (*G. g. gorilla*) exploits the most varied diet, with a significant fruit component. In contrast, chimpanzee diets are dominated by fruits, although it is unclear whether the bonobo (*P. paniscus*) exploits more terrestrial herbaceous vegetation than the common chimpanzee (*P. troglodytes*) (Taylor 2002).

Compared with the orangutan, African apes exhibit longer, lower, narrower neurocrania set at a lower level relative to the facial skeleton (klinorhynchy). The frontal contour is low and retreating, the parietal region flat, and the occipital more curved than in the large-bodied Asian ape. There is a prominent supraorbital torus that is usually continuous across the glabellar region as well as above each orbit, although in some *P. troglodytes* individuals it may be divided by a slight depression. A supratoral sulcus, its lateral limits defined by the anterior temporal lines, delimits the torus from the frontal squama. The orbits are subrectangular, usually broader than high, and interorbital breadth is greater than in the orangutan, reflecting the broader ethmoid of African apes. On the medial orbital wall, the ethmoid's orbital plate is reduced, and the ethmolacrimal suture is usually much less extensive than in the orangutan and in some individuals may be replaced by contact of the interposed frontal and maxilla. There is an extensive frontoethmoid sinus (Fig. 4). On the floor of the anterior cranial fossa, the frontal may separate the ethmoid from the sphenoid, more commonly in *Gorilla* (>50 %) than *Pan* (15 %). Frontotemporal contact predominates on the lateral cranial wall of the chimpanzee and gorilla, but sphenoparietal contact is common in the bonobo.

The root of the maxillary zygomatic process arises relatively close to the occlusal plane, above M^1 or M^2. In the chimpanzee, the zygoma's facial (malar) aspect is limited in height and breadth; in the gorilla, it is deeper and extends further laterally. In both apes, it is remarkably thin in sagittal cross section when compared with most early hominins but is strengthened by the sagittal angulation of its upper and lower portions. Rak (1983) has emphasized the structural importance of the zygomatic region as a transverse buttress, linking the lateral and medial components of the face and resisting masticatory forces. In both gorilla and chimpanzee, the zygoma's temporal process is sharply angled from its malar surface, with the zygomatic arches orientated parasagittally/posteriorly slightly divergent (*Pan*) and parasagittaly/posteriorly slightly convergent (*Gorilla*), reflecting differing ratios of mid-facial and bitemporal breadths in the two genera. The greater facial breadth in *Gorilla* means that the masseters, especially their anterior fibers, have a greater lateral component to their contraction than in *Pan*.

The zygomatic arch is thin in cross section but vertically deeper, its inferior border marked anteriorly for the superficial masseter fibers, and in *Gorilla* posteriorly scalloped for the origin of the muscle's deeper portion. A part of this, sometimes differentiated as the *zygomaticomandibularis* muscle, fuses with anterior *temporalis* fibers, to attach to the *temporalis* tendon, the coronoid process, and anterior ramus edge (Raven 1950; Sakka 1984; Aiello and Dean 1990). In mature male gorillas, the arch is reinforced sagittally in its mid-region by a "step" with convex upper border which increases its vertical depth compared with immediately adjacent areas and strengthened transversely toward its rear by the broad, flat base of the temporal's zygomatic process. Additional support against the masseter's pull is provided by the *temporalis* fascia, inserting on the upper border of the zygomatic arch; again, it is particularly extensive in male gorillas.

Anteriorly the face is braced against masseteric force by the zygomatic buttress (see above) and by the beam of the supraorbital torus, which links with the zygoma via its frontal process (Rak 1983). The greater facial breadth of *Gorilla* combined with its more marked postorbital constriction and so deeper infratemporal fossa means that the lateral component of the torus is unsupported behind by the anterior neurocranial wall and so is massively thickened vertically and sagittally, while the postorbital bar is broadened compared with *Pan*. These structures, the canine roots, and nasal septum also reinforce the palate and face against bending (sagittal), torsional (coronal), and shearing forces generated during biting by the anterior teeth. Such forces are highest rostrally and of greatest magnitude in large-jawed forms such as *Gorilla* (Preuschoft et al. 1986).

Within the nasal cavity, the incisive canal is wide and the fossae are broad and bowl shaped. In *Pan*, the extent by which the premaxilla overlaps the palate, and so the length of the incisive canal, is comparable to that in the orangutan, although the canal is angled more steeply than in the latter because of the African ape's less convex premaxilla (Fig. 2 upper right). In *Gorilla*, the overlap is much less and the incisive canal shorter, and there is always a distinct step in the nasal floor between premaxilla and palate (Fig. 2 lower right). In *Pan*, the step is much less marked and may be absent altogether in about one third of individuals, who evince a smooth floor comparable to that of the orangutan (McCollum and Ward 1997). In *Gorilla*, a long prevomer is interposed between the vomer and the premaxilla, with the inferior parts of both the former bones descending into the incisive canal, dividing its posterior wall and eventually partitioning it into two channels. A septal groove along the nasal sill is seen only in younger individuals; in adults, it is confined to the rear of the sill. In *Pan*, the prevomer is much smaller, and, while it descends into the incisive canal to divide the posterior wall, together with the vomer, complete partitioning into two channels is much less frequent than in *Gorilla*. Unlike the latter, a septal groove is present on the nasal sill in adults as well as younger individuals.

Fusion of the facial aspect of the premaxillomaxillary suture in chimpanzees begins prenatally and is usually completed before the permanent dentition is fully erupted, with the nasal aspect being completely fused around the eruption of M^2. Facial growth in *Gorilla* continues for longer, with both facial and nasal aspects of the premaxillomaxillary suture and the prevomeral-vomeral sutures remaining open until well into maturity (McCollum and Ward 1997). Accessory premaxillary sutures are also quite common (>20 %) in *Gorilla*, indicating separate ossification centers for the palate and facial components of the premaxilla (Schultz 1950).

The palate is long in both *Pan* and *Gorilla*; externally it is shallow anteriorly with no clear alveolar border but deeper along the postcanine row. Internally, the maxillary palatine process of *Pan* is distinctive in thickening anteriorly and containing the palatine recess, a medial extension of the maxillary sinus. Laterally the maxillary alveolar process is thin, with the contours of the tooth roots evident;

medially the process is thicker. Rak (1983) argues that the maxillary zygomatic process acts as a mid-palatal buttress, reinforcing the hard palate against shearing stresses generated between the chewing and balancing sides of the dental arcade, primarily from the latter's medial pterygoid muscle. Both medial and lateral pterygoids are particularly well developed in *Gorilla*.

As in the orangutan, the preglenoid plane of African apes is long, the articular eminence only slightly developed so the glenoid fossa is sagittally shallow, and the postglenoid tubercle is well developed. The roof of the glenoid fossa is coronally more horizontal than in the orangutan and the entoglenoid more distinctly differentiated from it, especially in *Gorilla*, where it is very large, extending beyond the level of the articular eminence and preventing any medial shift of the condyle prior to moving onto the preglenoid plane (Du Bruhl 1977). In some of these features and in temporal bone shape overall, *Pan* is more derived than *Gorilla* (Lockwood et al. 2004). Terhune (2012) notes that joint surfaces in the mandibular fossa are sagittally extended in chimpanzees, whereas in gorillas the surfaces are sagittally contracted and in orangutans intermediate, and that much variation is associated with morphologies that promote gape rather than bite force. A prominent temporomandibular ligament is present in *Gorilla* and is apparently variably developed in *Pan* (Aiello and Dean 1990).

In *Pan* species, the dentitions are basically similar, although *P. paniscus* teeth are smaller and less sexually dimorphic than those of *P. troglodytes*. A comparative study of root length development (Dean and Vesey 2008) revealed that in *P. troglodytes*, anterior tooth root growth rose quickly to higher rates and then plateaued, with the highest rates in canines, followed by incisors (the reverse of the *H. sapiens* pattern). In both modern humans and apes, molar tooth roots grew in a nonlinear pattern, with peak rates reducing from M1 to M3. A recent study (Boughner et al. 2012) showed no significant differences in the relative timing of permanent tooth crown and root formation in bonobos and chimpanzees. Similarly, dental topographic analyses that reflect contrasts in occlusal form related to diet among primate species identified differences between wear stages within subspecies in surface slope, relief, and angularity, but failed to differentiate between *Pan* subspecies (Klukkert et al. 2012). Discriminant analysis of size transformed and untransformed molar traits (Pilbrow 2006), however, yielded more effective separation (see below).

Smith et al. (2010) present data on crown and root formation in Taï Forest chimpanzees to evaluate claims that wild chimpanzees display delayed dental development compared with captive ones. They conclude that crown formation onset and development markedly overlap captive chimpanzees, whereas root development may be accelerated in captive specimens, and wild individuals fall near the middle or latter half of captive eruption ranges. Overall the authors conclude that while minor developmental differences are evident in some comparisons, the results do not show a consistent pattern of slower tooth formation in wild individuals. A later paper (Smith and Boesch 2011) extends the analysis to estimate that delayed tooth emergence in wild individuals is more moderate than previously recorded, averaging about 1 SD of the captive distribution, rising to 1.3 SD if age estimate criteria are relaxed; M_1 emergence is estimated at 3.66–3.75 years in wild chimpanzees. The authors point out that "wild" data are usually skewed, often deriving from diseased, debilitated, or otherwise pathologically affected corpses of immatures, who cannot be considered fully representative of a healthy population.

The maxillary incisors are curved mesiodistally, with I^1 larger than I^2, although the difference is smaller in *P. paniscus* than in *P. troglodytes*. In the mandibular incisors, these proportions are usually reversed. The upper canine is larger in males than females of both species; its mesial surface is more convex in *P. troglodytes* and, with the lingual surface, displays grooving absent in a small sample of *P. paniscus* (Swindler 1976). In the upper jaw, M^1 and M^2 are subequal in size, M^3 reduced, with the hypocone the smallest cusp and reducing progressively along the molar row. Reduction is more pronounced in *P. paniscus*, and the cusp may even be completely absent from M^1 and M^2 in some individuals, whereas it is always present on those teeth in *P. troglodytes*. The hypocone may be entirely absent on some M^3s of both species but is more weakly developed in bonobos (fully developed in 21 % of *P. troglodytes* teeth, compared with only 9 % of *P. paniscus*). The preprotocrista (anterior transverse crest between paracone and protocone) is more angled and transversely orientated in *P. paniscus*, running from closer to the protocone to mesial of the paracone rather than to its tip, as in *P. troglodytes*. The distoconule, an accessory cusp between hypocone and metacone, is absent in bonobos but present in all chimpanzee subspecies, generally at low frequency but up to 40 % of M^3 in one collection of *P. t. troglodytes* (Kinzey 1984). A lingual cingulum is often present, most frequently on M^1 but larger on M^3 and better developed (longer distally) in bonobos than chimpanzees.

M_2 is usually the largest mandibular molar, M_3 the smallest; a Y-5 cusp pattern is almost universal on M_1 but only occurs in <50 % of cases on M_3. The talonid is extensive, and a buccal cingulum is rarely (5–10 %) present (Swindler 1976). In *P. paniscus*, the metaconid is usually opposite the protoconid rather than distal to it as in *P. troglodytes*, resulting in a greater relative distance and a deeper groove, between the metaconid and entoconid in the former species (Kinzey 1984). Nonetheless, the two cusps are closely adjacent compared with *Gorilla*. The hypoconulid is usually slightly buccally positioned in chimpanzees and more centrally (lingually) placed in bonobos, while a tuberculum sextum is often present between hypoconulid and entoconid in the former species but more rarely in the latter, which Kinzey (1984) suggests may be associated with the more lingually positioned hypoconulid. *Pan* molars are often wrinkled but not to the extent seen in *Pongo*. Skinner et al. (2009) demonstrated that shape contrasts in the enamel-dentine junction of M_1 and M_2, especially in the relative height and position of the dentine horns, dentine crown height, and the shape of the base, serve to differentiate *Pan* species and subspecies, so extending the utility of teeth with worn occlusal surfaces for systematic identification.

Central to lateral incisor proportions in *Gorilla* are comparable to those of *Pan*, although compared to the postcanine teeth, the incisors are much smaller. Canines are large and markedly dimorphic, in the female projecting less beyond the other teeth. Contrary to the sequence in *Pan*, but like the orangutan, P_4 erupts before P_3, which is sectorial but with a vestigial metaconid, a large distal fossa for the P^3 protocone, and a well-developed lingual cingulum. On the upper molars, the hypocone is larger relative to the other cusps than in other apes; the mesial fossa is narrow, the distal one wide, and a lingual cingulum is usually present. On the lower molars, the metaconid and entoconid are widely separated, and there is an extensive talonid basin to receive the large protocone of the upper molar. A tuberculum intermedium is often present between metaconid and entoconid on M_1 and is almost invariably so on M_2 and M_3; a tuberculum sextum may also occur between the entoconid and the buccally positioned hypoconulid. A buccal cingulum is usually present on M_1, on about 50 % of M_2, and on a minority of M_3; overall, it is both more common and better developed in *Gorilla* than in other extant apes. In the upper jaw, M^2 is usually the largest tooth; in the lower jaw, M_1 is the smallest, with M_2 and M_3 subequal (Swindler 1976). Dimorphism in dental dimensions is extensive in *Gorilla*, with most teeth differing significantly in size between the sexes. Tooth enamel is smooth, without the wrinkling displayed by *Pongo* and *Pan*. Supernumerary molars may occur, more often in the upper jaw than the mandible.

McCollum (2007) investigated the relationships of diet, incisor wear, and incisor crown breadth in western lowland gorillas and chimpanzees, confirming that incisor dimensions are broadly similar in the two apes. She found that incisor wear was greater in the more folivorous gorilla than in the frugivorous chimpanzee, questioning Hylander's suggestion that larger incisors and enhanced resistance to wear are associated with frugivory and the need for greater incisal processing of large fruits. Using a more extensive database, however, Deane (2009) has demonstrated that increased mesiodistal incisor length and greater incisor crown curvature are correlated with greater frugivory, so reaffirming Hylander's proposed link. Hard-object frugivores show greater curvature than soft-object frugivores, while mixed folivores/frugivores display intermediate degrees of curvature compared with frugivores and folivores. Frugivores also have mesiodistally wider I_1, I_2, and I^2 crowns relative to their labiolingual lengths, while folivores have labiolingually broader crowns than mixed folivore/frugivores, and those of hard-object frugivores are broader than those of soft-object frugivores. McCollum and Deane's conflicting findings may result from their differing databases – two species with overlapping diets in McCollum's study compared with a larger number of taxa and wider dietary spectrum in Dean's case – and in their scaling to adjust for body size differences.

Cray et al. (2008) have shown that cranial vault suture closure mirrors consensus phylogeny, with *H. sapiens*, *P. troglodytes*, and *G. gorilla* sharing a similar lateral-anterior closure pattern, while *G. gorilla* displays a distinct vault pattern that follows a strong posterior to anterior gradient. *P. troglodytes* is thus more like *H. sapiens* in suture synostosis, in accord with these two species sharing a common ancestor after the *Gorilla* clade split off. *P. paniscus* was not included in the analysis.

Temporal muscles are well marked on the cranial walls in the chimpanzee, often forming raised ridges which in mature males may occasionally meet to form a sagittal crest. In male gorillas, a pronounced sagittal crest is present, thickened at the top where the two temporal laminae abut, and highest toward the rear of the vault where it unites with the nuchal crest, forming a beak-like posterior projection at the rear of the skull. The crest, besides enlarging the area for *temporalis* attachment, improves the power of the cheek teeth by increasing the relative length of the muscle insertion axis compared with the load and also serves to increase the effective height of the neurocranium, thereby enhancing its resistance to the vertical forces generated during mastication (Davis 1964).

A compound T/N crest (Robinson 1958) forms laterally in chimpanzees from the juxtaposition of the temporal and nuchal muscles, but these diverge medially, and there the perimeters of the temporal and nuchal muscles are marked by lines, slightly raised ridges, or a simple nuchal crest. In male gorillas, the nuchal muscles develop medially as well as laterally beyond the neurocranium proper, producing a compound T/N crest uniting with the sagittal crest as above and resulting in an extensive, triangular-shaped nuchal area.

Temporalis fibers originate from the lower part of the nuchal crest's anterior surface but do not attain its rim, which provides attachment for the *occipitofrontalis* scalp muscle (Sakka 1984; Aiello and Dean 1990). Medially *trapezius* and laterally *sternocleidomastoideus* insert on the posterior rim of the nuchal crest, with below these the rhomboids (medially), and the fleshy, laterally extensive *splenius capitis* muscles. Deep to these is the heavy *semispinalis capitis*, which may be divisible into medial, thick biventer, and more lateral, straplike, complexus portions (Aiello and Dean 1990), although this separation is said to be uncommon in *Pan* (Swindler and Wood 1973) and is not indicated in Raven's (1950) account of *Gorilla* anatomy.

On the cranial base, *rectus capitis lateralis* lies immediately lateral to the mid-rear portion of the occipital condyle in *Gorilla* and *Pongo* and to the front mid-portion of the condyle in *Pan* (Dean 1984; Raven 1950). It is unclear whether the rather more anterior insertion of the muscle in the chimpanzee reflects individual variation or a specific trait. Just lateral and slightly posterior to this muscle is the digastric; see above for its distinctive form in the orangutan. Just in front of the foramen magnum and close to the midline are the closely adjacent *rectus capitis anterior* muscles, and ventral to these the *longus capitis* muscles. The basilar suture fuses early in the African apes and the orangutan, severely limiting its utility for determining individual age (Poe 2011).

Nishimura et al. (2006) have documented vocal tract growth and development in three chimpanzees. In early infancy, they show rapid laryngeal descent with consequent changes in vocal tract proportions as a result of descent of the laryngeal skeleton relative to the hyoid. Subsequently, the hyoid also descends relative to the palate, maintaining rapid laryngeal descent, as in humans. They conclude that descent of the larynx evolved before the *Pan*-hominin split for a function unrelated to speech and that human speech capabilities resulted from facial flattening rather than laryngeal descent.

Individual Species Morphology and Intraspecific Diversity

Pan

Pan troglodytes

The commonly recognized subspecies may be distinguished cranially as below, based primarily on Groves (2001).

P. t. troglodytes possesses a very broad head combined with a comparatively narrow muzzle, a continuous, straight, medially thickened supraorbital torus, more concave facial profile, and more gradually sloping occipital than other subspecies. On the medial orbital wall, ethmo-lacrimal contact is very common, while supernumerary bones on the lambdoid suture are rare, as are multiple infraorbital foramina.

P. t. verus also has a broad, rather flat-topped cranium but a broader muzzle, a less sharply concave facial profile, and a more steeply curved occipital. The supraorbital torus is arched over each orbit and is laterally well developed. Ethmo-lacrimal contact is very rare, while additional bones at lambda and along the lambdoid suture are very common. The frequency of a single infraorbital foramen bilaterally is higher than in other subspecies.

P. t. schweinfurthii has a more rounded skull than other subspecies, with an elongated, gently sloping occipital. The facial profile tends to be straight or only slightly concave, and the muzzle narrow, although interorbital breadth is high. The straight, continuous supraorbital torus is thinner than in other subspecies, especially laterally, but is prominent at glabella. Multiple infraorbital foramina are very common, and frontotemporal contact at pterion virtually universal. In cranial nonmetric traits, generally it resembles *P. t. troglodytes* but is rather smaller and less sexually dimorphic than that subspecies. Despite this, Angst (quoted in Groves et al. 1992) has reported a higher average cranial capacity for *P. t. schweinfurthii* – 420 cm^3 – compared with virtually identical capacities for *P. t. troglodytes* and *P. t. verus* (401 and 404 cm^3, respectively). Highly variable in size and cranial proportions, *P. t. schweinfurthii* may incorporate more than one subspecies.

P. t. vellerosus is a recently recognized subspecies from Nigeria to Cameroon (Gonder et al. 1997), identified on mtDNA sequencing that showed it to be a sister taxon of *P. t. verus*. Cranially it is unlike *P. t. verus* but similar to *P. t. troglodytes* and *P. t. schweinfurthii* in its high frequency of ethmo-lacrimal contact and low frequency of Wormian bones at lambda and along the lambdoid suture (Groves 2001).

A study of chimpanzee molar development (Smith et al. 2007) indicated marked within cusp, between cusp, and between tooth variation in enamel formation times and in cuspal initiation and completion sequences, pointing to the need to take account of significant variation when interpreting hominoid and hominin developmental data. In contrast, discriminant analysis of upper and lower molar morphometrics (Pilbrow 2006) to assess the efficacy of dental evidence in distinguishing chimpanzee populations differentiated on geographical criteria (river boundaries) provided more consistent findings. The results showed clear distinction of *P. paniscus* (see below) and *P. troglodytes* at all molar positions, while within the latter *P. t. verus* was distinct from other *P. troglodytes* populations, *P. t. vellerosus* was also clearly differentiated, and *P. t. troglodytes* and *P. t. schweinfurthii* were dentally similar.

Pan paniscus

Bonobos are characterized by relatively smaller heads and teeth than common chimpanzees, but by comparably sized upper limbs, rather lighter, more slender trunks, and heavier hind limbs (Susman 1984; Zihlman 1984). The bonobo skull is smaller, smoother, and more lightly built than that of the chimpanzee, the mandible appreciably shorter, and the face considerably less prognathic and reduced in height (Fig. 5). Reflecting the less projecting face and jaws, the cranial base is more tightly flexed, with a mean angle of 140° compared with 145° in the chimpanzee (Cramer 1977). This flexion results from a basicranial growth pattern to adulthood in *P. paniscus* that resembles that of *P. troglodytes* curtailed at the subadult (M^2 eruption) stage (Laitman and Heimbuch 1984; see also below). The bonobo supraorbital torus is thinner and the supratoral sulcus weaker, while the frontal squama rises (and the occipital descends) more steeply than is usual in *P. troglodytes*. It is more common (57 %) for the sphenoid and parietal to suture at pterion (contrast *P. troglodytes* above), while on the orbital wall frontomaxillary contact is more frequent than in chimpanzees (24 % and 9 %, respectively, Cramer 1977). Following CT scanning, Balzeau et al. (2009a, b) provide further information on the type specimen of *P. paniscus*, including details of its internal cranial anatomy.

While bonobos exhibit some canine dimorphism, there are only very limited differences between sexes in the size of the incisors and cheek teeth (see above). Similarly, mean endocranial capacity is virtually identical in males and females at c. 350 cm^3 compared with 404 and 375 cm^3, respectively, in *P. troglodytes* (Cramer 1977). The nuchal area may be bounded by a low ridge or line, but a true crest with sharply defined rim is absent, as is any sign of sagittal cresting. Consistent with its more neotenous form, *P. paniscus* shows earlier closure of the facial component of the premaxillary/maxillary suture than *P. troglodytes* and much higher frequency of a completely open palatal component (>93 % cf. 19 %, respectively, of individuals with M^1 erupted; Braga 1998). This early synostosis results in a vertically and horizontally shorter face and reduced dental arch, consistent with the bonobo's significantly smaller incisors, compared with *P. troglodytes*. Kinzey (1984) notes the greater degree of incisor wear in *P. paniscus* than *P. troglodytes*, which he suggests may be related to a greater incidence of pith and leaf petioles in the diet; he also speculates that the combination of a more transversely orientated and angled preprotocrista, with a more mesially sited metaconid and deeper groove between protoconid and hypoconid into which the crest occludes (see above), produces a more efficient shearing mechanism that again may reflect a more folivorous dietary component in bonobos.

Comparison of small samples of immature captive and wild female *P. paniscus* with *P. troglodytes* showed similar patterns of skeletal fusion in the two captive groups with the pattern of tooth eruption to bone fusion also generally consistent between species save for minor variations in late juveniles and subadults. While displaying similar patterns, direct age comparisons showed skeletal growth in the captive bonobo group to be accelerated compared with both captive and wild *P. troglodytes* samples (Bolter and Zihlman 2012).

Morphometric studies illustrate the relative homogeneity of chimpanzee cranial form compared with other great apes. While usually distinguishing *P. paniscus* from *P. troglodytes*, differentiation within the latter is, not unexpectedly, less secure, with extensive overlap between subspecies; see, for example, Shea and

Coolidge (1988). These authors found that discrimination just about reached the subspecies threshold and that separation was considerably less than in orangutans or gorillas (see below). They considered that this comparative uniformity might reflect a more recent differentiation of *P. troglodytes* subspecies, more frequent or extensive contact – and so gene flow – between them, marked ecological flexibility for the species overall so precluding close matching of subspecific features to habitat, or any combination of these. A subsequent study (Groves et al. 1992), with specimens sorted by location rather than subspecies, produced neither meaningful geographic patterning nor subspecific grouping among males. Female crania, however, exhibited better separation, with *P. paniscus* distinct, *P. t. schweinfurthii* grading geographically toward *P. t. troglodytes*, and with evidence for east–west differentiation within *P. t. schweinfurthii* based on facial proportions.

Shea et al. (1993) compare the results of both raw and size-adjusted analyses. For the former, there is 100 % correct classification for *P. paniscus* females and about 75 % correct classification for *P. troglodytes*, of which *P. t. verus* and *P. t. schweinfurthii* are furthest apart, according with their geographic separation. Confining the analysis to *P. troglodytes*, however, removes this geographic gradient, with maximal separation now between *P. t. troglodytes* and *schweinfurthii*. As expected, size adjustment reduces separation of *P. paniscus* from *P. troglodytes*, so that the distance between *P. t. verus* and *P. t. schweinfurthii*, now the most widely divergent subspecies, approaches that between the latter and *P. paniscus*. Principal Components Analysis shows *P. paniscus* clustering with immature *P. troglodytes* crania along PC 1, indicating their common growth trajectories and emphasizing that shape contrasts between bonobo and chimpanzee reflect the smaller size and truncated growth of the former relative to the latter, within which the major differences between *P. t. troglodytes* and *P. t. schweinfurthii* are also due to size and associated allometric factors (see below).

Separate analysis of mandibular variation in *Pan* accords generally, but not completely, with the above (Taylor and Groves 2003). Mandibular separation within *P. troglodytes* is less than that within *Gorilla*, but contrasts between *P. paniscus* and *P. troglodytes* are greater than *Gorilla*, and there is clear separation of bonobos and chimpanzees. There is extensive overlap of *P. troglodytes* subspecies, maximally between *P. t. schweinfurthii* and *P. t. troglodytes*, and greatest distinction between the latter and *P. t. verus* (contrast to Shea et al.'s cranial finding of greatest overlap between *P. t. troglodytes* and *P. t. verus*). Size adjustment again reduces separation, so that bonobos, while remaining the most distinctive, now partly overlap with chimpanzees; and *P. t. verus*, while still the most isolated of chimpanzee subspecies, is now furthest from *P. t. schweinfurthii* (as on the cranial data). *P. t. verus's*; distinctiveness on mandibular traits, while relatively slight (Taylor and Groves 2003), nonetheless accords with Braga's finding (1998) that premaxillomaxillary suture closure differs significantly between *P. t. verus* and other subspecies, with *P. t. verus* displaying later complete closure of the suture's facial component and earlier closure of its palatal component compared with *P. t. troglodytes* and *P. t. schweinfurthii* (Braga 1998). This points to a longer, deeper lower face in *P. t. verus* than other subspecies.

A recent morphometric study of mandibular form (Robinson 2012) broadly accords with Taylor and Groves' findings: size-adjusted corpus shapes in *P. paniscus* and *P. troglodytes* could be assigned with 93 % accuracy, with much of the shape differences size related, but subspecies could only be correctly identified <75 % of the time. Robinson's findings indicate symphyseal shape to be especially informative in distinguishing *Pan* species, with potential implications for hominin systematics.

Zihlman et al. (2008) present cranial and postcranial data on 25 *P. t. verus* individuals of known age and sex from Taï National Park, Cote d'Ivoire, and compare them with a *P. t. schweinfurthii* sample from Gombe National Park, Tanzania, with *P. paniscus* as an additional comparator. Taï males and females differ in cranial capacity and, as do the Gombe sexes, in facial dimensions. The Tai sample has a smaller cranial capacity, longer palate and mandible, and greater trunk dimensions and limb lengths; most variation is in females, with males differing only in humeral and femoral lengths. A further study by Neubauer et al. (2012) of endocranial volumes (EV) in an ontogenetic series of Taï forest chimpanzees showed brain size to increase rapidly during early ontogeny and for sexual dimorphism in EV, with males larger than females, to be evident before adult EV was attained. The mean adult EV in this Taï Forest sample was just under 380 cm^3.

Gorilla

Most accounts of *Gorilla* cranial diversity are based on Groves' highly influential morphometric analysis of variation in 45 traits from >700 gorilla skulls, grouped by origin into 19 and 10 geographic localities for crania and mandibles, respectively (Groves 1967, 1970). D^2 values were calculated for each of the ten cranial and six mandibular representative variables, allowing the localities to be grouped into eight larger regions which could be further combined on the basis of intra- and intergroup differences into three clusters: a relatively homogeneous western cluster (four regions, of which the Cross River sample was rather more distant from the other three), a distinctive eastern group from the Virunga volcano region, and a further eastern group (three regions). These correspond to the western lowland gorilla (*G. g. gorilla*), the eastern highland gorilla (*G. g. beringei*), and the eastern lowland gorilla (*G. g. graueri*) (Fig. 6).

G. g. gorilla is the smallest subspecies, with fairly broad face, small jaws and teeth, a short palate, a single mental foramen under P_3 or P_4 (more usually under the latter), and a jaw condyle without a cleft. *G. g. graueri* is the largest subspecies, with a high, narrow face; larger jaws and teeth; and a longer palate. The mental foramen is often multiple and set under P_3, while the jaw condyle is often cleft. The mountain gorilla, *G. g. beringei*, is distinguished by a low, broad face; very large jaws and teeth; a very long tooth row and palate; anteriorly sited (under C or P_3) multiple mental foramina; and a jaw condyle that is usually cleft.

Stumpf et al. (1998), adjusting for size, demonstrated that the Cross River sample was more distinctive than Groves' original analyses indicated, so providing support to the growing movement advocating its recognition as a further subspecies, *G. g. diehli* (see Sarmiento and Oates 1999, 2000; Groves 2001, 2003). *G. g. diehli* is distinguished by its shorter skull, shorter molar row, narrower palate, shorter cranial base, and more steeply angled nuchal plane than other western gorillas, which Sarmiento and Oates speculate may be associated with a diet of smaller, drier, and harder food items than that of other western gorillas.

A further reanalysis of Groves' data (Stumpf et al. 2003) confirmed a primary east–west separation on the latter's smaller values for palatal and tooth row lengths, nasal aperture and nasal bone breadths, lateral facial height, and supraorbital torus thickness. They also demonstrated the distinctiveness of the Cross River and Virunga populations from other west and eastern groups on the basis of their narrower interorbital breadths, narrower palates, and reduced lateral facial height. Analyses restricted to the western populations further indicate the distinctiveness of *G. g. diehli* on overall and neurocranial lengths, bicanine and bimolar breadths, interorbital and neurocranial widths, palatal length, and medial and lateral facial heights. Stumpf et al., however, emphasize that the fundamental distinction is between east and west *Gorilla* populations, with the corollary that *G. g. graueri* is more closely related to *G. g. beringei* than it is to western lowland gorillas. The implications of this, together with recent data from molecular and other studies, have led Groves (2001, 2003) to revise his earlier taxonomy and to differentiate western and eastern gorillas at the species level as *G. gorilla* (*G. g. gorilla* and *G. g. diehli*) and *G. beringei* (*G. b. beringei* and *G. b. graueri*), respectively. This also accords with the zoogeographical evidence, but for consistency with other sources referred to herein, we retain the traditional single species classification.

Leigh et al. (2003), however, apply Wright's F_{ST} (an indicator of microdifferentiation, measuring the extent to which subdivision within species – i.e., between subspecies – departs from random mating) to Groves' craniometric data and to discrete trait variation and reach different conclusions. Their approach requires assumptions about population sizes and the heritability of craniometric traits but is considered to be robust, especially, when subspecies sizes differ markedly, as they do in *Gorilla*. F_{ST} calculated from the craniometric data yields unexpectedly low levels of between group variation, only c. 20 % between subspecies compared with 80 % within subspecies assuming equal population sizes. Adjusting for different population estimates between the subspecies results in even lower values of F_{ST}, with correspondingly more variation within subspecies. F_{ST} derived from discrete trait analysis gives rather higher, but still modest, levels of divergence. Leigh et al. argue that much gorilla variation reflects ontogenetic changes and sexual dimorphism, and as such is intra-subspecific, and that their results offer no support for differentiating eastern and western gorillas at the specific level. See also Albrecht et al. (2003) for a detailed analysis of *Gorilla* cranial diversity at locality, deme, subspecies and species levels, and its potential evolutionary and sociobiological implications. Interestingly, genetic data indicate much deeper levels of differentiation among African ape species than the morphological evidence does (Gagneux et al. 1999; Lockwood et al. 2004).

Caillaud et al. (2008) explore the possible sociobiological basis for sexual dimorphism – specifically male body size and head crest development – in *G. g. gorilla*, through photogrammetry and field observations. Their findings show the number of females belonging to a mature male correlates with head crest size, body length, and musculature and that female numbers at male-male encounters, where larger individuals could be expected to be at an advantage, strongly affect the number of male agonistic displays. Exaggerated male traits therefore convey a mating advantage, whether through male-male fighting or female mate choice. Similar drivers may well be influencing the evolution of dimorphism in other, larger-bodied gorilla taxa.

Breuer et al. (2012) also explored the relationships of body length, crest size, and gluteal muscle size with long-term male reproductive success in western gorillas. They found that all three traits correlated with the average number of mates per male, but that only crest size and gluteal development significantly correlated with offspring survival and the annual rate of siring offspring who survive to weaning.

Dental variation in *Gorilla* is considerable: molar shapes and cusp proportions, relatively invariant within subspecies, differ between subspecies, as do tooth dimensions (Uchida 1998a). Male (but not female) *G. g. beringei* canines are larger than those of *G. g. gorilla* and *G. g. graueri*. In the postcanine dentition, *G. g. graueri* is, surprisingly, significantly larger than *G. g. beringei*, which is larger than *G. g. gorilla*. While upper molars of *beringei* show B-L enlargement, those of *graueri* are expanded in both length and breadth. *G. g. gorilla* has wider incisors relative to molar length than the eastern subspecies, while *G. g. beringei* displays higher crowned cheek teeth with sharper cusps and ridges than *G. g. gorilla*. *G. g. graueri* has a relatively smaller talonid on P_4 and, together with *G. g. beringei*, has larger distal cusps on the upper and lower molars than *G. g. gorilla*. Patterns of dental sexual dimorphism differ among gorilla subspecies: *G. g. beringei* displays greatest dimorphism in canine and lower molar size, *graueri* greatest dimorphism in upper molars, with *G. g. gorilla* least dimorphic both in canines and molars. This reflects a larger canine relative to molar size in females of this subspecies, which Uchida considers to reflect heightened female-female competition, possibly related to greater frugivory. She stresses the importance of local dietary adaptation influencing tooth form and proportions, with considerable variation but with more extensive frugivory in *G. g. gorilla* and lowland *G. g. graueri* than in highland populations of that subspecies and *G. g beringei*.

Similarly, Pilbrow (2010) has analyzed molar morphometrics to assess gorilla geographical diversity. Her results support species distinction between *G. gorilla* and *G. beringei*, with subspecies *G. g. diehli*, *G. g. gorilla*, *G. b. graueri*, *G. b. beringei*, and a possible further subspecies, *G. b. rex-pygmaeorum*; dental metrics thus accord with other evidence for gorilla population diversity. Dental separation increased with altitude differences but not geographical distance, so that altitudinal segregation better explains gorilla population divergence better than isolation by distance. Pilbrow argues that the historic center of gorilla distribution was West Africa and that Plio-Pleistocene climatic oscillations combined with mountain building promoted drift and population differentiation. Further analyses of the gorilla masticatory system are discussed below.

Allometric and Biomechanical Studies

The greater size of the gorilla relative to the chimpanzee is an instance of peramorphosis (Shea 1983c). Length of maturation is comparable in all three African ape species, but gorillas grow much more rapidly and to greater sizes than chimpanzees, while bonobos grow somewhat more slowly than chimpanzees (rate hypermorphosis) to rather lesser sizes (although there is considerable overlap); within each species, males grow for longer than females (time hypermorphosis). The pattern indicates that the interspecies differences reflect selection for greater body size, perhaps associated with increasing terrestrial folivory rather than selection for delayed maturation (Shea 1983c).

Significant differences between *Pan* and *Gorilla* growth in body weight only become apparent after about 2 years, with gorillas pulling away increasingly strongly from the chimpanzee growth curve thereafter (Shea 1983d; Fig. 6). Since neural growth is predominantly prenatal/immediately postnatal, there is no corresponding increase in *Gorilla* brain size in later ontogeny; the natural consequence is that, while having absolutely larger brains than chimpanzees, gorillas have lower brain–body ratios and lower encephalization quotients, with male value particularly depressed compared with females. “In the case of the African pongid species . . . the developmental pathway utilized to increase body size ensures that relative brain size decreases as a consequence” (Shea 1983d, p 58). It follows that attempted explanations of behavioral and/or ecological contrasts between the species based on differences in relative brain size should be regarded with skepticism.

Shea (1983a, 1984) also summarizes evidence that the differences in body form between adult *P. troglodytes* and *P. paniscus* result from ontogenetic scaling. The extension of common growth allometries to different end sizes holds within the skull, trunk, and limbs but not between them, so that adult bonobos do not match any single stage in chimpanzee ontogeny. Relative to the latter, the *P. paniscus* skull is most strongly reduced in size, forelimbs and trunk less reduced, and hind limbs not reduced at all, so that for a given body size, *P. paniscus* has a smaller skull than *P. troglodytes*. This is turn results in a more paedomorphic cranial shape compared with the chimpanzee through the decoupling of growth rates for the head and body, with the former slowed relative to the latter – an instance of neoteny. The selective factors underlying this process are obscure, although Shea speculates that the reduced sexual dimorphism and different social organization of *P. paniscus* compared with *P. troglodytes* may be important drivers in the evolution of its distinctive cranial proportions.

A more recent morphometric study by Lieberman et al. (2007) also concluded that the bonobo skull is largely paedomorphic relative to the chimpanzee, but that not all shape differences between the species, particularly in the face, could be explained in such terms, and that other developmental differences were also responsible for the contrasts in form. Durrleman et al. (2012) document ontogenetic changes in endocranial size and shape in sizeable samples of *P. paniscus* (n = 60) and *P. troglodytes* (n = 59) aged on dental criteria. They identify in bonobos an early, strong anisotropic endocranial expansion and bending due to localized expansion of the frontal pole, occipital lobe, and superior parietal lobe, which contrasts with developmentally later endocranial expansion in the chimpanzee. Patterns of expansion also differ in magnitude between the species, with a phase of rapid increase in endocranial volume occurring later in chimpanzees than bonobos.

Earlier suggestions (Ackermann and Krovitz 2002) of a common cranial postnatal ontogenetic shape trajectory or of separate but parallel shape trajectories that merely accentuate differences established in early (prenatal) ontogeny have been refuted by Cobb and O'Higgins (2004), who show hominin postnatal shape trajectories to be divergent with differing shape changes between species, even in early postnatal ontogeny (Vidarsdottir and Cobb 2004). The directions of scaling trajectories between *Pan* species, however, are not significant (so changing postnatal facial shape in a similar manner from different starting points), whereas those between *Pan* and *Gorilla* are directionally distinct.

Cobb and O'Higgins (2007) explore the role of ontogenetic scaling in determining sexual dimorphism in the facial skeleton of African apes (*G. g. gorilla*, *P. paniscus* and *P. troglodytes*). Using geometric morphometric analysis, they found that on average males and females shared a common ontogenetic shape trajectory and a common ontogenetic scaling trajectory until around M2 eruption. Thereafter, males and females diverged from each other and from the common juvenile trajectories within each species, indicating ontogenetic scaling as a mechanism until around "puberty" and the development of secondary sexual characters, but that subsequent sexual dimorphism occurs through divergent trajectories and not via ontogenetic scaling.

In general, the degree of adult cranial sexual dimorphism is greater in the larger apes (gorilla and orangutan) than in the chimpanzee and bonobo. *Gorilla* males display more size and shape *variability* than females, and a similar difference appears to be present in *Pongo*, but not in *Pan* (O'Higgins and Dryden 1993). Most of the differences reflect greater male facial prognathism, in turn a consequence of canine dimorphism. Adult cranial dimorphism appears to result from distinct mechanisms in the African and Asian apes. Whereas in *Pan* and *Gorilla* cranial dimorphism follows from extending the growth period of males for most cranial proportions (Shea 1983c), in *Pongo* only about half the growth allometries exhibit this process, with the other half displaying accelerated growth in males compared with females (Leutnegger and Masterson 1989a, b).

Male and female chimpanzees display significant cranial size differences but no shape differences, perhaps because the period of extended growth is a short one and/or the scaling coefficients are minor, so resulting in insignificant shape differences given the comparatively modest size of chimpanzees. As with the bonobo-chimpanzee comparison above, these differing patterns of cranial dimorphism in the great ape genera have been linked to socioecological contrasts between them (O'Higgins and Dryden 1993); see also Caillaud et al. (2008) and above.

Shea has also explored allometric influences on African ape craniofacial and dental form and their relationships to diet using bivariate and multivariate techniques. Many facial proportions in the bonobo, chimpanzee, and gorilla exhibit ontogenetic scaling, i.e., a common pattern of size/shape change. There are also instances, however, where this does not obtain: for example, chimpanzees have shallower zygomatic roots, narrower bizygomatic breadths, smaller infratemporal fossae, and narrower anterior cranial bases than bonobos with the same basicranial lengths. In other words, these features are reduced in chimpanzees compared with the values expected in bonobos ontogenetically scaled to their sizes (Shea 1984). Similarly, in those features in which chimpanzees are reduced relative to bonobos, gorillas tend to be reduced relative to chimpanzees (Shea 1984). As Shea points out, such allometrically adjusted analyses point to the opposite conclusion from that usually drawn from the study of absolute skull sizes – cranially; bonobos are relatively the most robust, and gorillas relatively the most gracile of the African apes.

Additionally, gorillas have significantly longer and higher cranial vaults, higher orbits, and longer foramen magnums than chimpanzee crania of equivalent basicranial lengths. They also exhibit longer, more projecting nasal regions that are sited lower on the face, than comparably sized chimpanzees. As overall skull size increases in the sequence bonobo-chimpanzee-gorilla, the three species also exhibit relatively narrower faces and neurocrania, reflecting in the latter case, the fact that increased brain size results primarily from growth in length, not width, during the prenatal and early postnatal phases.

During late postnatal growth, occipital length and breadth in gorillas increase appreciably compared with chimpanzees, reflecting the development of sagittal and nuchal crests as a functional response to the enlarged temporal and nuchal muscles "outgrowing" their areas of attachment on the exterior cranial wall. This, in turn, is a consequence of the respectively positive and negative allometric relationships between splanchnocranial and neurocranial proportions and body size. Dental metrics indicate that gorillas have relatively smaller incisors and relatively larger cheek teeth than comparably sized chimpanzees, while, surprisingly, temporal fossa area (and so temporal muscle size) becomes relatively smaller across the three species as size increases. Despite these differences, the predominant pattern among the African apes is essentially one of similarity in craniofacial growth. Multivariate analysis yields a common allometry vector incorporating $>93\ \%$ of total variance confirming this general picture, with a second vector (3.4 %) distinguishing chimpanzees and gorillas.

Shea considers that the differences in midface proportions between *Pan* and *Gorilla* may reflect differences in soft-tissue function or dietary contrasts, although the influence of the latter is by no means clear. In fact, he notes that while dental contrasts between the two apes can fairly clearly be linked to diet, no significant reorganization of the face occurs, with its form being primarily determined by the endpoints of common allometric trajectories. This suggests that the face and masticatory apparatus may be less strongly coupled to diet than is the dentition and/or that chimpanzee and gorilla diets, while differing in their constituent items, may not differ appreciably in their physical properties, in particular the force required to process them. For Shea, the African ape masticatory complex provides an example of an integrated functional system preadapted to extension into new size ranges and dietary shifts.

Molar crown area scales positively in hominoids, so that larger forms have relatively as well as absolutely larger crown areas, associated with their generally increased folivory, primarily achieved through increased tooth lengths rather than breadths (Demes et al. 1986). There are associated increases in palatal and mandibular lengths and relative narrowing of upper and lower dental arcades in larger taxa. Allometrically determined snout elongation produces greater bite force in larger animals, by lengthening the horizontal distance between the mandibular joint and the molar row, which Demes et al. have shown scales with a mean value of c. +1.6 in hominoids. Bite force is maintained by lengthening the masticatory muscles' power arms, by increasing their cross-sectional area, or by a combination of these. The temporal muscle's power arm scales from +1.16 (male great apes) to +1.62 (female gibbons) and that of the masseters and medial pterygoids, which is strongly influenced by facial height, between +1.54 and +1.64. A rough estimate of *temporalis* cross-sectional area scales from c. +1.4 to +1.9, indicating that the greater load of the allometrically lengthened lever arm is more than matched in larger species by the positive allometry of the power arm and of muscle cross-sectional area and so muscle force.

Larger species produce more bite force for their size than smaller ones due to the allometric changes in masticatory biomechanics following from increased body size, a point neatly illustrated by Demes et al., who demonstrate that skulls of *H. klossi* and *P. paniscus* enlarged isometrically to the size of *H.* (*S.*) *symphylangus* and *G. gorilla*, respectively, produce lesser bite forces than the "real" latter two forms do. Bite pressure (bite force/crown area) is maintained if bite force increases at the same rate as crown area; broadly similar relationships for these variables hold within hylobatids and great apes, indicating that in hominoids, crown area and bite force increase at about the same rate, at least over the size range of extant taxa. Estimated bite pressure is generally greater in great apes than hylobatids, although the orangutan is an exception here. Bite pressure shows no obvious relationship to between-species differences in size or diet; interestingly, *P. troglodytes* males produce the greatest scaled bite pressure, exceeding even *G. gorilla* males. Within species, males generally produce greater pressures than females, although whether this is selected for (implying differences in food processing or paramasticatory activity between the sexes) or is a by-product of selection for larger body size is a moot point. Demes et al. make the important point that similar allometric relationships obtaining within hylobatids and great apes provide strong evidence that biomechanical constraints associated with increased body size elicit similar functional responses across the Hominoidea. This is strong presumptive evidence that they should also be applicable to fossil forms.

Ravosa (2000) undertook such a combined allometric analysis of mandible size and form in fossil and extant apes, comparing them with cercopithecoids. Deeper corpora counter parasagittal bending while the more robust cross sections of larger species, especially the fossils, counter axial torsion. The positive allometry of corpus and symphysis cross sections suggests increased masticatory stresses due to greater balancing side muscle activity during powerful mastication, probably reflecting a tougher, harder diet. In addition, the allometry of jaw length and breadth point to greater wishboning stresses at the symphysis at the end of the masticatory powerstroke, countered by a thicker symphysis and increased anterior jaw breadth. After allometric scaling, the most robust mandibles include *Proconsul africanus* and *P. nyanzae*, *Rangwapithecus*, *Turkanapithecus*, *Afropithecus*, *Ankarapithecus*, *Lufengpithecus*, and *Ouranopithecus*; the more slender include hylobatids, *Simiolus*, *Hispanopithecus laietanus*, *Pan paniscus*, and *P. troglodytes* (see also below).

In the broader context of fossil (as well as extant) hominoids, even *G. gorilla* has a comparatively low and slender corpus, only average symphyseal height and a slightly broader than expected symphysis for its mandible length. *Pongo* has a higher but rather thinner corpus than expected and a higher symphysis of expected width; *P. paniscus* has a corpus and symphysis of expected height but rather thinner than expected, while *P. troglodytes* has a shallower, narrower corpus and symphysis, although the latter is closer to the values expected on jaw length than the former. These findings have implications for the dietary reconstruction of fossil forms: many Middle/Later Miocene hominoids are notably more robust than modern apes and so are plausibly reconstructed as exploiting harder, more resistant food items requiring substantial force in processing, while the categorization of proconsulids as “frugivorous” may also well underplay the variety and toughness of their dietary items. Such reconstruction, however, is difficult to reconcile with the evidence provided by dental morphology and wear patterns in *Proconsul* and by some other aspects of jaw form (see below).

In some respects, hominoid and cercopithecoid mandibular cross-sectional scaling patterns are similar; smaller apes are notably gracile, resembling cercopithecine proportions, but larger ones have both deeper and relatively wider corpora more reminiscent of colobines to resist greater axial torsion during chewing – perhaps reflecting larger, more laterally placed masseters that contribute relatively more to unilateral mastication, together with the medial pterygoids. This is especially so in the largest apes which have absolutely and relatively very thick corpora exceeding colobine proportions, suggesting diets with at least comparable, and very possibly greater, physical properties of hardness and/or toughness.

Smaller apes also display symphyseal curvature comparable to cercopithecines, whereas, with increasing body size, curvature reduces to a shallower, colobine-like, arc, eventually falling below even that in the largest apes. This has traditionally been interpreted in dietary terms (frugivores requiring large incisors and so a wide anterior dental arcade), but the bulk of the fossil evidence points to diets other than frugivory. Ravosa (2000) therefore interprets the broader anterior dental arcade combined with a relatively thick symphysis as hominoid adaptations to resist concentrated wishboning forces at elevated levels resulting from a hard-object diet. The exception to this is *Afropithecus*, which has a notably narrow, tightly curved anterior mandible with, presumably, correspondingly concentrated wishboning forces, raising interesting issues about dietary composition and food processing activities in that genus. Again, findings from the dental evidence do not easily accord with those based on mandibular proportions.

More recently, Taylor (2002, 2003) has used morphometric methods to investigate masticatory variation in African apes as a function of dietary differences. She compared allometrically adjusted mandibular, cheek, and facial dimensions, quantifying masticatory parameters associated with bite force and load resistance in ontogenetic series of bonobo, chimpanzee, and gorilla, to test the hypothesis that more folivorous forms would show greater development of these features.

The results are complex. Unsurprisingly, all species show allometric increases during growth in traits indicating improved muscle and bite force and the capacity to resist greater loads. Masticatory muscle sizes are especially strongly allometric. After adjusting for allometry, however, only a few traits differ consistently across African ape species as predicted by dietary preferences. A more resistant diet is generally correlated with a thicker mandibular corpus, although the thicker corpus of chimpanzees compared with bonobos is not matched by evidence of corresponding dietary differences. Compared with *Pan*, *Gorilla* has a relatively wider mandibular corpus to resist axial torsion, a wider symphysis so resisting "wishboning," a higher temporomandibular joint which contributes to improved mechanical advantage of the jaw lever and distributes forces more evenly along the cheek teeth, and a higher mandibular ramus, increasing the moment arm of the temporal and masseter muscles and providing a larger attachment area for the latter and the medial pterygoids. Moreover, within *Gorilla*, eastern gorillas exhibit greater values than western ones and also have larger masseter muscle than the latter, in accord with their more resistant diet.

Other analyses, however, do not conform to the pattern predicted from diet; for example, gorillas do not have the relatively deeper corpora expected to resist parasagittal bending (Hylander 1979a, b), and there was no regular association of the deeper symphysis providing increased resistance to bending and shearing forces with greater folivory (see also Ravosa's findings summarized above, although Demes et al. (1984) and Wolff (1984) considered the torsional resistance of the gorilla mandible "remarkable," and maximal at the symphysis). Overall, gorillas do not have the shorter deeper faces and more anteriorly positioned masticatory muscles predicted to improve the mandible's power arm ratio and to reduce bending moments in the face, and there was no consistent differentiation of bonobos and chimpanzees. Taylor concludes that while some of the distinctive craniofacial features of the African apes can plausibly be considered as dietary adaptations, the link is not especially strong. Dental development and allometric and other ontogenetic constraints are doubtless important influences, while more information is needed on the composition, variability, and especially the physical properties of ape diets. The equivocal nature of these results accords with those from some other studies; for example, despite their dietary contrasts, Rak's indices quantifying relationships between the palate, masseter origin, and their positions relative to the calvaria fail to discriminate between *Pan* and *Gorilla* (Rak 1983: table 3, p 25).

Further analysis of the *Gorilla* masticatory system with larger samples, and including *G. g. graueri* in the analysis, confirms and extends the earlier findings (Taylor 2003). *G. g. beringei* has a significantly larger face than the other two subspecies and differs from *G. g. graueri* in the same features that distinguish it from *G. g. gorilla* and which differentiate *Gorilla* and *Pan*. Despite being more folivorous, however, *G. g. graueri* does not differ from *G. g. gorilla* in those features, and *G. g. beringei* fails to express the full set of masticatory traits predicted by its diet. In this last respect, it may well be the case that an investigative model assuming optimization of each and every variable is simply inappropriate; rather than a spectrum or continuum of values for every trait, some may be more appropriately considered in terms of thresholds. For example, if food availability is not a constraint and provided the face is structurally sufficiently strong to resist masticatory forces, there seems little reason to suppose that selection will necessarily promote further shortening and deepening of the face in hominoid folivores to achieve “optimal” values, particularly if to do so will disrupt pervasive, well-established allometric trajectories. Covariation within a tightly integrated functional system, such as the head, is likely to impose multiple constraints on the variation of any given character or character complex.

Taylor et al. (2008) report a detailed analysis of the relationships between jaw form, diet, and food properties in orangutans, chimpanzees, and gorillas, using area moments of inertia and condylar area ratios to estimate moments imposed on the mandible to assess relative ability to counter mandibular loads. They took data on elastic modulus and fracture toughness of food types to derive food material properties and generated bending and twisting moments on the mandible to estimate minimally required bite forces. Based on food properties, they hypothesized improved resistance to mandibular loads in *Pongo p. wurmbeii* compared to African apes and in *Gorilla b. beringei* compared to *Pan t. schweinfurthii*. The predictions were, in fact, only applicable when bite forces were estimated from maximum fracture toughness of non-fruit, non-leaf vegetation; for all other tissues (fruit, leaves) and material properties, results were contrary to predictions. As food material properties changed, moments imposed on the mandible changed, so altering ratios of relative load resistance to moment, so that species appear over- or under-designed for the moments imposed on the mandible. Reliable estimates of average and maximum bite forces from food material properties accordingly require information about the physical properties of the full range of dietary items.

A recent study (Taylor and Vinyard 2013) incorporates data on masticatory muscle physiologic cross-sectional area (PCSA) and muscle fiber length and broadly confirms an allometric influence on masticatory power while underlining the need for caution when inferring chewing forces from skull form. Hominoid muscle fiber architecture reflects both absolute size and allometric influences; PCSA is close to isometry relative to jaw length in anthropoids but trends to positive allometry in hominoids. Extant large-bodied apes therefore probably generate absolutely and relatively greater muscle forces compared with hylobatids and monkeys, possibly reflecting changes in food composition, ingestive behavior, and/or increased emphasis on mastication as opposed to ingestion with greater body size. The study also revealed that craniometric estimates of masseter and temporalis PCSA may be seriously awry, underestimating the actual figures by >50 % in gorillas and overestimating masseter PCSA by up to 30 % in humans.

Given the lack of concordance in masticatory morphology and diet in living hominoids, and the discongruities between craniofacial morphology and dental evidence among fossil forms, detailed dietary reconstruction based on craniofacial form in fossil hominoids appears questionable. There seems no secure basis on which to go beyond the most general of statements about dietary properties. Shea's conclusions about the relative decoupling of masticatory morphology and diet in the African apes may be applicable to hominoids generally (see also Daegling and Hylander (1998, 2000) and Daegling (2004)). Dental evidence (crown proportions and morphology, crest development and structure, chemical composition, and wear patterns) may well prove a better guide to hominoid diets than the analysis of craniofacial form, no matter how elaborate the biomechanical models employed (Ungar 1998; Teaford and Ungar 2000). These provisos should be kept in mind in relation to the following summary of craniofacial form in fossil hominoids, which for its framework draws especially on the chapters by Harrison, Begun, Kelley, and Ward and Duren in Hartwig (2002).

Fossil Hominoids

Africa

Oligocene/Early Miocene African Hominoids

The splitting event between the two crown groups of the Catarrhini, apes and Old World monkeys, was an African phenomenon, as the earliest members of both lineages are found in sub-Saharan Africa. The earliest evidence for the divergence is known from late Oligocene (25.2 Ma) deposits in the Rukwa Rift Basin in southwestern Tanzania; *Nsungwepithecus gunnelli* shows evidence of bilophodont, a cercopithecoid synapomorphy, while *Rukwapithecus fleaglei*, from the same deposits, shares two dental traits with crown hominoids – M_2 hypoconulid positioned buccally and a hypoconid positioned opposite the lingual notch between the metaconid and the entoconid (Stevens et al. 2013). The dental similarities of the latter taxon with *Rangwapithecus* from the early Miocene of Kenya may suggest a similar dietary adaptation, namely, folivory (see below).

Kamoyapithecus

The other known late Oligocene catarrhine that has been considered a possible hominoid is *Kamoyapithecus*, from Lothidok, Kenya (Leakey et al. 1995). No explicit shared derived traits link the form with later hominoids. Although very little can be said about the maxillary bone preserved in the type specimen, the dentition is consistent with a high degree of anterior tooth use, albeit with thinner dental enamel than that seen in later, similarly sized forms, such as *Afropithecus*.

More extensive evidence from Early Miocene sites in East Africa indicates an array of forms, variously regarded as hominoid or non-hominoid (see chapter "▶ Fossil Record of Miocene Hominoids," Vol. 2). Evidence from the oldest (19–20 Mya) sites of Songhor and Koru (Kenya) points to predominantly tropical forest habitats, with later (16–17 Mya) sites on Rusinga Island (Kenya) ranging from flood plain to riverine contexts. The picture here is of drier, more seasonal environments than Songhor or Koru, but with persistent wooded conditions, varying from forest to deciduous woodland according to rainfall (Andrews 1996; Andrews et al. 1997). Similar habitats are indicated at the rather later Middle Miocene sites of Maboko Island (15–16 Mya) and Fort Ternan (14.5 Mya; see below).

Micropithecus

The small (ca. 3.5 kg) *Micropithecus* contrasts the bulk of the Early Miocene non-cercopithecoid fauna dentally in having relatively larger anterior teeth compared to the cheek teeth, broad incisors, and narrow premolars and molars, with only weakly developed occlusal ridges. It differs cranially from the similarly sized *Dendropithecus* in its shallow, broader palate and nasal aperture, short face and clivus, and moderately high and lightly built mandible corpus, with only modest symphyseal tori. Phylogenetic analyses (Rae 1993, 1997; Stevens et al. 2013) suggest that this taxon may be a stem hominoid, as it lacks some of the characteristic hominoid cranial synapomorphies. The frequency of dental pitting and pit shape in *Micropithecus clarki* (19–20 Mya) points to folivory (Ungar et al. 2004), while *M. leakeyorum* (15–16 Mya) shows similarities to the rather earlier *Simiolus enjessi* (16.5–18 Mya) that probably also reflect folivorous adaptations (Harrison 1989; Benefit 1991).

Proconsul

At least two broad cranial morphologies are represented among the Lower Miocene fossils. The genus *Proconsul* is particularly well known, with species differing in size and dental and gnathic details, but linked by fundamental similarities in craniodental morphology (Fig. 7). Knowledge of *Proconsul* is primarily based on the material recovered from sites on Rusinga Island, Kenya, including much of a skull in 1948 (Le Gros Clark and Leakey 1951) and a partial skeleton from 1951 and subsequently (Napier and Davis 1959; Walker and Teaford 1989; Walker et al. 1993) supplemented by other material. Initially assigned to the type species *P. africanus*, the 1948 and 1951 specimens were later transferred to *P. heseloni* (Walker et al. 1993; Walker 1997) on the basis of differences in dental size and morphology and in mandibular proportions and symphyseal reinforcement from the type of *P. africanus* from Koru.

Fig. 7 (*Upper*) Frontal and profile views of *Proconsul heseloni* cranium (Photograph © National Museums of Kenya). (*Lower*) Frontal and profile views of *Proconsul nyanzae* part face (Photograph © National Museums of Kenya)

Compared with later hominoids, the *P. heseloni* cranium is lightly constructed: the globular neurocranium largely lacks pronounced tori or crests, although the medial portion of the nuchal crest is evident above the steeply angled nuchal area, and the external occipital protuberance is located high on the skull rear. The frontal is short but broad, reflecting the limited postorbital constriction, while the superior temporal lines are prominent anteriorly and converge toward the vault rear but do not meet to form a crest. On the face, the premaxilla rises on either side of the nasal aperture, contacting the nasal bones above their tip, so excluding the maxilla from the rim of the nasal aperture, which narrows inferiorly between the central incisor roots above a short nasoalveolar clivus. Above it, the nasal bones are nonprojecting, long, and narrow, extending upward beyond the frontomaxillary suture and expanding in breadth in the glabellar region. There is a prominent jugum above the upper canine root and a shallow canine fossa. The lightly built zygomatic arch originates low down, curving backward and upward, and has a well-developed malar tuberosity. The subrectangular orbits are widely separated, surmounted by weak supraorbital ridges and with a slightly swollen glabella over a large frontal sinus (which may represent a frontoethmoid sinus; see Rossie 2005) between, but there is no distinct supraorbital torus.

The palate is long, rectangular, and shallow. A large, transversely broad incisive fossa joins directly with the nasal cavity, so there is no true incisive canal, and the hard palate is retracted from the subnasal alveolar process (Ward and Pilbeam 1983; McCollum and Ward 1997). There is a pronounced tuberosity on the alveolar process behind M^3. The maxillary sinus extends anteriorly to the premolars and laterally into the root of the zygomatic arch. The articular eminence and postglenoid process are well developed, and the auditory region has a tubular ectotympanic as in modern catarrhines, while the prominent, well-pneumatized mastoid process is coronally narrow and rather bladelike.

The mandibular symphysis exhibits a moderately to well-developed superior transverse torus but a much weaker and variable inferior torus, absent altogether in some individuals. The corpus displays limited lateral buttressing below the cheek teeth and shallows posteriorly; the relatively high ramus is lightly constructed, and the gonial region only slightly marked by muscle attachments. The slightly earlier, similarly sized and evidently closely related *P. africanus* differs from *P. heseloni* in numerous dental details, mandibular proportions, and symphyseal reinforcement: the *P. africanus* corpus is deeper anteriorly and posteriorly shallows more strongly, while the symphysis lacks an inferior transverse torus but bears a pronounced superior torus (Walker et al. 1993). An inferior transverse torus is also absent in the larger *P. nyanzae*.

Views differ on *Proconsul's* brain size and encephalization: Walker et al. estimated the 1948 cranium's capacity as 167 cm^3 and inferred that *P. heseloni* was more encephalized than modern cercopithecoids of similar size. Manser and Harrison (1999), however, using foramen magnum area as a size surrogate, estimated brain size as the markedly lower 130 cm^3 and close to the mean encephalization value for anthropoids. The endocast's relatively small frontal lobe and cortical sulcal pattern were considered primitive and cercopithecoid by Le Gros Clark and Leakey (1951) and Le Gros Clark (1962) but definitely not so by Radinsky (1974) who judged it hominoid and most like gibbons. More recently, Falk (1983) has argued that the sulcal pattern resembles that of extant New World monkeys, such as *Ateles*, rather than any group of catarrhines and approximates the inferred common ancestral sulcal pattern for Anthropoidea.

Relative shearing-crest lengths in those *Proconsul* species studied (*P. heseloni*, *P. nyanzae*, and *P. major*, the last sometimes referred to the genus *Ugandapithecus*; see below) are less than those of any extant ape and considered to indicate frugivory (Kay and Ungar 1997), while the proportion of pits to scratches on molar wear facets (37–39 %) also indicates soft-fruit eating (Ungar 1998; Ungar et al. 2004). Despite the findings of Ravosa (2000), see above, mandibular form and proportions are also compatible with this interpretation. At the symphysis, the prominent superior transverse torus and minimal or absent inferior torus produce a broadly triangular cross section, especially in larger individuals, resistant to torsional or bending stresses produced by medial (jaw opening) or lateral (masticatory power stroke) bending (Hylander 1984; Brown 1997). Below the cheek teeth, the corpus is relatively deep vertically and narrow coronally, and, while it may be reinforced by the rear of the superior transverse torus, the mylohyoid ridge, and the lateral eminence, there is relatively little change in cross-sectional shape along the corpus compared with other fossil apes (Brown 1997). This suggests chewing activity generating comparatively high vertical forces but only limited transverse or torsional forces during food processing.

It is also possible to infer aspects of the locomotor pattern of fossil taxa with reference to their cranial morphology via the semicircular canals of the middle ear; there is a general correlation between the radius of curvature of the organ of balance and the relative agility of primate taxa (Ryan et al. 2012). The ancestral catarrhine adaptation, judged from stem forms such as *Aegyptopithecus*, is that of a

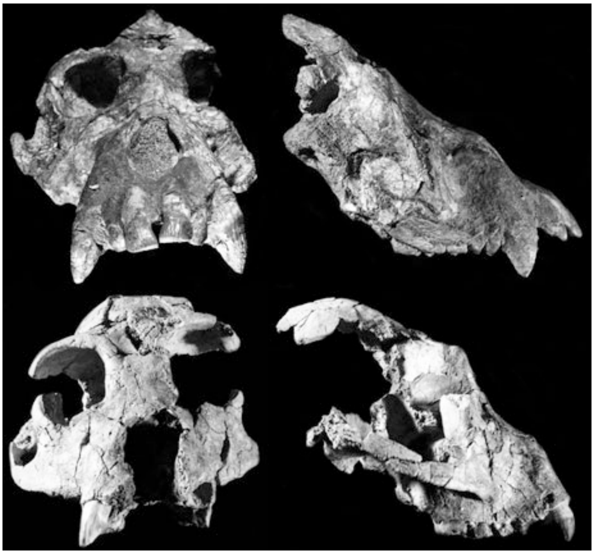

Fig. 8 (*Upper*) Frontal and profile views of *Afropithecus turkanensis* cranium (Photograph © National Museums of Kenya). (*Lower*) Frontal and profile views of *Turkanapithecus kalakolensis* cranium (Photograph © National Museums of Kenya)

medium-slow arboreal quadruped. *P. heseloni*, however, is characterized by larger semicircular canals, which suggests more agile, medium-speed locomotion, much like that seen in extant macaques.

One species previously assigned to *Proconsul* is now considered by some to be distinct at the generic level (Senut et al. 2000); *Ugandapithecus* is held to contain as many as four species of varying sizes and chronological ages (Pickford et al. 2009b), including the only-just-named *Proconsul meswae* (Harrison and Andrews 2009). The largest (and least contentious) of the species, *U. major* from Songhor in Kenya and Napak in Uganda, has little in the way of cranial material preserved, although all of the taxa assigned to *Ugandapithecus* are said to share a distinctive mandibular corpus that becomes shallower posteriorly. It is worth noting, however, that the generic distinction is not recognized universally (MacLatchy and Rossie 2005).

Afropithecus

The contemporary *Afropithecus turkanensis* contrasts markedly with *Proconsul* in its cranial form (Leakey and Walker 1997) (Fig. 8). The large face is dominated by the long domed muzzle and deep, flaring zygomatic processes. The projecting premaxilla forms a deep nasoalveolar clivus and extends up on both sides of the broad, oval nasal aperture to contact the narrow, medially elevated nasal bones. There is an extensive maxillary sinus; the shallow palate displays large paired openings for the incisive foramen. The canine roots form prominent juga; the root of the zygomatic process is deep, anteriorly inferiorly sloping, and originates low down on the face. The cordiform orbits are broader than high, inferolaterally sloping and widely separated. The glabellar region is prominent, the slender supraorbital torus curving above each orbit and delimiting a frontal trigon with its lateral limits marked by well-defined anterior temporal lines which merge to form a distinct sagittal crest. Postorbital constriction is marked, and the *temporalis* muscles are well developed. The mandibular corpus is very deep with a distinct fossa, while the ascending ramus is set obliquely to the corpus. The symphysis bears moderate superior and inferior transverse tori, a long and strongly sloping subincisive planum, and a low-genial pit, implying a deep, narrow tongue.

Overall facial proportions of *Afropithecus* are reminiscent of *A. zeuxis*, but absolutely much larger; finite element scaling analysis reveals marked size contrasts but minimal shape differences in the snout and some shape differences (but reduced size contrasts) in the zygomatic and maxillary tuberosity regions (Leakey et al. 1991). These authors conclude that the similarities in *Aegyptopithecus* and *Afropithecus* facial form indicate the persistence into the Early Miocene of a functionally integrated mosaic of features that characterized the primitive hominoid face. Benefit and McCrossin (1991) draw attention to craniofacial similarities between *Aegyptopithecus*, *Afropithecus*, and the Miocene cercopithecoid *Victoriapithecus*, indicating that many of these facial traits are primitive catarrhine characters rather than basal hominoid synapomorphies.

With its large, procumbent, and mesially inclined upper central incisors; stout, low-crowned canines; and cheek teeth covered with very thick enamel and complex wrinkling, *Afropithecus* has been compared, especially in its anterior dentition, to pithecines exploiting seeds and hard fruits, where the incisors crop food items and the large canines apply considerable force to puncture hard fruits, as in *Chiropotes* (Leakey and Walker 1997; Kinzey 1992). Cusp morphology, the high incidence of pitting in the single *Afropithecus* individual sampled – at 43 %, the highest of the early African forms studied (Ungar et al. 2004) – and a lack of prominent shearing crests on the cheek teeth are also consistent, like the anterior dentition, with frugivory.

Overall, Leakey and Walker (1997) conclude that *Afropithecus* was a sclerocarp forager. Other aspects of mandible reinforcement (e.g., strong basal buttressing, a pronounced lateral tubercle where the oblique line meets the corpus, a hollowed buccal surface above the mental foramen with a marked canine jugum anteriorly) that support this interpretation are also seen in *Sivapithecus* (see below) and probably reflect comparable biomechanical responses to reliance on food items with similar physical properties rather than any especially close phylogenetic link. The somewhat smaller but otherwise similar *Heliopithecus* from the early Middle Miocene of Saudi Arabia may be no more than specifically distinct from *Afropithecus* (Andrews et al. 1978; Andrews and Martin 1987).

Morotopithecus

The large (chimpanzee-sized) hominoid *Morotopithecus bishopi* (Gebo et al. 1997), based on the palate from Moroto initially assigned to *P. major* (Pilbeam 1969), resembles *Afropithecus* in many respects and may be congeneric with it. It is of

Early (20–21 Mya) or Middle (15–17 Mya) Miocene age, depending on ^{40}Ar^{39}/Ar dating (Gebo et al. 1997) or faunal correlation (Pickford et al. 1999). It combines an anteriorly broad palate with comparatively narrow, procumbent incisors offset by a pronounced diastema from the large, stout canines, whose massive roots form pronounced juga. The molars resemble those of *P. major* in their bunodont cusps, wrinkled enamel, and beaded lingual cingulum, but contrast in their relative sizes, while the anterior dentition is much larger and the interobital breadth narrower than in *P. major*. Overall the face is relatively long and narrow, with a broad nasal aperture, a short clivus, and an extensive maxillary sinus. The undoubted resemblances in face and dentition to *Afropithecus* may reflect dietary convergence in exploiting hard-cased fruits rather than phylogenetic propinquity. Postcrania referred to *Morotopithecus* resemble those of *Proconsul* in some respects but are also markedly more derived in the direction of modern hominoids in the lumbar, shoulder, hip, femur, and knee regions and point to forelimb suspension and slow brachiation, as well as climbing and quadrupedal activity in an arboreal habitat (MacLatchy 2004).

Nyanzapithecus

Nyanzapithecus is much less well known, but premaxillary and maxillary fragments of two species, *N. vancouveringorum* from the Early Miocene (17–18.5 Mya) and *N. pickfordi* from the Middle Miocene (15–16 Mya), indicate contrasts with *Afropithecus* in their smaller size; shorter faces; low, broad nasal apertures; and robust premaxillary regions (Harrison 2002). These species and the rather smaller Middle Miocene *N. harrisoni* (13–15 Mya) display broad, strongly built upper and lower incisors, while the cheek teeth are long and narrow; the molars bear low, expanded cusps and rounded occlusal crests. *Mabokopithecus*, represented by two isolated rear lower molars and an almost complete mandible, is dentally very similar to *N. pickfordi* and may well be congeneric with *Nyanzapithecus*, in which case the former genus has priority.

Rangwapithecus

The Early Miocene (19–20 Ma) *Rangwapithecus gordoni*, similar in size and probable locomotor pattern to the smaller *Proconsul* species, contrasts dentally with them in numerous respects, including molars with low cusps and well-developed crests, enamel wrinkling, and a pronounced wear differential. Cranial material indicates a comparatively short premaxilla and long, narrow palate widening toward the rear. The maxillary sinus is deep and the zygomatic root set low down the face above M^1–M^2; the mandible is deep and the symphysis reinforced with a pronounced superior transverse torus. Kay and Ungar (1997) and Ungar et al. (2004) have argued that, on the basis of its molar crest development (greater than that of any other Early Miocene form) and the low incidence and long, narrow form of dental pitting, *Rangwapithecus* is likely to have been folivorous. Dental proportions and macrowear, facial morphology, palatal proportions, and mandible structure are all compatible with this interpretation.

Turkanapithecus

The somewhat younger (16.6–17.7 Mya) *Turkanapithecus kalakolensis* is another medium-sized form, rather smaller than *P. heseloni*, and represented by a partial cranium preserving the upper dentition save for the incisors and a mandible with left M_2 and right M_3 (Fig. 8). The skull exhibits a relatively short face with broad, domed snout; a wide, oval nasal aperture flanked by prominent canine pillars, with expanded nasal bones; and a broad, flat interorbital region above. The palate is narrow, with posteriorly convergent tooth rows, and there is an extensive maxillary sinus. The zygomatic process originates low down on the face, and the arch is relatively deep and flaring. This, combined with pronounced postorbital constriction, makes for a deep infratemporal fossa and, presumably, well-developed *temporalis* muscle – a view also supported by the strongly marked and convergent temporal lines, pointing to a sagittal crest. The rear of the saddle-shaped glenoid cavity is bounded by a well-developed postglenoid process, but there is no distinct articular eminence. The nuchal area is comparatively short and the crest strongly developed, reflecting both the rugged facial architecture and comparatively small neurocranium, estimated at c. 85 cm^3 – absolutely and relatively smaller than *P. heseloni* (Manser and Harrison 1999).

Given this cranial morphology, it is rather surprising that the mandibular symphysis displays neither strongly developed superior nor inferior transverse tori. The corpus is shallow and relatively slender, with constant depth below the molars, while the ramus is broad, low, and sloping, with an expanded gonial region, so according with zygomatic architecture indicating well-developed masseter muscles – and a knoblike condyle. Upper first premolars are large, and while both upper and lower molar teeth increase in size posteriorly, the gradient is much less than in comparably sized *Proconsul* species. Overall, craniodental features suggest a resistant diet, possibly consisting of hard-cased fruits or leaves.

Dendropithecus

There is also a cluster of small- to medium-sized forms (perhaps 3–9 kg), usually grouped together as dendropithecoids. The siamang-sized *Dendropithecus macinnesi*, based on material originally assigned to *Limnopithecus*, displays narrow, high-crowned incisors; strongly dimorphic canines; broad premolars; and molars with high cusps, sharp occlusal crests, and well-defined foveae. The palate is narrow, as is the nasal aperture; the maxillary sinus is extensive and the mandible corpus low and robust, with the symphysis reinforced by fairly prominent superior and inferior transverse tori. Among Early Miocene hominoids, *Dendropithecus* has the least well-developed molar shearing crests of those studied other than *Proconsul* and a fairly high incidence of pitting, pointing to a predominantly soft-fruited dietary niche (Kay and Ungar 1997; Ungar et al. 2004).

Limnopithecus

Other small Early Miocene forms, known principally from isolated teeth and part jaws, include *Limnopithecus legetet* and *L. evansi*. These have a short lower face, with anteriorly positioned orbits; narrow, elliptical nasal aperture; and a shallow clivus, an inflated maxillary sinus, and a shallow, lightly built mandible reinforced symphyseally by a strongly developed superior transverse torus but with an inferior torus that is weak (*L. evansi*) or absent (*L. legetet*). *L. legetet* combines broad, low-crowned incisors and small canines with an ovoid P_3 that suggests only part development of the C–P_3 honing complex, and cheek teeth with high, sharp cusps and occlusal crests. *L. evansi* has narrower, higher crowned incisors, larger canines, and a better developed sectorial face on P_3, cheek teeth with lower, rounded cusps, and less sharply developed occlusal crests. Relative shearing-crest development suggests a fairly folivorous niche (Kay and Ungar 1997).

Kalepithecus

Less well known than these forms is the broadly contemporary *Kalepithecus songhorensis*, similar in dental size to *L. legetet*, but differing in most other respects. The anterior teeth are relatively large, with I^1 broader and more spatulate, the upper premolars relatively narrow but the molars relatively broad; P_3 is moderately sectorial, the short, broad lower molars with low, rounded, and expanded cusps, and poorly developed occlusal crests. *Kalepithecus* contrasts with other Early Miocene forms in its inferiorly broad nasal aperture and deep clivus, while dental morphology and proportions suggest a frugivorous diet.

Middle and Late Miocene African Hominoids

Fossil hominins apart, evidence of African hominoids from the Middle Miocene onward is limited, especially, when contrasted with the comparatively abundant Early Miocene material. Nonetheless, recent discoveries have both significantly increased the number of fossils (Ward and Duren 2002) and led to major reappraisals of earlier finds, notably of the material assigned to "*Kenyapithecus*" *africanus* (Leakey 1967), which has been reallocated to distinct taxa, with consequent systematic and phyletic implications.

Nacholapithecus

One such taxon is the large, markedly dimorphic *Nacholapithecus kerioi* (Ishida et al. 1999, 2004), based on material from Middle Miocene (15 Mya) sites in Samburu District, Kenya. Cranial remains display overlap of the posterior premaxilla and hard palate, forming a short incisive canal (Kunimatsu et al. 2004), which may indicate an intermediate condition between the nonoverlapping subnasal configuration of gibbons and fossil stem hominoids and the longer incisive canal that is a diagnostic trait of the clade that includes the extant large-bodied apes (Nakatsukasa and Kunimatsu 2009), or Hominidae. The incisive foramen is small, while the face bears strong canine pillars and deep fossae, and the zygomatic process originates low down on the maxilla. The mandible corpus is tall but thin, with a near vertical symphysis, a moderate inferior transverse torus, and a lateral fossa below the premolars. I^1 is high crowned and robust, while both lower incisors are tall and narrow. Canines are low crowned, upper premolars display marked cusp heteromorphy, and molars are thick enameled.

Equatorius

Other material previously assigned to "*K.*" *africanus* has been incorporated, along with new discoveries (including a part skeleton (KNM-TH 28860) from Kipsaramon, Tugen Hills, and multiple finds at Maboko Island and adjacent localities, Kenya), in another, broadly contemporary (14–15.5 Mya) large-bodied, dimorphic species *Equatorius africanus* (Ward et al. 1999). While initially criticized – see, for example, Begun (2000) and Benefit and McCrossin (2000) and response by Kelley et al. (2000) – the current consensus is that *E. africanus* is a valid taxon. The species is characterized by broad I^1s with marginal ridges, markedly asymmetrical lateral incisors, with a spiral lingual cingulum, and relatively large upper premolars with reduced cusp heteromorphy (contra *Nacholapithecus*). The procumbent, narrow lower incisors are tall, whereas the mandibular canines are low crowned with convergent roots. The thick-enameled, bunodont lower molars increase markedly in size along the tooth row.

The maxilla exhibits a very low, broad root for the zygomatic process and an extensive sinus extending into the premolar region, while the mandible displays a long, inclined sublingual planum, a prominent inferior transverse torus, and a robust corpus. The partial skeleton and other postcranial fossils indicate some resemblances to earlier forms such as *Proconsul* and *Afropithecus*, but with forelimb and hind limb contrasts that point to significant terrestriality (Sherwood et al. 2002; Patel et al. 2009). It remains to be determined whether ground vegetation formed an appreciable component of *Equatorius*' diet, but dental similarities to *Afropithecus* (and "*Heliopithecus*"), especially in canine form and premolar proportions, suggest resistant foods, such as seeds and/or hard-cased fruits, as major dietary items.

Kenyapithecus

The genus *Kenyapithecus* is retained for the rather later (14 Mya) species *K. wickeri*, known from partial jaws and isolated teeth from Ft. Ternan, Kenya. The maxilla exhibits marked canine fossae, a relatively low and anteriorly positioned origin for the zygomatic process above M^1, little extension of the maxillary sinus into the inflated alveolar process (in contrast to *Equatorius*), and a relatively highly arched palate. The upper incisors are markedly heteromorphic, with I^2 much smaller than I^1, which is reinforced by strong lingual marginal ridges extending across the base of the crown surface. The upper canines exhibit marked dimorphism: robust, tall, and externally rotated in presumed males, more conical in females. P^4 is relatively broad with subequal cusps; M^1 is quadritubercular and lacks a lingual cingulum, while M^2 is similar but larger. The postcanine teeth are closely packed, with low cusp relief and appreciable wear.

The mandible, considered female, displays a shallow symphysis, sharply retreating at 30–40° to the alveolar margin, with pronounced inferior transverse torus extending to below the mesial root of M_1, rather weak superior torus and long sublingual planum, a short incisor row, and a robust, comparatively shallow but thick corpus. As reconstructed, the mid-lower face overall was broad and flat, with wide cheeks and a short snout (Andrews 1971; Walker and Andrews 1973). The relatively tall-crowned lower canine bears only a slight lingual cingulum, while P_3 is obliquely set and sectorial, with a distinct honing facet for the upper canine, and P_4 bears prominent mesial and smaller, lower distal cusps; the poorly known lower molars apparently lack buccal cingula.

The narrow anterior dental arcade, procumbent incisors with curved roots, anteriorly positioned zygomatic origin, restricted maxillary sinus and mandible with markedly sloping symphysis, pronounced inferior transverse torus, and shallow, robust corpus differentiate *K. wickeri* from most other African hominoids. Andrews (1971) and Walker and Andrews (1973) interpret these traits as a functional set adapted for powerful chewing activity with a strong lateral grinding component and pronounced incisal action. There are similarities, especially in the anterior dentition, with *Afropithecus*, and, as with that genus, pithecines have been proposed as the most plausible dietary analogues (Leakey and Walker 1997; McCrossin and Benefit 1997). This model of *K. wickeri* as a sclerocarp feeder, exploiting hard-cased/hard-stoned fruits, seeds, and nuts, is compatible with reconstruction of the Ft. Ternan environment as drier and more seasonal than many earlier African sites, predominantly closed-canopy woodland with both open country and forested conditions nearby (Andrews 1996; Andrews et al. 1997). A second species of this genus, *K. kizili* (Kelley et al. 2008), has been named for material found outside of Africa and will be treated below.

Otavipithecus

Broadly contemporary at 13 + 1 Mya, the more southerly *Otavipithecus namibiensis* is known from a part mandible and frontal bone from Berg Aukas, Namibia (Conroy 1997; Conroy et al. 1992). The incisor region of the mandible is narrow and the symphysis reinforced by a short inferior transverse torus. The corpus is robust, of constant depth, and relatively long, with the ramus originating behind M3 and with a distinct retromolar space. Premolar and molar cusps are inflated and bunodont, mesial, and distal foveae small and enamel thin. The frontal bears superciliary ridges rather than a transverse torus, with marked temporal ridges adjacent to glabella, relatively wide interorbital dimensions and an extensive frontal sinus. The last of these traits has been used to link *Otavipithecus* with extant hominines (Pickford et al. 1997), but the current lack of clarity as to the polarity of frontal sinus evolution in catarrhines renders this interpretation premature at best. The narrow incisor region does not support a niche of specialized frugivory, while the thin enamel and minimal wear differential on the molar teeth point to a nonabrasive diet; there are no obvious dental adaptations to folivory. Conroy argues that *O. namibiensis* probably subsisted on a range of plant foods that required little preparation by the anterior teeth prior to chewing.

Samburupithecus

A later Miocene (9.5 Mya) large-bodied species from the Samburu Hills of north central Kenya named *Samburupithecus kiptalami* is known only from one left maxilla with P^3–M^3 crowns and the canine alveolus (Ishida and Pickford 1997). The palate displays a marked arch, a shallow postcanine fossa, a low origin for the zygomatic root, and invasion of the zygomatic process by the extensive maxillary sinus. The nasal floor has a sharp margin, and the tooth row is straight from the canine alveolus to M3. The three-rooted premolars have elongated crowns with coequal main cusps, while the molars display inflated, bunodont cusps and thick enamel. *S. kiptalami*'s affinities are unknown; some workers consider it to show some similarities with the gorilla, although there are also undoubted differences, e. g., the size of lingual cingulae. This and other traits make it most likely that *Samburupithecus* is a late-surviving part of the stem hominoid radiation that included *Proconsul* (Olejniczak et al. 2009).

Two newly discovered taxa have increased our knowledge of the later Miocene of Africa substantially. *Nakalipithecus nakayamai* is a large ape (>50 kg) from the early Late Miocene (9.9–9.8 Mya) site of Nakali, Kenya (Kunimatsu et al. 2007). Although known from only a few dentognathic remains, its striking resemblance to the slightly younger *Ouranopithecus* from Greece suggests that the popular paleobiogeographic scenario of large-bodied apes originating in Eurasia before reinvading Africa (Stewart and Disotell 1998) may need to be reexamined. The mandible of the holotype has a well-developed simian shelf (inferior transverse torus) and the thick dental enamel, reduced molar cingulae and reduced upper premolar cusp heteromorphy seen in Eurasian forms that have been considered more closely related to living hominids than African forms, although it retains the primitive non-compressed lower mesial premolar shape. A second large-bodied form, *Chororapithecus* is known from dental remains found in 10–10.5 Mya deposits in the Afar region of Ethiopia (Suwa et al. 2007). Aside from their similar size, the *Chororapithecus* molars are also similar to those of *Gorilla* in their relative development of molar shearing crests associated with folivory. Although not linked directly with the extant taxon, partly due to its thicker enamel caps, the resemblance suggests to the describers that it may belong to same clade. Two other possible new taxa, *Kogolepithecus* from the ca. 17 Mya site of Moroto II in Uganda (Pickford et al. 2003), and a single mandibular fragment from between 11 and 5 Mya in Niger (Pickford et al. 2009a) are too fragmentary to allow any convincing analysis.

Other, later taxa, closer to the Mio-Pliocene boundary (*Sahelanthropus*, *Orrorin*), are as yet only incompletely described but are claimed as basal hominins (see Senut, chapter "▶ The Miocene Hominoids and the Earliest Putative Hominids," Vol. 3). The known time span of *Pan* has recently been extended by the recovery of four fossil teeth (r and l I^1, l M^1, r M^3) from Middle Pleistocene deposits of the Kapthurin Formation of the Tugen Hills, Kenya, within the eastern Rift (McBrearty and Jablonski 2005). The broad, spatulate incisors bear deep mesial and distal foveae separated by a prominent lingual tubercle and the molars are low crowned, while all teeth exhibit thin enamel. The large hypocone on M^1 suggests *P. troglodytes* rather than *P. paniscus*, although McBrearty and Jablonksi are cautious in attributing specific identity, preferring assignment to *Pan* sp. indet. The finds date from around 0.5+ Mya, and the site lies some 600 km east of the present chimpanzee range. The teeth were discovered close to localities yielding part mandibles of *Homo* (*H. erectus* or *H. heidelbergensis*/*H. rhodesiensis*) pointing to sympatry and suggesting that adaptive scenarios which reconstruct differentiation of chimpanzee and hominin populations through the Rift Valley acting as an isolating barrier are unlikely to be correct. Fossil evidence for bonobos and gorillas is entirely lacking.

Europe and Asia Minor

While there is limited evidence dating from 15 to 17 Mya, the bulk of the European and west Asian hominoid material is from later Miocene sites between 6 and 12 Mya (Kay and Simons 1983; Pilbeam 2002). Many of these suggest subtropical seasonal forest or woodland as the dominant habitat; there is evidence of swamp conditions at some sites, while possibly harsher, more open environments are indicated at sites in Greece and Turkey yielding *Ouranopithecus* and *Ankarapithecus*, respectively.

Griphopithecus

The earliest evidence (13.5–17 Mya) consists of several low-crowned, large-cusped, and thick-enameled molars from Germany, Austria, and Slovakia assigned to *Griphopithecus*, a genus better known from Turkey, where a mandible with cheek teeth from Çandır and maxillary teeth from Paşalar dating from c. 15 Mya are referred to *G. alpani* (Alpagut et al. 1990). Like their European counterparts, the lower molars have bunodont, thick-enameled cusps, and well-developed buccal cingula. The upper central incisors are relatively narrow with a distinct median lingual pillar, and the male canines, especially in the upper jaw, are robust and comparatively low crowned. The mandible is strongly constructed, with both a prominent superior and well-developed inferior transverse torus at the symphysis and a long, shallowly inclined planum alveolare.

Heizmann and Begun (2001) suggest that *Griphopithecus* evolved from an *Afropithecus*/*Heliopithecus*-like thick-enameled ancestor and that this feature, together with the associated trait of low-dentine penetrance, was crucial to the expansion and success of dentally modern hominoids in the more seasonal Middle and Late Miocene habitats of Eurasia. However, at least one successful European form – *Dryopithecus* – had comparatively thin enamel, pointing to this as either a secondarily derived trait evolved from a thicker-enameled European ancestor or that the genus represents a second hominoid radiation into Europe.

Also at Paşalar, the species *Kenyapithecus kizili* (Kelley et al. 2008) is found. It has been linked to the African genus primarily due to the lack of lingual pillars in the upper central incisors, by which it differs from the other Paşalar hominoid *Griphopithecus*, although there are also some maxillary similarities. Unusually, the entire hypodigm of the taxon is thought to be from a single birth cohort, as all are the same developmental age and show identical enamel hypoplasias (Kelley 2008). As the molar teeth are extremely similar to those of *Griphopithecus*, it is assumed that their adaptation was similar, as well.

Dryopithecus

The thin molar enamel of *Dryopithecus* results in frequent dentine exposure, especially on the cusps, which lie close to the crown margins around a broad, shallow fovea. Below the narrow, low P_3 crown enamel extends onto the anterior root, pointing to at least partial honing against the upper canine (Begun 2002), while the upper central incisors are narrow and high crowned. Larger (presumed male) mandibles are generally more robust than in the Early Miocene east African forms but are not as strongly built as more thickly enameled taxa (Begun 2002). All species in which evidence is available display a relatively high root for the maxillary zygomatic process. Compared with *Proconsul* and other Early Miocene forms, *Dryopithecus* has reduced cingula, relatively short lower molars (Szalay and Delson 1979), expanded occlusal surfaces, and reduced molar crown flare and a mandibular symphysis reinforced by a prominent inferior transverse torus.

Until recently, the type species, *D. fontani* (11–12 Mya), was among the less well-known fossil hominoids cranially. New material from Catalonia, NE Spain (Moyà-Solà et al. 2009a, b), however, has dramatically improved our understanding of this chimpanzee-sized ape. A partial cranium dated to 11.8 Mya preserves several hominoid and hominid synapomorphies: a large nasal aperture with its widest portion located inferiorly and its margin constructed primarily of the maxilla,

Fig. 9 (*Upper*) Frontal and profile views of *Rudapithecus hungaricus* part skull (Photograph courtesy D. Begun). (*Lower*) Frontal and profile views of *Pierolapithecus catalaunicus* cranium (Photograph courtesy S. Moyà-Solà)

over a hard palate that is wide anteriorly. Unlike other large-bodied apes, however, the zygomatic slopes posteriorly from the orbital margin to the root, although there is mid-facial prognathism as well. The authors describe the steep face and vertical orientation of the nasal aperture as resembling extant *Gorilla*, in contrast to earlier stem hominoids with more sloping anterior maxillae. The subnasal morphology is stepped, as in extant hominines, but the premaxilla does not overlap the maxilla at the midline, which suggests a more primitive condition than that seen in *Nacholapithecus*. It has rather broader canines than other species, frequent cingula on the lower molars, while in larger mandibles the corpus shallows markedly from the symphysis toward the rear, unlike other species.

Rudapithecus

Although formerly placed in *Dryopithecus*, the slightly younger (9.5–10 Mya) *Rudapithecus hungaricus* (Kivell and Begun 2009) is also well known cranially (Fig. 9). Comparable in tooth size to *D. fontani*, it differs in its labio-lingually thicker incisors, narrower canines, reduced molar cingula, and more tapered M3. The mandibles have weak symphyseal tori, but the corpus is reinforced below M1–M2 by a lateral eminence. Cranial morphology is comparatively well known from several incomplete specimens from Rudabanya, Hungary (Begun and Kordos 1997;

Kordos and Begun 2001). The braincase is elongated, with a flat frontal displaying moderate postorbital constriction and strong anterior temporal ridges; supraorbital reinforcement is weak, but there is a fair-sized frontal sinus.

At the skull, rear inion is relatively highly positioned, while the mandibular fossa is transversely deep, with marked entoglenoid and postglenoid processes. The face is moderately projecting and deflected downward. The maxillary sinuses are larger than those of the East African fossils, and the nasal aperture has a broad base with subvertical sides. Again, in contrast to the early East African specimens where preserved, the subnasal floor is stepped, with the rear of the subnasal alveolar process extending over the palatal process of the maxilla, and an incisive canal is present. The long and projecting premaxilla is sagittally and transversely convex. The preserved semicircular canals suggest that *Rudapithecus* practiced relatively slow locomotion (Ryan et al. 2012).

Hispanopithecus

A smaller contemporary of *Rudapithecus* and also previously considered a species of *Dryopithecus* (Cameron 1997), *Hispanopithecus laietanus* is known from several sites in NE Spain (Begun 2002). Two partial skeletons have been discovered: a presumed male (39 kg) from Can Llobateres (Moyà-Solà and Köhler 1996) and a female (22–25 kg) from Can Feu (Alba et al. 2012). Mandibular teeth resemble those of *Rudapithecus*, but the premolars are relatively smaller, the molar cusps more rounded and expanded around the occlusal margins, and M_3 less tapered.

CLI-18800 preserves the upper dentition: the incisors are like those of *Rudapithecus*, the canines have strongly curved roots and narrow crowns, and the molar teeth increase in size posteriorly. In its known craniofacial structures, *Hispanopithecus* shows many similarities with *Rudapithecus*, including periorbital and maxillary morphology, the supraorbital region, frontal sinuses, and a locomotor pattern reconstructed as low, as determined via semicircular canal size. There are also contrasts, however, with CLI-18800 displaying a very high root for the zygomatic process and a relatively deep and flatter anterior aspect of the zygoma. The upper incisor row is more strongly curved, and the premaxilla is strongly biconvex. Overall the facial profile of *Hispanopithecus* is more concave.

The slightly earlier (c. 10.5 Mya) *H. crusafonti*, also from NE Spain, is known only from a mandible and some isolated teeth. Dentally slightly larger than *H. laietanus*, it is distinguished by comparatively broad upper canines, relatively longer upper premolars than in *Rudapithecus*, and relatively broader upper molars than *H. laietanus*. The mandible combines an exceptionally robust corpus with comparatively small tooth crowns; the symphysis is reinforced by a strong inferior transverse torus and the corpus bulges laterally below M1–M3. *Hispanopithecus* differs from the geographically close *Anoiapithecus* in that the molar crowns are relatively narrower, as are the buccal cuspulids, the hypoconulid is less centrally placed, and cingulids are lacking (Alba et al. 2012).

Overall, dental features of all three genera, such as relative shearing-crest development (Ungar 1996; Kay and Ungar 1997), pitting incidence of >35–<40 % (Ungar et al. 2004), thin enamel and dentine penetrance, and molar flare (Singleton 2003) accord with reconstructions of these forms as a frugivores, probably primarily soft-fruit feeders, in mildly seasonal subtropical forests (Andrews 1996). This is also consistent with mandibular corpus cross section which in many cases is like that of similar-sized *Proconsul*, although larger specimens resemble *Sivapithecus* in their shallow, more robust, and almost triangular section below M3 – proportions particularly effective in resisting torsion (Brown 1997) and raising the possibility of a tougher, more fibrous component in the diet of larger individuals to sustain their greater body bulk.

Anoiapithecus

Another new European Miocene form with a well-preserved cranium is *A. brevirostris*, known from the Middle Miocene (11.9 Mya) locality of Abocador de Can Mata in the Vallès-Penedès Basin of Spain (Moyà-Solà et al. 2009a). This unique short-faced taxon possesses the classic hominid features of a wide anterior palate, a nasal aperture widest at the base, but the upper premolars are moderately heteromorphic. There is also a frontal sinus, in which it differs from the condition seen in *Pierolapithecus*; the maxillary sinus is situated above the roots of the molars. The latter trait is considered to indicate a restricted sinus, but is often seen in extant hominoids that do not demonstrate reduced sinus volume. The molars themselves have thick enamel, cusps set toward the center of the tooth, small, compressed upper canines, and a robust mandible with a weak superior transverse torus. The extreme orthognathism and dentognathic traits could indicate a functional regime optimized for strong vertical crushing.

Pierolapithecus

The recently discovered Middle Miocene (12.5–13 Mya) partial skeleton of *Pierolapithecus catalaunicus* from Barranc de Can Vila 1, Els Hostalets de Pierola, Barcelona, Spain, provides extensive new evidence of European hominoids (Moyà-Solà et al. 2004). The specimen (IPS 21350) includes a virtually complete face and lower frontal, the upper dentition, and much postcranial material. The *Pierolapithecus* face is exceptionally prognathous compared with other Middle and Late Miocene Eurasian hominoids and, as such, is reminiscent of *Afropithecus*. It is low, with slender superciliary arches merging into a moderately swollen glabella region, below which the upper face is transversely flat. The orbits are broader than high, and the interorbital distance wide. In profile, the nasal bones are concave and salient over the wide piriform aperture, the inferior margin of which is well anterior to the tips of the nasal bones. The nasoalveolar clivus is high, convex, and markedly projecting. The deep, laterally expanded and strongly constructed zygomatics slope anteroinferiorly, with their root originating high above the alveolar margin of M^1. Internally, the paranasal sinus configuration of this taxon shows two specific similarities to extant *Pongo*: the maxillary sinus is limited in its anterior extent, but extends posteriorly toward the ethmoid, and the frontal sinus is absent (Pérez de los Ríosa et al. 2012). This, combined with the fact that the subnasal architecture does not include an overlapping premaxilla, suggests that *Pierolapithecus* bears no special relationship with extant African large-bodied apes, but may instead be part of the pongine clade.

The palate is short, wide, and deep, with the anterior dentition arcuate. I^1 is low crowned and procumbent, the large *C* low crowned and compressed. P^3 and P^4 are of similar size with reduced cusp heteromorphy, while M^1 and M^2 crowns are long and relatively narrow, with M^3 reduced. The lingual cusps are situated toward the crown edge and all the cheek teeth lack cingula.

This combination of dental and facial features distinguishes *Pierolapithecus* from all other Miocene hominoids; contrasts with *Dryopithecus* include the lower, more prognathous face; more anteriorly positioned zygomatic roots; shorter wider palate; larger, low-crowned anterior teeth; and relative molar crown size. In the view of Moyà-Solà et al. (2004), shared derived features of the two genera that link them to extant great apes include upper facial flatness, nasal bone projection and aperture form, a high zygomatic root, high nasoalveolar clivus, and deep palate. The postcranium also reveals shared derived traits with extant hominoids: a broad, shallow thorax and stiff lumbar region to the trunk, a dorsally positioned scapula, and apelike carpal bones with ulnar retreat from the wrist joint and evidence for the fibrous capsule of a semilunar meniscus, providing enhanced wrist abduction and supination. These traits, however, are combined with metacarpal and phalangeal features indicating the hand was palmigrade during locomotion and the fingers are short, as in monkeys, pointing to a dissociation in ape phylogeny between orthograde posture and climbing/below-branch suspension. The latter appears to have evolved later than the former and may well have arisen independently in several distinct lineages.

Similarities in craniofacial form and dental proportions with *Afropithecus* suggest a sclerocarp feeder, consistent with reconstructions of the *Pierolapithecus* habitat, based on the associated fauna, as wooded and relatively humid. Several Late Miocene hominoids (*Ouranopithecus*, *Ankarapithecus*, *Graecopithecus*) exhibit notably more ruggedly constructed crania and derive from drier, more fluctuating, and possibly more open environments.

Ouranopithecus

Ouranopithecus macedoniensis, represented by several jaws, teeth, and a fairly complete face from the c. 9-Myr-old northern Greek sites of Ravin de la Pluie, Xirochori, and Nikiti 1 (Fig. 10), is the largest European hominoid known, with males estimated to have been about female gorilla size. The face is strongly reinforced in its mid- and upper portions, pointing to powerful masticatory forces;

Fig. 10 (*Upper*) Frontal and profile views of *Ouranopithecus macedoniensis* part cranium (cast) (Photograph courtesy P. J. Andrews). (*Lower*) Frontal and profile views of *Ankarapithecus meteai* part skull (Photograph courtesy J. Kappelman)

the rectangular orbits are separated by a broad, stout interorbital area and laterally bounded by massive orbital pillars, while the nasal aperture is flanked by thick nasomaxillary (canine) pillars with broad, deep canine fossae beyond. The zygomatic region is very deep with, unusually for hominoids, a low origin for the zygomatic root on the maxilla. The premaxilla is strongly built, comparatively long, and markedly convex sagittally and transversely, with clivus, subnasal fossa, and incisive canal resembling *Dryopithecus*. The supraorbital torus bulges moderately above the orbits but less so medially; the strongly marked temporal lines indicate powerful anterior *temporalis* fibers.

The palate is deep and anteriorly broad; the incisors are set in an arc, offset from the other teeth by a pronounced diastema. The upper incisors are markedly heterodont, with the central teeth thick and broad and the laterals narrow and peg shaped; lower incisors are tall and slightly flared. Larger (male) canines are tall and laterally compressed but small when compared with molar size, while smaller (female) canines are very low crowned and almost premolariform.

Brown (1997) considers such low canines compatible with a greater degree of lateral mandibular movement than in modern apes. Both upper and (and especially) lower anterior premolars are triangular, the latter with a prominent mesial beak and lacking an anterior vertical honing facet from the upper canine. Instead wear occurs on the tip and along the protocristid, a feature judged reminiscent of *Australopithecus afarensis* (de Bonis and Koufos 2001). P^4 resembles P^3 in shape – another claimed *Australopithecus* – like trait and unlike other fossil and extant apes, while

P_4 is molarized, being elongate and with a high talonid. The molars are relatively large, with M^2 and M_3 the largest teeth; individual cusps are expanded, and both upper and lower rear molars possess accessory cusps. There is a marked wear gradient along the molar row: enamel is very thick and the cusps are worn almost flat before dentine appears.

Mandibles are robust, with thicker corpora than in extant apes, and larger (male) specimens are deep as well as thick. The symphysis is strongly reinforced by a broad, long planum and prominent inferior transverse torus. The lateral eminence originates opposite M_3, and the ramus ascends between M_2 and M_3. The gonial region is extensive and displays strongly marked ridging for the superficial masseter and medial pterygoid muscles. The condyle is relatively large and sagittally strongly convex.

Facial structure, muscle impressions, dental structure and proportions, occlusal morphology, and attritional wear gradients in *Ouranopithecus* all contrast with *Dryopithecus* and suggest extremely powerful masticatory activity, especially of the cheek teeth. This is further supported by microwear patterns which reveal a very high ratio of pits compared with striations on phase 2 facets of the cheek teeth (at >58 %, the highest of any fossil ape studied) and distinct wear on the incisors (Ungar 1996; Ungar et al. 2004), while the *Ouranopithecus* shearing quotient (and so relative shearing-crest development) is lower than that of any modern hominoid or other European fossil ape studied (Ungar and Kay 1995; Kay and Ungar 1997). In all these features, *Ouranopithecus* resembles extant hard-object feeders, pointing to exploitation of a similar niche – perhaps seeds, nuts, roots, and tubers, and other terrestrial vegetation. There are obvious resemblances here to some reconstructions of early (Plio-Pleistocene) hominine dietary niche(s), although these are unlikely to mirror any specially close phylogenetic link. De Bonis and Koufos (1997) argue that this model of *Ouranopithecus*' diet is consistent with reconstruction of its open habitat (De Bonis et al. 1992), although Andrews (1996) and Andrews et al. (1997) urge caution, considering the overall fauna to be undiagnostic other than indicating a strongly seasonal, possibly harsh, environment.

The poorly known *Graecopithecus freybergi* (von Koenigswald 1972), based on a single mandible from Tour la Reine, Pyrgos, Greece, and dated around 6.5–8 Mya, is often regarded as congeneric or even conspecific with *O. macedoniensis* (Martin and Andrews 1984; Andrews 1996), although Begun (2002) makes a strong case for its retention as a separate taxon based on molar size and mandible proportions.

Ankarapithecus

Ankarapithecus meteai (Ozansoy 1965), from sites in the Sinap Formation of Anatolia, Turkey, dated at c. 10 Mya, is a strongly built form known from cranial material including the type mandible and a partial face (Fig. 10), together with undescribed postcrania (Alpagut et al. 1996; Begun and Gulec 1998). The face is tall and markedly prognathic in both midface (unlike *Sivapithecus* and *Pongo*) and premaxillary regions. The clivus is biconvex, with large, low-crowned, and labiolingually thick central incisors and smaller lateral incisors. Male upper canines are relatively low crowned, and their roots form strong juga converging on the broad nasal aperture, with relatively shallow canine fossae beyond. The palate is deep, with the root of the zygomatic process set comparatively high above M^1 and into which the large maxillary sinuses extend. The vertically orientated, laterally flaring zygomatic process imparts strong anteriorly and laterally directed components to masseteric action, while the deep temporal fossa allows for a powerful *temporalis* muscle. The subnasal fossa is stepped and the incisive fossa large. The orbits are square, with a narrow interorbital space, very long nasal bones, broad, rounded orbital pillars, and prominent anterior temporal lines. Rather surprisingly in view of the rugged mid- and lower face, the superciliary arches above the orbits do not form a true torus.

The massive mandible is strongly buttressed, with a very deep, narrow, and vertical symphysis and the inferior traverse torus extending to the level of M_1. The rear of the corpus is very thick and the ramus broad. The lower incisors are labiolingually thick, narrow, and tall crowned, set almost vertically in a straight line between the low-crowned canines, which in males are more massive than in *Dryopithecus* or *Ouranopithecus* in basal section, while female canines are more premolariform, as in the latter genus. P_3 is large, oval, and elongated, with a large mesial beak comparable to *Dryopithecus* but smaller than *Ouranopithecus*, and P_4 is large and relatively broad, while M_1 is small relative to $M_{2.}$ Upper and lower molars are broader relative to their lengths than in other later Miocene forms; their occlusal surfaces have broad, flat cusps and shallow basins and lack cingula.

Andrews and Alpagut (2001) provide a valuable functional analysis of this taxon as a hard-object feeder in dry seasonal subtropical forest (Andrews 1996), illuminating aspects of *A. meteai* morphology and also that of other Miocene hominoids. In many features, *Ankarapithecus* resembles *Ouranopithecus*: dentally in the large, low-crowned and worn incisors; large cheek teeth; thick enamel; flat occlusal wear; poor shearing-crest development; and also in aspects of facial architecture and mandibular reinforcement. However, there are also differences: the supraorbital region differs, the *Ankarapithecus* interorbital region is narrower as are the lateral orbital margins, the midface is more prognathic, and the zygomatic root originates higher on the maxilla, while the mandibular corpus is massively thickened under the rear molars, so that it is actually broader than deep, whereas that of *Ouranopithecus* is deeper and narrower in cross section.

Oreopithecus

Oreopithecus bambolii, a comparatively large-bodied form dating from 6 to 7 Mya, is represented by multiple specimens from northern Italy, including a largely complete skeleton, making it the best-known European fossil primate. This has not prevented protracted debate about its affinities, although in recent years there has been a growing consensus that *Oreopithecus* is a primitive hominoid. Whatever its phyletic status, it is clear that *Oreopithecus* differs markedly in adaptive features and inferred niche from other Late Miocene European and West Asian hominoids.

The *Oreopithecus* skull combines a relatively small, low, but globular neurocranium with a deep, broad, and moderately projecting face that reflects anterior placement and projection of the midface and nasal region, for the premaxilla and clivus are short and comparatively vertical. The supraorbital torus is well developed, the interorbital region broad, and the nasal bones short and salient. Strong canine pillars are bounded by shallow canine fossae, while the zygomatic process is comparatively deep with a low, anteriorly placed root originating above P^4/M^1, and the zygomatic arch is long, flaring, and upwardly curved posteriorly. The alveolar region has deep but restricted sinuses. The saddle-shaped articular eminence is broad and long, with a large entoglenoid process. The articular and tympanic portions of the temporal are not fused, but the temporal petrous is hominid-like in its shallow, indistinct subarcuate fossa. The mastoid is broad and continuous with the extensive, strongly marked nuchal area. Zygomatic flare and mandibular proportions point to powerful, fleshy temporal muscles, as do the deep nuchal and sagittal crests, meeting high on the skull rear; the sagittal crest continues well forward before dividing into two prominent anterior temporal lines.

The strongly built mandible is large, with corpus height decreasing slightly along the cheek teeth row, and with strong reinforcement provided by the pronounced lateral eminence below the molar region. The ramus is broad and high with an expanded gonial region. There are pronounced markings for the masseters and medial pterygoids, while the condylar processes, below the broad and convex condyles, display strong markings for the lateral pterygoids.

Many of these cranial features can be considered representative of the primitive catarrhine morphotype (Harrison 1986); the exceptions are those features of the maxilla, zygomatic region, and mandible summarized above that can be related to masticatory power (see below). The dentition is highly derived: the incisor teeth are small overall and vertically implanted; those in the mandible are labiolingually compressed, while the uppers are heteromorphic with I^1 exhibiting a distinctive projecting lingual cusp. Canines are basally stout but not very tall and only loosely interlock, with a diastema small or absent. Larger (male) upper canines are strongly compressed and with a sharp rear edge, the lowers are more rounded in section; smaller (female) upper canines are rather incisiform. Much canine wear is from the tips; there was some C^1/C_1 honing, and some larger upper canines show evidence of slight honing against P_3, but smaller ones lack this, and the anterior face of C_1 did not hone against I^2. The lower premolars are bicuspid, with P_3 oval in outline and P_4 more rectangular; upper premolars are oval with subequal cusps. Upper and lower molars are elongated and bear tall, spiky cusps with deep notches between. Besides the four main upper molar cusps, a metaconule is positioned centrally on the crista obliqua, often linked to the hypocone by a crest. On the lower molars, the protoconid and hypoconid (buccally) and meta- and entoconid (lingually) are joined by sharp crests to a well-developed centroconid on the cristid obliqua, so mirroring the upper molars in their distinctive occlusal pattern. The hypoconulid is frequently split into several smaller cusps. M_1 usually bears a small paraconid, which is rarely present on M_2 and never on M_3. M_1 and M_2 are subequal in size, and M_3 is the largest tooth. The inner ear shows adaptations to medium-slow agility, somewhat more active than in *Rudapithecus*/*Hispanopithecus*, but marginally less so than *Proconsul*.

Although it displays some primitive features, the postcranial skeleton is apelike, indicating a degree of orthogrady, forelimb suspension, and strong grasping capabilities in the feet. The thorax is broad, the lumbar region short, and the iliac blades are short and broad, with a prominent anterior inferior iliac spine. The forelimbs are much longer than the hind limbs and display multiple adaptations to stability and hyperextension at the elbow joint and rotation in the forearm. There were a wide range of movements at the wrist, with short palms and long, curved fingers. The femora show weight-bearing adaptations at hip and knee, with flexible, wide-ranging movements at the ankle, and a short midfoot with long, strongly muscled digits including a powerful, opposed hallux.

Oreopithecus' reduced anterior dentition, expanded cheek teeth with complex occlusal morphology, relatively deep and orthognathic face, small neurocranium combined with large ectocranial crests and powerful chewing muscles, and robust mandible all point to a specialized folivorous diet of bulky, relatively low-grade food items which, judging by postcranial morphology and proportions, it exploited largely via an underbranch milieu. This conclusion is reinforced by study of relative shearing-crest development (Ungar and Kay 1995; Kay and Ungar 1997), which shows it to have the highest shearing quotient of any catarrhine studied, substantially in excess of any extant or other fossil hominoid. Further support is provided by dental microwear patterns, with a very low proportion (17 %) of pitting on phase II facets (Ungar 1996; King 2001; Ungar et al. 2004), consistent with extreme folivory. This wholly accords with reconstructions of *Oreopithecus*' paleoenvironment, which indicates lowland mixed broad-leaved and coniferous forest, with bushes, ferns, and sedges accumulated under swampy conditions (Andrews et al. 1997; Harrison and Rook 1997). However, see Alba et al. (2001) for an alternative and, to our minds, less convincing interpretation of the *Oreopithecus* skull based on biomechanical constraints associated with orthograde posture and bipedalism. These authors derive *Oreopithecus* cranial morphology from a *Dryopithecus*-like ancestor by a process of neoteny.

South and East Asia

Sivapithecus

The best-known Asian fossil ape genus is *Sivapithecus*, from Late Miocene (8.5–12.7 Mya) deposits in the Siwalik Hills of India and Pakistan and including material assigned to *Ramapithecus* prior to the 1980s (Pilbeam 2002). *Sivapithecus* is rare throughout the Siwalik record, comprising only c. 1 % of the mammalian community (Ward 1997). Despite this, aspects of its cranial morphology are relatively well known through discoveries over the last three decades; in particular,

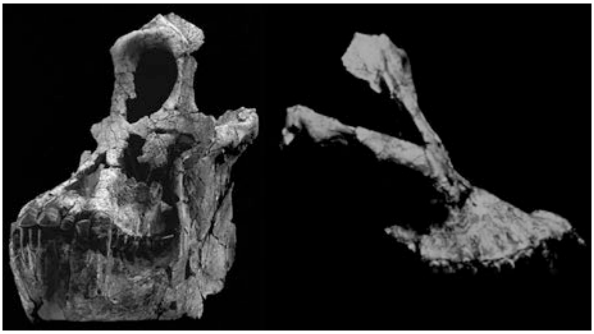

Fig. 11 Three-quarter frontal and profile views of *Sivapithecus indicus* (Photograph courtesy D. R. Pilbeam)

a partial skull (GSP 15000) from Potwar, Pakistan, provides much information on facial and gnathic morphology (Fig. 11). It consists of the left side of the face with zygomatic arch, palate, mandible, and complete adult dentition (Pilbeam 1982).

The specimen indicates many similarities with *Pongo* in its overall facial proportions (but see below): the orbits are taller than broad and high-set, ovoid in outline, and the zygomatic foramina are large. The interorbital distance is very narrow, while the lateral orbital pillars are slender, especially sagittally, and there are distinct supraorbital ridges but no continuous torus.

Postorbital constriction is marked, with the anterior temporal lines strongly convergent, implying a well-developed sagittal crest in larger individuals. The frontal rises more steeply above the orbits than in extant nonhuman African apes and is orangutan-like in its contour and the absence of a frontoethmoid sinus.

The nasoalveolar clivus is long and strongly curved, intersecting the alveolar plane at a shallow angle. As in the orangutan but in contrast to *Dryopithecus*, *Ouranopithecus*, and *Ankarapithecus*, the nasal floor is smooth, with the premaxilla curving into the nasal cavity and joining the palatal process without a step; the incisive fossa and incisive foramen are both tiny, linked by a very narrow incisive canal. The long, medially convergent canine roots are externally rotated, while the deep zygomatic process is thin and *Pongo*-like in its flare. These features result in exceptionally prominent canine pillars reinforcing the robust anterior midface and well-marked canine fossae lateral to them (Ward and Pilbeam 1983). The GSP 15,000 mandible is deep and strongly built, the symphysis exhibits pronounced buttressing, the corpus is of fairly constant depth along the tooth row, while the ramus is high and broadest at the level of the occlusal plane, tapering slightly superiorly. The facial contour is *Pongo*-like in its marked concavity, nasoalveolar clivus projection, superoposterior slope to the zygomatic process and lateral orbital pillar, and the upward inclination of the zygomatic arch itself.

Nonetheless, there are contrasts with the orangutan: the *Sivapithecus* midface is much longer, the nasal bones especially so, and the maxillary sinus is more restricted (Ward 1997). The mandible in particular contrasts with *Pongo* in most features other than its high ramus; while highly variable (Brown 1997), all *Sivapithecus* specimens display markings for the anterior digastric muscles which are absent in orangutans (see above), and the inferior transverse torus does not extend as posteriorly as in *Pongo* (Brown 1997). There are also contrasts in corpus cross section: *Sivapithecus* specimens have robust, broad corpora, ovoid below the premolars, more triangular below M_3, with smaller specimens relatively shallow, larger ones deeper. They show marked relief, with an intertoral sulcus near the lingual base below the cheek teeth, and a pronounced lateral eminence which continues to the base, whereas in orangutans the lateral eminence is usually a much less prominent swelling restricted to the upper part of the corpus. *Sivapithecus* mandible proportions have been interpreted as resisting sagittal bending loads on the balancing side and pronounced torsional and shearing loads on the working side, associated with powerful molar action and, as a possible secondary factor, incisal biting (Kelley and Pilbeam 1986; Brown 1997).

Dental features accord with this interpretation: the upper incisors are strongly heteromorphic, and the central teeth are very wide and spatulate with a heavily crenulated, extended lingual tubercle; the laterals are much narrower. The canines are moderately tall, compressed, and outwardly rotated and display only limited dimorphism. P^3 is larger than P^4, while the mandibular premolars are broad, with P_3 expanded mesiobuccally and displaying only limited evidence of upper canine honing. The thickly enameled molars lack cingula and display expanded, bunodont cusps and so limited occlusal foveae. In the upper jaw, M^2 is the largest tooth, while M_3 is the largest of the relatively short and broad lower molars. The cheek teeth are closely packed, with clear interproximal wear facets and, despite the thick enamel, often display a pronounced wear gradient with, in older individuals such as GSP 15,000, destruction of crown relief and extensive dentine exposure.

Overall, evidence points to *Sivapithecus* as a frugivore/hard-object feeder, possibly nuts, seeds, bark, or hard-pitted fruits, requiring powerful mastication by the postcanine teeth. Earlier scenarios of the genus as an open habitat form, exploiting terrestrial vegetation, have been replaced by reconstructions of its environment as predominantly seasonal tropical or subtropical closed-canopy forest or woodland, albeit with patchiness and expanding areas of more open grassland in the later phase of its presence in the Siwalik record (Andrews et al. 1997; Ward 1997). While this shift could reflect broader climatic changes that, through the contraction and break up of its forested habitat, eventually resulted in the extinction of *Sivapithecus*, it also might be the case that the taxon was more adapted to open habitats than previously thought. Analysis of some Siwalik carpals suggests that *Sivapithecus* may have been a knuckle-walker (Begun and Kivell 2011).

Three *Sivapithecus* species are recognized, differentiated primarily on dental proportions: *S. sivalenis* from Siwalik sites dating between 8.5 and 9.5 Mya is the type species. *S. indicus*, represented by GSP 15,000 and other material, is earlier (10.5–12.5 Mya) and with absolutely rather smaller teeth than *S. sivalensis*, but with a proportionately larger M_3 compared with M_2, and with a rather shorter premaxillary region. A humerus with a retroflexed and mediolaterally strongly curved shaft and a prominent deltopectoral crest is assigned to this species. *S. parvada* is a recently recognized, appreciably larger form, dating around 10 Mya. Its I^1 is particularly wide relative to its breadth, the premolars, especially the lower ones, are expanded relative to molar size, and M_3 is again much larger than M_2.

The mandible's symphysis and anterior corpus region are exceptionally deep, while a humerus referred to *S. parvada* broadly resembles that of *S. indicus* but is much bigger, implying larger body size overall.

Gigantopithecus

Many workers regard the Asian genus *Gigantopithecus* (von Koenigswald 1952) – known from massive mandibles and individual teeth from the Late Miocene/Pleistocene of southern China, Vietnam, and the Siwaliks of India and Pakistan – as closely related to *Sivapithecus*. While extremely large, it is characterized by a reduced anterior dentition, with relatively small lower incisors and low-crowned but basally large canines without honing facets, strongly worn down from the tip and functionally incorporated in the premolar/molar rows. The expanded premolars are strongly molarized: P^3 is bicuspid with a large talonid and is larger than P^4, which is almost square with a large trigonid taller than the talonid. The upper molars are almost square, the lowers elongated; all have very thick enamel, high crowns, and low cusps. The symphysis is reinforced by a moderate superior transverse torus and a much more extensive inferior torus that may extend as far back as M_1.

Gigantopithecus giganteus is known from specimens found from the 1960s onward from Haritalyangar and other Siwalik sites, especially a mandible CYP359/68 (Pilbeam et al. 1977), usually considered late in the Siwalik sequence at <7 Mya (Johnson et al. 1983). However, Pillans et al. (2005) argue for a date of 8.6 Mya for the mandible and report a newly discovered M^2 from the earlier (8.85 Mya) HD site at Haritalyangar which also yielded an incisor assigned to *Sivapithecus*, demonstrating sympatry of the two genera. Fossils of the more recent *G. blacki* are even larger than those of *G. giganteus*, with more pronounced molarization of the premolars, so that P_3 is more distinctly bicuspid and P_4 longer, while the molars are higher crowned, with low, expanded cusps, and multiple accessory cusplets. The mandibular symphysis is long and powerfully buttressed; the corpus is strongly reinforced by a thick lateral torus originating below M_1 and corpus depth increases posteriorly (Weidenreich 1945). Given these and other contrasts between the South and East Asian species, Cameron has recently reassigned the Haritalyangar mandible to *Indopithecus* (Cameron 2001, 2003; Pillans et al. 2005).

The size of *Gigantopithecus* fossils almost certainly precludes arboreality, and most reconstructions are of a ground-dwelling pongine exploiting a low-grade, bulky diet – perhaps bamboo (present at both Siwalik and Chinese localities) – although more varied diets, including fruits, have been suggested (Ciochon et al. 1990). Whatever the details, dental and gnathic features clearly indicate an extremely powerful masticatory apparatus with a premium on occlusal crushing and grinding by the cheek teeth, together with an anterior dentition capable of generating considerable bite forces for cropping food items. The short, premolariform canines, together with the mandible's symphyseal and corporal proportions, point to the generation of powerful torsional and shearing forces during food processing.

The same environmental changes that reduced forest and woodland cover, leading to the extinction of *Sivapithecus*, may well have favored the evolution of *Gigantopithecus* as a form better adapted to more open conditions and the exploitation of terrestrial vegetation (Ward 1997; Pillans et al. 2005).

Lufengpithecus

Lufengpithecus is another large-bodied Asian pongin, represented by extensive material, including several distorted crania and numerous teeth, from the Late Miocene (c. 8 Mya) of Lufeng, Yunnan province, southern China. Dental metrics indicate a degree of sexual dimorphism rather greater than that of any extant ape (Kelley and Qinghua 1991; Kelley 1993; Schwartz 1997). Cranial morphology contrasts with *Sivapithecus* in the relatively shorter midface, square orbits, broad interorbital and glabellar regions, and more prominent supraorbital torus above the medial superior orbital margins, resembling more the *Dryopithecus* pattern. The nasoalveolar clivus is relatively short and the mandibular symphysis strengthened by a moderate superior and strongly developed inferior transverse torus. The corpus is narrow and columnar with little sculpting or buttressing (Brown 1997), presumably resistant to vertical occlusal forces, but less well adapted to torsional or shearing forces generated by the cheek teeth.

The upper central incisors are tall and narrow but relatively thick and buttressed by a median pillar on the lingual surface, while the lower incisors are relatively narrow and moderately procumbent. Presumed male canines, especially the lowers, are tall, sharply tapering, and relatively slender. Molar enamel is moderately thick, and the crowns are narrow with the cusps situated toward the rim so that the foveae are extensive, and the occlusal surface bears a complex pattern of crenulations. Overall molar occlusal morphology is remarkably like that of the orangutan (Ward 1997), suggesting a frugivorous niche, as do the similarities with *Dryopithecus*. Paleoenvironmental indicators point to swampy moist tropical forest conditions, with ferns and epiphytes in which – again unlike *Sivapithecus* – *Lufengpithecus* was common, representing >33 % of the mammalian fossils (Andrews et al. 1997).

Kelley (2002) recognizes three species of *Lufengpithecus*: *L. lufengensis*, the type species, is the best known; *L. keiyuanensis* and *L. hudienensis* have smaller postcanine teeth and rather greater molar cingulum development than *L. lufengensis*, with *L. keiyuanensis* possibly also having thinner enamel.

Khoratpithecus

The recent discovery of teeth and a part mandible from Middle and Late Miocene deposits at sites in northern Thailand, and so within the geographical range of Pleistocene *Pongo*, sheds further light on orangutan ancestry (Chaimanee et al. 2003, 2004). The finds have been assigned to the new genus *Khoratpithecus* and display numerous dental and gnathic similarities with *Pongo*, as well as with

Lufengpithecus and, to a lesser extent, *Sivapithecus*. *Khoratpithecus piriyai* (9–7 Mya) is a large form (estimated 70–80 kg body weight) from a locality in Khorat, NE Thailand, and represented by a mandible body with the left canine – right I_2 roots – and with the right canine and all cheek teeth crowns preserved on both sides (Chaimanee et al. 2004). The symphysis is strongly sloping, thicker in overall cross section than usual in *Pongo*, with a weaker superior traverse torus, shallow genial fossa, and strongly developed inferior torus that, while wide and extending to below the anterior part of the M_1 crown, is less posteriorly extensive than in the orangutan. While the geniohyoid muscle facets are distinct, *Khoratpithecus*, like *Pongo*, lacks any impression for the anterior digastric muscle. The corpus is uniformly deep, with a marked depression on the lateral surface below the C/P_3 region and thickening posteriorly, accentuated by a pronounced lateral eminence below M_3.

Judging by anterior jaw proportions and alveoli, the procumbent incisors were larger than in *Lufengpithecus* but smaller than *Pongo* and arranged in a slightly convex arc. Enamel wrinkling, while present, is less complex than in the orangutan, the P_4 is shorter, and the molar cusps are more centrally located than in the modern ape. The site indicates a riverine setting with palms and dipterocarps, together with proboscids, anthracotheres, pigs, rhinos, bovids, and rare *Hipparion*, corresponding to the Upper Nagri/Lower Dhok Pathan Formation faunas in the Siwalik sequence.

An earlier species, *Khoratpithecus chiangmuanensis* (13.5–10 Mya), is based on upper and lower teeth of a single individual from Ban Sa in the Chiang Muan basin (Chaimanee et al. 2003). Enamel wrinkling, markedly heterodont upper incisors, P^3 crown form, lack of molar cingula and comparable degrees of relative enamel thickness, and dentine penetrance again align it with *Pongo*, but it differs from the latter in its smaller central incisors, in the weaker median lingual pillar of the upper and lower incisors, in the greater buccal flare of the lower molar crowns, and in its less intensive enamel wrinkling.

Contextual evidence associated with *K. chiangmuanensis* indicates a mosaic of tropical freshwater swamps and lowland forest that contrasts with the temperate flora from Lufeng, instead resembling modern African habitats such as those in the southern Sudan around the source of the White Nile. Chaimanee et al. take this to indicate a Middle Miocene floral and faunal dispersal corridor linking South East Asia and Africa that may have been critical in hominoid dispersion. Overall, *Khoratpithecus* closely resembles *Lufengpithecus* in its dentition, but its similarities with *Pongo*, especially the absence of digastric fossae, point to closer affinity with the modern genus than any other fossil ape.

Conclusions

Early Miocene hominoids already show considerable craniodental diversity, probably associated with dietary niche differentiation. Better known genera (*Afropithecus*, *Proconsul*) have contrasting morphologies but span a range of frugivory: *Proconsul* sp. and *Dendropithecus* were probably soft-fruit feeders, *Afropithecus* exploited hard-cased fruits. Among the less well-known genera, some (e.g., *Morotopithecus*, *Turkanapithecus*) bear cranial and/or dental similarities to *Afropithecus*, suggesting a hard-fruit niche, and that the most familiar cranial morphology – that of *Proconsul* – is not necessarily characteristic of many Early Miocene hominoids. *Limnopithecus* and *Micropithecus* appear to have been folivores on the basis of their dentition.

Middle and Late Miocene forms from the region (*Nacholapithecus*, *Equatorius*, *Kenyapithecus*, *Samburupithecus*) are thick enameled and probably hard-cased fruits and seed feeders, while environmental evidence suggests more open, rather drier, and more seasonal habitats. The more southerly *Otavipithecus* is an exception, with thin enamel and minimal dental wear, pointing to a soft-fruit diet.

By the Middle Miocene, hominoids are known from Europe and Western Asia. The earliest (*Griphopithecus*) are thick enameled, as are many later genera which are also generally more robust cranially than *Proconsul*, some especially so. At least one successful genus (*Dryopithecus*), however, has thin enamel and an only moderately strongly constructed cranium, although occlusal area, inferior symphyseal reinforcement, and, in larger individuals, mandibular cross section are expanded compared with *Proconsul*. *Dryopithecus* also contrasts with early East African fossils in its stepped nasal floor with the alveolar process overriding the palate and an incisive canal present. Overall, evidence suggests *Dryopithecus* primarily exploited soft fruits. The recently described, markedly prognathous *Pierolapithecus* is much more reminiscent of *Afropithecus* in its morphology and, as such, probably a sclerocarp feeder.

Broadly contemporary with the younger *Dryopithecus* species at 9–10 Mya, *Ouranopithecus* and *Ankarapithecus* are more strongly built forms whose cranial reinforcement, muscle markings, gnathic proportions, and dental features all point to impressive masticatory power and hard-object feeding, characteristics shared with the less well-known and rather younger *Graecopithecus*. Of about the same age (7–8 Mya) is the (masticatory power apart) generally contrasting *Oreopithecus*. This genus retains many primitive cranial traits together with features making for enhanced chewing capability and a distinctive dentition adapted to specialized folivory.

A similar trend to more robust morphologies is seen in South Asian hominoids, although details differ. The Late Miocene *Sivapithecus* (8.5–<13 Ma) is broadly *Pongo*-like in many aspects of cranial morphology, including periorbital proportions, mid-/lower facial prognathism and cheek orientation, nasal floor structure, and the presence of a narrow incisive canal, and remains among the most convincing instances of a comparatively close phylogenetic link between fossil and extant hominoid taxa, although *Sivapithecus* is unlikely to be directly ancestral to the orangutan. Cranial and dental features of *Sivapithecus* point to a frugivorous/hard-object feeding niche in increasingly patchy, fragmented habitats. These same environmental shifts probably underlie the appearance of *Gigantopithecus* [*Indopithecus*] *giganteus* in the Siwalik record, the oldest example of which is sympatric with *Sivapithecus*. *Gigantopithecus* mandibles are massive and powerfully reinforced, while occlusal area is expanded through increased molar size, premolar molarization, and incorporation of the low-crowned, worn flat canines into the cheek teeth rows. These features are evident in *G. giganteus* but even more pronounced in the later, East Asian, *G. blacki* (2–<1 Mya). Given its size, *Gigantopithecus* probably exploited bulky, low-grade terrestrial vegetation, with bamboo as the most likely predominant food source.

Also from East Asia and roughly contemporary with latest *Sivapithecus* and earliest *Gigantopithecus* is *Lufengpithecus*. In some respects, this is cranially rather reminiscent of *Dryopithecus*, contrasting with *Sivapithecus* in its broad upper face, supraorbital development and orbital proportions, thinner enamel, in its mandibular section which is less resistant to torsion and shear forces, and in its molar occlusal pattern which is more *Pongo*-like than that of *Sivapithecus*, all of which suggest a frugivorous diet.

The immediate ancestry of the extant great apes is obscure, while the entire early evolution of hylobatids is unknown. Both the distribution and diversity of contemporary *Hylobates* and *Pongo* populations indicate that climatic changes and associated sea-level fluctuations have been major determinants of their evolution over the last 2+ Ma. *Pongo* in particular is cranially highly variable: there are appreciable differences between Bornean groups separated by major river barriers, as well as marked contrasts between these and Sumatran orangutans, leading to recent proposals for species-level distinction between the two island populations. All orangutans lack the anterior digastric muscle, thereby contrasting with virtually all other hominoids including *Sivapithecus*, which does, however, share with *Pongo* a distinctively airorhynchous cranial form. The recently discovered Middle/Late Miocene *Khoratpithecus* from Thailand displays jaw and dental affinities with *Sivapithecus* and especially *Lufengpithecus* and *Pongo*, sharing with the last a lack of any indication of the anterior digastric muscle.

The notably klinorhynchous African apes contrast in this respect and exhibit multiple similarities that indicate a common cranial pattern differentiated by varying growth periods. Since a degree of airorhynchy seems common among fossil hominoids and differentiates hominoids from non-hominoids, the African ape condition appears derived. Despite the comparatively full Miocene fossil record, there are no especially convincing candidates for modern African ape ancestry, although *Chororapithecus* is a potential link. The sequence and timing of splitting of the gorilla, chimpanzee, and hominin clades is uncertain, although some evidence (dental, gnathic, temporal) suggests that *Gorilla* is more primitive and *Pan* more derived. Differentiation of bonobos and chimpanzees and of east and west gorilla populations perhaps occurred in the Late Pliocene/Pleistocene. Recently recovered fossil teeth provide evidence of *Pan* (probably *P. troglodytes*) from c. 0.5 Mya in the East African Rift.

While there are broad associations between African ape diet and cranial form, more detailed analyses fail to show an exact correspondence, in part because of dietary variability and also because of cranial variation. Evidence suggests that cranial features are less closely determined by diet than are characteristics of the dentition.

Bonobos show reduced levels of sexual dimorphism in craniodental features compared with chimpanzees, perhaps reflecting differences in sexual behavior and social organization. Surprisingly, bonobos are *relatively* the most robust of the African apes in some cranial traits, gorillas *relatively* the most gracile. When viewed in the broader context of the hominoid fossil record, all the living great ape crania are comparatively lightly constructed, raising issues about their representative nature or otherwise for the functional and adaptive modeling of earlier hominoids.

Dental Adaptations of African Apes

Mark F. Teaford and Peter S. Ungar

Contents

Abstract

Improvements in the primate fossil record, and in methods of data acquisition and analysis, have set the stage for new insights into the development, function, and evolution of hominoid teeth. This chapter is a brief review of recent advances. In essence, genetic analyses are changing our perspectives on the

evolution of morphology, while improved studies of dental development and microstructure have yielded permanent markers of developmental history and microstructural differences of functional significance. More realistic perspectives on the physical properties of foods are yielding new functional interpretations of differences in tooth size. Finally, landmark-free analyses of tooth shape and wear are giving researchers the chance to actually monitor how teeth are used in living primates and by extrapolation in fossil primates too. Through techniques such as these will come a better understanding of the intricacies of dental function and a clearer picture of our past.

Introduction

People have been fascinated by the similarities between apes and humans ever since the first reports of apes filtered out of Africa. Linnaeus struggled to incorporate them into his *System of Nature*, but anatomical studies by Tyson (1699) and Huxley (1863), among others, forced the world to recognize the striking resemblance between African apes, in particular, and modern humans. Now, with the ape and human fossil record raising more questions and technological advances generating new perspectives on morphology, it is time to take another look at the teeth of African apes, to see what is known and not known about them.

Dental Development

Some of the most revolutionary discoveries in all of morphology have come in the areas of genetics and dental development, where subtle genetic changes have been shown to have major impacts on morphology (Jernvall 2000; Salazar-Ciudad et al. 2003). Thus far, studies have been restricted to laboratory animals such as rodents, but the potential impact on studies of morphological change in ape and human evolution is immense. With that point in mind, what do we know about dental development in the African apes? Methods of data collection have sometimes overlapped and sometimes varied dramatically, but some general trends are still evident in the literature.

Longitudinal data for nonhuman primates are rare, and this is certainly true for studies of dental development in apes, where methods of monitoring crown and root development have generally involved either detailed dissections or radiographs of different individuals of known ages (e.g., Zuckerman 1928; Dean and Wood 1981; Swindler 1985; Beynon et al. 1991; Conroy and Mahoney 1991; Kuykendall 1996; Winkler 1995) (although see Anemone et al. 1991 for an exception to this). Net results have included estimates of the timing of tooth calcification and emergence and differences between teeth in those events. Analyses of chimpanzees have been far more common than those of other apes, due largely to the fact that chimps are often used in laboratory research. Ultimately, results are frequently compared with those for humans.

Estimates of the timing of tooth and root calcification have yielded some consistent similarities between apes and humans, but also some differences. Specifically, dental development in apes is completed much more quickly than in humans, at approximately 11–12 years as compared with approximately 18–20 years (Nissen and Riesen 1964; Conroy and Mahoney 1991; Kuykendall 1996). Yet apes and humans have fairly similar patterns of cusp initiation and tooth mineralization (Swindler 1985), and each tooth crown takes about the same time to develop (Dean and Wood 1981; Beynon et al. 1991). So how can the teeth of humans take longer to finish their development when individual human and ape tooth crowns take similar times to develop? First, there are significant differences in the degree of overlap between the development of certain teeth in apes and humans. For instance, in humans, each of the permanent molars completes its crown development before the next molar crown begins to develop. In apes, by contrast, there is a great deal of overlap in the timing of development of the molars (Reid et al. 1998; Dean 2000). A second factor helping to explain the faster completion of dental development in apes is a quicker rate of root growth after crown completion (Anemone et al. 1991, 1996; Simpson et al. 1992; Kuykendall 1996; Reid et al. 1998).

Finer-resolution differences in dental development may ultimately be discernible, both within and between species – e.g., differences between the sexes in some tooth mineralization stages (Kuykendall 1996) or differences in the formation time of specific molar cusps (Reid et al. 1998). However, additional resolution has also required further refinement of techniques (Winkler 1995; Beynon et al. 1998; Reid et al. 1998) which is now yielding additional insights. For instance, while the sequence of emergence of some teeth may distinguish bonobos from common chimpanzees (Bolter and Zihlman 2011), the relative timing of crown and root formation may not differ significantly between them (Boughner et al. 2012).

The net result of all of these developmental events is a complex pattern of sequences that can, by itself, be used to gain insights into primate life history (Smith 1991, 1994; see also chapter "▶ Primate Life Histories," Vol. 2) and morphological development (Boughner and Dean 2008). Schultz (1960) recognized a basic distinction between relatively rapid- and slow-growing primates, with the former gaining all of their permanent molars before the eruption of more anterior permanent teeth. Hominoids are all relatively slow growing, but variations in their sequences of dental eruption (so-called tooth sequence polymorphisms) (Garn and Lewis 1963) can still yield insights. For instance, comparisons of humans and common chimpanzees show that humans have much greater variability in the eruption of their canines and lower central incisors, whereas chimpanzees show greater variability in the eruption of their second molars (Smith 1994). Still, if the actual timing of dental eruption can also be calculated (see section "Incremental Microstructural Features" below), then the eruption of most pairs of teeth is highly correlated (Smith 1989), and the eruption of the first and last permanent teeth is, in turn, highly correlated with other life history variables (see chapter "▶ Estimation of Basic Life History Data of Fossil Hominoids," Vol. 1).

Dental Microstructure

Dental enamel is formed of hydroxyapatite crystals bundled together into prisms which are, in turn, often woven together in complex patterns, including radial enamel and decussating Hunter-Schreger bands (Martin et al. 1988; von Koenigswald and Clemens 1992; Rensberger 1997; Maas and Dumont 1999). This inherent complexity has left researchers with a wealth of research possibilities, ranging from permanent markers of developmental history to structural anisotropy of functional significance.

Incremental Microstructural Features

Close examination of enamel prisms has revealed so-called cross-striations (periodic thickenings) laid down in a circadian fashion (Schour and Hoffman 1939; Massler and Schour 1946; Boyde 1964). This, coupled with surface markers known as perikymata, has allowed researchers to estimate the amount of time necessary for crown completion in modern hominoids (Dean and Wood 1981; Beynon et al. 1998; Reid et al. 1998; Shellis 1998; Dean 2000). But it has also given insights into tooth formation time and age at death in fossils (Bromage and Dean 1985; Beynon and Dean 1988; Dean et al. 1993, 2001; Smith et al. 2010), thereby suggesting that most of the early hominins (including the earliest members of our genus) had a more rapid "ape-like" pattern of dental development that did not begin to change until the Middle Paleolithic. Recent methodological advances, most notably in the area of nondestructive synchrotron microtomography (Tafforeau and Smith 2008; Tafforeau et al. 2012), raise the possibility of a far better understanding of dental microstructure across teeth in any primate taxon.

Enamel Prism Patterns

Before histological studies of the timing of dental development, researchers felt that the shape of prisms in prepared tooth sections ("prism packing patterns") could be used in phylogenetic studies, as certain patterns might be characteristic of certain taxonomic groups (Shellis and Poole 1977; Gantt 1979, 1983; Xirotiris and Henke 1981). However, subsequent work showed that results were often dependent on methods of specimen preparation (Boyde et al. 1978; Vrba and Grine 1978). Detailed analyses of enamel at controlled depths subsequently suggested that hominoids might exhibit an unusual preponderance of "type 3" enamel (Boyde and Martin 1982; Martin et al. 1988). In this pattern, prism cross sections are open at the base. However, more work is still necessary to document the range of possibilities within and between large samples of teeth.

Enamel Thickness

One obvious result of the complex process of tooth formation in most mammals is an enamel cap covering the tooth crown – a cap that can vary rather dramatically in thickness. Studies of molar enamel thickness in hominoids have gradually progressed from simple linear measurements (e.g., Gantt 1977; Molnar and Gantt 1977; Kay 1981) to more complex measures designed to account for differences in body size (e.g., Martin 1983, 1985; Kono 2004; Smith et al. 2005, 2012; Gantt et al. 2006; Kono and Suwa 2008; Olejniczak et al. 2008). Given the complexity of crown shape and development, it is perhaps no wonder that there have been ongoing discussions about proper methods of analysis (e.g., Grine 1991; Macho and Thackeray 1992; Macho and Berner 1993; Macho 1994; Dumont 1995; Grine 2002, 2005; see also chapters "▶ General Principles of Evolutionary Morphology," and "▶ Virtual Anthropology and Biomechanics," Vol. 1). However, recent work has begun to refine the understanding of enamel thickness, as researchers move from summary characterizations of hominoids having relatively thin molar enamel compared with that of modern humans (Shellis et al. 1998) to more subtle differences in enamel distribution across molar tooth crowns (Schwartz 2000; Kono 2004; Smith et al. 2005; Kono and Suwa 2008; Constantino et al. 2009). Of course, along with such differences come questions of the functional significance of those differences. Given the inherent complexity of primate foods and diets (see chapter "▶ Evolutionary Biology of Ape and Monkey Feeding and Nutrition," Vol. 2), it is not surprising that the correlation between enamel thickness and diet is not a perfect one (Maas and Dumont 1999), nor that the physical and chemical properties of enamel may vary within the tooth crown (Cuy et al. 2002; Lee et al. 2010) but surprisingly little between species (Constantino et al. 2012). This has led some to suggest that these properties are "highly conserved" in primate evolution (e.g., Constantino et al. 2012). Over the past two decades, conventional wisdom has dictated that thick enamel enabled primates to consume either more abrasive foods (Molnar and Gantt 1977; Rabenold and Pearson 2011) or harder ones (Kay 1981; Dumont 1995). However, that perspective is changing, largely because researchers are gaining a better appreciation for the functional implications of the structural complexity of enamel. On the one hand, prism decussation serves as an admirable crack-stopping mechanism (Pfretzschner 1986; von Koenigswald et al. 1987; Rensberger 1993, 2000; Maas and Dumont 1999) and thus may be a correlate of hard-object feeding in some situations (Martin et al. 2003; Lucas et al. 2008). On the other, not all tooth cracks originate from the occlusal surface (Lucas et al. 2008). Thus the distribution of enamel, and its decussation, may also be a correlate of feeding on hard *or* abrasive objects (Constantino et al. 2009). In either case, differences in the structure and properties of molar enamel in African apes are beginning to be tied to differences in so-called fallback foods (Lambert 2007; Marshall and Wrangham 2007; see also chapter "▶ Evolutionary Biology of Ape and Monkey Feeding and Nutrition," Vol. 2) as chimps pursue softer foods while gorillas pursue tougher foods when preferred resources are not available (Constantino et al. 2009). Finally, we cannot forget that enamel *thinness* can be selected for too, for surface sculpting to form sharp edges when wear breaks through to the softer dentin (Ungar 2008).

Tooth Size

Measurements of tooth size have been the focus of some classic studies of ape and human dentitions (e.g., Ashton and Zuckerman 1950; Schuman and Brace 1955; Garn et al. 1965; Pilbeam 1969; Mahler 1973; Johanson 1974; Swindler 1976). However, while some interspecific and intraspecific differences in tooth size are undoubtedly associated with differences in body size (Garn et al. 1968; Gingerich et al. 1982; Conroy 1987), the more intriguing trends are those differing from the standard assumption that larger animals have concomitantly larger teeth that scale one to one with body size. Similarly, the degree and pattern of variation in tooth size may also be informative.

For instance, investigators have long known that humans have relatively small canines compared to modern apes (e.g., Gregory 1922). However, among modern apes, chimpanzees and orangutans have relatively larger incisors than do gorillas and gibbons (Jolly 1970; Hylander 1975; Kay and Hylander 1978). As a result, differences in incisor size may reflect differences in the degree of incisor use in ingestion (Ungar 1996).

*Intra*specific differences in canine size have also been used as indicators of sexual dimorphism, with gibbons and humans showing relatively little sexual dimorphism, and chimps, bonobos, gorillas, and orangs all showing significantly more (Ashton and Zuckerman 1950; Johanson 1974; Swindler 1976; Kinzey 1984). This has led to further inferences about differences in social behavior (e.g., Kelley 1986; Plavcan 1990; Plavcan et al. 1995; Plavcan and van Schaik 1997), with, for instance, species showing high degrees of sexual dimorphism also showing polygynous mating systems (see chapters "▶ Great Ape Social Systems," and "▶ Cooperation, Coalition, Alliances," Vol. 2).

However, if analyses of tooth size are going to move from simple correlations (between morphological and behavioral differences) to explanations of causation, they need to be based on a better appreciation of the complexities of such relationships. In the 1970s, discussions began on the exact nature of the relationship between tooth size and body size, with initial studies suggesting close ties between postcanine tooth area and body metabolism (Pilbeam and Gould 1974; Gould 1975) but subsequent analyses showing such a relationship to be grossly oversimplified (Kay 1975; Fortelius 1985). The confounding variables apparently come in three forms. First, different analytical protocols have suggested different scaling relationships between tooth size and body mass in primates independent of anything else (Smith 2009; Copes and Schwartz 2010; Ungar 2014). Second, analyses of modern primates have shown that the relationship between diet and food processing is extremely complicated (Fortelius 1985; Lucas 2004). Thus, for example, both the rate of chewing and the physical response of food to chewing may influence the relationship between tooth size and diet. And third, analyses of fossil primates have shown that phylogenetic history may also complicate analyses of tooth size (Kay and Ungar 1997; Ungar 2002). For instance, the average Miocene ape incisor is narrower than that of modern apes. Perhaps Miocene apes had a different morphological starting point than extant apes, rather than simply being more folivorous (see chapters "▶ Fossil Record of Miocene Hominoids," "▶ The Biotic Environments of the Late Miocene Hominoids," Vol. 2 and "▶ Potential Hominoid Ancestors for Hominidae," Vol. 3).

Work by Lucas and co-workers (Lucas et al. 1986; Lucas 2004) has brought another perspective to the discussion of the functional implications of differences in tooth size. In essence, anterior teeth and postcanine teeth are probably responding to different types of functional demands and thus need to be treated differently. Anterior tooth size is linked to the size of ingested particles, whereas posterior tooth size may depend on the deformability of the food, including a variety of properties like stickiness, particle shape, etc. Thus, perhaps relative differences in tooth size between incisors and molars in modern apes are giving more subtle clues about the dietary differences between species. For instance, the fact that the gorilla has relatively small incisors compared to its molars may *not* simply indicate less reliance on the incisors in ingestion. It may also reflect the fact that the molars of gorillas often process relatively small food particles that are not very sticky (Lucas 2004). Clearly, however, more work is needed on the relationship between tooth size and the properties of foods.

Dental Morphology and Wear

As Aristotle noted nearly two and a half millennia ago in *De Generatione Animalium*, tooth form reflects function. Studies of mammalian dental functional morphology do not date back quite that far, but they certainly boast a long and celebrated history nonetheless (Owen 1840; Gregory 1922). Early work on mammalian teeth, for example, suggested that their molars evolved to improve mechanical efficiency for particular masticatory movements (Simpson 1933; Crompton and Sita-Lumsden 1970; Kay and Hiiemae 1974). Subsequent work has continued to push this biomechanical perspective forward, focusing on relationships between tooth shape, on the one hand, and the strength, toughness, and deformability of foods on the other (e.g., Kay 1975; Rosenberger and Kinzey 1976; Seligsohn and Szalay 1978; Strait 1993; Lucas and Teaford 1994; Spears and Crompton 1996; Yamashita 1998; Lucas 2004; Lucas et al. 2004). In essence, primates that specialize on tough foods, such as insect exoskeletons and mature leaves (foods that are difficult to fracture), generally have reciprocally concave, highly crested molars for shearing and slicing. In contrast, those that prefer hard, brittle foods (those that resist initial puncture but are easy to fracture once a crack has started), such as many seeds, nuts, and palm fronds, tend to have rounder, flatter molar teeth for processing such items. Such contrasts, however, have left African apes somewhere in between these two extremes, with members of the genus *Gorilla* leaning slightly towards more crested molars as compared with members of the genus *Pan*. Of course, such morphological differences are ultimately due to a complex mix of phylogeny and function, where one factor might, once again, complicate the interpretation of the other (Rensberger 1973; Kay 1975; Maier 1984; Hartman 1989; Uchida 1998; Butler 2000). Thus, quantification and statistical comparison were to prove essential in deciphering these interrelationships.

Quantifying Functional Aspects of Tooth Form

Innumerable quantitative methods of characterizing tooth shape have been developed over the past few decades. Early investigations used length/width measures of teeth to compute basal areas of teeth and cusps, which were then used as indicators of tooth "shape" (e.g., Biggerstaff 1969; Corruccini 1977, 1978; Lavelle 1978). While initial efforts focused on documenting differences between taxa, with an eye towards discrimination of fossil taxa (e.g., Wood and Abbott 1983; Wood and Engelman 1988), elaborations of this approach have led to possible insights into intraspecific dietary variations within *Pan* and *Gorilla* (Uchida 1992, 1996, 1998).

Meanwhile, studies of chewing efficiency in primates (Kay and Hiiemae 1974; Walker and Murray 1975; Sheine and Kay 1977) prompted a series of classic papers delving into the functional significance of variations in occlusal morphology (Kay 1975; Rosenberger and Kinzey 1976; Maier 1977; Osborn and Lumsden 1978; Lucas 1979).

These have then spawned many attempts over the past few decades to characterize/measure the shape of features on the occlusal surfaces of teeth (e.g., Seligsohn and Szalay 1978; Teaford 1983; Hartman 1989; Pilbrow 2003; Ungar and M'Kirera 2003). The most well known of these is still probably Kay's Shearing Quotient (SQ) method for analysis of molars (Kay 1978, 1984). The lengths of mesiodistal crests are measured on unworn molars of several closely related species with similar diets. A least-squares regression line is fit to summed crest length and mesiodistal occlusal surface length in logarithmic space. SQs are computed as residuals or deviations from the regression line. This approach tracks diets of living apes fairly well, as the more folivorous siamang and gorilla have relatively longer shearing crests than do extant frugivorous hominoids (Kay 1977; Kay and Ungar 1997).

Spears and Crompton (1996) have suggested an alternative approach, measuring great ape cusp slopes from molar cross sections. They found that gorillas had high-angled occlusal surfaces, orangutans had gradually sloping surfaces, and chimpanzees had shallow "supporting" cusps but steeper "guiding" slopes. These findings are taken to suggest that orangutans are adapted to reduce a hard/brittle diet, whereas gorillas can more efficiently fracture small food particles by shear. Chimpanzees, on the other hand, seem to be better suited to a diet with a wide range of mechanical properties.

Still, with advancements in data collection and analysis (e.g., dental topographic analysis, geometric morphometrics, and finite element modeling), there will undoubtedly be an upsurge in morphological analysis that will yield new insights. For instance, recent finite element analyses emphasize that variations in occlusal morphology must also strike a balance between chewing mechanics and stress resistance (Berthaume et al. 2010; Benazzi et al. 2013). This should give pause for thought in thinking about functional differences in tooth shape among African apes, as those differences may not be so easily tied to differences in chewing efficiency.

Of course, most of what has been done thus far has focused on *molar* occlusal shape. Some of that is due to the fact that the anterior dentition has a simpler morphology than that of the molars, and some is due to the fact that we have a better understanding of how primates use their cheek teeth. Thus, despite the aforementioned studies pointing to differences between taxa in incisor size (Jolly 1970; Hylander 1975; Kay and Hylander 1978), little more had been done on incisor morphology until recently. Pilbrow has now documented differences between apes in the incidence of discrete/nonmetric traits, but the functional significance of those differences has yet to be examined (Pilbrow 2006). However, Deane (2009) has recently used measures of incisor crown curvature as an indicator of diet differences among modern apes, and these measures show some promise in allowing more robust functional interpretations, with, for example, chimpanzees showing more pronounced curvature than gorillas. Of course such interpretations are only as good as our knowledge of how these teeth function.

Analyses of canine size and shape have been used primarily in taxonomic work and in studies of sexual dimorphism (e.g., Leutenegger and Shell 1987; Wood et al. 1991; Plavcan 1993; Plavcan and van Schaik 1993; Kelley 1995; Kelley et al. 1995). Still, more recent work has begun to sort through the functional implications of variations in canine morphology (e.g., Plavcan and Ruff 2008; Deane 2012), many of which may hinge upon interspecific differences in gape and display rather than diet, especially in African apes.

Premolars, by contrast, are a bit of an enigma. Their shape often rivals that of molars in its complexity. They often bracket a functional transition in the dentition between the anterior dentition focused on ingestion and the posterior dentition focused on mastication (Wood and Uytterschaut 1987; Greenfield and Washburn 1992). However, after a series of initial studies of interspecific differences in the length and breadth or premolar crowns and crown components (e.g., Corruccini 1977, 1978; Wood and Uytterschaut 1987), little else has been done with their morphology. Recent debates surrounding the dental adaptations of the early hominins (e.g., Strait et al. 2009, 2012, 2013; Grine et al. 2010, 2012; Daegling et al. 2013), in particular, the importance of premolar food processing, is beginning to spawn new research in this area (e.g., Delezene et al. 2013).

Tooth Wear Analyses

While studies of tooth morphology give glimpses of the complex relationship between primate tooth shape and diet, most such work has been limited to unworn teeth. This is a major limitation because it leads to an incomplete picture of the form-function relationship. Wear is a normal phenomenon that begins as soon as a primate's teeth come into occlusion. Thus, natural selection should also act on worn teeth, favoring morphologies that wear in a manner that keep them mechanically efficient for fracturing foods (Kay 1981, 1985; Teaford 1983; Teaford and Glander 1996; Ungar and Williamson 2000). In essence, since tooth wear occurs throughout an animal's lifetime, a great deal of information will be missed if worn teeth are excluded from future analyses. Another limitation of studies that depend exclusively on unworn teeth is the lack of sufficient numbers of specimens for many (especially fossil) taxa. For instance, the entire published sample of early hominins from South Africa still boasts less than ten unworn M_2s (the teeth most often used in functional studies).

The tooth wear of apes has occasionally been the focus of work in previous investigations. Early studies examined the *degree* of tooth wear in apes and humans in attempts to correlate tough, abrasive diets with the presence of increased tooth wear (Black 1902; Campbell 1925; Schultz 1935; Ashton and Zuckerman 1950; Welsch 1967). As noted by Wolpoff (1971), however, such interpretations are complicated by the complexities of diet and mastication, not to mention methodological difficulties associated with incorporating differences in dental eruption timing into such analyses.

Some investigators have made more detailed comparisons along the tooth row, noting, for example, that chimpanzees exhibit heavier incisor wear than do other apes (Ashton and Zuckerman 1950; Welsch 1967), again suggesting heavier incisor use in chimpanzees. More recently, Dean et al. (1992) have noted that later-erupting molars in chimpanzees and gorillas may actually show heavier wear than their predecessors, suggesting that occlusal loading is greatest on the last molar in the tooth row. It is perhaps no wonder then that molars in these species may also exhibit compensatory eruption as wear progresses (Dean et al. 1992) similar to that documented for some human populations (Whittaker et al. 1982, 1985).

With the advent of cineradiographic and electromyographic studies of mastication, studies of molar wear facets began to document subtle differences in jaw movement between primate species, with modern apes generally showing an increased emphasis on crushing and grinding as compared with some other catarrhines (Kay 1977; Maier and Schneck 1981). With these suggestions, analyses of tooth wear took another crucial step towards deciphering the relationship between dental form and function. This type of work has since been brought into the twenty-first century through a combination of laser scanning and metrology software that now allows quantification of wear facet patterns on teeth, in what is now referred to as "occlusal fingerprint analyses" (OFA) (Kullmer et al. 2009). Interestingly, virtually all of this work to date has focused on analyses of fossil material, yielding insights into possible functional differences between populations (e.g., Fiorenza and Kullmer 2013) and modifications of fossil reconstructions (e.g., Kullmer et al. 2013). What are now needed are analyses of extant primates, to see if, for instance, differences in these patterns of wear might indicate even more subtle differences in jaw movement and/or tooth use.

Of course, OFA essentially works with slightly worn teeth (e.g., those with wear facets but not massive dentin exposures). If it *does* yield insights into dental function in apes, could larger-scale differences in wear-related changes in tooth *shape* yield even more information? A look through the literature reveals a striking paucity of such studies. Why? Quite simply, it is not easy to measure tooth shape on worn teeth. Traditional dental morphometrics depend on measuring distances between landmarks that are quickly obliterated by wear. Smith (1999) attempted to control for wear using a technique modified from Wood and coauthors (Wood et al. 1983). Molar occlusal views were captured on video and individual cusp areas were identified on a computer screen by mouse-driven cursor. This allowed calculation of relative 2D (planimetric) areas of cusps on unworn to moderately worn teeth (as long as cusp boundaries were identifiable). Smith's results suggest that cusp proportions do indeed reflect diet to some degree – e.g., chimpanzees are linked with gibbons, rather than with gorillas.

Even this approach though, is not ideal. First, specimens must still be sufficiently unworn to distinguish individual cusp boundaries, and these disappear pretty quickly, especially on thin enameled molars, such as those of chimpanzees and gorillas. More importantly, planimetric area studies do not adequately characterize the third dimension of dental morphology. This is a problem because mastication occurs in a 3D environment, and two teeth with similar projected 2D areas may differ greatly in cusp relief.

The ability to collect elevation data is vital to studies of dental functional morphology. If cheek teeth are indeed guides for jaw movements (Simpson 1933; Crompton and Sita-Lumsden 1970; Hiiemae and Kay 1972), then surface relief is critical to the angle of approach of mandibular and maxillary teeth as facets come into occlusion during mastication. This in turn determines the biomechanical efficiency with which items of given mechanical properties are fractured (e.g., whether foods are sheared or crushed).

Clearly, what has been needed is a way to consider worn teeth in 3D studies of dental functional morphology. Dental topographic analysis is now beginning to serve that purpose. Elevation data representing an occlusal surface are collected using a 3D scanner, and the tooth is modeled and analyzed using geographic information systems (GIS) software (Zuccotti et al. 1998; Jernvall and Selänne 1999) (Fig. 1). Because dental topographic analysis does not depend on specific landmarks for measurement, it is equally useful for measuring unworn and worn teeth.

Some results for studies of living great apes are summarized and combined here to provide an example. Ungar and co-workers studied dental topography of *Gorilla gorilla gorilla* and *Pan troglodytes troglodytes* (Ungar and M'Kirera 2003; M'Kirera and Ungar 2003). These taxa were chosen for analysis because of the modest degree to which they differ in the material properties of the foods they consume. At sites where the two taxa are sympatric, such as Lopé, Gabon, Central African chimpanzees and western lowland gorillas overlap considerably in their diets, preferring soft, succulent fruits. The two taxa do differ though, especially at times of fruit scarcity. At such times, gorillas fall back more on tough, fibrous foods than do chimpanzees (Tutin et al. 1991; Remis 1997). Average annual food type

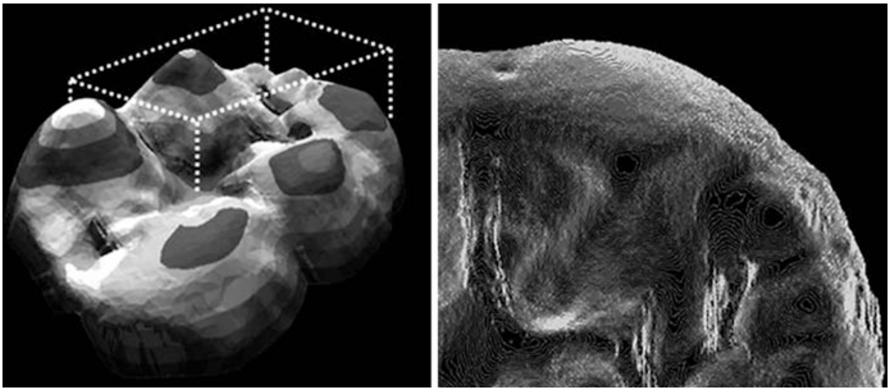

Fig. 1 Digital elevation model (*left*) and contour map (*right*) of a tooth. The contour interval is 25.4 μm, with a field of view corresponding to the area represented by the *box*

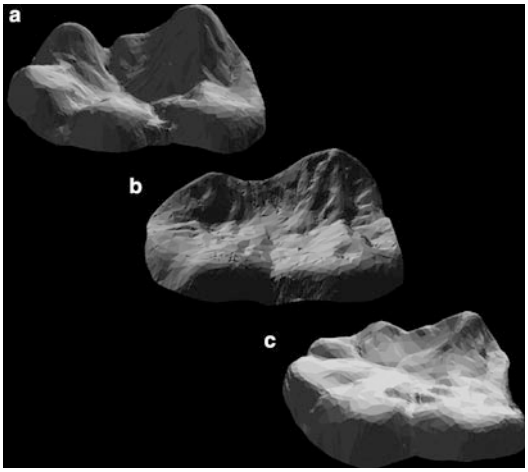
proportions reported for Central African common chimpanzees include about 70–80 % fruit flesh, as compared with 45–55 % fruit flesh for western lowland gorillas (Williamson et al. 1990; Kuroda 1992; Nishihara 1992; Tutin et al. 1997).

Dental topographic analysis of *Pongo pygmaeus pygmaeus* (Ungar and Taylor 2005) can add further insights into great ape molar form and function. Bornean orangutans consume an enormous variety of foods ranging from hard-husked, brittle nuts to soft fruits, to leaves, bark, and insects (MacKinnon 1977; Rodman 1977; Leighton 1993). While items consumed depend greatly on seasonal availability, average annual fruit to leaf proportions for *Pongo pygmaeus pygmaeus* are intermediate between those reported for *Pan troglodytes troglodytes* and *Gorilla gorilla gorilla*, with an average fruit percentage of about 55–65 % reported for the orangutans (MacKinnon 1977; Rodman 1977) – noting caveats concerning differences in data collection methods (Doran et al. 2002).

Data on average surface slope and occlusal relief are illustrated in Figs. 2, 3, and 4. These data are based on variably worn M_2s of *Pongo pygmaeus pygmaeus* ($n = 51$), *Pan troglodytes troglodytes* ($n = 54$), and *Gorilla gorilla gorilla* ($n = 47$). Methods of data collection are presented in detail elsewhere (Ungar and Williamson 2000; M'Kirera and Ungar 2003; Ungar and M'Kirera 2003). Occlusal surfaces were scanned as point clouds with lateral and vertical resolutions of 25.4 μm using a laser scanner. Resulting data files were opened as tables in ArcView 3.2 (ESRI Corp) Geographic Information Systems software, and digital elevation models were cropped to exclude areas below the lowest point of the occlusal basin. Average slope between adjacent points (surface slope) and the ratio of 3D to 2D planimetric area (occlusal relief) were then recorded for each specimen.

Results are illustrated in Figs. 2, 3, and 4. The species overlapped in three wear stages (as defined in Ungar 2004). As expected, more worn molar surfaces of each taxon showed less occlusal relief and shallower slopes. At any given stage of wear, however, gorillas had the steepest slopes and most occlusal relief, followed by orangutans. Chimpanzees had the shallowest molar cusps and least occlusal relief.

Fig. 2 Triangulated irregular network representations of surface data for M_2s of representative specimens at wear stage 1 (corresponding to Scott scores 10–14 (Scott 1979)): (**a**) *Gorilla gorilla gorilla* (CMNH B1781), (**b**) *Pongo pygmaeus pygmaeus* (SAPM 1981/62)



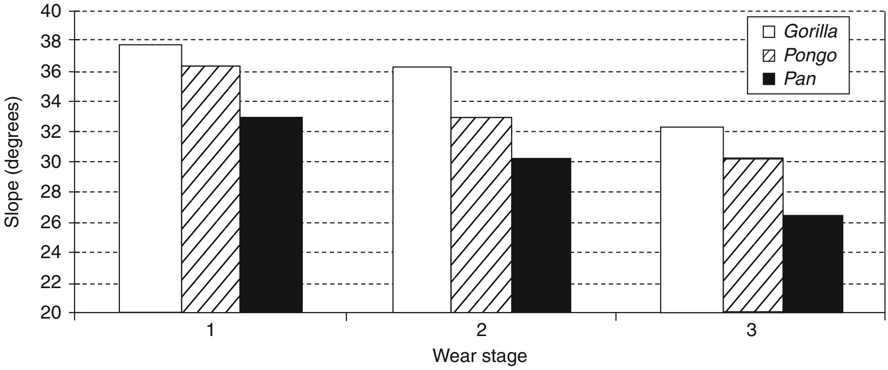


Fig. 3 Comparisons of mean surface slope values for given wear stages. Wear stages correspond to Scott wear scores as follows: (*1*) 10–14, (*2*) 15–19, (*3*) 20–24 (Scott 1979)

This example suggests several things. First, tooth shape changes with wear. As teeth wear down, cusp slopes and occlusal relief both decline. Such changes likely affect functional efficiency, and once teeth lose enough enamel, they essentially become dysfunctional (King et al. 2005). Further, apes with varying diets differ in the shapes of their teeth in ways that reflect the mechanical properties of foods that they eat. Species adapted to shearing and slicing tough leaves should have more occlusal relief and steeper sloped cusps than those adapted to crushing and grinding fruit. Cusp slope and occlusal relief values do mirror leaf-to-fruit ratios quite nicely for the great apes.

Another important point to come from this example is the notion that differences between species are of the same magnitude at different stages of wear. In fact, two-factor ANOVA results show no significant interaction between species and

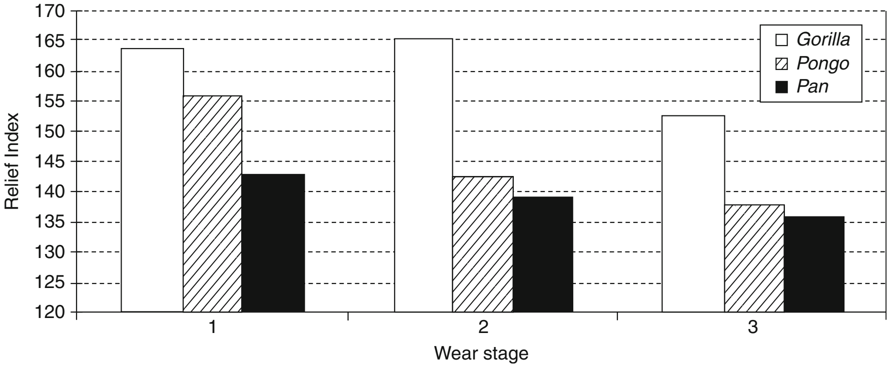

Fig. 4 Comparisons of mean surface occlusal relief values for given wear stages. Wear stages correspond to Scott wear scores as follows: (*1*) 10–14, (*2*) 15–19, (*3*) 20–24 (Scott 1979)

wear stage for any of the variables examined (M'Kirera and Ungar 2003; Ungar and M'Kirera 2003; Ungar 2004; Ungar and Taylor 2005; see also Klukkert et al. 2012). This basically means that differences between species remain consistent through the wear sequence. In other words, chimps, gorillas, and orangutans can be compared at any given wear stage and yield the same results, at least until very late in the game when teeth approach senescence, or their functional death (see King et al. 2005). This is important because it means that species need not be represented by unworn teeth as long as there is a baseline of comparative data for specimens with similar degrees of wear. This will allow reconstructions of diet for a whole new assortment of fossil taxa that could not be analyzed in the past for lack of available methods.

Fallback Foods and Dental Functional Morphology

As noted above, apes have a penchant for succulent, sugar-rich foods, a legacy of the ancestral catarrhine dietary adaptation (Ross 2000; Milton 2002; Ungar 2005). Differences in diet between catarrhines often rest largely with the seasonal shift to fallback foods taken when preferred resources are less available (e.g. Rogers et al. 1992; Lambert et al. 2004). In these cases, preferred resources are easy to digest, offer a low cost-benefit ratio, and may not result in selective pressures that would tax functional morphology. On the other hand, less desirable but seasonally critical fallback foods might require some morphological specialization (Robinson and Wilson 1998). This is not a new idea. Kinzey (1978), for example, noted that while *Callicebus moloch* and *C. torquatus* are both primarily frugivorous, the former evince longer shearing crests for slicing leaves and the latter have larger talonid basins for crushing insect chitin. He reasoned that dental morphology therefore reflects adaptations not only to primary foods but also to less frequently eaten but still critical ones.

As a result, gross differences in dental functional morphology need not relate to gross differences in preferred foods. Gorillas and chimpanzees at Lopé, for example, eat similar fruits much of the year (Williamson et al. 1990; Tutin and Fernandez 1993) but diverge at "crunch times" when preferred fruits are scarce. At such times, gorillas fall back more on leaves and other fibrous plant parts. The same is true for sympatric mountain gorillas and chimpanzees at the Bwindi Impenetrable National Park in Uganda (Stanford and Nkurunungi 2003). Differences between gorilla and chimpanzee occlusal morphology described here might then reflect fallback food choice more than everyday dietary preferences per se.

Function and Phylogeny

As indicated earlier, in discussions of tooth size, another issue to consider when inferring dietary adaptations from morphology is the effect of phylogeny. Phylogenetic inertia or baggage plays an important role in how adaptations manifest themselves (Kay and Ungar 1997). For example, while shearing quotients track diet within cercopithecoids, hominoids, and platyrrhines (with folivores having longer crests than frugivores within each of these higher-level taxa), cercopithecoids have relatively longer shearing crests than hominoids, and hominoids have relatively longer shearing crests than platyrrhines *independent of diet* (Kay and Covert 1984).

Because phylogeny determines the starting point for morphology, care must be taken when considering an extant baseline series to which an extinct species should be compared. Clearly, the choice of traits, out-groups, and methodology can all have a significant influence on the outcome of any analysis (e.g., Collard and Wood 2000; Lockwood et al. 2004; Strait and Grine 2004; Bjarnason et al. 2011). However, when all is said and done, early Miocene apes tend to have less well-developed shearing crests than do extant hominoids – though their ranges of SQ values are similar. It appears as if the extant hominoid range is upshifted relative to the early Miocene ape range but reflects a comparable array of diets (Kay and Ungar 1997; Ungar et al. 2004). This can be confirmed by "anchoring" the range using independent data, such as dental microwear patterning.

Dental Microwear Analyses

Investigators have known they could gain insights into jaw movement and tooth use through light microscope analyses of wear patterns on teeth for nearly a century (Simpson 1926; Butler 1952; Dahlberg 1960; Dahlberg and Kinzey 1962). Subsequent work rekindled interest in the topic (Grine 1977; Rensberger 1978; Walker et al. 1978; Puech and Prone 1979; Ryan 1979), as many workers shifted to using the scanning electron microscope. Since then, analyses of modern and fossil material have yielded insights into dietary variations within and between species and also new perspectives on the evolution of tooth use and diet in animals ranging from dinosaurs to human ancestors (see Teaford 1994; Rose and Ungar 1998; and Ungar 2002 for reviews).

The advantage of dental microwear analysis is that it provides evidence of what an animal was actually *doing* during its lifetime, not merely what it was capable of doing. The disadvantage, of course, is that it begins to document variations in diet in all its complexity. Thus, data samples of museum material need to include either exceptionally well-provenienced material or extremely large samples, and there needs to be some control, or awareness, of habitat differences between collection sites. Unfortunately, initial analyses of modern hominoids were generally based on small sample sizes (Gordon 1982, 1984; Teaford and Walker 1984; Teaford 1988; King et al. 1999), a factor which cannot be ignored when considering microwear data for animals, like chimpanzees and orangutans, with variable diets. Also, the earliest quantitative studies involved digitization of features on SEM images, a technique that has a subjective component that may complicate comparisons of results between different investigators (Grine et al. 2002). Still, initial results suggested diets dominated by soft fruit for the chimpanzee; fruit with perhaps some hard objects for the orangutan; and tough, leafy vegetation for the mountain gorilla (Teaford and Walker 1984; Teaford 1988) (see Fig. 5). Interestingly, comparisons of results for lowland and mountain gorillas yield microwear differences suggestive of the dietary differences documented in the literature (Tutin and Fernandez 1993; Remis 1997), with lowland gorillas showing a higher incidence of pitting on their molars as compared with mountain gorillas (King et al. 1999) (see Fig. 6).

As with studies of tooth morphology, dental microwear analyses have recently benefitted from a change to high-resolution 3D imaging and more sophisticated analyses (e.g., Ungar et al. 2003; Merceron et al. 2005; Scott et al. 2005, 2006). This has allowed more objective analyses of far larger samples, with the net result that populations of species are now being compared for intraspecific patterns of microwear and dental function (e.g., Krueger and Ungar 2010; Merceron et al. 2010; Daegling et al. 2011), and interspecific comparisons are now beginning to document the true range of microwear variation within taxa and between habitats. For African apes, however, the net result is perhaps not as clear as one would like. This is still probably due, in part, to a reliance on a relatively small, poorly provenienced sample, for even the most thorough recent studies of primate dental microwear (Calandra et al. 2012; Scott et al. 2012) have included samples of less than 20 specimens each of *Gorilla gorilla*, *G. beringei*, and *Pan troglodytes*. Thus, some results are what might be expected given what is known about African ape diets. For instance, the chimpanzee tends to clump together with known primate frugivores (Calandra et al. 2012; Scott et al. 2012). However, while *G. gorilla* was recognized as a consumer of abrasive plants in one study (Calandra et al. 2012), the addition of *G. beringei* to the other analysis introduced enough variation into the "gorilla" sample to make simple comparisons between genera more complicated (Scott et al. 2012). The net result is that, while there are suggestions of differences between *G. gorilla* and *G. beringei*, more work there is clearly necessary, and comparisons of *P. paniscus* with the other African apes are still lacking.

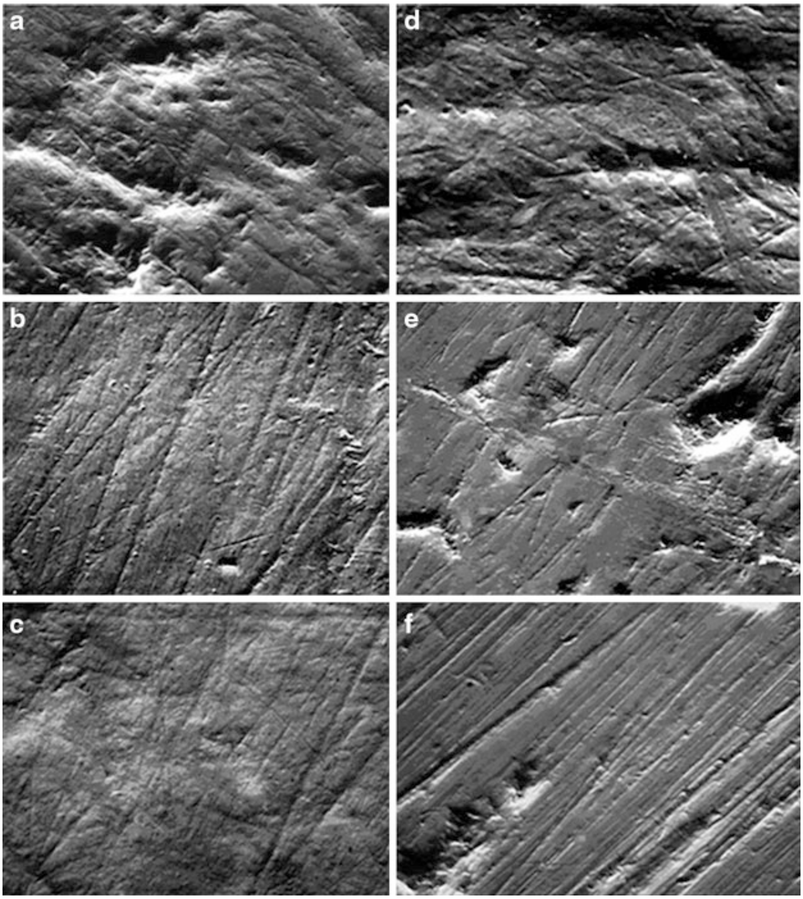

Fig. 5 Scanning electron micrographs of modern and fossil molars. (**a**) *Cebus apella*, (**b**) *Homo sapiens* (Arikara), (**c**) *Homo habilis*, (**d**) *Homo erectus*, (**e**) *Pan troglodytes*, (**f**) *Gorilla beringei*

As most studies of dental functional morphology hinge ultimately upon assumptions of the usefulness and selective advantage of the structures being measured, dental microwear analysis can certainly provide corroborative evidence for other hypotheses, for instance (as noted earlier), by "anchoring" analyses of dental morphological variation. Thus, dental microwear and molar shearing crest analyses for Eurasian fossil hominoids suggest that *Oreopithecus* was a folivore, *Ouranopithecus* was a hard-object feeder, and remaining forms such as *Dryopithecus* were soft-fruit eaters (Ungar et al. 2004; see also chapters "▶ Fossil Record of Miocene Hominoids," "▶ Hominoid Cranial Diversity and Adaptation," Vol. 2 and "▶ Potential Hominoid Ancestors for Hominidae," Vol. 3). By contrast, molar shearing crest analyses of African Miocene hominoids suggest at first glance that all were either soft-fruit eaters or hard-object feeders. However, the microwear evidence suggests that molar shearing quotients for the African Miocene taxa are

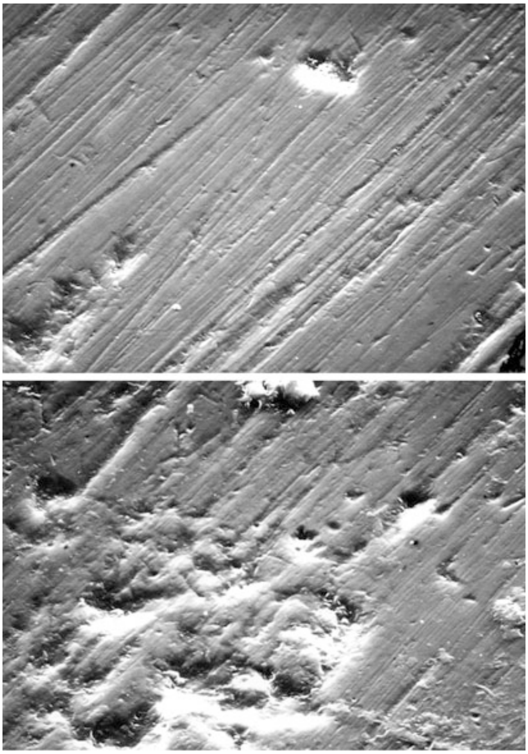

Fig. 6 Scanning electron micrographs of *Gorilla beringei* (*top*) and *Gorilla gorilla* (*bottom*)

"downshifted" by about 50 %, with *Rangwapithecus* as a folivore and the remaining taxa as soft-fruit eaters. This is exactly the same sort of shift we see comparing New World and Old World monkeys.

Obviously, given current knowledge about primate diets, dietary categorizations such as these are gross oversimplifications. Either fallback foods or preferred foods may be of crucial importance for the survival and reproduction of individuals. Thus, either may be a selective force to be reckoned with in the evolution of morphological differences. So how can they be teased apart? The key lies in the collaborative use of as many lines of evidence as possible, on samples that are as large as possible (Teaford et al. 1996; Teaford 2007). Of course, the fossil record will always be the ultimate arbiter of sample sizes in such analyses. Still, the combination of dental microwear analyses and other paleobiological data has allowed researchers to gain new perspectives on the dietary capabilities of the earliest hominins (Ungar et al. 2008; Grine et al. 2012). This has then spawned ongoing discussions about the proximate and ultimate causes of morphological differences among early hominins (Strait et al. 2009, 2013; Grine et al. 2012; Daegling et al. 2013), including, once again, insights into the distinction between dental *capabilities* and dental *use*, and also discussions of the ecological significance of observed differences in dental microwear (Daegling et al. 2013; Strait et al. 2013; Teaford et al. 2013). The bottom line is that researchers have only begun to tap into a wealth of data from innumerable sources ranging from laser scanning and dental microtextures to finite element modeling and nanoindentation. Through techniques such as these, researchers cannot help but gain a better grasp of variations in modern animals, and from that a better understanding of the intricacies of dental function, and a clearer picture of the past.

Conclusion

We live in an age of explosive technological advancement. Virtually every year, new techniques are used to answer new questions. The study of teeth has been but one small beneficiary of this phenomenon as recent advances in data collection and analysis are constantly being applied in new ways to studies of dental microstructure and development, tooth size and shape, and dental wear. This work is changing our perspectives on the lives and life histories of modern apes and human ancestors.

Evolution of the Primate Brain

Dean Falk

Contents

Abstract

The active intelligence of today's primates flowered from trends that sculpted primate brain evolution across deep time: an increase in absolute brain size but a decrease in relative brain size (RBS, the ratio of brain size to body size) in bigger-bodied compared to smaller-bodied species (reflecting developmental scaling within species), increased RBS in highly "encephalized" species, and increased complexity of brain organization in conjunction with major adaptive shifts and selection for neurological specializations. Indices that quantify encephalization are discussed, as are developmental and physiological factors that constrain brain size. Data are provided which suggest that absolute brain size and RBS increased steadily rather than erratically during the last 3 Ma of hominin evolution, and the "received wisdom" that human frontal lobes are disproportionately enlarged is questioned. Despite the enormous importance

attributed to the evolution of primate brain size, the conviction remains that size alone is not enough to account for the observed diversity in primate behavior and that circuitry, neurochemistry, and subsystems (modules) were reorganized within brains to accommodate evolving behavioral repertoires (such as those entailed in language). Arguments about the relative evolutionary merits of brain size versus neurological reorganization are reviewed and, to some extent, reconciled.

Introduction

The mammalian order Primates is known for a variety of species that are lively, curious, social, and intelligent. Nonhuman primates are of special interest to people not only because they are appealing and entertaining to watch but also because certain species (e.g., of macaques or baboons) are genetically close to humans, which makes them excellent animal models for medical research. As curious primates ourselves, we wonder about our evolutionary origins. One way to address this topic is to study and compare species from living primates that are thought to approximate broad stages (or grades) that occurred during some 65 Ma of primate evolution. Thus, one may compare particular anatomical structures or behaviors across appropriate representatives from the series prosimian → monkey → ape → human. When possible, such a *comparative method* should be supplemented with the *direct method* of studying fossil primates, which adds elements of specificity and time to the picture.

Within this broader context, we are also interested in the more specific question of how humans came to be not only the largest-brained primate but also the most intelligent species on Earth. In order to address this question, one must study primate brain evolution. From our general understanding of primate evolution, we know that certain major adaptations occurred in some groups and that these changed and sculpted evolving brains during many millions of years. For example, the anthropoid ancestors of living monkeys, apes, and humans became diurnal, and this shift from night living to day living dramatically impacted the lives and nervous systems of their descendants forever after. Thus, brains of diurnal primates have relatively enhanced visual compared to olfactory “modules.” Another broad shift that greatly impacted the nervous system occurred when very early primates shifted from primarily ground living to living in trees. This newfound arboreal life underscored the adaptive value of keen vision with depth perception and also led to improvements in sensory/motor coordination in conjunction with a variety of locomotor patterns that evolved in different arboreal species. More recently, some of these species shifted back to terrestrial living; and this, too, left its imprint on their nervous systems.

As with many groups of mammals (Jerison 1973; Radinsky 1979), relative brain size (RBS, the ratio of brain to body size) increased during the course of primate evolution. Some years ago, Radinsky (1979, p. 24) noted that “elucidation of the factors responsible for the widespread evolutionary trend of increase in RBS in mammals, and for the extreme to which that trend was carried in humans, remains a fascinating unsolved problem." Even before Radinsky's observation, Jerison was pondering the laws that governed the evolutionary increase in brain size for various groups of primates (and other animals) and partitioning the respective total increases into two parts: those associated with allometric scaling expected for given body sizes and any remaining increases (or decreases) in brain size, known as "residuals." Other workers, most notably Holloway (1974, 1979), emphasized the evolutionary importance of neurological reorganization that alters the quantitative relationships between brain nuclei, fiber tracts, and neuroreceptor sites (Holloway et al. 2004), thus allowing for rewired and altered neurochemistry in brains of similar (or different) size. Although the debate about the respective importance of brain size versus neurological reorganization is a false dichotomy (Gould 2001) (both are important, of course), it continues today (Falk and Gibson 2001). Bringing welcome balance, Holloway et al. (2004) note that the concept of reorganization in brain evolution is of less concern when one is examining broad genetic and evolutionary conservatism between large numbers of taxa (Jerison 1973; Finlay and Darlington 1995; Finlay et al. 2001; Kaskan and Finlay 2001), but more important when one attempts to explain species-specific differences in behavior (Preuss 2001; Holloway et al. 2004).

General Methods for Studying Primate Brain Evolution

The *direct method* of studying fossilized braincases and casts of their interiors (endocranial casts or endocasts) is the bread and butter of paleoneurology (literally "old" neurology). Cranial capacities that approximate brain volume in cm^3 (and also brain mass in grams) may be measured from skulls by traditional methods such as filling braincases with mustard seed that is then measured in a graduated cylinder or by obtaining volumes electronically from braincases (skulls) that have been subjected to three-dimensional computed tomography (3DCT). Indeed, because 3DCT is able to resolve small density differences, such as those between fossilized bone and attached rock matrix, it is particularly good for investigating fossils (Spoor et al. 2000) and has become useful as a noninvasive method for visualizing "virtual endocasts," e.g., by flood-filling the virtual braincase (Falk 2004b). Although brain size is actually slightly smaller than cranial capacity because of the fluids, vessels, and brain coverings (meninges) that occupy the braincase along with brain tissue, the difference is insignificant compared to other sources of intraspecific variation in brain size (according to Hofman (1983), cranial capacity = 1.05 brain size), and the two variables are frequently used interchangeably. An advantage of using cranial capacities across the board in comparative studies is that, unlike actual brains, cranial capacities may readily be obtained from available skulls of fossil and extant primates.

Endocasts sometimes occur naturally under propitious geological conditions (such as those that exist in parts of South Africa) or they may be prepared artificially from skulls using liquid latex (see Falk (1986) for details). Over the past 20 years, the use of 3DCT data for reconstructing and measuring virtual endocasts has undergone numerous validation studies (Conroy and Vannier 1985; Conroy et al. 1990, 1998; Spoor et al. 2000) and is rapidly becoming a preferred method (Falk 2004b). Physical endocasts may be measured to determine cranial capacity, e.g., by displacing them in water (see Holloway et al. (2004) for details), and as noted, the volumes of virtual endocasts may be measured electronically. Additionally, both kinds of endocasts (depending on their quality) may reveal positions of vessels and cranial nerves; details of suture closure, venous sinuses, and emissary veins (foramina); information about cortical asymmetries including brain shape (petalia) patterns; and information about sulcal patterns. Curiously, the most detailed endocasts are produced from skulls of relatively young individuals within a species (Connolly 1950) and from skulls of smaller-brained species within a group of related species (Radinsky 1972). The former may relate to the timing of suture closure during development, while the latter may explain why some of the South African australopithecine natural endocasts reproduce a good bit of detail (Falk 1980a, b).

By comparison, those using the *indirect method* of comparing neuroanatomical structures among living species have a veritable arsenal of methods at their disposal. Specific cortical areas may be investigated using currently available histochemical and immunocytochemical techniques (Preuss 2001; Sherwood et al. 2008), in addition to relying on classic cytoarchitectural studies (Amunts et al. 1999). Questions can therefore be asked about the types, sizes, density, distribution, and connections pertaining to individual neurons, cell columns, or layers of the cerebral cortex (within and across particular regions). The comparative neuroscientist is able to ponder whether or not (and how) additional cortical areas have been “added” during primate evolution and the extent to which they might be associated with enlarged brains (Felleman and Van Essen 1991; Preuss and Goldman-Rakic 1991; Sherwood et al. 2008). Whereas CT is ideal for imaging fossil material, magnetic resonance imaging (MRI) is more suitable for imaging the soft tissue structures that comparative neuroscientists study and may be performed noninvasively and in vivo. (Instead of relying on an X-ray source, MRI uses pulses of radiofrequency energy to map specimens that have been subjected to a strong magnetic field.) Even better, positron emission tomography (PET) and functional MRI (fMRI) are now commonly used to study functional processing in living human brains, and these techniques are beginning to be applied to nonhuman primates (Semendeferi 2001).

Although the increasingly sophisticated information gleaned from comparative brain studies is indispensable for interpreting paleoneurological data, the logistics of synthesizing findings from the *direct* and *indirect methods* for studying primate brain evolution remain tricky.

Structural, functional, and developmental disciplinary approaches have started to coalesce whereby brain structures can be seen developing and functioning through the many new noninvasive imaging techniques that are available today (Hofman and Falk 2012). All this allows better understanding not only of how the brain works in terms of movement and sensation but also of how it functions during sleep, during preparation for action, during thinking, and during emotions. These lines of investigation, which have major implications for normal as well as diseased human brain function, employ more and more complex methods and reveal the workings of smaller and smaller brain components. Consequently, the logistical problems of carrying out such studies in an evolutionary perspective and timescale loom ever larger (Oxnard 2004, pp. 1128–1129).

Quantifying Primate Brain Size

Certain allometric factors govern the general external and internal morphology of primate brains. Larger primate (indeed, mammalian) brains are characterized by more convolutions (gyri and sulci) than smaller ones (Radinsky 1975), which appears to be a mechanism for maintaining the ratio of surface (cortex) area to brain volume as brains enlarge (Falk 1980b; Jerison 1982). (This is not to say that sulci and convolutions are never associated nonallometrically with specialized features. Sometimes they are (Falk 1982), e.g., brains of prehensile-tailed New World monkeys have tail representations that are delimited by special sulci.) Neuronal density decreases with increased brain size, although mean neuronal size does not appear to scale allometrically with brain volume (Haug 1987). Compared to other mammals, the primate cerebral cortex is thicker and its layer IV is highly granulated (Haug 1987). The volume of gray matter is basically a linear function of brain volume, whereas the mass of interconnections that form the underlying white matter increases disproportionately with brain size (Ringo 1991; Hofman 2001). Curiously, women have relatively more gray matter than men (Haug 1987, see Falk (2001) for details regarding sexual dimorphism in primate brains).

Absolute brain size is hugely variable across living primates. Cranial capacities of living prosimians, monkeys, and gibbons overlap and together range between 1 and 205 cm^3, which is separate from the great ape range of 275–752 cm^3 (Falk 1986) (Fig. 1). The human range is above that for great apes and extends from around ~1,100 to 1,700 cm^3, excluding extreme outliers for purposes of comparison. But there is a problem here. The world's smallest primate, the pygmy mouse lemur (*Microcebus myoxinus*), has a body weight of approximately 30 g (~1 oz), so how can we possibly compare its tiny brain size to those of larger primates such as the great apes? Clearly, a more meaningful parameter would be the ratio between brain size and body size, known as RBS. However, RBS is itself confounded by certain very powerful allometric scaling constraints that apply ontogenetically as individuals develop from smaller-bodied babies to adults (Passingham 1975b) and in interspecific comparisons of smaller-bodied with larger-bodied primates (Schultz 1956) (Fig. 2). Allometric scaling is why human babies appear to have relatively big heads (brains) compared to adults despite the fact that their absolute brain sizes are smaller, and it is why we should not be particularly impressed by the fact that little squirrel monkeys have an average RBS of about 0.02, which is equivalent to that of humans (Falk and Dudek 1993).

In order to "subtract" the effects of allometric scaling, comparative studies of primate brain size have traditionally relied on quotients that express "residual"

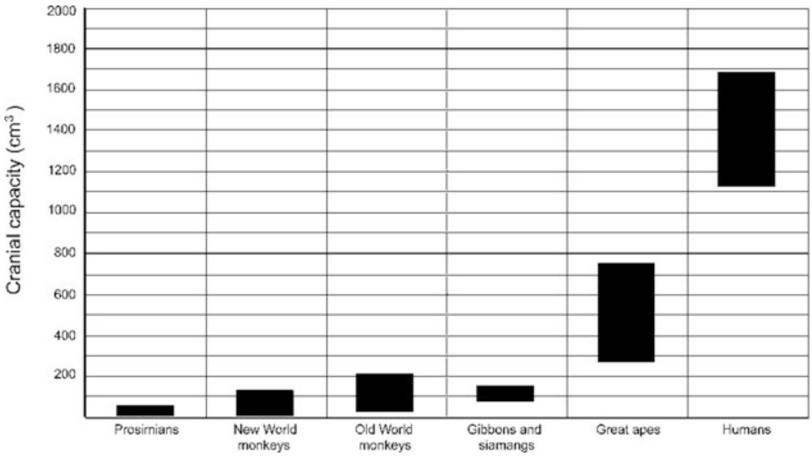

Fig. 1 Ranges of cranial capacities in living primates, excluding far-reaching extremes in humans for comparative purposes (Modified from Falk 1986)

factors after the effects of body size have been removed from paleoneurological data (Falk 1980b). Thus, Bauchot and Stephan (1966, 1969) and Stephan (1972) developed the index of progression (IP) by using brain weight/body weight data from basal insectivores and calculating the regression equation:

$$\log\ h = 1.632 + 0.63\ \log\ k \tag{1}$$

where h = brain weight and k = body weight. From this equation, "basal" brain weight (BG) can be predicted for a given primate species by substituting its mean body weight into the equation. The ratio between actual mean brain weight of the species (progressive size = PrG) and the predicted "basal size" (BG) equals IP, the index of progression,

$$\mathrm{IP} = \frac{\mathrm{PrG}}{\mathrm{BG}} \tag{2}$$

Jerison's (1973) famous encephalization quotient (EQ) is similar but uses brain weight/body weight data from living mammals rather than insectivores to establish the baseline regression and resulting classic formula:

$$\mathrm{EQ} = \frac{E_i}{0.12P_i^{67}} \tag{3}$$

where E_i = actual brain size and P_i = predicted brain size.

(Like other workers (Martin 1982, 1990), Jerison (2001) now uses a regression equation with an exponent of 0.75, instead of 0.67.) It should be noted, however, that the comparative results of EQ studies depend very much on the group selected for the baseline data (Holloway and Post 1982) and that there is an artifactual

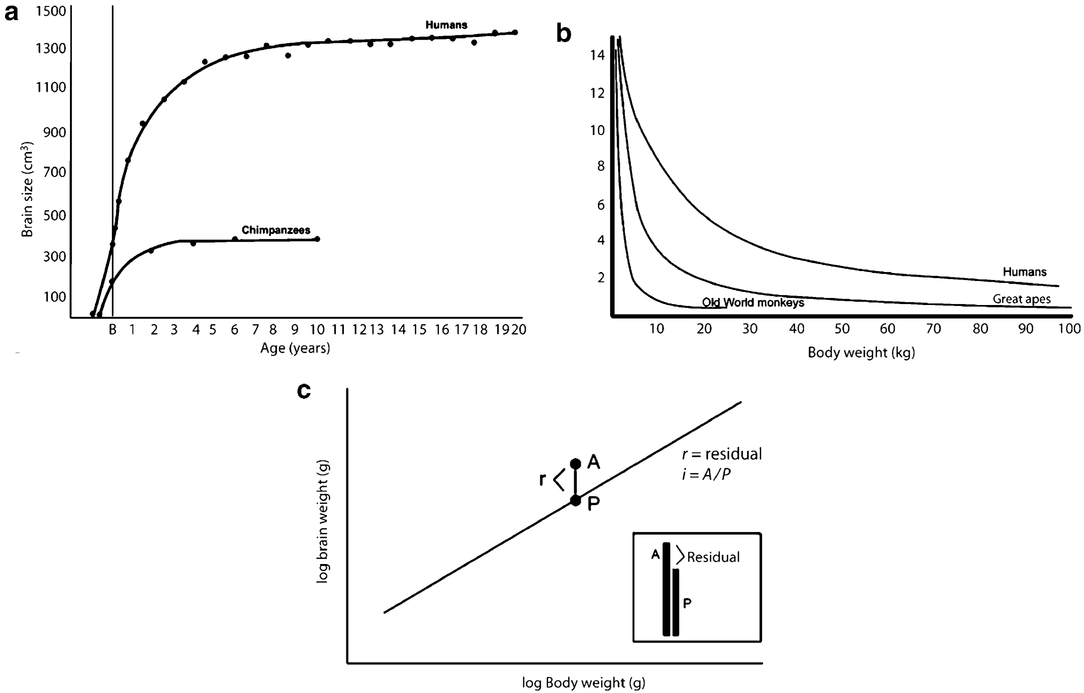

Fig. 2 Brain size and relative brain size (RBS) in humans and other primates. (**a**) Brain size growth in humans and chimpanzees. Brain growth in humans is at a higher rate after birth (**b**), which results in larger cranial capacities (and brain masses) for humans than chimpanzees at any given age (or body weight) (Modified after Passingham 1975b). (**b**) Relative brain size (RBS, brain size/body size) plotted against body weight for humans, great apes, and Old World monkeys. The shapes of these curves are inverse to those above (in (**a**)) and, again, are stacked because of different rates of postnatal brain growth in the three groups. At any given body weight (and age), humans have RBS above those of apes, which are above those of monkeys. At smaller body weights (and therefore ages), primates have greater RBS (which is why human infants appear to have big heads) (Modified from Schultz 1956). (**c**) Simple schematic that illustrates indices of relative

tendency for encephalization to be overestimated for smaller-bodied species but underestimated for larger ones (Radinsky 1982). One may also utilize similar regressions to estimate residual numbers of extra neurons (Jerison's extra neuron index, Nc) or to determine how "encephalized" particular parts of the brain are. Toward these ends, Stephan et al.'s (1970) widely cited data for primate brains have been a gold mine for evolutionary studies.

The Evolution of Primate Brain Size

Compared to basal insectivores, primates evolved enlarged brain size/body size ratios (Radinsky 1975). Cranial capacity estimates for a dozen available Eocene and Oligocene prosimian skulls are all under 11 cm^3, and their EQs suggest that the Eocene adapiforms *Smilodectes*, *Adapis*, and *Notharctus* were relatively smaller-brained than modern prosimians and those for Tarsiiformes (for which there is a brief series) increased through time (Radinsky 1975; Gurche 1982). By about 45 Ma, some prosimians appear to have RBS at the lower end of modern ranges (Radinsky 1975). Radinsky (1974) noted that an Oligocene anthropoid, *Aegyptopithecus*, had a cranial capacity of approximately 32 cm^3 but had nevertheless attained an anthropoid level of RBS. The Miocene hominoid *Proconsul* had a comparatively whopping endocranial volume of 167 cm^3 and an estimated body weight of ~11 kg, giving it a relatively bigger brain than modern monkeys of comparable body size (Walker et al. 1983). Recent analyses confirm that selection for enlarged brains began early in primate evolution but also indicate that brain size decreased independently in certain branches of strepsirhines, New World monkeys, and Old World monkeys (Montgomery et al. 2010). Over a quarter of a century ago, Radinsky (1974) summarized his findings from the "scanty" fossil record of primate brain evolution by observing that increased RBS dramatically distinguishes human brains from those of other primates, and he further suggested that this increase occurred relatively recently, beginning no more than 4–5 Ma (Radinsky 1975).

Although most modern anthropoids have brains that are relatively larger than those of modern prosimians (Bauchot and Stephan 1969), caution must be exercised when using EQs or similar indices to assess cognitive capacities. Despite the fact that EQs correlate to some degree with primate feeding behaviors

Fig. 2 (continued) brain size (i), the names of which vary (EQ, IP) with the reference group for the linear regression. When transformed to logarithms, brain size versus body size data (such as those in (**a**)) have a linear relationship (the *straight line* or linear regression shown in (**c**)). *P* is the mean value for brain size predicted by the regression for a species at a given mean body weight; *A* is the actual mean value of brain size for that species. The index of RBS (or encephalization), *i*, is the ratio of *A* to *P*. The difference between *P* and *A*, the residual (*r*), is the extra (or reduced) mean brain size that a species has compared to a species of similar mean body size in the reference group. The reference group (be it composed of mammals, insectivores, or just monkeys) is very important for interpreting indices (frugivorous primates are more encephalized than folivorous ones (Jerison 1973; Clutton-Brock and Harvey 1980; Milton 1988) and nonhuman primates that are omnivorous extractive foragers generally have higher IPs than the others (Gibson 1986), such indices fail to predict relative cognitive capacities. Gibson (2001) argues persuasively that compared to monkeys, great apes possess greater mental constructional capacities and cognitive abilities in realms once thought to be uniquely human. Using a test for mental flexibility that separates apes from monkeys (the Transfer Index), she demonstrates that absolute brain size, body size, and extra neurons all correlate with performance, while EQ does not. Gibson therefore suggests that "the most practical measure for distinguishing intelligence and predicting the presence of humanlike mental skills in hominid fossils is absolute brain size" (Gibson 2001, p. 92). Other studies also emphasize absolute over RBS as the best predictor of advanced cognition. Thus, "Only in terms of absolute mass and the rate of change in absolute mass has the increase in brain size been exceptional along the terminal branch leading to humans. Once scaling effects with body mass have been accounted for the rate of increase in relative brain mass remains high but is not exceptional" (Montgomery et al. 2010, p. 11). Others reinforce this suggestion (Deaner et al. 2007; Herculano-Houzel 2009, 2012). For example, "the functional integration of different brain regions is so strong that the brain as a whole is a relevant unit for cognitive performance" (Deaner et al. 2007, p. 121), and "the most likely brain alteration resulting from selection for any behavioral ability may be a coordinated enlargement of the entire nonolfactory brain" (Finlay and Darlington 1995, p. 1578).

The relationship between primate brain size and cognition may also be explored by investigating the interaction between life-history adaptations, brain growth, and cognitive levels (primate cognitive ecology Garber (2004)). In one study, postnatal brain growth patterns were found to be highly variable among anthropoids (Leigh 2004). Leigh discerned two alternate life-history strategies that concern the metabolic costs of infant brain growth. In one, favored by Old World monkeys, relatively large-bodied mothers mature late and give birth to infants that require relatively little postnatal brain growth. This strategy requires high maternal metabolic investments during pregnancy. In the second strategy, exploited by tamarins, females mature especially early and produce offspring with brains that grow for a relatively long period of time during the postnatal period, which shifts some of their metabolic costs away from the mother and to others (including the offspring). Leigh notes that chimpanzees and humans are difficult to categorize in terms of these two strategies and adds that differences in patterns of brain growth should be viewed as part of a more general complex of life-history traits rather than as direct pacesetters of life histories. Citing comparative studies on the cognitive abilities of squirrel monkeys, tamarins, and baboons, Leigh concludes that life-history strategies may have coevolved with cognitive abilities in association with evolutionary changes in brain development.

Other studies investigate the perplexing question of how primates (including humans) were energetically able to grow relatively large brains that are metabolically "expensive" to maintain compared to the whole body. The maternal energy hypothesis (MEH) proposes that the mother's relative basal metabolic rate (BMR) during an infant's gestation determines its neonatal brain mass and that subsequent maternal investment while the infant is nutritionally dependent is also an important factor for developing big brains (Martin 1996). The MEH is sometimes contrasted with the expensive-tissue hypothesis (ETH), which proposes that relatively encephalized primates are able to maintain their brain's metabolic requirements because there has been an evolutionary trade-off in which brain tissue has increased at the expense (decrease in mass) of other metabolically expensive tissues such as guts, heart, liver, or kidney (Aiello and Wheeler 1995; Aiello et al. 2001). The two hypotheses should be viewed as complementary rather than contradictory because the MEH focuses on maternal energetics invested in offspring during gestation and lactation, while the ETH picks up from there by focusing on metabolic dynamics of brain growth and maintenance after weaning (Aiello et al. 2001). While the wider applicability of both hypotheses to mammals has been challenged by findings for bats (Jones and MacLarnon 2004), the recent trend toward studies that explore physiological and metabolic constraints on brain size and development is welcome and dovetails nicely with primate life-history studies. (Another constraint hypothesis about brain size evolution, the radiator hypothesis, concerns the evolution of vascular anatomy in response to brain temperature regulation combined with selection for bipedalism (Falk 1990, 2007)).

Parsing Brain Size Evolution

But what are the possible neurological correlates of increased brain size during primate evolution? To address this, Finlay and colleagues concentrated on critical factors that drove mammalian (including primate) brain size, especially the kinds and numbers of neurons generated during development (Finlay and Darlington 1995; Finlay et al. 2001). They found that the longer cytogenesis is prolonged for a given structure (based on timing of the peak in "neuronal birthdays"), the larger the structure will ultimately be. Since mammalian neurogenesis of brain parts proceeds uniformly (i.e., the order is conserved), "by far the most useful predictors of structure sizes are the sizes of other brain structures" (Finlay et al. 2001, p. 268). It should be noted, however, that olfactory bulbs (and medulla) are an exception to this rule because they are smaller overall in anthropoids than prosimians and may map onto nocturnal versus diurnal niches (Barton et al. 1995). A result of this regularity is that most parts of mammalian brains enlarged together, which led Finlay et al. to suggest that enlarged isocortices could have been by-products of structural developmental constraints (spandrels) that were only later co-opted for specific functions. The suggestion that the sizes of different brain structures are a consequence of overall brain size has been the subject of more controversy than it should have (Barton and Harvey 2000; Barton 2001; Oxnard 2004), because the Finlay et al. model in fact accommodates independent variation of individual brain parts that may be associated with specific behavioral advantages (e.g., foraging ability). Generally, this latter type of brain growth, which makes up the unaccounted-for variance in Finlay et al.'s (2001) model, underlies a small (but presumably evolutionarily important) variation of individual structure size on the order of two- to threefold.

Evolution of Brain Size in Hominins

As noted, cranial capacities may be obtained for fossil hominins by measuring their endocasts (actual or virtual). Error may be introduced, however, because fossil endocasts are rarely whole and, thus, usually require partial reconstruction. Because morphological differences were found to distinguish the frontal lobes and temporal poles of robust (*Paranthropus*) and gracile (*Australopithecus africanus*) australopithecines, new endocast reconstructions were provided for four *Paranthropus* specimens, which reduced the mean cranial capacity for the genus to the point where it approximated that of *A. africanus* (see Falk et al. (2000) for details). These cranial capacities and others appear in Table 1 and Fig. 3. (For more extensive data, the reader is referred to Appendix 1 of Holloway et al. (2004)).

A number of conclusions regarding the evolution of absolute brain size in hominins are suggested by Fig. 3. Although brain size remained conservative during the evolution of *Paranthropus*, it increased in *Australopithecus* and between the latter and specimens that lived more recently (~1.7–1.9 Ma) in Africa and the Republic of Georgia. The overall morphology of these more recent specimens is transitional enough so that some workers place them in *Australopithecus* while others include them in early *Homo* (Wood and Collard 1999; Balter and Gibbons 2002). If, indeed, these specimens are transitional, then the received wisdom that brain size suddenly "took off" in the genus *Homo* around 2.0 Ma needs serious reevaluation (Falk et al. 2000; Falk 2004b). Thus, rather than there being a jump in cranial capacity in early *Homo*, cranial capacity may have begun increasing in the *Australopithecus* ancestors of *Homo* a million years earlier (Falk et al. 2000). With the redating of Java sites (Swisher et al. 1994; Huffman 2001) pushing certain cranial capacities further into the past, there is no longer the discontinuity in the trend for increasing cranial capacity (Falk 1987b, 1998) that once contributed to the suggestion that brain size evolution underwent "punctuated" events (Hofman 1983; Leigh 1992; Ruff et al. 1997). Rather, the recent discovery of LB1, the small-brained type specimen for *Homo floresiensis* (Brown et al. 2004; Morwood et al. 2004), lends an entirely new perspective to the study of hominin brain size evolution (Falk et al. 2005): From australopithecines through extant *Homo*, upward selection widened the range of brain size variation, while australopithecine-sized brains may have continued to provide the lower boundary (at least, until very recently). Thus, to some extent, Fig. 3 encapsulates the interplay between selection for brain size (vertical vector) and selection for neurological reorganization (horizontal vector).

But what about the evolution of RBS in hominins? After all, LB1 was tiny, only about a meter in stature (Brown et al. 2004), which must certainly account for much of

Following Holloway et al. (2004), the chronological data are approximate middle values of the ranges for estimated dates (see also Falk et al. 2000). See Fig. 3 for plots of data

the recent variation in brain size. Although many workers have estimated EQs for fossil hominins, these estimates must be taken with a grain of salt because of the difficulty of determining surrogates for body mass. Without an associated skull, how does one identify the species of postcrania such as femurs that are often used to predict body mass or stature? Needless to say, the few known hominin partial skeletons are extremely important in this endeavor. Conservatively, we know exactly this much about encephalization in hominins: living people have brains and (separately) neocortices that are approximately three times as large as expected for nonhuman primates of the same body size (Stephan et al. 1970; Passingham 1973, 1975a; Passingham and Ettlinger 1974), and, surprisingly, this is true using regression equations based on all nonhuman primates, just monkeys and apes, or just apes (Stephan 1972; Falk 1980b). Turning to the hominin fossil record, there are two skeletons that provide important data. First, there is the approximately 3′6″ Lucy (AL 288-1), dated to a bit over 3.0 Ma. Although a definitive cranial capacity could not be obtained from this specimen, hominin cranial capacities of less than 400 cm^3 occurred in other hominins from that time and place (Table 1), so it is safe to say that small-bodied australopithecines from Hadar, Ethiopia, had ape-sized body masses that were probably associated with ape-sized brains (giving them an RBS index of $i = 1$). Fast-forwarding to ~1.5 Ma, the *H. erectus* skeleton from Nariokotome, Kenya (KNM-WT 15000), paints quite a different picture. By the time he reached adulthood, it was projected that this “lad” would have reached a stature of over 6 f. and a cranial capacity of 909 cm^3 (Walker and Leakey 1993). That capacity is twice the means for both *A. africanus* and *Paranthropus* (Table 1) and roughly twice the means for living great apes (490 cm^3 for gorillas, 375 cm^3 for common chimpanzees and for orangutans (Falk 2000b), p. 312). It is also 2/3 of 1,364 cm^3, which is very close to the oft-cited world mean for contemporary *H. sapiens* of 1,350 cm^3. It therefore looks as if African *H. erectus* that lived ~1.5 Ma may have had a brain mass that was twice the size predicted for a living nonhuman primate of equivalent body mass ($i = 2$) or, put another way, that *H. erectus* was two-thirds as encephalized as *H. sapiens*. These few data provide nice 1-2-3 estimates for indices of RBS at ~3.0 Ma, ~1.5 Ma, and today (Fig. 3). Beyond this, conjecture about the past evolution of hominin encephalization remains just that.

One can, however, make reasoned inferences about future brain size evolution. In fascinating research, Hofman (2001, 2012) applied the design principles and

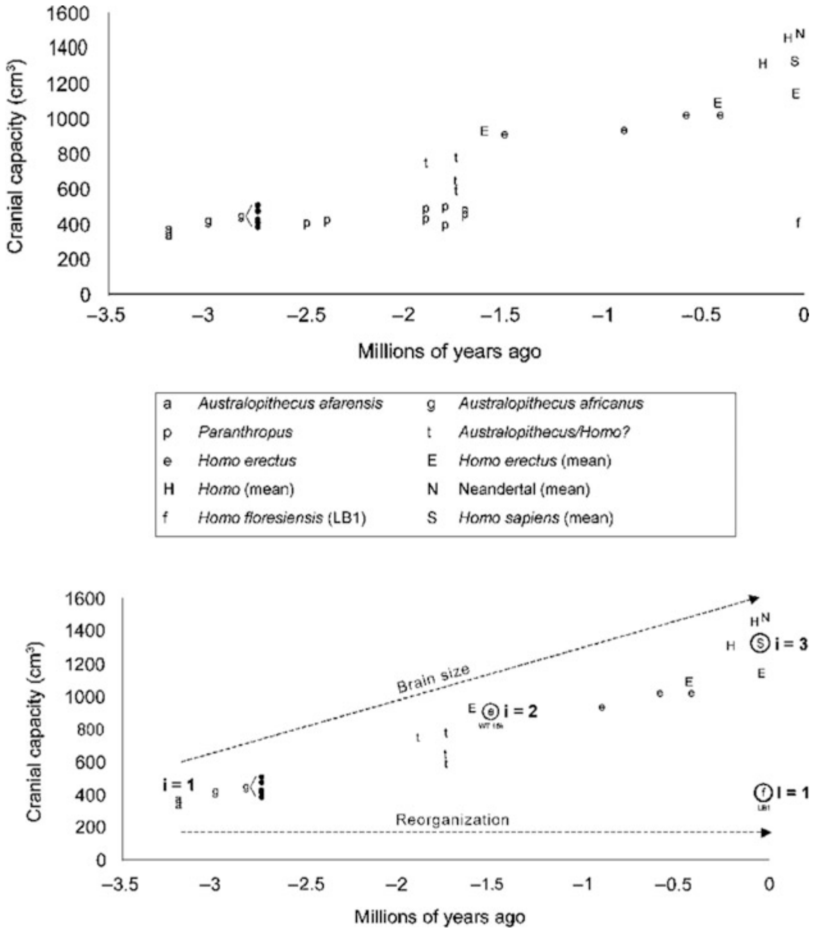

Fig. 3 Cranial capacities of select hominins plotted against time (Data from Table 1) (*Above*). Plot includes capacities for robust australopithecines (*Paranthropus*). The trend for brain size increase appears flat until around 2.0 Ma and then begins to increase in *Homo*. (*Below*). The same plot, but without the *Paranthropus* specimens (generally thought not to be ancestral to *Homo*). The trend toward brain size increase now appears to increase from before 3.0 Ma. Part of the reason for this is the recently described "transitional" specimens from Dmanisi, Republic of Georgia (listed under *Australopithecus*/*Homo* in Table 1). The earliest australopithecines and relatively recent LB1 (*H. floresiensis*) have brain sizes expected for apes of equivalent body sizes ($i = 1$), *H. erectus* from Nariokotome (KNM-WT 15000) has a brain that is twice the size expected for similarly sized apes ($i = 2$), and contemporary *H. sapiens*' mean brain size is three times that expected for apes of equivalent body size ($i = 3$). This figure illustrates the trends for increasing brain size (*vertical axis*) and ongoing neurological reorganization (*horizontal axis*)

operational modes (including energetic and neural processing constraints) that underlie information processing in primate brains to the task of modeling the limits of future brain size evolution in *H. sapiens*. His model predicts that as brain size increases beyond a certain critical point, subcortical volume (cerebellum, brain stem, diencephalon, etc.) will decrease in conjunction with increasing white matter. The net result would be that hominins with brains enlarged beyond that critical point would have a declining capability for neuronal integration despite an increased number of neurons. The critical point is ~3,500 cm^3, beyond which "any further step in the evolution of intelligence will then have to take place outside our nervous system, in a technological world where the selection mechanisms and forces are radically different from those operating in nature" (Hofman 2001 p. 125). Although Hofman's model does not incorporate anatomical constraints that govern head size and parturition, perhaps the technological world he envisions will, indeed, make it possible for women to bear (presumably) bigger-brained neonates.

The Evolution of Neurological Reorganization

Despite the enormous energy that paleoneurologists have devoted to studying primate brain size evolution, there remains a conviction that size alone is not enough to account for the observed diversity in primate behavior and that circuitry, neurochemistry, and subsystems (modules) must have become reorganized within brains to accommodate evolving behavioral repertoires (Preuss 2001; Holloway et al. 2004). Preuss, in fact, goes so far as to suggest that "the cortex is a veritable hotbed of evolutionary reorganization" (2001, p. 140). Although reorganization was undoubtedly important, deciphering the details of internal brain evolution is much more difficult than studying the gross phenomenon of brain size. Nevertheless, information yielded by both *direct* and *indirect methods* sheds some light on at least the broad aspects of neurological reorganization that occurred during primate evolution.

Comparisons of brains of basal insectivores and living primates suggest early evolutionary trends in primates that included not only the larger brain size/body size ratios noted above but also relatively enlarged neocortices for brain size, a decrease in the relative size of the olfactory bulbs, an increase in the amount of visual cortex, and development of a central sulcus in anthropoids rather than the coronal sulcus seen in prosimians (Radinsky 1975). At histological levels, layer 4 of the posterior cingulate cortex appears to be less densely packed with small cells in prosimians than anthropoids (Zilles et al. 1986), a finding that has now been extended to include much of the parietal and temporal cortices (Preuss and Goldman-Rakic 1991). The fossil record of prosimian endocasts helps to pin down the approximate dates when some of these primate specializations occurred (Radinsky 1974, 1975; Gurche 1982). Thus, visual and temporal cortices had expanded to comparable modern levels in some ancestral tarsiiform and lemuriform primates by ~55 Ma (Early Eocene), but frontal lobes were still relatively small except in the line leading to *Adapis* (Radinsky 1975; Gurche 1982). Analysis of the fossil record of anthropoid endocasts, particularly partial endocasts of *Aegyptopithecus*, reveals that by ~25–30 Ma (Oligocene), olfactory lobes had reduced and visual cortices had expanded compared to prosimians. Although its frontal lobes appeared to be small compared to modern anthropoids, *Aegyptopithecus* had an anthropoid-like central sulcus instead of a longitudinally oriented fissure, the coronal sulcus, which separates head from forelimb representations in primary somatosensory cortices of prosimians (Radinsky 1975). The oldest record of an anthropoid endocast of modern appearance is that of ~18 Ma *Proconsul* (Falk 1983; Walker et al. 1983). Regarding neurological reorganization during primate evolution, Radinsky (1974, p. 25) summarized:

> Since *Aegyptopithecus*, *Dolichocebus*, and *Apidium* are among the oldest known pongids, ceboids, and cercopithecoids, respectively, it is likely that elaborations of visual abilities and reduction of olfaction were among the features involved in the initial emergence of higher primates from prosimians. It is interesting that those same features, although not as extensively developed, appear to have been among the key adaptive features at the base of the great Eocene prosimian radiations.

A comparative study of endocasts from extant New and Old World monkeys describes various cortical specializations that were independently evolved in both groups as well as similarities that were retained from a common ancestor (Falk 1981). Within Old World monkeys, cercopithecine sulcal patterns appear to be more derived than colobines as manifested in relative expansion of prefrontal and inferior temporal integration cortices (Falk 1978). Radinsky (1974) showed that a cercopithecoid endocast from *Mesopithecus*, dated to ~9 Ma, exhibits the typical colobine pattern and is similar to the brain of ~6 Ma *Libypithecus*. Thus, the modern colobine sulcal pattern, which appears to represent the more primitive condition, had occurred by at least 9 Ma. He also noted that the derived cercopithecine sulcal pattern had appeared by ~2 Ma in *Paradolichopithecus*.

The addition of new cortical areas may have provided an opportunity for the evolution of new behavioral capacities (Kaas 1987, 1995; Kass and Preuss 2008; Allman 1990, 1977; Felleman and Van Essen 1991; Preuss and Goldman-Rakic 1991). To date, primates are known to possess 50–100 cortical areas, and it has been hypothesized that many of these may be higher-order areas that are unique such as dorsolateral prefrontal, posterior parietal, and inferotemporal cortices (Preuss 2001). Preuss also notes that higher-order association regions of primates are strongly connected with each other and these regions are all connected with a prominent thalamic structure, the medial pulvinar, which has no obvious counterpart in other mammals. He further suggests, “not only do primates possess primate-specific higher-order cortical territories, but these territories form a distinctive connectional system” (Preuss 2001, p. 153). The suggestion that new cortical areas constitute a natural by-product of increasing brain size is consistent with Ringo’s (1991) mechanistic observation that enlarging brains would become swamped with white matter without neurological reorganization that increased the number of local (as opposed to longer corticocortical) connections and therefore areas (Hofman 2001).

Relatively recent comparative work also suggests that the cerebellum, long known to be important for motor coordination and now thought to contribute to higher cognitive functions in humans (Fiez 1996; Muller et al. 1998; MacLeod 2012), underwent neurological reorganization during primate evolution. Thus, the lateral cerebellar system is relatively large in chimpanzees and gibbons, while a central nucleus (the dentate nucleus, the output of which influences the cerebral motor cortex) is larger in humans than apes (Matano et al. 1985; Matano and Hirasaki 1997). This is particularly interesting in light of the fact that the human cerebellum appears to be smaller than expected for an ape brain of human size (Semendeferi and Damasio 2000).

It is important to keep in mind that a part of the brain does not need to be "new" or grossly enlarged for reorganization to occur. For example, Armstrong et al. (1987) investigated which thalamic nuclei changed in volume relative to the rest of the thalamus and found that, after controlling for the size of the brain, anthropoids that lived in single-male societies had more anterior principal thalamic neurons than primates that lived in multimale societies. Since limbic structures are known to be important for social life, it is not surprising that the sizes and reorganizations of limbic structures may link more than those of other structures to specific behaviors and niches (e.g., the relationship of olfactory bulbs with nocturnal and diurnal niches) (Finlay et al. 2001). Along somewhat related lines but focusing on gross brain size rather than reorganization, the "social brain" [or Machiavellian intelligence] hypothesis incorporates data showing that neocortical size correlates with social group size and proposes that large primate brains evolved in response to living in complexly bonded social groups (Falk and Dudek 1993; Dunbar 1998, 2003; Byrne 2000).

While complex social life may indeed have contributed directly or indirectly to selection for large primate brains, partitioning the types of internal reorganization that characterize different groups hones in on other aspects of lifestyle. In a follow-up to Finlay et al.'s research, de Winter and Oxnard (2001) performed similar multivariate analyses on a greatly enlarged data set that confirmed earlier findings (Finlay and Darlington 1995) and extended earlier multivariate analyses to include a series of brain-part ratios that partly reflected input/output relationships within the brain. Rather than grouping primates according to phylogenetic relationships, however, the groups that emerged from the comparisons were based on similar lifestyles, such as lower-limb-dominated lifestyles that involve much leaping (tarsiers, indriids, galagos, mouse lemurs) and four-limb-dominated lifestyles (some strepsirhines, New and Old World monkeys) (de Winter and Oxnard 2001; Oxnard 2004). Genera with upper-limb-dominated lifestyles involving hand-feeding in arboreal habitats and escaping by upper-limb acrobatics (*Ateles*, *Lagothrix*, *Hylobates*, *Pan*, and *Gorilla*) also emerged as a cluster.

The brain organization that is involved in the trend along the axis toward the forelimb dominant species is increasing expansion of the neocortex, striatum, cerebellum, and diencephalon relative to medulla. This particular pattern of brain organization could involve brain functions based on expansion of higher levels of voluntary sensory and motor control. In turn, they could relate to a trend toward creatures with greater degrees of complex voluntary behavior and increased capacity to plan strategically and to control complex motor actions (Oxnard 2004, p. 1147).

Significantly, similar multivariate analyses separate humans from chimpanzees to a degree that rivals the extent of separation within all Old World monkeys and apes, which is not only contrary to the much-cited close genetic relationship between *Pan* and *Homo* but also implies that the internal organization of the human brain is quantitatively different from any other living primate (Oxnard 2004). Further, the differences between chimpanzees and humans are not related to brain size alone and may relate to the existence of internal functional interactions, loops, or modules (Oxnard 2004).

Neurological Reorganization in Hominins

In light of the theoretical emphasis neurological reorganization has been given in the literature, surprisingly little precise information is available about its nature during hominin evolution. However, recent work by a few workers provides a glimpse of what might have happened. Contrary to earlier notions about "mosaic evolution," the research of Finlay, Oxnard, and colleagues discussed above suggests that major steps in neurological reorganization (i.e., as opposed to, say, fine-tuning of individual nuclei) rarely, if ever, entailed isolated structures within the brain but, instead, were probably distributed across multiple structures (or modules) within the brain. This hypothesis is concordant with functional imaging studies that indicate higher-order cognitive tasks engage numerous cortical areas that are dispersed across the cortical mantle (Frackowiak et al. 1997). Such distributed reorganization is inconsistent, however, with the suggestion (based on controversial identifications of the lunate sulcus on endocasts from fossil hominins) that early australopithecines with apelike sulcal patterns were reorganized only in their posterior parietal association cortices (Holloway et al. 2004; Falk 2011, 2014).

As detailed elsewhere (Falk 2009, 2011, 2014), ongoing controversy about the lunate sulcus has had a prolonged and, in my opinion, negative impact on the field of paleoneurology since the beginning of the twentieth century. Briefly, the anterior border of the primary visual cortex in monkeys and apes is usually delineated approximately by a crescent-shaped lunate sulcus (reddened in the chimpanzee brain in Fig. 4). Until recently, some human brains were thought to manifest lunate sulci, albeit in a posterior position in keeping with the fact that their representation of primary visual cortex occupies significantly less of the outside surface of the occipital lobe compared to monkeys and apes. Lunate sulci were, thus, thought to have "migrated" posteriorly as the parietotemporo-occipital association regions expanded in front of them. When Raymond Dart described the first australopithecine fossil (Taung), he misidentified a suture reproduced on its endocast as a lunate sulcus and interpreted its posterior position as indicating that Taung's ape-sized brain had been reorganized toward a human-like condition (Dart 1925). More recent workers interpreted Dart's analysis to indicate that early hominin brains reorganized in a "mosaic" fashion, in which occipital reorganization preceded that in other parts of the brain. A recently emerged unpublished manuscript that Dart wrote in 1929 now makes it clear, however, that he believed australopithecine brains reorganized globally rather than in a mosaic fashion (Falk 2009). Furthermore, a recent high-resolution MRI

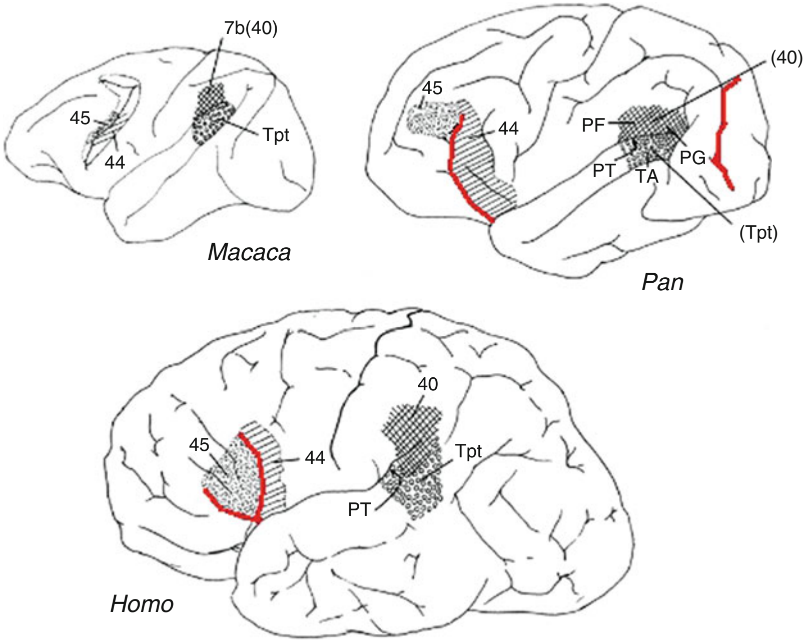

Fig. 4 Gross language areas in humans and their proposed homologs in macaques and common chimpanzees. In the left hemispheres of humans, Brodmann's areas 45 (pars triangularis) and 44 comprise Broca's speech area, while areas Tpt (temporoparietal), PT (planum temporale, buried within depths of Sylvian fissure), and Brodmann's area 40 are parts of Wernicke's receptive language area. Human area 40, macaque area 7b, and chimpanzee area PF/PG are proposed homologs, as are human and macaque areas Tpt and chimpanzee area TA. The proposed homologs are based on cytoarchitectonic and functional similarities and should be viewed as tentative. The fronto-orbital sulcus (bordering area 44) and lunate sulcus (approximately bordering primary visual cortex) are shown in *red* for *Pan*, as are the anterior horizontal and ascending branches of the Sylvian fissure in *Homo*, which approximately border area 45 (data from Preuss (2000), Amunts et al. (1999), Gannon et al. (1998), Aboitiz and Ricardo (1997), Galaburda and Pandya (1982), Crosby et al. (1962), Jackson et al. (1969), Bailey et al. (1950), von Bonin (1949), Falk (2012))

study that assessed the presence/absence of lunate sulci in brains from 110 adult humans (Allen et al. 2006) revealed that this sulcus was lost during human evolution. Elsewhere (Falk 2012, 2014), the loss of the lunate sulcus in humans is interpreted in light of Van Essen's (1997) tension-based theory about how convolutions and sulci develop.

Research of Semendeferi and colleagues (Semendeferi et al. 1997; Semendeferi and Damasio 2000; Semendeferi 2001) sheds light on neurological reorganization in hominins at the level of large sectors including whole lobes. Semendeferi and Damasio (2000) obtained MRI scans of brains from nearly 30 living humans and apes, processed the data to obtain volumes of the various lobes, and performed comparative statistical analyses of the absolute and relative volumes of each lobe. Although the overall relative sizes of the lobes of the brain changed little after the phylogenetic split of hominins from great apes, this study revealed that the temporal lobe (involved in recognition and memory) may have differentially enlarged during hominin evolution, while the human cerebellum is significantly smaller than expected from allometric predictions. The insula, which processes autonomic functions, internal stimuli, taste, and speech articulation (Dronkers 1996), may also be somewhat enlarged in humans. Contrary to Semendeferi's (2001) finding of no increase beyond allometric expectations for the large parieto-occipital sector of the human brain, those of another study (utilizing geometric morphometrics) suggest that modern humans are characterized by relatively great development of the parietal lobes (Bruner 2004), a conclusion that awaits further confirmation.

Equally important, by analyzing 3D MR reconstructions of brains from living apes and humans (Semendeferi et al. 1997) in conjunction with comparative histological sections from postmortem specimens, Semendeferi and her colleagues have helped dispel old myths (indeed, some might even say "received wisdom") about the evolution of human frontal lobes. Until recently, many believed that higher cognitive abilities in humans evolved in conjunction with differentially enlarged frontal lobes. Semendeferi's comparative imaging work dispelled this notion, however, by quantifying the allometric nature of human frontal lobe enlargement (i.e., they are the size one would expect in ape brains enlarged to the size of human brains).

Turning to the important question of neurological reorganization within larger sectors, comparative cytoarchitectonic studies suggest that human frontal lobe evolution entailed internal rewiring and enlargement in some areas (e.g., Brodmann's area 10; Semendeferi et al. 2001, 2002) and a decrease in others (Brodmann's area 13; Semendeferi et al. 1998) rather than an increase in overall frontal lobe size. It was therefore concluded that area 13 of the posterior orbitofrontal cortex, a part of the limbic system that is involved in emotional reactions to social stimuli, is a conserved feature in brain evolution, whereas the relative size of area 10 that forms the frontal pole in ape and human brains, and contributes to planning and the undertaking of initiatives, increased during hominin evolution. A remarkable increase in the proportion of white matter volume of the human precentral cortex was also found (Semendeferi et al. 1997), which again speaks to the fact that human frontal lobes are more complexly wired rather than relatively larger than those of their ape cousins.

Semendeferi and her colleagues compared the spacing of neurons in layer III in frontopolar (BA 10), primary motor (BA 4), primary somatosensory (BA 3), and primary visual (BA 17) cortices in great and lesser apes and humans (Semendeferi et al. 2011). They found that the horizontal spacing distance (HSD) between neurons increased in BA 10 (but not the other areas) in hominins after they split from chimpanzees. Such spacing is interpreted as facilitating complex interconnectivity, which contributes to information processing related to anticipating future events, multitasking, and integrating limbic input to arousal, motivation, and intentions, among other functions. A similar histological finding has been reported for human BA 44/45 (Broca's speech area) (Schenker et al. 2008), which suggests that the frontal lobe may have been widely reorganized during human cognitive evolution.

Other research suggests that the visual system was also reorganized during human evolution (Preuss et al. 1999), which surprised even the investigators because "it is axiomatic among neuroscientists and psychologists that the visual abilities of humans and monkeys are virtually identical" (Preuss 2001, p. 156). Specifically, the authors report histological evidence suggesting that the human primary visual area differs from that of apes and monkeys in the way that information is segregated from layers of the lateral geniculate nucleus. Interestingly, they suggest that humans have enhanced capacities for analyzing moving stimuli and speculate that these changes may have occurred in response to the challenge of visually decoding rapid mouth movements entailed in speech and its accompanying manual gestures (Preuss 2001).

Neurological Reorganization Related to Language, Handedness, and Music

It is tempting to hypothesize that the expansion of the human cortex was accompanied by the addition of new areas and that the classic language areas in the left hemisphere (Broca's speech area [Brodmann's areas 44 and 45] and Wernicke's language receptive area [Brodmann's areas 21, 22 plus, when defined more broadly, 37, 39, 40]) are neomorphic structures (Preuss 2001). However, Preuss notes that "at the present time, there is no good evidence that humans possess species-specific cortical areas" (Preuss 2001, p. 155). Indeed, cytoarchitectonic studies on macaques suggest that the inferior limb of the arcuate sulcus contains homologs of areas 44 and 45 (Galaburda and Pandya 1982; Deacon 1992; Preuss 2000), and homologs of posterior language areas (Wernicke's area) have been identified in the macaque superior temporal and inferior parietal lobes (Galaburda and Pandya 1982; Preuss 2000) (Fig. 4). Simple movements of the mouth and hands activate ventral premotor cortex in monkeys, as they do its likely homolog, Broca's area, in humans (Petersen et al. 1988; Colebatch et al. 1991; Gallese et al. 1996; Rizzolatti et al. 1996), and these "mirror neurons" also discharge when similar actions are observed in others (Rizzolatti et al. 1996). Because of their discovery in human and nonhuman primates, mirror neurons are hypothesized to be part of an action-perception network that facilitates gestural (manual and orofacial) communication in apes and humans as well as linguistic communication in the latter (Falk 2004c, d). From a functional perspective, it is also interesting that, like humans, macaques are thought to be left hemisphere dominant for processing certain socially meaningful (as opposed to neutral) vocalizations (Petersen et al. 1978, 1984; Heffner and Heffner 1984, 1986).

Paleoneurologists have long speculated about whether a chimpanzee-like frontal lobe in early hominins could have given rise to a humanlike Broca's area, but these efforts have been hampered by a lack of consensus about the identities of homologous sulci and gyri in great apes and humans, which were traditionally proposed mainly on the basis of relative positions of sulci rather than on cytoarchitectonic grounds (Connolly 1950). Unlike frontal lobes of humans, a fronto-orbital sulcus (*fo*) of chimpanzees (reddened in Fig. 4) typically incises the lateral border of the dorsal frontal lobe and extends onto its orbital surface where it courses caudally toward the temporal pole (Connolly 1950). The bulge delimited by *fo*, or so-called orbital cap, represents Brodmann's area 44 (Bailey 1948; Bailey et al. 1950; Connolly 1950; Jackson et al. 1969) (Fig. 4) and to varying degrees the addition of part of area 45 (Sherwood et al. 2003) in chimpanzees. Sherwood et al. (2003) explored the relationship of sulci to cytoarchitectural areas 44 and 45 in brains from five adult chimpanzees and found that just as the border between cytoarchitectonic areas 44 and 45 of humans is not always defined by sulci (Amunts et al. 1999), the border between the two areas in chimpanzees does not always coincide with the surface of the fronto-orbital sulcus. Rather, intersubject variability was high and area 45 tended to spill over caudally into the presumed domain of area 44 in both species. It is also important to stress that the similar bulge that appears at the level of the temporal pole in humans, the orbital cap (or so-called Broca's cap), is *not* homologous to that of chimpanzees (Falk 2014) because it contains areas 45 and 47 rather than the areas located in the chimpanzee cap, namely, area 44 (Connolly 1950) and (sometimes) 45 (Sherwood et al. 2003). Although it has recently been suggested that area 44 is larger in the left than the right hemisphere of chimpanzees (Cantalupo and Hopkins 2001), as reported for humans (Amunts et al. 1999), for methodological reasons, the jury is still out on whether or not the homolog of Broca's area in great apes exhibits humanlike asymmetry (Sherwood et al. 2003).

There is more agreement about asymmetry in the chimpanzee homolog of at least part of Wernicke's area. Gannon et al. (1998, 2001) investigated the homolog of the planum temporale (PT) in 18 chimpanzee brains and determined that the left PT was significantly larger in 17 of the 18 brains (94 %). This region is a component of Wernicke's area in the left hemisphere of humans, in whom it manifests a similar anatomical pattern and left hemisphere size predominance. The authors concluded that human language may have been founded on this basal anatomical substrate and that it may have been lateralized to the left hemisphere in the common ancestor of chimpanzees and humans millions of years ago (Gannon et al. 1998).

More than a century after Broca's area was identified, it is recognized that it has certain nonlinguistic functions and that the act of speech activates wider areas of the cerebral cortex. Nevertheless, the importance of this area for speech and Wernicke's area for human language reception cannot be denied, and the evolutionary details of their coordinated neurological reorganization (including with other parts of the brain) remain open to investigation (Sherwood et al. 2003; Holloway et al. 2004).

One may, however, engage in reasoned speculation about the evolution of a suite of unique behaviors in hominins and their underlying interconnected and reorganized neurological structures. We know, for example, that people are more neurologically lateralized than other primates and that certain cortical asymmetries underpin behaviors that are unique to the human primate (Falk 1987a), such as the universally high frequency of right-handedness, symbolic language, and humanlike creative abilities related to music, art, and technology (Falk 2000a, 2004a). One may explore the evolution of brain lateralization by studying shape asymmetries in endocasts of fossil hominins (Holloway et al. 2004), since in living people these petalias (which exist to a lesser extent in nonhuman primates LeMay et al. 1982) are statistically associated with handedness patterns and sex (LeMay 1977; Bear et al. 1986). We also know that men and women differ somewhat in the anatomies of their brains and that these differences are hypothesized to have evolved as correlates of different reproductive strategies (Falk 1997, 2001; Falk et al. 1999). Although a review of the literature on primate brain lateralization is beyond the scope of this chapter, it is worth noting that Hofman's (2001, 2012) exploration of design principles that govern the evolution of large brains led him to conclude that large brains tend to increase the number of distinct cortical areas in order to maintain processing capacity and that this may be related to the high degree of brain lateralization in humans.

It is possible that large-brained species develop some degree of brain lateralization as a direct consequence of size. If there is evolutionary pressure on certain functions that require a high degree of local processing and sequential control, such as linguistic communication in human brains, these will have a strong tendency to develop in one hemisphere (Aboitiz 1996; Hofman 2001, p. 123).

Conclusions

Primate nervous systems became more variable over the course of evolution. During the Eocene, brain sizes were all small. Today, there are still small-brained species, but also larger-brained ones due to a widening range of variation as the Cenozoic progressed. The same can be said for RBS. Over 30 years ago, Radinsky (1974) pointed out that elaboration of visual abilities and reduction of olfaction were among the features involved at the base of prosimian radiations and, again, in the later emergence of higher primates from prosimian stock. The broad visual and limbic systems that subserve these features were (and are) extremely important for primate species-specific communication. Over time, the various neurological components of these systems became variably elaborated and reorganized within different groups. Preuss' (2001) suggestion that the "surprisingly" reorganized human visual system may have evolved in response to the challenge of visually decoding rapid mouth movements entailed in speech and its accompanying manual gestures underscores the ongoing continuity of adaptations that occurred extremely early in primate evolution. Semendeferi's (2001) seminal work on hominoid prefrontal cortices (Brodmann's areas 10 and 13) illustrates that executive parts of the cerebral cortex eventually got into the act and were also subjected to evolutionary reorganization (Semendeferi et al. 2001).

The arguments about the relative evolutionary merits of brain size versus neurological reorganization are unnecessary (Gould 2001). The suggestion by Finlay and colleagues (Finlay and Darlington 1995; Finlay et al. 2001; Kaskan and Finlay 2001) that the sizes of different brain structures are a consequence of overall brain size, not only in primates but also in other mammals, is an important contribution to our understanding of ontogenetic brain development and brain evolution. What has sometimes been lost is that Finlay's model leaves room for evolution of the kinds of neurological specializations that interest paleoneurologists. Oxnard and de Winter's models for parsing brain size evolution may also shed light on the evolution of broad (but presumably intertwined) subsections of the nervous system that subserve very different lifestyles, separate from phylogenetic considerations (de Winter and Oxnard 2001; Oxnard 2004). These findings extend, rather than contradict, those of Finlay and colleagues. Add to the mix, neurological reorganization that can take place with, or without, an increase in brain size and the potential for evolving internal functional interactions, loops, or modules (Oxnard 2004) becomes realized. Primate cortices may, indeed, represent "veritable hotbed(s) of evolutionary reorganization" (Preuss 2001, p. 140). As students of paleoneurology have discerned, however, the high intelligence of today's primates flowered from trends in primate brain evolution that reach back into deep time (Radinsky 1974). Given the complexities involved in disentangling the evolutionary dynamics of increasing brain size from the intricate (and often hidden) subtleties of neurological reorganization, that insight is somehow very satisfying.

Abstract

The life history of any species is determined by traits that characterize its developmental and reproductive rates as well as the reproductive effort spent over its lifetime. This chapter will present an overview of the current knowledge on the diversity of primate life history. It will explore potential links between life history and major biological factors, which are suggested as a partial explanation for the existing interspecific variations in life history. Furthermore, it will outline general principles and current hypotheses on the evolution of primate life history. This review will show that extant primates ranging from nocturnal ancestral primates to apes provide an important biological substrate illuminating the evolutionary roots and selective forces that shaped human life history.

Introduction

The life history of any species is determined by traits that characterize its developmental and reproductive rates, as well as the reproductive effort spent over its lifetime (Stearns 1992). For mammals, these traits are usually expressed in the gestation length, number and size of offspring at birth, body mass and age at weaning, patterns of postnatal growth, age at first reproduction, interbirth interval, and life span. Life history pattern and variation can be studied on an interspecific or intraspecific level.

Intraspecific variations arise because life history traits are modified by ecology, and different populations of a single species can therefore be expected to show some differences in life history according to the specific ecological settings they experience (Lee and Kappeler 2003). Life history traits of a given species should therefore be taken as predispositions toward certain ranges of potential values (Kappeler et al. 2003), and these ranges can, on the other hand, be taken to explore the effects of different socioecological parameters on life histories. Broad interspecific comparisons of life history traits, on the other hand, form the basis for most existing life history models. Both levels of comparisons will be employed in this chapter in order to illuminate the major evolutionary forces shaping primate life history patterns.

Many aspects of biological timing show a systematic covariation with body mass (Calder 1984), such that body mass has been recognized to be a major predictor of life history variation among species. For example, a large species usually takes longer to grow to maturity and will have larger neonates than does a small one (Harvey et al. 1987; Ross 1998). The relationship with body mass is not an isometric function in which life history traits vary in direct proportion to body mass. Instead, a trait (P) will typically vary in an allometric fashion (W) that is based on the formula: $P = aW^b$. The growth constant a (allometric coefficient) and b (allometric exponent) describe the specific nature of the scaling relationship in any given case. If this formula is logarithmically transformed, it describes a straight line with a slope b. The growth constant a varies between 0.19 and 0.61 in primates (Mumby and Vinicius 2008) and the primate mean $a = 0.35$ is clearly smaller than the average value of $a = 1$ for other mammals (Charnov 1993). Due to fundamental interdependencies among body mass and most biological traits, allometric analyses are obligatory when exploring variations in primate life histories and are taken into consideration in all parts of this chapter. In allometric analyses, it is commonly observed that the data are divided into two or more subsets that show a similar scaling trend (allometric exponent or slope value) but that are vertically separated (i.e., show different intercepts). These subsets can be referred to as “grades” and the vertical separation between them can be termed a “grade shift” (Purvis et al. 2003).

This chapter will present an overview of our current knowledge on life history diversity among extant primates (including humans); explore potential links between life history and major biological factors, which are suggested as a partial explanation for the existing interspecific variations; and outline general principles and current hypotheses of life history evolution.

General Features of Primate Life Histories in Comparison to Other Mammals

The “speed” of life, or reproductive turnover, is a central concept in the field of life history research (Stearns 1992). Primate life histories lie at the slow end of the fast-slow continuum that has been described for mammals in general (Harvey and Clutton-Brock 1985; Charnov and Berrigan 1993; Ross 1998; Dobson and Oli 2008; Jones 2011). This is expressed in altered allometric relationships for many primate life history traits in comparison to those of other mammals. In particular, primates have longer gestation periods, smaller litter sizes, larger neonates, slower postnatal growth rates, a later age at first reproduction, a lower annual fertility, and a longer life span than most other mammals of the same body weight (Fig. 1; Martin and MacLarnon 1985, 1988; Charnov 1991; Lee et al. 1991; Charnov and Berrigan 1993; Ross 1998; Jones 2011). As a consequence, primates possess an extended period of infancy and juvenility and have lower reproductive rates in comparison to other mammals of the same size (Charnov 1993; Charnov and Berrigan 1993).

Many hypotheses have been suggested that may explain why primates are so different. They can be broadly categorized into three groups of related arguments.

The first group of explanations deals with the evolutionary relationship among life history variables and brain size. Allometric analyses have shown that large-brained primates generally have long gestation periods, slow, prolonged growth periods, late sexual maturation, and long lives (Harvey et al. 1987; Allman et al. 1993; Charnov and Berrigan 1993; Hakeem et al. 1996; Barton 1999; Ross and Jones 1999; Ross 2003; Barrickman et al. 2008; Schuppli et al. 2012). Existing brain size hypotheses aim to explain the underlying evolutionary pathways (see below).

The second group of explanations is related to different mortality schedules that are environmentally imposed (Promislow and Harvey 1990; Charnov 1991, 1993; Stearns 1992; Janson and van Schaik 1993; Ross and Jones 1999). Primate-specific avenues have been suggested to act in the form of relatively high juvenile mortality (Janson and van Schaik 1993) or a high juvenile recruitment uncertainty (Jones 2011) that may both favor the evolution of slow growth, i.e., extended periods of juvenility, or relatively low rates of adult mortality that may be connected to a late age of first

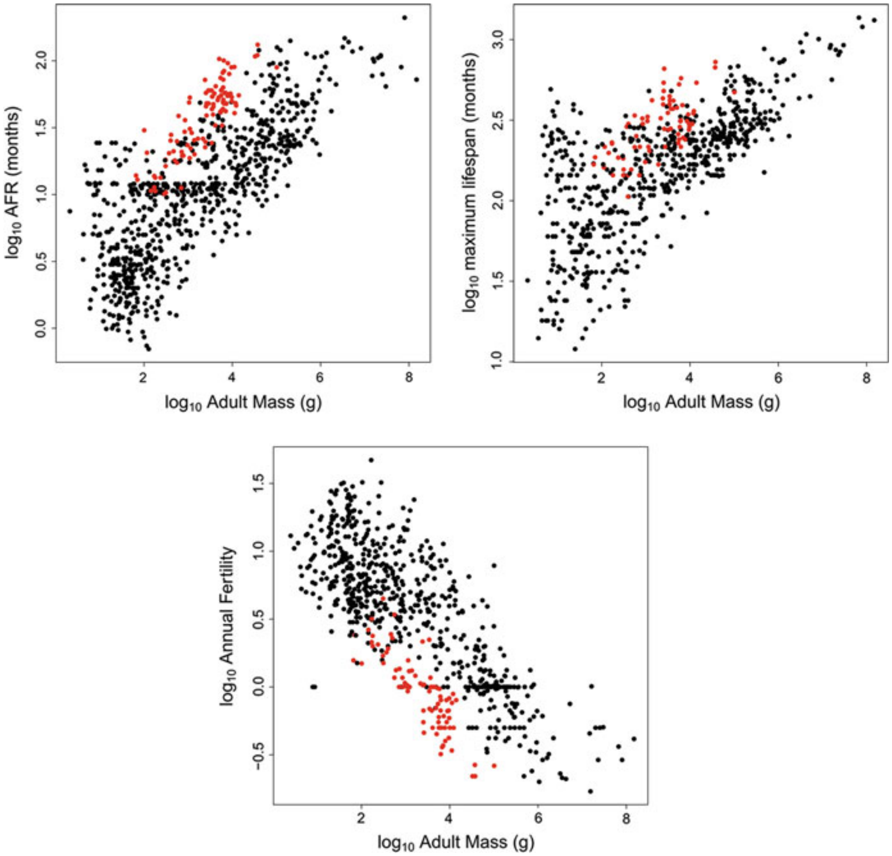

Fig. 1 Scaling relationships between adult female body mass and three life history variables in mammals, age at first reproduction (*left*, *AFR*), maximum life span (*middle*), and annual fertility (*right*) for primates (*red dots*) and other mammals (*black dots*) (Modified after Jones 2011)

reproduction and therefore delayed maturation (Promislow and Harvey 1990; Stearns 1992; Charnov 1993, see below).

The third group of explanatory hypotheses stresses the importance of ecological factors (i.e., diet, predation) on productive rates (birth rates, age at first reproduction) and therefore the speed of life (Rowell and Richards 1979; Eisenberg 1981; Ross 1988, 1992a, b; van Schaik and Deaner 2002, see below). It should be noted that the second and third group of hypotheses may be partly connected via the parameter of mortality.

Variability in Primate Life History Traits

The previous considerations contrasted primate life histories as a whole with those of other mammals. This generalization disregards the finding that primates themselves contain a broad variety of life history pattern (Fig. 2).

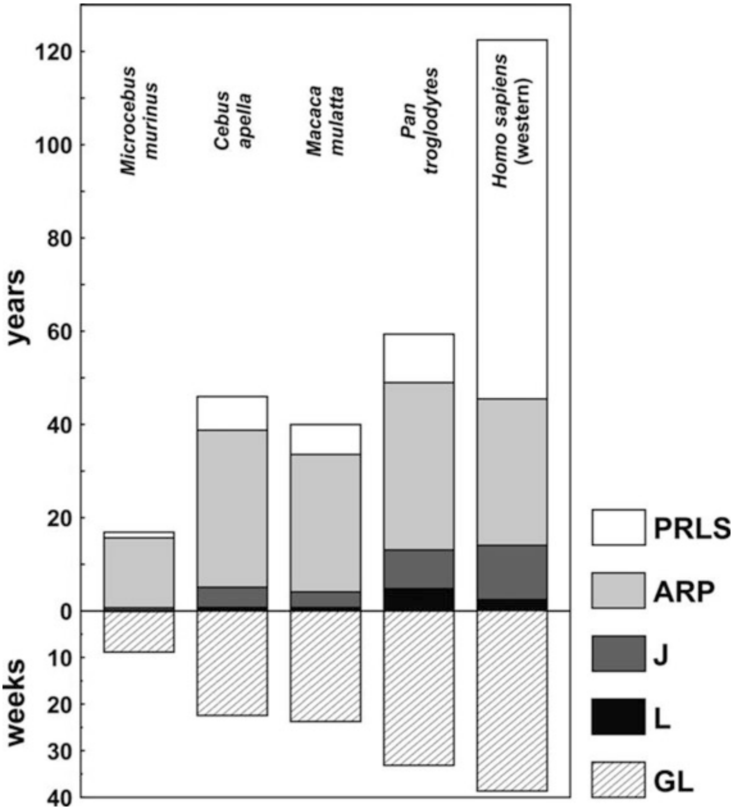

Fig. 2 Diversity of primate life histories (*PRLS* postreproductive life span ((maximum life span from Appendix – *J*)*PrR, *PrR* proportion of adult years which are postreproductive, species-specific PrR-values taken from Levitis and Lackey 2011), *ARP* adult reproductive period (upper limit: maximum life span – PRLS), *J* juvenility (upper limit: average AFR from Appendix), *L* lactation (upper limit: average WA from Appendix), *GL* gestation length (average *GL* from Appendix))

Gestation Length

Gestation length in primates (see Appendix) varies considerably from 52 days in the gray-brown mouse lemur (*Microcebus griseorufus*) to 285 days in the gorilla (*Gorilla gorilla*). Gestation length is correlated with adult female body mass ($r = 0.74$) and even more so with neonatal body mass ($r = 0.82$) (Harvey et al. 1987). Gestation length in the order Primates seems to follow quite well the allometric Equation $G = kW^{0.15}$ (Martin et al. 2005) with W indicating adult body mass. Among all studied primate taxa, only lemurs with larger litters that are parked in a nest for some time after birth (like *Cheirogaleus*, *Microcebus*, *Mirza*, and *Varecia*) have a much shorter gestation period than predicted from the best-fit line (Martin 2007). In general, correlations between the developmental state of the young and life history variables indicate that species with poorly developed (relatively altricial) young characteristically have small body mass and relatively short gestation periods, have limited motor and thermoregulatory abilities at birth, are nocturnal, and use nests (Martin 1990; Ross 2003). Species with more precocial young tend to have the opposite set of characteristics.

Neonatal Body Mass

Neonatal body mass ranges from about 4 g in *Microcebus lehilahytsara* to more than 3,000 g in *Homo sapiens* (see Appendix) and is largely predicted by adult female body mass ($r^2 = 0.917$) and in addition by gestation length ($r^2 = 0.593$), i.e., large mothers and long gestation periods produce large neonates (Wells et al. 2012). It has been shown, however, that strepsirhine primate neonates are generally smaller relative to adult body mass than haplorhine primate neonates (Martin et al. 2005). There is additional variation in relative neonatal body mass that requires an explanation. Besides the obvious altricial-precocial dichotomy, one parameter has repeatedly received attention in this context, namely, litter size. It had been hypothesized that litter size should correlate negatively with neonatal body mass (Leutenegger 1973). Although this has been disputed by some authors (Harvey et al. 1987), others have found statistical support for this relationship, at least at an intraspecific level (Ross and Jones 1999). In general, however, it must be stated that the reduction in litter size and the "decision" for few and large infants were probably made very early in primate evolution, which limits observable variation in the primate order. Other arguments have emphasized that the species-specific mode of placentation may constrain neonatal mass (Leutenegger 1973, 1976). Species with hemochorial placentas (anthropoid primates) may be able to nourish their fetus longer (and therefore to larger size) than species with an epitheliochorial placenta (most lemurs and lorises). Although this may explain some neonatal mass variations in primates, this does not hold for other mammalian orders (Martin 1984), and its general explanatory value is therefore unclear.

Litter Size

Litter size in primate species is generally small and ranges from one to a maximum of four (average: 1–2, see Appendix). A litter size of one is typical for most primates, and a litter size of two is the rule only for several mostly nocturnal strepsirhines and most callitrichids. A phylogenetic reconstruction revealed that the ancestral primate most likely had only a litter size of one and that litter size increased again secondarily several times (Kappeler 1998; see also Leutenegger 1979). Two different avenues have been suggested for the evolution of larger litters within the primate lineage. Larger litters occur together with relatively altricial development when infants still have their eyes closed at birth and do not cling to their mother's fur continuously (parkers in the strepsirhines, see section "Mode of Infant Care"). The alternative route has evolved in the family Callitrichidae, where relatively precocial twin litters are carried and raised not only by their mothers but with high proportions of allocare (Goldizen 1987; Ross 1991, 2003; Rothe et al. 1993; Dunbar 1995; Garber 1997; Bales et al. 2000; but see Mitani and Watts 1997). In view of the high energetic demands of twin production, coupled with a postpartum estrous in callitrichids, Dunbar (1995) and Ross (1991) suggested that the evolution of paternal care in this group preceded the evolution of twinning. An alternative explanation was offered by Chapman et al. (1990) who found a positive relationship between litter size and the proportion of insects in primate diets in a comparative study that included 70 primate species. They argued that insects may provide crucial energy supply in times of seasonal food shortage, which may then allow certain lineages to produce larger litters.

Age and Body Mass at Weaning

Weaning is not a simple event but is instead a process that may occur over an extended period of time. Definitions of weaning may be as different as the "first intake of solid food," the "beginning of maternal control of suckling," the "complete termination of suckling," or the "mother's resumption of sexual activity" (reviewed in Lee 1996). As a general approximation, weaning age in primates ranges from about 33 days in *Microcebus murinus* to about 2,555 days (7 years) in *Pongo abelii* (see Appendix). Body mass at weaning ranges from about 33 g in *Microcebus murinus* and some callitrichids to about 19.8 kg in *Gorilla gorilla*. Body mass at weaning, however, is so far only available for a relatively small proportion ($n = 55$, 13.1 %, see Appendix) of all 420 primate species listed at the IUCN at present. The age of weaning is highly correlated with neonatal body mass ($r = 0.94$) and with adult female body mass ($r = 0.91$), i.e., large mothers produce large neonates that are weaned later than those of smaller mothers (Harvey et al. 1987). Within primates, at least three grades have been identified in the relationship between weaning age and female body mass (Martin 2007): Lemurs have the relatively shortest weaning age, intermediate weaning ages can be found in Old World monkeys, and weaning ages are longest in the hominoids (Martin 2007). Weaning age scales positively with weaning mass, which is highly proportional to neonatal mass (Lee et al. 1991). This relationship appears to be relatively constant, such that when an infant reaches about four times its birth weight, it is weaned irrespective of the duration of lactation (Lee et al. 1991). Another general pattern has been suggested with the mass at weaning equaling about one-third of the adult body mass (Lee et al. 1991; Lee 1996), although this relationship is debated (Godfrey et al. 2003; Purvis et al. 2003). It is apparent from many allometric analyses that primates show considerable variation in the duration of lactation (infants can be weaned at an earlier or later age), but not in the body mass that is achieved at weaning. Lactation itself is a costly process for the mother who has to convert maternal energy to milk. It requires, for example, additional energetic intake at a rate of approximately 1.3 times the normal intake for humans or 1.5 times for baboons (Prentice and Whitehead 1987; Altmann and Samuels 1992).

Mothers should balance these costs over time, and trade-offs should take into account not only the survival probabilities of the current offspring of a given mass and the energetic demands of mother and offspring during lactation but also survival costs for the mother and the relationship between weaning age, subsequent interbirth interval, and therefore future reproductive rates (Lee 1999; Ross and MacLarnon 2000; Walker et al. 2008; Garcia et al. 2009). Factors that have been suggested to shape the species-specific evolutionary pathways in postnatal growth rates and weaning age are brain growth pattern as a metabolic constraint on infant somatic growth (Martin 1996; Lee 1999), environmental variability acting via differential juvenile mortality on maternal investment (age at weaning) and growth rates to weaning (Ross 1988; Leigh 1994; Garber and Leigh 1997; Lee 1999), milk composition and the degree of close mother-infant contact (Hinde and Milligan 2011), and the extent of available allocare (Ross and MacLarnon 2000; Ross 2003).

Pattern of Postnatal Growth

Compared to other mammals, primates have the longest juvenile periods for their body size (Pereira and Fairbanks 1993). They range from 175 days in *Galago moholi* to 12.5 years in *Homo sapiens* (see Appendix). Juvenility spans the time from weaning to sexual maturity, but is not necessarily a period of continuous growth and acquisition of skills. Two major ways have been identified in which growth may vary within and among primate species (Leigh 1994, 1996): Postnatal body mass growth rates may slowly decrease from birth to sexual maturity, as can be seen, for example, in the common marmoset (*Callithrix jacchus*, Fig. 3) or in *Cebus albifrons* (Young et al. 2010). The second pattern consists of slow growth rates early in life followed by sharp accelerations, so-called growth spurts, prior to sexual maturation. This pattern is characteristic for sexually dimorphic primate species such as baboons (Leigh 1996) or vervet monkeys (Whitten and Turner 2009). Combinations of both basic patterns have generated a great variety of different growth-rate curves in primates. However, they do not correlate well either with other life history variables or with body mass, with brain growth rates, or with dental development (Pereira and Leigh 2003). For example, male *Cercopithecus diana* attains relatively small body mass after growing longer than male *Colobus guereza* (Pereira and Leigh 2003). It has been stated that such ontogenetic divergences presumably reflect life history adaptations to contrasting socioecologies (Leigh and Shea 1995; Pereira 1995; Pereira and Leigh 2003). For example, infant parking and nesting has been recently shown to influence postnatal growth rates in Malagasy lemurs: Species that park infants exhibited faster postnatal growth rates than species with infant-carrying habits (Tecot et al. 2012). Life history theory predicts a general trade-off between juvenile growth and the age at first reproduction, since reproduction and growth are both costly processes that should rarely overlap (Charnov 1993, 1997). Mumby and Vinicius (2008) provided evidence for a significant negative correlation between the growth constant *a* and both age at first reproduction and the duration of the juvenile period, indicating that slower growth coincides with a longer juvenile period

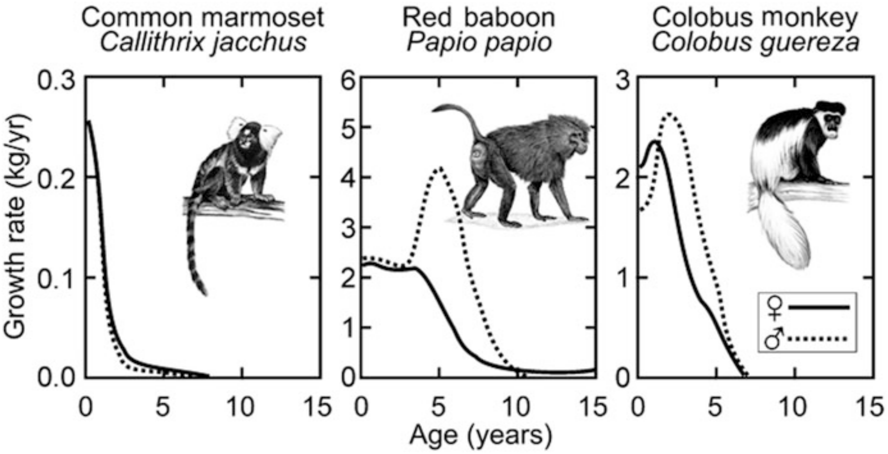

Fig. 3 Development of growth rates and pattern of growth spurts for different primate species. Explanations are given in the text (Modified after Leigh 1994)

and a later onset of reproduction in primates. Other parameters that are discussed as shaping growth curves are risks imposed on juveniles by predation or intraspecific competition for food and social partners, as well as dominance of the mother (Janson and van Schaik 1993; Leigh 1994; Godfrey et al. 2003; Pereira and Leigh 2003; Mumby and Vinicius 2008; Garcia et al. 2009). Finally, intrasexual competition has been shown, for example, to accelerate or extend male growth (bimaturism: Jarman 1983) and can even lead to alternative routes of reproduction (Utami et al. 2002; Wich et al. 2004 for the Sumatran orangutan, *Pongo abelii*).

Age at First Reproduction

The age at first reproduction varies greatly among primates from about 7–8 months for *Galago moholi* or *Microcebus murinus* to more than 15 years for *Pongo abelii* (see Appendix). The age at first reproduction marks a very important step in life since it affects the length of time available for reproduction and therefore limits the reproductive life span of males and females. Furthermore, it has an enormous influence on the intrinsic rate of population increase. In comparison to other mammals, maturity is reached late in primates (Ross 1988; Charnov and Berrigan 1993) and several hypotheses have been developed to explain this extended juvenility. First, allometric influences of adult body size and adult brain size must be addressed. There is a high correlation between adult body mass and age at first reproduction (Pagel and Harvey 1993), although this seems to be largely based on the effect of adult brain size (Harvey et al. 1987; Ross 2003; Barrickman et al. 2008; Barton and Capellini 2011). Large brains have been confirmed independently several times to correlate with late maturation and extended juvenile growth (Harvey et al. 1987; Allman and Hasenstaub 1999; Barton 1999; Ross and Jones

1999; Ross 2003; Barrickman et al. 2008; Barton and Capellini 2011). Barrickman et al. (2008) recently proposed an adaptive explanatory framework and suggested the necessity of such an extended juvenile growth period for the acquisition of foraging or social skills and improved predator avoidance that may explain reduced adult mortality and extended reproductive life span of larger-brained primates (but see Barton and Capellini 2011). Finally, there has been some support for the hypothesis that juvenile mortality rates are correlated negatively with the length of the juvenile period, i.e., primates with high rates of prereproductive mortality reproduce at an early age and thereby speed up reproduction (Ross and Jones 1999).

Interbirth Interval

The interbirth intervals of nonhuman primates range from 3 months in *Microcebus murinus* and *Microcebus lehilahytsara* up to more than 110 months in *Pongo abelii* (see Appendix). The interbirth interval and its variance is strongly influenced by maternal mass (Harvey et al. 1987; Lee 1999), i.e., large mothers have longer interbirth intervals and have a greater potential to extend it further than smaller mothers. The minimum interbirth interval is usually given by the joined duration of gestation and lactation since in many species lactation prevents ovulation (lactation amenorrhea). This phenomenon is adaptive if lactation costs are too high to be combined with the costs of gestation or if lactation is needed for a much longer time span than the gestation would take. In this case, females would risk having two generations of dependent offspring at the same time. Some primate species, such as some callitrichids (Dixson 1992; Tardif et al. 2003) or mouse lemurs (Schmelting et al. 2000), have evolved a postpartum estrus. In these species, infant development is relatively fast and females can afford to lactate and resume reproduction simultaneously due to an early age of weaning.

Three other parameters have been identified that may shape the length of interbirth intervals. First, seasonality in food availability may constrain reproductive rates and even force species into a yearly cycle of reproduction (Lindburg 1987; Di Bitetti and Janson 2000). For example, gray mouse lemurs (*Microcebus murinus*) have been shown to reproduce twice per season given about 1,500-mm rainfall per year (Schmelting et al. 2000), whereas they produce only one litter per year given about 800-mm rainfall per year (Eberle and Kappeler 2004). Second, within social groups of the same species, interbirth intervals also depend on maternal condition. It could be shown, for example, that better-fed (i.e., high-ranking) female olive baboons (*Papio anubis*) have shorter interbirth intervals and higher infant survival than low-ranking females (Packer et al. 1995). Similar results have been found in other species (Cheney et al. 1988 for *Chlorocebus aethiops*; Lee and Bowman 1995 for *Macaca fuscata*). Third, interbirth intervals in lemurs have been shown to correlate negatively with the degree of infant parking and nesting (Tecot et al. 2012). It was hypothesized by the authors that nesting and parking infants reduces the energetic burden of mothers and thereby allows these species to increase infant growth rates and decrease interbirth intervals.

Life Span

Primate life span is notoriously difficult to measure, since either the age of captive animals is often well known but may not necessarily reflect the life span that is typically achieved under natural conditions or its determination in the field requires a long-term commitment of researchers to individually known populations that may span even more than a whole scientific career. Available life span data of nonhuman primates range from an average of 4 years in captive golden angwantibos (*Arctocebus aureus*) to a maximum of about 59 years for chimpanzees (*Pan troglodytes*) and orangutans (see Appendix). In comparison to other mammals, primates have longer lives for their size (Charnov and Berrigan 1993; Jones and MacLarnon 2001). Allometric analyses showed that life span within the primate lineage is positively correlated with body mass and brain size (Harvey et al. 1987; Austad and Fischer 1992; Allman et al. 1993; Allman 1995; Deaner et al. 2003; Barrickman et al. 2008; Kamilar et al. 2010). Brain size seems to be more influential than body size since the partial correlation between life span and brain size remains positive after the effects of body size have been removed but not vice versa (Sacher 1959; Harvey et al. 1987; Allman et al. 1993; Deaner et al. 2003; Barrickman et al. 2008). In addition, age at maturity correlates strongly with life span, and it has even been suggested that life span and brain size may be primarily linked to age at maturity and may be only secondarily correlated with each other via the intervening variable age at maturity (Harvey et al. 1987). Both, life span and age at maturity affect and limit the time period available for reproduction, i.e., the reproductive life span. Reproductive life spans can be quite similar even among species with a divergent pattern of postnatal growth and maturation if, for example, longer lives may compensate for late maturation or vice versa.

The general question is, why did longevity evolve in primates and how can interspecific differences in primate life span be explained? In other words, what are the selective benefits of a long old age? In evolutionary terms, benefits are usually expressed as fitness consequences. On an individual level, an extended life span may result in a larger number of offspring and may therefore provide direct fitness benefits (Fedigan and Pavelka 2001 for *Macaca fuscata*). On the species level, however, a longer life span does not necessarily relate to a higher number of surviving offspring. A female chimpanzee may live up to 50 years but may have only about seven offspring due to late maturation and long interbirth intervals, whereas a rhesus macaque with a life span of 21 years or a mouse lemur of 10 years may each have given birth to about 18 offspring over their lifetime. If the number of offspring does not explain long life span, selective benefits are more likely to be found in offspring quality, which may be linked to other life history variables, in particular to an extended period of juvenility, delayed maturation, reduced rates of adult mortality, and larger brains. It has, for example, been shown that encephalization is significantly correlated with an extension of the reproductive life span, suggesting a balance between brain size, the costs of growing a brain, and the survival benefits provided by enlarged brains (Barrickman et al. 2008; but see Barton and Capellini 2011).

Extrinsic mortality rates have repeatedly been investigated as a potential explanation for life history variations (Kamilar et al. 2010; see section Age-Specific

Mortality Rates). Their connection to life span is suggestive since extrinsic mortality influences the probability of survival to old age and thereby determines the selection pressure upon genes that regulate somatic repair (Kirkwood and Rose 1991). This relation between mortality rates and longevity is supported by several theoretical and empirical studies (Promislow and Harvey 1990; Charnov 1991, 1993; Stearns 1992; Ricklefs 1998; Harvey and Purvis 1999; Ross and Jones 1999; Alvarez 2000; Blomquist et al. 2003). An integrating explanation is offered by the "Cognitive Buffer Hypothesis" (see section "Brain Size").

Variables Linked to Primate Life History Traits

The evolution of primate life history is shaped by differences in brain sizes, phylogeny, and the different ecological and social factors outlined in the following sections.

Brain Size

Brain size and brain growth pattern are strongly interrelated with almost all life history traits. Large-brained primates usually have long gestation periods, have high neonatal body mass, and give birth to few offspring that have a late age of first reproduction and long lives (Harvey et al. 1987; Austad and Fischer 1992; Allman et al. 1993; Charnov and Berrigan 1993; Purvis and Harvey 1995; Allman and Hasenstaub 1999). These relationships exist independently of body size (Sacher 1959; Allman et al. 1993; Martin 1996; Barton 1999; Dunbar and Shultz 2007; Barrickman et al. 2008; Lefebvre 2012) and have been functionally linked either to high energetic costs of large brains (Foley and Lee 1992; Martin 1996; Ross and Jones 1999) or to long developmental processes (learning) during the juvenile period that require large brains (Harvey et al. 1987; Joffe 1997; Barton 1999; Dunbar 2003; van Schaik et al. 2012).

Five influential hypotheses, not mutually exclusive, have been put forth that link brain size to primate life histories

The "Delayed Benefits Hypothesis" aims to explain the relationship between large brain size and longevity (Deaner et al. 2003). Large brains incur high costs (time and risks) but allow an animal to develop skills or knowledge that may lead to fitness benefits later in life. These benefits must exceed the costs of developing them, and long-lived animals have a longer time span to accumulate the benefits (Dukas 1998; Kaplan et al. 2000). Therefore, an evolutionary increase in longevity should increase the likelihood of an evolutionary increase in brain size. A strong correlation (without the outliers, bats) between brain size and life span across the eutherian mammalian orders supports the major prediction derived from this hypothesis (Deaner et al. 2003).

The "Cognitive Buffer Hypothesis" (Sol 2009) argues that large brains offer behavioral flexibility and higher learning capacities to unusual, novel, or complex socioecological challenges. This buffer effect should enhance survival rates and favor longer reproductive life, compensating for the loss of delayed reproduction.

This hypothesis finds some support in the correlation between brain size and life span described by several authors (Harvey et al. 1987; Austad and Fischer 1992; Allman et al. 1993), in the higher cognitive flexibility of large-brained animals (Sol 2009) and in a positive correlation of neocortex size (representing most structures involved in higher-order cognition) with life span (Deaner et al. 2003). Following this hypothesis, the main selective pressure was on brain size, and life history traits were either constrained by (e.g., extended juvenility or age at first reproduction) or coevolved together with brain size.

The "Maternal Energy Hypothesis" (Martin et al. 2005; Martin 2007; Martin and Isler 2010) focuses on energy supplied by the mother during infant brain development up to weaning. It postulates that the evolution of large-brained offspring has required a longer gestation and lactation period or a higher energy input through higher metabolic turnover from mother to offspring. Empirical findings from extant and fossil primates, cetaceans, and carnivores support this hypothesis (Martin and Isler 2010).

The "Brain Malnutrition Risk Hypothesis" or "Developmental Cost Hypothesis" concentrates on the high energetic costs of growing large brains (Martin 1981, 1996; Armstrong 1983; Leonard and Robertson 1992; Aiello and Wheeler 1995; Ross and Jones 1999; Kaplan et al. 2000; Barton and Capellini 2011) and is based on the assumptions (a) that the brain is more sensitive to energy shortage than the rest of the body and energy restrictions during brain development may lead to long-lasting or even permanent brain damage, which has to be prevented, and (b) that body growth trajectories lag behind brain growth trajectories in a general fashion that reflects a functional balance between behavioral capabilities and body size (Deaner et al. 2003). This model can explain the relationship between large brain size and late maturation, as the extension of the body growth period may allow the evolutionary increase in brain size. Furthermore, its predictions correspond well with the observed growth trajectories during lactation and after weaning including growth spurts that occur in certain species (Count 1947; Cheek 1975; Janson and van Schaik 1993; Leigh 1996; Bogin 1999; Deaner et al. 2003; Pereira and Leigh 2003) or the relation between the rate of fetal brain growth and energy turnover of the mother (Barton and Capellini 2011). Supportive evidence for an extension of the "Brain Malnutrition Risk Hypothesis" was presented by Leigh (2004) who identified two different maternal strategies within the primate lineage with regard to pre- and postnatal brain size development, metabolic needs, and age at maturation: the first strategy is followed by females who mature late with large body size and produce infants with relatively large brains (see also Harvey and Clutton-Brock 1985). Late maternal maturation was hypothesized to allow mothers to carry the metabolic costs of very early (fetal or infantile) brain growth through larger size. As a consequence, offspring may be more precocious in terms of cognition, locomotion, foraging, and social behavior. Squirrel monkeys or Old World monkeys as a group appear to follow this strategy (Leigh 2004). The second strategy consists of early maturation, coupled with a slow postnatal brain growth pattern over a long period of time, which may free the mother from extensive postnatal investment by "distributing" the costs of offspring brain growth to the offspring itself or to other group members. Tamarin females seem to follow this second strategy and give birth to offspring early, with short interbirth intervals (Leigh 2004). The differences between these two strategies would reflect different metabolic risks and trade-offs faced by various species at different stages of their life cycles.

Compatible with the latter hypothesis is the “Expansive Brain Hypothesis” (Isler and van Schaik 2009; van Schaik et al. 2012) explaining variation in relative brain size among homoiothermic vertebrates. It claims that costs of a relatively large brain must be met by a combination of increased energy turnover or reduced energy allocation to another expensive function such as digestion, locomotion, or production (growth rate, reproduction). This hypothesis gained support by a large mammalian dataset, including primates, showing that an increase in brain size leads to a longer period of immaturity among monotokous, precocial species, but not among the polytokous altricial ones, which instead decrease litter size (Isler and van Schaik 2009). Relatively large-brained mammals showed reduced annual fertility rates compared to smaller-brained relatives (Isler and van Schaik 2009) and often a compensatory increase in life span (Isler and van Schaik 2009; Gonzales-Lagos et al. 2010).

The five hypotheses differ not only in the life history trait which is most closely linked to brain size (age at first reproduction versus longevity) but also in their causal connection. For example, the “Brain Malnutrition Risk Hypothesis” and the “Expansive Brain Hypothesis” argue that delayed maturation preceded the evolution of larger brains. The “Cognitive Buffer Hypothesis” postulates that larger brains facilitated the evolution of longevity, whereas in the “Delayed Benefits Hypothesis,” longevity preceded the evolution of large brains. Future studies have to derive competing and testable predictions from these hypotheses to clarify the pathways that were most relevant in primate evolution.

Phylogeny

Phylogeny has long been recognized to constrain the evolution of life history. Thus, closely related taxa, such as congeneric species, may show similar life history traits because they are likely to differ less in body size and ecology than more distantly related species (Harvey and Pagel 1991; but see Kappeler 1996). Primate life histories are highly conservative within lineages and show two major clades where strepsirhines as a group lie more to the fast end of the fast-slow continuum than haplorhines (Martin and MacLarnon 1990; Martin 2003; Purvis et al. 2003). Species within each clade share similar life history traits. Neonatal body mass of strepsirhines, for example, is almost three times below that of haplorhines of the same body size (Leutenegger 1973; Harvey et al. 1987; Martin 2003), but strepsirhines tend to have more infants per litter (Chapman et al. 1990). Strepsirhine mothers allocate less energy to prenatal growth per unit time than haplorhines (Martin and MacLarnon 1988; Ross 1988; Young et al. 1990), whereas the two major haplorhine groups, the New World and the Old World monkeys, do not differ in this respect from each other (Ross 1991). After birth, the situation is reversed for the two clades, i.e., strepsirhines grow faster than haplorhines (Martin 2003; Fig. 4). Differences in reproductive output of females between the two clades have led to

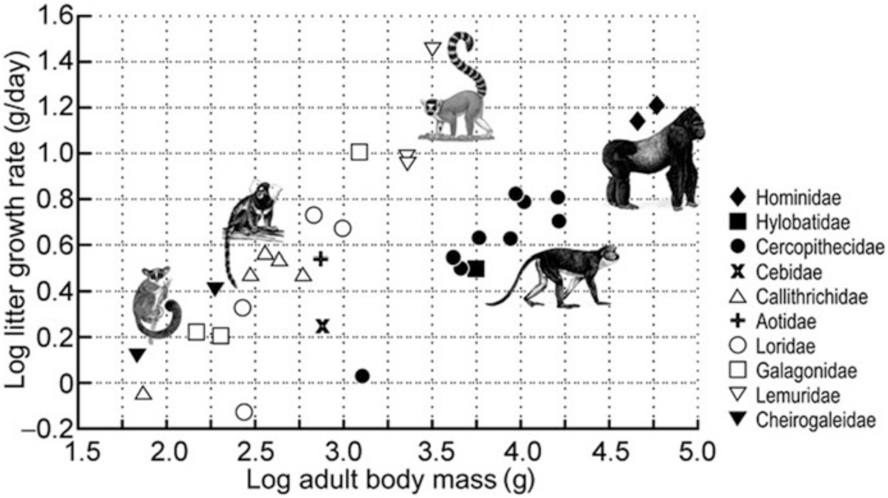

Fig. 4 Grades of primate litter growth rates (Modified after Ross 1998)

the suggestion that haplorhines trade time for energetic investment in infant growth while strepsirhines opt for numbers (Lee and Kappeler 2003). Furthermore, relative brain size in strepsirhines is lower than in haplorhines (Martin 1990; Barton 1999; Deaner et al. 2003). Recently, evidence was provided (Purvis et al. 2003) for a mosaic evolution of life history patterns across five major primate clades (strepsirhines, platyrrhines, cercopithecines, colobines, and hominoids). The rate of accumulation of life history variation differed among the clades in a pattern that seems to correlate with their ecological diversification, i.e., strepsirhines showed the highest rate. Different phylogenetic groups have different patterns of variations, suggesting that they are moving differently on the fast-slow continuum, i.e., some by changing litter sizes, others by varying the age of sexual maturity, and so on. No evidence was found, however, for the claim that life history shaped primate phylogeny by affecting speciation or extinction rates.

Various methods have been introduced to remove the so-called confounding effect of phylogeny in comparative studies (Harvey and Pagel 1991; Purvis et al. 2003) so that potential covariation among life history traits and their evolutionary interplay with demographic, ecological, and social factors may be assessed.

Age-Specific Mortality Rates

Extrinsic mortality rates during different phases of the life cycle have been used repeatedly to explain life history variations. Findings of Promislow and Harvey (1990) suggested, for example, that in mammals both high juvenile mortality and high adult mortality are linked to an early age at first reproduction when the effects of body size are removed. Charnov (1993) developed a comprehensive and very influential model that explains life history variation and in particular age at first reproduction as a consequence of adult mortality rates, which are in turn determined by the environment. When adult mortality is high, animals should mature early in order to minimize the risk of dying before reproducing. The Charnov model is based on a growth law that constrains the relationship between age and body mass before maturity and is able to explain the allometric relationships of many life history traits with body mass, but recent studies shed doubts on its general explanatory value for life history variations in primates (see Purvis et al. 2003 for discussion). Despite this criticism, the general influence of mortality rates on life history pattern and on life span and age at first reproduction in particular is undisputed and supported by many studies (Janson and van Schaik 1993; Owens and Bennett 1995; Purvis and Harvey 1995; Charnov 1997; Kozlowski and Weiner 1997; Ricklefs 1998; Harvey and Purvis 1999; Ross and Jones 1999; Alvarez 2000) even if the exact mathematical model for their relationship is not yet formulated. It can be expected that this relationship is a result of balancing the benefits of reproducing early with relatively high birth rates with the benefits of delayed maturity that leads to larger mothers that may be more successful in raising young and the costs and survival risks that are connected with each of these strategies (Ross 1998; Alvarez 2000). Recently, a comparative individual-based dataset from longitudinal studies of wild populations of seven nonhuman primate species computed actuarial estimates of age-specific survival, and revealed similar mortality patterns across primates, putatively shaped by local selective forces rather than phylogenetic history (Bronikowski et al. 2011).

Diet

Primates feed on a variety of different food items. According to their specialization on fruits, leaves, and animal protein (e.g., insects, arachnids, small vertebrates, eggs), they are usually classified as frugivores, folivores, and faunivores (Fleagle 1999). Since variation in reproductive capacity of a species is strongly affected by the availability and quality of food (Ganzhorn et al. 2003), diet has been hypothesized to influence life history variation between species in a predictable way. To date, however, results on the effect of diet adaptations on life history traits are inconclusive.

Diet appears to have little effect either on prenatal maternal investment (litter weight/gestation length) or on the intrinsic rate of natural increase of a population of anthropoids (Ross 1988). However, a clear association between body mass, ontogeny, and diet was found in another study (Leigh 1994). In the latter, infant growth rate was faster in folivores than in comparably sized nonfolivores. In a study with a much larger sample size including strepsirhines and focusing on intra- and interspecific variations, no significant effect of diet on life history traits was revealed once body mass was removed (Lee and Kappeler 2003). It was shown, furthermore, that the duration of postnatal growth as reflected in the age of weaning was longer for frugivores among anthropoids, whereas it was longer for folivores among strepsirhines.

Dietary strategies were found to affect mortality patterns in seasonal environments in particular during the wet season (Gogarten et al. 2012). Then, folivores showed a higher mortality than frugivores. Comparing life history traits in Asian folivores and frugivores, often living in sympatry, it was found that both groups showed a similar age at birth and interbirth interval, but differed with regard to gestation length (Borries et al. 2011). The latter was longer in folivores than frugivores suggesting a slower fetal growth rate (lower maternal energy) and/or advanced dental or gut development.

Predation

Predation is a major ecological factor influencing mortality patterns in primate populations. It is known to be dependent on body size, such that larger-bodied animals face a lower predation risk than smaller-bodied ones (Read and Harvey 1989; Isbell 1994; Janson 2003; Scheumann et al. 2007). It is therefore expected that predation varies according to body size and affects reproductive output in primate females.

In order to explore the effect of predation on life history, researchers have often used subjective assessments of predation risks (Janson 2003; Lee and Kappeler 2003). For example, predation risk was estimated based on the response to predators and on predator encounter rates, and then ranked as low, medium, and high (Lee and Kappeler 2003). However, only a clade difference on relative reproductive output has been found so far (Lee and Kappeler 2003). Thus, short gestation periods were associated with high risks of predation in strepsirhines. Neonatal body mass and mass at weaning varied as a function of predation risk in anthropoids, such that under high-risk infants were born large but weaned small, minimizing not only the risks after birth but also maternal investment during the postnatal growth phase associated with high risks (Lee 1999). Recently, a new theoretical model was introduced linking life history variation between species with predation risk and social grouping pattern (Janson 2003). It was observed that primate species with large body size or living in large cohesive bisexual groups, both assumed to be adaptations to high predation risk, tend to have low predation rates. Based on the new model, it could be shown that interspecies variations in longevity can explain these observations, assuming that predation risk remains fairly constant across primates. If longevity increases with increasing body mass, as has been shown empirically, then larger species face the cost of predation over a longer time span than smaller ones and consequently will gain a larger fitness benefit by evolving sophisticated antipredator responses (e.g., increased sociality, alarm calls).

Social Grouping Pattern

Three major patterns of social organization are found in primates (Kappeler and van Schaik 2002). Neighborhood systems (Richard 1985; Radespiel 2000), in which individuals forage separately and either sleep alone or come together at the end of their activity period to form permanent and long-lasting unisex or mixed-sexed sleeping groups, are found within the nocturnal strepsirhines, in tarsiers, as well as in one diurnal anthropoid, the orangutan. In these systems, home ranges may overlap within and between sexes. Dispersed and cohesive pairs (Müller and Thalmann 2000; Rasoloharijaona et al. 2003; Ramanankirahina et al. 2011), where both sexes forage either alone or in synchronized association and mostly sleep together, are found in various strepsirhines, in tarsiids, and in various New World monkeys, as well as in gibbons. Sexes share the same home range and defend it against conspecifics. Paternal care of both sexes is a widespread phenomenon within pair-living primates (see section "Mode of Infant Care"). Group-living in cohesive bisexual groups with high variations in size, sex ratio, and temporal stability is the most common pattern of social organization in diurnal primates (Kappeler and van Schaik 2002). Variations in group size depend on the dispersal regime of a particular sex and species as well as on the benefits of foraging and sleeping together and the costs of feeding competition, predation, and infanticide in the respective environment.

Relative group size and residence strategy (both sexes disperse, male philopatry, female philopatry) is associated with relative reproductive output. In a recent study in which the effect of group size [categorized as small (<4), medium (4–20), and large (>20)] and residency on intra- and interspecific life history variations was examined (Lee and Kappeler 2003), large groups of group-living anthropoids had a smaller relative neonatal mass and a higher relative mass at weaning than the other groups. These differences in life history variation between groups of different sizes might be explained either by a differential mortality risk in infants or juveniles due to predation or infanticide (Janson and Goldsmith 1995; Hill and Lee 1998; Janson and van Schaik 2000) or by a different degree of within- and between-group-feeding competitions (van Schaik and van Hooff 1983; Isbell 1991). Furthermore, in group-living primates with male philopatry, a longer relative gestation period, a later age at first reproduction, and a longer birth interval were revealed (Lee and Kappeler 2003). It was speculated that lower rates of extrinsic mortality, suggested to be related to group-living, may facilitate a higher maternal investment.

Life history theory also predicts a relation between social grouping patterns and species longevity over evolutionary times through reduced risk of extrinsic mortality in larger social groups. According to a recent study using a dataset of 253 mammal species (including primates), social group size was, however, a poor predictor of maximum longevity across mammals, as well as within primates, challenging the link between group size and this life history trait (Kamilar et al. 2010).

Mode of Infant Care

Parental investment theory suggests that parental care should be allocated among offspring in ways that maximize the parent's expected lifetime reproductive success (Clutton-Brock 1991). Since the energy that can be devoted to reproduction by an individual is limited, trade-offs between energy investments in infant growth reflected by different modes of infant care and birth rates were suggested to explain some variation in life histories. Primates show a diversity of infant care patterns, which are found to be linked to the reproductive output of mothers.

All nocturnal strepsirhines (except woolly lemurs) as well as tarsiers leave their infants for extended periods of time cached at safe shelters, e.g., tree holes, nests, or dense vegetation, during foraging (Kappeler 1998; Rasoloharijaona et al. 2000; Lutermann 2001; Ross 2003). When changing shelters, mothers carry their infants either orally or clinging to their belly or by both modes of transportation. Species displaying this mode of infant care are called parkers (Ross 2001). In contrast, two nocturnal genera of strepsirhines (*Loris*, *Avahi*), almost all cathemeral lemurs (except *Hapalemur*), all diurnal lemurs, as well as all anthropoids (except *Procolobus verus*) maintain close body contact with their infants during foraging while transporting them clinging to their body (Nicolson 1987; Whitten 1987; Ross 2003). Species with this mode of infant care, with no observed nesting and parking, are called riders (Ross 2001). Anthropoid riders show various degrees of allocare where other females, juveniles, or adult males (often related to the infant) help in infant care.

Parkers with oral infant transport tend to have multiple offspring per litter with low litter mass, born after a short gestation time (Kappeler 1998; Ross 2001; Wrogemann et al. 2001; Ross 2003; but see Randrianambinina et al. 2007, for *Lepilemur*). In contrast, parkers who transport infants clinging to their belly have relative long gestation periods and a single offspring with relatively low body mass (Zimmermann 1989; Ross 2003), suggesting that nesting may be more closely associated to the birth of multiple offspring than to the small size of offspring (Ross 2003). Whether a short gestation period selects for using nests or tree holes to rear offspring or vice versa is not yet clear.

Riding evolved repeatedly in different lineages of primates (Kappeler 1998; Ross 2003) and was most likely selected for reducing mortality risks in infants. Once evolved, it has been conserved, perhaps due to physiological coadaptations. For example, riders have developed a less-energy-rich milk compared to parkers (Tilden and Oftedal 1997). Riders are usually larger than related parkers suggesting that the evolution of large body size and infant fur-clinging may be linked (Kappeler 1998; Ross 2001). Riders have the same birth rates as parkers but wean and breed later when adjusted to body size and phylogeny. They also maintain smaller home ranges than parkers of the same mass (Ross 2001), indicating that carrying infants during foraging incurs energetic and reproductive costs.

Allocare is described in a variety of anthropoid riders (Nicolson 1987; Whitten 1987; Ross 2003) and discussed to enhance the reproductive potential of mothers (Mitani and Watts 1997; Ross and MacLarnon 2000; Ross et al. 2010). Species with high amounts of allocare show more rapid postnatal growth and wean their infants at a younger age (but at the same relative size) than those with low allocare (of the same body mass, Fig. 5). This early weaning allows higher birth rates but does not lead to earlier maturation of the infants because of brain size constraints (Ross 2003). A recent comparative study on allocare and life history evolution across mammals (including not only

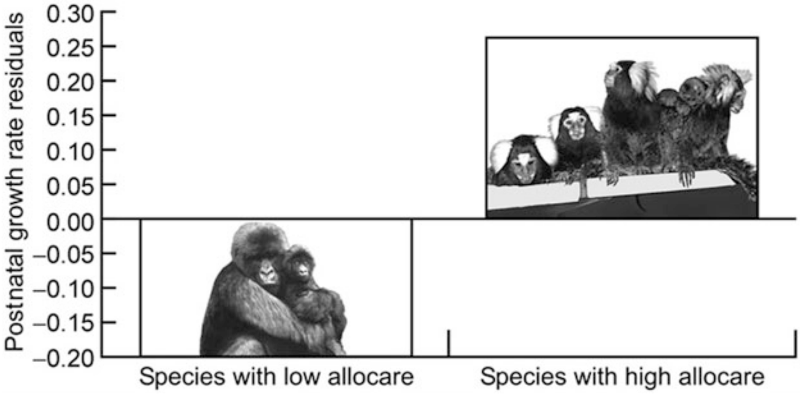

Fig. 5 Relationship between allocare and relative growth rates (Modified after Ross 1998)

haplorhines but also strepsirhines) revealed that only in primates does a strong link exist between the presence of allocare and fertility (Isler and van Schaik 2012). This relationship was due to the exceptional cooperative breeding pattern of callitrichids, in which infants are provisioned by the father and other caregivers, a behavior that benefits the mother by reducing energetic costs of infant rearing. Another recent study, exploring the effect of infant parking, nesting, and allomaternal care and life history in a previously neglected group of strepsirhines, the Malagasy lemurs, yielded unexpected results (Tecot et al. 2012). It showed that, in contrast to haplorhines, allocare in lemurs did not impact reproductive output (assessed by fetal or postnatal growth rates, interbirth intervals). However, infant parking and nesting were positively related to faster fetal and postnatal growth, while nesting was negatively associated with interbirth interval (Tecot et al. 2012). These findings coincide with those on nonprimate mammals and were interpreted as representing an adaptation to infant survival in Madagascar’s harsh and unpredictable environment.

Human Life History

Humans (*Homo sapiens*) differ fundamentally from all other primates in four life history traits: neonatal weight, age at first reproduction, interbirth interval, and life span (Smith and Tompkins 1995; Kaplan 2002; Hawkes et al. 2003). Compared to apes, human babies are relatively large at birth, but they grow more slowly and have a fairly extended childhood (period following infancy when youngster is weaned but still depends on caregivers for feeding and protection (Bogin 1999)). Furthermore, humans reach reproductive age much later and have shorter interbirth intervals and a higher longevity than apes (Leigh and Park 1998; Kaplan et al. 2000; Mace 2000; Lee 2012).

Maximum life span in humans is reported to range between 90 and 122 years (Weiss 1981), which is about twice as long as in chimpanzees and gorillas (Kaplan and Robson 2002). A large proportion of this time is postreproductive in women, i.e., after woman have entered menopause, implying that total life span and fertile life span are disconnected in humans. For example, an 85-year-old woman has spent about 41 % of her life in a postreproductive state, which is very much in contrast to nonhuman primates, whose postreproductive periods are usually short and coincide with frailty and somatic deterioration (Hawkes et al. 1998; Johnson and Kapsalis 1998; Pavelka and Fedigan 1999). Whereas the fertile life span of humans is quite similar to that of great apes (Alvarez 2000; Kachel and Premo 2012), woman can have a much higher fecundity due to much shorter interbirth intervals (Hawkes et al. 2003).

In addition to these specialized life history patterns, human brain size is three- to fourfold larger than in chimpanzees and gorillas (Kaplan and Robson 2002) and much higher than expected for primates when adjusted to body size (Pagel and Harvey 1989). The human brain grows faster and continues to grow longer after birth (Bogin 1999; Kaplan 2002; Reiches et al. 2009; Leigh 2012).

Furthermore, humans show broad intraspecies variations in growth rate, age of maturation, birth rate, age-specific mortality, and senescence, which not only depends on ecological factors but also on food technology, medical care, and culture (Mace 2000; Kaplan 2002; Hawkes et al. 2003; Schuppli et al. 2012). In developed countries during the last 150 years, the average age at menarche among girls has decreased by about 4 years; birth rate in women has changed from six to about two children per family, and the percentage of people reaching more than 100 years of age has increased manifold (Kaplan 2002).

To date, there has been much lively debate, but no consensus, on how to explain these human peculiarities in life history patterns. Some researchers argue, for example, that the strongly extended life span of humans, with the emergence of a long menopause in women, is nonadaptive and represents an artifact of a quite recent increase in longevity caused by improved living conditions (Broadfield 2010). This view is supported by empirical data showing that captive and domesticated animals also live longer than their wild counterparts (Austad 1994). Others argue that an increased longevity in humans evolved as a by-product of selection acting elsewhere in human life history ("reserve capacity hypothesis," Larke and Crews 2006; Bogin 2009; and "embodied capital hypothesis," Kaplan 2002; Kaplan et al. 2003) or propose that our long life span is adaptive in itself ("grandmother hypothesis," Hawkes et al. 1998, 2003).

The "embodied capital hypothesis" (Kaplan et al. 2000, 2003; Kaplan and Robson 2002) proposes that the prolonged longevity and the large brain size of humans are products of coevolutionary selection favored by the exploration of a new, cognitively challenging feeding niche. Ecological factors increasing the

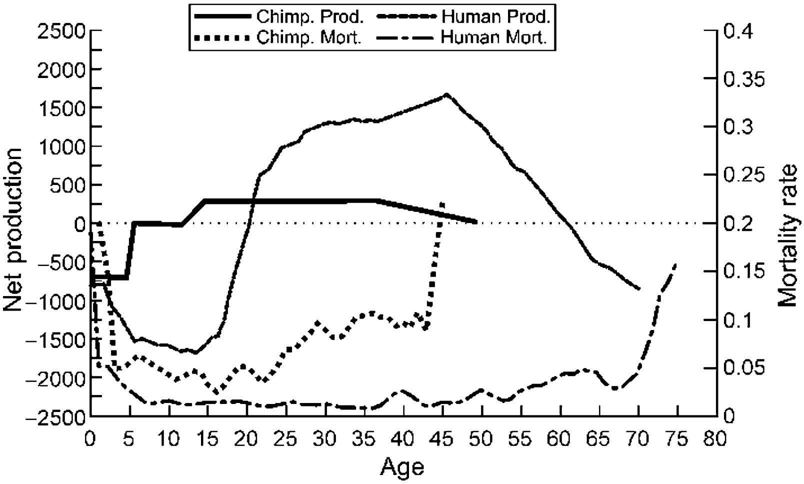

Fig. 6 Net food production and mortality in human hunter-gatherer populations and chimpanzee populations (Modified after Kaplan and Robson 2002)

productivity of investments in developmental embodied capital, such as the brain, should increase both time spent as a child and investments to reduce mortality.

Supporting evidence for this hypothesis was gained by studies on foraging activity, net food production, and mortality in chimpanzee and contemporary hunter-gatherer populations (Kaplan et al. 2000; Kaplan and Robson 2002). Hunter-gatherers showed a much lower mortality rate during childhood and adulthood than chimpanzees along with a quite different net food production profile (difference between food produced and food consumed; see Fig. 6). Chimpanzee and human infants depended nutritionally on their mothers until weaning displaying a negative net food production. In contrast to chimpanzees, humans showed an extended juvenility with further nutritional provisioning by parents up to puberty lowering juvenile mortality. This extraordinary long juvenile dependency paid off later in life when the highly efficient foraging strategies of adults allowed them to obtain a much greater quantity of valuable food than required for personal subsistence, which is reflected in a positive net food production. Whereas these results suggest why longevity may have been extended and brain size enlarged in humans compared to apes, the discovery of the apolipoprotein E Allele-system, which affects neurite growth and aging, offers a potential candidate for the genetic basis of such a coevolutionary process (Kaplan and Robson 2002; Finch and Stanford 2004).

Recently, a comparative study on foraging skill competence in 57 mammal and bird species (Schuppli et al. 2012) within a life history context provided broad biological and empirical support for the “embodied capital hypothesis.” The study revealed that most mammals reach adult-level foraging skills well before the end of their developmental periods, suggesting that energy constraints affect the age at first reproduction. In more complex ecological niches, the age of adult-level skills comes closer to the age of first reproduction. Gregariousness, slow conservative development, and postweaning provisioning favor the late age at skill competence. According to some authors the unusually late age at skill competence among humans arose because our hominin ancestors added cooperative breeding and hunting to the slow development inherited from great apes with complex ecological niches.

The “grandmother hypothesis” (Hawkes et al. 1998, 2003; Alvarez 2002; Lahdenperä et al. 2004; Kim et al. 2012) is based on Charnov (1993) and assumes that prolonged postreproductive life span will evolve when postreproductive females gain greater fitness by increasing the success of their offspring than by continuing to breed themselves. The greater longevity favored delayed maturity because lower adult mortality rates reduce the fitness costs of prolonged growth.

Empirical support for this hypothesis comes from some contemporary and historical populations (Blurton Jones et al. 1989; Mace 2000; Jamison et al. 2002; Voland and Beise 2002; Hawkes 2003), but not all (Hill and Hurtado 1991, 1996, 1999). These studies showed that grandparents may assist philopatric offspring by transferring knowledge and by participating in household tasks and child care. This help may increase offspring breeding probability and grandchild nutrition and survival. A recent comprehensive study on fitness benefits of prolonged postreproductive life span in women using multigenerational individual-based datasets from historical farming communities in Finland ($n \sim 500$ women) and Canada ($n \sim 2{,}300$ women) during the eighteenth and nineteenth centuries (Lahdenperä et al. 2004) provides additional support. Postreproductive women, living in the same household or close to their offspring, have more grandchildren, and greater fitness, because they enhance the lifetime reproductive success of their offspring by allowing them to breed earlier, more frequently and more successfully. Fitness benefits, however, disappear as the reproductive output of the offspring declines. Rates of female mortality accelerate as their offspring cease reproduction. Recently, evolutionary modeling supported that increased longevity in humans can evolve from grandmothering (Kim et al. 2012).

Conclusion

As shown in this chapter, primate life histories are among the slowest in mammals and nevertheless show a fascinating diversity in pattern and variations within and between the more than 420 extant species. The basic traits of life history, such as gestation length, neonatal body mass, number of offspring, age and body mass at weaning, postnatal growth, age at first reproduction, interbirth interval, as well as life span, are linked in complex ways, and to varying degrees, across taxa by physiology (e.g., trade-offs in growth and reproduction) and genetics (e.g., pleiotropy). However, despite more than 40 years of intensive research, the causes of the unique slowness of primate life histories remain poorly understood. The three suggested major determinants, energetic costs of brain growth, age-specific mortality, and socioecology, explain in part the low developmental and reproductive rates of primates but do not yet deliver a comprehensive and conclusive explanation. For example, we do not know whether the energetic costs for brain growth or body growth drive life history evolution, or vice versa, or whether there are unexplored factors driving their coevolution. Further progress in the development of life history theory is necessary and further empirical data from different primate lineages under different ecological settings, including primate genomics, transcriptomics, and proteomics, have to be compiled to convincingly identify targets of natural selection and to understand the full adaptive significance of life history variation among primates.

Differences in basic life history traits between species are suggested to be adaptive responses to past environments. As phylogenetic constraints they may limit growth and mortality patterns of extant primate populations and as a consequence affect their survival in rapidly changing environments. Most extant nonhuman primate species are now at risk of extinction. A better knowledge of their life history schedules and the limits of their phenotypic plasticity across distribution ranges along with information on their population dynamics and genetic variation may not only illuminate pathways for evolution but also help in establishing effective conservation and management programs. Since respective information on the link between distribution patterns, ecology, and life history is available for only a few species, comparative long-term field studies applying similar methodologies are urgently needed. These studies may also shed light on an interesting paradox in life history research, namely, that correlations for life history traits sometimes diverge in intra- and interspecific comparisons (Martin 2003).

Finally, understanding the peculiarities of human evolution will require further comparative research on nonhuman primates and their life histories. Thus, for instance, recent socioecological studies have unraveled an unexpected complexity in primate sociality, from solitary foraging and sleeping over dispersed or cohesive group-living to more flexible fission-fusion societies. Since these different degrees of sociality require quite different levels of brain complexity for spatial and social memory, integrative and comparative studies on life history, socioecology, communication, and cognition within and across the different primate lineages offer an excellent opportunity to illuminate our biological roots and the selective forces that shaped our own life history.

Principal life history data are presented for each currently recognized primate species when they could be found in the literature. One should note the large number of empty cells and the variation in some variables used in the literature. All values without superscript are from Rowe and Myers (2013). Other sources are listed below

BM (body mass) = mean body mass (g) of wild adult females, ~ indicates mixed or unknown sex sample; AFR (age at first reproduction) = mean age (years) of first female reproduction; GL (gestation length) = mean gestation length (days); IBI (interbirth interval) = mean interbirth interval (month); LS (litter size) = modal litter size; NNM (neonatal mass) = mean body mass (g) of neonate females, ~ indicates mixed or unknown sex sample; WA (weaning age) = mean age at weaning (days); WM (weaning mass) = mean body mass (g) at weaning; L (longevity) = maximal recorded life span in years. Parameters are expressed as ranges if single mean values are not provided in the cited literature, LR = low range (= minimum), HR = high range (= maximum)

Great Ape Social Systems

Angela Meder

Contents

Abstract

For decades, the social systems of the great ape species were described as being fundamentally different, but long-term field studies have questioned this idea. Although orangutans seem to be less social than the African apes, they have the ability to socialize and spend much time in contact with conspecifics if ecological conditions permit. Although the social behavior of chimpanzees and bonobos seems very different, their social structure is similar. The social systems of all great apes have common traits. They are characterized by weak ties, female transfer is common, they have a tendency toward fission-fusion grouping and a complex social network, females lack sharply defined dominance relations, and intrasexual bonds among non-kin can be relatively strong. There is remarkable

intraspecific variability in social organization and structure; differences in ecological conditions seem to be very important in determining this. Frugivory especially requires a mobile and flexible social system. Compared to the great apes, humans show even greater variability.

Introduction

Great apes share a common ancestor, they live in similar habitats (at least some populations), they are rather large, and they have slow life histories. Despite these similarities, they developed different social structures. What are the similarities? What are the differences and why did they develop? What social structure might the common ancestor have had? What does this mean for *Homo*, which emerged from within the great apes?

These questions have occupied primatologists for decades. Many hypotheses and models were developed and had to be abandoned because the growing evidence from field research did not support them. Some questions cannot be answered satisfactorily yet, but researchers have a much better idea now of the social systems of man's closest relatives. This knowledge is summarized here. Ecology and life history are also briefly portrayed for each species because they are key factors for the understanding of group structures and dynamics.

Primate Social Systems

Animals may live in groups to increase their survival and reproductive success, but these groups have different structures for each species. To explain social systems, Kappeler and van Schaik (2002) distinguish three components: social organization (group size and organization), mating system, and social structure (relationships between group members). These three components are used here to clarify the social structures of the ape species.

Dunbar (1988) lists four reasons why primates should associate (stay and move) with conspecifics: better protection against predators, defense of resources, foraging efficiency, and improved caregiving opportunities. But sociality also has costs, especially higher intraspecific competition. Competition means usually competition for food (Kummer 1971; Wrangham 1979). Large groups deplete food more quickly and have to travel further in a day; this may influence female grouping patterns and restrict travel and sociality of females with infants (Sommer and Reichard 2000).

Folivores do not need to travel far each day and can live in relatively large groups without high levels of competition. The distance a group of a frugivore species has to travel is related to group size, so food distribution limits the number of group members (at least during feeding). Therefore, frugivores should either live in small groups or in fluctuating grouping patterns.

According to Dunbar (1988), several other factors may also influence primate group structure, at least theoretically. An important factor in this respect is the risk of male infanticide. Females with long lactation (like great apes) face an increased risk of infanticide, particularly when a reproductively capable male comes into a position of top dominance (van Schaik 2000). Usually male infanticide is seen, especially in one-male groups, as a strategy to increase reproductive success: the female will become receptive again sooner and the bond between the partners will be strengthened.

Regarding reproductive systems, the ape species have traditionally been classified as follows (Sommer and Reichard 2000):

- One male-many females (*polygyny*): gorillas
- One male-one female (*monogamy*): gibbons
- Many males-many females (*polygynandry*): chimpanzees
- Many males-one female (*polyandry*): not generally present in apes

As in this list, certain social systems have often been attributed to certain mating systems, but this is much too simple, not only in apes but also in primates in general. A social unit has its own history; a group may be polygynous or polyandrous, for example, and temporarily this may mean monogamy, but one individual may have several successive partners during its lifetime. Moreover, primates, and especially the great apes, show considerable flexibility and variability in their social behavior.

Finally, grouping levels may form a hierarchy. In great apes, the fission-fusion society is such a multilevel social system. Fission-fusion means that groups with different size and different composition may form for limited periods of time but that above this lowest grouping level, there is a higher, stable social unit. According to Lehmann et al. (2007) the advantage of fission-fusion societies is that the community size can increase.

The “Lesser” Apes

Although this chapter concentrates on the family Hominidae [used here to include great apes as well as humans], the sister family Hylobatidae will be briefly discussed. Gibbons are much smaller than the great apes: they weigh about 5–11 kg, with the siamang being the largest species. They live mostly in evergreen rain forest, with some populations in semideciduous and mixed evergreen forest. They are strictly arboreal and are primarily frugivorous.

For a long time gibbons were regarded as one of the few monogamous primate taxa, but this concept has been questioned. Change or replacement of a partner occurs in many species; in Khao Yai (Thailand), where the population density is very high, there is intense competition for females. The majority of adults copulate or attempt to copulate with partners other than their mates. Social polyandry is not uncommon, and male immigration into existing monogamous groups is observed.

Extensive overlap of territories and a wide range of affiliative interactions with neighbors have been described in several gibbon species (Sommer and Reichard 2000). They show a high interspecies variation in social structure, but even if Brockelman et al. (1998) question it, their basic social structure seems to be the nuclear family unit.

Traditionally, the male-female relationship was regarded as pair-bonded, but it seems that gibbons rather live in small groups, most probably because selective pressures do not permit large groups. At least in some species, these social units are not really two-adult groups, although it is the norm. There is a remarkable intraspecific flexibility in social organization and affiliation (Reichard and Barelli 2008). Sommer and Reichard (2000) suggest that male gibbons associate with females in order to provide a constraint to roving males and thus protect their offspring from infanticide.

The Great Apes

The species of great apes, and their distributions, are summarized in the table below:

Orangutans (Genus *Pongo*)

Bornean and Sumatran orangutans are today usually classed as two distinct species (Table 1). There seem to be characteristic differences between the two species in behavior and social organization.

Ecology

Orangutans live in rainforest habitats with a high tree species diversity from sea-level swamp forests to mountain slopes (Galdikas 1988; Knott 1999). They prefer the lowland forest up to about 1,000 m, usually close to streams and rivers as well as swamps. Galdikas (1988) lists 317 food types for Tanjung Puting. The orangutan diet consists of 61 % fruit; figs are their staple food. They eat meat (small mammals) on rare occasions (Rijksen and Meijaard 1999). Part of their habitat is characterized by extreme fluctuations in the type and quantity of fruit available, and this results in dramatic differences in nutritional intake and body weight (Knott 1999).

Orangutans require a large area that typically includes varied habitats. Resident females have stable, overlapping home ranges with an area of 0.5–6 km^2 in Borneo and 1–3 km^2 in Sumatra. The ranges are not actively defended and overlap considerably. The size of a resident adult male's home range is 1–8 km^2 on Borneo and 6–10 km^2 on Sumatra. It is neither exclusive nor stable (van Schaik and van Hooff 1996; Rijksen and Meijaard 1999; Singleton and van Schaik 2002; Stoinski et al. 2009). Daily travel distances vary from 90 m to 3.1 km (mean: 0.79 km) in Tanjung Puting.

Table 1 Great ape species and subspecies and their distribution

Species/subspecies	Distribution	Study sites mentioned here	Habitat
Pongo abelii Sumatran orangutan	Sumatra	Gunung Leuser (Ketambe, Suaq Balimbing)	Rain forest, swamp forest

Pan troglodytes-chimpanzee			
Pan troglodytes schweinfurthii Eastern chimpanzee	D. R. Congo, north of the Congo River from its junction with the Oubangui into South Sudan and the Ituri region to the Rutshuru district, Uganda, Rwanda, Burundi, Tanzania	Gombe, Mahale, Bwindi, Budongo, Kibale, Semliki, Kahuzi-Biega	Rain forest, woodland, gallery forest, semideciduous forest, lowland and montane rain forest

(*continued*)

Table 1 (continued)

Species/subspecies	Distribution	Study sites mentioned here	Habitat
Pan troglodytes troglodytes Central chimpanzee	From the Congo River mouth to the Congo Republic and the Central African Republic to Cameroon, north to the Sanaga River	Lossi, Lopé, Río Muni, Ndoki	Rain forest
Pan troglodytes ellioti East Nigeria-West Cameroon chimpanzee	Nigeria and Cameroon to the Sanaga River	Gashaka	Lowland forest, montane forest, woodland
Pan troglodytes verus West African chimpanzee	West Africa to Togo in the east	Taï, Assirik, Bossou	Savanna, deciduous forest, rain forest
Pan paniscus Bonobo	D. R. Congo, south of the Congo River	Lomako, Wamba, Lukuru	Rain forest, swamp forest, occasionally grassland, dry forest

Taxonomy according to IUCN 2012

Orangutans are the largest arboreal animals. Females move almost exclusively at between 10- and 25-m height in the trees. In Tanjung Puting, males sometimes walk on the ground, where they also forage and rest, but not in Sumatra, where tigers occur (Sugardjito et al. 1987; Galdikas 1988).

Life Histories and Dispersal

Orangutans may be nursed until 6 years old, longer than any other ape species. The mean interbirth interval in Sumatra is 8–9 years and in Borneo 6–7.7 years (Wich et al. 2009). Females may conceive from about 11 years (Knott 1999). Fully adult (flanged) Bornean males weigh 86.2 kg on average and females 38.7 kg; a single Sumatran male weighed 86.2 kg and Sumatran females on average 38.3 kg (Markham and Groves 1990). Apparently mature but unflanged males weigh about 60–70 kg. In captivity, orangutans have reached as much as 58 years of age, whereas in the wild their maximum age is estimated at 45 years (Leighton et al. 1995).

On reaching adulthood, males develop typical secondary sexual characteristics: flanged cheeks and a big throat sac which enables them to produce loud calls ("flanged" males). Some males show an extended subadult appearance ("unflanged" males) in some cases until the age of 30. This parallel existence of two morphs of mature males is called bimaturism (Utami Atmoko and van Hooff 2004). Orangutan male bimaturism is socially influenced; the close presence of a flanged male suppresses the development of secondary sexual characteristics in subordinate males (van Hooff 1995).

Females often stay in ranges that overlap or are close to their natal area (Galdikas 1984; Singleton and van Schaik 2002). Despite these observations, Utami et al. (2002) found that adult males and females are mostly unrelated in Sumatra – this means that both sexes disperse. Males generally seem to disperse more widely (van Schaik and van Hooff 1996; Morrogh-Bernard et al. 2011; van Noordwijk et al. 2012).

Regarding their ranging behavior, Rijksen and Meijaard (1999) discern three types of orangutans: residents, who stay in the same area for years; commuters, who appear regularly and have a very large home range; and wanderers, who are seen very infrequently and seem to have no home range at all. There are considerable between-site differences in the percentage of these types. In some sites in Sumatra, no residents are found at all. In Ketambe, commuters are the majority of the population (Rijksen and Meijaard 1999; van Schaik 1999).

Size and Structure of Associations

In both species of orangutans, the individuals move independently most of the time. Usually, trees do not provide enough food for several adults. It is difficult to get statistical data on the sizes of associations, because all field studies bias toward larger party sizes, since they are found more easily. The mean daily party size is 1.67 independent individuals in Suaq Balimbing, and the largest sustained party size that has been observed so far was 10.67 (van Schaik 1999).

It is sometimes difficult to decide whether orangutan associations can be called social or whether the apes just meet during their search for food and tolerate the presence of each other. According to Galdikas (1984), in Kutai only 6 out of 13 groups could be considered “social”: a consorting adult pair and two female-offspring units. In Tanjung Puting, Galdikas (1995) observed that 94 % of the time adolescent females who are in contact with others included true social interaction; the rest is nonsocial aggregation. In other age/sex classes, roughly 80–90 % of associations are true social groupings.

The most common grouping is one subadult male and one unreceptive adolescent female (Galdikas 1988). Subadult males and adolescent females spend about 40 % of their time in contact with other units in Tanjung Puting, adult males 16.8 %, and adult females 13.5 % (Galdikas 1995). Adult females in Borneo are far more solitary than those in Sumatra; this reflects the difference in average orangutan density (van Schaik 1999). Fully adult males suffer energetically from association and thus are extremely solitary (van Schaik and van Hooff 1996; Knott 2009). The largest stable parties in Suaq Balimbing develop when females converge upon a dominant male. Sexual associations seem to last longer there and involve more animals than elsewhere (van Schaik 1999).

Male-Female Relationships and Mating Strategies

Contacts of adolescent females with adult males in Tanjung Puting are almost totally restricted to consortships which the female initiates, maintains, and terminates. In general, adult females either avoid contact with males or ignore them, while adolescent females (9–14 years) spend 56 % of their contact time exclusively with males. Toward adult males, nonreceptive adolescent and adult females show avoidance or indifference; if they are receptive, however, they are highly motivated to maintain contact with the seemingly indifferent adult males and may respond to their long calls by immediate approach. With subadult males, adolescent females have long-term associations with no copulation, which may be called friendships, as well as short associations, but no consortships (Wich et al. 2006). The subadult males are responsible for maintaining contact with nonreceptive adolescent females, and sometimes they travel with them for weeks (Galdikas 1984, 1995).

There are two behavioral tactics in the mating strategy of male orangutans: resident flanged males sit, utter long calls, and wait for females (residents, commuters, and wanderers), while unflanged and nonresident flanged males actively search for females and mate with them, irrespective of their receptivity (Utami Atmoko and van Hooff 2004; Stumpf et al. 2008; Knott 2009). Rijksen and Meijaard (1999) assume that these “rapes” are a sexual strategy of young males because the ascent to a higher social status is associated with long-lasting sexual relationships with several females, and this status may be the prerequisite for the development of the full sexual characteristics (Utami et al. 2002). During consortship, the partners travel closely for days or even weeks, usually with the adult male following (Galdikas 1984; Singleton and van Schaik 2002). Severe mating competition is usual among fully adult orangutan males, but no infanticide attempts have ever been seen so far.

Both mating tactics are successful. A paternity analysis in Ketambe, Sumatra, showed that all but one of 11 infants were sired by resident males; out of these ten infants, six were sired by unflanged males (Utami et al. 2002). There is more variation in orangutan mating patterns than previously thought (Utami Atmoko et al. 2009a). In general, however, unflanged males seem to have a slightly lower reproductive success (Satkoski et al. 2004).

Female-Female Relationships

Competition for access to limited resources is rare. In Sumatra, where the population density is high, female home ranges overlap considerably and the rates of association between females are high compared to Borneo (Singleton and van Schaik 2002; Knott et al. 2008). The longest association Galdikas (1984) observed between two adult females in Tanjung Puting was 3 days and 2 nights. Sometimes females travel together, but few direct interactions are observed. Their behavior toward each other varies from aggression and avoidance to affiliative activities, but only very rarely does a female touch another female affiliatively.

Adolescent females often travel together after encounters. The longest association Galdikas (1995) saw lasted at least 10 days. Although adult females are often intolerant to and may attack adolescent females, the adolescents try to associate with them.

Male-Male Relationships

Flanged males avoid each other. They produce long calls that carry for up to 1 km, especially when they approach another individual, after they have defeated another adult male or before they travel over long distances. When adult males come close to each other, agonistic interactions are observed. They have the highest incidence of disfigurements among orangutans, presumably from injurious fights. They dominate unflanged males but may tolerate them as long as they keep a certain distance (van Schaik and van Hooff 1996; Utami Atmoko et al. 2009b).

Discussion: Genus *Pongo*

An older model of orangutan social relationships is that a fully adult male controls a relatively large range that includes the smaller ranges of several females. Calculations proved, however, that a male can maximally defend 0.37–0.57 km^2, which is less than the size of a single female's range. Moreover, adult male ranges overlap and mating is promiscuous (van Schaik and van Hooff 1996).

Orangutans have been regarded as solitary, but they have the ability to socialize and spend much time in contact with conspecifics if ecological conditions permit. That they are not antisocial is documented from zoos, where they have been kept in rather large groups (Poole 1987). Restrictions on group size must therefore lie in the environment in the wild (Harrison and Chivers 2007).

To associate with conspecifics in feeding parties is costly if the food in one tree is not sufficient for several adults (especially for large males). But social contacts are important, particularly for the development of various behaviors and of social competence and relationships. Females with new offspring therefore form "nursery groups" in which new and weaned offspring can socialize (Galdikas 1995; van Schaik 1999; van Noordwijk et al. 2012). Infants learn there how to behave correctly toward conspecifics. Even in independent immature animals, social contact is still necessary for further development. According to Galdikas (1995), adolescent females use social contacts to establish their own home range and to form relationships with the individuals in adjacent ranges. Sugardjito et al. (1987) discuss more benefits of grouping.

Orangutans show the greatest degree of sexual dimorphism of all great apes. Such an extreme dimorphism may be a result of female choice or male-male competition. Other species with such sexual dimorphism are usually either living in one-male groups or have a lek-type mating system. Rijksen and Meijaard (1999) suggest that orangutans have a very complex lek-type mating system. Males meet in a "social arena," an area with especially abundant food resources, where the ranges of several residents overlap and where commuters and wanderers visit regularly. In that arena they emit long calls to attract females.

Two models for the description of the orangutan social system are discussed by van Schaik and van Hooff (1996): either a roving male promiscuity system (an estrous female attracts multiple males who compete vehemently for sexual access to her) with no higher-level social unit or a spatially dispersed but socially distinct community organized around one or more large adult males. Both models have weaknesses: well-defined communities do not seem to exist in any orang population and orangutan females do not mate with any available male. They seem to show distinct preferences; individual relationships and bonding are important

(Galdikas 1984; van Schaik and van Hooff 1996; Rijksen and Meijaard 1999; van Schaik 1999; Utami et al. 2002; Stumpf et al. 2008; Utami Atmoko et al. 2009a). The roving male promiscuity system seems to be closer to the situation of the Bornean orangutans, and the socially distinct community system organized around a dominant male fits better for the Sumatran population (Singleton and van Schaik 2002; Mitra Setia et al. 2009).

Although orangutan communities comparable to those of chimpanzees do not exist, orangutans obviously have a social network. Residents and commuters in a certain area seem to know each other well, while wanderers are strangers to them. An explanation could be provided by a suggestion by Rijksen and Meijaard (1999) and van Schaik (1999) that the individual-based fission-fusion social system that is characteristic for chimpanzees may also be typical for orangutan societies; the differences are in degree rather than in quality.

Gorillas (Genus *Gorilla*)

Eastern and western gorillas are today usually classed as two distinct species (Table 1). Long-term studies are available now for both species from several sites.

Ecology

Gorillas live in a variety of habitats: lowland rain forest, swamp forest, marshy clearings (bais), and montane forest. The lowest densities of western lowland gorillas are observed in areas without Marantaceae and Zingiberaceae, their preferred food are plants, and the highest densities in Marantaceae and swamp forest (Poulsen and Clark 2004; Rogers et al. 2004).

Mountain gorillas mainly feed on green plant parts, whereas lowland gorillas eat a lot of fruit (but still markedly less than chimpanzees and orangutans). Utilization of fruit and of herbaceous vegetation varies seasonally. Western lowland gorillas eat about 250 food items with up to about 100 fruit species, while the mountain gorillas of the Virunga Volcanoes eat only up to 72 different plant species and very few fruits (Tutin and Fernandez 1993; McNeilage 2001; Doran et al. 2002a). Gorillas do not kill vertebrates but eat small animals, mainly insects.

Gorillas do not occupy territories. Their annual home range covers about 8 km^2 in the Virunga gorillas, about 30–40 km^2 in Grauer's gorillas, and 11–30 km^2 in western lowland gorillas. The size depends on the distribution of food sources and group size; home ranges overlap (Tutin 1996; Remis 1997; McNeilage 2001; Yamagiwa et al. 2003a, 2012; Bermejo 2004). In general, gorilla groups move an average of 0.5–2 km a day to forage. Folivorous gorilla populations in montane forest show a shorter daily journey length than more frugivorous populations (Yamagiwa et al. 2003a, b; Robbins et al. 2006).

Apart from humans, gorillas do not really have "predators." The only predator is the leopard (Tutin and Fernandez 1991; Fay et al. 1995). They live primarily on the ground, particularly in the Virunga Volcanoes, where females spend only 7 % of the time above the ground and males 2 % (Doran and McNeilage 1998). Silverback males do not often leave the ground because of their great weight. Gorillas sleep on bare earth or in nests, which they build on the ground or in trees (Poulsen and Clark 2004).

Life Histories and Dispersal

Gorilla infants are nursed for at least 2–3 years in Virunga gorillas, which develop faster than other populations, and for 4 years in western lowland gorillas; the interbirth interval is about 4–5 years (Breuer et al. 2009). Gorillas grow faster and breed more rapidly than other hominids (Groves and Meder 2001). Females may first reproduce between about 8 and 9 years of age in the wild (Watts 1991; Robbins et al. 2004). Males are fully grown at approximately 15 years of age and are called silverbacks. Young mature males without the secondary sexual characteristics are called blackbacks. Western lowland gorilla males have a mean weight of 149 kg and females 71.5 kg, mountain gorilla males weigh 157 kg and females 97.7 kg, and Grauer's gorilla males 171 kg and females 80 kg (Meder 1993; Rowe 1996). Adults have a relatively short life expectancy; silverback males, in particular, seem to have a hard life and die young (Groves and Meder 2001). In the wild, they probably reach 40–45 years; in captivity, several individuals have lived more than 50 years.

Reaching adulthood, female gorillas usually leave the group they were born in and join a new unit. They emigrate only if they encounter another male and may transfer several times before they settle down in a certain group (Watts 1996; Sicotte 2001; Stokes et al. 2003). In Kahuzi-Biega, the simultaneous transfer of several individuals was observed (Yamagiwa and Kahekwa 2001; Yamagiwa et al. 2009).

In western gorillas and Grauer's gorillas, male emigration is common, while among mountain gorillas less than 50 % of the males emigrate (Stoinski et al. 2009a). If they leave, they either become solitary or join all-male groups in some populations (Watts 2000; Yamagiwa et al. 2003a; Robbins et al. 2004). In western lowland gorillas (Lokoué Bai, Congo), even subadults and juveniles may emigrate (Gatti et al. 2004). Solitary males may travel very long distances (Douadi et al. 2007).

Size and Structure of Social Units

In a gorilla group there is a clear hierarchy. The leading silverback has the highest rank, and adult females are dominant over young animals. In most populations, groups usually consist of one adult male, several females, and their offspring (Magliocca et al. 1999; Yamagiwa et al. 2003a; Gatti et al. 2004). In the Virunga mountains, in Bwindi and Bai Hokou, however, a large percentage of the groups include more than one adult male (Table 2; Goldsmith 2003; Kalpers et al. 2003; Yamagiwa et al. 2012).

As groups contain more females than males, many males are "left over." Gatti et al. (2004) found that at Lokoué Bai, 42 % of the silverbacks are unmated: 31 % are solitary and 11 % live in nonbreeding groups. Solitary males make up 5–10 % of

Table 2 Gorilla group sizes (including unweaned immatures)

	10.7	2–27	36		Robbins et al. (2011)

the western lowland gorilla populations. Among eastern gorillas, the percentage seems to be lower: up to 3.5 % in Kahuzi-Biega and 1.8–4.0 % in mountain gorillas.

Gorillas occasionally form all-male groups, usually with one mature male and a few younger males. Such nonreproductive groups have a similar size to breeding groups; they have been observed in western lowland as well as mountain gorillas, although not in Grauer's gorillas (Robbins et al. 2004; Levréro et al. 2006). These groups as units may be long-lasting, but their membership changes quite often due to male migrations. They seem to be transition units in both gorilla species (Gatti et al. 2004; Levréro et al. 2006).

Gorilla groups can have very different histories (Robbins 2001). When the dominant male dies, the group may disperse if no subordinate silverback is there to take over the leadership; if there are two younger silverbacks, the group may split. Parnell (2002) lists five stages in the development of a typical western lowland gorilla group: nascent (one silverback + one female without offspring), infant (one silverback + one or more females with dependent offspring), juvenile (one silverback + one or more females with a range of offspring), mature (one silverback + one or more females and a range of offspring from infants to young silverbacks), and senescent (one old silverback, few or no females, only older offspring). Group takeovers by outside males have not been reported so far (Robbins et al. 2004), but in zoos new males have been introduced successfully to established groups in many cases.

The size of gorilla groups is very variable but similar among the subspecies (Table 2). An average group contains about nine to ten members (Parnell 2002; Yamagiwa et al. 2003a). Possibly groups can grow especially large where the density of their staple food is very high (Robbins et al. 2006). The largest group observed so far was Pablo's group in Rwanda with 65 members.

Male-Female Relationships and Mating Strategies

In the social system of gorillas, the high cohesiveness of a group is usually attributed to the attractiveness of the leading male to females (Yamagiwa et al. 2003a, but see Stokes 2004). Adult male-adult female relationships are considered to be the "core" of the social group; they vary depending on kinship, length of tenure, and reproductive status. Male aggression to females is common and often can be regarded as "courtship aggression." It is higher if the female is in estrus; females usually respond submissively (Robbins 2003; Bradley et al. 2005).

Wrangham (1979) suggests that a gorilla group represents a "permanent consortship." Adult females usually prefer to mate with the leading male and subadult females with subordinate males (Robbins 1999; Bradley et al. 2005; Stoinski et al. 2009b). Females in multimale groups often copulate with more than one male, despite interference by dominants (Sicotte 2001); this may confuse paternity and induce all the males to protect the infants against infanticide.

If a mountain gorilla mother transfers between groups while she has a baby, if a dominant male dies, or if another silverback male takes over the group, the baby is frequently killed by the new male (Fossey 1984; Watts 1989). Infanticide causes 37 % of infant deaths in the gorillas of the Virunga Volcanoes in one-male groups (Bradley et al. 2005; Robbins et al. 2007). Recently, evidence for infanticides was reported for Kahuzi-Biega too; possibly it had been suppressed earlier because the males of neighboring groups were related (Yamagiwa and Kahekwa 2004). Infanticide is suspected also in several cases in western lowland gorillas, when infants disappeared (Yamagiwa et al. 2009).

Female-Female Relationships

Dominance relations between females are weak, their rank depending on factors such as how long they have been in the group (Watts 2001; Kapsalis 2004). Females in large groups sometimes harass new immigrants, and aggression between females is not unusual (Watts 1996).

As females usually leave their natal group to join another group, it was long assumed that all females in gorilla groups are unrelated. In mountain gorillas, however, more than 70 % of the females spend at least some of their reproductive careers with female relatives. In western lowland gorillas, Bradley et al. (2007) found that 40 % of the adult females had an adult female relative in the same group. Female maternal relatives are close associates, often interacting affinitively and supporting each other (Watts 1996, 2000, 2001).

Male-Male relationships

As between females, there are few affiliative interactions among adult males. Severe contact aggression between males within a group is not usual (Sicotte 1994; Stoinski et al. 2009a).

Patrilineal kinship is important for mountain gorilla males because they often remain in their natal group instead of dispersing. There they assist their fathers in resisting threats or incursions from extragroup males (Robbins 1995). Mature followers and older adolescents cooperate with dominant males against extragroup males (Watts 2000). Dominant males try to prevent these followers, however, from mating with females other than the dominants' daughters. Coalitions of brothers may occur but are probably uncommon (Watts 1996).

Intergroup Interactions

The home ranges of various gorilla groups and of lone silverback males overlap, so encounters are frequent, but the leaders of breeding groups generally avoid them. In mountain gorillas on average, about one encounter per month is observed; it often includes aggression between silverback males. They try to drive competitors away by displaying or attacking (Yamagiwa 1987; Watts 1991; Robbins 2003). During such encounters, extragroup matings have been observed (Sicotte 2001).

Western lowland gorilla males generally show less contact aggression during encounters than mountain gorillas. They often meet in swamps or fruiting trees; the groups may feed together without hostility (Tutin 1996; Magliocca and

Gautier-Hion 2004). They occasionally intermingle peacefully and even may nest together for one night (Kuroda et al. 1996; Doran and McNeilage 1998; Bermejo 2004). In Lossi, silverbacks often react aggressively to lone males, but usually they tolerate other groups – their reaction varies, however, and depends on the identity of the silverback (Bermejo 2004).

Discussion: Genus *Gorilla*

Differences in ecological conditions seem to be more important in determining the social system of a gorilla population than its taxonomy. Mean group sizes seem to be similar across the genus *Gorilla* (Table 2), but in populations with a highly folivorous diet, the groups may become larger (Goldsmith 2003).

There seems to be a considerable influence of fruit availability on ranging and grouping patterns. During the fruiting season, large groups travel farther than small groups in western lowland gorillas as well as Bwindi gorillas. To reduce competition, the groups may spread more widely during feeding and/or form temporary foraging subgroups in western lowland gorillas and Grauer’s gorillas (Tutin 1996; Remis 1997; Parnell 2002; Goldsmith 2003; Yamagiwa et al. 2003a), which may feed and even nest more than 1 km away from the rest of the group (Bermejo 2004).

Parnell (2002) assumes that a high proportion of multimale groups in some populations may have developed because solitary males face unusually high odds against establishing a group and the current demographic conditions deter maturing males from emigration. As multimale groups provide better protection from infanticide, females may prefer groups with more than one male in the future (Watts 1996, 2000; Yamagiwa et al. 2003a; Yamagiwa and Kahekwa 2004). Dominant males may tolerate the presence of mating activities of younger males to reduce the risk of later infanticide (Robbins 1995).

Maryanski (1987) introduced the hypothesis that gorillas, like chimpanzees, live in an “open-group system”: several gorilla groups and lone males share a home range where they meet preferred groups, socialize, and then depart. There is no evidence that a higher unit like the chimpanzee community exists in gorillas, but in some gorilla populations, there do seem to be strong ties between different groups. Yamagiwa and Kahekwa (2004) observed group fission in Kahuzi-Biega, which resulted in several neighboring groups with related males.

It seems that two types of association among related males evolved in gorillas: association within a group and tolerance between males of neighboring groups. The occurrence of infanticide may promote the former, and its absence may promote the latter. The social structure of gorillas may be very flexible and allow them to choose either type of social organization, even in the same population (Yamagiwa and Kahekwa 2004).

Chimpanzees (Genus *Pan*)

Although the two species of the genus *Pan* (the “common” or robust chimpanzee and the “pygmy” or gracile chimpanzee, or bonobo) share many characteristics – physical as well as social – there are marked differences. These presumably result from their separation by the Congo River. One of the common characters distinguishing them from the other apes is a low degree of sexual dimorphism in body size, but instead a large swelling of the anogenital region in females and large testicles and penises in males.

Chimpanzee (*Pan troglodytes*)

Ecology

Chimpanzees have been studied at a number of sites (Table 1). They live in a wide variety of habitats in tropical Africa, from rain forest to closed and open forest, gallery forest, open savanna and grassland, as well as montane rain forest up to 2,400 m. In Ndoki, Poulsen and Clark (2004) found the highest density in swamp forest.

Chimpanzees are mainly frugivorous. Their diet consists of 48–82 % fruit, the rest consisting of leaves and other plant parts, and also more animals than other great apes, including insects as well as vertebrates, which are hunted communally (Goodall 1986; Chapman et al. 1994). The number of plant food items ranges from 55 to 328, depending on the habitat. Their diet varies seasonally, and this results in seasonal body weight fluctuations (Nishida 1990; Tutin and Fernandez 1993; Basabose 2002).

The home ranges (or territories) of chimpanzee communities vary according to habitat, season, community size, and the risk of encountering neighboring communities. The mean size is 21.6 km^2. In open landscapes, where food is dispersed widely, the density is very low and the home range extraordinarily large, up to 560 km^2. Home ranges of neighboring communities overlap (Yamagiwa 1999; Boesch and Boesch-Achermann 2000).

Within the community's home range, each adult has his/her own core area. Most females show strong fidelity to an area once they settle there as an adult (Williams et al. 2002b, 2004). Males have larger home ranges than females (Hasegawa 1990; Chapman and Wrangham 1993; Lehmann and Boesch 2005). The mean daily travel distance of individuals is about 3 km (Doran 1997; Boesch and Boesch-Achermann 2000).

In Taï, leopards attack chimpanzee; at other sites, lions prey on them (Tsukahara 1993; Boesch and Boesch-Achermann 2000). About 50 % of the day chimpanzees stay above ground level. They spend the night in nests that are usually built in trees up to 50-m high (Poulsen and Clark 2004), although terrestrial nesting has also been observed in some areas, for example, in Guinea (Koops et al. 2004).

Life Histories and Dispersal

Chimpanzee infants are nursed for about 3–4 years. The interbirth interval is usually 4–7 years (Nishida et al. 1990; Boesch and Boesch-Achermann 2000). Females may first conceive at about 9–11 years.

The mean weight of adult male *Pan troglodytes troglodytes* is 53 kg, of females 43.8 kg; *Pan troglodytes schweinfurthii* males weigh 40.5 kg and females 32.9 kg (Groves 2001), but even within each subspecies, there is great variation both within and between populations.

The maximal age of wild chimpanzees is not yet very well known. Boesch and Boesch-Achermann (2000) assume that they may reach 50 years. In captivity, they have lived for almost 60 years.

In most populations, females usually leave their natal groups upon maturity. At Gombe, most or all adolescent females visit other communities, and some may even conceive there, but only 50 % of them emigrate permanently, the others returning to their natal communities (Pusey et al. 1997). In Taï, on the other hand, almost all females transfer (Boesch and Boesch-Achermann 2000). In Mahale, the transfer process lasts from 6 months to 2 years, while the females associate and mate with the males of the two communities, and 13 % of the females transfer more than once there (Nishida et al. 1990). Male chimpanzees do not emigrate and cannot migrate between communities (Goodall 1986). Nevertheless, captive chimpanzees can be induced to accept new males into their group (Wilson and Wrangham 2003).

Size and Structure of Social Units

Chimpanzees live in fission-fusion groups within their communities. They have two levels of social unit: the smaller association unit is the party or subgroup – temporary and very variable – and the higher-level unit is the (stable) community or unit group (Table 3). Members of a community meet occasionally (fusion) and travel for longer or shorter periods in parties until they separate again (fission). On average, a party stays constant in size and composition for 24 min in Taï, in Gombe for 69, in Bossou for 126, and in Budongo for 14 min (Boesch and Boesch-Achermann 2000).

In Gombe, the average party size is 3.5 for females only, 10.7 for mixed parties, and 4.0 for males only. Single-sex parties are significantly smaller than mixed-sex parties, and parties with more estrous females contain more males (Williams et al. 2002a). Estrous females are more gregarious than other classes, and they are especially associated with males (Goodall 1986; Pepper et al. 1999).

In several populations, nursery parties – several females with their infants – have been observed. In Gombe, females spend 65 % of their time alone or with their offspring, in Kibale even 70 %, while in Taï they are alone only 18 % of their time when fruits are abundant (Wrangham et al. 1996; Pusey et al. 1997; Lehmann and Boesch 2004). During fruit scarcity, their day range is reduced and the mean party size decreased (Doran 1997). In Mahale and Kibale, food availability and the number of estrous females are positively correlated with party size (Mitani et al. 2002), but in Budongo, Newton-Fisher et al. (2000) found no positive correlation, and Basabose (2004) found in Kahuzi-Biega that fruit abundance per se does not affect party size but seasonality and fruit distribution do.

Party size is also determined by their function. During hunts for vertebrate prey, such as monkeys in Kibale, Watts and Mitani (2002) found a significant positive

Table 3 Mean party and community size in chimpanzees (including unweaned immatures)

relationship between hunting party size and the number of kills per hunt. Success also increases with the number of males per hunting party at Gombe and Taï.

Party size depends also on community size; in large communities parties occasionally are larger than a whole small community. Therefore, Boesch and Boesch-Achermann (2000) suggest that relative mean party sizes should be compared. According to their calculation, chimpanzees have a relative mean party size of 9–21 % of the community size.

The community size may lie between 20 and 150 members. It must contain at least one adult male, but a higher number of males is usual, often more than ten.

It seems that small communities retain a fission-fusion structure, but this loses much of its flexibility and the parties remain stable for much longer periods of time than in larger communities.

Male-Female Relationships and Mating Strategies

Relationships between male and female chimpanzees are usually not very close. Grooming between them, for example, is rather infrequent compared with male-male grooming. Constant and frequent proximity is particularly found in mother-son dyads.

Chimpanzee females use a tactical strategy of mating promiscuously to confuse paternity (Stumpf et al. 2008). In Gombe, consortships have been observed in all males, and 25 % of conceptions occur during consortships (Constable et al. 2001). In Mahale, however, they are very rare and only 8.3 % of conceptions are the result of consortship (Hasegawa and Hiraiwa-Hasegawa 1990), while in Taï only one offspring was conceived during consortship; half of the males and 56 % of the females are never seen to consort.

Matsumoto-Oda (2002) reported from Mahale that females copulate more often with continuously affiliative males; therefore, males interact with anestrous females to increase the chance of mating when they are in estrus. Most authors, however, found persistent coercing male aggression for eastern chimpanzees and the females most frequently solicited the most aggressive males (Muller et al. 2011). Prime males dominate all adult females and often try to monopolize them. Estrous females are more selective in their partners (Stumpf and Boesch 2006) and most frequently stay around the alpha male in Mahale and Kibale (Takahata 1990a; Muller et al. 2011). In Gombe, the alpha male is responsible for 36–45 % of all conceptions and high-ranking males for 50 %; in Taï, 71 % of all infants are sired by high-ranking males (Constable et al. 2001; Boesch et al. 2006).

According to Williams et al. (2002b), male aggression in boundary areas forces the females to be members of their community by settling in the center of their home range. Male coercion of females is an important element, and violence toward unfamiliar females near the edges of the defended range is particularly fierce. Nevertheless, estrous females sometimes disappear for a few days and may make temporary visits to neighboring males (Boesch and Boesch-Achermann 2000). In Gombe, 13 % of copulations are with males from other communities (Goodall 1986). These extracommunity matings do not very often result in conception: in Taï, extragroup paternity was found only for 7 % of the offspring (one infant), and in Gombe, all tested offspring were sired by males of the same community (Constable et al. 2001; Vigilant et al. 2001).

Infanticide has been observed in several chimpanzee populations, especially in Mahale (Nishida et al. 1990). In Taï and Gombe, infanticide and cannibalism by females were observed (Pusey et al. 1997; Boesch and Boesch-Achermann 2000; Pusey et al. 2008). In Gombe and Mahale, more cases of infanticide were recorded within the community than between communities. These cases do not provide any evidence that infanticide is a successful male reproductive strategy in chimpanzees (Wilson and Wrangham 2003).

Female-Female Relationships

High-ranking females are the most social with other females; low-ranking females are the least. This suggests that contest competition is an important aspect of female association patterns. In Mahale and Gombe, immigrant females experience aggression from resident females (Williams et al. 2002a, b; Pusey et al. 2008).

But females may also have affiliative relationships (Lehmann and Boesch 2008; Langergraber et al. 2009). In Taï, close female associations (friendships) can last for years and are very stable; some pairs spend up to 79 % of their time together. According to Boesch and Boesch-Achermann (2000), higher intrasexual competition and higher involvement in the social interactions of males make it profitable for females in Taï to develop long-term friendships with other females and to form stable alliances.

Male-Male Relationships

Male chimpanzees associate more strongly with one another than do females with other females and males with females. They form coalitions in all populations studied (Boesch and Boesch-Achermann 2000; Newton-Fisher 2002), and apart from coalitions, friendship between males has also been observed (Nishida and Hosaka 1996). Which individuals form affiliative relationships is not clear; genetic studies in Kibale showed that maternal kinship is not strongly associated with male-male association (Kapsalis 2004).

Among the males there is a linear dominance hierarchy, and rank reversal generally results from dyadic fights (Takahata 1990b; Muller 2002). The alpha male is the most active groomer; he tends to move first and be followed by subordinates (Takahata 1990b). In Taï, the leader of a community announces his presence by drumming; this also gives information to other individuals about the direction and speed of group movement (Boesch and Boesch-Achermann 2000).

Agonistic confrontations between males are observed regularly, and they are most aggressive between the two highest-ranking males. Coalitions in attacks are frequent; in Taï it is mostly low-ranking males coalescing against dominant individuals (Boesch and Boesch-Achermann 2000). Coalitions are also formed for hunting, for the intragroup control of widely dispersed females, and to monitor territorial borders (Stanford 1998).

Intergroup Interactions

Most interactions of chimpanzee males with neighboring communities involve only auditory contact-pant-hoots, a long-distance call. These pant-hoots are also used to advertise their presence and numerical strength. Males almost always show fear or hostility to strange males (Wilson and Wrangham 2003).

Chimpanzee males invest considerable time and energy in defending the home range of their community or locating their neighbors; the home range is controlled by groups of at least four males on a weekly basis in Taï (Boesch and Boesch-Achermann 2000). During those patrols, they remain silent and actively search for signs of the neighbors. They make incursions into the home ranges of the neighbor communities, sometimes of more than 1 km, and if they encounter strange males, they attack them. In Tai, they are sometimes joined by females (Lehmann and Boesch 2005). Not only males are attacked but females too, except for tumescent females (Pusey 2001; Williams et al. 2004; Watts et al. 2006). Females with or without infants often join attacks, but they tend to avoid direct physical contact with members of the other community.

Hostile intercommunity relations have been observed at all sites. Intraspecific violence is one of the leading causes of mortality for eastern chimpanzees (Wilson et al. 2004). At Gombe and Mahale, the destruction of a small community by a larger one, including systematic attacks and killing of individuals by males from a larger community, has been observed. Wilson and Wrangham (2003) provide a good overview of such intercommunity conflicts. So far, there is no consistent evidence from the field that the communities find more or better sexual partners and new resources as a result of the fights (Boesch and Boesch-Achermann 2000, but see Mitani et al. 2010). Extensive female transfer after a violent fight between communities was observed only in Mahale (Wilson and Wrangham 2003). In Gombe, adult parous females join other communities only when all males of their community have been killed.

Williams et al. (2004) conclude that male chimpanzees cooperatively defend territories that contain food resources for themselves, their long-term female mates, and their offspring, and they try to extend the size of the community's home range because a larger area means greater availability of food and higher female reproduction. Infanticide during intercommunity encounters can also be interpreted as the removal of future competitors. Concerning intercommunity killings by adult males, data from various study sites most strongly support the hypothesis that attackers reduce the future coalition strength of rival communities.

Bonobo (*Pan paniscus*)

The most important sites where bonobos have been studied are listed in Table 1.

Ecology

The typical habitat for bonobos is the lowland rain forests and swamp forests of the Congo Basin. In some areas, they also live in dry forest and visit grassland. They eat up to 147 food items; 72–90 % of their diet consists of fruits (Kano and Mulavwa 1984; White 1992; Yamagiwa 2004). The amount of meat consumption is not as high as in some chimpanzee populations but seems to fall within the general range of chimpanzees. Bonobos (including females) hunt small mammals, usually solitarily (Fruth and Hohmann 2002; Surbeck and Hohmann 2008).

In Wamba as well as in Lomako, the home ranges of communities overlap extensively (Idani 1990; Hohmann and Fruth 2002). Their size lies between 22 and 58 km^2 in Wamba (Idani 1990). Each adult has an individual home range or core area within the community's home range (White 1996).

Bonobos may experience lower leopard predation pressure than chimpanzees because they spend more time off the ground (Boesch 1991). Outside the forest, they seem to be very careful; if they feed on fruit in the grassland, they remain quiet (Myers Thompson 2002).

Life Histories and Dispersal

Bonobo infants are weaned at 3–4 years of age, and the interbirth interval is about 4–7 years (Lee 1999; Yamagiwa 2004). Females conceive for the first time at about 10–14 years. Adult males have a mean weight of 39.2 kg, and females weigh 31.5 kg (Groves 1986).

Females transfer to other communities as older juveniles or early adolescents (Furuichi 1989). Paternity analyses suggest that there must be a large exchange of females between communities (Gerloff et al. 1999). Males tend to stay in their natal community. Occasionally, they may transfer to other communities, but this is rare (Hohmann 2001).

Size and Structure of Social Units

Much like common chimpanzees, bonobos live in a fission-fusion social system. Parties usually contain mature individuals of both sexes with more females than males. The proportion of all-female parties in Lomako is high and of all-male parties low (Hohmann and Fruth 2002). If estrous females are present, the proportion of males increases (Hohmann and Fruth 2002). Lone individuals are rare – usually males travel alone (White 1996).

Party sizes are determined by food availability: if more fruits are available and if the food patch is large, the parties grow larger. Males disperse when food becomes scarce, but females do not (White 1998; Furuichi et al. 2008). As bonobo food includes herbaceous plants that are abundant in the rain forest during all seasons, feeding competition is low.

In general, bonobo parties are large in Lomako and Wamba, compared to chimpanzees. While chimpanzee parties are 9–21 % of the community size, bonobo parties consist of 21–89 % of the community. Bonobo parties last longer than those of the chimpanzees at Taï and Gombe (in Wamba 86 min, in Lomako 102 min; Boesch and Boesch-Achermann 2000).

Community sizes in Wamba are very variable, ranging from 33 to more than 100 members (Idani 1990). The cohesion of community members is high, and they stay together most of the time. In Lomako, several parties may congregate in the evening to nest in proximity to each other (Hohmann and Fruth 2002). Community members may be separated by kilometers for days or weeks (White 1996).

Male-Female Relationships and Mating Strategies

It is usually stated that in bonobo communities, either females are dominant over males or both sexes are codominant/egalitarian (Gerloff et al. 1999), but recent studies suggest that males dominate females – except for feeding situations (White and Wood 2007). Long-term bonds are found predominantly between heterosexual dyads and involve not only close kin but also unrelated individuals. Relatives associate and groom more often, however, and kinship ties are important between males and females. The highest association rates are observed between adult females and their adult sons: males receive agonistic aid from their mothers in conflicts with other males (Hohmann et al. 1999; Kapsalis 2004). Aggression by males toward females is less intense than in chimpanzees. Females may form alliances to attack males (Furuichi 1989; Hohmann and Fruth 2002).

Bonobo mating is opportunistic and promiscuous and involves no or little aggression between males. The maximal swelling lasts for a large proportion of the cycle; therefore, males establish long-term bonds with females that exceed tumescence (Fruth et al. 1999). Nevertheless, sexual coercion is found in some populations; high-ranking males have a strong tendency to monopolize tumescent females and they sire more offspring (Kano 1996; Gerloff et al. 1999; White and Wood 2007; Surbeck et al. 2011). In low- and mid-ranking males, the mother's presence increases mating success (Surbeck et al. 2011).

Extracommunity copulations are not uncommon, and females are rarely prevented from mating with members of neighboring communities. The number of infants sired by nonresident males is low; more than 80 % of the infants in Lomako are fathered by resident males. No infanticide was observed so far in bonobos (Fruth et al. 1999; Gerloff et al. 1999).

Female-Female Relationships

Female bonobos are more affiliative and cohesive with each other than chimpanzees. Contact frequencies between females are higher than between females and males or between males. They associate and forage in larger parties for most of the year, share food, and support each other in food defense (Hohmann and Fruth 2002). These affiliative bonds are not particularly observed between related females; female associations are not based on kinship (Kapsalis 2004).

Female bonobos groom less than male-male and male-female dyads but show a unique behavior called genito-genital rubbing, especially in the context of feeding: two females embrace each other ventro-ventrally and rub their genital swellings together with rapid sideways movements. The function of this behavior was discussed by various authors, such as Hohmann and Fruth (2000), who observed genito-genital rubbing six times as often as female-female aggression. According to their analysis it serves reconciliation and tension regulation.

Male-Male Relationships

Although strong bonds between males exist, especially at Wamba, they are less prominent than the bonds among females (Hohmann and Fruth 2002). Unlike chimpanzee males, bonobo males have even fewer contacts with other males than with females (White 1998). High-association rates are observed between maternally related adult brothers (Kapsalis 2004). Alliances are unusual between males (Hohmann et al. 1999). The males establish dominance relationships with each other, but aggression is less intense than in chimpanzees and conflicts are often settled in a nonagonistic way (Hohmann and Fruth 2002; Surbeck et al. 2011).

Intergroup Interactions

Bonobo communities do not seem to search for and contact neighboring communities. Lomako males have never been seen to make border patrols (Hohmann and Fruth 2002). In Wamba, intergroup encounters vary from group fights to peaceful intermingling. In general, encounters are peaceful and communities may spend hours together. Females take the initiative in the temporary fusion of communities. During these community meetings, males keep a certain distance from the males of the other group. The most prominent form of intergroup interaction between males and females is copulation, and relations between resident and unknown females are characterized by friendly contacts (Idani 1990; Kano 1996; Gerloff et al. 1999).

There are frequently aggressive interactions between males when they approach, but direct body contact and cooperative attacks are rare; the aggressive interactions are never as fierce as those reported for chimpanzees (Idani 1990; Hohmann and Fruth 2002). Agonistic aid during conflicts between members of different communities has never been reported. Severe aggression does occur, however, when mixed-sex parties encounter unknown males; in such a case, the strangers are charged by the males and also by the females (Hohmann et al. 1999). No fatal aggression was observed between bonobo communities at Wamba (Kano 1996).

Discussion: Genus *Pan*

Usually the chimpanzee social system has been regarded as male-bonded, with strong kinship ties between the males of a community but no relationships between the females. Experience from various field sites does not always support this idea and indicates that it is much more complicated and variable. In Taï, males within a community are on average not significantly more related than females, and the group members have more relatives within their home community than outside (Vigilant et al. 2001). Association patterns do not support the view of strong bonds between males in general (Pepper et al. 1999).

Taï chimpanzees may be bisexually bonded, while other populations are male-bonded, and more cooperation is found in Taï than in eastern chimpanzees. The reasons are presumably differences in habitat. Boesch and Boesch-Achermann (2000) assume that the forest environment allows or forces bonobos and chimpanzees to build larger and more cohesive parties. Doran et al. (2002b) hypothesize that permanent female association with males is a female counterstrategy to infanticide risk and that more infanticide occurs in habitats with considerable annual variance in fruit production. Bonobos live in a still more stable environment than Taï chimpanzees – this may lead to even more stable party sizes (Doran 1997). Bonobo parties seem to be large compared to chimpanzees (Table 3), but the within-species variation is larger than the interspecies variation (Hohmann and Fruth 2002; Furuichi 2009).

Bonobo communities seem to be composed of unrelated females who are highly affiliative with each other and related males who are not highly affiliative with each other; females directly control competition with homosexual behavior (Boesch and Boesch-Achermann 2000). Aggression between males and between the sexes is less intense than in chimpanzees, and conflicts are often settled in a nonagonistic way. Bonobos in general have more relaxed relationships than chimpanzees that do not depend on kinship, as paternity studies show that there is no matrilineal organization (Gerloff et al. 1999).

The typical chimpanzee/bonobo social structure is a multimale group with a fission-fusion structure. Similarities are obvious with respect to party size and association patterns. Female bonding in bonobos does not exceed that of some chimpanzee populations; differences between the two species are the proportion of female party members and the frequency of mixed parties (Hohmann and Fruth 2002). Chimpanzees as well as bonobos have the potential for great social variability, with considerable capacity for cooperation, reciprocal interactions, and coalitional behavior (Boesch and Boesch-Achermann 2000).

Despite the common basis, the two species show some differences in social behavior. Wrangham et al. (1996) think that this can partly be explained by the differences in feeding competition: chimpanzees and gorillas live sympatrically in many areas while bonobos do not have a great ape competitor.

Sympatric Ape Populations

Sympatric apes share a great part of their diet – in Asia as well as in Africa (Morgan and Sanz 2006; Vogel et al. 2009; Yamagiwa et al. 2012). This is especially visible in fruits. Sugardjito et al. (1987) observed some competition between orangutans and siamangs in Gunung Leuser, and one benefit of grouping for Sumatran orangutans may be that siamangs cannot drive the youngsters away from fruiting trees. More obvious, however, is the interspecific competition between chimpanzees and gorillas in Africa.

The dietary overlap between gorillas and chimpanzees ranges from about 50 % at Kahuzi-Biega to 60–80 % at Lopé and Ndoki. In Kahuzi-Biega, all fruit species eaten by gorillas are also eaten by chimpanzees. Overt interspecific competition between chimpanzees and gorillas has not been observed at any site; instead, competition avoidance is commonly seen (Kuroda et al. 1996; Morgan and Sanz 2006; Head et al. 2011). Interspecies relationships are more peaceful than intergroup relationships within the two species (Yamagiwa et al. 2003b). In Gabon, Okayasu (2004) observed close interactions between gorillas and chimpanzees; occasionally the groups would mix and play and even sleep at the same site.

During fruit scarcity, gorillas increase the proportion of herbaceous vegetation in their diet, while chimpanzees as obligatory frugivores continue to search for fruit. The two species obviously find different niches (Yamagiwa et al. 2003b, 2012), and some habitats are used almost exclusively by one species (Tutin and Fernandez 1993; Malenky et al. 1994; Kuroda et al. 1996; Rogers et al. 2004).

Kuroda et al. (1996) suggest that the low population densities of gorillas and chimpanzees in Lopé and Kahuzi-Biega might partly be due to competition. Possibly interspecific competition over food affects foraging strategies and may have caused divergence in grouping patterns. The larger party sizes of bonobos are possible because of the high density of terrestrial herbaceous vegetation; as gorillas mainly eat these plants, sympatric chimpanzees may be forced to take a different foraging strategy and to form smaller parties (Wrangham et al. 1996; Yamagiwa and Takenoshita 2004). The effects of competition have not been analyzed yet, but they are difficult to study – also because additional competitors like elephants have to be considered (Rogers et al. 2004).

Conclusions and the Genus *Homo*

Although some great ape populations have been studied for decades, their social systems are not yet completely understood. The Asian apes seem to be less social than the African apes; this may be due to food types and distributions in Southeast Asian forest, which may differ strongly from African forests. All great apes lead “individual-centered lives,” but they need interaction with familiar conspecifics. Despite their tendency to congregate, their social structure is characterized by weak ties, compared to female philopatric primates.

Female transfer is common to all species. They have a tendency toward fission-fusion grouping; females lack sharply defined dominance relations, and intrasexual bonds among non-kin can be relatively strong. Van Noordwijk et al. (2012) hypothesize that this ability to form and maintain bonds has freed females from the necessity to be strictly philopatric. It is difficult to assign a social system to each ape species (or to the family Hominidae in general) because there is remarkable intraspecific variability in social organization and structure. Especially frugivory requires a mobile and flexible population.

Compared to the great apes, humans show an even greater variability in social structure – nevertheless, there are certain trends across all human societies (Rodseth et al. 1991): males maintain consanguineal kin ties; females maintain consanguineal kin ties; males cooperate in conflicts against other males; and females also cooperate but rarely in physical conflicts with other females.

According to Knauft (1991), simple human societies are decentralized, and there tends to be active and assiduous devaluation of adult male status differentiation. Among complex hunter-gatherers and with the advent of sedentism and horticulture/agriculture, male status differentiation increased. There seems to be a similarity between great apes and middle-range human societies in terms of competitive male dominance hierarchies. Such dominance relations may not be particularly adaptive in environments of low resource density and predictability; this may have led to the simple egalitarian hunter-gatherer societies that nowadays live in extreme environments.

Most human societies are characterized by female-biased dispersal and male philopatry. Long-term pair bonds between males and females are common, although their form, strength, and duration vary between societies. Moreover, these bonds are not identical with mating and grouping patterns (Pusey 2001). And according to the cooperative breeding model, these bonds allowed the increase of brain size during the development of *Homo* (Hrdy 2005; van Schaik and Burkart 2010; Isler and van Schaik 2012).

There has been much speculation on the "natural" human mating system. Although fossils of man's early ancestors show extreme sexual dimorphism, modern human males are only about 15 % larger than females; the relative size of testes in humans is much smaller than in chimpanzees and comparable to "monogamous" or one-male group species. Polygamy with only some males producing many offspring thus cannot be the common mating system in humans, but social monogamy is not common either (Low 2003). According to Plavcan (2012) size dimorphism is not a robust indicator for breeding systems.

The social system of humans certainly has several levels, like the social system of *Pan* (Layton et al. 2012). Dunbar (1993) developed the hypothesis that there is a species-specific upper limit to group size that is set by cognitive constraints. This would mean that human groups can be much larger than those of the great apes. According to Dunbar, group size depends on the maximum number of individuals with whom an individual can maintain personal contact. He discerns (in modern hunter-gatherer societies) the group levels overnight camp (30–50 members), band/village (100–200 members), and tribe (1,000–2,000 members). Dunbar's overnight camp certainly is not the smallest human grouping above the individual. Rodseth et al. (1991) and Pusey (2001) state that the majority of human societies consist of conjugal families united in stable communities, but also relatively autonomous families. Apart from these units, associations of men usually play an important role too (Rodseth 2012).

But what is the central, stable component of the human social system? Even ape specialists have contradictory opinions. De Waal (2001) thinks that the nuclear family is the basic social grouping of humans and that this unit is unique to the species *Homo sapiens*, although Low (2003) states that it is rather unusual in human societies. Perhaps the nuclear family is an especially successful social structure in modern industrialized societies. Ghiglieri (1989) calls the social structure of humans a multimale kin group, a stable, semiclosed fission-fusion community.

Evolutionary Biology of Ape and Monkey Feeding and Nutrition

Joanna E. Lambert

Contents

Abstract

Like all animals, primates must garner sufficient energy and nutrients from their habitat to accomplish other biological imperatives such as mating and avoiding predators. The order Primates exhibits an extraordinary diversity of feeding and foraging-related adaptations to meet this imperative, some of which are shared with other taxa, others of which are unique to primates. In this chapter, I explore the evolutionary underpinnings of these adaptations as well as evaluate their ecological implications. I first discuss several unique aspects of primate feeding biology, including the evolution of large brains, trichromatic color vision, and tool use. I then move on to evaluate the fundamental problems of plant fiber and chemical defenses and conclude by arguing that primate adaptations for

fermenting fiber and detoxifying plant chemical defenses have implications for primate species adaptations, abundance, and richness since the Miocene. Because of the implications for understanding adaptations in our own lineage, in this latter section I pay particular attention to Catarrhini of Africa; I employ a strongly comparative approach and evaluate hominoid feeding biology in light of what we know about Cercopithecoidea.

Introduction

Feeding is a biological imperative. Like all animals, primates must garner sufficient energy and nutrients from their habitat to accomplish other biological imperatives such as mating and avoiding predators. This rather obvious fact has not gone unnoticed by primate biologists and inquiries into how and what primates consume have been central to primate studies since the 1970s (Clutton-Brock 1977; Chivers et al. 1984; Rodman and Cant 1984; Altmann 1998).

Most primates are omnivorous and, by definition, consume both plant and animal matter. Nonetheless, primate requirements for energy and nutrients are met largely by plants (Milton 1993). The system of energy transfer from plants to animals via herbivory evolved during the Permian, ca. 255 Myr.This is the food chain with which we are most familiar [i.e., producer (plants) to primary consumer (herbivores) to secondary consumer (carnivores)]; the addition of an herbivore trophic level represents a marked shift from previous time periods that lacked primary consumers (Potts 1996). This changed dramatically throughout the Mesozoic as angiosperms (flowering plants) evolved and as amphibians, reptiles, and eventually mammals radiated into a diversity of plant-consuming niches. Primates is thus among these modern orders that evolved to feed primarily from the kingdom Plantae, and they do so with staggering diversity in their foraging and feeding adaptations. Indeed, extant primates forage in literally every possible social permutation: as solitary animals, as mated pairs, in feeding parties that fission and fuse, and in cohesive social groups (Strier 2010). Primates procure food in a diversity of ways as well, and there is virtually nothing that some primate species will not eat, from fungi and lichen, grass and palm nuts, and nectar and termites to snakes and antelopes. Accordingly, primates exhibit a diversity of feeding-related morphological adaptations in dentition, digestion, locomotor apparatus, and myriad cranial and postcranial features.

Evolution is a wondrous thing, resulting in adaptations that are unique to species (autapomorphies), shared by several related taxa (usually synapomorphies but sometimes homoplasies) or inherited from an original, ancestral state (plesiomorphy). Moreover, "natural selection, acting in various guises at various levels, seems together with genetic drift to account for almost all features of organisms once the appropriate raw material has arisen by mutation and recombination" (Futuyma 1979, p. 438). Hence, we can assume that feeding-related features observed in primate species today are (1) the result of natural selection and other microevolutionary forces and are either (2) unique to a species (e.g., mandibular morphology), shared by a subset of primate taxa (e.g., cercopithecine cheek pouches), shared by all primates (e.g., postorbital bar), or are ancestral to mammals (e.g., heterodonty) or animals generally (e.g., reliance on ingestion).

Given this extraordinary diversity at multiple scales, I cannot do justice to the entire array of strategies employed by primate species for procuring nutrients from their environments (for more information, see Garber 1987; Milton 1993; Janson and Chapman 1999; Lambert 2011; Chapman et al. 2013). Instead, my focus here is to first evaluate several noteworthy – indeed, unique to the order – aspects of primate feeding biology. Thus, in the first part of this chapter, I evaluate the feeding implications of large brains, trichromatic color vision, and tool use in primates. I next discuss the fundamental problem, shared by all plant-consuming animals, of plant fiber and chemical defenses. I conclude by arguing that primate adaptations for fermenting fiber and detoxifying plant chemical defenses have had implications for primate species adaptations, abundance, and richness since the Miocene. While primates encounter such feeding challenges in all biogeographic areas in which they are found, because of the implications for understanding adaptations in our own lineage, I pay particular attention to the Catarrhini of Africa. I employ a strongly comparative approach and evaluate hominoid feeding biology in light of what we know about Cercopithecoidea.

Feeding Adaptations Unique to Primates: Evolution of Large Brains, Color Vision, and Tool Use

Roughly three-fourths of all primate species forage and feed in cohesive social groups (Strier 2010). The observed size of a primate social group is generally expected to be one that is big enough to provide protection from predators while concomitantly small enough that group members do not incur too great a cost from increasing feeding competition (Struhsaker 1981; Terborgh and Janson 1986; Dunbar 1988; Garber 1988; Janson and van Schaik 1988; van Schaik 1989; Chapman 1990; Isbell 1991; Janson 1992; van Schaik and Kappeler 1993; Chapman et al. 1995; Janson and Goldsmith 1995; Treves and Chapman 1996; Sterck et al. 1997; Boinski et al. 2000; Chapman and Chapman 2002; Koenig 2002; Snaith and Chapman 2007). As a consequence of extreme variability in food availability in different habitats, primate species and populations experience the cost of feeding competition to varying degrees (Snaith and Chapman 2007).

Regardless of the degree to which primates do or do not compete for food, they must meet their basic nutritional needs for macronutrients (carbohydrates, protein, lipids) and micronutrients (vitamins, minerals, and water). Primates require the full suite of nutrients needed by mammals in general (45–47 in total of amino acids, fatty acids, vitamins, and minerals); large quantities of macronutrients are required for energy related to growth and maintenance, while micronutrients are vitally important for innumerable physiological processes (Oftedal and Allen 1996; Leonard 2000). In meeting these needs, primates are confronted with an array of feeding challenges that influence food quality. These challenges can be intrinsic, representing some inherent chemical, nutritional, or structural feature of the food, or extrinsic, a function of availability of that food and the costs (e.g., increased ranging, competition) associated with feeding on it as a consequence of that availability (Lambert 2011). Primates are not unique in having to deal with feeding challenges, but several (characteristically primate) adaptations are particularly deserving of further discussion because of their significance to feeding: brain expansion, trichromatic color vision, and tool use.

Brains

"The most distinctive characteristic of primates is the size and complexity of the brain" (Napier and Napier 1985, p. 34). In making this comment, the Napiers echoed the work of Le Gros Clark (1959) who argued that the extreme neocortical expansion observed in modern humans is a continuation of a trend in mammals in general (whose brains are on average 10× larger than those of reptiles) and primates in particular (Deaner et al. 2007; Dunbar and Shultz 2007). Indeed, primates as an order have a brain that is 2× larger than what would be expected of mammals of a particular body size, apes roughly 3–4×, and modern humans 7–8× (Jerison 1973; Martin 1996). The increase in brain size is particularly notable in the neocortex and especially in those areas of the brain concerned with vision and higher functioning (Radinsky 1977; Martin 1990).

It is thus not surprising that discussions regarding primate evolution generally – and human evolution specifically – almost invariably center on the biological and ecological variables that may have been of particular selective importance in the evolution of brain size (Dunbar and Shultz 2007). Given that, in addition to being the most encephalized, primates are also among the most social of mammals, a number of hypotheses regarding brain expansion have centered on the cognitive demands of negotiating and maintaining complicated social relationships (Byrne and Whiten 1988; Dunbar 1992; Barton 2000; Dunbar and Shultz 2007). Others, however, are focused on the relationships among brain size, metabolism, and dietary quality, while still others have evaluated the role of foraging in ecologically complex landscapes in selecting cognitive capacity (Milton 1988; Aiello and Wheeler 1995; Garber 2000). These scenarios (i.e., sociality versus diet or ecology selecting for brain size) are not necessarily mutually exclusive (Dunbar and Shultz 2007). Indeed, the social brain hypothesis has sometimes been interpreted as though it was ecology-free and represented a contrast between ecology and sociality as the driving force of brain evolution. This is possibly because, in the original analyses (Dunbar 1992), sociality was pitted against a set of alternative ecological hypotheses. It is important to remember that the social brain hypothesis is itself an "ecological hypothesis" (Dunbar and Shultz 2007, p. 650).

Brain tissue is metabolically expensive and requires more energy (in the form of glucose) than any other tissue in the body (Aiello and Wheeler 1995; Isler and van Schaik 2006; Barrickman et al. 2008). There are also differences in total number of neurons and relative brain size among primate species, suggesting differences in energetic demands (Fonseca-Azevedo and Herculano-Houzel 2012). Although earlier analyses (e.g., McNab and Eisenberg 1989) suggested no correlation between relative brain size and basal metabolic rates (BMR) in mammals, more recent work (Martin 1998; Isler and van Schaik 2006; Fonseca-Azevedo and Herculano-Houzel 2012) suggests that after correcting for phylogeny and body size effects, BMR and brain mass correlate positively and energy requirements scale linearly with total number of neurons. It has thus been hypothesized ("expensive -tissue hypothesis") that the metabolic expense of maintaining a large brain is offset by a reduction in other energetically expensive tissues, especially the digestive tract (Aiello and Wheeler 1995). Navarrete et al. (2011) recently tested this hypothesis. In a sample of brain size and organ mass that included 100 mammal species (23 primates), these authors found that there was no evident negative correlation with brain size or gut mass – or any other organs. However, they did find that brain size and adipose storage depots are negatively correlated. While these results do not support the expensive-tissue hypothesis directly, they are consistent with a broader "energy-based hypothesis," as encephalization and fat storage are alternative strategies for buffering against energy deficits (Navarrete et al. 2011).

While an energetic trade-off in total mass of digestive and brain tissue has received mixed support, it is evident that gastrointestinal morphology and proportions are reasonably predictable of the nutrient density and "packaging" (sensu Altmann 2009) of foods that primates consume. Chivers and Hladik (1980), for example, determined that mammals relying primarily on vertebrate prey have a simple stomach, an unspecialized colon, and a long, complex small intestine. In contrast, species relying heavily on vegetative plant parts are typically characterized in having large chambers (stomach, cecum, colon) in the gut for fermenting structural carbohydrates (fiber), while mammals that rely on fruit are noted for their relatively unspecialized gut. Differences in gut morphology among frugivores are generally attributed to the degree to which each species relies on either insects or leaves for protein to supplement its fruit diet.

Relatively more encephalized primate species have also been noted to be those primate species with a more nutrient dense and readily digestible diet (Milton 1988; Aiello and Wheeler 1995; Navarrete et al. 2011). Foods differ widely both in nutrient density and in their digestibility, and some require more digestive processing (either by endogenous enzymes or by microbial fermentation) than others before energy is yielded (Lambert 1998). Fruit, for example, while exhibiting wide interspecific variation, is generally a source of easily digested, nonstructural carbohydrates (esp. fructose), and leaves tend to be higher in structural polysaccharides (fiber) and require more time and digestion before energy is yielded. Insects (both mature and larval) can be a good source of protein and lipids, although the costs of searching and handling time and the polysaccharides of chitinous exoskeletons mitigate net energy yield and digestibility. Meat from vertebrate animals is an excellent source of protein and fats and is easily digested (by the action of pepsin, trypsin, and chymotrypsin in the stomach; Tortora and Anagnostakos 1987).

The concomitant facts that modern humans have the largest relative brain size among animals, a simple and relatively small total gut for their body size, and an evolutionary history of meat consumption are of considerable interest to paleoanthropologists and primate feeding biologists alike (see chapter "▶ Evolution of the Primate Brain," Vol. 2). Indeed, with regard to human evolution, Milton (1999) has argued that: "by routinely including animal protein in their diet, they [i.e., humans] were able to reap some nutritional advantages enjoyed by carnivores, even though they have features of gut anatomy and digestive kinetics of herbivores" (p. 11). In other words, by increasingly including meat (a readily digested food) in the diet, our human ancestors garnered the requisite energy for maintaining an increase in body size while at the same time evolving a larger brain at the expense of total gut size (Aiello and Wheeler 1995; Milton 1999).

Some scholars have also noted the relationships among brain size, cognitive capacity, and food distribution and availability (Milton 1988; Dunbar and Shultz 2007; Taylor and van Schaik 2007). As mentioned, primates consume a broad diversity of food types, largely of plant origin, and to a lesser degree of invertebrate and vertebrate animals. For ease of discussion, plant foods are often lumped into broad feeding categories, including vegetative plant parts (e.g., leaves) and reproductive plant parts (e.g., fruit, seeds, flowers). Vegetative and reproductive plant foods in a habitat are distributed neither evenly nor equally in space and time, and there is wide variation within and between habitats and species in their richness, abundance, and nutritional quality. Consequently, the initial challenge to all animal consumers is finding food in the first place: not an insignificant task (Oates 1987; White 1998). "Typical" habitats do not exist, and generally speaking, primate food resources are difficult to find (Milton 1988; Janson and Chapman 1999). Indeed, in an analysis of tree abundance in Barro Colorado Island, Panama, Milton (1988) found that 65 % of all tree species were encountered less than once per hectare and ripe fruits were available for individual trees only 0.8 months/annum. Nonetheless, there are gross differences in availability among broad food types, and, for example, within a given habitat, vegetative plant parts such as mature leaves tend to be more abundant and predictably available relative to reproductive plant parts such as fruits, seeds, flowers, and nectar which are more patchy in space and time (Milton 1980; Isbell 1991). This is a function of the fact that most tropical forests are characterized by tree species with differences in seasonal and annual fruit production and by trees that either produce fruit in small quantities or produce abundant fruit in widely scattered trees (Janzen 1967; Frankie et al. 1974; Whitmore 1990; van Schaik et al. 1993).

That primate foods differ in their distribution and availability suggests differing selective pressures with regard to cognitive capacity: some foods are intrinsically more difficult to monitor and locate than others (Garber 2004). Parker and Gibson (1977), for example, suggested that large brain size correlates with omnivorous feeding in primates. Milton's (1988) long-term research on *Alouatta palliata* (mantled howler monkeys) and *Ateles geoffroyi* (spider monkey) identified important differences in foraging and feeding that also correspond to brain size. The relatively small-brained howler monkey, while at times of the year highly frugivorous, in general relies heavily on leaves, which are both more abundantly distributed and more refractory to digestion than fruit. During some seasons, howler monkeys can spend upward of 90 % of daily feeding time on leaves. Conversely, the relatively larger-brained spider monkey is highly frugivorous and spends an annual average of 72 % daily feeding time on fruit. The overall differences in time devoted to fruit versus leaves and in distribution and availability of vegetative and reproductive plant parts are reflected in total home range size of the two species: 31 ha in howler monkeys and 800 ha in spider monkeys. Thus, Milton argues (1988, p. 289) that: “spider monkeys are faced with a far more complex problem than howlers with respect to locating their food sources since, in effect, they are dealing with a supplying area over 25 times as large.” A more patchily distributed food source requires greater cognitive capacities for dealing with a more complex ecological matrix. Spider monkeys exhibit a relative brain size and degree of neural complexity approximately 2× that of howler monkeys (*Ateles* body size: 7.6; brain weight: 107 g; *Alouatta* body size: 6.2 kg; brain weight: 28 g). And while it is recognized that indices of relative brain size are not necessarily direct indicators of cognitive capacity, in this case Milton (1988) argues that it does appear that selective pressure for spatial memory is more intense for spider monkeys (a frugivore) than howler monkeys (a folivore), which too may help to explain differences in gross brain size and complexity.

Along these lines, Potts (2004) has posited a “fruit-habitat hypothesis” suggesting the evolution of the large relative brain size and concomitant cognitive capacity among great apes can be explained by a “causal connection between ape ancestral diets, habitats, and environmental history” (p. 224). In short, he argues that as preferred fruit resources became increasingly rare as a function of forest reductions and climatic shifts in the African Miocene, ancestral apes were under extreme selective pressure for evolving cognitive means (e.g., complex mental representational ability) to deal with food source uncertainty.

More recently, Taylor and van Schaik (2007) explained differences in brain mass among orangutan populations in terms of habitat quality and food availability and explicitly integrated ideas related to the energetics of encephalization. Using cranial capacity (CC) as an index of brain mass, these authors found – after adjusting for body size – significant variation in CC in populations of *Pongo pygmaeus* and *P. abelii*. *Pongo pygmaeus morio* had a significantly smaller CC than any other orangutan population and is also found in the least productive habitat – regularly undergoing food scarcity and lean periods. The authors suggest their results are consistent with the hypothesis that decreased brain mass can be explained in part by overall habitat quality, diet, and access to energy.

Other feeding-related features, such as extractive foraging, have been linked to relative brain size (Barton 2000). For example, members of the most encephalized platyrrhine genus, *Cebus*, are highly manipulative, destructive foragers and are highly adept at extracting resources from tree cavities, as well as difficult to penetrate food types such as hard palm nuts. The aye-aye (*Daubentonia madagascariensis*) is among the most encephalized prosimian species, and a majority of its calories are derived from arthropod grubs that they have extracted deep from within branches. Common chimpanzees in dry savanna habitats are known to use spears to extract prey from within tree cavities and fishing wands to extract termites from otherwise impenetrable termite nests (Pruetz and Bertolani 2007; more on these examples in the subsequent section on "Tool Use").

Trichromatic Color Vision

Primates exhibit a diversity of visual adaptations that distinguish them from other mammals, several of which have been related directly to feeding and foraging. Primates, for example, have very large eyes relative to body size and a high degree of orbital convergence; both traits are argued to be of selective advantage for nocturnal visual predation (Cartmill 1992; Ross 2000). Primates, too, are unique among mammals in having trichromatic color vision. Color vision relies on the presence of photoreceptors that contain light-sensitive opsin proteins (cones). Most vertebrates (including reptiles, birds, and some fish) have four such photoreceptors (hence, "tetrachromacy"), each with different peak light spectral sensitivity (Ross 2000; Dominy 2004; Dominy et al. 2004; Jacobs 2008). However, early in the radiation of mammals, at least two of these photoreceptors were lost, the legacy of which is that most extant Eutherian mammals have only two opsin proteins, resulting in dichromatic color vision. This is often explained by the fact that the earliest niche occupied by mammals was a nocturnal one; since cones perform poorly under low-light conditions, the selection for their maintenance was relaxed (Jacobs 2008). Although, it is noteworthy that most recently Melin et al. (2013) have suggested that the anthropoid visual system – including the L/M opsin gene – evolved under low-light conditions and challenges the perspective that while basal primates were nocturnal, stem anthropoids were diurnal (see chapter "▶ Primate Origins and Supraordinal Relationships: Morphological Evidence," Vol. 2).

It is of considerable interest that in Primates, trichromacy has not only evolved once but potentially several times. The primitive mammalian condition includes one short-wave (430 nm, "S") and one long-wave (560 nm "L") sensitive cone pigment, with the long-wave pigment gene located on the X-chromosome. Subsequent gene duplications on the X-chromosome in catarrhines resulted in separate middle-wave (530 nm, "M") and long-wave pigments; all cercopithecoids and hominoids tested to date exhibit the three cone opsins. Platyrrhines are highly variable in their perception of color, since there is a single X-chromosome locus for the opsin gene. With the exception of *Aotus* (a monochromat) and *Alouatta* (routinely trichromatic), all tested platyrrhines are polymorphic at the locus for the long-wave pigment and have mixed populations of dichromats (males and homozygous females) and trichromats (heterozygous females) (Ross 2000; Dominy 2004). Although the gene duplication in *Alouatta* is similar to that of Catarrhini, it is an independent evolutionary event and probably occurred quite recently (Jacobs 1996; Dominy 2004).

The combination of three opsins in the retina being tuned to different wavelengths facilitates perception of an enormous range of color hues, and there are multiple competing hypotheses regarding the selective pressure for the evolution of this visual system in primates. For example, Changizi et al. (2006) suggested that trichromacy was selected for discriminating important signals of sociosexual, threat, and emotional states via color modulation on the skin of conspecifics. Isbell (2006) has suggested that detection of a wide range of color hues (including along the red-orange channel) was selected for in pre-attentional visual perception of fearful stimuli such as snakes.

However, the fact that foods in natural habitats exhibit an equally large range of color has resulted in several feeding- and foraging-related hypotheses for the explanation of the evolution of color vision in primates. Generally, these hypotheses emphasize the advantages of color vision in detecting fruit, leaves, or both (Ridley 1894; Snodderley 1979; Lucas et al. 1998; Dominy 2004). For example, since at the least the turn of the century, it has been suggested that color vision is linked to the evolution of colorful fruit in angiosperms (Ridley 1894; Polyak 1957; Snodderley 1979; Regan et al. 1998). In this putatively coevolved relationship, flowering tree species evolved colorful fruit to ensure the attraction of seed dispersers (such as primates) and (some) primates became better at finding such fruit as a result of their trichromatic color vision.

There is no doubt that primates are important seed dispersers; as a taxon they are often the most abundant arboreal frugivores in tropical forests (Lambert 2002a; Lambert and Chapman 2005). Whether primate feeding has selected for fruit color and whether color vision coevolved with frugivory is much less clear. “Coevolution” is a narrowly defined process, wherein there is “an evolutionary change in a trait of the individuals in one population in response to a trait of the individuals of a second population, followed by an evolutionary response to the change in the first” (Janzen 1980, p. 611). As such, coevolution represents a highly specialized and interdependent step-by-step process of interrelated evolutionary change in two or more species and differs from both adaptation and exaptation in terms of the duration, strength, and mutual historical relationships between the interacting species.

In a detailed analysis of both catarrhine and platyrrhine frugivory and seed handling, Lambert and Garber (1998) found that primates in both allopatry and sympatry exploit a wide variety of plant species exhibiting a very broad and unpredictable array of fruit colors. Moreover, across taxa, these researchers found no evidence for any particular or consistent suite of fruit traits or patterns in the way fruits are processed and dispersed. Consistent with these findings, Dominy (2004) determined that primate frugivory is highly generalized with respect to hue and argues that rather than fruit color, it is either abundance or accessibility (or both) that is the more important determinant of fruit choice by primates. Moreover, the relationship between fruit color and nutritional properties (especially in terms of the sugar “reward”) is equivocal; hue and sugar are uncorrelated in Costa Rica and Peru (Wheelwright and Janson 1985; Dominy 2004). Nonetheless, the “old idea that primate trichromacy evolved in the context of fruit detection and identification enjoys some current support” (Jacobs 1996, p. 198).

Lucas et al. (1998) proposed an alternative hypothesis imputing leaf selection, rather than fruit, as the important agent of evolution for trichromacy.

As demonstrated by these researchers, leaf toughness is highly correlated with leaf color; toughness is also positively correlated with high fiber and negatively correlated with protein. These authors thus suggest that trichromatic vision may provide an important advantage in finding palatable and nutritious leaves in the tropics where many tree species delay the “greening” of leaves in an apparent attempt to ward off herbivores. In a study that focused on two colobine species, one cercopithecine, and one ape (*Pan troglodytes*) in the Kibale National Park, Uganda, Dominy and Lucas (2001) demonstrated that increasing reddishness of edible leaves is significantly correlated with reduced toughness and protein. Such a relationship was not found with fruit, and the fact that *Alouatta* – a folivore – is the only routine trichromat in the New World generally lends support to leaf-related hypothesis. The evolutionary context for trichromacy and its function in leaf detection may stem from early Anthropoidea. Climatologically, the Eocene-Oligocene transition is generally marked by dramatic cooling, which, in addition to many other ecological shifts, resulted in extinction or reduction in palms in Africa and Asia, although not in Madagascar or South America (Morley 2000; Dominy 2004). Dominy (2004) suggests with the loss of this critical keystone resource (i.e., palms), stem catarrhines turned to protein-rich young leaves; a chance mutation on the duplication of an opsin gene would have provided the underlying visual mechanism to exploit this new resource effectively. Primates in South America or Madagascar would not have been under such intense selection, given the availability of palms as an important resource.

However, social- and feeding-related selective pressures need not be mutually exclusive. Indeed, Fernandez and Morris (2007) have proposed a two-step process that involves both a foraging efficiency early phase and a sociosexual later phase. More specifically, they hypothesize that trichromacy in some primate lineages is the result of a preexisting bias (“exaptation” sensu Gould and Vrba 1982) for detection of red-orange that evolved for nonsocial, feeding purposes. Once evolved, trichromatism facilitated the sexual selection of red skin and hair that served as signals of emotional and sexual status.

Tool Use

Several animal species (e.g., sea otters, woodpecker finches, burrowing owls, naked mole rats, crows) have been noted for their use of objects in their environment and hence meet the definition of tool use: “the employment of an unattached environmental object to alter more efficiently the form, position, or condition of another object, organism, or the user itself” (Beck 1980, p. 10). Given this definition, tool use involves both an object of change and an agent of change (the tool) (Panger 2011). No species other than humans make tools to make tools (McGrew 1992), but tool use in nonhuman primates differs from that of other animals in several respects, including the long period of learning, the complexity of skills, the imputed cognitive abilities, and, in the case of common chimpanzees (*Pan troglodytes*), the diversity of tool kits and use of tool composites (Strier 2010).

Panger (1998, 2011) makes the distinction between *tool use* per se, which involves the manipulation of both an object and a tool, and *object manipulation*, which involves manipulation of only an object of change and not manipulation of the agent of change (e.g., licking objects, carrying objects while feeding).

Many species – both primate and non-primate – can be induced to use tools and manipulate objects in captive settings (Panger 2011). However, tool use is rare in nature (Garber 2004). Only *Homo sapiens* and common chimpanzees spontaneously and habitually (defined as the use of tools repeated by several individuals in a population over time) manufacture tools in the wild, orangutans (*Pongo*) less so (McGrew and Marchant 1992; Panger 2011). Bonobos (*Pan paniscus*), baboons (*Papio* spp.), and macaques (*Macaca* spp.) will use tools in the wild (although neither regularly nor habitually). The descriptions of *Cebus apella libidinosus* using hammer and anvil technology in dry forests of Brazil (Fragaszy et al. 2004; de Moura and Lee 2004) were of considerable interest to biological anthropologists not only because these were the first descriptions of routine tool use by a monkey species but also because stone tools were being used by a non-catarrhine taxon. Gorillas (*Gorilla* spp.) have yet to be observed using tools in the wild.

In most cases, primate tool use is undertaken within the context of feeding, the most famous example coming from Gombe National Park, Tanzania, where in 1960 Jane Goodall first observed and described chimpanzees extracting termites (*Macrotermes bellicosus*) from their mounds by using modified plant stems:

> Passages into a termite mound are narrow and not completely straight, so the materials used must be smooth and fairly pliable if they are to be effective. Tools are fashioned from grasses, vines, bark, twigs, or palm frondlets. Sometimes a chimpanzee will pick up almost any suitable material that is nearby, including the discard tools of others who have worked the mound previously. At other times clumps of grass, tangles of vines, and so on are carefully inspected before a tool is selected; a length may be picked, then discarded immediately before it has been used, and another choice made. To some extent the procedure reflects individual differences, but dry-season termiting call for more skill and more care in the choice of material that wet-season fishing, when (a) the insects are near the surface and (b) the soldiers are on the defensive and quick to bite at any foreign material inserted into the nest. (Goodall 1986, p. 536)

Pongo pygmaeus, too, has been observed to extract social insects (e.g., ants, termites) from crevices and holes in trees, as well as use twigs to pry seeds from *Neesia* spp. fruit (van Schaik and Fox 1996). In addition to fishing for termites and other social insects, the best-known feeding-related tool use in chimpanzees includes hammer and anvil technology for cracking open nuts. This form of tool use, wherein a stone or log is used as an anvil in combination with a rock hammer, is generally viewed as the most complex form of tool use in any nonhuman animal (Fragaszy et al. 2004). It is a tool composite ("two or more tools having different functions that are used sequentially and in association to achieve a single goal"; Sugiyama 1997, p. 25), and it involves employing multiple spatial relations in sequence.

Dramatic examples of tool use have been reported at the Fongoli chimpanzee research site in southeastern Senegal (Pruetz and Bertolani 2007). Between March

2005 and July 2006, Pruetz and Bertolani (2007) observed Fongoli chimpanzees craft and use spears to hunt lesser bush babies (*Galago senegalensis*). The manufacture and use of the spears involved multiple steps in a hierarchically organized sequence in which some steps could be omitted and others that were repeated. These steps include (1) locating the potential nest cavity in which the prey could be found, (2) locating a branch of appropriate size, (3) breaking off a tree branch and stripping off leaves and side branches, (4) removal of one or both ends of branch and/or bark, (5) stripping tip of tool, and (6) employing tool and then either discarding it and repeating steps 1–3 or enlarging the cavity opening in which prey is found. The number (and hierarchical nature) of steps undertaken by the Fongoli study subjects is indicative of a sophisticated level of planning and cognitive complexity hitherto assumed to only occur in hominids. The fact that females and immature chimpanzees hunt with spears more frequently than males has significant implications for interpreting the evolution of tool use in hunting in our own lineage (Pruetz and Bertolani 2007). Observations of using spears for hunting continue at Fongoli, as well as other remarkable behaviors such as cave use and evidence of a hominid-like concept of fire (Pruetz 2007; Pruetz and LaDuke 2009).

Marked contrasts in tool use and tool kits are found across populations of chimpanzees in Africa; some of these differences are clearly cultural, resulting from social traditions rather than ecological differences or availability of materials (McGrew 1992; Whiten et al. 1999, 2001). Hammer/anvil technology and spear use, for example, appear to be unique to West African populations of chimpanzees (Pruetz and Bertolani 2007). Although tool use by nonhuman primates, especially chimpanzees, differs in terms of what the tool is made of, how they are made, the contexts they are used in, and the tasks they are used for, a picture of their utility in dealing with food scarcity is beginning to emerge. As discussed previously, fruit as a primate food resource is particularly patchy both spatially and temporally. As it happens, the two primate taxa for which tool use is commonly reported (i.e., *P. troglodytes* and *Cebus* spp.) are also highly encephalized, highly frugivorous, extractive foragers. Fruit is an ephemeral resource and foraging frugivores must have strategies for dealing with those times of the year when their preferred foods are not available. In many cases, primate species "fall back" on alternate foods (e.g., bark, leaves, terrestrial herbaceous vegetation). If these resources are negatively correlated with the availability of preferred food, they then meet the definition for "fallback food" which are typically consumed in quantities that compensate for the scarcity of the animals' main foods (Gilbert 1980; Terborgh 1986; Lambert et al. 2004; Lambert 2007, 2009; Marshall and Wrangham 2007; Marshall et al 2009). Several authors have suggested that the use of tools during such periods may facilitate the use of fallback foods not otherwise available to them (Yamakoshi 1998; Fragaszy et al. 2004; de Moura and Lee 2004; Lambert 2007) and that tool use is a behavioral trait that is most likely to be selected for in extreme and marginal habitats.

The chimpanzee population at Fongoli, Senegal, is certainly supportive of this hypothesis; indeed, Fongoli is among the hottest, driest habitats in which chimpanzees occur (Pruetz and Bertolani 2007). As another example, the habituated chimpanzee community at Bossou, Guinea, lives in both a very small (5 km^2) and an isolated forest, leaving this community without the ability to either shift food types or expand their range in search of fallback foods (Yamakoshi 1998). Overall resource richness is low, and seasonality of fruit availability in this region of West Africa is extreme. Chimpanzees in this area employ a number of feeding-related tools, including hammer and anvil, pestle pounding, ant dipping, and algae scooping with leaves. Tool use in these chimpanzees facilitates the consumption of two important keystone resources: nut cracking for oil palm nuts and pestle pounding for oil palm pith. Both resources are heavily mechanically protected and cannot be exploited without the use of tools (Yamakoshi 1998). Similarly, de Moura and Lee (2004) have argued that "energy bottlenecks" create contexts for capuchins (*Cebus apella*) to derive benefits from tool technology. In the Caatinga dry forest of northeastern Brazil, capuchins have commonly been observed to use tools and do so during the extended dry season of this region. During such times, preferred foods are not available; resources that are available without tool use are not sufficient for nutritional requirements, and the capuchins forage terrestrially for tubers. Several tools and tool-facilitated behaviors have been found in four habituated capuchin groups foraging in these areas, including digging for tubers with stones, cracking open seeds and branches with stones, breaking tubers with stones, and using stones as hammers in combination with wooden anvils to crack seeds. These monkeys consume 41 plant foods; tool use increases the use of at least three of these plant species. The researchers argue that *Cebus* foraging for embedded resources in habitats that experience "energy bottlenecks" is facilitated by innovative tool use (de Moura and Lee 2004). A similar argument is made for *Cebus apella* in another dry region of Brazil, where capuchins commonly use hammer and anvil technology to crack nuts during the dry season when preferred resources are scarce (Fragaszy et al. 2004).

Such observations suggest that foraging-related tool use serves a critical function (sensu Rosenberger 1992; Kinzey 1978; Lambert et al. 2004; Lambert 2007), i.e., that, regardless of phenotypic variation (e.g., differences in cultural traditions), these behaviors were initially selected for during critical periods when other, more preferred foods are not available. This may have implications for understanding tool use in early human ancestors (Teaford and Ungar 2000) and can be understood in light of the work of Robinson and Wilson (1998), who have pointed that some resources are intrinsically easy to use and are widely preferred, while others require specialized features (in this case, tool use) on the part of the consumer. This allows consumers to exploit nonpreferred resources without compromising their ability to use preferred resources (Lambert 2007, 2009).

Primate Feeding Adaptations to a General Problem: Fiber and Plant Defense Chemicals

> The plant world is not colored green; it is colored morphine, caffeine, tannin, phenol, terpene, canavanine, latex, phytohaemagglutinin, oxalic acid, saponin, L-dopa, etc. We now hunger for the details. (Janzen 1978, p. 73)

The fact that primate evolutionary history is marked by plant consumption is not insignificant from a chemical perspective. Angiosperms have not been passive recipients of herbivory over the last 65 Myr; they have instead responded to predation by arming themselves with an extraordinary diversity of defensive chemicals (Harborne 1994; Iason et al. 2013). To date, approximately 100s of thousands of such chemical defenses have been identified, a number viewed to represent only a fraction of extant plant chemical diversity (Levin 1971, 1976; Freeland and Janzen 1974; McKey 1974; McKey et al. 1978; Rosenthal and Janzen 1979; Gartlan et al. 1980; Harborne 1994, 2002; references in Iason et al. 2013). In chemical defense, organic substances are accumulated in plant tissues in such a way that if they are consumed or tasted by an animal, feeding is deterred (Harborne 1994). Such substances may be bitter, have an unappealing odor, be poisonous, or have an antinutritional impact. These compounds are typically categorized into two broad categories: (1) digestion inhibitors, which interfere with the efficiency with which nutrients are obtained by the animal, and (2) true toxins, which are harmful to the animal in that they interfere with normal physiology and may result in death (Feeny 1976; Waterman and Mole 1994).

Because most chemical defenses are not directly involved in the primary processes of plant growth and reproduction, they are often collectively referred to as "secondary" compounds or secondary metabolites. However, some authors (Cork and Foley 1991) have argued that despite their roles in primary plant processes, complex structural carbohydrates (fiber) of plant cell walls should be considered defensive chemicals because of their antifeedant/antinutritional effects on consumers. Carbohydrates take the form of monosaccharide sugars, disaccharides, and polysaccharides (NRC 2003). The nonstarch polysaccharides are the fiber components of plant cell walls and can be further divided into the soluble nonstarch carbohydrates (soluble fiber) and the insoluble nonstarch polysaccharides (insoluble fiber). The insoluble, nonstarch polysaccharides comprise the structural components of the plant cell walls (hence, "structural polysaccharides") and include hemicellulose, cellulose, and lignin. Cellulose is the most abundantly distributed carbohydrate in the world (Sharon 1980) and represents a large proportion of the available energy content of plant foods (Blaxter 1962; Alexander 1993), although no vertebrate has the cellulose-digesting enzyme (cellulase) for breaking down this carbohydrate. The structural carbohydrates must instead be broken down in the gut with the assistance of fungi, protozoans, or, most commonly, bacterial symbionts in a process known as fermentation (Lambert 1998). Like cellulose, hemicellulose generally cannot be digested enzymatically but instead is broken down by fermentation (Milton and Demment 1988; NRC 2003). Lignin is completely unavailable to a primate consumer and is refractory to both endogenous enzymes and bacterial fermentation.

Primates have thus evolved in a chemically inhospitable environment and cannot simply consume any plant that they encounter. Stuart Altmann (2009, p. 615) sums up the issue perfectly: "For omnivorous primates, as for other selective omnivores, the array of potential foods in their home ranges present a twofold problem: not all nutrients are present in any food in the requisite amounts or proportions and not all toxins and other costs are absent. Costs and benefits are inextricably linked.

This so-called ‘packaging problem’ is particularly acute during periods, often seasonal, when the benefit-to-cost ratios of available foods are especially low.”

Indeed, there is ample evidence that primates are extremely selective feeders and consume only a fraction of the plant species available to them in a habitat (Oates 1977, 1987; Glander 1978; Milton 1984). Selective feeding behavior is also exhibited in terms of the times of day a primate will consume a given plant species (quantity/quality of toxins and antifeedants in a plant ebb and flow throughout the day), as well as which portions of the plant (e.g., leaf tips or petioles, but not the entire leaf), and the total quantity of a particular plant food that is consumed (Glander 1978; Struhsaker 1978; Oates 1987; Rothman et al. 2006; Altmann 2009; Lambert 2011; Chapman et al. 2013).

In addition to behavioral adaptations, like all herbivores primates have evolved an array of anatomical and physiological solutions for dealing with plant defenses. Alternative solutions to the “packaging problem” (sensu Altmann 2009) are well illustrated by the extant Cercopithecoidea (including Cercopithecinae and Colobinae) and the African Hominoidea. Here, I suggest that the ways in which these taxa ferment fiber and detoxify chemical defenses may have important implications for their abundance and diversity, both in the Miocene and today.

Making Sense of Dietary Differences: What Monkeys Eat, but Apes Do Not

The relationship between body mass and basal metabolism is a negatively allometric one. Smaller mammals thus require relatively more energy to maintain endothermic homeothermy, and larger mammals relatively less (Kleiber 1961; Bell 1971; Jarman 1974; Parra 1978; Gaulin 1979; Schmidt-Nielsen 1984, 1997; Martin 1990). This negative relationship can have important implications for diet, with smaller-bodied mammals generally expected to have relatively higher energetic requirements consumed than larger-bodied mammals (Bell 1971; Jarman 1974; Gaulin 1979).

Yet, contrary to what might be predicted by the so-called Jarman/Bell principle, wherever the diets of African apes have been studied in comparison to monkeys, apes are invariably called dietary specialists, relying on more nutrient-dense foods comprising less structural polysaccharides and toxins compared to sympatric, smaller-bodied cercopithecoids whose diets often include high levels of fiber and toxins (e.g., leaves, seeds, bark). For example, in Kibale National Park, Uganda, cercopithecines maintain a diverse diet at all times, whereas chimpanzees confine their diet almost exclusively to ripe fruit (Lambert 1997, 2002a, b, 2005; Wrangham et al. 1998; Watts et al. 2011a, b). When ripe fruit is scarce, chimpanzees either range further to procure ripe fruit or fall back on the pith of terrestrial herbaceous vegetation. Wrangham et al. (1998) have found that for every month studied over an 11-month period, sympatric chimpanzees had more ripe fruit in their diets than *Cercopithecus ascanius*, *Cercopithecus mitis*, and *Lophocebus albigena* and do not consume any more fiber in the diet than do these much smaller monkeys. Moreover, chimpanzees consume significantly less digestion inhibitors and toxins (e.g., condensed tannins, monoterpenoids, and triterpenoids) in their annual diet than cercopithecines.

This pattern holds for other African apes as well. Bonobos (*Pan paniscus*) focus most of their feeding time on ripe fruits (White 1998). On the basis of the research on mountain gorillas (*Gorilla gorilla beringei*), gorillas in general were long thought to be folivorous; it is now evident that this subspecies is only folivorous because of a complete lack of succulent fruit in their montane habitat. Indeed, Nishihara (1999) has found that western lowland gorillas (*Gorilla gorilla gorilla*) spend 63 % of their feeding time on fruit. And in a review comprising data from all long-term western lowland gorilla sites, Rogers et al. (2004) have found that these apes will maintain fruit in their diet throughout the year; the authors indeed call *G. g. gorilla* “fruit pursuers, with strong preferences for particular and often rare fruit species, for which they will incur significant foraging costs” (p. 175). Lowland gorillas are also highly selective when consuming vegetative plant foods and chose plant parts that contain the least fiber and tannin and most sugar (Remis et al. 2001).

While African apes focus on fruit, cercopithecines in general are noted for their eclectic diet and feeding flexibility (Rudran 1978; Struhsaker 1978; Gautier-Hion 1988; Beeson 1989; Richard et al. 1989; Maisels 1993; Chapman et al. 2002; Lambert 2002b; Altmann 2009). By the age of 1 year, *Papio cynocephalus* in Kenya, for example, have already ingested over 200 food types (Altmann 1998). Foods consumed by cercopithecines include those that are both readily digested and high in structural polysaccharides; they maintain a higher percentage of nonfruit plant parts in the diet – regardless of fruit abundance (Rudran 1978; Struhsaker 1978; Cords 1986; Kaplin et al. 1998; Lambert 2002b). In addition, as noted above, cercopithecines have long been noted for their capacity to consume plant foods with greater defensive chemical loads than those consumed by sympatric apes (Waser 1977; Andrews 1981; Conklin-Brittain et al. 1998; Wrangham et al. 1998; Lambert 2000, 2001).

Relative to cercopithecines, colobines are more dietarily restricted. These monkeys generally do not consume arthropods for dietary protein, and while some colobine species consume unripe fruit pulp, an alkaline forestomach pH (and the potential for acidosis) precludes colobines from consuming high levels of ripe fruit (Kay and Davies 1994). However, because of their specialized foregut fermentation strategy (see next section), colobines can very efficiently digest plant foods with high levels of both fiber and secondary metabolites not consumed by sympatric cercopithecines or apes (Kay and Davies 1994; Lambert 1998, 2002b; Lambert and Fellner 2012).

The dietary differences among monkeys and great apes of the Old World can be explained by alternative digestion, fermentation, and detoxification systems in Cercopithecoidea and African apes (Lambert and Fellner 2012).

Plant Fiber and Fermentation

The degree to which the nonlignin structural carbohydrates of plant cell walls can be used as a source of energy depends in part on the length of time that these components are retained in the fermenting chamber(s) of the gastrointestinal tract.

The two regions of the primate gastrointestinal tract that have undergone the most specialization for carbohydrate fermentation are the stomach and the large intestine (Chivers and Hladik 1980). In forestomach-fermenting primates, the primary fermentation chamber is a modified stomach. Members of the subfamily Colobinae are unique among primates in having this fermentation system (Kay and Davies 1994). Their specialized, complex stomach is divided into three or four chambers; diverse cellulolytic microorganisms (esp. bacteria) are harbored in the first of these chambers (the forestomach). Caeco-colic fermenters are those animals that have an enlarged cecum or colon as the primary fermentation chamber. Enlarged caeco-colic regions in primates are common and found in some species of prosimians, platyrrhines, cercopithecines, and hominoids. Cercopithecines and hominoids in particular have well-developed colons (Hill 1958; Milton 1993; Lambert 1998).

Plant cell walls require considerable fermentation before they are useful as an energy source, and longer digestive retention times result in more fermentation (Milton 1981, 1984, 1986, 1993; Lambert 1998; Remis 2000; Lambert and Fellner 2012). It is typically argued that "both the total capacity of the digestive tract and the capacity available for microbial fermentation are almost directly proportional to body mass" and that only an increase in body size would allow longer retention times (Cork and Foley 1991, p. 139; Kay and Davies 1994). As such, it has historically been assumed that smaller primates will have (both absolutely and relatively) faster food passage rates than larger species, thereby limiting their capacity to ferment fibrous plant components (Parra 1978; Kay 1985; Cork and Foley 1991; Kay and Davies 1994; Van Soest 1996).

Yet, both cercopithecoid subfamilies have relatively longer digestive retention times than the much larger African apes (Lambert 2002c; Blaine and Lambert 2012). This is not unexpected among the Colobinae; on average, their mean digestive retention times range from roughly 40 to 60 h (Lambert 1998; Caton 1999). Neither cercopithecines nor hominoids exhibit such derived anatomy, their simple-stomached gastrointestinal anatomy is very similar. Yet, in an analysis regressing digestive retention times as a function of body size, Lambert (1998) found that the cercopithecines in the analysis were significantly further above the regression line than any other primate taxon. A more recent analysis, including more species (Blaine and Lambert 2012), corroborated this pattern. Indeed, despite being on average an order of magnitude smaller than African apes, all tested cercopithecines exhibit mean digestive retention times averaging 31 h (*P. troglodytes*, 31.5–48 h; *G. gorilla*, 36.5–61.9 h (Lambert 1998, 2002c; Milton and Demment 1988; Remis 2000)). These digestive results have important implications for understanding how monkeys can consume either similar or greater levels of fiber than larger-bodied apes (Lambert 2002c; Blaine and Lambert 2012).

Chemical Defenses and Detoxification

There are two primary mechanisms for detoxifying plant toxins: (1) microbial activity in a specialized stomach and (2) microsomal enzymes (Freeland and Janzen 1974).

Colobines rely on their microbial community in their derived stomach, while cercopithecines and apes must rely on microsomal enzymes. While we know extremely little about such microbial mechanisms in colobines, the potential of the specialized stomach with a diverse and dense microbial community to act as a detoxification chamber has been demonstrated in ruminating ungulates (Keeler et al. 1978; Waterman and Kool 1994).

Mammals without the advantage of forestomach microbial activity rely heavily on microsomal enzymes to detoxify plant toxins (Freeland and Janzen 1974). Microsomal enzymes are located in the endoplasmic reticula of hepatocytes and are activated in the presence of toxins, usually after digesta has left the stomach and entered the intestines. All noncolobine primates rely on this system.

Being smaller in body size can be advantageous for enzyme production since rates of enzymatic activity scale negatively with mammal body size (Walker 1978; Freeland 1991). Freeland (1991) thus suggests that smaller mammals are at an advantage for detoxifying plant secondary metabolites and that the larger the mammal, the greater the preference for foods with low amounts of toxic plant metabolites. These assertions rest largely on results by Walker (1978) who has expressed rates of enzyme activity in rats as a function of liver mass relative to body mass. On average, cercopithecines are smaller than colobines and apes, which may facilitate their consumption of chemically defended plants not available to apes and only available to colobines as a consequence of their specialized stomachs.

Accordingly, relative to apes, cercopithecoids are at an advantage in their capacity to deal with fiber and plant defenses. Colobines thoroughly digest their high-fiber foods via a specialized stomach and tolerate potentially high levels of plant toxins via a diverse microbial community in this stomach. Cercopithecines, on the other hand, have a simple stomach and instead extract nutrients out of the diet via extensive digestive retention. By staying small relative to apes, cercopithecines are able to maintain high levels of enzyme production for dealing with toxins. Incidentally, staying small also keeps absolute requirements for food low and also facilitates a faster life history strategy with higher reproductive output than apes. African apes, too, have a simple stomach, but have the digestive retention times expected for their body mass (Milton and Demment 1988; Lambert 1997, 2002c; Remis 2000). These larger-bodied primates avoid exposure to toxins and maintain higher-quality dietary components throughout the year, regardless of their scarcity; in the case of chimpanzees, this is facilitated by tool use. Like other African apes, early hominins probably also generally avoided toxins and high fiber, but eventually evolved myriad cultural adaptations for breaking down fiber and toxins, including soaking and cooking foods (Aiello and Wheeler 1995; Johns 1996; Milton 1999; Wrangham et al. 1999; Wrangham 2009).

Ecological and Evolutionary Implications

These digestive and feeding adaptations have implications for interpreting extant and extinct patterns of African monkey and ape species diversity (including both abundance and richness). Cercopithecidae is the most successful extant primate taxon and is so in all ways in which evolutionary and ecological success is defined: speciosity, abundance, and distribution. Indeed, despite being the youngest of all primate lineages, Cercopithecidae comprises more taxa than any other extant primate family and exhibits rates of cladogenesis approximately double that of all other primate taxa (Purvis et al. 1995). Moreover, cercopithecid taxocenes achieve the highest abundance of all extant primate communities (Fleagle 2013; Janson and Chapman 1999). In addition, Cercopithecidae is the most geographically widespread of all primate families and has successfully colonized habitats spanning the full spectrum of seasonality and food resource availability and distribution (Richard et al. 1989; Jolly and Whitehead 2000; Jablonski 2002).

Remaining fairly small keeps cercopithecoid absolute requirements for foods low relative to apes. Moreover, the carrying capacity for monkeys in a given habitat is essentially higher: a function of the fact that more items are food for cercopithecoids. These two factors may account for striking differences in monkey and ape density and biomass in Africa. For example, cercopithecoid density in Kibale National Park, Uganda, is 420 kg/km^2, while chimpanzee density is 3 kg/km^2; the biomass differences are 2,611 and 85 kg/km^2, respectively (Chapman and Lambert 2000). This pattern holds elsewhere in Africa. In Tai Forest, for example, the cercopithecoid biomass compared to that of chimpanzees is 951.7 versus 58.3 kg/km^2 (Chapman et al. 1999). In Budongo, Uganda, the biomass of cercopithecines is 354 kg/km^2 and chimpanzees 89 kg/km^2, and in the Lope Reserve, Gabon, where both *P. troglodytes* and *G. gorilla* are found, the monkey biomass is 251.4 kg/km^2, and ape biomass is 65.8 kg/km^2 (Plumptre and Reynolds 1995; Chapman et al. 1999).

Extant cercopithecoids are also greatly more speciose than apes. As has been noted by a number of authors, this pattern of diversity is a relatively recent one and has changed dramatically since the Miocene. During that epoch (23–5 Myr), hominoid species richness was at its maximum. In their species diversity and range of ecological adaptations and body sizes, Miocene apes paralleled the diversity of modern Cercopithecoidea (Andrews 1981; Kelley 1992). Since the Miocene, however, hominoid species diversity has steadily decreased, from a maximum of four to six sympatric species in the earlier millennia of the epoch to no more than two species living in a single habitat in the later Miocene and present (Andrews 1981). Conversely, while cercopithecoid diversity was relatively low in the Early Miocene, it has increased steadily, eventually achieving levels comparable to extant patterns (Purvis et al. 1995).

Several explanations have been proposed to account for this shift in hominoid-cercopithecoid diversity (Napier 1970; Ripley 1979; Andrews 1981; Temerin and Cant 1983). Each explanation is based on the concomitant assumptions that there was competition for increasingly scarce food resources between Miocene monkeys and apes and that this competition resulted in an ape adaptive pattern and a monkey adaptive pattern for foraging and feeding. Early African monkeys and apes are viewed to have been in competition for increasingly scarce fruiting resources during a time of extensive environmental change (cooler, dryer) in Miocene Africa

(Andrews and Van Couvering 1975). Napier (1970) argued that, in the face of increasingly patchy fruit availability in a changing East African habitat, the divergence of the cercopithecoids was directly related to their ability, via specialized bilophodont molars, to consume leaves. Similarly, Ripley (1979) argues that increasing East African forest seasonality played an important role in Old World monkey/ape divergence, although rather than on the dentition, she places emphasis on locomotor differences. Andrews (1981) refined Napier's (1970) hypothesis on cercopithecoid-hominoid divergence and suggested that monkeys diverged from apes as a result of their being able to exploit unripe fruits. Like Napier's scheme, his support stems largely from dental evidence.

Temerin and Cant (1983) proposed a model of ecological energetics to explain the differences in monkeys and apes. In this scheme, the authors argue that "when consuming the same category of food items (ripe fruit, leaf shoots, young leaves, etc.) apes exploit more widely distributed and/or smaller patches on average than do OWM" (Temerin and Cant 1983, p. 343). Their fundamental premise is that in the same environment, with access to the same resources, monkeys emphasize energy gain, while apes decrease energy expenditure because of their more efficient, specialized locomotion. They argue that in a habitat with increasingly rare fruit resources, Miocene monkeys did not move greater distances to maintain a heavily frugivorous diet; rather, they shifted to other food types. Conversely, apes did not shift their dietary proportions, but instead traveled longer distances to exploit increasingly rare fruit; this was facilitated by their specialized postcrania and efficient locomotion.

Several predictions have been made regarding Old World monkey and ape ecological distinctions and the shift in hominoid-cercopithecoid diversity from the Miocene to the present (Napier 1970; Ripley 1979; Andrews 1981; Temerin and Cant 1983). For example, Temerin and Cant (1983) predicted that, in a given environment, monkeys will eat more leaves and unripe fruit than apes and that monkeys will have higher assimilation efficiencies than apes on diets containing plant fiber. Similarly, Andrews (1981, p. 49) has argued:

> a critical distinction between apes and monkeys is the greater tolerance of the latter for a variety of plant secondary compounds, including tannins and alkaloids. Conversely, hominoid species avoid food with high levels of toxicity, and in particular they avoid unripe fruit that is eaten by monkeys. In developing a tolerance for tannins and other secondary compounds, therefore, the cercopithecines are able to tolerate less ripe fruit than the hominoids and thus gain access to fruiting trees before the hominoids.

These predictions have been borne out in the subsequent decades of primate field research. Yet, to date, there have been no explicit hypotheses regarding what these "assimilation efficiencies" and "tolerances" are or how they work. I suggest that they are specialized features of digestive and detoxification systems, including either long retention times/relatively high rates of microsomal enzyme production in the case of cercopithecines (in addition to amylase producing cheek pouches; Lambert 2005) or specialized stomach and microbial action in the case of the colobines.

On the basis of the variation in shearing quotients (SQ) in fossil apes, Ungar and Kay (1995) argue that the dietary breadth of Miocene hominoids was much greater than it is today, with fossil ape species occupying a variety of trophic niches, including folivory, soft-object frugivory, and hard-object feeding (seeds). That Miocene apes ranged in size from the small *Micropithecus clarki* at 3.5 kg to *Afropithecus* and *Proconsul major* weighing in at about 50 kg (Fleagle 2013) has been used in support of arguments regarding dietary range in Miocene apes. However, my proposition deflates the theoretical importance of body mass in driving the Miocene monkey/ape divergence. While it is commonly held that large-bodied primates have a greater capacity for fermentation and longer retention times (Gaulin 1979; Fleagle 2013), it appears that, in fact, cercopithecines successfully evolved this capacity without necessarily evolving large body size. Smaller mammals do have relatively greater metabolic needs than larger ones. However, rather than requiring a high-quality diet that is digested and processed quickly in order to maintain a high rate of incoming food, cercopithecines simply make *more* out of a lower-quality diet via detoxification and fermentation. Indeed, I suggest that from a dietary perspective, smaller, "monkey-sized" apes of the Early Miocene were not necessarily analogs of later similarly sized monkeys. Although Miocene apes may have had the dental features correlated with folivory and seed eating (i.e., high SQ), they may have ultimately been outcompeted by cercopithecoids, because monkeys had both dietary *and* digestive features that enabled them to deal with a broader diet (i.e., colobines had a sacculated stomach and microbial detoxification, and cercopithecines long retention times, high rates of enzyme production, and cheek pouches) and were simply *better* at extracting nutrients/resources out of a variety of food types (Lambert 2005). Thus, cercopithecoids of the Miocene and thereafter were better equipped to deal with the variety of niches originally occupied by the dental apes. Apes of the Middle to Late Miocene may have been essentially outcompeted (digestively) in these other niches and, as a result, became better frugivores, resulting in the highly selective fruit-feeding behavior we see today.

Conclusion

In short, I suggest that at some point early in their radiation, cercopithecines increased the breadth of their dietary niche and did so by remaining small and evolving digestive adaptations in the form of long retention times and cheek pouches (Lambert 2005). As the cercopithecoids diverged, colobines took off on a different evolutionary trajectory and opted for a previously unfilled primate dietary niche (specialized arboreal folivore) by evolving a specialized stomach. Relative to apes, cercopithecoids have a faster life history strategy (see chapter "▶ Primate Life Histories," Vol. 2), with much greater reproductive output; a consequence of this is that these smaller primates tend to evolve more quickly, which may explain their greater speciosity (Cowlishaw and Dunbar 2000). Hominoids opted for a specialized strategy and are essentially "trophically restricted" (sensu Ungar and Kay 1995) relative to the smaller cercopithecoids, while hominins pursued a trajectory of increasing dietary quality both by increasingly including vertebrate meat into the diet and by cultural adaptations such as cooking (Milton 1999; Wrangham et al. 1999; Wrangham 2009; Stanford and Bunn 2001).

large variation exists. Red colobus monkeys (*Piliocolobus* sp.) appear to be the preferred prey, but intensity and frequency of hunting vary from month to month and among populations. Hunting is a predominately male activity and is typically opportunistic, although there is some evidence of searching for prey. The degree of cooperation during hunting, as well as prey selection, varies between East and West African populations and may be related to the way the kill is divided: in West Africa, hunters often collaborate, with kills tending to be shared according to participation, whereas in East Africa, cooperation in hunting is more limited, and the kill is typically consumed selfishly or divided in response to harassment (begging) by others. In some cases, it may be shared tactically, trading meat with other males to strengthen alliances. The adaptive function of chimpanzee hunting is not well understood, and a variety of hypotheses have been proposed. Ideas that chimpanzees hunt to make up for nutritional shortfalls, or to acquire meat to trade for sex, have failed to find empirical support, while recent work favors nutritional benefits of some kind. Nevertheless, cross-population studies evaluating multiple hypotheses are in their infancy, and there is much to be learned. In particular, very little is known about hunting of nonprimates, particularly ungulates, or the impact that variation in levels of hunting, and of carcasses to share and consume, has on patterns of chimpanzee behavior. If one goal of studying this topic is to shed light on the behavioral ecology of hominins, then efforts to understand the diversity of hunting and carnivory in wild chimpanzees are needed.

Introduction

Hunting – the pursuit, capture, and consumption of small- and medium-sized vertebrates – appears to be typical of all chimpanzee (*Pan troglodytes*) populations. Such behavior has aroused considerable interest among anthropologists since it was first reported (Goodall 1963). Hunting, the division of the kill, and the consumption of meat all play an important role in the lives of modern hunter-gatherer societies (Lee 1979; Kaplan and Hill 1985; Hawkes et al. 2001; Hawkes and Bird 2002) and factor in a number of hypotheses concerning human evolution (Washburn and Lancaster 1968; Isaac 1978; Hill 1982; Tooby and DeVore 1987; Stanford 1996, 1998, 2001). While early ideas such as "Man the Hunter" (Washburn and Lancaster 1968) have been largely discredited, hunting as a means to acquire meat remains important in many modern scenarios (Domínguez-Rodrigo 2002; Hawkes and Bird 2002). Animal tissue has high calorific value relative to plant material, is rich in fat and protein, and contains essential amino acids (Milton 1999). It is therefore a valuable resource. The nonrandom sharing of meat has been proposed as an important selective force driving the evolution of intelligence (Stanford 2001), and the consumption of meat has been invoked as an important proximate factor enabling the evolution of larger brains in the *Homo* lineage (Aiello and Wheeler 1995).

Chimpanzees show large variation between populations in the choice of prey species, frequency of hunting, and the techniques employed. Understanding both how and why chimpanzees hunt is important for the framing of evolutionary hypotheses; chimpanzees provide our best evidence for the behavioral capabilities of early hominins (Domínguez-Rodrigo 2002). In this chapter, substantially revised and updated from the previous version (Newton-Fisher 2007), I review the data concerning hunting behavior among wild chimpanzees and address current hypotheses concerning the reasons why chimpanzees hunt, drawing out both similarities and differences between populations in their hunting behavior.

Characteristics of Chimpanzee Hunting

All known populations of chimpanzees show some evidence of hunting and consuming vertebrate prey. Such hunting has been documented systematically among the East African chimpanzees (*Pan troglodytes schweinfurthii*) of the Gombe (van Lawick-Goodall 1968; Teleki 1973; Busse 1977; Stanford 1998; Gilby 2006; Gilby et al. 2006, 2010) and Mahale (Nishida et al. 1979; Takahata et al. 1984; Uehara 1997) National Parks in Tanzania and of the Kibale Forest National Park (Mitani and Watts 1999; Watts and Mitani 2002; Teelen 2008; Gilby et al. 2008; Watts and Amsler 2013) in Uganda, as well as among the West African chimpanzees (*P. t. verus*) of the Taï National Park, Cote d'Ivoire (Boesch and Boesch 1989; Boesch and Boesch-Achermann 2000; Gomes and Boesch 2009). Other reports of hunting by chimpanzees come from East African populations in the Budongo Forest, Uganda (Newton-Fisher et al. 2002), Kahuzi-Biega National Park, DRC (Basabose and Yamagiwa 1997), Kasakati, Tanzania (Kawabe 1966), and Semliki, Uganda (Hunt and McGrew 2002); from central African populations (*P. t. troglodytes*) of Lopé, Gabon (Tutin and Fernandez 1993) and Ndoki, Cameroon (Kuroda et al. 1996; Takenoshita 1996); from the Ebo forest, Cameroon (*P. t. ellioti*) (Morgan et al. 2013); and from West African populations of Mt. Assirik, Senegal (McGrew 1983; Hunt and McGrew 2002), Bossou, Guinea-Bissau (Sugiyama and Koman 1987), and Tenkere, Sierra Leone (Alp and Kitchener 1993).

Prey Diversity

Across populations, prey diversity is high with at least 40 species of vertebrates targeted. Chimpanzees show a clear focus on mammalian prey (Table 1) and are known to consume a variety of primate species as well as ungulates and rodents but will also eat birds, lizards, and frogs. Some populations have a diverse range of prey, whereas others are more specialized. The Mahale chimpanzees, for instance, are known to hunt at least 17 species of mammals, while in Taï, chimpanzees hunt only 7 (all primates) of the 15 sympatric mammal species (Boesch and Boesch-Achermann 2000; Boesch et al. 2002). Prey are typically small, up to a maximum of

Populations (study sites) of chimpanzees are arranged by subspecies. A ✓ indicates that the species has been recorded being killed or consumed. Not all species of prey are present at all sites around 20 kg – the weight of an adult male black and white colobus monkey (*Colobus guereza*) (Kingdon 1997) or a part-grown bushpig (*Potamochoerus porcus*) – but often much smaller (Goodall 1986).

Prey Specialization

Monkeys, in particular colobus monkeys, appear to be the main prey of chimpanzees wherever the species are sympatric. Red colobus (*Piliocolobus tephrosceles* in East Africa, *Piliocolobus badius* in West Africa) are the primary prey for many populations of chimpanzees, with black and white colobus (*Colobus guereza* in East Africa, *Colobus polykomos* in West Africa) as a secondary target.

The degree to which chimpanzees specialize on monkeys to the exclusion of other prey species varies between populations. In the Taï Forest, chimpanzees show a notably strong specialization. Between 1984 and 1995, 249 of 267 known kills were of colobus monkeys: 80.5 % red colobus (*Piliocolobus badius*) and 12.7 % black and white colobus (*Colobus polykomos*) (Boesch and Boesch-Achermann 2000). A similar specialization is apparent among the Ngogo chimpanzees of the Kibale forest, where between 1995 and 2000, 92.5 % of all prey were colobus monkeys: 87.8 % red colobus (*Piliocolobus tephrosceles*) and 4.7 % black and white colobus (*Colobus guereza*). At Gombe, the specialization is less extreme but still noticeable: red colobus (there are no black and white colobus at this site) constituted 59 % of the chimpanzees' prey between 1970 and 1975, 66 % between 1976 and 1981, and 84.5 % between 1990 and 1995 (Goodall 1986; Stanford 1998).

By contrast, red colobus constituted only 53 % of all prey for the Mahale chimpanzees (Nishida et al. 1992), while black and white colobus (*Colobus guereza*) were 43.8 % of all prey for the Sonso chimpanzees of the Budongo Forest, where there are no red colobus (Newton-Fisher et al. 2002). These two populations appear to differ from the others in that the chimpanzees also prey upon small ungulates, particularly blue duiker (*Cephalophus monticola*), to an appreciable degree: 34 % of all prey in Mahale (Nishida et al. 1992) and 25 % of all prey in Budongo (Newton-Fisher et al. 2002). Data from Budongo are sparse, but observations support the idea that these chimpanzees do not demonstrate the extreme prey specialization seen in Taï and Ngogo (Newton-Fisher unpublished data). Forest ungulates, particularly duiker and bushpig, are in fact hunted by all the East African chimpanzee populations that have been studied (Gombe: Goodall 1986; Mahale: Nishida et al. 1992; Budongo: Newton-Fisher et al. 2002; Kibale: H. Sherrow personal communication) but do not appear to be regarded as prey by West African chimpanzees (Uehara 1997; Boesch and Boesch-Achermann 2000). More research is needed regarding chimpanzee predation on ungulates.

Chimpanzee populations also appear to differ in their choice of the age and sex of prey. For the Taï chimpanzees, half of their colobus monkey prey are adult, mostly females (Boesch and Boesch-Achermann 2000). This is in contrast to chimpanzees at Mahale and Gombe, where the vast majority of colobus prey are juveniles and infants (Goodall 1986; Uehara 1997) and some chimpanzee hunters target very young colobus monkeys, snatching them from their mothers (Stanford 1998). Somewhere between 75 % (Stanford et al. 1994) and 86 % (Stanford 1998) of red colobus prey at Gombe are immature individuals. For the Ngogo (Kibale) chimpanzee, the figure is somewhat less: 53–75 % (Mitani and Watts 1999; Watts and Mitani 2002). There is less information on the age and sex of non-colobus prey. Among the ungulates, bushbucks are targeted only as infants (fawns), as typically are bushpig (piglets) (Goodall 1986). Age and sex estimates of duiker kills are more difficult to obtain, given that the prey is rapidly torn apart and consumed entirely by the chimpanzees; however, it is clear that chimpanzees are quite capable of killing adult blue duiker (personal observations).

Sex Bias in Hunting

The hunting of monkeys is a predominately male activity. Among the chimpanzees of the Ngogo (Kibale) community, adult or adolescent males made 98.8 % of all kills recorded between 1995 and 2000 (Watts and Mitani 2002). In two decades of data from Gombe, adult males were responsible for 91.5 % of all kills (Stanford 1998). Female chimpanzees will and do hunt, however. Data from Gombe for 1977–1979 showed that females joined an average of 26 % (median: 25 %, range: 0–67 %) of red colobus hunts for which they were present and those females who were more likely to join males in a hunt were also more likely to hunt when apart from the males (Goodall 1986). One female, Gigi, contributed 4 % of the total kills (Stanford 1998). Any kills that females made as part of mixed-sex hunting party were likely to be taken by males (Goodall 1986), however, which may in part explain female unwillingness to hunt when males are present. Females may prey more on ungulates (Uehara 1997), but quantitative data are difficult to collect, in part due to the nature of ungulate hunting. The hunting of lesser bushbabies (*Galago senegalensis*) in Fongoli, Senegal, is rather different to the typical group hunts of monkeys: it is tool assisted, extractive, and individualistic; it also shows a strong female bias, with 14 of 22 observations of female hunters and only one of an adult male hunting in this way (Pruetz and Bertolani 2007).

Hunting Frequency

Detecting hunting in a chimpanzee population can be problematic, particularly if the chimpanzees are poorly habituated to human observers. Typically in this situation, hunting is rarely if ever seen, and studies rely on finding animal remains such as skin or bone in chimpanzee feces (McGrew 1992). Unfortunately, feces do not appear to provide a reliable indicator of hunting: while the presence of remains can confirm that consumption does occur, little can be said about its frequency (cf. Uehara 1997). For example, long-term observations of habituated chimpanzees in the Taï Forest have revealed a pattern of frequent hunting and consumption that is not mirrored in the pattern of prey remains found in fecal samples (Boesch and

Boesch-Achermann 2000). Further, fecal sampling can say nothing about the number of hunting attempts that fail to secure prey, the division of the prey once obtained, or the relative importance of scavenging as a method of acquiring meat. Similar problems may also occur when hunting is actually rare or when prey species are alerted or scared away by the presence of humans accompanying the chimpanzees, although in some cases chimpanzees may exploit their prey's fear of humans to increase hunting success (Goodall 1986; Boesch 1994).

Predation Pressure

While in some populations chimpanzees hunt only rarely, in others they are significant predators who hunt at levels that appear to be unsustainable (Goodall 1986; Wrangham and van Zinnicq Bergmann Riss 1990; Teelen 2008; Watts and Amsler 2013). Estimates for Gombe suggest that anything from 8 % to 42 % of the colobus population can be killed annually, with this proportion varying from year to year, 8–13 % (1973–1974: Busse 1977), 41.6 % (1972–1975: Wrangham and van Zinnicq Bergmann Riss 1990), and 16.8–32.9 % (1982–1991: Stanford et al. 1994), while at Taï during the 1980s, the figure was between 3 % and 8 % (Boesch and Boesch-Achermann 2000). For Ngogo, Teelen (2008) estimated 15–53 % of the red colobus population is killed by chimpanzees annually, while Watts and Amsler (2013) estimated that almost 2,500 red colobus monkeys were killed in the period 1998–2012, an average of 20.4–24.8 % of the population per year. By contrast, the Mahale chimpanzees were estimated to kill only around 1 % of the red colobus population each year during the 1980s (Boesch et al. 2002). Basabose and Yamagiwa (1997) estimate that the chimpanzees of Kahuzi-Biega kill 11–18 % of the *Cercopithecus* monkey population each year (predominately *Cercopithecus mitis* but also *Cercopithecus l'hoesti*). Hunting of ungulates may also impose high levels of mortality. Wrangham and van Zinnicq Bergmann Riss (1990) estimated chimpanzee-imposed mortality on bushbuck at 27 % (although this figure includes bushbuck fawns killed by baboons and subsequently stolen by chimpanzees) and on bushpig at 7 %, for populations in the Gombe National Park between 1972 and 1975.

These estimates, both for primates and ungulates, are based on comparing the number of kills with the population density of prey within the chimpanzee community's home range. There is potential for error in the estimates of each of these variables. If, for example, home range is overestimated (cf. Newton-Fisher 2004), then predation pressure will be underestimated, while underestimating the number of potential prey will inflate the estimate of predation pressure (Wrangham and van Zinnicq Bergmann Riss 1990).

Nevertheless, the level of predation by some chimpanzee communities on red colobus monkeys is extreme. As a reference point, predation by crowned eagles on the total cercopithecoid monkey population at Ngogo is estimated at 2 %: Mitani et al. (2001). There is good evidence that a significant decline in red colobus monkeys in the Ngogo region of the Kibale forest, at least since the mid- to late

1990s and possibly since the 1970s, is the result of chimpanzee predation (Teelen 2008; Lwanga et al. 2011; Watts and Amsler 2013). Simulations using 3 years (2001–2003) of Ngogo data showed that chimpanzee predation was likely to drive the red colobus population to local extinction within two decades without a dramatic change in the level, or success, of chimpanzee hunting (Teelen 2008). Local extinction is more probable if neighboring communities of chimpanzees also impose significant predation pressure (Watts and Amsler 2013) as this removes any "source" population from which immigrants can be drawn (*contra* Lwanga et al. 2011). The decline in red colobus in Ngogo has, however, been accompanied by a decline in chimpanzee hunting (encounters, hunts, and prey offtake) which appears to be a consequence of the reduced availability of prey: when these chimpanzees expanded their territory in 2009 (Mitani et al. 2010), they increased rates of both prey encounters and hunting (Watts and Amsler 2013).

Variation in Hunting Frequency

Estimates of hunting frequency and predation pressure typically disguise wide variation. Within a single community, the total number of hunts can vary from month to month and year to year. Across populations, chimpanzees appear to have hunting "seasons" during which the number of kills increases as a result of either more hunting, more successful hunting, or both. For the chimpanzees at Gombe, Mahale, and Taï, this hunting season falls toward the end of the year, peaking in September and October. At Gombe, this corresponds to the later part of the dry season (Stanford 1998; Gilby 2004). At Mahale, the peak is slightly later, reaching into November, and appears to coincide with the end of the dry season and the first rains of the wet season (Takahata et al. 1984). Preliminary work at Budongo suggested a dry season (December to February) peak in hunting activity (Newton-Fisher et al. 2002), but subsequent work has failed to confirm this idea (Newton-Fisher unpublished data).

The hunting behavior of the Ngogo chimpanzees does not appear to correspond to timing of rainfall, but hunting seasons instead occur during periods of fruit abundance (Watts and Mitani 2002) that are not correlated with rainfall (Mitani et al. 2002). Similarly, the hunting season at Mahale occurs when more fruit is available (Uehara 1997), and among the Kanyawara chimpanzees of the Kibale forest, hunting rates were higher when preferred species of ripe fruit were abundant (Gilby and Wrangham 2007). At Taï, the hunting season runs from mid-August to mid-November, between periods of low and high fruit abundance, and ends when chimpanzees switch to highly calorific *Coula edulis* nuts from which they gain sugar, protein, and fat. The peak in hunting is also in September and October, but this is during the wet season at the time of greatest rainfall (Boesch and Boesch-Achermann 2000).

In addition to these seasonal changes, hunting frequency within a single community varies between years, which may be related to changes in the abundance of prey species or the number of chimpanzees who might hunt. A comparison of hunting success for Mahale chimpanzees between the 1980s and early- to mid-1990s showed a threefold increase in the percentage of the red colobus population killed by the chimpanzees, rising from around 1 % to at least 3 % of the population per year (Boesch et al. 2002). This seemed to accompany an expansion in the red colobus population. Hunting success then fell in the later part of the 1990s, following a decrease in the number of chimpanzees in the study community (Boesch et al. 2002): a similar reduction in the level of hunting was seen following a decrease in the number of adult males in the study community in the Taï Forest (Boesch and Boesch-Achermann 2000).

Impact Hunters

Chimpanzees may also experience greater hunting success when individuals with a flair for hunting are present. These individuals ("impact" hunters) demonstrate both a high willingness to hunt and a consistently high probability of success (Goodall 1986; Stanford 1998; Boesch and Boesch-Achermann 2000). Typically, one or two males in each study populations where monkey hunting is prevalent have been identified as impact hunters (Goodall 1986; Stanford 1998; Boesch and Boesch-Achermann 2000; Gilby et al. 2008), with anecdotal evidence suggesting that these individuals are responsible for initiating hunts, climbing first toward prey. Other male chimpanzees may be spurred into hunting by the actions of these impact hunters. A recent increase in hunting of black and white colobus monkeys by Sonso (Budongo) chimpanzees has been ascribed to the actions of a particular male, while Stanford (1998) found that two males of the Kasekela (Gombe) community were highly successful when hunting alone and that one of these, Frodo, was both a catalyst for hunts and a fearsome predator of red colobus monkeys, killing at least 50 in the period 1990–1992. Gilby et al. (2008) tested the influence of impact hunters among the Kanyawara (Kibale) chimpanzees and found that the likelihood of a hunt occurring was much greater when an impact hunter was present, even when controlling for the number of adult males, and that the chance of other males joining a hunt increased if an impact hunter was hunting.

Hunting Binges

A further source of variation in hunting frequency within a community is the occurrence of hunting "crazes" (van Lawick-Goodall 1968) or "binges" (Stanford 1998). These are periods during which the chimpanzees hunt "almost daily": more than three hunts in a 7-day period, with chimpanzees appearing to hunt on contact with prey (Stanford 1998). In the Kasekela (Gombe) community, 23 binges were recorded between 1990 and 1995. The longest of these lasted 74 days and consisted of 38 observed hunts and at least 76 kills, all red colobus. Correcting the number of kills for observation time suggests that over 100 colobus monkeys were killed during this 74-day period (Stanford 1998). The Ngogo chimpanzees went on a 57-day hunting binge in 1998, during which they hunted 22 times, killing 69 red colobus, one mangabey (*Lophocebus albigena*), and one red duiker

(*Cephalophus* sp.). Only 4 of the 22 hunts were unsuccessful, including two attempts to hunt black and white colobus (*Colobus guereza*). This and other hunting binges at Ngogo coincided with major fruit crops, and most hunting occurred when large parties of males were traveling together (Watts and Mitani 2002). Large parties with high numbers of males also seem to be linked to hunting binges at Gombe (Stanford 1998). Large numbers of chimpanzees traveling together suggest that fruit is particularly abundant, and so hunting binges at Gombe may also be linked to periods of food abundance.

How Do Chimpanzees Hunt?

Many hunts are opportunistic, in that chimpanzees appear to decide to hunt after encountering prey during the course of normal foraging activities or travel around the home range. This seems to be the typical pattern at Gombe (Goodall 1986; Stanford 1998) and at Ngogo (Mitani and Watts 2001). Chimpanzees in Taï, however, show evidence of actively searching for prey, listing for the vocalizations of either colobus monkeys or Diana monkeys (*Cercopithecus diana*) with whom the colobus are frequently associated (Boesch 1994; Boesch and Boesch-Achermann 2000). The likelihood of a hunt when chimpanzees encounter potential prey varies: it is relatively high for the Kasekela (Gombe) community (40 %: Gilby et al. 2006) and the Ngogo (Kibale) community (37 %: Mitani and Watts 2001) but somewhat lower in the Kanyawara (Kibale) community (15 %: Wrangham, cited in Gilby et al. 2006).

Chimpanzees hunt the majority of their prey without the use of tools or weapons, although there are a few reports of rocks or branches being hurled, possibly in an attempt to panic defensive formations of adults (Goodall 1986), and tools (sticks and leaves) are sometimes used to aid in the processing of the carcass (McGrew 1992). In Fongoli, Senegal, chimpanzees fashion tools from branches, at times biting the end to create a point, which are forcibly jabbed into tree cavities: observations suggest that this is done to immobilize or kill lesser bushbabies (*Galago senegalensis*) that are then extracted and consumed (Pruetz and Bertolani 2007).

During a monkey hunt, prey are typically chased, seized, and then killed either by a bite, by disembowelment, or by being torn apart (Goodall 1986). Hunts may yield single or multiple kills (or, indeed, may fail completely). Between 1973 and 1981, Gombe chimpanzees made multiple kills in 37.5 % of colobus hunts; most of these were two kills per hunt. A typical colobus hunt at Gombe will produce two (Watts and Mitani 2002) or three (Stanford 1998) kills and at Ngogo, four kills (Mitani and Watts 2001). Single kills seem to be more usual for Taï chimpanzee hunters (Stanford 1998), although typically such kills are of adult monkeys (mean number of kills per successful hunt: 1.2: Watts and Mitani 2002). Failure rates (i.e., failure to kill any prey during a hunt) vary between communities. For the Tai and Gombe chimpanzees, around 50 % of hunts fail (Boesch and Boesch-Achermann 2000; Gilby et al. 2006), while for Ngogo chimpanzees the rate is lower, at 16 %

(Mitani and Watts 2001). In an analysis of hunting by chimpanzees of the Kanyawara community, Gilby et al. (2008) found that an individual hunter had around a 65 % chance of acquiring meat in any hunt that was successful; among the Taï chimpanzees, a male had access to meat in around 48 % of successful hunts (Boesch and Boesch-Achermann 2000).

Analysis of hunting data from both Ngogo (Watts and Mitani 2002) and Gombe (Wrangham 1975; Stanford et al. 1994; Gilby et al. 2010) indicates that hunting is responsive to habitat structure. At Ngogo, chimpanzees were more likely to hunt red colobus when encountering prey in, or close to, areas with broken or no tree canopy than when in primary forest (Watts and Mitani 2002); at Gombe, hunts were more likely and more successful in woodland and semi-deciduous forest than in evergreen forest. These observations suggest that, as with obligate predators, chimpanzees are more likely to hunt in areas where it is harder for prey to escape and hunting costs are lower (Gilby et al. 2010).

The hunting of ungulates is less well described. Bushpigs are probably the most difficult of ungulate prey. Chimpanzees are wary, if not fearful, of the adults, and they retreat to the trees in the face of aggression by adult pigs (personal observations). At Gombe, chimpanzees have been described using stealth to seize piglets before the adults are alerted to their presence and also of using aggressive displays to panic the adults, capturing piglets either in the confusion or if abandoned by adults that run off (Goodall 1986). Bushbuck fawns hide in dense cover as an antipredator strategy, while adults typically freeze or flee. Chimpanzees search for hiding fawns when their attention is drawn to particular areas by the presence of adult bushbuck or possibly auditory or olfactory cues. A captured fawn's mother may be aggressive toward chimpanzees, but this is difficult to determine as human presence causes them to flee (Goodall 1986). Duiker captures are typically opportunistic, with chimpanzees seizing them if they come within reach. Chimpanzees sometimes show interest in duiker vocalizations (personal observations), but the extent to which they search for duiker is unclear.

Cooperative Hunting?

Chimpanzees will hunt alone as well as in the company of others. Solitary hunts occur rarely at Taï (16 % of hunts: Boesch and Boesch-Achermann 2000) and Mahale (28 % of hunts: Takahata et al. 1984; Uehara et al. 1992), while they are more common at Gombe (64 % of hunts: Busse 1978; Teleki 1973) where the chimpanzees appear to be highly effective solo hunters. Boesch (1994) found that Gombe chimpanzees had a success rate of around 50 % when hunting alone, capturing an average of 2.46 kg of prey within 7 min of hunting. In contrast, his estimate for the success rate of lone hunters at Taï was only 13 %. The forest canopy is lower and more broken at Gombe than it is at Taï, which may make it easier for lone chimpanzees to isolate colobus monkeys and so allow them to capture and kill their prey more often and more quickly (Boesch 1994).

Group hunts are often a case of individual chimpanzees making their own efforts in a collective setting, perhaps exploiting the panic in the prey produced by the presence of multiple hunters, and reacting to the actions of other chimpanzees. Collaborative hunting, where males take particular roles such as “drivers” and “blockers” (Boesch and Boesch 1989), appears to be the primary form of hunting among the Taï chimpanzees (77 % of hunts: Boesch and Boesch-Achermann 2000) but is rare among the East African chimpanzees (Boesch 1994; Stanford 1998; Boesch and Boesch-Achermann 2000; Watts and Mitani 2002). A division of roles between those that pursue the prey and those that wait on the ground to capture monkeys that fall from the canopy is, however, fairly common among East African chimpanzees.

There is little consensus over the degree to which such collaborative hunting can be described as cooperative. To the extent that chimpanzees take different roles and are responsive to one another’s behavior during a hunt targeting monkeys, there is good evidence for social cooperation. To demonstrate that chimpanzee hunting is functionally cooperative, however, individuals need to do better when hunting as a group. Thus, if cooperation occurs, hunting attempts should be more successful when more individuals take part, or at least certain number of hunters should be more successful than solitary hunters. At Gombe, Ngogo, and Taï, the probability of killing prey during a red colobus hunt increases with the number of hunters present, but this appears to be a simple effect of more hands grabbing at the monkeys; there does not appear to be an additional effect from males working together (Stanford 1998; Gilby et al. 2006); at Kanyawara, however, there does appear to a synergistic effect (Gilby et al. 2008). Many chimpanzees, hunting together, may be able to overwhelm the defensive strategies of the red colobus and reduce the opportunities for panicked monkeys to escape. However, the mass of prey obtained per hunter does not correlate with the number of males hunting at Ngogo (Watts and Mitani 2002), and while Stanford (1998) found that Gombe chimpanzees gained a higher return (greater mass of prey per hunter) when more than seven are hunting together, Gilby et al. (2006), using a larger dataset from the same community, found that the mass of prey per hunter actually decreased with the number of adult male chimpanzees present. By contrast, among Taï chimpanzees the number of hunters is strongly correlated with the mass of prey caught because the likelihood of capturing an adult monkey increases, but gains per hunter peak at four males (Stanford 1998) presumably because most hunts terminate after the first kill.

Scavenging

Chimpanzees are reluctant scavengers: only a handful of reports describe such behavior. Most of these observations concern the seizing of fresh kills from other predators, a behavior often labeled “piracy” (Goodall 1986; Uehara 1997; Stanford 1998), although “plundering” – the forcible stealing of goods – might be more appropriate term. At Gombe, chimpanzees have been recorded plundering fresh kills from baboons (Morris and Goodall 1977; Goodall 1986), and at Budongo, the body of infant blue monkey (*Cercopithecus mitis*) was stolen from the adult blue monkey who killed it (Newton-Fisher et al. 2002). Boesch and Boesch-Achermann (2000) report three instances of Taï chimpanzees plundering red colobus captures from eagles while the monkeys were still alive and a further four instances of chimpanzees eating the kills of eagles: presumably these monkeys were freshly killed, although this information is not reported. Given that chimpanzees are quite willing, if they can steal or beg part of the carcass, to eat prey that chimpanzees other than themselves have killed, it is not surprising that they are similarly willing to take fresh kills from other species.

True scavenging – acquiring meat from an abandoned carcass – appears particularly rare, however. In 36 years of observation at Gombe, fewer than 20 instances were recorded (Stanford 1998), and at least nine of these (all red colobus) were likely, or known, to have been previous chimpanzee kills (Goodall 1986). Similar low rates have been recorded at Mahale, seven cases in over 25 years of observation: six ungulates and one red-tailed monkey (*Cercopithecus ascanius*) (Hasegawa et al. 1983; Uehara 1997). Scavenging has not been reported from Taï: Boesch and Boesch-Achermann (2000) record ten encounters with fresh carcasses, none of which were eaten by the chimpanzees.

Most encounters with fresh carcasses result in apparently curiosity-driven behaviors in the chimpanzees, with no indication that the chimpanzees regard these carcasses as a source of meat. Stanford (1998) reports an observation from Gombe of a juvenile male briefly chewing on 1- or 2-day-old colobus meat that was ignored by the adults, and Muller et al. (1995) record a further observation from the same community of a party of chimpanzees encountering a dead bushbuck, presumed to be killed by a leopard. The chimpanzees showed strong curiosity over the body, even grooming it, and one female rolled around inside the eviscerated carcass, but they did not feed (Muller et al. 1995). By contrast, chimpanzees at Mahale did feed on the carcasses of two adult bushbuck thought to be the remains of leopard kills (Hasegawa et al. 1983).

Meat Eating

All populations of chimpanzees subsist on a primarily frugivorous diet. Typically, fruit constitutes 60–80 % of the time spent feeding (Gombe: 63 %, Wrangham 1977; Kibale: 79 %, Wrangham et al. 1996; Budongo: 64.5 %, Newton-Fisher 1999a). This is supplemented by leaves, as well as other plant materials. Even in communities that hunt frequently, such behavior constitutes a very small portion of the time spent foraging. Watts and Mitani (2002) recorded 131 predation episodes in 6 years at Ngogo (1.8 hunts per month), while Boesch and Boesch-Achermann (2000) recorded 413 hunts in a 12-year period at Taï (2.9 hunts per month). Nevertheless, as discussed above, chimpanzees do hunt, kill, and consume meat, while competition over the division of the kill can be high.

The Value of Meat

Animal tissue, including muscle, internal organs, brain, and bone marrow, provides an easily digestible nutritious package (Stanford 1996; Milton 1999). Beyond any particular calorific value, it provides high-quality protein containing all essential amino acids, as well as long-chain polyunsaturated fatty acids, and a range of key micronutrients such as calcium, potassium, magnesium, zinc, B-group vitamins, and vitamin K. Commonly, chimpanzees consume the entire animal, including bones and skin, and will compete for the smallest scraps. A single carcass can, therefore, represent an important resource, despite variation in body size between prey species: adult *Colobus guereza* weigh up to 23 kg, although Ugandan populations may not reach this size, while the western black and white colobus (*Colobus polykomos*: adult male body weight of 8–12 kg) is smaller and similar in size to the eastern red colobus (*Piliocolobus tephrosceles*: adult male body weight of 13 kg); the western red colobus (*Piliocolobus badius*) are lighter, with an adult body weight of only 5–10 kg (Kingdon 1997); and blue duiker (*Cephalophus monticola*) can weigh up to around 9 kg, with duiker (*Cephalophus* sp.) meat providing 20.8 g/100 g of protein and 3.4 g/100 g of fat (Ntiamoa-Baidu (FAO) 1997).

The quantity of meat, including the associated elements of the carcass, that is consumed by some individuals may be relatively significant. In good hunting years, the total amount of meat consumed may be more than double that consumed in poorer years. The 45 chimpanzees of the Kasekela (Gombe) community in 1992 consumed over 500 kg of red colobus meat, and their total meat consumption for the year was probably close to 700 kg. The previous year (1991), colobus meat consumption was less than 200 kg, and in 1988, this figure was less than 150 kg (Stanford 1998). Averaged over years, the level of consumption in the 1980s and 1990s seems similar to the estimate of 441 kg of meat per year for the same community in the 1970s (Wrangham and van Zinnicq Bergmann Riss 1990; Stanford 1998).

Boesch and Boesch-Achermann (2000) estimated that, averaged across the year, male Taï chimpanzees consumed 186 g per day, while females consumed 25 g per day. Their estimates for Gombe chimpanzees, similarly averaged, were 55 g per day for males and 7 g per day for females. These are similar to estimates made by Stanford (1998) of 70 g per day for males during peak hunting season and by Wrangham (1975) of 22 g averaged over males and females. Gilby (2006) estimated that, for adult males of this community in 1999–2002, an individual in possession of a kill consumed between 0.25 and 2.5 kg (mean = 1.16 kg) of meat during each feeding bout. For the Taï chimpanzees between 1987 and 1991, males consumed a mean of 0.48 kg of meat per successful hunt, while females consumed a mean of 0.13 kg (Boesch and Boesch-Achermann 2000).

Thus, meat should be a valued resource for chimpanzees, although there are observations that question this conclusion. In particular, captured prey may be eaten only partly before being discarded. In the Taï Forest, adult cercopithecine monkeys have been treated in this way (Boesch and Boesch-Achermann 2000); at Gombe, chimpanzees have been observed discarding captured adult red colobus in favor of pursing immature monkeys (Boesch 1994; Stanford 1998) and giving a carcass to another individual in order to hunt again (Goodall 1986), while in the Budongo Forest, an adult male chimpanzee captured and killed an elephant shrew (*Rhynchocyon* sp.) but took only a single bite before discarding the carcass (Newton-Fisher unpublished data). Similarly, bodies of infant chimpanzees killed by adults are sometimes only partially eaten before being handed on to another individual or discarded completely (Newton-Fisher 1999b). Furthermore, any kills made during a group hunt are typically divided in some way among some or all of the chimpanzees present.

Begging and Food Sharing

Following a kill, there is commonly a degree of competition for the meat, the intensity of which reinforces the idea that chimpanzees desire and value this resource. If the chimpanzee in possession of the carcass has companions, these individuals will attempt to acquire part of the carcass. More dominant individuals may attempt to steal the entire carcass for themselves. Others will sit around the possessor and beg for a share of the meat. Begging individuals seem to exert a lot of pressure both by their presence and by their harassing gestures and vocalizations. Chimpanzees unwilling to share will commonly move away from the crowd of begging individuals, although they are likely to be followed. When harassed by one or two others, a chimpanzee may simply turn its back to prevent them reaching toward the carcass.

Sharing of prey can be either an active or passive process. Most sharing is passive and ranges from an individual patiently scrounging the scraps that fall from a carcass as the possessor feeds, through harassment of the owner of the carcass by gestures and vocalizations, to an individual who is not in possession of the kill taking a portion of carcass without the use of aggression. Active sharing is less common and involves the individual who possesses the carcass handing part, or all, of the carcass to another chimpanzee. There are a number of theories to explain why food should be shared and the patterns of sharing observed. These include tolerated theft, reciprocity, kin selection, mutualism, buy-off, and harassment. As they apply to chimpanzees, these theories have been discussed extensively elsewhere (de Waal 1989; Mitani and Watts 2001; Fruth and Hohmann 2002; Stevens 2004; Stevens and Gilby 2004; Gilby 2006).

Patterns of sharing appear to differ between West and East African chimpanzees. In the Taï Forest, West African chimpanzees tend to divide the kill among the individuals who participated in the hunt. Older and more dominant males gain a greater share of the meat, but hunters tend to receive more than nonhunters, even when socially subordinate. The amount of meat obtained by females is not dependent on participation in the hunt, but females will support hunters over nonhunters when there is competition (Boesch and Boesch-Achermann 2000). In East Africa, at Gombe (Stanford 1998), Mahale (Nishida and Hosaka 1996), Ngogo (Mitani and Watts 2001), and Budongo (Newton-Fisher unpublished data), chimpanzees use a different strategy for the division of the carcass: males tend to monopolize the carcass and share only with particular other adults, both male and female (although it is worth noting that while Gilby (2006) found that Kasekela (Gombe) males, particularly the alpha, controlled carcasses, these males only shared preferentially with adult females with whom they exchanged grooming and did not preferentially share with particular males).

The particular sharing strategy employed by West African chimpanzees may oblige them to hunt adult monkeys. Collaborative group hunting appears necessary to increase hunting success and to reduce the time spent hunting in a habitat that favors escape by the prey but may only work if males are rewarded for participating in the hunt (Stanford 1998). Colobus monkeys are smaller in West Africa than they are in East Africa, and this might make targeting juveniles unprofitable if the meat has to be shared among all hunters. For East African chimpanzees, the larger body size of the colobus monkeys may pose a greater hazard, and East African chimpanzees show greater fear of adult colobus monkeys than do those in West Africa. Adult colobus monkeys can successfully threaten and rout chimpanzees, chasing them from trees on occasion (Nishida et al. 1979; Goodall 1986; Boesch and Boesch 1989). Given that the strategy adopted by East African chimpanzees of targeting juvenile and infant chimpanzees appears to be profitable (Boesch 1994), the additional costs of targeting adult monkeys together with a less reliable, more individualistic approach to sharing may make hunting adult monkeys a less attractive option.

Why Do Chimpanzees Hunt?

This question, which addresses the adaptive value of hunting, remains to be answered. It is only recently that quantitative analyses comparing the various hypotheses have been undertaken (Mitani and Watts 2001; Gilby et al. 2006) and, while there are efforts to draw together results from different populations (Uehara 1997; Boesch et al. 2002), systematic analyses across populations are limited (Gilby et al. 2010). Chimpanzees are omnivores, and while those who eat meat, particularly in large quantities, should gain nutritional benefits, carnivory does not appear to be critical for survival or reproduction, and thus various hypotheses have been advanced to explain the existence of their hunting behavior.

Hunting for Nutrition

Early views of chimpanzee hunting favored the view that it was driven by nutritional demands. Teleki (1973) proposed that Gombe chimpanzees hunt to compensate for nutritional shortfalls, given the strong seasonality at this site. The body weights of Gombe chimpanzees are lower during the dry season (Williams et al. 2002), which may to be the consequence of low food availability, and hunting at Gombe is more pronounced during the dry season than it is during the wet season

(Stanford 1998; Gilby et al. 2006). A nutritional perspective was also emphasized by Wrangham (1975), with a similar view emerging from research at Mahale (Takahata et al. 1984).

Energy Shortfall

The particular hypothesis that chimpanzees switch to hunting to compensate for energy shortfalls finds little support: Gilby et al. (2006) found that once party size and number of swollen (i.e., likely to be ovulating and therefore sexually attractive) females were taken into account, there was no association between diet quality and hunting among the Gombe chimpanzees. Furthermore, Mitani and Watts (2001) and Gilby and Wrangham (2007) found that chimpanzees from the Kibale forest hunted more frequently as fruit became more abundant, suggesting that chimpanzees are more likely to hunt when they have enough surplus energy. This makes sense if hunting is energetically costly, and individuals risk not gaining enough meat following division of the kill to offset such costs.

Whether this relationship between food abundance and frequent hunting applies to all populations of chimpanzees remains to be determined, but, as discussed above, hunting seasons coincide with fruit abundance in Mahale (Takahata et al. 1984; Uehara 1997) although apparently not at Taï (Boesch and Boesch-Achermann 2000) where chimpanzees may gain shares of the kill that depend on their participation in hunting (Boesch 1994). If the Taï chimpanzees capture and kill a sufficiently large prey in each hunt and if they can rely on this system of dividing the meat, then net nutritional gains would accrue to all participants.

Meat Scraps

Boesch and Boesch-Achermann (2000) suggested that the nutritional value of meat beyond its calorific value might make even small amounts significant for chimpanzees. Gilby et al. (2008) and Tennie et al. (2009) formalized this idea as the “meat-scrap” hypothesis, which assumes that hunting functions as a means of acquiring micronutrients such as vitamins B_{12} and B_6 and the minerals iron and zinc which are important for primate health and present at relatively high levels in meat but at low levels or virtually absent from primate plant foods. By consuming small amounts of meat (“scraps”), chimpanzees gain these micronutrients without having to consume vast quantities of plant material. This hypothesis assumes a threshold, a minimum amount of meat necessary to accomplish this goal (Tennie et al. 2009).

Both Gilby et al. (2008) and Tennie et al. (2009) provide support for this hypothesis. Among the Kasekela (Gombe) chimpanzees, the probability of an individual acquiring some meat increased by 18 % with each additional hunter, while the total amount of meat per hunter was not correlated to the number of hunters (Tennie et al. 2009) and in fact declined when all adult males present were considered (Gilby et al. 2006). For chimpanzees of the Kanyawara (Kibale) community, males were also more likely to obtain meat as the number of hunters increased, although once there were five or more hunters, males could do as well by begging: accordingly, focal males were less likely to hunt when more than five other males were present (Gilby et al. 2008).

Hunting for Trade Goods

The nutritional content of meat and associated tissue, together with the fact that it is both divisible and portable, means that each portion has an inherent value and can be either consumed or given to another individual. Meat could therefore be considered to be a commodity that can be traded with other individuals for other goods or services, which for chimpanzees are likely to be biases in future social interactions such as support in agonistic confrontation or increased levels of grooming. Such a "biological markets" (Noë and Hammerstein 1995) perspective is implicit in two further hypotheses concerning chimpanzee hunting, both of which see an adaptation in the nonrandom sharing of kills. While the "meat-for-sex" and "male-social-bonding" hypotheses are commonly presented as alternatives (Mitani and Watts 2001; Watts and Mitani 2002), they could be considered to be different, context-dependent outcomes of the same social strategy. This "meat-as-commodity" hypothesis proposes that chimpanzees hunt to gain possession of a commodity (part or all of an animal carcass) which has economic value within chimpanzee society (Stanford 1998); they can then trade this to further whatever proximate goals are most pressing, providing meat to females in an effort to coerce their mating behavior or to allies when they have need of them.

Meat for Sex

The first of these trade-based hypotheses, labeled "meat for sex" by Mitani and Watts (2001), was proposed by Teleki (1973). He noted that cycling females with conspicuous anogenital swellings tended to receive meat from adult males more frequently than did females without these sexual swellings and suggested that males shared meat with females in exchange for sexual access. Swollen females are attractive to males (Dixson 1998) as the swellings generally indicate approaching ovulation, although females will also show swellings when pregnant (Wallis and Lemmon 1986). Supporting evidence for this hypotheses was provided by Stanford (1998) who found that, at Gombe, the presence of a swollen female in a party of chimpanzees was the best predictor of a hunt occurring when encountering a group of red colobus and reported five observations of females begging for meat from males and only being given part of the kill after copulating.

However, in detailed analyses of the Gombe data together with data from the Kanyawara community, Gilby et al. (2006, 2010) found no support for the "meat-for-sex" hypothesis: specifically, males did not preferentially share with potentially ovulating females, and males were not more likely to hunt when such females were present. Furthermore, very few copulations occurred in close temporal proximity to meat-sharing events (Gombe: 0.6 %; Kanyawara: 0.1 %: Gilby et al. 2010), and when sharing of meat did occur between a male and a swollen female, mating was equally likely before as after (Gilby et al. 2010). Parous females at Gombe were more successful than nulliparous females at obtaining meat from males, but this was the case whether swollen (72 % vs. 44 % of bouts) or not

(60 % vs. 30 % of bouts), and Kanyawara females showed a similar trend (Gilby et al. 2010). This is likely to be due to increased persistence or intensity of begging by parous females, rather than strategic sharing by males.

Similarly, at Ngogo, the presence of swollen females was not a significant predictor of hunting once the effect of the number of males was removed. Males of this community did preferentially share meat with swollen females but did not copulate with those females at a level above chance after sharing. Furthermore, they did not gain a larger share of matings if they did share with a female, comparing female cycles in which the male shared with those in which he did not (Watts and Mitani 2002). Among the Taï chimpanzees, Gomes and Boesch (2009) found no evidence of direct exchanges of meat for sex or of a relationship between meat sharing and mating frequency.

There are also theoretical reasons to question this particular hypothesis. Female chimpanzees show a highly promiscuous mating strategy (Nishida 1968; Sugiyama 1968), typically copulating hundreds of times with multiple males during a single ovulatory cycle (Wrangham 2002). As a result, it seems unlikely that they would require meat from males before mating; furthermore, males in possession of meat are typically high ranking: such males may be those most able to coerce female mating behavior through the use of aggression and so the least likely to need to trade anything with females in return for sex. For a more detailed discussion of this topic, see Gilby et al. (2010).

Male Social Bonding

The other theory that involves using prey as a trade good is the “male-social-bonding” hypothesis. Nishida (Nishida et al. 1992; Nishida and Hosaka 1996) provided data to support the idea that males trade meat with other males in order to develop and maintain the alliances that are thought to play an important role in male-male competition for status. Mitani and Watts (2001) showed that, at least for the Ngogo chimpanzees, while the presence of a female with a sexual swelling was a significant predictor of the decision to hunt, this was an artifact of the relationship between the presence of such females and the number of adult males and that it was the number of adult males alone that predicted hunting. They also showed that males shared reciprocally, at least when considering all pairs of males simultaneously, and that there was a positive association between sharing of carcasses and support in agonistic coalitions (Mitani and Watts 2001; Watts and Mitani 2002).

By contrast, this hypothesis did not account for patterns of sharing between male chimpanzees at Gombe (Gilby et al. 2006). Hunting was more likely in parties with more males, but increasing male party size did not increase the likelihood that an individual focal male would hunt. Furthermore, these males did not share preferentially with those with whom they groomed or associated frequently (Gilby 2006). Similarly, an analysis of hunting among chimpanzees of the Kanwayara community found no support for this hypothesis, again using grooming and association as proxies for alliance partnerships (Gilby et al. 2008).

Hunting to Assess Reliability

Male chimpanzees vary in their hunting ability, as demonstrated by the proportion of hunts that they join, the number of kills that they make, and their success at hunting alone (Stanford et al. 1994; Stanford 1998; Boesch and Boesch-Achermann 2000; Watts and Mitani 2002). Among the Ngogo chimpanzees, and potentially elsewhere, good hunters are also more frequent members of the territorial patrols that monitor and probe boundaries with neighboring communities. Furthermore, males that hunt together patrol together, and the frequency of joint patrolling is correlated with the frequency with which males form coalitions and the amount of grooming between them (Watts and Mitani 2001, 2002). This leads to the hypothesis that hunting itself may have a function that is independent from acquiring meat: it demonstrates risk-taking and allows males to assess the reliability of others when faced with danger (Watts and Mitani 2001). This is essentially a refinement of Kortlandt's (1972) "hunting-to-display-social-prowess" hypothesis.

Given the risks associated with patrolling and intercommunity encounters (Goodall et al. 1979; Boesch and Boesch-Achermann 2000; Muller 2002), these kinds of mutual assessments may be important for male chimpanzees. The "hunting-as-risk-assessment" hypothesis might apply to the monkey-hunting specialists of the Taï Forest, as it appears to apply to the Ngogo chimpanzees, although it will be necessary to disentangle "hunting to assess reliability" from "male social bonding" (meat for allies) in testing the relative importance of these two ideas at both sites. This hypothesis may be interesting to consider in relation to the "show-off" hypothesis proposed to explain hunting behavior in human males (Hawkes 1991; Hawkes and Bird 2002).

So Why Do Chimpanzees Hunt?

The possibility that chimpanzees achieve nutritional benefits directly from hunting cannot be easily dismissed. The necessary nutritional studies quantifying chimpanzee diet have not been conducted, and for either of the trade-goods hypotheses to operate, there must be a nutritional gain to the individuals who receive and consume parts of the carcass. If there were not, the carcass would hold no value and could not be traded.

While it appears that chimpanzees hunt to gain meat, this is not to compensate for nutritional shortfalls. There is also essentially no support for the meat-for-sex trading hypothesis, and this can be largely discounted. That said, Gomes and Boesch (2009) found some evidence for this over a longer term (i.e., not in the immediate sharing context) among the Taï chimpanzees, which remains intriguing. The one context where females refrain from their promiscuous mating strategy is the consortship mating context (Tutin 1979). Does previous meat sharing by males increase the likelihood that females will comply with male efforts to initiate or maintain consortships? This remains to be determined.

While it seems that nutritional (i.e., calorific) gain appears to be sufficient to explain hunting in West African chimpanzees (at least at Taï: Stanford 1998) given the pattern of sharing in relation to participation, evidence that 47 % of individuals sharing a carcass appear to cheat the system (Boesch and Boesch-Achermann 2000), as well as the possibility that other factors influence hunting, needs investigation before any firm conclusions can be drawn. For the Ngogo chimpanzees, there is evidence for both the male social bonding and assessing reliability hypotheses. For the Gombe chimpanzees on the other hand, sharing appears to come down to successful harassment of those individuals possessing meat (begging), and there is no support for the male social bonding hypothesis.

The adaptive value – the function – of hunting thus remains unclear. Future work will need to consider variation in both predator and prey demography and perhaps determine more precisely the nutritional gains and energetic costs of hunting. It may also be worth testing hypotheses that address the behavior directly, rather than looking for a function in terms of relationships. It is becoming clear that chimpanzees hunt monkeys more frequently in locations where hunting costs are lower or at least where the prey should find it harder to escape; that hunting typically occurs when other food is abundant, such that hunters can absorb the calorific costs of failure; and that hunters who secure meat can gain substantial quantities in any particular bout. The question that needs to be addressed is whether the additional nutrition gained from meat translates into fitness: is there a direct fitness benefit to hunting?

Marginal Gains

McGrew (1992) showed that female chimpanzees who were more successful at gaining meat had greater numbers of surviving offspring, but it remains unclear whether males who gain more meat also derive fitness benefits. While it seems unlikely in calorific terms (there is no support for the energy shortfall hypothesis), there may be particular nutrients that are valuable, as suggested by the "meat-scrap" hypothesis. That hypothesis, however, focuses specifically on micronutrients, considering macronutrients such as protein and fat merely as helping to reduce dietary bulk (Tennie et al. 2009), and, with its focus on the minimum threshold, encounters problems explaining the variation in hunting between communities: if obtaining these micronutrients is critical, why are chimpanzees from communities where meat eating is rare able to maintain health and fertility? If the threshold is so low that these chimpanzees can reach it, why do then chimpanzees hunt substantially more frequently elsewhere?

The route out of this conundrum is to recognize that fitness is relative and that for male chimpanzees their primary reproductive competitors are the other males of their community. Thus, any benefits of meat eating need to be evaluated against these rivals, rather than in absolute terms. Here, I propose a new hypothesis that broadens the "meat-scrap" hypothesis as well as recognizes this relative nature of fitness. This new "marginal gains" hypothesis assumes (1) that meat is valuable specifically for *both* macro- *and* micronutrients, rather than its calorific value, and (2) that individuals benefit through marginal gains over their competitors.

For instance, small amounts of high-quality protein may provide an edge in sustaining muscle mass and thereby improving success in competing for high social rank. This "marginal gains" hypothesis predicts that individuals should value even the smallest scraps, as there is no threshold, and should attempt to gain more than rivals.

"Marginal gains" is therefore consistent with patterns of begging and food sharing seen in East African chimpanzees: individuals without meat are strongly motivated to acquire whatever they can, yet males gain over their rivals by not sharing and so need to suffer harassment costs before sharing. In communities where males willingly share with alliance partners, the need for allies may also outweigh any marginal gains from consumption: it may be no accident that the strongest evidence for sharing with allies comes from the community (Ngogo) with the largest number of adult males. If marginal gains show diminishing returns, this would account for individuals relinquishing possession of kills after feeding and diminishing motivation to acquire and consume meat with the quantity ingested.

Parenting Effort

As a final note, even if there are no nutritional benefits to be gained by males, simply by virtue of hunting they create a resource supply (converting live prey into food) for females that would be otherwise unavailable. If, on average, the most successful hunters are also, for whatever reason, the most successful at fathering offspring, then hunting will function as a form of parenting effort (as has been suggested for male chimpanzee territoriality: Watts and Mitani 2001) without any need for active sharing or provisioning by males. The natural variation in hunting and meat eating within and across chimpanzee communities should provide the opportunity to test such ideas, and more detailed, cross-site studies are needed.

Conclusions

Chimpanzees are not the only primates that hunt vertebrate prey. Baboons (*Papio* spp.) also hunt opportunistically, targeting small ungulates (Morris and Goodall 1977; Strum 1987), while red-tailed monkeys (*Cercopithecus ascanius*) stalk green pigeons (*Treron calva*) (Furuichi 2006). Among New World primates, capuchin monkeys (*Cebus* spp.) prey upon a variety of species with *Cebus capucinus*, perhaps best studied, showing a focus on squirrels, infant coatis, and birds (Rose 1997; Rose et al. 2003), while some squirrel monkeys (*Saimiri* sp.) hunt bats (Boinski and Timm 1985; Souza et al. 1997).

Among the great apes, vertebrate predation appears to be rare or absent in both gorillas and orangutans, although bonobos (*Pan paniscus*), the phylogenetic sister species to chimpanzees, do hunt vertebrates. Recorded prey species include black and white colobus (*Colobus angolensis*), red-tailed monkeys (*Cercopithecus ascanius*) (Sabater Pi et al. 1993), bushbabies (*Galago demidovii*) (Hohmann and Fruth 2008), flying squirrels (Kano and Mulavwa 1984), and forest duiker (*Cephalophus* spp.) (Hohmann and Fruth 1993; Fruth and Hohmann 2002).

Hunting by bonobos typically occurs at a lower rate than in chimpanzees: Fruth and Hohmann (2002) report only nine kills in 46 months of observation, seven of which were duiker, although data from the Lui Kotale site shows higher rates of predation: 18 kills in 60 months of observation (Hohmann and Fruth 2008).

While hunting is thus not unique to chimpanzees among the primates, it does appear to be a ubiquitous aspect of their behavior, occurring in all populations studied thus far. The picture that has emerged from these studies is one of diversity but with some common themes. Across populations, hunting is a predominately male activity. Chimpanzees hunt a variety of vertebrate prey, but there is a common focus on medium-sized mammals, particularly primates, and especially colobus monkeys. Red colobus appear to be the preferred prey, although the species (and body size) of red colobus varies across Africa. Chimpanzees appear to impose significant predation pressure on their main prey species, but the intensity and frequency of hunting vary between populations and from month to month within single communities. Hunting is typically opportunistic on encountering potential prey, although there is some evidence of searching. Hunts can be solo or group efforts, and the degree to which individual chimpanzees hunt together varies between East and West African populations. This appears to be related to the way the kill is divided following the hunt. In West Africa, the kill tends to be shared according to participation in the hunt and individual hunters collaborate, taking different roles, whereas in East Africa, the kill is often consumed selfishly or shared under pressure and may be shared with other males in the hope of future coalitional support; group hunts are more akin to multiple, simultaneous individual efforts to secure prey. In both East and West African populations, the presence of particularly skilled or motivated "impact" hunters increases hunting frequency and success.

It is important to recognize that this picture comes largely from detailed systematic studies of only a handful of communities (Gombe, Mahale, Taï, Ngogo, Kanyawara). Comparable systematic studies of hunting by chimpanzees in other populations are lacking, although some data are available from almost every population studied. In addition, much of the research effort has focused on chimpanzees and red colobus monkeys. Far less is known about chimpanzee hunting of other species and the nature and importance of hunting in populations that are not sympatric with red colobus. Certainly, chimpanzees without red colobus to hunt appear to hunt less frequently (Basabose and Yamagiwa 1997; Newton-Fisher et al. 2002), and it is unclear what impact low levels of hunting, providing fewer carcasses to share and consume, have on patterns of chimpanzee behavior.

Addressing these shortcomings is essential if we are to use an understanding of chimpanzee hunting behavior to shed light on the behavioral ecology of the hominins. The ubiquitous nature of chimpanzee hunting, the common occurrence of food sharing, and the diversity in the patterns of these behaviors, together with the close phylogenetic relationship between chimpanzees and humans, ensure that consideration of chimpanzee hunting is essential in any discussion of the role played by meat eating and food sharing in the behavioral ecology of early hominin species. The radiation of early hominins encompassed a number of species with different morphologies, and it seems likely that these hominins showed both within and between species variation in habitat and behavioral ecology (Foley 1997). The chimpanzee-red colobus system may be a useful model for some of that variation, but it remains necessary to understand the role of hunting and meat eating across chimpanzee populations, including those with an impoverished resource base. Already it is clear that different populations target different arrays of species, specialize or generalize their choice of prey, and hunt and use meat in different ways. Future studies of new populations are likely to increase this picture of diversity, and systematic tests of the hypotheses for hunting and meat sharing will clarify both why chimpanzees hunt and the importance of this behavior for the study of human evolution.

Contents

Abstract

In primates, cooperative acts have been observed such as communal rearing of offspring, cooperative mobbing of predators, supporting others in fights, and grooming others. Grooming builds up a social bond between the partners, helps in repairing relationships, and produces all kinds of benefits for the groomee, such as the reduction of parasites and of tension. Although the costs for the groomer are low, it has been regarded as an altruistic act and therefore is expected to be preferably directed toward kin or to be repaid by being reciprocated or exchanged for another service (e.g., support in fights, help in rearing offspring in the case of communal breeding systems, or access to some object, such as food, or some individual such as a female, an infant, or members of another group).

The formation of coalitions may result in the maintenance or in the increase of the dominance of an individual, in the expulsion of certain individuals from a group, in taking over a group, in the defense of the home range against other groups, in getting access to estrous females, and in the protection of an infant or adult female. The degree of cognition involved in coalitions is unclear.

Which members of a group cooperate differs from species to species; it may be influenced by genetic and social relationships, by the size and the composition of the group (the sex ratio), by the degree of competition, and by the distribution of food.

Introduction

Cooperation in primates varies greatly among members of a group. For instance, individuals groom the fur of others, help others in fights, collect food together (for communal hunting in chimpanzees, see chapter "▶ The Hunting Behavior and Carnivory of Wild Chimpanzees," Vol. 2), share food, and may help in raising the offspring of others. Furthermore, group members cooperate against danger from the outside. They mob predators together and form coalitions to defend their home range against other groups.

For a long time, behavioral acts such as coalition formation, grooming, and food sharing have been regarded as "altruistic" (costing the actor more than it receives), and therefore, the main explanations have been the theories of kin selection (Hamilton 1964) and reciprocal altruism (Trivers 1971). However, it has become increasingly clear that these supposedly altruistic acts are beneficial for both cooperation partners. For instance, grooming not only reduces tension in the receiver but also in the performer (Shutt et al. 2007), and grooming a high-ranking individual serves as a protection against aggression for the subordinate. Coalition partners may increase their access to fertile females or help maintain their status quo within the dominance hierarchy. Furthermore, whereas coalitions were originally supposed to require high cognitive abilities, it is increasingly acknowledged that these patterns may arise from simple behavioral rules (as for cognitive mechanisms, see also chapters "▶ Evolution of the Primate Brain," Vol. 2, "▶ Great Ape Social Systems," Vol. 2, and "▶ Primate Intelligence," Vol. 2). Besides, cooperation depends on the social system and the kind of primate involved (such as Old World monkeys vs. New World monkeys). We will treat these aspects below.

Social System

Cooperation among individuals of a group depends on the species and its social system. There are many species of primates, and they live in many different kinds of social systems, as solitary individuals, monogamous pairs, single-male groups, multimale groups, or fission-fusion systems (see chapter "▶ Great Ape Social Systems," Vol. 2). In group-living species with many females, the males usually migrate and the females remain in their natal group for life (female-philopatry), e.g., baboons, macaques, and vervets. Wrangham (1980) refers to these species as “female-bonded,” because the females are more kin related than the males. In such groups, female social relationships and cooperation are developed much further than among the males of the group and also further than among females of species that are not female-bonded, the so-called female-transfer species. In line with this, grooming reciprocation among individuals of the resident sex is higher than among those of the sex that transfer (Hemelrijk and Luteijn 1998). In chimpanzees, for instance, males stay together and females migrate. Here, relationships among males are more cooperative than among females (male bonded). Greater cooperation among the resident than the migrating sex has been attributed to the closer relatedness of the resident sex. Evidence for closer relatedness in the resident sex is found among macaques (Ruiter 1998) and chimpanzees (Goldberg and Wrangham 1997). Although it has also been argued that male chimpanzees that cooperate are more often more closely related than those that do not, this is not supported by evidence from DNA-typing methods (Goldberg and Wrangham 1997; Langergraber et al. 2007). Furthermore, social relationships differ between Old World monkeys and New World monkeys: among Old World monkeys, they are more developed (Dunbar 1993). The causes of these differences are unknown.

Grooming

Grooming occurs in all primate species (Goosen 1987), and of all affiliative social acts, it is the one that is displayed most frequently. It consists in picking through the fur to remove parasites and to clean small injuries. An individual may clean its own fur (autogrooming) or that of another (allogrooming). Because allogrooming is a social act, it has sometimes been questioned whether it has any cleaning function at all. That allogrooming actually aims at cleaning is shown by Zamma (2002): Japanese macaques groom more often those spots of others and of themselves that tend to house more lice and eggs. Furthermore, in his study of 17 spots on the bodies of 19 species of primates, Barton (1985) has shown that individuals groom others particularly at spots that they themselves cannot easily reach. Therefore, spots on the skin that are groomed more often by others are groomed less often by the individual itself and vice versa.

Since in species that live in larger groups, individuals spend more time grooming, grooming clearly also has a social function (Dunbar 1991, 2003). Note that this correlation with group size appears more clearly among Old World monkeys than among New World monkeys. This may arise because coalition formation is more important in Old World monkeys and grooming may be helpful in building up alliances. In line with this, it has been found that individuals groom more often those partners they also support more frequently. This has been observed in several species such as female chimpanzees (Hemelrijk and Ek 1991), male chimpanzees (Watts 2002), gorillas (Watts 1997), baboons (Seyfarth 1976; Smuts 1985b), female vervet monkeys (Seyfarth 1980), and several species of macaques (Hemelrijk 1994; Kapsalis and Berman 1996; Schino et al. 2007; Silk 1992b; Ventura et al. 2006).

Grooming relationships among males of the genus *Macaca* (Hill 1994) and among females of a number of female-bonded species (Hemelrijk and Luteijn 1998) are influenced by the identity of the migrating sex and by the composition of the group, namely, the sex ratio. As to the sex ratio, it has been shown that food provisioning led to a female-biased sex ratio in a number of groups of species of the genus *Macaca* (Hill 1994, 1999). This arose because provisioned food was offered in clumps and thus led to stronger competition, and this drove several males away. Groups that were not provisioned had a more equal sex ratio, because in these groups, competition for concentrated food sources was less. This may have allowed males to be friendlier among themselves and groom each other more often. Further, in the case of an even sex ratio, more grooming among males may arise because the number of males to be groomed is greater and the number of females to groom with is smaller than in groups with a female-biased sex ratio. This results in a higher number of potential male partners to affiliate with and therefore more affiliation among males. Among females, grooming relationships seem to be influenced by competition for access to males. In a large comparative study of female-bonded species of primates, Hemelrijk and Luteijn (1998) discovered that the degree of reciprocation of grooming among females increased with the increase in the relative number of adult males in the group. This was attributed to female competition for access to males; the lower the number of males present, the stronger the competition among females to affiliate with males. This competition hindered females from building up good relationships among themselves. This argument is supported by the fact that grooming reciprocation increases more strongly with sex ratio among females in a single-male group (where sex ratio depends on group size) than in a multimale group. Even if the number of males increases in multimale groups, this increase is not entirely to the profit of the time the males have available for females. There are two reasons for this: first, because males will intervene in interactions of other males with females and second, because males will interact among themselves, which reduces the time available for positive social interaction with females. In single-male groups, however, interactions and interventions among males are lacking.

The positive effect of grooming on relationships is supposed to be a reduction of tension, increase of trust, and restoration of the relationship after a fight. As regards tension, grooming calms and relaxes the groomee and the groomer (Terry 1970; Goosen 1975; Shutt et al. 2007). In the groomee, the heartbeat slows down (Boccia et al. 1989) and the rate at which it shows a displacement behavior, such as scratching, decreases (Schino et al. 1988). Keverne and coauthors (1989) have shown that being groomed is pleasurable because it increases the concentration of endorphins in the brain. Grooming is supposed to maintain relationships in the light of competition, because hamadryas females with an established relationship are observed to groom each other more often if a dyad is accompanied by others than if the dyad is temporarily separated in cages (Stammbach and Kummer 1982). Furthermore, grooming is also supposed to restore a relationship: often after fights, the frequency of grooming and other affiliative behavioral acts between former opponents is higher than when no fights take place. This is known as "reconciliation" and has been shown to occur in species of all major radiations of primates (Aureli et al. 2002; Silk 2002). Being attacked implies that there is a high chance that more aggression will follow. Friendly postconflict reunions reduce this aggression and restore the relationship. This function appears from the elegant experiments by Cords (1992). She determined at what distance pairs of long-tailed macaques could drink next to each other without trouble. Then she showed that after aggression among the members of a pair, its ability to jointly exploit the resource was seriously reduced. If, however, after such a conflict, a friendly reunion took place, the use of the resource was completely restored to normal. Relationships are, however, not always damaged by aggression; the damage depends on the context in which the aggression takes place. In the case of competition over food, the relationship keeps its status quo even without reconciliation. Furthermore, the occurrence of reconciliation depends on the value of the relationship. According to the "valuable relationship hypothesis," reconciliation particularly occurs in relationships of great value (Aureli et al. 2002; Silk 2002). This theory is supported by the following experiment by Cords and Thurnheer (1993): when macaque partners are obliged to cooperate with each other to obtain food, they reconcile three times more often than when cooperation is not necessary. In line with this, reconciliation has been shown to occur more often in those relationships that are characterized by a high frequency of support (such as in macaques among members of a matriline; and in gorillas reconciliation occurs in the cooperative relationship between the sexes rather than among females (Watts 1995a, b)). Further, in general, more friendly postconflict reunion occurs among those individuals that exchange high levels of friendly behavior.

As to the cognition used in displaying reconciliation, there is debate. According to de Waal and Yoshihara (1983), the cognitive capacities needed are memory of the former opponent and conciliatory predisposition. On the other hand, the cognitive requirements must be slight because juveniles already reconcile in the same way as adults do (Aureli et al. 2002). No cognition specific for reconciliation is required however according to an individual-based model concerned with individuals that group, groom, and fight (GrooFiWorld, see Puga-Gonzalez et al. 2009). According to this spatially explicit model, statistically "reconciliation" is observed, because former opponents are closer after a fight than they are on average otherwise. Consequently, former opponents have more opportunities to groom each other after a fight than otherwise. Since individuals are more likely to groom partners that are close by and to groom others when they themselves feel stressed (which individuals do after a fight), this results in behavior which primatologists have labeled reconciliation. Thus, empirical studies should control for effects of proximity. Indeed in the few empirical studies that controlled to some degree for proximity, the rate of reconciliation was significantly reduced (Call 1999; Call et al. 1999; Majolo et al. 2009; Matsumura 1996). Another reason to take the need for further control of proximity seriously is that the model GrooFiWorld also shows that the reconciliation-like behavior happens, like in empirical data, more often among "valuable relationships." Yet, individuals in the model are not aware of who their friends are. Further, like in empirical data, reconciliation-like behavior in the model is more frequent in egalitarian than in despotic societies. In the model, this is a side effect of the relative rate of grooming versus fighting which is higher in egalitarian than in despotic societies; in empirical data, it was supposed to be caused by a greater uncertainty about dominance relationships in egalitarian societies.

Further, it has been shown that the frequency and stability of grooming relationships over time have a positive impact on the fitness of the individual. For instance, in a population of wild baboons studied over 15 years, Silk and coauthors (Silk et al. 2010, 2003, 2009) show that strong social bonds among females increase their life span and that of their offspring. This effect was independent of dominance rank and environmental conditions. Similarly, in a study of wild Assamese macaques, the strength of the social bonds among males appeared to be directly and positively related to the number of offspring they sired (Schuelke et al. 2010).

Grooming: Kin Selection, Reciprocation, and Exchange

Grooming does not only lead to social bonding but may also be considered an altruistic trait because of the costs to the actor and the advantage for the receiver. Although its cost (expenditure of energy) is low (Wilkinson 1988), grooming may cost time that might be used for (a) vigilance and (b) foraging. Two studies report a decrease in vigilance, one among captive rhesus monkeys and the other among wild blue monkeys. In rhesus macaques, mothers become less vigilant during grooming, and consequently their infants were more often harassed by group members (Maestripieri 1993). Blue monkeys became significantly less watchful of predators when grooming than when foraging or resting (Cords 1995). Grooming does not diminish time for foraging (Dunbar and Sharman 1984): in two species of baboons (olive baboons and gelada baboons), increased foraging time was associated with a decrease in the length of time spent resting, but time spent grooming remained the same. This may be an indication of the importance of grooming. Indeed, baboons and macaques devote up to 20 % of their time to grooming others (Dunbar 1988).

Within the framework of grooming as an altruistic act, the distribution of grooming partners can be explained either by the theory of kin preference (Hamilton 1964) or by reciprocal altruism (Trivers 1971). In support of kin selection, the most intense grooming bonds are found between mother and offspring, and in general in most primates, individuals aim their grooming primarily at their kin (Gouzoules and Gouzoules 1987; Schino 2001).

When altruistic acts are directed toward unrelated individuals, the expectation is that something should be received in return (Trivers 1971). Recent models suggest that parceling of grooming bouts in small periods, in which the role of actor and receiver alternates, is a method of achieving reciprocation (Connor 1995). During a certain part of their grooming bouts – ranging from 5–7 % for *M. radiata* (Manson et al. 2004) to 74 % in *Callithrix jacchus* (Lazaro-Perea et al. 2004) – partners groom each other alternately. In grooming bouts of female chacma baboons, where both partners groom each other in turn, the total grooming duration by both partners is indeed significantly correlated between bouts (Barrett et al. 1999, 2000). Similar findings were made in white-faced capuchin monkeys and bonnet macaques (Manson et al. 2004) but not in Japanese macaques (Schino et al. 2003).

Furthermore, it was argued that the time during which an individual grooms another should increase as a sign of the increasing trust among partners (model of "raise the stakes," Roberts and Sherratt 1998). Increasing bout lengths have not, however, been confirmed in empirical studies of either capuchin monkeys or baboons (white-faced capuchins, Manson et al. 2004; chacma baboons, Barrett et al. 2000). Instead in chacma baboons, bout length even decreased over time.

Grooming may either be reciprocated for its own sake or interchanged for another service, e.g., support, reduction of aggression, or access to something or someone (such as food, a female, an infant, or another group) or support in rearing offspring (in communal breeding systems). Here, a major problem is how to define reciprocation operationally. Reciprocation and interchange may be considered as a correlation between the number of times each individual gives something to a partner and how often it receives this service from him/her in return. This summed value over a period of time may be studied at the group level, the so-called actor-receiver model (Hemelrijk 1990a, b). Reciprocation in grooming occurs in many species, for instance, among both males and females in chimpanzees in captivity (Hemelrijk and Ek 1991) and among male chimpanzees under natural conditions (Watts 2000a), among female Samango monkeys (Payne et al. 2003), blue monkeys (Rowell et al. 1991), baboons (Seyfarth 1976), marmosets (Lazaro-Perea et al. 2004), female Japanese macaques (Schino et al. 2003), and gorillas (Watts 1994). Such a correlation of reciprocation may, of course, occur as a side effect of other correlations. For instance, when higher-ranking individuals groom others more often and when everyone grooms others more often according to the rank of the partner, grooming reciprocation follows automatically (Hemelrijk 1990b). To exclude such alternative explanations, partial matrix correlations are useful (Hemelrijk 1990a). Both in chimpanzee males and females (Hemelrijk and Ek 1991; Watts 2002) and in savanna baboons (Seyfarth 1976; Hemelrijk 1991), grooming reciprocation remained significant even after partialling out the effect of other variables such as dominance and support. In other studies, grooming reciprocation was present while controlling for kinship (hamadryas baboons, Stammbach 1978; vervet monkeys, Fairbanks 1980; Japanese macaques, Muroyama 1991). Only in a few studies no reciprocation of grooming was observed (bonobos, Franz 1999). Recently, reciprocation of grooming among female primates was confirmed in a meta-analysis of 48 groups of 22 species. Results remained significant even after controlling for kinship (Schino and Aureli 2008a).

Apart from being reciprocated, grooming may also be exchanged for other services. For instance, Seyfarth (1977) argues that higher-ranking females are more attractive to groom because from them more effective support in fights can be expected in return. Since females will compete to groom the highest-ranking partners, and since higher-ranking females will win this competition, each female will in the end groom most frequently with those partners adjacent in rank and be groomed most often by those ranking just below her. Seyfarth used this model to explain the observation that in several female-bonded primate species, such as baboons (Seyfarth 1976), vervets (Fairbanks 1980), and stump-tailed macaques (Estrada et al. 1977), females aimed at grooming up the hierarchy and mainly at those that were next in hierarchy (Seyfarth 1980). Since then, these patterns have statistically been studied in many species. In a number of them, particularly Old World monkeys (such as certain species of macaques, e.g., rhesus monkeys (Kapsalis and Berman 1996), chimpanzees (Hemelrijk and Ek 1991; Watts 2000b), and bonobos (Franz 1999; Vervaecke et al. 2000)), these patterns were, at least partly, confirmed, but in others evidence is lacking, for instance, in female langurs (Borries et al. 1994), in blue monkeys (Cords 2000, 2002), and in New World monkeys, such as wedge-capped capuchins, *Cebus olivaceus* (O'Brien 1993), and tufted capuchins, *Cebus apella*, in both wild (Di Bitetti 1997) and captive colonies (Parr et al. 1997; Schino et al. 2009), but not always (see Tiddi et al. 2012). There was even a trend against grooming higher-ranking animals because individuals groomed down the hierarchy among capuchins and in callitrichids (Lazaro-Perea et al. 2004). In callitrichids, this is suggested to have a function in the communal breeding system: the breeding female (i.e., the alpha-female) uses grooming to make lower-ranking individuals stay in her group in order to help her bring up her young.

Furthermore, the relation between grooming and the receipt of support is doubted. Although correlations were found in studies of several species, such as vervets (Seyfarth 1980), baboons (Seyfarth 1976; Hemelrijk 1990a), female chimpanzees (Hemelrijk and Ek 1991), male chimpanzees (Watts 2002), bonobos (Vervaecke et al. 2000), capuchins (O'Brien 1993), and one group of bonnet macaques (Silk 1992a), they were lacking in an earlier study of the same group of bonnet macaques (Silk 1982), in rhesus macaques (de Waal and Luttrell 1986), and female baboons (Silk et al. 2004). The relation is supported by two experimental studies dealing with vervets and long-tailed macaques. Seyfarth and Cheney (1984) recorded a call of vervets that seems to solicit support from others. They played it back to individuals of a natural colony of vervets that had recently been groomed by the caller and to others that had not. The length of time individuals looked up at the speaker was considered to be an indication of the tendency to support the caller. Among nonrelatives, individuals looked at the speaker longer when the caller had recently groomed them. In this experiment, it remains uncertain, however, whether looking up at the speaker actually indicates a readiness to support him or her. Therefore, in an experiment with long-tailed macaques (Hemelrijk 1994), actual support was measured directly. Trios of females were separated from the group. After two high-ranking individuals had been given the opportunity to groom, a fight was provoked between one of them and a low-ranking female. The frequency with which the third high-ranking female intervened in the fight was counted. The third female appeared to support only the other high-ranking female, and she did so more often after she had been groomed by her than if not. This supports the notion of a relationship between being groomed and supporting. It is not definitive evidence for an exchange, however, because being groomed may increase the tendency to support in general, even on behalf of those by whom the supporter was not groomed at all. Furthermore, individuals appear to support the aggressor but not the victim; therefore, it is as yet unknown whether a similar association with grooming holds also for victim support (which is more risky). Besides, these experiments do not show whether varying amounts of grooming lead to varying amounts of support. A recent meta-analysis of grooming and support based on 36 studies from 14 species of primates, Schino (2007) states that pairs of females that groomed each other preferentially also supported each other more. However, in this study, it was not specified whether grooming was given or received, and thus it is not clear whether an actual positive correlation for the exchange between grooming and support exists at all in their data.

Henzi and Barrett (1999) suggest that the receipt of support is not the major benefit of grooming because grooming occurs also among females that do not support at all, for instance, in certain groups of chacma baboons (in the Drakensberg). Instead, they argue that the short-term benefit of grooming is the decrease risk of aggression and harassment from others during the grooming bout itself (as suggested for bonnet macaques (Silk 1982) and capuchin monkeys (O'Brien 1993)), because support is rare in female-bonded species, although those females groom each other. Further, Henzi and Barrett (1999) argue that the degree to which grooming should be reciprocated or exchanged for something else depends on the competitive regime; when resources are widely distributed and cannot be monopolized, competition is weak, individuals equal each other in power, and grooming should be reciprocated. If resources can be monopolized, however, competition is intense, power differences are great, and grooming should be exchanged for increased access to resources. In line with this, in a comparison between groups and in a study of the changes in the same group over time, grooming appears to be reciprocated if competition is weak rather than intense (Barrett et al. 1999, 2002). Similarly, in a meta-analysis (Schino and Aureli 2008b) and in an individual-based model (Puga-Gonzalez et al. 2009), grooming reciprocation becomes weaker when the dominance hierarchy is steeper (thus competition is stronger). For this, different cognitive explanations are given. Schino and Aureli (2008b) argue that individual primates adjust their distribution of grooming depending on their competitive regime. According to the computational model, GrooFiWorld model (Puga-Gonzalez et al. 2009), reciprocation of grooming is directly influenced by the asymmetry of risks of losing a fight from an opponent. Here, reciprocation of grooming decreases if the hierarchy is steeper because high-ranking individuals experience less risk in attacking the lower-ranking ones, and therefore, they are more likely to attack them than to groom them, whereas for the lower-ranking ones, the opposite holds. Conversely, if the hierarchy is weaker, risk asymmetries are smaller and individuals are more similar in their tendency to attack and groom each other. A third explanation for the decrease of reciprocation of grooming when competition is more intense is found in the fact that intense competition is associated with a sex ratio that is more skewed toward adult females. Weaker grooming reciprocation in groups with more females has been discovered in several primate species by Hemelrijk and Luteijn (1998) and is attributed to stronger competition among females for access to males. Note that differences in degree of competition for access to males may also explain the pattern of grooming reciprocation in the baboons studied by Barrett and coworkers.

Grooming is also supposed to be exchanged for access to food. The best evidence for this comes from two experiments, one with long-tailed macaques by Stammbach (1988) and the other with vervet monkeys by Fruteau et al. (2009).

In both studies, authors trained individual members of a group to become experts in operating a food apparatus. During the period in which it was the expert, this individual appeared to be groomed significantly more often.

Note that “food sharing” in primates almost exclusively means passive tolerance toward others when others take away a bit of food and that active giving is extremely rare (McGrew 1992). In a food exchange experiment among captive chimpanzees, de Waal (1997) found some evidence that females allow others to take away food more easily if they have been groomed by them in the preceding 2 h than if not. Food sharing and its reciprocation seems, however, largely a matter of mutual tolerance rather than intentional reciprocation, as is shown in experiments with brown capuchin monkeys (Waal 2000).

If males groom females, this is further supposed to increase a male’s access to mating partners and thus reproductive success, for instance, in chimpanzees, baboons, and rhesus monkeys. In chimpanzees, this has been regarded as a kind of “bargaining for sex” (Goodall 1986). For instance, Gumert (2007) shows that male long-tailed macaques groomed preferentially those females with whom they mated more. Similarly, chimpanzee males groomed more often those females with whom they mated more frequently mainly during the period of female tumescence; this relation, however, resulted neither in a long-term bond (Hemelrijk et al. 1992) nor led to more offspring from the females that were groomed more often by the male (Hemelrijk et al. 1999; Meier et al. 2000). Hence, male grooming of females may simply function to calm down the male’s aggressive tendency or the tendency of the female partner to flee, and therefore, it need not be considered as a kind of exchange or currency. Furthermore, male rhesus monkeys mainly groom females during the mating season, and captive females prefer males who groom them most (Michael et al. 1978); yet, there are no long-term reciprocal bonds between the sexes (Maestripieri 2000). Long-term sociopositive relationships between males and females have been described, however, for savanna baboons (Seyfarth 1978a, b; Smuts 1985b; Palombit et al. 2000).

In several species, grooming and embraces are used to get access to newborn infants, e.g., in baboons (Rowell 1968; Frank and Silk 2009), patas monkeys (Muroyama 1994), moor macaques (Matsumura 1997), sooty mangabeys and vervet monkeys (Fruteau et al. 2011), and spider monkeys (Slater et al. 2007). Furthermore, if low-ranking female chacma baboons want access to a newborn from a higher-ranking mother, they need to groom the mother longer in proportion to the size of the difference in rank (Henzi and Barrett 2002).

Coalition Formation

Here we deal only with those coalitions that are targeted at other group members and not at other groups (for coalitions against other groups, see section “Collective Defense of Home Ranges”). A coalition (or alliance) is a coordinated attack by two or more individuals (the coalition partners or allies) on one or more opponents, the so-called targets (Chapais 1995). Coalitions may start in several ways: two individuals may attack a common victim, a coalition partner may spontaneously participate in an ongoing fight, or it may join after being enlisted by one of the combatants. Several types of coalitions are distinguished on the basis of their form and their effect (Chapais 1995; van Schaik et al. 2004). As regards form, the distinction is between coalitions of members (a) that rank above the target (called "all-down"), (b) that rank below the target (called "all-up"), or (c) of which one ranks above the target and another below it (called "bridging" coalitions or alliances). As regards effects, a distinction is made between (a) alliances that reinforce the existing rank order and therefore are "conservative"; (b) coalitions that cause one individual to change rank and thus are "rank changing"; or (c) coalitions that cause more individuals to change rank, e.g., when two lower-ranking individuals defeat a top male, and thus are "revolutionary." Coalitions usually involve three individuals (a triad), but more individuals may participate (a polyad).

As regards the cognition involved in the formation of coalitions, opinions differ. Harcourt (1988) suggests that primates form coalitions for strategic reasons and that they must take into account a complex set of information about their own power and that of their allies in comparison to that of their opponent and allies. For instance, when recruiting support, an individual should not only be aware of the social relationships between itself and other individuals but also of the relationships among the other individuals, so-called triadic awareness (Harcourt and de Waal 1992; Paxton et al. 2010; Schino et al. 2006; Silk 1999). Along these lines, in a comparative study between a captive group of long-tailed macaques and one of chimpanzees, coalitions of chimpanzees appeared to be more frequent and larger than those of macaques, and this was considered as an indication of their greater cognition (de Waal and Harcourt 1992). Others argue, however, that coalition behavior may develop with little planning and anticipation of the results because individuals may passively learn to recognize the advantage of joining forces (Chapais 1995). Along similar lines, the pattern of coalitions in sooty mangabeys and Barbary macaques may result from simple behavioral rules such as "support the higher-ranking individual in a conflict," "solicit support from potential allies that outrank yourself and the target," and "choose the strongest partner at hand" (Range and Noë 2005; Bissonnette et al. 2009). The simplest cognition involved in coalitions is given in a modeling study of individuals that group and attack each other diadically (Hemelrijk and Puga-Gonzalez 2012). Here incidental coalitions were observed following the empirical definition of coalitions, namely, that after a fight between two individuals, a third nearby individual attacked one of the former opponents. Remarkably, these incidental coalitions are of the three different types (i.e., conservative, bridging, and revolutionary) with a frequency of occurrence similar to that in empirical data.

During fights, individuals may display so-called enlisting behavior by which they seem to try to attract others into the fight. This may consist of a rapid movement of the head between the opponent and the individual from whom help is requested, called "headflagging" and "pointing" (de Waal et al. 1976; Noë 1992; Silk 1999). Male bonnet macaques recruit support via "headflagging" with a success rate of 24 % (Silk 1999). In chimpanzees, several behavioral actions are shown by fighting animals to a third individual that is not (yet) involved in the fight, and these are indicated as "side-directed behavior" (de Waal and van Hooff 1981). One action is the so-called "hold-out-hand" gesture in which an individual stretches out its hand toward a potential helper (de Waal and van Hooff 1981). The effectiveness of such solicitation behavior in chimpanzees is unclear. In contrast to the positive results by de Waal and van Hooff (1981), in another study of the same colony by Hemelrijk et al. (1991), most support was obtained without preceding side-directed behavior, and it was clear that side-directed behavior was not a precondition for acquiring help in fights. Besides, side-directed behavior was rarely followed by support, and there was no indication that it increased the chance of receiving help. Note that also if the analysis was confined to cases of hold-out-hand behavior, hold-out-hand appeared not to result in obtaining support. This is in line with the experimental observations of chimpanzees by Hare and coauthors (2004): they discovered that chimpanzees are unable to understand pointing toward an object (Tomasello et al. 1997) but that chimpanzees easily anticipate the stretching arms of those who want to take away something that is of interest to them. Thus, it appears that they are better equipped to compete than to cooperate. Side-directed behavior is mostly displayed by females when they are threatened and is significantly concentrated on higher-ranking individuals; thus, side-directed behavior may be beneficial to the soliciting individuals in the sense that it tends to bring them nearer to a high-ranking individual, which may have a protective effect as a threat to the original opponents (Hemelrijk et al. 1991).

In interventions in fights, it is usually the aggressor and the winner of the fight that is supported. This is less risky than supporting the victim. Notable exceptions are mothers supporting their offspring (see section "Youngsters") and the "control role" of the alpha-male. For instance, in a captive colony of Japanese macaques (Watanabe 1979), the alpha-male more often than other males supports aggressees, in particular babies and youngsters, against adults. This is called a "control role." A similar control role in the form of supporting losers is described for the alpha-male in gorilla groups by Watts (1997). Here, males intervene in fights among females. Because this may promote egalitarianism among females, the male may use it to keep females in his group. Male intervention hinders, however, the formation of alliances among females.

Functions of Coalition

As regards their function, Smuts (1987) distinguishes a number of main types of coalitions:

1. Coalitions to take over a single-male group: This has been reported for males of gray langurs (Hrdy 1977).
2. Coalitions among males to get access to an estrous female that is in consort with another male: These coalitions do not affect dominance relationship and are common in savanna baboons (Smuts 1985a). Coalition partners are typically of

middle rank (Noë and Sluijter 1995). Packer (1977) found that the male that enlisted help from another was the one to obtain the female, but in a later study, Bercovitch (1988) showed that males that were solicited were as likely to obtain the female as those that solicited, and Noë (1992) himself observed that both partners of a coalition may enlist each other's help simultaneously.

3. Coalitions to repel outside males: This has been reported among females as well as among males. Coalitions among males occur between groups of species living in single-male groups such as gorillas, hamadryas baboons, and gelada baboons. Coalitions among males of a single group have been described in multimale groups of chimpanzees, red colobus monkeys, spider monkeys, white-faced capuchin monkeys, and sometimes also among savanna baboons. In chimpanzees (Wrangham 1999; Wilson and Wrangham 2003) and white-faced capuchin monkeys (Gros-Louis et al. 2003), male coalitions may even result in killing an adult of another group.
4. Coalitions among females or between a male and a female to protect infants: Although the main protectors of youngsters are their mothers, in all species virtually all group members will defend an infant if it is in danger (for instance, against an attack by an adult male), and female baboons are even suggested to maintain close associations with particular males in order to be protected against aggression from males (Palombit et al. 2000, 1997).
5. Coalitions among females to protect an adult female against an attack by a male: Mobbing a male to protect a female may be useful for females (even unrelated ones) since it warns males that hostility to females is risky.
6. Coalitions to increase the dominance position of one or both member(s): Here, we will treat results for youngsters and for adults separately.

Adults

Coalitions to increase the dominance position among adults have been reported for Japanese macaques, rhesus, Barbary macaques, stump-tailed macaques, mantled howlers, red howlers, chimpanzees, and gray langurs.

When females are observed to attack males together, they are assumed to increase their dominance over males. This is mentioned for Japanese monkeys, rhesus monkeys, and bonobos (Chapais 1981; Thierry 1990; Parish 1994), and indeed in these species, certain females are dominant over certain males. Such coalitions may not be a precondition for female dominance, however, because a spatial model of individuals that group and compete (via dominance interactions) shows that female dominance can also arise only from competitive interactions in the absence of coalitions (Hemelrijk et al. 2003, 2008). According to this model, the stronger female dominance in bonobos compared to common chimpanzees may be due to their greater cohesion in grouping. Furthermore, stronger female dominance among rhesus macaques as compared to Celebes macaques (Thierry 1990) may arise from their higher intensity of aggression. Besides, also a higher percentage of males in the group increases intensity of aggression on average in the group and, herewith, female dominance relative to males. Both factors, cohesion and intensity of aggression, increase hierarchical differentiation; and this reduces the size of the initial difference in dominance between the sexes (Hemelrijk et al. 2003, 2008).

When males support females, males usually benefit in terms of dominance. For instance, in Japanese macaques, an alpha-male supported females of lower-ranking matrilines against the alpha-female with whom he had an unstable dominance relationship. Similarly, in rhesus monkeys and chimpanzees, females supported the alpha-male against other males, and in vervets support by females influenced dominance relations among males (Chapais 1995).

Among the three top-ranking males in chimpanzees, coalitions may induce changes of dominance in several ways. For instance, among wild chimpanzees, a top-ranking alpha-male (A) had an unstable relationship with the stronger beta (B). When the gamma-male (C) supported the alpha against the beta, (C) rose in rank above (B) (Nishida 1983). One-and-a-half years later, however, support by the now gamma-male to the alpha-male caused them (B and C) to reverse dominance again (Uehara et al. 1994). Thus, the gamma-male played out the alpha-male against the beta-male and this happened also in captivity (de Waal 1982).

In captivity, at other times, the beta-male and gamma-male were observed to join against the alpha-male (a revolutionary alliance). Thus, both rose in rank above the alpha-male (de Waal 1982). Such competition among males has sometimes fatal consequences (Watts 2004). Revolutionary alliances have further been described for male langurs, Barbary macaques, and rhesus macaques (Chapais 1995; Higham and Maestripieri 2010; Bissonnette et al. 2011). However, in none of these species did males form coalitions to obtain estrous females.

Youngsters

In a number of female-bonded species (Wrangham 1980), there is also a complex support system that provides young females with approximately the dominance rank of the mother. It has been called a “matrilineal dominance system” and a “nepotistic hierarchy,” because the support involves kin. The nepotistic hierarchy implies that all daughters rank immediately below their mother and that among sisters the youngest sister has the highest rank (so-called youngest ascendancy). This classical form of a nepotistic dominance hierarchy is found in rhesus macaques, Japanese macaques, and long-tailed macaques. The formation of hierarchies between matrilines has been investigated in a series of admirable experimental studies of Japanese and long-tailed macaques by Chapais and coworkers (Chapais 1995, 1996; Chapais et al. 2001; Chapais and Gauthier 2004). They created subgroups of three or six juvenile Japanese macaques (with one or two peers of the same matriline) and then added an adult. In this situation, a low-ranking juvenile female appeared to be able to outrank peers in the presence of closely related females but not in the presence of more distantly related kin, such as aunts, grandaunts, or cousins, due to lack of support from them. After female dominance over a lower-ranking matriline was “assigned,” it was maintained by mutual support among members of the same matriline against those of a lower matriline: from that time onward, the young females joined opportunistically in ongoing conflicts against lower-ranking females (called “the common targeting principle”).

Within matrilines, younger sisters become dominant over older ones, the so-called "youngest ascendancy" rule. This is caused by the mother's support of a younger daughter against her older ones. If the mother is absent, dominant unrelated individuals will also support younger sisters against older ones. Thus, the network of alliances of females extends beyond her kin.

However, in some groups, the matrilineal dominance system is incomplete (weakly nepotistic) (Chapais 2004). For instance, youngest ascendancy is lacking in some feral groups of Japanese macaques (Hill and Okayasu 1995), provisioned groups of Barbary macaques (Prud'homme and Chapais 1993), and one captive group of Tonkean macaques (Thierry 2000). Furthermore, in baboons, daughters may outrank their mother during adulthood (Combes and Altmann 2001). Chapais and Lecomte (1995) give three explanations of weak nepotism: demographic, (phylo)-genetic, and ecological.

The demographic explanation comes from a model by Datta and Beauchamp (1991), who simulated the effects of demography on female dominance relations by comparing two populations that differ in their growth rate. One population is growing fast (with 2.8 offspring per female) and the other is declining (with 0.6 offspring per female). Thus, in the declining population, matrilines are smaller, and potential allies are fewer than in the increasing population. Since a mother needs support from one of her dominant sisters to remain dominant over her daughter (s) and this ally is more likely to be lacking in a declining population than a growing one, mothers will more often become subordinate to their daughters. Similarly, for a youngster to become dominant over her older sister, she needs another sister and her mother as allies. These are more often alive in a growing than in a declining population, and according to Datta (1992), this explains the consistency of the youngest ascendancy rule in provisioned and expanding groups of rhesus macaques and Japanese macaques and the lower occurrence of outranking older sisters in the declining population of baboons.

A genetic explanation is given to explain the absence of the youngest ascendancy rule in provisioned colonies of Barbary macaques and in a feral colony of Japanese macaques, where allies were present. In Barbary macaques, Prud'homme and Chapais (1993) suggest this difference may be a genetic one because they discovered that unrelated individuals rarely supported a younger sister against her older sister (although they support her against lower-born females). This differs from what is known of rhesus macaques and Japanese macaques.

An ecological cause is suggested for the absence of the youngest ascendancy rule in feral colonies of Japanese macaques (Hill and Okayasu 1995). Due to the wide spatial dispersion during foraging, the frequency of aggression was rare, and, consequently, support was rare too.

Note that apart from species that are weakly nepotistic, there are also those that are clearly non-nepotistic such as Hanuman langurs (Koenig 2000). Furthermore, in nonfemale-bonded species, such as gorillas and chimpanzees, matrilineal dominance does not exist and young females rank according to their age and power.

How can we explain why the matrilineal system evolved in some female-bonded species but not in others? In a comparative study of egalitarian and despotic species of the genus *Macaca*, Thierry (2000) attributes this to differences in degree of despotism. He argues that the matrilineal dominance system is more complete in despotic species due to the higher frequency of support among kin (so that more power differentiation develops between matrilines). He believes that this also implies a lower frequency of acts of support among non-kin and that in egalitarian species support is distributed the opposite way, that is, it is more frequent among non-kin than among kin. Furthermore, he shows that dominance styles are phylogenetically conserved (Thierry et al. 2000). This begs the question of what caused the start of the interspecific differences in degree of nepotism between egalitarian and despotic macaques. According to Chapais (2004), this originates from a difference in the "strength of competition" due to the distribution of food. In the case of clumped food, supporting others will be more advantageous. Thus, a nepotistic system develops in which there is a high frequency of support of both kin and non-kin (in contrast to only kin as suggested by Thierry). When food is dispersed and causes scramble competition, it cannot be monopolized and support becomes less useful (both among kin and among non-kin).

Support: Kin Selection, Reciprocation, and Exchange

Support in fights, or coalition formation, is often thought to be "altruistic" because of the energetic costs and risks of injury to the actor and the benefits to the receiver.

As regards the benefits of receiving support, it increases the likelihood of winning a fight, as larger coalitions beat smaller ones (wedge-capped capuchin monkeys (Robinson 1988), bonnet macaques (Silk 1992a)).

The cost of coalitions is difficult to estimate, but often it is assumed that one partner bears most of the costs while the other reaps the benefits (presenting thus a case of altruism). If so, the theory of kin selection and that of reciprocal altruism are believed to explain these supposedly altruistic acts.

As regards kin selection, in Old World primates, individuals support kin more often than non-kin, e.g., in pigtails (Massey 1977), rhesus (Widdig et al. 2006), Japanese (Chapais et al. 1997), Tonkean (Petit and Thierry 1994), Barbary macaques (Widdig et al. 2000), chacma and yellow baboons (Silk et al. 2004; Walters 1980), and gorillas. Furthermore, individuals aid kin more often if they are more closely related (pig-tailed macaques, chimpanzees, and rhesus monkeys).

In cases of reciprocal altruism, support is supposed to be reciprocated or exchanged for something else. Reciprocation of support is found in a comparative study of rhesus macaques, stump-tailed macaques, and chimpanzees by de Waal and Luttrell (1988). Since the authors statistically partialled out effects of proximity, kinship, and same-sex combination, they argue that reciprocation indicates that individuals keep mental records of the number of acts received from each individual and that they match the number of acts they give to what they have received from each partner, so-called calculated reciprocity. However, in this study, the effects of dominance ranks and grooming behavior are ignored, and data over five consecutive seasons were lumped together. Therefore, what seems to be proof of keeping mental records may have been simply a side effect. Reciprocation appears to be a side effect, for instance, in the long-term study of the same colony of chimpanzees analyzed per season by Hemelrijk and Ek (1991). It involves a sex difference since chimpanzee males reciprocated support whereas females did not. Males, however, only reciprocated support if their hierarchy was stable; if it was unstable, males supported those they groomed (Hemelrijk and Ek 1991). Because of this, and since there was insufficient indication that there was any negotiation for support because individuals did not significantly comply with requests from others (Hemelrijk et al. 1991), it seemed that males might have joined in one another's fights opportunistically in order to attack common rivals. This may have been the cause of the reciprocation among males. Since males may benefit directly from such joint attacks, supporting behavior is selfish (Bercovitch 1988; Noë 1990; Chapais 1996; Prud'homme and Chapais 1996), and there is no need for the participants to keep records.

Also a modeling study confirms the possible occurrence of reciprocation and exchange as a side effect (Hemelrijk and Puga-Gonzalez 2012). The model represents grouping individuals that groom and fight with others nearby. It suggests that reciprocation and interchange emerge as a side effect of proximity. In the model, the spatial position of individuals in the group appears to be relatively stable, and thus individuals interact more frequently with partners that are in proximity than those that are far away. Therefore, they groom, fight, and support each other more frequently which results in the emergence of these patterns (Hemelrijk and Puga-Gonzalez 2012).

As in chimpanzee males, reciprocation of support has been reported in one study of male baboons (Packer 1977) but not in another (Bercovitch 1988). This difference possibly is related to a difference in the stability of the hierarchy (Hemelrijk and Ek 1991).

The sex difference in reciprocation of support is in line with detailed earlier studies by de Waal (1978, 1984), in which he found that coalitions by males were mainly opportunistic and only corresponded with their social bonds during periods in which the position of the alpha-male was clear (de Waal 1984). Female coalitions, however, were more stable and always coincided with their social bonds (Hemelrijk and Ek 1991). Thus, whereas male coalitions seem to serve status competition, female coalitions are directed toward protection of kin and affiliation partners.

Recently, an alternative mechanism to explain reciprocity has been proposed, "emotional bookkeeping" (Schino and Aureli 2009). It suggests that the frequency and quality of previous and present social interactions with a particular partner elicits a specific emotional state. This emotional state may lead to reciprocation and interchange of beneficial acts without relying on high cognitive mechanisms.

Furthermore, de Waal and Luttrell (1988) studied reciprocity of "revenge." By revenge, one means attacking someone while supporting another for the reason that the subject has received similar "contra-support" before. In this study, it was found that revenge is reciprocated only among chimpanzees, not among the two monkey species (i.e., macaques). This is interpreted as if the individuals aim their support against some individual because they have been attacked in a similar way: they have suffered support against themselves. De Waal and Luttrell consider this a sign of a greater cognitive capacity in chimpanzees because chimpanzees keep track not only of acts of support but also of revenge. However, there are three alternative explanations for this pattern. First, the authors lumped together data of five seasons despite changes in dominance ranks and in the stability of the power of the top male. In a study in the same colony, but in an analysis of support data per season, Hemelrijk and Ek (1991) found no reciprocation of revenge. Therefore, the apparent reciprocation of revenge may have resulted from the lumping together of data, and in any case, it is unlikely that individuals keep track of acts of revenge over a period longer than one season. Second, reciprocation of revenge has also been observed in monkeys, e.g., bonnet macaques (Silk 1992a), and also among related female gorillas (Watts 1997), which pleads against the hypothesis of the need of high cognition for such reciprocation. Third, reciprocity of "revenge" emerges in an individual-based model as a side effect of the gradient of the hierarchy (Hemelrijk and Puga-Gonzalez 2012). When the hierarchy is shallow, aggression is known to be bidirectional, because it involves little risks for both partners, and when the hierarchy is steep, aggression is unidirectional (i.e., from dominants to subordinates). In this model, incidental coalitions are observed when, by accident, after a fight between two individuals, a third nearby individual attacks one of the former opponents. Opposition in such incidental coalitions follows automatically the same pattern as dyadic aggression: it is unidirectional when the dominance hierarchy is steep and bidirectional when the dominance hierarchy is shallow. This is statistically recorded as reciprocation of contra-support or opposition but lacks cognitive rules for revenge and for its reciprocation.

Communal Rearing and Allomothering

Usually the mother takes care of the infant alone. In callitrichids (tamarins and marmosets), however, everyone (both parents and mature offspring) assists in rearing the newborns by carrying them and provisioning them. Mature offspring postpone their departure from their natal territory and delay independent breeding (Rapaport 2001). In a number of female-bonded species, youngsters are protected and helped in fights so that they rank immediately below their mothers (matrilineal dominance system, see preceding section), and in all species youngsters are protected in fights that are dangerous. Furthermore, in many species, unrelated individuals may nurse and carry youngsters (allomothering); they cuddle the infant, embrace it, groom, and protect it (McKenna 1979). Allomothers are usually young, nulliparous females, ranking below the mother; often they are sisters of the infant. In this way, the allomother learns how to handle an infant, which increases the chance of survival of her own offspring (Lancaster 1971). An advantage to the mother seems to be the shortening of the interbirth interval (Fairbanks 1990) and the increase of her reproductive success (Ross and MacLarnon 2000). On the basis of detailed comparative studies of macaques, Thierry (2004) argues that two assumptions suffice to explain interspecific variation in degree of allomothering in *Macaca*: (a) attraction to infants and (b) constraints of social structure

(McKenna 1979). First, all females are strongly attracted to all infants. Second, in certain species, mothers protect the infants with greater care than in others, and therefore, in these species, allomothering is counteracted. These species are the species that belong to the two despotic grades of macaques, whose aggression is intense and among whom power differences are great. This may cause problems for females when they have to retrieve their infants. In contrast to this, in egalitarian species, power differences are small and aggression is mild. Thus, differences in the degree of allomothering result from a kind of social epigenesis.

Collective Defense of Home Ranges

Species and groups differ in the way in which they use their home range. Depending on this, fights with other groups may aim at the defense of only one food source (e.g., fruit tree) or of a whole territory (Cheney 1987). A number of species have special intergroup calls that are meant to separate the groups spatially (e.g., in mantled howler, capuchin, mangabey, siamang, yellow-headed titi). Most territorial species, however, have intergroup calls that incite the other group to fight them (e.g., dusky titi, gibbon spp., vervet, colobus).

If actual fights between groups occur, in chimpanzees this may lead to killing an adult of the other group (Wilson and Wrangham 2003; Wilson et al. 2004).

Usually, males are more active than females in fights between groups. In macaques, however, females may also participate. In both sexes, higher-ranking individuals participate more often than lower-ranking ones (Cooper 2004).

Behavior Against Predators

When primates meet a predator, they flee individually (so do large species) or hide (in particular, smaller species). Furthermore, they may protect themselves and their group members in other ways such as (a) by mobbing the predator, (b) by scanning the environment for early discovery of predators, and (c) by warning other group members.

Mobbing predators has been described for baboons, rhesus monkeys, and all three ape species. Each of these species was observed to attack tigers or lions (Cheney and Wrangham 1987). Scanning the environment has been described for a number of primate species such as red-bellied tamarins (Caine 1984) and chacma baboons (Hall 1960). In a series of experiments, tamarins appeared to scan most frequently during the most dangerous periods of the day and in the presence of the most dangerous stimuli. Further, tamarins appeared to divide the duty of scanning among group members. In relation to protection against predators, the spatial distribution of the individuals of the different sex age categories in progressions has also been studied in baboons (Altmann 1979; Rhine and Westland 1981).

Most primates use alarm calls to warn against predators. Such calls are altruistic in the sense that they are harmful to the sender, because it attracts the attention of the predator to the caller, but beneficial to others that are close by. It has been debated whether kin selection is the main evolutionary force behind these calls because it is usually kin that is protected by these calls. However, newly immigrant males also tend to call loudly in spite of the fact that they have no kin members in the group (Cheney and Seyfarth 1981). Many species of primates use different alarm calls for different predators. Such a differentiation is described for vervets, red colobus, Goeldi marmosets, pygmy marmosets, cotton-top tamarins, and gibbons (Cheney and Wrangham 1987; Dugatkin 1997). Vervets emit different calls when the predator is a leopard, an eagle, or a snake (Struhsaker 1976). In playback experiments of the different calls, vervets appeared to respond to leopard alarms by climbing into the trees; at eagle alarms they looked up, and at snake alarms they looked down. Because of the fine distinction between these alarm calls (almost resembling human language), it has been asked whether alarm calling can be considered intentional warning. Evidence points against this, because vervets continue to give alarm calls after everyone in the group has heard them (Cheney and Seyfarth 1985) and because the intensity of these alarm calls and other protective actions by mothers remained similar whether or not their daughters were informed about the presence of the predator (Cheney and Seyfarth 1990).

Conclusion

Cooperation within a group of primates mainly concerns grooming and coalition formation. Sometimes it involves communal hunting, food sharing, and helping to raise young of others and defense against danger from the outside. Such defense involves collective defense of a home range against another group or defense of a group against a predator. The specific patterns of cooperation depend on the social system and the kind of primate involved. Behavioral acts, such as grooming, coalition formation, and tolerance during feeding, have originally been considered as “altruistic” but are presently often considered advantageous for both parties, the actor and receiver. Furthermore, patterns of coalitions and their exchange and patterns of grooming (such as “reconciliation” and “consolation”) have for long been considered to reflect sophisticated cognition, but it is increasingly acknowledged that these patterns may also arise from simple behavioral rules.

Primate Intelligence

Richard W. Byrne

Contents

Abstract

Brain size has traditionally been employed as a measurable proxy for species intelligence. Using allometric scaling of brain size relative to body size shows the biological cost suffered from investment in brain tissue. Shifts in diet type are the engine permitting increased investment in brain tissue because higher energy diets allow a larger brain at any given body size. Relative brain size, however, confounds effects of gut size required for particular diets with effects of brain size required for enhanced cognitive function. In contrast, the absolute size of brain parts specialized for particular functions gives evidence of the computational power of those systems. Correlational analyses strongly imply that demands of social complexity, rather than difficulties associated with frugivory or embedded foods, led to evolutionary increase in simian primate brain size. Primate brain expansion has largely involved the neocortex, with correlated increases in the cerebellum; among living primates, neocortex size

predicts frequency of use of tactical deception and of innovative responses. These capacities likely rely on extensive memory for social information. Only among great apes is there evidence of understanding how systems work, whether social or technical, and this ape/monkey difference may be mediated by specifically cerebellar expansion. Representational understanding may derive from the ability to parse complex behavior, allowing imitative learning of elaborate new skills.

Introduction

There are three ways in which physical anthropologists might be interested in primate intelligence, corresponding to different theoretical formulations. Firstly, a very widespread view among social scientists is that human intelligence is *unique and indivisible*, shared with no other species (Macphail 1982, 1985). This does not mean "unique, just as each species' intelligence is unique," nor simply "uniquely large," both of which are undeniable; rather, human intelligence is seen as incomparable, and anyone seeking seriously to relate animal and human intelligences is misled. Human intelligence is taken to be a consequence of developing the faculties of language and speech. Thus, on this stance, the key question for human evolution is at what point in human evolution did our makeup change in a way that permitted the development of language. The (unique) origin of intelligence equates to the (unique) origin of language. Replacing a hard question with a famously intractable one leads to no obvious avenue for further research. Moreover, while in the end it may turn out that the gulf between human intelligence and that of any other animal is an unusually large one, to assume a priori that there is no comparison makes good sense only for a creationist. This position will therefore not be considered further.

At the opposite extreme, intelligence has been treated as a continuously varying *quantity*: traditionally called "g" in psychometric psychology, for "general intelligence," or IQ in common parlance. On this view, the evolutionary issue is whether intelligence changed gradually or in steps, and comparative phylogenetic data of primates can be used to pin down when in human evolution such changes occurred (see chapters "▶ Principles of Taxonomy and Classification: Current Procedures for Naming and Classifying Organisms," and "▶ Modeling the Past: The Primatological Approach," Vol. 1). Further, by exploring the ecological correlates of intelligence in living primate species, insight can be gained into the current adaptive value (usefulness) of intelligence and thereby reveal clues to its evolutionary origin. What primatology needs to bring to this enterprise is the equivalent of an intelligence test for animals: a fair way of comparing the intellects of living species. This has been the most popular and to date the most productive approach to primate intelligence, but in this chapter, I will suggest that it is only a rough approximation to the truth and may be of limited future value.

Finally, lying between the two extremes of intelligence-as-language and intelligence-as-quantity, intelligence can be treated as a heterogeneous *skill package*:

a mixed bag of devices and processes, endowments, and aptitudes, in fact all those capacities that lead us to label everyday behavior as "intelligent." I will argue that this rather messy vision in fact offers the most promise for the future use of comparative data in understanding the evolution of our most vaunted feature, human intelligence.

Intelligence-as-Quantity

Intelligence as measured within psychology is a matter of differences in ability among people. Strictly speaking, then, intelligence is an individual-level phenomenon. However, over and above the differences in problem-solving ability among humans (and presumably also in other species), individuals share a "common denominator" potential for intelligence by virtue of species membership. It is this genetically based, common denominator that is meant by talking of "differences in intelligence between species." Species differences in intelligence are clearly liable to be much greater than the small differences within human intelligence.

How can *species intelligence* be measured? An obvious starting point is to co-opt and adapt the tools of psychometric psychology: surely measures designed for the small variations in human intelligence will prove sensitive enough for the larger species differences. In practice, this is not as easy as it might seem. One reason is that, although most people consider they can deduce intelligence from everyday behavior, psychologists have preferred to define intelligence operationally, as "what IQ tests measure." As a result, sadly little expertise in psychometrics is available to inform how to infer intelligence from behavior. Still, a considerable battery of tests, broadly comparable to the items of an IQ test, has been applied to animals, using the tools of the animal learning laboratory: Skinner boxes, Wisconsin General Test Apparatus, and so on. Unfortunately, the results have been disappointing, as far as measuring species intelligence goes – and perhaps this should not be a surprise. Human intelligence testing has shown the inappropriateness of grabbing a test, devised in one culture, and using it on people from another culture. The problem is that tests must be calibrated against some other achievement (for human IQ tests, usually educational success), and these measures of achievement are not culture-free; the difficulty is obviously far greater across species. Only a few animals are motivated by rewards similar to those that motivate us, see the world in rather human ways, and interact with the world in a similar way to humans. If researchers rely on human estimation of difficulty in some "behavioral IQ test for animals," they are liable to equate cleverness with similarity to humans. The history of laboratory-based comparative psychology has gone through a series of cycles, with striking species differences in intelligence first claimed and then the difference later discovered to lie rather in perceptual capacity, motivation, or species-typical traits better understood as special-purpose adaptations for particular environmental features (see reviews by Warren 1973; Macphail 1985). Goldfish were once considered less intelligent than rats, because they could not learn visual discrimination tasks – until it was realized that their visual acuity was greater in a downward direction. When tasks were presented on the bottom of the tank, the difference vanished. Among primates, colobines were (and still often are) considered unintelligent compared to cercopithecines – but the latter are frugivorous, readily motivated to perform tasks in return for fruit or other concentrated food. Colobines are folivores, not adapted to compete for (or even able to digest) small items of high-quality food; it is hardly a level playing field. Barn swallows show phenomenal abilities to find their way over great distances to return to the same barn after many months, using the positions of sun and stars, polarized light, and magnetic fields; but they show no other signs of great intelligence, and migratory abilities are not helpfully seen as evidence of intellectual level. Small wonder then that some biologists have doubted whether intelligence is an appropriate measure by which to compare animals at all. Animal adaptations are fascinating, they argue, but calling that intelligence adds nothing to our understanding. Often, psychologists' definitions of intelligence stress the need to deal with environmental challenges: e.g., "the aggregate or global capacity of the individual to act purposefully, think rationally, and to deal effectively with his environment" (Wechsler 1944) or "the faculty of adapting oneself to circumstances" (Binet and Simon 1915). If intelligent for an animal species means "well adapted to the environment," then presumably all species are "intelligent" in their own, nonhuman ways. And while many performances of animals *look* intelligent in the human sense, there is every reason to suppose that their development is under tight genetic guidance.

Surely, however, adaptations specific to solving particular environmental problems should be distinguishable from real intelligence by its quality of *flexibility*, allowing individuals to find their own solutions even to novel problems. Species-typical performances are most likely adaptations (although not all will prove to be: the wearing of bodily adornment or coverings is, after all, species-typical in humans!). But the importance of species-level intelligence is its potential for allowing *individual* flexibility in learning and problem solving. This approach points to the use of observational data of natural behavior to deduce intelligence, just as we do every day among ourselves. However, in examining natural behavior for signs of the individual-level flexibility and creativity that can signal species intelligence, the same danger of confusing genetic adaptations with flexible intelligence occurs as with laboratory testing. An anecdote of my own error may serve as a cautionary tale. Watching border collies herd sheep, I did not doubt the dog's greater intelligence. The sheepdog responds to the whistles of a shepherd with flawless outmaneuvering and controlling of a hundred sheep. Of course, this wonderful performance depends on the innate antipredator reactions of sheep. Bunching and running in tight-packed flocks when attacked makes it difficult for a wolf to single out a potential kill but easy for a sheepdog to maneuver a group. The dog is also equipped with innate tactics, partly as a result of its wolf ancestry and partly as a result of thousands of years of domestication; these tactics can be seen in any untrained sheepdog let out to chase some sheep. But the dog is also able to learn the complex system of whistle signals and is then able to deploy its tactics to order; the sheep, in contrast, are unable to overcome their innate restrictions. My faith in this simple picture was shattered by spending some time with Gujarati shepherds on the Little Rann of Kutch in India. Like British shepherds, they whistle their commands; it seemed a familiar scene. Eventually, I noticed the sheepdogs: asleep. The sheep in Gujarat learn to understand the shepherds' commands and follow them, treating the shepherd as herd leader. The dogs' role is not one of herder but only a source of protection from wolves. Dogs may seem especially intelligent to people because they happen to use facial musculature for visual communication, giving rise to expressions that resemble our own and have similar meanings, and because their forward-facing eyes and long nose make their direction of attention obvious. We can "see" what they are thinking, and recent work shows that domestication has equipped dogs with particular traits that fit into this two-way cooperation (Miklosi et al. 2004). Sheep are foreign to us, because they rely more on olfaction and their facial expressions are relatively cryptic to us, but it is premature to assume them unintelligent.

A proper comparison of intelligence, shown by each of the species relevant to reconstructing human cognitive evolution, is therefore a tall order. Attempts to use general-purpose laboratory tests have often foundered on extraneous differences in natural aptitudes, perceptual capacities, and motivation; in any case, relatively few species are available for detailed examination in captive settings, and comparative phylogenetic analysis depends on using a broad range of species. Yet to accurately attribute differences in natural behavior to intelligence, rather than other evolved aspects of the species biology, requires in-depth study of each species under a range of conditions and so is almost as restricted in what data are available. In consequence, most progress in evaluating animal intelligence as a quantity has been made by using an indirect indication of intelligence, brain size, which can be accurately measured anatomically.

Brain Size as a Measure of Intelligence

The clearest evidence that brain enlargement confers adaptive advantage comes from examining the costs of a large brain: species can tolerate retention of neutral traits, but for a costly organ to evolve necessitates compensating advantages. Brain tissue is metabolically expensive (Aiello and Wheeler 1995). In adulthood, the human brain consumes about 20 % of the basal metabolic rate, and during childhood this percentage rises to 50 %. Moreover, this demand for energy is remorseless: unlike other organs, the energy supply to the brain has to be constant, and irreparable damage results from only a few minutes of interruption. Having a large brain has incurred other disadvantages for us, as well as this energetic drain. At birth, the human child's head is a tight fit in the birth canal compared with the easy passage of other great ape babies (Leutenegger 1982). Birth is consequently a prolonged, often painful, and sometimes dangerous process for mothers; among other great apes, birth takes only a few minutes. Finally, human brains grow for an unusual amount of time, considering their already-large size at birth (Harvey and Clutton-Brock 1985). During this phase of postnatal brain growth, human babies are relatively immature and helpless, so they require years of time-consuming care from the mother or family. Among primates, the only plausible explanation for brain enlargement in the face of such clear costs is an intellectual benefit. To measure species intelligence, then, it should be possible to use brain enlargement. Difficulties arise, however, in deciding the baseline for measuring enlargement.

Larger animals, in general, have larger brains. As the absolute size of living things changes, the relative proportions of their parts are generally found to change. In this case, absolutely larger animals have relatively smaller brains than expected from linearly scaling-up smaller ones (Jerison 1963, 1973). These regular trends have led to the use of allometry to calibrate brain enlargement, against a baseline of the size expected from body weight. In allometric scaling, for a given group of animals, a double logarithmic plot of the parameter at issue is made against body size; provided some sort of power relationship is involved, this forces the species points onto a straight line. For brain size, plotting against body size on logarithmic coordinates gives a reasonably straight line for primates, as for other groups of animals (Passingham 1981). Whether a species lies *above* the line (has a relatively larger brain than expected), *on* the line (has average brain size), or *below* the line (has a relatively small brain) is taken to index its intelligence. For instance, "encephalization quotient" refers to the actual size of a mammal's brain divided by that expected for a typical mammal of its body size (Jerison 1973; see also Clutton-Brock and Harvey 1980). This technique has been used most often in evolutionary analyses of animal intelligence.

However, comparing species in intellectual ability by using their relative brain sizes calibrated with allometric scaling leads to a paradox which brings the whole approach into question. Scaling brain size against body size is implicitly making a strong claim about the functioning of neural tissue. The implication is that an animal with an expected brain size of 2.0 g and a real brain weighing 2.1 g and an animal with an expected brain size of 200 g and a real brain weighing 210 g are "really" equally brainy – even though the latter differs from the expected brain weight by 100 times as much neural tissue as the former. This is a very puzzling result for anyone used to computational (Turing) machines, since these are ultimately limited in power by the number of their elements. The paradox comes from mixing metaphors of what the brain is doing. If the brain is a sort of "on-board computer" (Dawkins 1976) that governs intelligent function, then the *absolute* number of neurons available for computation must be relevant, not the number relative to body size. (The logic here is that neural transmission speed is known to be the same in all mammalian brains, and evolution will have optimized neural programming in each species: thus differences will not reflect relative efficiency or hardware or software, as is the case in most artificial computers.) Bigger brains will be better brains, when it comes to flexible and intelligent responses, regardless of the species' body size. In contrast, using allometric scaling against body size presupposes a more traditional scheme in which animal brains function by making responses to stimuli in a more-or-less reflex manner. The underlying model of the mind is then closer to an automatic telephone exchange than to a computer. Lines from/to subscribers in the telephone system model correspond, in bodies, to sensory and motor neurons. So, input/output connections will determine how big the system to handle them needs minimally to be. Larger bodies need larger brains for these prosaic purposes, and only measuring brain tissue *relative* to body size will show the extent to which processing can be more flexible and intelligent than the minimum. The on-board computer and telephone exchange models cannot both be right – or rather, they will be appropriate for *different* systems within a single brain, and the error is to assume that one or other can be neglected entirely (Byrne 1995b, 1996b). Accepting this more complex view, those brain parts involved in noncomputational body function should increase in size in some regular way with body size, whereas those parts used for computation should not. The *absolute amount of brain tissue free for computation* should give us an idea of the potential intelligence the brain can show, not the amount relative to body size. (Note that it is slightly more complicated than that, as neurons vary in size and packing density across species.) It should be no surprise, then, that allometric analysis of brain size relative to body size and alternative methods that in some way measure absolute sizes produce conflicting results (see Deaner et al. 2000).

Relative Brain Size: The Value of a Brain

Allometric scaling shows that, among mammals, the primate order as a whole is larger brained than most other groups (Jerison 1973). But when strepsirhine primates are partitioned from the rest, they turn out to have brains about the size predicted from mammalian body size (Passingham and Ettlinger 1974). The monkeys and apes, however, have brains twice as large as those of average mammals of their size. What does this mean? Following the arguments of this chapter, disproportionate brain size in relation to body size is not simply a matter of greater intelligence and must be understood in terms of costs as well as benefits. Any species with brain relatively large for its body size inevitably incurs greater risks than a small-brained relative, from the remorseless demand for higher metabolic energy. The relatively large-brained monkeys and apes are thus bearing a much greater cost from their larger brains, on average, than most mammals: how, and why, are these increased costs acceptable?

Primates with home ranges that are large in area tend to have relatively large brains (Clutton-Brock and Harvey 1980), and this has been used to argue that environmental complexity has a powerful influence on primate brain size. But there is an alternative explanation for that correlation: as an artifact of selection for bigger bodies in more folivorous species (Byrne 1996b). Folivory relies on a complex or at least large stomach: for example, the foregut fermentation chamber of colobine monkeys or the large hindgut of gorillas. Leaves are relatively abundant in most primate habitats, so primates with more folivorous diets can find sufficient food for their nutrition in smaller home ranges. By contrast, frugivory requires a larger range area, for year-round access to a variety of fruit species and other sources of nutrients, but the high sugar content allows digestion by a shorter gut. Other things being equal, primates that eat more fruit will have smaller bodies and larger home ranges than those that eat more leaves, causing a correlation between

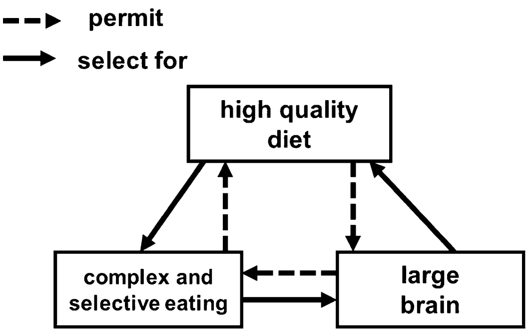

Fig. 1 Brain size and diet. Schematic illustration of the relationships for primates among diet quality, brain encephalization (i.e., size in relation to body size), and the cognitive skills required to find and process foods. Note that specialization in *low-quality food/cognitively undemanding/relatively small brain* is just as effective as an evolutionary strategy as *high-quality food/cognitively demanding/relatively large brain*

frugivory and relative brain size, regardless of any differences in intelligence. Variations in brain size relative to body size may therefore be a side effect of differences in body size due to diet type rather than a direct result of selection for larger brain size.

Since gut tissue is metabolically as costly as brain tissue, and diets requiring only small guts (frugivory, meat eating) often provide a surplus of energy by the time a nutritional balance is obtained, primates with small guts are on the whole likely to be better able to “afford” larger brains (Aiello and Wheeler 1995). Clearly, the grade shift toward meat-based diets in the later hominins might be related to the massive brain expansion in these species. The relationship between energy supply and the size of brain that can be afforded for a given body size does not, however, explain why larger brains should have evolved in some taxa and not others: the opposite is just as feasible, a trend toward smaller brains in species with less need for high-quality diets (see Fig. 1). Moreover, the fact that the energy demands of the brain are constant suggests that the large brain/high-energy diet is a particularly risky evolutionary strategy for which a compelling competitive advantage must exist.

One possibility is that a niche for a high-quality diet specialist may happen to become available, and the survival cost of large brain size is thereby lessened for any species that exploits that opportunity, resulting in a new equilibrium at a higher relative brain size. However, higher quality diets are usually based on sparse, hard-to-find, hard-to-access, or hard-to-process foods (e.g., fruit, nuts, meat), so this is not entirely plausible. More often, the causal chain is likely to run in the opposite direction: from a real need for higher intelligence, precisely in order to exploit a new, high-quality food supply. It might even sometimes be the case that ecological pressures for greater intelligence – and thus a larger brain – drive selection for a larger body, in order to support it. The frequently noted trend over geologic time for species of the same taxa to increase in size might sometimes be a consequence of an arms race of intellectual competition, selecting for larger brains and consequently larger bodies to support them at the same level of survival risk, coevolving with changes in diet.

Absolute Brain Size: The Power of a Brain

To measure the computational power of a brain, it will be necessary to estimate the absolute number of neurons available for flexible, problem-solving purposes: the lack of any overwhelming correlation between overall brain size and observed smartness in animals suggests that simply using the total brain volume will not do. Jerison (1973) was well aware of the need and developed an index of "extra neurons" by calculating the absolute number of neurons beyond what was minimally necessary for bodily function. With a similar aim, Bauchot and Stephan (1966) attempted to identify the taxonomic group with least intelligence, as a baseline from which all others deviated. However, difficulties in deciding what volume of neural tissue is minimally necessary, or whether any species entirely lacks flexible intelligence, have prevented general adoption of these approaches. In recent years, the same problem has generally been tackled in a different way by comparing the volume of one part of the brain, the neocortex, against the rest. There are two assumptions involved here. First, that the primate brain has undergone mosaic evolution, with some parts growing in size and power at the expense of others, for a given overall size (Barton 1998; Barton and Harvey 2000). On a broad scale, this assumption is hard to doubt: for instance, haplorhine primate brains are clearly more dominated by visual cortex and less by olfactory lobes than those of most other mammals, including strepsirhines. The second assumption is that a primary function can be safely assigned to expansions of particular regions – in particular, that the neocortex is involved in abstraction, thinking, and executive functions such as effective problem solving. This is supported by a long history of deducing brain function from task failures after accidentally or deliberately inflicted lesions, somewhat problematic to interpret but consistent in pattern, and more recently supplemented by the differences in patterns of energy use revealed by brain imaging. (Note, however, that most published brain images conveniently omit the "lower" cerebellum: I return to the role of the cerebellum later in the chapter.) More pragmatically, it can be noted that the increase in brain volume in the primates over that of other mammal groups is chiefly due to neocortical enlargement; and among primates, it is the neocortex that varies most strikingly between species, with correlated changes in cerebellum (Whiting and Barton 2003), whereas the rest of the brain shows much less evolutionary change. This implies a strong selection pressure for neocortical enlargement in primates, and an intellectual function is the only serious candidate for this selection pressure.

If it is taken, then, that primate neocortical enlargement measures specialization in some sort of intelligence, can ecological correlates indicate the function it subserves? Sawaguchi and Kudo (1990) found that the neocortex was larger in species living in bigger social groups, both in strepsirhines and in frugivorous platyrrhines. Also, in frugivorous haplorhines, polygynous species (one male living with more than one female) had larger neocortices than monogamous species. These findings hint at a social origin of intelligence (Jolly 1966; Humphrey 1976; Byrne and Whiten 1988), and Dunbar (1992, 1995, 1998) has gone further to support this idea, examining whether neocortex size correlates with measures of social or environmental complexity in living primates. He used both raw neocortical volume and several more complex functions; all gave similar trends but *neocortex ratio* (ratio of neocortex size to that of the rest of the brain) gave the clearest effects. Measures of environmental complexity – range area, day journey length, and the amount of fruit in the diet – were found to be unrelated to neocortex ratio when body size effects were removed. In contrast, average species group size correlated with measures of neocortical enlargement, supporting a predominantly social function of primate intellect. Dunbar proposes specifically that neocortical size limits the social complexity that an individual can cope with: social complexity increases with group size, so groups begin to fragment when their size increases past a complexity limit set by neocortical size. These analyses can be criticized on statistical grounds – for instance, neocortical ratio is correlated with body size, and using species as data points brings problems of phylogenetic independence – but the broad findings have been confirmed, using absolute neocortex volume and the volume of the rest of the brain as independent predictors and the method of independent contrasts to avoid phylogenetic bias (Barton 1996; Barton and Dunbar 1997; Barton and Harvey 2000). Neocortical expansion is clearly linked with increased social group size in primates (and indeed also in bats, carnivores, and cetaceans).

These correlations give little clue, however, as to precisely what social skills are possible, or enhanced, by the possession of a larger neocortex. The problem is, of course, the difficulty of finding a species-fair and widely applicable measure of social skill, but there are now some steps in this direction. The most detailed analyses so far have been applied to the use of deception by primates within their own social group. Social manipulation of affiliated conspecifics, avoiding the disruptive use of violence, lies at the heart of the Machiavellian intelligence hypothesis (Humphrey 1976; Byrne and Whiten 1988). Cases where an individual achieves its ends by successfully deceiving another have long fascinated primatologists (Goodall 1971; de Waal 1982, 1986; Byrne and Whiten 1985), which made it possible to assemble an extensive corpus of carefully documented records, spanning all major groups of primates (Byrne and Whiten 1990). Preliminary analyses showed that most acts of deception were carried out with little sign of intentional understanding but nevertheless served effectively to manipulate the visual attention of other individuals and thence their understanding of the situations (Whiten and Byrne 1988a, b). These visual perspective-taking abilities were confirmed experimentally, in chimpanzees, when researchers modified naturally occurring situations of food competition for laboratory testing (Hare et al. 2000, 2001); the field data indicates, however, that visual perspective taking is widespread also in monkeys. A larger corpus confirmed that only in the great apes did any of the accounts seem most parsimoniously explained as a result of mental state attribution

(Byrne and Whiten 1991, 1992); even in these cases, alternative, nonmentalistic possibilities are entirely possible (Byrne 1993; Povinelli and Vonk 2003). However, the frequency of use of deception was clearly not uniform across species, nor easily explained as a result of observer effort (Byrne and Whiten 1992). Byrne and Corp (2004) investigated whether neocortical specialization was involved. Correcting the raw frequencies of observed deception for observer effort by using the number of long-term field studies of habituated individuals over the period, and using independent contrasts to correct for phylogenetic bias, they found that neocortical enlargement – whether measured by neocortex ratio or absolute volume – strongly predicted the rate of use of deception. In contrast, neither the volume of the rest of the brain nor even the species' average group size had significant effects (note that the number of species for which data were available was smaller than in Dunbar and Barton's analyses of group size, so the difference may relate to statistical power). It seems that the use of deception for social manipulation critically depends on neocortex size.

What cognitive processes are likely to be involved in using deception? Given the lack, in the vast majority of cases, of any sign of intentionally planned deceit (Byrne and Whiten 1992; Byrne 1997a), the main attribute would seem to be rapid memory in social contexts: memory of who was present on which occasion, who did what to whom, and so forth (Byrne 1996a). This suggestion finds support from the finding that social grooming is correlated with group size in Old World primate species (Dunbar 1993): for grooming to be valuable as a social currency, a good memory of grooming debts to and from social companions is essential. Innovation of novelty has been shown, similarly, to vary with neocortical enlargement in primates (Reader and Laland 2001). It is less clear what may be minimally needed for the ability to innovate successfully, but an analysis of the innovations employed in primate deception found that most cases involved only generalization of familiar behavior to slightly novel contexts (Byrne 2003b).

The Intelligence to Understand the World

Learning and memory are certainly critical aspects of intelligence to the extent that they allow efficient, rapid, and flexible performance. But there is more to human intelligence than quick learning and reliable memory: to quote one definition, "grasping the essentials in a situation and responding appropriately to them" (Heim 1970). Putting this in more cognitive terms, intelligence implies the ability to *represent* the processes, social or physical, which are going on around us, and to use those mental representations to plan actions that may later be put into effect. Can evidence from living primates be used to deduce when, and in which ancestral species, this sort of intelligence evolved? Getting evidence of such capacities without using the medium of language is tricky, but this is a topic of extensive current research and some progress has been made. With very few exceptions, the evidence comes from great apes, although the interpretation of negative evidence is always problematic. Outside the great ape clade, it is very possible that primate behavior is not based on representational, mental models; even for great apes, interpretations remain controversial and are likely to change both as a result of improved data and sharper theoretical analyses.

Signs of *social understanding*, which include some level of theory of mind ability, have long been reported from analyses of observational data; these have included empathy and sympathy, intentional deception, and pedagogical teaching (de Waal 1982; Boesch 1991; Byrne and Whiten 1991). Until recently, however, the consensus of laboratory experimentation was that great apes entirely lacked any such ability (Povinelli and Eddy 1996; Tomasello and Call 1997; Heyes 1998; Tomasello 1998). However, a number of experimental results have now brought the experimental and observational data sets into closer alignment (for reviews, see Call 2001 and Tomasello et al. 2003): using more naturalistic paradigms to examine great ape problem solving, a series of experiments have shown aspects of intentional understanding. These capacities closely match those apparent in some of the most complex cases of great ape deception, mentioned above (see Byrne and Whiten 1991): the ability to respond appropriately to differences in intention (e.g., accidental versus deliberate, inability versus unwillingness), visual perspective (hidden to a competitor but in view to self, partial versus completely hidden), and other individuals' knowledge (e.g., known to one competitor but not another).

Signs of *technical understanding* have long been claimed for apes, because of the evidence of tool use and tool manufacture in the chimpanzee (and one population of orangutan), but there has been little attempt to work out exactly what understanding is needed for these skills to be learnt (Seed and Byrne 2010). Many animals use detached objects as tools (Beck 1980), the process of tool manufacture is usually quite simple (McGrew 1992), and the strongest argument that great ape tool use relies on representational understanding is that sometimes tools are prepared or selected in advance, out of sight of the place of use (Byrne 1998; Byrne et al. 2013). Most studies of chimpanzee tool use emphasize product rather than process, and in fact the evidence for unusual abilities in manual skill learning is stronger for the case of plant processing than tool use (Byrne 2004). Circumventing the physical defenses of herbivorous plants leads to the use of complex processing (Corp and Byrne 2002a), and both mountain gorillas and chimpanzees have been found to employ hierarchically organized procedures consisting of several modules employed in series or as subroutines (Byrne 1999b; Byrne and Byrne 1993; Byrne and Russon 1998; Byrne et al. 2001; Stokes and Byrne 2001; Corp and Byrne 2002b).

Learning by imitation links social and technical intelligence: by means of social learning, technical skills are acquired. Imitation, in the rich sense of learning new, useful behavioral routines directly from observation, is often thought to rely on prior understanding of mental entities, e.g., "the child must imaginatively place herself in the circumstances of the adult and determine what is the *purpose* of the behavior and *how one goes about* accomplishing that purpose" (Tomasello et al. 1993; my italics). Acquisition of novel behavioral routines by observation has been strongly argued for mountain gorillas, orangutans, and chimpanzees

(Russon and Galdikas 1993; Byrne and Russon 1998; Byrne 1999a, b, 2002; Byrne and Stokes 2002; Lonsdorf et al. 2004), variously on the basis of (a) resemblance in fine detail between behavior of mother and offspring, (b) the fact that disabled individuals learn group-typical manual processes rather than devising more efficient, idiosyncratic versions, and (c) the sheer improbability of highly specific and complex organizations of behavior developing so similarly in each individual without some learning by imitation. It is also usually presumed that the site-specific differences in chimpanzee behavior reflect socially learned traditions in which useful skills are passed on by imitative learning of the critical aspects of processes which are hard for any individual to discover on any reasonable timescale, simple "cultures" (Whiten et al. 1999; Whiten 2000; but see Byrne et al. 2004, Laland and Janik 2006, for caveats).

A tidy picture is thereby painted of great apes – and perhaps only great apes – able to understand other individuals' behavior in terms of intentional properties, giving them the ability to learn novel technical procedures from watching others who already have skills, leading to the elaborate, group-specific traditions in skills of significant technical sophistication described in wild chimpanzees. Given the close relationship of chimpanzees to ourselves, these similarities to human intelligence would be interpreted as resulting from common descent from a shared Miocene ancestor, having the ability to mentally represent intentional and causal-functional aspects of complex processes.

This picture may not be all it seems, however. Over just the same 20-year period in which evidence of richly complex behavior in great apes, once dismissed by experimentalists, has become hard to doubt, a number of theoretical analyses have begun to question what the evidence implies about the mental processes involved. It is important to stress that this challenge is not a reworking of early behaviorist critiques; behaviorism was hamstrung by its insistence on not postulating mental processes as "intervening variables," whereas that is no longer at issue. However, if great apes were equipped with powerful systems for detecting and extracting patterns of statistical regularity in the world around them – patterns that *correspond to* intentions, plans, and cause-and-effect relationships – such use of statistical regularities might be sufficient to explain what the apes do, without their having concepts that correspond to human ideas of mental states and causal relationships. Those may all be dependent on language and function in other ways than as primary causes of behavior.

Consider the case of imitation. There is a body of evidence, sketched above, that suggests great apes are able to learn by imitation the organizational structures of complex skills: how actions are grouped into often-used modules, how modules may be incorporated as subroutines into an overall plan (and thus repeated or omitted, depending on particular conditions of a given task), how sequential ordering affects outcomes, and so on. This is called program-level imitation (Byrne and Byrne 1993; Byrne 1995b; Byrne and Russon 1998) and involves the use of hierarchical organization to structure novel actions. But where do the programs come from: is it essential to discern the demonstrator's intentions, and the cause-effect of how actions achieve their results, to derive a useful program? Not necessarily: if a sufficiently large corpus of behavior can be observed, then recurring patterns among the natural variability of behavior can in principle reveal all the organization underlying skilled action that is necessary for program-level imitation (Byrne 1999a, 2002): “imitation without intentionality” is a real possibility. The process of extracting statistical regularities from the messiness of natural, goal-directed action has been termed *behavior parsing* (Byrne 2003a) and serves to reveal the underlying deep structure of behavior, but it does not depend on explicit representation of intentions and causes. Instead, the extracted structures of behavior link prior circumstances to resulting outcomes, so that if a particular outcome is desired, then those circumstances can be sought and that structure of behavior applied (see also Byrne 1995a, b).

In principle, it is possible that behavior parsing might also underwrite other behavioral routines that appear to rely on understanding ignorance, knowledge, intentions, and dispositions of others. While nothing so specific as for imitation has been worked out to date, Povinelli and Vonk (2003) point out that claimed mental processes of chimpanzees are “suspiciously similar” to those of humans and suggest that this may be because humans (alone) construe behavior in those terms. The implication is that the cognitive system of nonhuman great apes is adept at extracting and using complex patterns of behavioral action but does not represent these patterns in the form of attributions about the mental states of others.

None of these critics suggest that humans *lack* the powerful mental processes for extracting statistical regularities from behavioral observations: indeed, even 8-month-old infants are able to extract statistical regularities from spoken strings of letters, after only a few hours of exposure to monotonously spoken letter strings built according to particular rules (Saffran et al. 1996). And the area of the brain most closely associated with development of patterned motor behavior (Marr 1969), the cerebellum, is especially enlarged in humans, even as compared to other great apes and greatly more than in monkeys (Barton 2012). The point is rather that the way we describe behavior in everyday talk, in terms of goals, plans, and intentions, may be uniquely human. Mention of “everyday talk” may give the clue to the function of intentional-causal representation: rather than primary cause of behavior, such representations may be valuable because they allow pedagogy, explanation, and deliberate retrospective misrepresentation of behavior, using the medium of spoken language (Byrne 2006). Heretical as it may sound, it is worth questioning whether much everyday human behavior relies on intentional-causal analyses of situations: the alternative is that the same, powerful mechanisms for automatically extracting and using statistical regularities (regularities that themselves result, of course, from underlying intentions and causal dependencies) allow us to function in a “fast and mindless” fashion, responding appropriately and efficiently without deep thought about underlying mechanisms (and see Bargh and Chartrand 1999). Perhaps only when in contemplative mood, when asked directly or when trying to explain (away) our actions, do we invoke the machinery of causal-intentional representation.

Conclusion

People often speak as if intelligence were unitary, as if it could be measured on a single scale, but that is perhaps unlikely. If it is accepted that intelligence is not a single "thing" but rather a mixed bag of devices and processes, endowments, and aptitudes that together produce behavior we see as "intelligent," then it makes sense to study separate facets of intelligence independently of each other. Modern psychometric work, following Rozin (1976), recognizes several "intelligences": social-empathic, technical-mathematical, and commonsense-practical (Sternberg and Kaufman 2002). Presumably, in comparing across species, the different types of intelligence are likely to be even more sharply defined, and many cognitive capacities may need to be distinguished – each of them contributing to an impression of intelligent action but originating in different evolutionary circumstances and often at different periods of evolutionary history. Taking that line, it is possible to summarize what is currently most likely to have happened over the evolutionary timescale that we share with living primates.

Primate evolution has seen two separate changes in intellectual potential, with concomitant brain changes. In the first, well-accepted, evolutionary event, selective pressures to cope with and succeed within larger social groups led to a greater ability to learn in social situations, resulting in species with enhanced abilities in social perception (including sophisticated visual recognition of identity and demeanor) and memory (including subtle correlates of past events). This intellectual change was permitted by increased neocortical capacity, with correlated cerebellar enlargement, and gave the ability to learn impressive-seeming tactics of behavior such as deception and cooperation. Deep understanding of the mechanism of these social tactics was lacking in the individuals of these species themselves, and they (like modern monkeys) were not able to imitate novel skills or show insight into causal relationships in the physical sphere.

In the second evolutionary event, ancestral great apes acquired extra abilities. The selective pressure that resulted in this change may indeed have been competition from Old World monkeys, species that now compete with apes for food in almost all their habitats and have clear advantages in terms of more efficient long-range locomotion and digestion (Byrne 1997b). The result was a clade of modern great apes, all of which have "special" abilities valuable for food acquisition, based on their ability to learn novel routines of skilled, bimanually coordinated manual action, sometimes involving tool use, sometimes involving locomotion, and reliant on imitation by behavior parsing as well as exploration. This intellectual change was permitted by an increase in cerebellum size, going beyond that expected from the already large brains of animals much larger than monkeys. Behavior parsing gave these apes a rudimentary ability to understand the *intentions* (as physically attainable goals) of other individuals and a rudimentary ability to understand the *causal logic* (as correlational likelihood) of physical events.

For individuals to go beyond this "behavioral approximation" of intentions and causality, to a deeper understanding of theory of mind and cause and effect, may have required representation of propositions for which there is no evidence in living nonhuman species – and it may indeed have required language. Comparative psychology cannot help, in that case, since the necessary adaptations must be uniquely human. On the other hand, widening the scope of comparative analysis beyond the nonhuman primates, to examine other taxa entirely, offers the prospect of a more general understanding of the evolution of intelligence. Already a promising start has been made, with some cognitively sophisticated species: parrots (Pepperberg 1999), cetaceans (Herman 1986; Rendell and Whitehead 2001), pigs (Held et al. 2000, 2001, 2002), canids (Miklosi et al. 2004), elephants (Bates et al. 2008; Plotnik et al. 2011; Smet and Byrne 2013), corvids (Emery and Clayton 2004; Dally et al. 2010), and tortoises (Wilkinson and Bugnyar 2012). With converging evidence from all these taxa, and a solid body of data on a significant range of nonhuman primates, it will be time to attack once more the persisting problems of studying intelligence: How many kinds of intelligence are there? To what extent are different intellectual capacities localized in the brain? What adaptive pressures select for particular abilities? And so on.

Theory of Mind: A Primatological Perspective

Juliane Kaminski

Contents

Abstract

Human social cognition is unique because humans can, in some situations, make predictions about others' mental states, an ability referred to as "Theory of Mind." Whether other primates also have the ability to attribute mental states to others is a highly debated question. While members of different primate species seem to follow other individuals' gazes and are sensitive to others' attentional states, there is as yet evidence in only a few species for an understanding of others' visual perspectives, knowledge states, or intentions. The hallmark of mental state attribution, false belief understanding, appears to be a uniquely human skill. At present there is no evidence that any animal species understands that others' beliefs can contradict reality, and therefore be false. This is why the consensus is, for now, that although certain primate species understand certain psychological states in others, there is not sufficient evidence

for true mental state attribution. It remains to be seen whether this view continues to be supported by future studies; in other areas of comparative cognitive science, new results led to dramatic paradigm shifts in recent years.

Introduction

Human social cognition is unique. Like no other species, humans can make predictions about others' mental states – that is, others' intentions, desires, beliefs, and so forth. This ability is referred to as "Theory of Mind" (ToM), a term first introduced by Premack and Woodruff (1978) in their seminal paper asking the question "Does the chimpanzee have a Theory of Mind?" It is called a "theory" because mental states are not directly observable and therefore need to be inferred. Humans develop an understanding of others' psychological states relatively early in life. Children start following others' gaze direction and tracking others' line of sight during their first year (D'Entremont et al. 1997; Moll and Tomasello 2004; Scaife and Bruner 1975). They also seem to understand the function of the eyes while doing so: an infant can distinguish situations during which an observed person's eyes are open and she is therefore able to see from situations during which the observed person's eyes are closed (Brooks and Meltzoff 2002; Butterworth and Jarrett 1991; Lempers 1979; Tomasello et al. 2007). Similarly, around this age already, children understand when others' line of sight is blocked, e.g., by a barrier hiding an object (Moll and Tomasello 2004). Later in life, at around 2 years of age, children start to also understand others' past visual access, namely what they have and have not seen (Dunham et al. 2000; Moll and Tomasello 2007; O'Neill 1996; Tomasello and Haberl 2003), suggesting that the latter ability is cognitively more demanding (Wellman and Liu 2004). It is also by that time that children appreciate that others have desires that can deviate from their own (Rakoczy et al.2007).

However, ToM understanding is only considered to be ontogenetically full-fledged once children understand that others can have false beliefs, a stage which children in Western cultures normally reach around 3.5 years of age (Wellman et al. 2001). Understanding that others have a false belief requires for the individual to understand that another individual's mental state contradicts their own and reality. Therefore, understanding that others have false beliefs requires a fully representational ToM (Wellman et al. 2001), which is why ToM development is considered to be the benchmark for the capability to attribute mental states to others. The standard test for false belief understanding is called the Sally-Anne test (Wimmer and Perner 1983). In this type of test, participants are presented with a hypothetical or re-enacted scenario in which two characters, "Sally" and "Anne," interact over a set of two containers. In the original version, Sally has a basket and Anne has a box. Participants now witness, or listen to, a description of a simple scene in which Sally puts a marble in her basket and then leaves the room. While Sally is away and cannot watch, Anne takes the marble out of Sally's basket and puts it into her own box. Sally then returns and the children are asked where they think she will look for her marble. Children are said to "pass" the test if they understand that Sally will most likely look inside *her* basket first, before realizing that the marble isn't there but in Anne's box.

One question is to what extent these abilities are unique to humans – whether there are any facets of them that we share with other members of our phylogenetic family, the primates. Social cognitive skills would be beneficial to have for many social species, as the social environment often changes rapidly and the individual needs to draw on flexible cognitive skills to adapt to these ongoing changes. The social intelligence hypothesis, formulated by Humphrey (1976), states that social cognitive skills evolved in particular for life in complex social environments, because they help the individual to maneuver freely and adapt flexibly to the constantly changing social environment. The Machiavellian intelligence hypothesis formulated later by Whiten and Byrne (1988) adds competition as a major driving force to this scenario. This hypothesis claims that social cognitive skills evolved mainly to outwit potential competitors in the battle for resources such as food and potential mates. Both hypotheses suggest that we should find social cognitive skills in other species besides humans. To what extent the predicted shared skills would involve an understanding of others' mental states, and could therefore be called ToM, is a very interesting open question.

Gaze Following Behavior in Primates

One of the most basic social cognitive skills is gaze following. Following other individuals' gaze puts the individual in position to gather information about certain aspects of the environment, such as the location of food or predators. This is what makes gaze following a beneficial skill for group-living animals generally. Many primate species follow their conspecifics' or a human's gaze towards outside entities (Povinelli and Eddy 1997; Tomasello et al. 1998).

In a study conducted by Bräuer et al. (2005) with all species of great apes (chimpanzees [*Pan troglodytes*], bonobos [*Pan paniscus*], gorillas [*Gorilla gorilla*], and orangutans [*Pongo abelii*]), a human sat opposite the ape, feeding the subject with food. Then, at a predetermined time during the trial, the human stopped feeding and looked up at the ceiling as if there was something interesting to see there. All great ape species followed the human's gaze by looking up also. This was then compared to a control condition during which the human also stopped the feeding but did not look up, instead looking directly at the wall opposite her. The apes did not look up either in this condition, clearly showing that it was the human's gaze shift which had made them look up in the earlier condition (Bräuer et al. 2005).

There is also evidence that different monkey species, Old World and New World, as well as lemurs, follow the gaze of others (e.g., Burkart and Heschl 2006; Ruiz et al. 2009; Sandel et al. 2011; Tomasello et al. 1998; for a review see Rosati and Hare 2009). Researchers today assume that gaze following is widespread among primates and certain other mammalian species. But whether the ability to follow others' gaze involves an understanding of others' line of sight and perspective and therefore others' psychological state, or whether it is a comparatively automatic response to seeing another individual's gaze shifting in a certain direction, is not possible to determine using this paradigm alone.

This is why researchers designed another paradigm to test if primates also follow the gaze of other individuals around a barrier and therefore geometrically (Tomasello et al. 1999). In this paradigm, instead of looking up at the ceiling, the human looks at a location out of the subject's current view – for example, one side of an opaque barrier which the subject cannot currently see. If subjects just followed another individual's gaze automatically, they would merely shift their gaze in the same direction as the other individual, resulting in them looking at, in this example, their side of the barrier. If, on the other hand, subjects understand something about the other individual's line of sight, they should be motivated to follow the human's gaze to the specific location that the human is looking at. In order to do so, they have to move around the barrier, such that they can see everything from the same angle as the human. Great apes follow a human's gaze around a barrier even if they have to move a certain distance in order to do so (Bräuer et al. 2005). There is also evidence that some monkey species – e.g., common marmosets (*Callithrix jacchus*), Geoffroy's spider monkeys (*Ateles geoffroyi*), and capuchin monkeys (*Cebus apella*) – are able to follow the gaze of others geometrically, indicating that these species, like the apes, do not just automatically react to the gaze shift of others, but actually track the other individual's line of sight, presumedly because they understand another individual's perspective as being different from their own (Amici et al. 2009; Burkart and Heschl 2006).

Another interesting behavior during gaze following experiments, which was first observed in chimpanzees, is so-called "checking back" behavior (Call et al. 1998). The chimpanzees check back, looking again at the human's face, when they have not seen anything interesting after following the human's gaze (Bräuer et al. 2005; Call et al. 1998). Researchers take that as another indication that chimpanzees really do understand the human's perspective in this setting and that they want to confirm the human's line of sight after not being able to see what the human was seeing. Interestingly, there seem to be species differences regarding checking back behavior. While this behavior seems to be robustly present in all the great apes, it is absent in the small ape, i.e., the gibbons. Liebal and Kaminski (2012) examined four different species of gibbons (*Hylobates pileatus*, *H. moloch*, *H. lar*, and *Symphalangus syndactylus*) for their ability to follow the gaze of a human. While the subjects clearly followed the human's gaze, there was no evidence for checking back behavior, indicating that probably the gibbons' gaze following did not include an understanding of the other individual's perspective (Liebal and Kaminski 2012). The same was true for spider and capuchin monkeys, which also follow another individual's gaze, but do not check back after not finding anything interesting (Amici et al. 2009).

To further investigate what primates understand about other individuals' psychological states, researchers have also looked at primates' understanding of the function of the eyes and primates' general understanding of attentional states in others.

Primates' Understanding of Others' Attention

There is much evidence to suggest that various primate species attend to others' attention. All four of the great ape species alter their gestural communication based on the addressed individual's attentional state (Cantero et al. 2001; Kaminski et al. 2004; Leavens et al. 2004; Povinelli and Eddy 1996; Tempelmann et al. 2011). The apes produce more visual gestures, such as reaching, when the recipient of the gesture is in their visual field (Kaminski et al. 2004; Liebal et al. 2004) and produce more tactile gestures, such as touching, when the recipient is not (Liebal et al. 2004). When begging for food from a human, great apes produce visual gestures at a higher frequency when the human's face is oriented (Hostetter et al. 2007) towards them than when it is oriented away, or when the human is bodily oriented towards them rather than oriented away (Call and Tomasello 1994; Kaminski et al. 2004; Povinelli and Eddy 1996; Tempelmann et al. 2011). Chimpanzees seem to attend to the status of the eyes specifically, with studies showing that chimpanzees produce more visual gestures when the human's eyes are visible than when they are not. Chimpanzees also produce more vocalizations when the human's eyes are closed than when they are open (Hostetter et al. 2007). For the other great apes the evidence to date suggests that they may not attend to the status of the eyes specifically, but only to the overall orientation of the face (Kaminski et al. 2004). However, this difference could also be due to a smaller sample size in the relevant studies with other great apes, compared to the studies with chimpanzees.

Different monkey species also attend to others' attentional states. In one study, rhesus macaques preferentially begged from a person whose eyes were oriented towards them, rather than from a person whose eyes were oriented away or covered with a barrier (Flombaum and Santos 2005). Maille et al. (2012) worked with another Old World monkey species, the red-capped mangabeys (*Cercocebus torquatus*). The monkeys in this study also attended to the human's body orientation and begged at higher frequency when the human was oriented towards them rather than away from them. Interestingly, the mangabeys ignored the more subtle cues, like the status of the eyes (Maille et al. 2012). In contrast, capuchin monkeys, which are New World monkeys, seem to be very attentive to others' attentional states, including the status of the eyes. In one study, capuchins looked at a human's face longer when the human looked at them, compared to when the human looked at the ceiling; they also looked at the human's face longer when the human's eyes were open rather than closed (Hattori et al. 2007). There is also evidence for a lemur species attending to others' attention. In a study involving a competitive situation over food, ring-tailed lemurs (*Lemur catta*) avoided food that the human was facing, preferring food that the experimenter was not facing (Sandel et al. 2011). Interestingly, other lemur species tested in the same study did not show the same sensitivity to the human's attention. The authors attribute this difference to the fact that ring-tailed lemurs live in groups with a notably more complex social structure than the other species, supporting the so-called social intelligence hypothesis, mentioned above, which states that social cognitive skills evolved to maneuver in more complex social environments (Humphrey 1976).

Primates' Understanding of Others' Visual Perspective

One way of testing whether primates, like humans, understand others' visual perspective is to confront them with a situation during which they need to assess another individual's visual access to, say, a certain location, in order to achieve their goal. In Flavel's et al. (1978) terminology, an individual proves to have "Level 1 perspective taking" if it understands that another individual's line of sight is blocked by, e.g., a barrier (Flavell et al. 1978). Povinelli and Eddy (1996) tested chimpanzees' understanding of others' visual perspective by confronting them with a situation during which the chimpanzees had to decide which of two humans to beg from. Both humans were holding a piece of food (e.g., an apple); one of them could always see the chimpanzees, whereas the other individual's visual access was blocked – say, by a bucket this person was wearing over the head. (The human who had visual access was also holding a bucket, but held it placed on his shoulder so that it would not block his view.) The chimpanzees in this setting begged from both people indiscriminately and therefore did not seem to attend to whether the humans' visual access to their communicative attempts was blocked or not. In recent years, however, researchers have argued for a paradigm shift that would change the interpretation of this experiment. The revised view is that chimpanzees' cognitive skills might have evolved in the context of competition over resources, rather than to aid more cooperative interactions. This is why researchers now argue that it is more natural for chimpanzees to compete over food rather than to expect another individual to behave cooperatively towards them.

To obtain data that might clarify the situation, Hare et al. (2000) designed a situation during which two chimpanzees, one dominant over the other, compete over two pieces of food. While both pieces are visible to the subordinate animal, only one piece of food is visible to the dominant animal, whereas the other piece is hidden by an opaque barrier from the dominant individual's view. To rule out that the subordinate chimpanzee would simply orient his behavior towards the behavior of the dominant, the subordinate chimpanzee got a head start while the dominant's door was still closed. Once the subordinate had clearly made a choice, the dominant's door was opened and she could enter the arena. The subordinate chimpanzees in this situation clearly preferred to approach the food piece hidden from the dominant to the food piece that both of them had visual access to. To rule out that the subordinate chimpanzees were just seeking to be protected from the dominant individual by the physical barrier, instead of truly understanding anything about the other individual's perspective, the researchers conducted a control experiment. In the control condition there was also a physical barrier, but it was transparent. If the subordinate chimpanzees were just seeking physical protection, then this transparent barrier should have had the same effect as the opaque barrier, but it did not. When the barrier was transparent and the dominant chimpanzee could therefore see both food pieces, then the subordinate chimpanzees did not differentiate between the two locations (Hare et al. 2000).

In a later study Hare et al. (2006) showed that chimpanzees also actively conceal behavior from the view of a human competitor. As part of their decision which of two food pieces to approach, the chimpanzees had to decide which route to take based on the human's visual access to the two food pieces. While one approach route provided cover from the human's view, the other route did not. This was because, in a first condition, the human's face was oriented towards one piece of food but not the other, or, in a second condition, the chimpanzees could approach from behind either a transparent barrier or an opaque occluder. In a third condition, one piece of food was behind a barrier that fully shielded the chimpanzees' approach, while the other piece of food was behind a barrier that only partially shielded their approach. In all three conditions, the chimpanzees preferred to approach the food via the hidden route, which was not the case in situations during which no competitor was present (Hare et al. 2006).

Some researchers argue that, rather than understanding which route the human had visual access to, the chimpanzees in this study were following the more egocentric approach of simply avoiding the route from which they could see the human. Melis et al. (2006) tested this hypothesis by conducting another study in which chimpanzees competed with a human over two pieces of food. This time, both pieces were visible to the human but at no moment could the chimpanzees see the human while approaching one or the other piece. However, as there was a transparent tunnel leading to one piece of food and an opaque tunnel leading to the other piece, the human could observe the chimpanzee's hand reaching for one piece but not the other. In this situation (but not when they were alone and no competitor was around) chimpanzees preferred to reach through the opaque tunnel, presumably because they were able to imagine what the human could see from her – the human – perspective and understood that the human could not see their – the chimpanzee's – hand (Hare et al. 2006; Melis et al. 2006).

Interestingly, orangutans in a similar paradigm behave differently from chimpanzees. The orangutans in one study also preferred to reach through the opaque tunnel, but did so after initially inspecting (looking through) the transparent tunnel. This suggests that the orangutans' decision in this paradigm was driven more by egocentric behavioral preferences, such as avoiding the tunnel through which they could see the human (Gretscher et al. 2012).

That there might be significant species differences among the great apes when it comes to perspective-taking abilities is also supported by a study from Okamoto-Barth et al. (2007). In this study a human gazed in the direction of a target on the opposite side of a wall. In some situations a barrier was completely obstructing the human's view, whereas in other situations the obstruction had a window and the human could see the target. Chimpanzees, bonobos, and gorillas followed the human's gaze significantly more often when the obstruction had a window in it than when it did not – presumably because they understood that the human was actually able to see what was behind the barrier in one but not the other condition. The orangutans, however, did not differentiate between the two situations, suggesting that they did not attend to the human's perspective in this experiment (Okamoto-Barth et al. 2007).

Though there is convincing evidence that chimpanzees understand others' *visual* perspective, there is mixed evidence about chimpanzees' understanding of others' *auditory* perspective (Bräuer et al. 2007; Melis et al. 2006). While one study suggests that chimpanzees understand what other can and cannot hear (Melis et al. 2006), another study suggests that they do not (Bräuer et al. 2007). Melis et al. (2006) put chimpanzees in a competitive situation with a human over food. To get at the food the chimpanzees had to make the decision whether to reach through a noisy tunnel, which produced a loud rattling sound when opened, or through a silent tunnel. When competing with the human, the chimpanzees preferably reached through the silent tunnel, in an attempt to conceal their behavior. When the chimpanzees were alone and there was no competition, they did not differentiate between the two tunnels (see Santos et al. 2006, for similar results with rhesus monkeys).

Bräuer et al. (2007) put two chimpanzees, one dominant over the other, in a competitive situation over food and placed two obstacles between them. A human then placed one piece of food in a very noisy manner behind one of the obstacles. The subordinate saw that piece of food, whereas the dominant individual could only hear the placement. A second piece was then placed silently behind the second obstacle; again, the subordinate could see this take place, but the dominant had no information about the second piece of food. In this situation, subordinate chimpanzees did not prefer one piece over the other, indicating that they did not take the auditory perspective of the dominant individual into account. One significant difference between Bräuer's study and that of Melis et al. described above is that in the latter, the chimpanzees themselves produced the noise they heard, by reaching through the noisy tunnel; whereas in the study by Bräuer et al. the noise was produced by the human. A possible conclusion might be that it is easier for chimpanzees to attend to sound when they are the producer of the noise rather than just the noise receptor. It could also be, however, that the chimpanzees in Bräuer et al.'s study had simply learned that producing sounds in the experimental situation had consequences (Bräuer et al. 2007).

Primates' Understanding of Knowledge and Ignorance in Others

The evidence presented above shows that a number of different primate species can follow others' gaze, attend to others' attention, and, in some cases, have a flexible understanding of others' visual perspective. But going further, some primate species also seem to understand what others "know" – in the sense of having seen or experienced it in the past.

Hare et al. (2001) presented two chimpanzees, one dominant over the other, with a competitive situation over a piece of food. Between the two individuals were two opaque barriers. A human placed a piece of food behind one of the two barriers; either both chimpanzees watched this event or only the subordinate chimpanzee did. In the condition during which the subordinate knew that the dominant had not seen the food being placed, she reached for the food significantly more often than in the condition where the dominant had seen the placement. Subordinate chimpanzees also reached for the food in conditions during which the dominant had seen the initial placement of the food, but the food had then been moved to another location without the dominant's knowledge. They did so more often than in conditions during which the food was also moved to a new location but in full view of the dominant (Hare et al. 2001).

Kaminski et al. (2008) confronted chimpanzees with a situation during which two of the animals – one the actual experimental subject, and one serving as competitor – sat at opposite sides of a table. Mounted on the table was a sliding board with three cups on it, which a human slid back and forth between the two chimpanzees. Two of the three cups were baited with a piece of food. While the subject animal had witnessed the baiting of both cups and also had information on which cup remained empty, the competitor was only informed about one baited location, but had not witnessed the baiting of the second cup and also had no information as to which cup remained empty. In one condition, the competitor was the first to be given a choice between cups (and the subject did not see him do so), after which it was the subject's turn. If subjects understood that their competitor's choice was based on what the competitor had witnessed, they should then also understand that the one piece of food the competitor had seen being placed was now gone, and should aim for the other piece. This is exactly what the chimpanzees did. In this condition, the subject chimpanzees significantly preferred to pick the cup which contained the piece of food only they themselves had seen being placed. This was compared to a second condition, during which the general course of events was similar, except that this time, after the baiting was finished, it was the subject who got to choose first (and the competitor did not see that). Now subjects had the chance to maximize their food outcome if they changed their strategy and switched to a preference for the one piece of food the competitor had seen. When it was her turn, the competitor would then aim for an empty cup, which would give the subject the chance to obtain the second piece when it was her turn again. In this condition, chimpanzees did not show a preference for one over the other piece but chose randomly, indicating that they were not thinking prospectively (Kaminski et al. 2008). However, there was a significant difference between the two conditions in how often subjects aimed for the piece of food the competitor had not seen, indicating that the chimpanzees did not follow a simply associative rule like, e.g., "Avoid the piece of food the competitor has looked at."

That chimpanzees may even make inferences about other individuals' inferences is suggested by a study conducted by Schmelz et al. (2011), using a very similar paradigm to the one described above. Instead of cups there were two opaque boards on the table, and there was one piece of food hidden under one of these, resulting in that board being slanted. When their competitor had chosen before them, chimpanzees avoided the slanted board – presumably on the assumption that their competitor had already made the inference as to where the food was, based on seeing one board being slanted (Schmelz et al. 2011).

Taken together, the experimental evidence presented above suggests that chimpanzees have some understanding of knowledge and ignorance in others. This is also supported by evidence from wild-living chimpanzees. Crockford et al. (2012) showed that wild-living chimpanzees were more likely to produce alarm calls about a snake in the presence of group members who were not aware of the snake than in the presence of group members who were aware of it. This shows that chimpanzees monitor the knowledge states of their group members and can take them into account where appropriate (Crockford et al. 2011).

Primates' Understanding of Others' Intentions

In their original study, concerned with the question whether chimpanzees have a ToM, Premack and Woodruff (1978) designed an experiment to see whether Sarah, a female chimpanzee, was able to solve problems based on her understanding of others' intentions and goals. Understanding others' intentions is a highly beneficial skill for any species living in a complex social environment, as it enables the individual to anticipate others' behavior in certain situations. Sarah was shown videotaped scenes of a human actor being confronted with a variety of problems, e.g., an inaccessible banana or being locked in a compartment. Then Sarah was shown a series of photographs, one of which indicated the solution to the problem, e.g., a picture of a stick with which to reach for the inaccessible banana. Sarah had no difficulty picking the photograph depicting the solution to each respective problem. Premack and Woodruff (1978) argued that this could be seen as evidence that Sarah understood the human's goals and chose the correct means to the end. These studies were criticized, however, based on the suggestion that the problems posed could be solved by simple association and did not necessarily require for the chimpanzee to understand the human's goals (Savage-Rumbaugh et al. 1978).

Later Call and Tomasello (1998) confronted chimpanzees and orangutans with a situation during which a human indicated a baited box by placing a marker on top of it. The apes had no information about the location of the food and therefore relied on this communicative cue to find the correct location. Then the human placed a marker on top of each of two boxes. One marker was placed deliberately and intentionally, while the other marker, which ended up on the other box, was not placed with a clear intent but dropped seemingly accidentally. The apes clearly distinguished the boxes based on the human behaving differently towards each box, and on the level of intentionality with which the markers were placed. Again, one criticism of this study, as of that of Premack and Woodruff (1978), was that the chimpanzees required some training to understand that the marker indicated food, etc. The chimpanzees' behavior could therefore again be explained by association rather than by an understanding of others' goals (Call and Tomasello 1998).

Call et al. (2004) consequently designed a study in which no training was necessary. In this study the researchers compared chimpanzees' behavior in situations during which the human was either unwilling or unable to hand over a piece of food. The chimpanzees in this experiment were used to receiving their food through holes in a clear Plexiglas panel. When the human was unwilling to hand over the food, he would, e.g., merely present the food on his side of the glass, alternating his gaze between the food and the chimpanzee, but then pull the food back with no intention to hand it over. When the human was unable to hand over the food he would, e.g., present it while trying to pass it through a small hole in the Plexiglas panel – a hole through which it simply could not fit – and, while doing so, alternate his gaze between the food and the chimpanzee, then pull the food back after his failure to hand it over. The chimpanzees stayed away from the Plexiglas panel longer when the human was unwilling to give them food than when he was unable, indicating that they do distinguish these situations – presumably because they attend to the human's different goals in the different situations (Call et al. 2004; see Phillips et al. 2009, for similar results with capuchin monkeys).

Another context during which attending to others' goals is important is the social learning context. To copy another individual's actions successfully and focus on the relevant aspects of their behavior, it is beneficial for the observer to understand the demonstrator's goals. Gergely et al. (2002) did a study which suggests that human children imitate rationally, meaning that children in certain situations only copy another individual's actions when those actions represent intended behavior, but not when the behavior was produced because it was forced by certain constraints. The children in that study saw an adult switch on a light by pressing a button with his or her forehead. Sometimes use of the forehead was a choice, since the adult's hands were free, as visible for the child. At other times the adult was forced to use his or her forehead because the adult's hands were occupied. The children in this study copied the action of using the forehead to switch on the light more when it was the demonstrator's chosen action, but less when the action was forced because the person's hands were occupied. Buttelmann et al. (2007) designed a similar study for chimpanzees and confronted specially trained circus chimpanzees with a situation during which a human demonstrator performed a certain action. For example, very similar to the study by Gergely et al. (2002), the human would switch on a light with his forehead either with his hands free (which meant it was his choice to use his forehead) or with his hands occupied (which meant he was forced to use the forehead). These specially trained chimpanzees attended to the rationality of the human's actions, insofar as they copied those actions more often when they were freely chosen and less often when they were forced by circumstances (Buttelmann et al. 2007).

To see if great apes can infer others' goals based on contextual cues alone, without additional behavioral cues, Buttelmann et al. (2012) confronted apes with another situation during which food was handed over to them by a human. In order to hand over the food, the human at some point had to get up and step over a barrier, to reach one of two buckets from which he was feeding the apes. To see whether or not the apes simply anticipated what the human would do based on the latter's "intention movement" of getting up and stepping over the barrier, in the relevant experimental conditions there was additional contextual information which, if the apes could interpret it, would help to clarify the human's goals at the moment when the human was getting up. In one condition, for example, the human got a call through a walkie-talkie, which was placed on the floor. In this context the human's stepping over the barrier was necessary merely to pick up the walkie-talkie and talk to the other person. This was compared to a baseline condition during which the human stood up with the intent to feed the apes from the bucket and no additional contextual information was presented. The animals in this study clearly differentiated between these situations, presenting further evidence that apes not only attend and react to behavioral cues but might indeed interpret the human's goals in the different situations (Buttelmann et al. 2012).

Primates' Understanding That Others Have False Beliefs

As noted in the Introduction, the benchmark for the capability to attribute mental states to others is false belief understanding. This is because understanding that others have false beliefs requires a fully representational ToM (Wellman et al. 2001); it requires for the individual to understand that others' knowledge about the world can deviate from one's own, as well as from reality. As of yet, there is no evidence that any nonhuman animal can pass a false belief test.

Call and Tomasello (1999) designed a nonverbal false belief task for children as well as chimpanzees and orangutans. In this task one person (the "hider") hid a reward in one of two containers, and the other person (the "communicator"), after observing the initial hiding event, communicated the location of the reward to the subject by placing a marker on top of the baited container. The initial phase of the study showed that the children as well as the apes clearly understood the marker to be an indicator for the reward. In the actual false belief condition, the communicator had seen the baiting process but then left the area, upon which the other person, the hider, would switch the locations of the containers. Now the communicator's marking of one of the containers was wrong, since this person had a false belief about the location of the reward. Therefore, for subjects to get at the reward they now needed to avoid the location marked by the communicator, as reality contradicted the communicator's belief. The children in this setting had no problem solving the task and made the correct decision of avoiding the cup the communicator had marked in the false belief condition. The apes, however, still preferred the marked location, even if the marker in this situation was placed by a person who had a false belief about the container's content (Call and Tomasello 1999).

One problem with this study is that it is possible that the apes simply learned an associative rule – associating the marker with the food and never truly understanding it as a means to communicate. Another weakness is that the general structure of the paradigm is cooperative, when other studies have shown that chimpanzees seem to be most attentive to the general course of events when the context is competitive (Hare et al. 2001). Kaminski et al. (2008) therefore designed a study involving a competitive scenario. Two chimpanzees had to compete over a piece of desirable food. The animals sat opposite each other, with a table between them with three cups on it. Both chimpanzees, subject and competitor, had access to the three cups on the table and could choose alternately. The subject, however, had exclusive access to an additional cup, which also contained a piece of food – one which was of lesser quality than the piece of food on the table. This second piece of food served as the "opt out" option, which subjects could choose should they assume that all cups on the table are empty.

Both individuals then observed how the human placed the piece of high-quality food in one of the three cups on the table. After this initial baiting event, the human did one of two things: he either turned the cup and lifted the piece of food out again, then placed it back ("lift"); or, he turned the cup, lifted the piece of food, and then shifted it to another location ("shift"). The competitor either watched this second manipulation or not. The actual false belief condition was, therefore, the condition during which the food was shifted to a new location and the competitor did not see this. After all baiting was completed, the competitor always chose first; the subject did not see her choice. When it was the subject's choice, she had to make the decision whether to aim for the high-quality food on the table or, in case she assumed that it was gone, opt out and aim for the lower-quality food next to her. The chimpanzees in this situation aimed for the high-quality food significantly less often when the competitor had seen the second baiting event than when the competitor had not, which again supports the notion that chimpanzees are sensitive to knowledge ignorance in others. However, whether or not the food was only lifted (and the competitor's belief about its location was therefore still true) or shifted (and the competitor's belief about the location of the food was therefore false) did not affect subjects' choices, which supports the assumption that chimpanzees do not understand when others' beliefs are false (Kaminski et al. 2008).

This view is also supported by evidence from a study by Krachun et al. (2009), who set up a situation during which the chimpanzees competed with a human over food. The human competitor observed another, second person hide a reward in one of two containers. Then the competitor left the room (or turned around), and the other person switched the locations of the containers. The competitor re-entered and reached towards the container which he thought contained the food. While children tested in the exact same paradigm inferred that the competitor now had a false belief and therefore chose the container the competitor did *not* reach for, the apes did not attend to the competitor's false belief and did not avoid the container he reached for (Krachun et al. 2009).

Subsequently, in a looking paradigm designed by Marticorena et al. (2011) the authors showed that rhesus macaques, just like chimpanzees, understand knowledge ignorance in others but not false beliefs. In this study the monkeys, interacting with a human, looked longer at a location where they expected the human to search for an object the human had knowledge about. However, whether or not the human's belief about the location was false did not affect the monkey's looking behavior (Marticorena et al. 2011).

Conclusion

The ability to attribute mental states to others is a distinctive feature of human social cognition. Whether this is a uniquely human skill or shared with other species is highly debated. Recent research suggests that some primate species, especially the great apes, seem to understand certain psychological states in other individuals. It appears that primate species follow other individuals' gaze and consider it a relevant cue. Various primates, including monkeys and apes, are also sensitive to others' attention states. This is apparent in communicative situations during which primates modulate their gestural signals to the attentional state of the recipient. This ability seems to be rather widespread in the primate world, suggesting that it serves an important evolutionary function for gregarious species. There is also evidence in some primate species for the ability to take the visual perspective of others, and for an understanding that it can differ from one's own. While chimpanzees, humans' closest living relatives, also seem to understand something about others' knowledge and attention states, there is no evidence as yet that members of any primate species besides humans can understand when others' beliefs contradict reality and are therefore false. As false belief understanding is seen as the hallmark of a fully developed Theory of Mind, we need to take this as evidence that no nonhuman primate species have the capacity to truly attribute mental states to others.

Part III

Phylogeny of Hominins

Potential Hominoid Ancestors for Hominidae

George D. Koufos

Contents

Abstract

Human origin and evolution are a prominent topic among scientists, one on which there continues to be disagreement. Each new finding raises new questions and arguments. This chapter summarizes the currently available data and hypotheses on hominid origins. The origin of the hominids may be traceable to Oligocene anthropoids such as *Aegyptopithecus*, which share some derived features with the early hominoids. The Latest Oligocene taxon *Kamoyapithecus* could be the oldest known hominoid, as it has relationships with some Miocene taxa. *Proconsul* is the most plausible taxon linking the hominoids to the great ape and human clades, as it preserves a mosaic of features from both groups. The Middle Miocene European hominoids seem to play an important role, and could include the possible link between more archaic hominoids and the great ape and human clades; candidates are numerous among both European and African forms. Among Late Miocene taxa, the craniodental morphology of

Ouranopithecus provides the closest and most plausible link connecting the hominoids to the extant great apes and humans; its strong relationships to the australopiths and *Homo* put this taxon among the best candidates for this role at the moment. The Latest Miocene *Sahelanthropus* and *Orrorin* seem to be important links in the evolution of the hominids, whereas the Asian Middle-Late Miocene hominoids have strong similarities with the modern orangutans and are related to the "*Pongo*-lineage."

Introduction

The presence, origin, and future of man on earth are problems that have long preoccupied humans. Questions like "Who is my ancestor?", "What was it like?", or "Where do I come from?" were among the first for which answers were sought. Humanity's need to find answers to these questions led, first, to origin myths, and later, after the development of science, to theories of human origins. Anthropology and biology offer answers based on the comparative anatomy, behavior, and genetics of humans and other animals. The evolutionary approach to understanding human origins seeks to identify all the characters that humans share with apes (our closest relatives) and with other animals. The ancient Greek philosopher Aristotle was among the first to recognize the affinities of man with the animals and placed man in the animal kingdom. Much later, the Swedish taxonomist Linnaeus classified humans laterally to the apes and monkeys, while the pre-Darwinian French naturalist Buffon as well laid out the view that humans have similarities with the apes, creating a link in the long chain of the beings.

Paleoanthropology is the branch of paleontology that addresses the above questions based on the primate fossil record. Paleoanthropologists try to find the links between various fossil and extant taxa in order to complete the "chain" leading to humans. This is difficult and time-consuming work, as fossils are relatively rare and widely dispersed; in most cases the remains are fragmentary, providing limited data. The discovery of new fossils over the last 50 years and the development of new methods for studying, comparing, and dating fossils, as well as for reconstructing their locomotion and paleoenvironment, have significantly increased our knowledge about the morphology and evolutionary relationships of primates. One of the main goals of paleoanthropology is to find the ancestor of humans – usually referred to as "hominids" – among the common stock of hominids and apes – known as "hominoids". The hominoids constitute a group of African and Eurasian forms that lived during the Miocene epoch and are assumed to include the common ancestor of humans and apes.

The following is a brief sketch of what we know about the hominoids. Later sections of this chapter will go into more detail on evidence from different time periods. The chapter does not answer what are still open research questions; its goal is merely to survey the available data about the potential hominoid ancestor of the hominids, providing a comprehensive overview.

The first known hominoids are from Africa. The earliest possible representative of the hominoids originates in the Oligocene, the time of the genera

Aegyptopithecus and *Kamoyapithecus*. Hominoids are more securely represented by the large set of Early Miocene proconsulids. The majority of the Early Miocene hominoids are restricted to Africa and are only found in East Africa and the Arabian Peninsula. A large number of taxa are recognized (*Proconsul, Afropithecus, Heliopithecus, Nyanzapithecus, Mabokopithecus, Rangwapithecus, Turkanipithecus, Dendropithecus, Micropithecus, Simiolus, Morotopithecus, Limnopithecus, Kalepithecus*), but most of them are known from only a few fragmentary fossils. Their size varied from small monkey sized (~3 kg) to large great ape sized (~80 kg), while their locomotion was quadrupedal and arboreal. The majority were fruit or leaf eaters. *Kenyapithecus*, who appeared at the end of the Middle Miocene (~14 Ma), was probably a hard-object feeder. The uppermost Middle Miocene and Late Miocene hominoids of Africa are rare and poorly known compared to Early/Middle Miocene forms (*Kenyapithecus, Samburupithecus, Otavipithecus, Orrorin, Equatorius, Sahelanthropus*).

Towards the end of the Middle Miocene, the "story" of hominoid evolution continued in Eurasia, where hominoids were abundant until the Late Miocene (~7.5 Ma). Hominoids that migrated to Eurasia are represented by the taxa *Griphopithecus* and *Kenyapithecus*. After their arrival, they strongly diversified; several new taxa (*Dryopithecus, Pierolapithecus, Anoiapithecus, Oreopithecus, Ouranopithecus, Sivapithecus, Ankarapithecus, Lufengpithecus*) appeared between 8.0 and 13.0 Ma. The size of these taxa varies from medium to large, while their dietary type ranges from soft-object feeders, like *Dryopithecus* and *Oreopithecus*, to hard-object feeders like *Ouranopithecus, Ankarapithecus, Lufengpithecus*, and *Gigantopithecus*. Postcranial remains are relatively rare, and the available material indicates quadrupedal locomotion; however, one of these taxa, *Pierolapithecus*, is interpreted as an early orthograde (Moyà-Solà and Köhler 1996).

The occurrence of the oldest australopithecines is dated to ~4.5 Ma, whereas the last Miocene hominoids date to the Middle Turolian (~7.5 Ma). There is thus a large gap of ~3 Ma between them. Until the beginning of the twenty-first century, no fossils were known from this time interval. The discovery in 2000 of the African hominoid *Orrorin*, dated to ~6 Ma (Senut et al. 2001), provided the first evidence to fill the gap. One year later, the skull of *Sahelanthropus*, found in Chad and dated to 6.0–7.0 Ma, offered more data about this unknown time interval (Brunet et al. 2002). Most recently, some cranial remains of a hominoid from the Turolian of Turkey (Begun et al. 2003; Güleç et al. 2007) and an isolated tooth of a hominoid possibly from the Middle Turolian of Bulgaria (Spassov et al. 2012) have added further evidence.

Origin of the Miocene Hominoids

The origin of the Miocene hominoids is to be found among the Oligocene primates. The division of the anthropoids into two main groups – the Platyrrhini (New World monkeys) and the Catarrhini (Old World monkeys) – is thought to have occurred at the Eocene/Oligocene boundary. One of the oldest and best-known catarrhines is

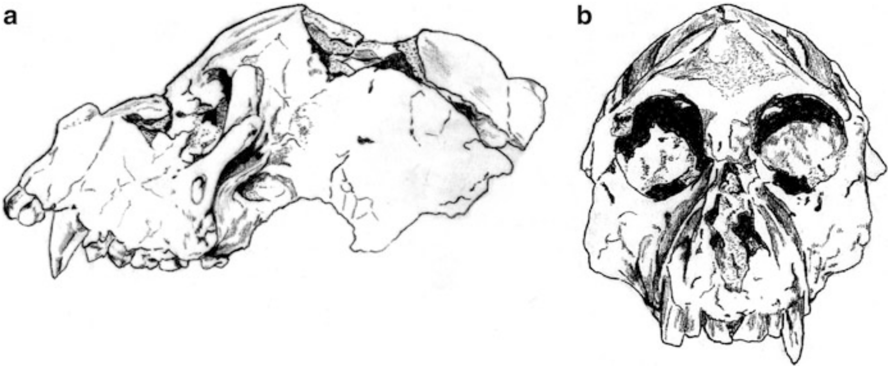

Fig. 1 *Aegyptopithecus zeuxis*, sketch of the skull found in 1966. (**a**) Lateral and (**b**) frontal view (Drawn from the photo of Szalay and Delson (1979; Fig. 222))

Aegyptopithecus (Fig. 1), from the Fayum province of Egypt, with an estimated age from 32.0 to 35.0 Ma (Tattersall et al. 1988). Since the Eocene/Oligocene boundary is estimated to be at ~35 Ma, the splitting of the catarrhines and platyrrhines coincides with the beginning of the Oligocene and bridges the gap between the Eocene Prosimii and the Miocene hominoids.

Aegyptopithecus preserves some characters of the platyrrhines, such as the absence of an auditory tube in the external ear, but it has two premolars in each half of the jaw, a feature that serves to classify it within the catarrhines, being among the most primitive of them. The main morphological characters of *Aegyptopithecus* (Fig. 1) are an elongated skull with strong prognathism, strong postorbital constriction, large and completely enclosed orbits, weak supraorbital torus, large interorbital distance, a posteriorly developed sagittal crest, well-developed sexual dimorphism in the canines, and broad molars with rounded and low cusps, well-developed cingulum, and thin enamel. The braincase is small: its capacity is estimated at ~30 cm^3 (Conroy 1990). The endocasts indicate morphology falling between the primitive and more derived anthropoids (Radinsky 1973). The humerus is relatively stout, with a large medial epicondyle and relatively wide trochlea. The morphology of the metapodials and phalanges suggests powerful grasping. The overall morphology of *Aegyptopithecus* indicates quadrupedal climbing, while the morphology of the skull and teeth suggests a soft-object feeder. This type of diet fits well with its postcranial morphology, indicating a good climber.

The presence of some derived characters in *Aegyptopithecus* has been interpreted in different ways. Simons (1965), focusing on features shared between *Aegyptopithecus* and *Proconsul*, suggested a close phyletic relationship between the two genera. Later, Andrews (1978) reported close similarities between the upper molars of *Aegyptopithecus zeuxis* and *Proconsul africanus*, but could not identify clearly shared derived features. The cranial proportions and the external ear showing a clear auditory tube in *P. africanus* are more derived features than those of *Aegyptopithecus* (Szalay and Delson 1979). The primitive robust postcrania of *Aegyptopithecus*, with less joint mobility, suggest relatively more leaping locomotion, whereas in the Miocene hominoids leaping constitutes only a small share of locomotion (Gebo 1993). Tattersall et al. (1988) suggested that *Aegyptopithecus* represents an early catarrhine close to the split between platyrrhines and catarrhines. *Aegyptopithecus* is a mosaic of primitive and derived characters, linking Eocene anthropoids to modern apes and monkeys, and could represent or be close to their common ancestor – a notion evidenced by its Greek species name *zeuxis*, meaning "way of connecting, bridge." However, the available data do not fully support this view. Despite the possible link between *Aegyptopithecus* and the hominoids, there is no clear bridge, but in fact a 10.0 Ma gap in the fossil record between *Aegyptopithecus* and the first Miocene hominoids.

The earliest possible representative of the hominoids is the Latest Oligocene *Kamoyapithecus* from Lothidok (Kenya), which is dated from 27.8 to 23.9 Ma (Leakey et al. 1995). The large size of *Kamoyapithecus*, although not decisive evidence, is similar to that of some early Late Miocene apes, suggesting that it could be the earliest known hominid (Leakey et al. 1995). During the Oligocene, several Afro-Arabian taxa of early catarrhines are known to have existed (*Catopithecus, Oligopithecus, Moeripithecus, Propliopithecus*), which could also be related to the Miocene hominoids.

The Miocene Hominoids

Whereas the Eocene was the period of the prosimians and the Oligocene that of the early anthropoids, the subsequent Miocene represents the epoch of the hominoids, with many named genera and species. The taxonomic expansion is due in part to the limited material evidence allowing for differences in opinion among scientists, and in part to a tendency among paleoanthropologists to postulate new taxa. The hominoids expanded across the Old World from Spain to China and from South Africa to northern Europe (Fig. 2). During the last 40 years, extensive field campaigns carried out in the Old World by several scientific groups have brought to light numerous fossils. In addition, the revision of old material and new "discoveries" made in museum collections have increased the Miocene hominoid fossil record. This great knowledge gain of the last decades has led to the recognition of several new taxa, well defined through the application of several new methods, and to the recognition that the Miocene was an epoch of high diversification among hominoids.

During the Miocene, several geotectonic movements took place in the Old World that caused geographic and environmental changes with either positive (diversification, expansion, migration) or negative (reduction or even extinction) effects on the hominoids. Many new hominoids appeared in Eurasia after their arrival from Africa during the upper part of the Middle Miocene. For a long time scientists believed that the Turolian dryness and the arrival of the cercopithecids were the main reasons for the extinction of the hominoids at the end of the Vallesian

Fig. 2 Geographic map indicating the most important sites with hominoids; *blue square* = Oligocene and *red circle* = Miocene localities

in Eurasia. This idea changed after the discovery of Turolian hominoids in Turkey and Bulgaria (Güleç et al 2007; Spassov et al. 2012). In Asia *Gigantopithecus* survived, as we know from finds in the Pleistocene of Southern China and Vietman (Kelley 2002). In Africa, hominoids existed in the Turolian as well; new discoveries during the last years have increased our estimate of their number (Kunimatsu et al. 2007; Brunet et al. 2002; Suwa et al. 2007; Senut et al. 2001). The paleogeographic and paleoclimatic changes that took place during the Miocene were strong factors contributing to the rapid evolution and diversification of the hominoids, leading to more derived and better adapted forms. Although the increasing severity of the ecological conditions eventually caused the extinction of most Miocene hominoids, for some of them the environmental pressure created an opportunity to develop comparatively more derived and evolved characters, which enabled their adaptation to the new conditions.

As mentioned above, *Aegyptopithecus* and *Kamoyapithecus* might be the ancestors of the Miocene hominoids; the possible common ancestor of humans and apes, then, must be looked for among the stem Miocene hominoids. From this point of view, the hominoids are a very important and interesting group of primates. Over the last 50 years, several hominoids have been presented as possible ancestors of the hominids, but so far there is no one candidate that has clearly won out. The problem is complicated and cannot be solved easily, as the relationships among the fossil hominoids, as well as between extinct and extant members of this superfamily, are not fully known. The data for the fossil hominoids in most cases are limited and do not permit clear definitions and comparisons. The number of specimens is another problem. No fossil hominoid is known well enough to allow for complete understanding of its morphology and relationships. There are several important time gaps between the various forms, which prevent clear establishment of their relationships. When there is so much uncertainty to contend with, subjectivity of interpretation is also an issue: it can be difficult for researchers not to engage in speculation. As we proceed below to discuss the evidence for the most probable ancestors of the hominids, the Miocene hominoids, these caveats must all be borne in mind.

Knowing the age of fossil hominoids is important for establishing their evolutionary relations. Yet here too lies a source of uncertainty and debate. Efforts at age determination must often confront contradictory data and give rise to differences of opinion. Nevertheless, for most hominoids satisfactory age correlation has been achieved by either biochronology, or radio-/magneto-chronology, or both. The stratigraphic distribution of the main Miocene hominoids of Africa and Eurasia is given in Fig. 3. The figure also shows the European land mammal stages and zones, which are mentioned in the text. The continuous line indicates the stratigraphic distribution of the taxa, the dashed line their possible distribution, and an asterisk denotes that the taxon is known from a single site or all known material has similar age. It is quite clear from Fig. 3 that the hominoids are already well known from the Early–Middle Miocene of Africa, while in Eurasia, they are more common during the Late Miocene.

The Early Miocene

Early Miocene hominoids are known only from Africa. The best known taxon is *Proconsul* (Fig. 4) (Walker 1997). The oldest remains of *Proconsul* (*P. africanus, P. major*) were found in Kenya and Uganda and are dated to 19.0–20.0 Ma. Two other species (*P. nyanzae* and *P. heseloni*) are known from Kenya and dated to 17.0–18.5 Ma (Harrison 2002) (Fig. 4).

Proconsul has an estimated body size that varies from that of a small monkey to that of a female gorilla. It shows sexual dimorphism in body size, as well as in the size and morphology of the canines. This sexual dimorphism is a primitive feature for *Proconsul*. The nasomaxillary region of *Proconsul* has a primitive internal structure with a large fossa incisiva. In addition, the maxillary processus palatinus is clearly lower than the premaxilla (Ward and Kimbel 1983; Ward and Pilbeam 1983). This nasomaxillary morphology ("African type," according to the latter authors) is similar to that of *Australopithecus, Dryopithecus, Ouranopithecus*, and the recent *Gorilla*. The skull has a moderately short and broad face compared to that of *Aegyptopithecus*, and a broad and relatively rhomboid-shaped nasal aperture, trapezoid orbits with rounded corners, a slight supraorbital torus with slightly swollen glabella, and a clear auditory tube like the recent cercopithecoids and hominoids (Szalay and Delson 1979; Walker 1997; Harrison 2002).

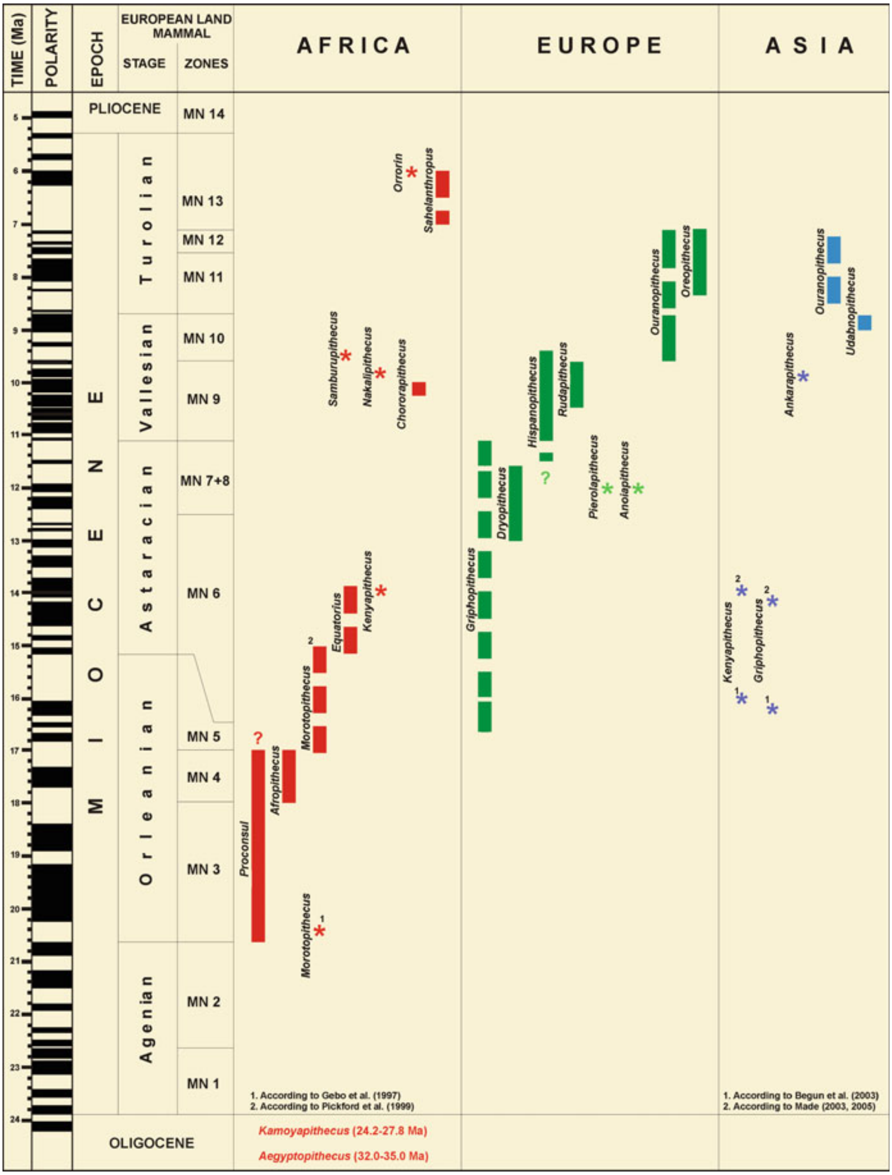

Fig. 3 Stratigraphic distribution of the main Miocene hominoids; *continuous line*: stratigraphic distribution of a taxon; *dashed line*: possible distribution of a taxon; *asterisk*: taxon known from a single site or from several localities of the same age

The dentition of *Proconsul* preserves primitive features, such as relatively long and broad canines, a well-developed cingulum, asymmetric upper premolars with large paracones (buccal cusps), and the presence of a honing facet on the P3. Although the dental morphology of *Proconsul*, which indicates a soft fruit feeder

Fig. 4 *Proconsul heseloni*. Sketch of the first skull found in 1948 by M. Leakey on Rusinga Island, Lake Victoria (Drawn from a photo of Harrison (2002))

(Kay and Ungar 1997), is well known, there are no clear synapomorphies with either the hominoids or the cercopithecoids. In many ways, it is similar to the dentition of the Oligocene Fayum catarrhines.

The known postcrania of *Proconsul* are relatively abundant and provide a large set of characters. However, the systematic interpretation of these characters leads to contradictory results. *Proconsul* has anterior and posterior limbs of more or less similar length, indicating quadrupedal arboreal locomotion. The recent hominoids have a more erect posture (knuckle walking and brachiation). The robustness of the long bones of *Proconsul* suggests similarities to cercopithecoids, chimpanzees, and to ceboids with less elongated limbs. The distal extremity of the *Proconsul* humerus resembles that of small apes, while the distal extremity of the ulna is relatively straight, as in most anthropoids. The carpals indicate a climbing primate, whereas the phalangeal proportions are very close to macaques, suggesting a quadrupedal form (Walker and Pickford 1983; Ruff et al. 1989; Rose 1992, 1993).

Most authors consider *Proconsul* to be a stem hominoid close to the origin of the Hominoidea (Hopwood 1933; Pilbeam 1969; Rose 1983, 1992, 1993; Andrews 1985; Begun et al. 1997; Kelley 1997; Ward 1997). These authors conclude that *Proconsul* shared derived characters with the extant hominoids. A different opinion suggests that *Proconsul* is a sister taxon of the recent great apes and humans (Walker and Teaford 1989; Rae 1997; Walker 1997). Neither opinion is accepted by Harrison (2002), whose detailed and critical analysis of key synapomorphies of the face, ear region, and postcrania shared by extant hominoids leads him to conclude that these are lacking in *Proconsul*. In contrast, Walker (1997) does refer to shared derived characters between *Proconsul* and more advanced hominoids, but he also recognizes possible features in the postcrania indicating a primitive catarrhine.

The frontal sinus in the skull of *Proconsul* could be a derived character – one shared with the extant hominoids and great apes (Andrews 1992). Although the frontal sinus is absent in Old World monkeys, it is clearly present in New World monkeys, which complicates the analysis of this feature. The absence of a tail is a derived character of the hominoids; the lack of a tail in *Proconsul* (Ward et al. 1991) thus suggests a relationship to the hominoids. The presence of six lumbar vertebrae rather than seven in *Proconsul* (Ward et al. 1993) also indicates a similarity to the hominoids and distinguishes it from monkeys. Several characters of the phalanges could be derived and shared with extant apes (Begun et al. 1994). The morphology of the trapezium and first metacarpal of *Proconsul* could be viewed as derived, with several characters shared between *Proconsul* and extant hominoids (Rose 1992). The relatively greater deviation of the ulna of *Proconsul* is, again, a derived character of the hominoids (Beard et al. 1986); in non-hominoid catarrhines the deviation of the ulna is not as strong. Rae (1997) studied a set of facial characters in the Early Miocene and modern hominoids and found that Early Miocene hominoids, including *Proconsul*, are linked to modern hominoids, in particular to great apes. As mentioned, Walker (1997) recognized *Proconsul* as a morphologically primitive hominoid, sharing several derived characters with the extant hominoids.

In sum, *Proconsul* has a set of characters that link it with the Miocene hominoids, and even with the extant great apes and humans, but controversies remain. Future research may provide additional data, permitting more definitive conclusions about its phylogenetic relationships.

In addition to *Proconsul*, several other taxa are known from the Early Miocene of Africa that could be related to the extant great apes and humans. It is appropriate here to give some information about the most important of them and their relationships.

The genus *Afropithecus* was recognized in Kenya based on finds from localities dated to the early Miocene; the age of these finds is estimated between 17.0 and 18.0 Ma (Leakey and Walker 1997). *Afropithecus* is characterized by its relatively large size (similar to the recent chimpanzee), long and wide skull, narrow palate, large diastema, narrow and protruding premaxilla, large interorbital distance, asymmetrical orbits, slender supraorbital torus, frontal sinus extending to the glabella, lack of the superior transverse torus in the mandible, and an oblique angle between ascending ramus and mandibular corpus. The upper canine has a round basal section and deep mesial groove, while the lower canine is low crowned and laterally compressed. The upper premolars are wide and without lingual cingulum, while the cusps are moderately heteromorphic. The upper molars are narrow, with moderately developed lingual cingulum and very thick enamel. The dentition of *Afropithecus* thus differs clearly from that of *Proconsul* (Begun 2013), but the few known postcrania resemble those of *P. nyanzae* in size and morphology (Leakey and Leakey 1986; Leakey et al. 1988; Leakey and Walker 1997; Ward 2007).

Afropithecus is a large hominoid whose facial shape resembles that of *Aegyptopithecus zeuxis* (Leakey et al. 1991), but whose postcrania are more derived than those of *Aegyptopithecus* and closer to *Proconsul* (Harrison 2002; Ward 2007). The teeth of *Afropithecus* are more derived than those of the Oligocene forms, featuring enlarged and procumbent incisors and thick canines. These characters as well as the very thickly enameled teeth suggest a hard-object eater, which places *Afropithecus* closer to *Kenyapithecus*. The lack of these characters in the dentition of *Proconsul* indicates a less derived feature, but its derived facial shape is closer to the later hominoids.

Morotopithecus is known from Uganda from a single species, *M. bishopi*, which was originally described as *Proconsul major*. Its age is debatable: the correlation of the fauna and older K^{40}/Ar^{39} datings suggest a Middle Miocene age, 17.0–15.0 Ma (Bishop et al. 1969; Pickford et al. 1999), whereas $^{40}Ar/^{39}Ar$ datings suggest an Early Miocene age at ~20.6 Ma (Gebo et al. 1997). *Morotopithecus* is relatively small sized, smaller than *P. major*. The skull is characterized by a long, high, and narrow face, short premaxilla, wide palate, narrow interorbital distance, large diastema, and a primitive nasomaxillary region with a large fossa incisiva. There is strong sexual dimorphism in the upper canines. The upper premolars are broad and relatively large. The molars have bunodont cusps, wrinkled enamel, and a well-developed lingual cingulum, similar to those of *P. major* (Pilbeam 1969; Andrews 1978; Harrison 2002). Although *Morotopithecus* differs from *Proconsul* in several features, its cranial and dental characters suggest that it is closer to the proconsulids.

The postcrania of *Morotopithecus* are few but provide some significant characters for the genus. The anatomy of the lumbar vertebrae shares some derived features (robust pedicles, reduced ventral keeling) with the extant hominoids. The scapula (some authors do not agree that it belongs to this genus) has a rounded and expanded upward glenoid articular surface, as in hominoids. Finally, the morphology of the femur and phalanges resembles that of *Proconsul* and indicates an arboreal form (Walker and Rose 1968; Gebo et al. 1997; MacLatchy et al. 2000; Harrison 2002). On the basis of its postcranial morphology, *Morotopithecus* could be considered as belonging to the Hominoidea (Gebo et al. 1997; Harrison 2002). However, Andrews (1992) reported that the morphology of the skull and teeth of *Morotopithecus* are less derived than in proconsulids, while the upper teeth share derived features with afropithecines. Thus *Morotopithecus* seems to belong to the Hominoidea given its postcranial morphology, but to pattern with the proconsulids in its cranial and dental characters. It is recognized as a stem hominoid (Gebo et al. 1997; MacLatchy et al. 2000; Harrison 2002). Harrison (2002) raises the question whether the derived features of the vertebral column might be an adaptation to increased orthogrady.

As apparent from this overview, a great number of Early Miocene hominoid taxa are included in the proconsulids, but the majority is known from only one specimen or isolated teeth. They are referred to under various names, and as mentioned, their relationships to each other, as well as to the other extinct and extant hominoids, are questionable. Nevertheless, the ancestor of the Early/Middle Miocene hominoids is now deemed to be a member of this group. The reason is that taxa like *Proconsul* seem to have more similarities to the later hominoids in their various derived characters, while also retaining some primitive features. The derived characters of the face, the teeth, and the postcrania of the proconsulids allow for any one of them to have a close relationship to the younger forms.

The Middle Miocene

Compared to the Early Miocene African hominoids, the Middle Miocene ones are few in number. One of the most important taxa is *Kenyapithecus*, known from Kenya (Leakey 1962) and dated to 14.0 Ma (Kelley and Pilbeam 1986). It is a medium-sized hominoid with clear canine fossa, highly zygomatic arches, clear sexual dimorphism, strong inferior torus, robust mandibular corpus, less asymmetric P4, large upper molars without lingual cingulum, and a P3 with a honing facet and buccal cingulum (Ward and Duren 2002). Few postcrania of *Kenyapithecus* are known, but those that have been found display some evolved characters, such as a posteriorly directed medial epicondyle and a wide trochlea in relation to the breadth of the capitulum of the humerus (Andrews and Walker 1976). The phylogenetic relationships of *Kenyapithecus* are still debated. *Kenyapithecus* has derived mandibular and dental characters (larger inferior than superior transverse torus, relatively short and wide corpus) that are shared with extant hominoids. Compared to the Early Miocene hominoids, it is characterized by a reduction or absence of cingulum in the molars, an increase of the enamel thickness, large upper premolars relative to the molars, and a more molarized dp3 close to that of *Gorilla* and *Pan* (McCrossin and Benefit 1997). All of these features are shared with *Ouranopithecus, Sivapithecus*, and *Griphopithecus*.

Equatorius is a Middle Miocene African hominoid found in Kenya. It is dated between 15.5 and 14.0 Ma (Feibel et al. 1989; Ward et al. 1999). *Equatorius* is medium sized, with strong sexual dimorphism, more symmetrical upper premolars, reduced or absent lingual cingulum, less heteromorphic lower premolars, thick enamel, as well as a P3 with a honing facet and variably developed buccal cingulum. It is considered a primitive hominoid, belonging to a derived clade of *Afropithecus* (Ward and Duren 2002).

The morphological characters of the teeth and mandible of *Equatorius* and *Kenyapithecus wickeri* suggest that there is no generic difference between the two taxa, which can be synonymized (Benefit and McCrossin 2000). Begun (2000) questioned the generic distinction between *Equatorius* and *Griphopithecus* from Europe, suggesting evidence of a biogeographic link between the two. Ward et al. (1999) and Kelley et al. (2000) reported that the incisor, canine, and maxillary morphology of *K. wickeri* are more derived than in *Equatorius* and distinguish the two genera. The robust mandible and the large inferior torus of *Griphopithecus alpani* (known from Paşalar and Çandir, Turkey) are similar to those of *Kenyapithecus*, but the upper jaw is less robust than that of *Equatorius*, while the dental morphology is similar (Andrews and Harrison 2005). Moreover, *K. wickeri* exhibits similarities to the rarely represented hominoid of the Paşalar sample, which are enough to attribute both to the same genus (Martin and Andrews 1993; Ward et al. 1999; Kelley et al. 2000) (see below).

The Eurasian Middle Miocene hominoid fossil record is richer than the African one and includes several genera. *Griphopithecus* was originally found in the locality of Devinska Nova Ves of Slovakia (Abel 1902), and was later recognized in the localities of Klein-Hadersdorf, Austria (Steininger 1967), and Engelswies, Germany, by the species *G. suessi* (Heizmann 1992; Heizmann et al. 1996), as well as in Paşalar and Çandir, Turkey, by the species *G. alpani* (Andrews et al. 1996). The fossiliferous site Engelswies is considered the oldest in Eurasia; it is designated to the European Mammal Zone MN 5 (Mein 1999). According to Casanovas-Vilar et al. (2011), the localities of Devinska Nova Ves and Klein-Hadersdorf might be younger than 11.6 Ma, corresponding to the upper part of the European Mammal Zone MN 7 + 8 or younger. A similar uncertainty surrounds the age of the Turkish localities; they are correlated either to the European Mammal Zone MN 5 (Begun et al. 2003) or to MN 6 (Made 2003; 2005), (Fig. 3). Considering these data, it seems that the history of the hominoids in Eurasia starts at ~16.0 Ma. According to Rögl (1999) the physical connection between Africa and Eurasia was gradually completed during this period. Three main migration waves are recognized to have occurred at that time, including the arrival of the hominoids in Eurasia.

Griphopithecus is comparable in dental size to *Pan*, and has a robust mandible, strong superior and inferior transverse torus, very elongated and strongly inclined planum alveolar, and low-crowned molars with rounded cusps, thick enamel, and a buccal cingulum. The few known fragmentary postcrania indicate an arboreal adaptation (Begun 2002; Kelley 2002). *Griphopithecus* fossils consist mainly of isolated teeth and are difficult to use as evidence for establishing phylogenetic relationships either to the African Middle Miocene hominoids or to the Late Miocene Eurasian ones. The limited maxillary and mandibular fragments from Paşalar preserve mainly primitive hominoid characters (Andrews et al. 1996). The taxon's relationships with the Late Miocene Eurasian hominoids are not clear.

A second, rare Paşalar hominoid was described as a new species under the name *Kenyapithecus kizili* by Kelley et al. (2008). It shares several characters with the African *K. wickeri*, such as the robust and moderately deep maxillary alveolar processes, the restricted maxillary sinus, and the zygomatic process which originates almost above the alveolar margin (Kelley et al. 2008). The presence of *Kenyapithecus* in Paşalar is a piece of evidence linking the African and Eurasian hominoids.

A rich sample of Middle Miocene hominoids has been recovered from the Vallès Penedès Basin (Spain). The material was discovered in the long section of Abocador de Can Mata. It is ascribed to three different hominoid taxa: *Pierolapithecus catalaunicus, Anoiapithecus brevirostris*, and *Dryopithecus fontani*, (Moyà-Solà et al. 2004, 2009a, b) (Fig. 5).

Pierolapithecus catalaunicus is known by a partial skeleton; it is dated to the European Mammal Zone MN 7 + 8, with an estimated age of ~11.9 Ma (Moyà-Solà et al. 2004). The main characters of *Pierolapithecus* are a low face, flat nasals, posteriorly situated glabella, highly originated zygomatic arches situated anteriorly

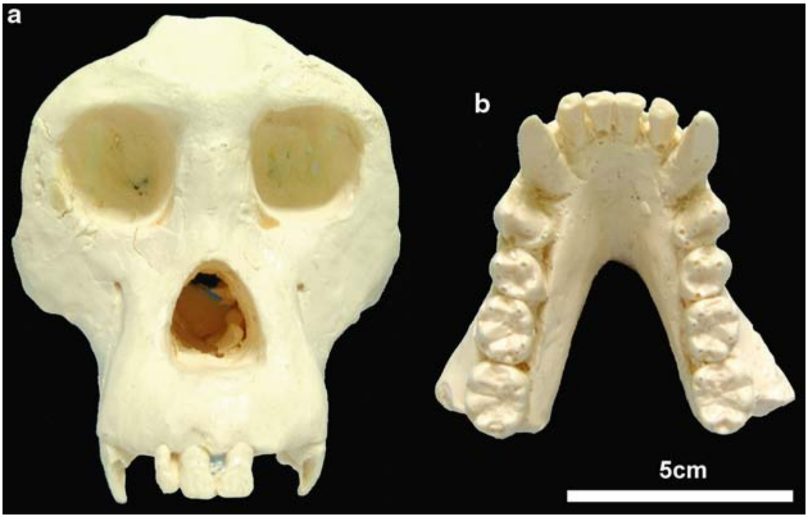

Fig. 5 (**a**) *Dryopithecus laietanus*, Can Llobateres I, Vallès Penedès, Spain. Cast of the reconstructed skull CLI 18000; (**b**) *Rudapithecus hungaricus*, Rudabànya, Hungary. Cast of the mandible RUD-14; the casts are to me by D. Begun

at the level of M1, high nasoalveolar clivus, reduced heteromorphy in the premolars, elongated molars, absence of a cingulum, large, low-crowned, and compressed upper canines, strong rib curvature, a large and robust clavicle, and short metacarpals and phalanges. The morphology of the thorax (wide and anteroposteriorly shallow), the lumbar vertebrae, and the wrists indicate suspensory, orthograde adaptations. The facial morphology displays the main derived characters of the extant great apes. *Pierolapithecus* retains some primitive characters, such as the short phalanges, suggesting palmigrade features. The overall facial and dental structures of *Pierolapithecus* indicate that it is probably close to the last common ancestor of great apes and humans (Moyà-Solà et al. 2004).

The second Spanish hominoid found in Abocador de can Mata, named *Anoiapithecus brevirostris*, is dated at ~11. 9 Ma (Moyà-Solà et al. 2009a). Despite its primitive features (low-crowned teeth, labial and lingual flare in the cheek teeth, short roots in the canines, heteromorphic cusps in the upper premolars) and the autapomorphic facial morphology, *Anoiapithecus* shares some characters with the afropithecids and the Middle-Late Miocene hominoids (Moyà-Solà et al. 2009a). According to last authors the combination of some autapomorphic features of this taxon with the kenyapithecines and hominid synapomorphies, as well as the presence of both groups in Eurasia during the Middle Miocene, support the “Back to Africa” hypothesis.

Among the Middle Miocene hominoids of Europe, *Dryopithecus fontani* is one of the oldest known from western and central Europe (Fig. 3). It was originally described from La Grive, France, and is correlated to the European Mammal Zone MN 7 + 8 (Casanovas-Vilar et al. 2011). According to Moyà-Solà et al. (2009b), the facial pattern of *D. fontani* resembles that of *Gorilla*; this resemblance could indicate an early member of the hominins or a stem hominid convergent with the lower facial pattern of *Gorilla*.

The Late Miocene

African Late Miocene hominoids are rare; they are represented by few remains, the majority of which have been unearthed only recently. A maxillary fragment of a large-sized hominoid from Kenya has been known since 1982; it is referred to as *Samburupithecus kiptalami* and dated to 9.5 Ma (Ishida and Pickford 1997). This sole known maxillary fragment has been claimed to have similarities with the modern gorilla by some researchers (Ishida and Pickford 1997), but others have recognized primitive *Proconsul* features and analyzed it as a survivor of *Proconsul* lineage during the Late Miocene (Begun 2007). The maxilla of *Samburupithecus* has some similarities to the Eurasian *Ouranopithecus*, such as the low origin of the zygomatic arches and the thick enamel; the taxon's relationships with the extinct and extant hominoids are unclear.

A mandibular fragment with extremely worn teeth, as well as some isolated teeth of a hominoid, have been described from Nakali, Kenya as the new species *Nakalipithecus nakayamae*, with an age of ~9.8 Ma; the Nakali material has strong similarities to *Ouranopithecus* and is considered a possible ancestor of the latter (Kunimatsu et al. 2007). The isolated canine of *Nakalipithecus* is similar to that of *Ouranopithecus*; likely an unworn M3 (KNM-NA46436) from Nakali is similar to that of *Ouranopithecus*, differing in the more developed buccal cingulum and the slightly smaller width. Except for geographic reasons, these small differences cannot support a different genus; even their age difference is very small and falls within the error range. More and better material from *Nakalipithecus* will be needed to clarify its relationships to the other Late Miocene hominoids.

Chororapithecus known from few isolated teeth from Ethiopia and dated to 10.5-10.0 Ma, is considered as is more closely related to African apes and the human clade than any Eurasian taxon. (Suwa et al. 2007). Although the last authors suggest similarity to the modern *Gorilla*, the material is very scanty for definite conclusions.

Some hominoid remains from the Latest Miocene of Africa (Fig. 3) provide more interesting data about the evolution of apes and hominines. A few mandibular and postcranial remains of a hominoid named *Orrorin* have been found in Kenya; the locality is dated at ~6.0 Ma (Senut et al. 2001). *Orrorin* is characterized by jugal teeth that are smaller than those of australopiths, a small dentition relative to body size, large and not shovel-like I1, short C, relatively deep mandibular corpus, and small M2 and M3 with thick enamel. The femur has a spherical head rotated anteriorly, an elongated neck with oval section, and a mesially salient lesser trochanter. The humerus has a vertical brachioradial crest, and the proximal manual phalanx is curved (Senut et al. 2001). *Orrorin* preserves some primitive ape characters (deep mandibular ramus, anterior teeth, and P4), as well as some more hominid ones (postcanine megadontia, postcranial pieces of evidence of bipedalism). According to Pickford et al. (2002), the femur of *Orrorin* shares some derived features with australopiths and *Homo*, but none with *Pan* or *Gorilla*, and among the Hominidae, it is closer to *Homo* than to australopiths.

In 2001, a skull with some mandibular and dental remains of a Late Miocene hominoid named *Sahelanthropus tchadensis* were found in Chad; the associated mammal fauna indicates a Latest Miocene age, 6.0–7.0 Ma (Brunet et al. 2002). The taxon is characterized by weak prognathism, a small braincase, a long and narrow basicranium, large canine fossa, a small and narrow U-shaped dental arch, a very wide interorbital distance, a thick and continuous supraorbital torus, relatively small incisors and canines, rounded cusps in the molars, and moderate enamel thickness (Brunet et al. 2002). *Sahelanthropus* exhibits several primitive features, like the small braincase, the morphology of the basioccipital bone, and the position of the petrous portion of the temporal bone. But it also preserves a set of derived features, such as small apically worn canines, medium-thick enamel, a horizontally oriented and anteriorly situated foramen magnum, reduced prognathism, a large and continuous supraorbital torus, and the absence of canine diastema, which indicate close relationship to the hominid clade. On the basis of the presence of this mosaic of characters and the age of *Sahelanthropus*, Brunet et al. (2002) suggested that it belongs to the hominid clade and is closer to the common ancestor of *Homo* and chimpanzees. Contrary to this opinion, Wolpoff et al. (2002) concluded that the dental, facial, and cranial characters of this skull cannot define its position among hominids.

The sparse material of both *Orrorin* and *Sahelanthropus* does not permit clear definition of their phylogenetic relationships with each other and with the other hominids. Given that there is little evidence for the presence of hominoids in the time interval from ~7.5 to 4.5 Ma, these two Late Miocene African hominoids constitute a link between the Miocene and Plio-Pleistocene hominids.

The Late Miocene Eurasian hominoids show impressive diversification and include the first indication of a relationship with the great apes and human clade. Different opinions have been expressed about their taxonomy and evolutionary relationships. They are classified with the pongines (Moyà-Solà and Köhler 1995, 1996), the dryopithecines (Casanovas-Vilar et al. 2011), and the hominines (Begun 2009, 2013) or, alternatively, as a dead group without relationship to the modern apes (Kunimatsu et al. 2007; Suwa et al. 2007).

The earliest known Late Miocene European hominoid is *Rudapithecus* from Rudabanya, Hungary, with an age of ~10.0 Ma (Kordos and Begun 2002). At the same time *Hispanopithecus* appeared in Spain (Casanovas-Vilar et al. 2011). Two skulls of *Rudapithecus* are known, which are characterized by a short face, an elongated neurocranium, weak but distinct supraorbital torus, biconvex vertically directed and relatively short premaxilla, narrow nasal aperture, high and broad root of the zygomatic arches situated above the mesial half of M2, shallow canine fossa, large interorbital distance, squared-to-rounded orbits, and a reduced foramen incisivum with short incisive canal (Kordos and Begun 1997, 2001). The cranial capacity of the Rudabànya skulls is estimated at a mean 320 cm^3 for RUD-77 and

305 cm^3 for RUD-197–200 (Kordos and Begun 1998, 2001). *Rudapithecus* shared a significant number of craniodental characters with the great apes and hominines (Begun et al. 2012; Table 1) and could be related to the ancestor of these groups. The postcranials of *Rudapithecus* preserve a mixture of characters between *Pongo* and the great apes. The humerus, ulna, femur, and phalanges are similar to those of the great apes, while the wrist bones have mixed pongine and great ape characters (Begun 1993; Begun and Kordos 2011).

Hispanopithecus is also known by a rich sample from the Vallesian of Spain (Fig. 3), including a partial face and skeleton (Moyà-Solà and Köhler 1995, 1996). The morphology of a lumbar vertebra suggests orthogrady, as in the modern great apes, while the femur and the phalanges are reminiscent of *Pongo* (Moyà-Solà and Köhler 1996; Almècija et al. 2007). Despite the mixed clues about their taxonomy, these early Late Miocene hominoids give strong indication of more affinities with the modern great apes and human clade than the Middle Miocene ones. They share several derived characters with the younger hominids and recent great apes, linking the Early Miocene African with the Late Miocene Eurasian hominoids.

A well-known hominoid from the eastern Mediterranean region is *Ouranopithecus*, which is represented by the two species *O. macedoniensis* and *O. turkae*, while one P4 from Bulgaria also bears strong similarities to this genus (de Bonis et al. 1973; 1990; de Bonis and Koufos 1993, Koufos and de Bonis 2004; Koufos 1993, 1995; Güleç et al. 2007; Spassov et al. 2012). The type species *O. macedoniensis* is known from three localities in northern Greece by numerous craniodental remains. All localities are correlated to the Late Vallesian or to European Mammal Zone MN 10. The bio- and magneto-chronology suggest an age between 9.6 and 8.7 Ma (Koufos 2006, 2013).

O. macedoniensis has a large body size, in the range of variation of gorillas. There is strong sexual dimorphism expressed in the overall size of the dentition and in the size and morphology of the canines. In brief, the morphological characters of *O. macedoniensis* (Fig. 6) are as follows: a well-developed supraorbital torus with a small glabellar depression, large interorbital distance, relatively short nasals, small, low, and quadrangular orbits, primitive nasoalveolar area with a large fossa incisiva, strong and low-rooted zygomatic arches, narrow and convex mandibular condyle, low and thick horizontal ramus, long planum alveolare with well-developed fossa genioglossa, strong superior and inferior torus, shovel-like incisors, relatively reduced canines, relatively symmetric upper premolars, low cusps in the molars, more symmetric P3 without honing facet, thick enamel, and an absent or very weak cingulum (de Bonis and Melentis 1977, 1978, 1985; de Bonis and Koufos 1993; Koufos 1993, 1995; de Bonis et al. 1998; Koufos and de Bonis 2004). The species is a hard-object feeder (Merceron et al. 2005, 2007), living in an open environment with shrubs, bushes, and small trees, and thick grass floor such as savanna woodland (de Bonis et al. 1992, 1999; Koufos 1980, 2006).

The phylogenetic position of *O. macedoniensis* among the hominids is very important, as it shares several derived characters with *Australopithecus* and *Homo*. Some of these characters are discussed in more detail below.

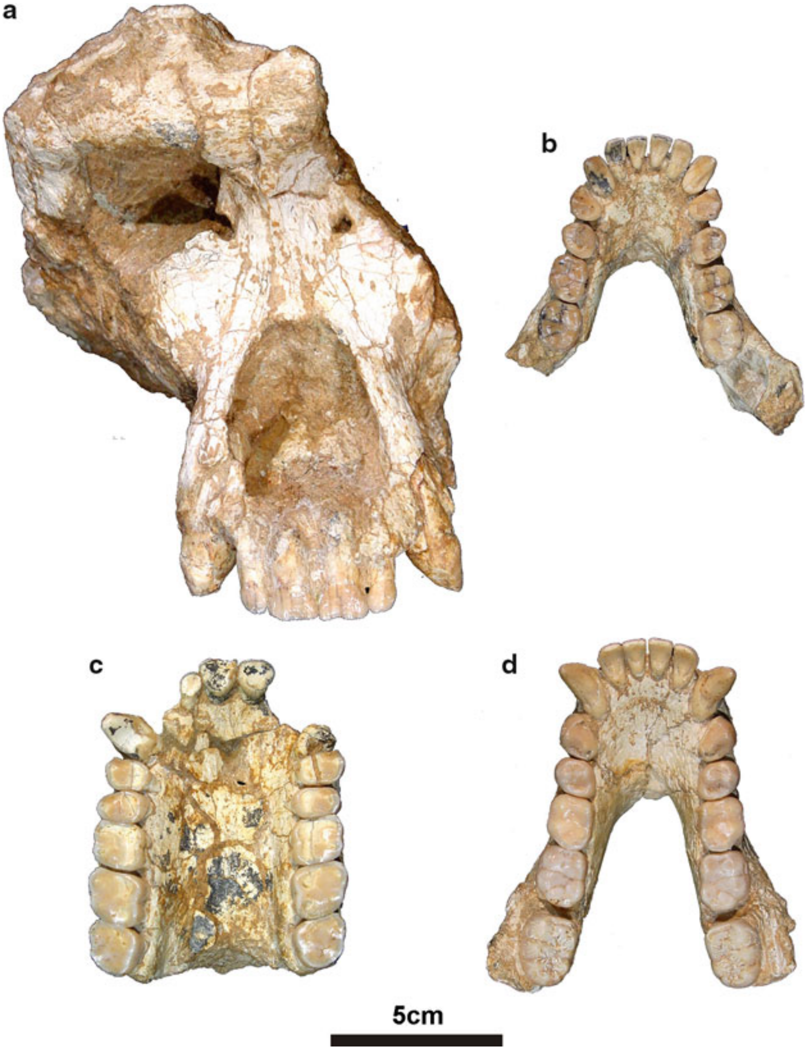

Fig. 6 *Ouranopithecus macedoniensis*, Axios Valley, Macedonia, Greece. (**a**) Male skull from Xirochori-1, XIR-1; (**b**) female mandible from Ravin de la Pluie, RPl-54, HOLOTYPE; (**c**) male maxilla from Ravin de la Pluie, RPl-128; (**d**) male mandible from Ravin de la Pluie, RPl-55

The lateral outline of the upper face is a derived character, since in primitive Early–Middle Miocene hominoids it was more oblique, while in *O. macedoniensis* it is more vertical. The glabella–nasion–prosthion angle is 120°, while in the fossil and extant apes it reaches 140°. In *Australopithecus africanus* it is 115° and in *A. boisei* 150°, because of the flattening of the face (de Bonis and Koufos 1993).

The structure of the naso-alveolar area of *O. macedoniensis* belongs to the primitive "African pattern," as also seen in *Dryopithecus* and *Gorilla*. It is different from that of *Pongo* and *Sivapithecus*, while it is closer to *Australopithecus* (de Bonis and Melentis 1987; de Bonis and Koufos 1994). However, it is more derived than *Proconsul* and *Morotopithecus* and less derived than *Australopithecus afarensis* and the recent chimpanzee.

The narrow mandibular condyle of *O. macedoniensis* is a more hominine-like character. In the apes, the mandibular condyle is only slightly convex, while in *Homo* it is narrower and more convex. In *A. afarensis* it is more apelike (de Bonis and Koufos 1997, 2001). The narrowness of the mandibular condyle can be measured by the index [cranial–caudal diameter × 100/medial–lateral diameter]. In *O. macedoniensis* this index is 44.4, in *A. robustus* 33.8, in modern *Homo* 41.4–45.7, in *Gorilla* 46–56, in *Pan* 47–53, and in *Pongo* 43.3–43.9 (de Bonis and Koufos 1993). Both the narrowness and the shape of the mandibular condyle are related to the form of the temporomandibular joint. The latter is large and relatively flat in apes, while in hominines its anterior part is cylindrical and followed by a mediolateral directed fossa (Picq 1990). The capitulum of the *O. macedoniensis* mandible could correspond to the latter kind of temporomandibular joint.

The cingulum is absent or very weak in all cheek teeth of *O. macedoniensis*; compared to the strong cingula of *Proconsul* and the pliopithecids; this is a derived character. The presence of accessory cusps (cuspids) at the distal ends of the upper and lower third molars, as in *Australopithecus afarensis*, is a derived character for *O. macedoniensis* – one that is related to the function of the teeth. The enamel thickness relative to the body weight of *O. macedoniensis* can be compared to that of some australopiths (*Paranthropus*, *Australopithecus africanus*),but it is thicker than in *Dryopithecus*, *Sivapithecus*, *Proconsul africanus, P. major, Gorilla, Pan*, and *Pongo* (de Bonis and Koufos 2001). Thus, enamel thickness could be a primitive feature relative to the recent hominoids, but derived when compared to the Early–Middle Miocene hominoids. Enamel thickness depends also upon the hardness of the food. A change to a more open environment, such as woodland or wooded savanna, is associated with harder food items. In the eastern Mediterranean an environmental change which brought about more open habitats occurred at the end of the Middle Miocene (Koufos 2006), leading to thick enamel in hominoids like *Ouranopithecus* and *Ankarapithecus*. At the same time, in western and central Europe the environment continued to be more forested (until the Middle Vallesian), and correspondingly the hominoids from those regions are thin-enameled (*Dryopithecus, Rudapithecus*).

The morphology of the P3 in *O. macedoniensis* (not elongated, rounded occlusal outline, more symmetric buccal face, absence of a honing facet, less oblique protocristid) distinguishes it from the apes. The wear pattern of the crown in the P3 is similar to that in *Australopithecus afarensis*, as a result of the absence of a honing facet in both forms and the similar function of the tooth (de Bonis and Koufos 2001). Indeed, the wear pattern of the whole dentition of *O. macedoniensis* is similar to that of *A. afarensis* (Koufos and de Bonis 2006).

The size of the upper canine of *O. macedoniensis* is a derived character. The plesiomorphic characters of the canine are the high, buccolingually flattened crown and the presence of a sharp distal crest on the buccolingual surface. This feature is present in cercopithecids, as well as in extant and Early–Middle Miocene hominoids. The shape of the canine is more rounded and in this respect very close to *Australopithecus afarensis*. The height of the upper canine of *O. macedoniensis* is relatively reduced (de Bonis and Koufos 1993), while its morphology is completely different from that of the primitive hominids. The height of the crown is less reduced than in *Australopithecus afarensis* (Johanson et al. 1982). In comparison, the canine of *Proconsul* is three times larger than that of *O. macedoniensis*. The size of the canine compared to the size of the cheek teeth is also small in *O. macedoniensis*, and is similar to that in *Australopithecus afarensis* and female *Gorilla*. It is much larger (more than 120) in the Early–Middle Miocene and extant hominoids (de Bonis and Koufos 1993).

In regards to the lower deciduous dentition, *O. macedoniensis* shares some derived characters with the Plio-Pleistocene hominines. The deciduous canine of *O. macedoniensis* is more reduced, compared to the molars, than that of *Proconsul* and *Ardipithecus*, but less reduced than that of australopiths and *Homo*. The lower deciduous premolars of *O. macedoniensis* are more derived than in Early–Middle Miocene and recent hominoids, and less derived than in australopiths and *Homo* (Koufos and de Bonis 2004).

All of these characters suggest that *O. macedoniensis* has strong relationships to the Plio-Pleistocene hominines: it shares several derived characters with them and can be considered their ancestor. A cladistic analysis of 22 derived characters of *O. macedoniensis* shared with the extinct and extant hominoids, as well as with *Australopithecus* and *Homo*, suggests that (i) *O. macedoniensis* can be included in the subfamily Homininae; (ii) the splitting of *Homo* and the African apes is dated at more than 9.5 Ma; and (iii) *O. macedoniensis* can be considered a sister group to *Australopithecus* and *Homo* (de Bonis and Koufos 1997).

Ouranopithecus macedoniensis also has several characters similar to those of australopiths; some of them are plesiomorphic (shape of symphysis, large interorbital distance, shallow or absent supratoral sulcus, large M3, development of nasomaxillary area). However, it preserves a set of apomorphic features. Some of them, such as thick-enameled teeth or canine reduction, may be homoplasies, but it would be peculiar and exceptional for all of them to be homoplasies (de Bonis and Koufos 1999). There are some differences of opinion concerning this hypothesis. Begun (1992) suggests a relationship between *Gorilla* and *O. macedoniensis* and concludes that *Dryopithecus* has slightly more evidence (gnathic structures and positional behavior) in its favor for being ancestral to African apes and humans. But the postcranial morphology, and consequently the positional behavior of *O. macedoniensis*, are unknown. The two available phalanges of *O. macedoniensis* are different from those of all arboreal primates and closer to terrestrial forms. Begun (2002, p. 365) states that “it is not clear which taxon, *Dryopithecus* or *Ouranopithecus*, comes closer to the ancestral morphology of the African apes and humans”. Although he gives a slight precedence to *Dryopithecus*, he refers that the unknown positional behavior of *Ouranopithecus* is a disadvantage. Begun subsequently links *O. macedoniensis* with the dryopithecines (*Dryopithecus*, *Hispanopithecus*, *Rudapithecus*) “as a group that is the sister clade to African apes and humans" (Begun 2009). Earlier, Andrews et al. (1996) made the statement that *O. macedoniensis* "is recognized as a hominine, related to the African ape and human clade and possibly close to the ancestry of the living species of this group." In their phylogeny of the Hominoidea, *O. macedoniensis* is the possible ancestor of the gorilla, chimpanzee, and humans (Andrews et al. 1996, Fig. 12-7). Benefit and McCrossin (1995) considered *O. macedoniensis* to be linked with the African ape and human clade, because of the presence of a supraorbital torus and the rectangular orbits. They also link *Samburupithecus* with *Ouranopithecus*, suggesting that the former may be a potential candidate for membership in the African ape and human clade. However, the dental morphology of *Samburupithecus* differs from that of *Ouranopithecus* in having more voluminous and higher cusps. Recently Clarke (2012, p. 45) noted that "the one Miocene ape that does show remarkable dental similarity to the early hominid *Australopithecus* is *Graecopithecus-Ouranopithecus macedoniensis*."

The first edition of this handbook (Koufos 2007, p. 23), in discussing the phylogenetic position of *O. macedoniensis* and the various opinions about it, stated: "But Africa is a huge region and who knows what will be discovered in the future." Indeed, two new articles, published in the same year, described new Late Miocene hominoid material from Kenya and Ethiopia (Kunimatsu et al. 2007; Suwa et al. 2007). Despite the poor material, both samples have similarities to *O. macedoniensis*, especially *Nakalipithecus*, and might belong to the subtribe Ouranopithecina of Begun (2009), linking the Late Miocene African and Eurasian hominoids.

Ouranopithecus turkae is a new species found in Turkey (Güleç et al. 2007); together with the sole P4 from Bulgaria (Spassov et al. 2012) they represent the Turolian evidence for hominoids in Eurasia. Its classification as *Ouranopithecus* has been questioned (Begun 2009), although it does have similarities with this genus, as well as with *Indopithecus* (Begun 2013).

Another Asian Late Miocene hominoid is *Ankarapithecus*, found at Sinap Tepe (Turkey) and known from three cranial remains. This hominoid is dated at ~10.0 Ma (Kappelman et al. 2003) and seems to be slightly older than *Ouranopithecus*. It was interpreted as having relationships with hominids (Alpagut et al. 1996), but recent analysis indicates phylogenetic relationships with the *Sivapithecus–Pongo* clade based on shared characters (massive maxilla, broad nasal aperture, high-placed zygomatic arches, narrow interorbital distance, very elongated nasal bones, absence of real supraorbital tori) (Begun and Güleç 1998). Thus, *Ankarapithecus* seems to be closely related to *Sivapithecus* and recent *Pongo* or to the Asian hominoids.

Oreopithecus is known from Italy only, where it has been found at the localities of Bacinello, Casteani, Ribolla, Montebamboli, and Fiume Santo and is in each case associated with an endemic fauna (Rook et al. 1999). The localities have been dated to the Middle–Late Turolian (Late Miocene), or at about 6.0–7.0 Ma (Harrison and Rook 1997; Steininger 1999). *Oreopithecus* is known by numerous cranial and postcranial remains, including a complete skeleton. It can be considered the best-represented European Late Miocene hominoid.

The very small braincase, low zygomatic root, short and gracile premaxilla, long and narrow palate, narrow nasal cavity, projecting midface, and relatively high canines of *Oreopithecus* are primitive features distinguishing it from all great apes (Begun et al. 1997; Harrison and Rook 1997). The postcranial morphology of *Oreopithecus* resembles that of the hylobatids and is related to suspensory positional behavior. It is also similar to that of the hominids and is related to large body mass in suspensory quadrupeds, with powerful grasping and high joint mobility (Harrison and Rook 1997). The majority of the morphological characters of *Oreopithecus* indicate that it is the most primitive known great ape (Harrison 1986b; Harrison and Rook 1997). Nevertheless, some researchers instead consider it a highly derived member of the clade including all Eurasian Late Miocene hominoids (Moyà-Solà and Köhler 1995, 1997) and is situated at the base of the hominoid radiation representing ancestral hominid morphology (Harrison and Rook 1997; Begun 2002). However, it is necessary to keep in mind that *Oreopithecus* belongs to an endemic fauna and that some of its characters may be secondary adaptations to the local conditions.

There are a number of Asian hominoids, like *Sivapithecus*, *Indopithecus*, *Khoratpithecus*, and *Gigantopithecus* (Andrews et al. 1996; Kelley 2002; Chaimanee et al. 2006; Jaeger et al. 2011), which are known from ~12.0–7.0 Ma. All these hominoids have strong relationships with the modern orangutan and are related to the *Pongo* clade. Besides the Middle Miocene *Griphopithecus* and *Kenyapithecus* and the late Miocene *Ouranopithecus*, there is another Asian hominoid, *Udabnopithecus garedziensis* from Georgia. The known material includes two molars; *Udabnopithecus* is somewhat confusingly classified either as *Dryopithecus* (Andrews et al. 1996; Gabunia et al. 2001) or under its original name (Lordkipanidze et al. 2008). The concentration in the most western part of Asia of these Middle–Late Miocene hominoids that are related to the great apes and the human clade, while in the rest of the continent only pongines have been found, indicates that Asia Minor was a migration route from Africa to Eurasia and vice versa.

Conclusion

The ancestor of the hominids and recent great apes is included in the stem of the Miocene hominoids, the common stock of hominids and apes. Despite the great expansion of the hominoid fossil record during the last decades, that fossil record is still quite poor and limits analysis and conclusions. From millions of hominoids that lived for a long time (∼20 Ma), only very few and fragmentary remains are available, based on which scientists are trying to complete the chain of hominid evolution link by link. The absence of some links makes their work more difficult, and at times even the discovery of a possible link may cause more problems than it solves. The limited conclusions we can draw based on recent data and known material include the following:

- Oligocene *Aegyptopithecus* and *Kamoyapithecus* could be the possible ancestor of the Miocene hominoids, as they share some derived features with the early hominoids. However, the large time gap between these taxa, and between them and the first proconsulids, is a source of uncertainty.
- Among the Early Miocene hominoids, *Proconsul* is the most plausible link connecting the hominoids to the modern great apes and the hominines. Controversy over particulars notwithstanding, it can be said to display a mosaic of features that indicate relations to the extant great apes and humans. Several other hominoid taxa known from the Early Miocene might also represent the sought-after link; but their limited and fragmentary material prevents definite comparisons and results.
- The Middle Miocene hominoids of Europe seem to be an important group, which could include a possible link. Certain Middle Miocene hominoids from Africa could also represent a link, but their poor material does not allow reliable comparisons, and their relationships to other taxa are still being discussed.
- The overall cranial and dental morphology of *Ouranopithecus* seems to be closer to the hominids; possibly it is this taxon that constitutes the Late Miocene link connecting the hominoids to the extant great apes and humans – either as a sister group to *Australopithecus* and *Homo* (de Bonis and Koufos 1997) or as a sister clade to the African apes and humans (Begun 2009).
- The similarities of *Sahelanthropus* and *Ouranopithecus* (Brunet et al. 2002) indicate a close relationship between them, narrowing the gap between *Ouaranopithecus* and *Australopithecus*.
- All known Asian hominoids, such as *Sivapithecus*, *Indopithecus*, *Ankarapithecus*, *Khoratpithecus*, and *Lufengpithecus*, are closely related to the modern orangutans.

The question of human origin will preoccupy scientists for a long time. Each new discovery will add further data, but will also raise new questions and possibly controversies. Despite these challenges, it is very important that scientists continue their effort to collect more material and study all fossil and modern hominoids in systematic detail, in order to better understand their evolutionary relationships. Continued research efforts and the development of new methods will bring us ever closer to a full understanding of human origins.

Acknowledgments I wish to thank very much Dr I. Sylvestrou for her nice work on figures 1 and 4l.

Defining Hominidae

Jeffrey H. Schwartz

Contents

Abstract

A array of relevant cranial, postcranial, and dental morphologies are reviewed in an attempt to delineate shared derived features that would unite a group that includes extant humans and their fossil relatives to the exclusion of other hominoids. This group is now often referred to as tribe Hominini, but systematic practicality suggests that family Hominidae be retained, since the lower rank de facto limits even current, and certainly future, recognition of subclades. Potential hominid postcranial synapomorphies include a distinct angle at L5–S1, a long pubic ramus, a superoinferiorly short ilium that is roundedly expanded posteriorly, some thickening in the region of an iliac (crest) tubercle, a well-developed and

knoblike anterior inferior iliac spine that lies noticeably superior to and somewhat back over the superior acetabular rim, a defined and deep greater sciatic notch, differential distribution of cortical bone of the femoral neck, anteroposteriorly long femoral condyles, and an outwardly slanted femoral shaft. Although "a weakly defined linea aspera" and "a concave rather than convex medial tibial condylar facet that lies level with the primitively concave lateral facet with the two facets being separated by a pair of distinct tibial tubercles" have been suggested as hominid apomorphies, this appears not to be the case – unless the apelike specimens commonly taken as hominid (e.g., from Hadar) are not. The only possible cranial feature appears to be alignment in the adult of the biporionic chord and basion (on the anterior margin of the foramen magnum). Derived dental features that might unite Hominidae also characterize an orangutan clade and thus must be explained away (e.g., as homoplasies) or dismissed as phylogenetically relevant in order to justify the former group. Of further note is the presence of *Pongo* clade-like facial features in australopiths and various specimens of *Homo*. These and the dental similarities suggest that focusing on *Pan* alone as the out-group from which to judge hominid-defining features is comparatively too narrow and, consequently, phylogenetically misleading. Within Hominidae, various subclades can be justified, suggesting that the relationships of various specimens referred to genus *Homo* lie within a clade that also subsumes "australopiths." Much work remains before clade Hominidae can be more fully defined.

Introduction

By the twenty-first century, one would think that paleoanthropology would long ago have left behind the legacy of Linnaeus' (1735) ultra-vague and systematically useless definition of our species, *Homo sapiens*: nosce te ipsum (know thyself). Yet, in spite of the incredible number of discoveries of fossils attributed to our clade (i.e., the clade that includes *H. sapiens* but excludes apes) since the mid-to-late nineteenth century – when discovery of the Feldhofer Grotto Neanderthal and ultimately the Spy Neanderthals undermined the notion that humans were not antediluvian – the history of paleoanthropology contrasts with that of the centuries-old disciplines of vertebrate and invertebrate paleontology in its increasing rejection of taxonomic and systematic rigor. Consequently, the task of defining Hominidae is not as straightforward as one might imagine it should be.

Historical Background

In the first detailed attempt to support Linnaeus' inclusion of humans within a specific group of mammals, and particularly in grouping humans with apes, Thomas Henry Huxley (1863b) sought evidence of this relationship not only in comparative hard- and some soft-tissue morphology but also in comparative development. Through ontogenetic comparison, he argued that if a monkey could be distinguished developmentally from other vertebrates as a mammal generally, and a primate more specifically, so, too, could humans. Hence, if a monkey was a primate, so, too, was a human. Huxley then turned to "man's place in nature" within Primates. He began with the premise that humans were most similar to gorillas and then organized his comparisons first between gorillas and, when needed, other apes and then between them and monkeys. His rationale was if a morphological "gulf" existed between gorillas and monkeys, but not between gorillas and other apes, then humans could also be allied with the apes. But while Linnaeus claimed that, in essence, morphology barely distinguished humans from apes (Schwartz 1999), Huxley believed otherwise. Consequently, in spite of demonstrating that anatomies as distinctive as the human foot were basically comparable to the grasping feet of apes and monkeys, Huxley concluded that humans were still sufficiently unique to warrant their own taxonomic status apart from the great apes, all of which he relegated to a separate family. In hard-tissue morphology, Huxley remained as impressed by aspects of the postcranial skeleton as Aristotle had been of the human thumb and Johann Friedrich Blumenbach of the human pelvic girdle and foot.

With his emphasis on aspects of the human postcranium and dentition, Blumenbach should be regarded as the "father of paleoanthropology" inasmuch as the criteria he used to distinguish humans from other animals eventually became those that paleoanthropologists used to decide if a fossil qualified as a "hominid" (Schwartz 1999). Indeed, in 1795, in *On the Difference of Man from Other Animals*, Blumenbach (1969) emphasized various aspects of "the external conformation of the human body" as paramount to defining *Homo sapiens*: erect posture, broad and flat pelvis, two hands, non-divergent hallux, close-set and serially related anterior teeth, and some aspects of mandibular morphology.

With regard to erect posture, Blumenbach argued that, in contrast to other animals, this stance was natural and specific to *H. sapiens* as noted, for instance, in the ossification of tarsals before carpals. He claimed that only humans have a "true" pelvis, in which the broad and expanded ilia form a basin that cups the viscera. Like Aristotle, he regarded the human hand as special because of its long thumb. In addition, because of the uniqueness of the human foot, with its non-divergent hallux, Blumenbach believed that possession of only two "true" hands was significant. He also considered the human dentition distinctive in presenting orthally implanted lower incisors; canines not longer than, or separated from, the incisors; and molars with rounded cusps. He described the human mandible as quite short, bearing a prominent chin, and having a distinctive articulation with the skull (presumably referring to the depth of the articular fossa), which, he suggested, was correlated with human omnivory.

Although he recognized that humans differ from many mammals in lacking a distinct premaxilla, Blumenbach also, but mistakenly, believed that other primates were similar in this regard – a claim he then used to argue against separating humans from other primates taxonomically. [Goethe (1820) made a similar argument but did so on the incorrect belief that he could identify a premaxilla in humans.]

In addition to "the external conformation of the body," and in keeping with concerns of eighteenth-century philosophers, Blumenbach (as well as Goethe) addressed the "internal conformation" of humans, i.e., the importance of reasoning (as well as other mental attributes) as a criterion by which to distinguish humans from other animals, including other primates. Although not stated in these terms, we might point to a focus on mental attributes as underlying the later emphasis in paleoanthropology on the size and external morphology of the brain [features that also attracted the attention of the eighteenth-century naturalists Buffon and Bonaparte (Schwartz 1987)].

Blumenbach's criteria for distinguishing humans from other animals were imported into paleoanthropology with the discovery of *Homo* (*Pithecanthropus*) *erectus* from Trinil, Indonesia (Schwartz 1999). This historical twist is likely due to Huxley's (1863a) argument that the Feldhofer Grotto Neanderthal was an extinct human whose cranial features extended into the past a "perceived" continuum of racial "brutishness" from the most "civilized" to the most "brutish" of living humans. In turn, these notions of ancientness equating with primitiveness and of a continuum that proceeded from a brutish primitiveness to human modernity came to inform much of paleoanthropology (Schwartz 1999).

The Trinil specimens, however, undermined Blumenbach's *H. sapiens*-defining criteria. While the femur provided evidence of humanlike bipedalism (Blumenbach's "erect posture"), the skullcap depicted an individual that had been less than fully human in its brain (and thus in its mental capacities). This unexpected combination of human and less-than-human features prompted Dubois to assign his new *erectus* first to the genus *Anthropopithecus* (the taxonomic alternative to *Pan*) (Dubois 1892) and then to Haeckel's proposed genus for a hypothetical extinct, speechless human relative, *Pithecanthropus* (="ape-man") (Dubois 1894). The implication, of course, was that the emergence of erect posture and bipedalism preceded expansion and elaboration of the brain.

While lending itself to Darwin's (1871) suggestion of a smooth transition from a semi-quadrupedal African ape to an erect bipedal human, this picture – bipedalism first, brain second – appeared contradicted with the discovery in the early 1900s at Piltdown, England, of a large, thin-boned, and rounded humanlike cranium; an apelike partial mandible preserving two molars; and an apelike lower canine. Under the presumption that these specimens were associated, the Trinil-based scenario of human evolution was turned around: early human relatives became human first in their brains and then in the rest of the body (as inferred from the mandible and teeth). That is, the brain enlarged prior to the attainment of fully erect posture and bipedal locomotion. It was not until the 1950s, when the Piltdown fraud was exposed, that this alternative notion of human evolution – brain first, body second – was rejected. Before then, however, the discovery of the Taung child and, more importantly, Dart's (1925) interpretation of the specimen continued the intellectual trajectory Blumenbach had begun. But Dart conceived his scenario in the context of Darwin's incorrect biogeographic premise of finding fossil evidence in Africa of intermediate forms that provided evidence of a morphological continuum between African apes and humans.

As Dart (1925, p. 196) summarized his overall impression of the preserved craniodental features of the Taung specimen, this individual represented "an extinct race of apes *intermediate between living anthropoids and man*." Dart depicted specific features – such as the configurations of the brow, nasal bones, zygomatic regions, orbits, and upper and lower jaws as well as the inferred skull shape – as being of "delicate and humanoid character" (Dart 1925). Most central to his speculations were the size and potential details of the preserved partial endocast and also the forward position of the foramen magnum (as indicated by bone adherent to the endocast). Dart (1925, p. 197) assumed the latter was proof of this "humanoid's" erect posture and then made the following extrapolations:

> The improved poise of the head, and the better posture of the whole body framework which accompanied this alteration in the angle at which its dominant member was supported, is of great significance. It means that a greater reliance was being placed by this group upon the feet as organs of progression, and that the hands were being freed from their more primitive function of accessory organs of locomotion. Bipedal animals, their hands were assuming a higher evolutionary rôle not only as delicate tactual, examining organs which were adding copiously to the animal's knowledge of its physical environment, but also as instruments of the growing intelligence in carrying out more elaborate, purposeful, and skilled movements, and as organs of offence and "defence". The latter is rendered the more probable, in view, first of their failure to develop massive canines and hideous features, and secondly, of the fact that even living baboons and anthropoid apes can and do use sticks and stones as implements and as weapons of offence.

Regarding the Taung child's brain (as represented by the endocast), Dart suggested that, since it was already as large as a chimpanzee's and almost as large as a gorilla's, it would have continued to enlarge, following a humanlike growth curve. In addition, as in humans but not apes, the Taung child's brain was high and rounded, somewhat expanded in the temporal region, and apparently a posteriorly and inferiorly placed lunate sulcus. Believing his specimen to be more human- than apelike, Dart inferred that this "humanoid" had also been humanlike in its faculties of "associative memory and intelligent activity." The expanded cerebral cortex (as indicated by the presumed lunate sulcus) also suggested to Dart that, in contrast to apes, the Taung "humanoid" had experienced increased sensory stimulation, both via vision (because of the forward position of the approximated orbits) and tactile sensation (because erect posture and bipedality supposedly freed the hands from involvement in locomotion). But the Taung child's brain was not sufficiently enlarged in the temporal region for it to have reached the "necessary milestone in the acquisition of articulate speech" (Dart 1925, p. 198).

For Dart, the Taung child, the name bearer of his genus and species *Australopithecus africanus*, displaced both Piltdown's *Eoanthropus dawsoni* and Trinil's *Pithecanthropus erectus* as viable "links" between humans and their apelike ancestors. Indeed, in spite of Dart's conceiving this extinct juvenile as intermediate between humans and apes, his interpretation reflected Blumenbach's criteria for distinguishing *Homo sapiens*. In 1925, then, in spite of their differences, the three scenarios regarding human ancestry embraced the notion of an evolutionary continuum that proceeded from an apelike precursor, through an unknown series of intermediates, to the most modern looking of living humans.

In terms of the focus of this chapter – defining Hominidae – subsequent discoveries of potential extinct human relatives are less relevant than attempts to integrate these fossils into a systematic framework that had originally been based on living *Homo sapiens*. In this regard, after a decade-and-a-half of successful fossil hunting in the limestone caves of South Africa and in caves and deposits in Europe and Asia, and a proliferation of genus and species names, and debates over the relationships of what I will refer to as "australopiths" (based initially on South African specimens), Le Gros Clark (1940) was compelled to review the available evidence in order to determine the hominid status of any australopith.

In addition to echoing Huxley and Darwin's assumption of a linear transformation from ape to human, Le Gros Clark based his conclusions on what he later called the "total morphological pattern" (Le Gros Clark 1955). From this perspective, he considered a fossil as being hominid not in terms of derived features it shared with humans but whether, overall, it resembled humans more than great apes. As will become obvious, this approach complicated matters further because the great apes were then considered evolutionarily united. Thus, a feature to compare with humans or potential hominid fossils could be extracted from any ape and deemed exemplary of the entire group, even if it only characterized the one ape [Gregory (1922) employed this device of "pick and choose" in arguing for an African ape-human relationship (Schwartz 2005)]. The irony of Le Gros Clark's phenetic approach is that in 1955 he made one of the clearest statements about distinguishing between primitive and derived characters in generating hypotheses of relatedness.

Although Le Gros Clark (1940, p. 317) concluded that australopiths were "more human than simian" especially in their teeth, his comparisons then and in subsequent publications were biased toward the African taxa. If, however, he had included *Pongo*, he might have been struck by the similarities between this hominoid and australopiths in many details of facial and dental morphology (Schwartz 2004a, 2005). Perhaps then he might have expanded his comparisons to include at least small-bodied hominoids and some Old World monkeys, thereby providing paleoanthropology with the precedent of a more broad-based approach to phylogenetic reconstruction. Unfortunately, he did not, thus making his efforts to define Hominidae as useless as his definition of the order Primates [i.e., being characterized by their lack rather than sharing of derived feature/s (Le Gros Clark 1959)].

Mayr's (1950) influential article on fossil hominids did not clarify the situation. Rather, on the grounds that all hominids were adaptively similar because they were bipedal, Mayr collapsed all named taxa into one genus, *Homo*. After claiming that because living humans are so diverse and occupy all available econiches the same had been true for all hominids (thus precluding the opportunity and prerequisite for speciation) (Mayr 1963), he subdivided his genus *Homo* into three time-sequential species: *transvaalensis*, *erectus*, and *sapiens*. Even though a much enlarged human fossil record later provoked Mayr (1953) to "accept" *Australopithecus* and acknowledge also *Paranthropus*, but as side branches that went extinct without issue, his concession did not elucidate how one determined in the first place if a specimen was hominid, especially if postcranial remains were unknown. This is, indeed, a problem. For while it may be true that some scholars (e.g., Le Gros Clark, Mayr, Washburn) decided "that the most important single factor in the evolutionary emergence of the Hominidae as a separate and independent line of development was related to the specialized functions of erect bipedal locomotion" (Le Gros Clark 1964, p. 14), the preponderance in the human fossil record of usually fragmentary skulls and jaws and isolated teeth makes impossible identifying a specimen as "hominid" on the basis of anatomical features believed to be reflective of bipedal locomotion. The cranial exception, of course, is the region of the foramen magnum and occipital condyles.

Toward a Definition of Hominidae

The task of defining Hominidae is twofold. First is a taxonomic decision. How expansive is the classificatory net Hominidae? To chimpanzees? Chimpanzees and gorillas? All great apes? Although Le Gros Clark (1955, 1964) wrote at a time when all great apes were relegated to the taxonomic family, Pongidae, his rationale for recognizing family Hominidae is, I believe, still viable and useful. Namely, Hominidae is a monophyletic group that subsumes extant humans and their fossil relatives, to the exclusion of any living relative. (It is in this sense that I use Hominidae/hominid/hominids throughout this contribution.) Accepting this proposition does not impinge on one's preferred version of ape as closest living human relative. Further, it also allows more systematic space in which to accommodate the still taxonomically expanding human fossil record – which collapsing *Pan* and all hominids into genus *Homo*, on the grounds that this is "cladistic" (Goldberg et al. 2003), obviates. Indeed, the only thing "cladistic" about this, in the spirit of Hennig (1966), is translating a preferred scheme of relationship directly into a classificatory representation of it – which is not the same as generating the theory of relationship.

With this suggestion in mind, we can turn to the matter of defining Hominidae, but not from the perspective of looking for the "defining" moment in a transition from a presumed apelike condition to something seemingly hominid (either by a subtle hint of a supposed hominid trait or traces of a presumably primitive and retained feature). Rather, it seems logical and reasonable to return to Blumenbach's list of criteria, to which other features have been added, as defining a clade that includes humans and their extinct relatives.

Defining Characters of Hominidae?

Traditionally Accepted Features of "Erect Posture"

As reviewed above, Blumenbach's emphasis on "erect posture" and "two handedness" – or, as Le Gros Clark (1964, p. 14) put it, on "specialized functions of erect bipedal locomotion" – has remained central to considerations of our clade. Pilbeam (1972, p. 62), for example, summarized some of the "adaptations" apparently associated with these "specialized functions of erect bipedal locomotion": a vertebral column with a distinct lumbar curve that is set at a sharp angle relative to the sacrum; a "carrying angle," wherein the lateral femoral condyle is larger and more weight bearing than the medial condyle and the femoral shaft angles up and laterally away from the knee joint; a non-grasping foot with short toes and non-divergent hallux through which weight is transmitted during locomotion; and metacarpals in which the heads contact the substrate while the distal ends are elevated to form a springlike, transverse arch. We might also include Blumenbach's description of the pelvic region as bowl shaped (i.e., broad and shallow) and having a short, potentially laterally flaring, posteriorly expanded, anteriorly truncated ilium; a somewhat forwardly oriented acetabulum (which is also reflected in the orientation of the proximal femur relative to the shaft); a defined greater sciatic notch; and a broad, short sacrum, wherein the alae are not remarkably small relative to the size of the lumbar facet (Schultz 1968). Clearly, these features distinguish living *Homo sapiens* from other extant primates. However, the degree to which these characteristics are expressed in what have been identified as fossil hominids, and whether the appropriate postcranial remains are known, is still up for debate.

For instance, among fossil specimens attributed to "anatomically modern" *Homo sapiens* that probably represent this taxon (Schwartz and Tattersall 2000a, b; Schwartz and Tattersall 2003, 2010), only Qafzeh 9 is known from a fairly complete, albeit extremely crushed, postcranium. Inasmuch as distortion of its skull and mandible compromises definitive identification of a bipartite brow with a "glabellar butterfly" and a mandible with a "true" chin with an inverted "T" configuration and thickened inferior symphyseal margin (Schwartz and Tattersall 2000a, b; Schwartz and Tattersall 2003, 2010), the pelvic region appears to present *H. sapiens*, not Neanderthal, morphology (Rak 1990) (personal observation). Other cranial and/or mandibular specimens conventionally attributed to "anatomically modern" *H. sapiens* and preserving critical morphology, especially Qafzeh 6 and all from Skhūl, do not present a bipartite brow or an inverted mandibular symphyseal "T" (Schwartz and Tattersall 2000a, b). Known Skhūl postcranial remains are incompletely representative and so crushed and poorly reconstructed that one can only sense their conforming to the abovementioned pelvic configurations (personal observations).

While Neanderthal postcranial morphology associated with bipedal locomotion differs from *Homo sapiens* in details of size, shape, and morphology [e.g., more posteriorly expanded ilia, superoinferiorly tall and anteroposteriorly compressed pubic symphyseal region, relatively long pubic ramus (and thus very wide/obtuse subpubic angle), smoothly "hook-shaped" greater sciatic notch, smaller and differently oriented iliac auricular region, relatively large proximal and distal femoral ends, very large acetabulum, truncated calcaneus (Rak 1990; Sawyer and Maley 2005; Trinkaus 1983; Trinkaus and Howells 1979)], they conform to the basic configurations summarized above, including a femoral "carrying angle" and a lumbar curve. Known Middle Pleistocene pelvic remains from Sima de los Huesos (Arsuaga et al. 1997), Arago (Day 1982) (personal observation), and Jinniushan (Rosenberg and Lu 1997) differ from *Homo sapiens* in some iliac details (e.g., flare, anterior superior iliac spine) but can otherwise be accommodated by Pilbeam's pelvic criteria. The Sima de los Huesos femora also present a carrying angle (Day 1986).

According to Rose (1984), os coxae KNM-ER 1808, KNM-ER 3228, and OH 28 are generally similar to *Homo sapiens* and *H. neanderthalensis* but differ in having relatively larger anterior iliac regions. Scrutiny of OH 28 (cast) reveals,

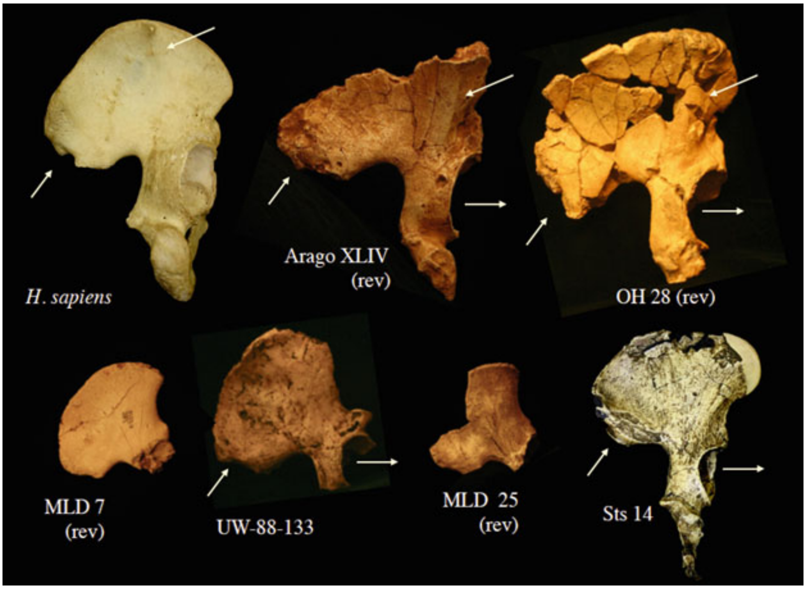

Fig. 1 Os coxae of *Homo sapiens* and various hominids with the ilium oriented laterally. Note differences in development of iliac pillar in *H. sapiens*, Arago XLIV, and OH 28, and virtual nondevelopment in "australopiths." Also note differences in anterior and posterior iliac expression and especially in orientation of the acetabulum, which, if in the anatomical position, would reposition the ilium of all but *H. sapiens* posteriorly. See text for further discussion; not to scale; *rev* reversed (All specimens except *H. sapiens* and Sts 14 courtesy of the American Museum of Natural History)

however, that this specimen contrasts with *H. sapiens* as *H. neanderthalensis* does, e.g., in asymmetry of anterior versus posterior iliac proportions and curvature, thickness and anterior position of the external iliac pillar, thickness of the ilium posteriorly, and small size of the auricular surface (personal observation) (Fig. 1). Further, although Day (1986) claimed morphological similarity between OH 28 and Arago XLIV, the latter clearly differs not only in the massiveness of its ilium but in details such as a sigmoidally symmetrical and shallow anteroposterior iliac crest curvature, deep and uniform greater sciatic notch angle, large auricular surface, and huge acetabulum (personal observation) (Fig. 1). These inconsistencies raise questions not only about the suggested similarities between the pairs previously compared OH 28-Arago XLIV, KNM-ER 1808–3229, and Nariokotome KNM-WT 15000-Gona BSN49/P27 partial os coxae, but also about similarities claimed to exist among them all (Day 1986; Simpson et al. 2008; Walker and Leakey 1993).

A preliminary reassessment of the comparability of these OH, Arago, KNM, and BSN pelvic specimens based on casts and published images proves potentially interesting. For example, when orienting the acetabula in anatomical position, the "inner" iliac blade surfaces of all specimens face forward/anteriorly, as they do in Sts 14 and Al 288-1, and not medially, as in *H. sapiens*, *H. neanderthalensis*, and SK 50. Further, reconstructions of KNM-WT 15000 (e.g., as in the Neanderthal Museum)

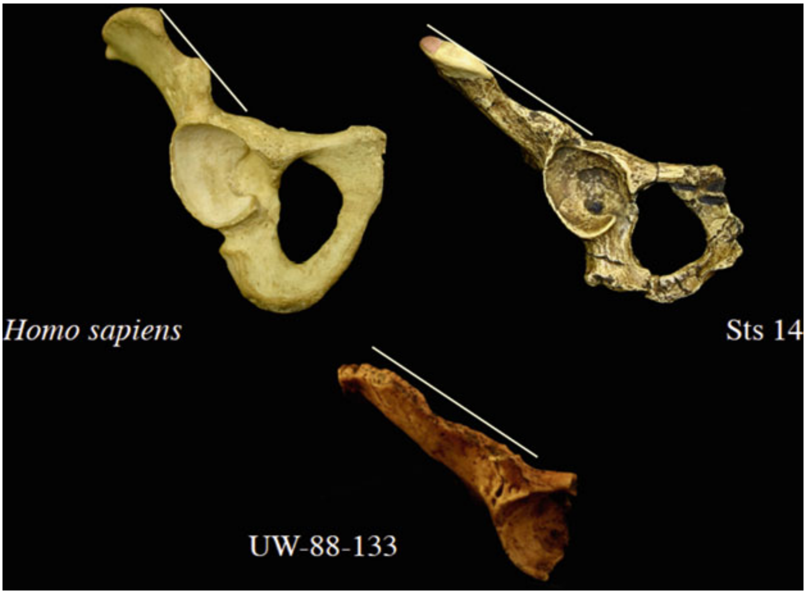

Fig. 2 Right os coxae of *Homo sapiens*, Sts 4, and Malapa MH1 (UW-88-133) to illustrate, e.g., differences between the former and the latter two in details of the pubic and ischial regions and especially iliac superoinferior height and lateral flare. See text for further discussion; not to scale; reproduced to same size (Cast of UW-88-133 courtesy of the American Museum of Natural History)

and the Gona pelvis, BSN49/P27 (Simpson et al. 2008), portray the respective ilia tilting laterally outward with their “inner” surfaces turning somewhat upward, albeit not as markedly as in some australopiths (see below, e.g., Sts 14, Al 288-1).

Sts 14’s superoinferiorly low and squat, posteriorly rounded and expanded, and clearly anteroposteriorly long ilia incorporate a well-defined greater sciatic notch (Figs. 1 and 2). In these features, the small Hadar AL 288-1 left os coxa, juvenile Makapansgat ilia MLD 7 and 25, Malapa UW-88-133, the virtually reconstructed *Ardipithecus* ARA-VP-6/500, and apparently the Swartkrans right partial os coxa SK 50 are similar to Sts 14 (Kibii et al. 2011; Lovejoy et al. 2009b) (see Figs. 1 and 2). Adult ilia Sts 14, AL 288-1, and likely also SK 50 differ from earlier-discussed specimens in being oriented more laterally outward than vertically, with concomitantly greater superior exposure of the internal iliac surface and more subdued “S”-shaped iliac crests; further, these specimens bear only moderately thickened iliac (crest) tubercular regions and poorly developed iliac pillars (Day 1986; Johanson et al. 1982; Robinson 1972). The virtual reconstruction of *Ardipithecus* portrays a more vertically and anteriorly oriented ilium, more open and poorly delineated greater sciatic notch (especially regarding defined posterior superior and inferior iliac spines), and a longer pubic ramus than the virtual reconstruction of Al 288-1 (Lovejoy et al. 2009b).

Australopith anterior ilia present a dichotomy of morphology. In the better-preserved left os coxa of Sts 14, this region appears to be roundedly expanded anteriorly (Robinson 1972), as in StW 431 (Toussaint et al. 2003) and AL 288-1 (Johanson et al. 1982). Thus, a definitive anterior superior iliac spine cannot be identified. But in SK 50, even though its iliac crest is damaged along much of its length, what is preserved continues forward to become a well-defined, beak-shaped anterior superior iliac spine that projects markedly anterior to a bluntly thickened, almost knoblike anterior inferior iliac spine (Day 1986; Robinson 1972). The smaller Makapansgat juvenile ilia (MLD 7 and 25) are similar to SK 50 (but not to Sts 14 and AL 288-1) in having a projecting, beaklike anterior superior iliac spine (Dart 1957). Although differing from SK 50 and MLD 7 and 25 in the region of the anterior superior iliac spine, Sts 14 and AL 288-1 are similar to them in developing a knoblike anterior inferior iliac spine that lies noticeably superior to and back over the superior margin of the acetabulum, as in other potential hominids surveyed above.

Although australopiths have traditionally been interpreted as postcranially intermediate between knuckle-walking great apes and *Homo* – as noted, for instance, in their developing a humanlike posterior iliac expansion while supposedly retaining an apelike anterior iliac distension – this scenario seems inappropriate: not all specimens present similarly configured anterior superior iliac spines. Indeed, only SK 50 and MLD 7 and 25 compare favorably with great apes in having a beaklike anterior superior iliac spine that continues forward the trajectory of the iliac crest. The rounded anterior expansion of this region in Sts 14, AL 288-1, and apparently also in Malapa UW-88-133, while absolutely and relatively large compared to *Homo sapiens* and other possible fossil hominids, is, nevertheless, derived in its own right.

The preserved pubic rami of Sts 14 and AL 288-1 are reminiscent of this region in Neanderthals and the Jinniushan specimen in being relatively long, but the symphyseal regions of the australopith specimens are not also superoinferiorly tall and anteroposteriorly compressed (Rosenberg 1998). A superior view of the articulated Sts 14 pelvis illustrates (in contrast to *Homo sapiens*) the relation of the elongate pubic rami to the relatively wide pelvic canal and the relatively posterior positioning of the outwardly flared ilia (Robinson 1972). Further, while in *H. sapiens* (and other Pleistocene specimens surveyed above) the curve of the iliac crest positions the anterior superior iliac spine just lateral to the parasagittal plane intersecting the posterior superior iliac spine, in Sts 14, the anterior portion of the ilium would have been situated well lateral to the plane of the sacroiliac articulation (Robinson 1972). The known left os coxa of AL 288-1 was likely similar to Sts 14 (Johanson et al. 1982). Although SK 80's iliac crest is similar to Sts 14 in not being strongly "S shaped," when their iliac blades are oriented in the same plane, SK 80's acetabulum is similar to *H. sapiens* in facing laterally and slightly downward (Robinson 1972). In contrast, the fairly vertically aligned Sts 14 acetabulum faces forward. When compared in anatomical position, the Sts 14 ilium is again more outwardly and obliquely oriented, while SK 50 is more anteroposteriorly arranged, as in *H. sapiens* and various other specimens attributed to *Homo*.

Although Malapa MH1 and MH2 are presented as having medially facing and vertically oriented ilia (Kibii et al. 2011), the largely complete right *Australopithecus sediba* ilium UW-88-133 (cast) can reasonably be oriented with more outward lateral flare (Figs. 1 and 2). This also appears to be the case with the reconstructed os coxa of *Ardipithecus ramidus* ARA-VP-6/500 (Lovejoy et al. 2009b) (see below).

Another feature of potential phylogenetic significance is the distance between the ischial tuberosity and the inferior acetabular lip, which is quite pronounced in great apes and apparently in catarrhines in general (Aiello and Dean 1999). The separation is marked in SK 50, shorter in Sts 14 and KNM-WT 15000, and minimal in *Homo sapiens*, in which a deep groove intervenes between the two structures. Perhaps further study of this region will prove enlightening, if not in defining features of clade Hominidae, perhaps in delineating a subclade/s within Hominidae.

Unfortunately, many details of the vertebral column in general are unknown. Of particular note is that while the lumbar region of KNM-WT 15000 is somewhat curved and angled inward at L5-S1, unlike *H. sapiens, H. neanderthalensis*, and large-bodied apes, this individual had six rather than five lumbar vertebrae (Walker and Leakey 1993).

Regarding femora, KNM-WT 15000, KNM-ER 1481 and 1472, Sts 34A, AL 129-1a, and UW 88-63 (casts) and D4167 (original) present carrying angles that set them apart from Sts 34B, AL 333-4, Trinil 3/Pith I, and Spy 1 (Table 1; see also Fig. 3) (Lordkipanidze et al. 2007; Walker and Leakey 1993). For the former seven specimens, medial distal femoral angles range between 103° and 110° and lateral angles between 70° and 77°; using Martin's bicondylar angle [measured between the axis perpendicular to the distal articular plane and the lateral angle (Martin 1928)], the range of this sample is 13–20°. In contrast, distal femoral angles of the Sts 34B et al. specimens are lower, i.e., below 103° (medial), 77° (lateral), and 13° (Martin's scale). Further, Sts 34A and Sts 34B also differ in size and detail of condylar shape and orientation (Table 1). As tabulated by Tardieu and Trinkaus (Tardieu and Trinkaus 1994), bicondylar angles for several living human populations (males and females pooled) range between 8.5° and 10.5° (Martin's scale). The fact that two "groups" are distinguishable on the basis of distal femoral angle – with *Homo sapiens* falling into, or at least not with, one of them – raises doubt about the allocation to genus *Homo* of specimens preserving the distal femur (especially KNM-WT 15000, KNM-ER 1481 and 1472, and D4167) as well as specimens presenting pelvic as well as vertebral and other features not covered here that have been deemed australopith-like. Indeed, as will become clearer below, these inconsistencies redound, in broad perspective, on defining genus *Homo* on the basis of *sapiens*-like "striding bipedalism" (Wood and Collard 1999) (see also chapter "▶ Defining the Genus *Homo*," Vol. 3) and, more specifically, on assuming because of similar age and/or location, that specimens (e.g., those from Dmanisi) must represent not only the same taxon but a paleodeme of it that morphological difference represents not taxi diversity but merely individual variation (Lordkipanidze et al. 2013; Margvelashvili et al. 2013). In the case of the Dmanisi specimens, if, as the skulls and mandibles have been designated, D4167 represents *H. erectus*, then, at least with regard to distal femoral angle, there is no basis for taxonomically discriminating between any of the specimens discussed here where similar distinctions are demonstrable (see below).

Table 1 Distal femur: carrying angle and morphology

Specimen	Medial condyle angle (°)	Lateral condyle angle (°)	Martin's bicondylar angle (°)	Published bicondylar angle (°)[a]	Medial vs. lateral condyle height	Patellar facet	Popliteal fossa	Inferior profile	Medial vs. lateral condyle configuration
Extant humans				10.5–8.5 (sexes pooled)	Shorter anteriorly	Asymmetric, narrow	Narrow "V"	Tall, narrow trapezoid	
AL 129-1a	110	70	20	13	Shorter anteriorly	Asymmetric, wide	Wide	Very wide rectangle	Both curve, parallel
KNM-WT 15000	108	72	18	18	Equal height	Symmetric, wide	Moderately wide	Moderately wide trapezoid	Both straight, diverge
D4167	105	75	15		Much taller anteriorly	Asymmetric, wide	Moderately wide	Wide, odd trapezoid	Both curve
Sts 34A	105	75	15	15	Shorter anteriorly	Asymmetric, narrow	Narrow "V"	Rounded, wide, semi-trapezoid	Medial A/P deeper, both curved
AL 333w-56	105	75	15		Taller anteriorly	Asymmetric, wide, shallow	Narrow, widens?	Wide, rectangle	Slight arc, parallel
KNM-ER 1481	104	76	14	10	Much shorter anteriorly	Asymmetric, moderately wide	Wide, deep	Moderately tall, odd trapezoid	Medial angle > lateral
Sts 34B	103	77	13		Equal	Symmetric, wide, deep	Widens posteriorly	Wide, short-angle triangle	Medial teardrop, lateral straight
KNM-ER 1472	103	77	13	13	Taller anteriorly	Asymmetric, moderately wide	Moderately wide, deep	Wide trapezoid	Medial curve > lateral

(*continued*)

Table 1 (continued)

Specimen	Medial condyle angle (°)	Lateral condyle angle (°)	Martin's bicondylar angle (°)	Published bicondylar angle (°)[a]	Medial vs. lateral condyle height	Patellar facet	Popliteal fossa	Inferior profile	Medial vs. lateral condyle configuration
UW-88-63	103	77	13		Much shorter anteriorly	Asymmetric, wide	Moderately deep, wide	Wide, moderate trapezoid	Medial curve, lateral straighter
TM 1513	103	77	13		Shorter anteriorly	Asymmetric, narrow	Narrow	Tall, narrow trapezoid	Medial curve, lateral straighter
LB1	102	78	12		n.a.	n.a.	n.a.	n.a.	n.a.
Spy 1	98	82	8	9	Much shorter anteriorly	Asymmetric, narrow, deep	Deep, moderate	Moderately wide trapezoid	Medial slight curve, lateral straight
AL 333-4	98	82	8	9	Equal height	Symmetric wide, shallow	Wide, deep	Very wide rectangle	Medial curve, lateral straighter

[a] See Table 2 in Tardieu and Trinkaus (1994)

Fig. 3 Femora of *Homo sapiens*, TM 1513, Dmanisi D4167, KNM-WT 15000, and Sts 34B illustrating similarities in all but *H. sapiens* distally in bicondylar/carrying angle and proximally in lack of a distinct intertrochanteric line and posterior orientation of the lesser trochanter. See text for further discussion; not to scale (Copyright © J. H. Schwartz)

As Robinson (1972) long ago recognized, the distal femur presents much morphology of potential significance (see Fig. 4). For instance, as he saw it, when viewed from below, distal femora TM 1513 (left) and Sts 34 (right distal femur, now identified as Sts 34B) are generally similar to those of large-bodied apes in disparity and/or orientation of medial versus lateral condyle but differ in being deeper anteroposteriorly and more trapezoidal (mediolaterally narrower anteriorly) rather than rectangular in outline and in having a somewhat more concave and slightly asymmetrical patellar fossae, in concert with the lateral margin being more anteriorly distended than the medial margin (in other words, when viewed from below, the lateral condyle is anteroposteriorly longer than the medial, regardless of differences in configuration). Robinson's enthusiasm notwithstanding, study of casts of these specimens reveals that while TM 1513 displays (slight) patellar fossa and condyle asymmetry, Sts 34B's fossa is symmetrical and its condyles equally distended anteriorly (Table 1). Also, the curvature of the medial condyle is much more severe in TM 1513 than in Sts 34B, in which (uniquely for hominids studied here) it is "teardrop" shaped (Table 1). Interestingly, Sts 34B also differs markedly from Sts 34A in overall and specific distal femoral features – which is consistent with the craniodental nonuniformity of Sterkfontein fossils (Schwartz and Tattersall 2005).

Distal femora AL 129-1a and AL 333-4, of which the latter is the larger (McHenry 1986), also differ in morphological detail (Table 1). Lague (2002) acknowledges size and some morphological difference between the two

Fig. 4 Distal views of right femora of *Pan troglodytes* (=*Pan trog.*), Sterkfontein TM 1513, *Homo sapiens*, AL 333–4, KNM-ER 1472, AL 288-1a, and UW 88–63 (Malapa hominid 1) and left femora of KNM-ER 1482 and KNM-WT 15000. Note differences in, e.g., anteroposterior length, orientation and relative sizes of medial and lateral condyles, and relative depth and symmetry versus asymmetry of the patellar surface. Also note specific differences between AL 333–4 and AL 129-1a in, e.g., anteroposterior length, crispness of lateral patellar surface border, lateral epicondylar morphology, and divergence posteriorly of medial and lateral condyles; although AL 129-1a is damaged anteromedially, it is likely that this region would not have projected as far anteriorly as in AL 333–4. Of further note is that UW 88–63 resembles only KNM-ER 1481 and only in degree of asymmetry of the region of the patellar surface. See text for detailed discussion; not to scale; images reproduced to similar mediolateral width; *r* reversed (Except for TM 1513, all casts courtesy of the American Museum of Natural History)

specimens – especially the anterior projection of the medial margin of the patella fossa – but claims this merely reflects sexual dimorphic variation typical of extant populations of large-bodied hominoid species. If true, then a number of fossils that differ in ways similar to AL 129-1a and AL 333-4, or in other morphologies (Table 1), should be regarded as variants of the same subspecies. I am not suggesting that one ignore intraspecific variation, which includes sexually dimorphic differences. However, one can only address this topic after hypothesizing "groups" (e.g., morphs at least) within the morphological parameters of which individual variation can be assessed (Schwartz 2007b). Further, by focusing on general shape and outline, Lague overlooks differences between AL 129-1a and AL 333-4 not only in carrying/bicondylar angle but also in morphological detail (Table 1), beyond which are yet-to-be studied distinctions in, e.g., condylar side, epicondylar, epicondylar line, popliteal surface, and diaphyseal cross-section configurations (personal observations). Indeed, it appears that at present geometric-morphometric analyses are not capable of capturing the morphological details required of systematic analyses (e.g., see Lordkipanidze et al. 2013; see also Ulhaas 2007).

Turning to the proximal femur (Table 2), the most commonly reported "feature" is the femoral neck-shaft angle (measured inferiorly/medially at the intersection of the long central axes of the neck and shaft). As implied by DeSilva et al. (2013), Neanderthals display a moderate amount of variation and *Homo sapiens* considerable variation, the range of the latter encompassing virtually all other hominids. Gilligan et al. (2013) have argued that differences among *sapiens* populations in femoral neck-shaft angle are strongly correlated with differences in climate as well as in aspects of lifestyle, including types and use of clothing. Although neither the ontogeny of this angle nor its relation to the carrying/bicondylar angle has been studied, Gilligan et al.'s conclusion, at least with regard to the influence of lifestyle and clothing, is intriguing. For, if even partially correct, it suggests that the variability recorded for *sapiens*, and likely also for *neanderthalensis*, does not negatively impact the potential phylogenetic significance of the proximal femoral morphology of hominid species that were not geographically widespread and thus subject to disparate climates. Geographic and climatic restrictiveness also suggests that at least femoral neck-shaft angle differences are not due to climate-related clothing, if consideration of clothing of any sort is actually relevant. In other words, morphological variability in the species *Homo sapiens*, as well as in the species *H. neanderthalensis*, does not necessarily lead to the conclusion that variability is the sole explanation for difference among hominid specimens. Thus, while White (2003, 2012) remains steadfastly and zealously critical of paleoanthropologists who are "biased" toward identifying taxic diversity in the human fossil record, he is not exempt from bias toward explaining virtually all morphological difference as variation. Both claims should be regarded as hypotheses in need of testing (see also chapter "▶ General Principles of Evolutionary Morphology," Vol. 1).

Returning to the femoral neck-shaft angle, it is potentially noteworthy that non-*sapiens*/*neanderthalensis* specimens commonly regarded as *Homo* do not cluster together (Table 2). Rather, in this sample, the angle in the majority of specimens is 120°, in two it is 125°, and in most others it is 130°. Further, no "group," even excluding those with 125° angles, conforms to any traditionally recognized hominid taxon or clade. Interestingly, Dmanisi D4167 has the lowest angle: 113°. The paucity of complete femora limits comparisons involving femoral shaft-neck and carrying/bicondylar angles, which, as seen, for instance, in D4167 (113°/15°), KNM-WT 15000 (120°/18°), KNM-ER 1472 (120°/13°), and Trinil 3/Pith I (120°/7°) (Tables 1 and 2) would appear informative for both systematic and locomotory deliberations.

Elsewhere, I (Schwartz 2007a) suggested that the posterior position/orientation of the lesser trochanter in South and East African "australopiths" and also KNM-WT 15000 (posterior) distinguished them not only from mammals in general but also from *Homo sapiens*, *H. neanderthalensis*, and from *Orrorin*, in which this structure points medially and is therefore visible when the femur is viewed anteriorly (Figs. 5, 6, and 7). Additional scrutiny of specimens (actual and casts) as well as review of the literature not only substantiates this observation but also

Table 2 Proximal femur: neck/shaft angle and morphology

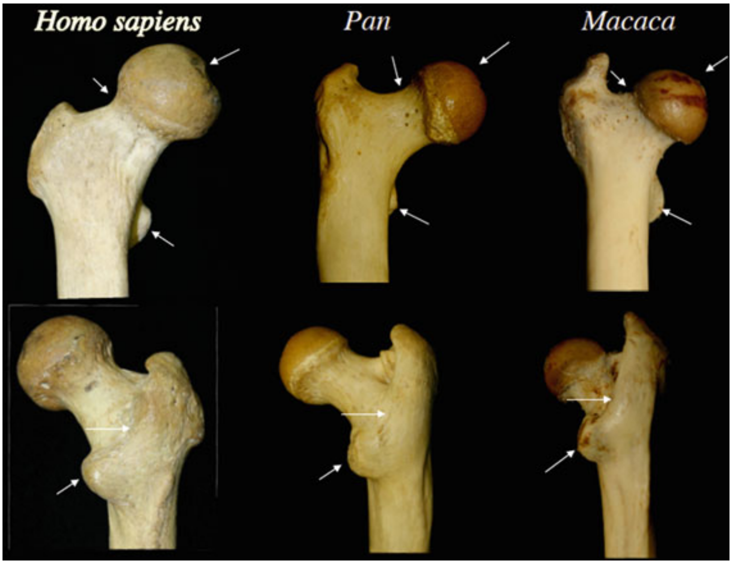

Fig. 5 Right proximal femora of *Homo sapiens*, *Pan*, and *Macaca* (*top row*, anterior; *bottom row*, posterior) illustrating typical primate/mammalian features, e.g., short neck, large rounded head, medially projecting lesser trochanter, and stout intertrochanteric line (*arrows*). See text for further discussion; not to scale (Copyright © J. H. Schwartz)

demonstrates that, like KNM-WT 15000, many specimens allocated to *Homo*, including D4167 (Lordkipanidze et al. 2007), are "australopith"-like in having a somewhat-to-extremely posteriorly oriented lesser trochanter (Table 2; Fig. 6). These specimens are also "australopith"-like in presenting, for example, a relatively long, medially tapering, and somewhat anteroposteriorly compressed femoral neck; relatively small-to-moderate femoral head with little or no distension beyond the perimeter of the neck, especially proximally; and a weakly developed intertrochanteric line (see Table 2 for additional features).

Since, as previously pointed out (Schwartz 2007a), some features seen in *H. sapiens* are typical of mammals, and essentially of all primates (e.g., Fig. 5), those that differ – as in "australopiths" and "australopith-like *Homo*" – are plausibly interpreted as derived or clade informative. In other words, such non-*sapiens* features would unite a group that consists of various specimens ascribed to *Homo*, to the exclusion of *H. sapiens* and *sapiens*-like hominids including, given preserved femoral morphology, *Orrorin* and *Ardipithecus* (see Tables 1 and 2). Consequently, because in the broad comparison "australopith"-like features emerge as derived relative to *sapiens*-like features, no "australopith"-like taxon (e.g., *Australopithecus sediba* represented by Malapa UW-88-04/05/39) should be considered "ancestral" to any specimens, and consequently taxa, that may constitute a *Homo* clade.

Further, as noted previously (Bartsiokas and Day 1993; Day 1973; Kennedy 1983), Trinil 3/Pith I (complete) and Trinil 6/Pith II (partial proximal) femora are

Fig. 6 Proximal femora of various hominids: Dmanisi D4167 and casts of KNM-WT 15000, SK 97, and KNM-738 (*top row*, anterior; *bottom row*, posterior) illustrating atypical primate/mammalian features, e.g., long neck, small head, posteriorly projecting lesser trochanter (*arrows*), and weak intertrochanteric, spiral, and/or gluteal lines. Fig. 7 Left proximal femur of *Orrorin* (*left*, anterior; *right*, posterior views). See text for further discussion; not to scale (Copyright © J. H. Schwartz)

morphologically dissimilar. More specifically, the former specimen presents *sapiens*- and the latter "australopith"-like features (Table 2). However, contrary to suggestions that all non-Trinil 3 (complete) femora constitute a group (Bartsiokas and Day 1993; Day 1973; Kennedy 1983), Trinil 3/Pith I (complete), Trinil 3/Pith III (shaft), and Trinil 9/Pith IX (shaft) are distinguished in diaphyseal shape and proximal morphological detail from Trinil 6/Pith III, and Trinil 8/Pith IV (shaft), which resemble each other morphologically (personal observations).

Regarding pedal morphology, foot bones attributed to *Ardipithecus ramidus* (Lovejoy et al. 2009c) and a specimen described as *Ardipithecus*-like (Haile-Selassie et al. 2012) lacked an arch, had fully opposable halluces, and did not "toe off" with this digit. Day and Napier (1964a, b) reconstructed the OH 8 foot bones with an arch and a first digit in alignment with the other digits; but restudy suggests that the hallux was probably semi-opposable and, by extension, there was an absence of an arch (Clarke and Tobias 1995). The latter two features characterized StW 573 ("Little Foot") (Clarke and Tobias 1995). In contrast, tarsals attributed to *Australopithecus afarensis* (Latimer and Lovejoy 1990; Ward et al. 2011) and *Au. sediba* (DeSilva et al. 2013; Zipfel et al. 2011) are interpreted as presenting an arch, with other preserved pedal elements of *Au. afarensis* indicating a fully adducted hallux. Clearly, Pilbeam's pedal features do not define a hominid clade.

To review, some features of the os coxa and femur, in contrast to at least other catarrhines, appear to distinguish a hominoid clade that we could call "hominid," i.e., a long pubic ramus, a superoinferiorly short ilium that is roundedly expanded posteriorly, some thickening in the region of an iliac (crest) tubercle, a well-developed and knoblike anterior inferior iliac spine that lies noticeably superior to and somewhat back over the superior acetabular rim, a deep greater sciatic notch, a defined linea aspera, development of an obliquely oriented femoral shaft (producing a carrying/bicondylar angle), and a concave lateral tibial facet for the femur that is at the same level as the (also but primitively concave) medial facet, with the two facets being separated by well-developed tubercles. Within this potential clade, a subclade appears to be distinguishable even just on features of the proximal femur – e.g., long neck, posteriorly directed lesser trochanter, poorly delineated head/neck cervical region, and weakly defined intertrochanteric line – and another, which may be a subclade of the latter, in presenting a medially tapering neck.

More Recently Suggested Postcranial Features of "Erect Posture"

With the discovery at Kanapoi and Allia Bay, Kenya of specimens attributed to the species *Australopithecus anamensis*, Leakey et al. (1995) presented features of the proximal tibia (via right proximal tibia KNM-KP 29285A) they thought distinguished hominids from apes and, by extension, from other catarrhines. For example, in apes, the medial tibial condylar facet is convex and in posterior view situated slightly higher than the gently concave lateral condylar facet and, in frontal view, the shaft does not flare out smoothly and evenly to the margins of the proximal articular surface (i.e., the proximal articular surface extends especially medially and laterally farther than

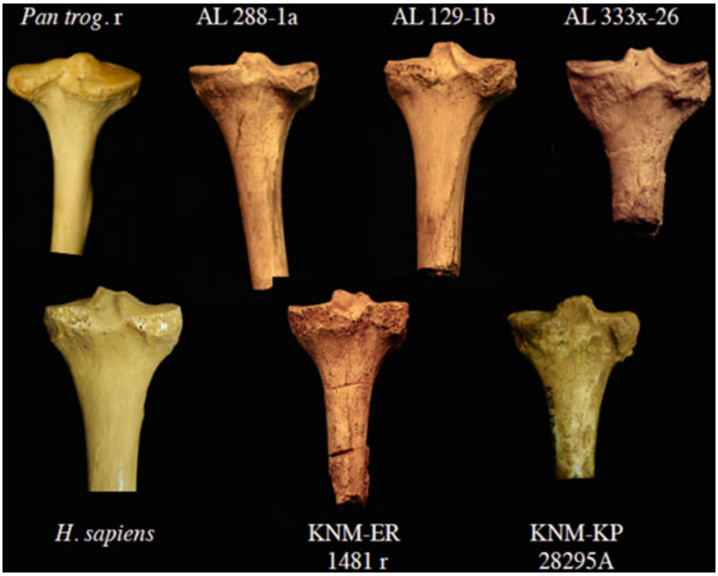

Fig. 8 Posterior views of right proximal tibiae of *Homo sapiens*, AL 288-1a, AL 129-1a, AL 333x-26, and KNM-KP 28295A and left proximal tibiae of *Pan troglodytes* (=*Pan trog.*) and KNM-ER 1481. See text for further discussion; not to scale; *r* reversed (Casts of AL 288-1a, AL 129-1a, AL 33x-26, and KNM-ER 1481 courtesy of the American Museum of Natural History)

the respective margins of the shaft). Further in apes, the two condylar facets are separated by a single, blunt tubercle [see also Aiello and Dean (1999)]. In contrast, Leakey et al. suggested, in specimens attributed to "accepted" australopith taxa as well to species of *Homo*, both tibial condylar facets are at least somewhat concave, separated by a pair of well-defined tubercles and, in posterior view, level with one another. Further in hominids, in anterior view, the tibial shaft flares out to meet the medial and lateral margins of the proximal articular surface. Although these distinctions apply in general to apes and extant humans (in which the tubercles are actually variably distinct), they do not completely describe "australopiths" (Fig. 8).

For example, in right proximal tibia AL 288-1a (cast), the lateral condylar facet is slightly convex while the medial is slightly concave; viewed from behind, medial facet lies slightly below the level of the lateral facet (Fig. 8). Further, the apically indistinct tibial tubercles are separated by and incorporated into a mediolaterally wide blunt, loph-like structure that is anteroposteriorly obliquely oriented from the medial to the lateral side. Right proximal tibia AL 129-1b (cast) is similar to Al 288-1a in overall size, concaveness versus convexity and disparity in height of the condylar facets, and in having indistinct tubercles incorporated into a loph-like structure but differs in the shapes of the facets, a more posterior placement of a taller intertubercular loph, and in a different orientation of the shaft. In the large right proximal tibia AL 333x-26 (cast), the cuplike condylar facets are markedly concave (more so than any other suspected hominid) and, as seen from behind, lie at the same level; also the tibial tubercles are symmetrically distinct at their tips and incorporated into a tall loph that is mediolaterally oriented and situated farther posteriorly. As seen in a cast of the large right proximal tibia KNM-KP 29285A, which is part of the published hypodigm of *Australopithecus anamensis* (Leakey et al. 1995), the lateral condylar facet is faintly while the medial facet is a bit more obviously concave; the two facets are separated by indistinct tubercles that present themselves as a single blunt, high-rising structure that is posteriorly situated on the proximal surface. From behind, the posteriorly sloping lateral condylar facet lies slightly higher than the medial facet. Finally, in left proximal tibia KNM-ER 1481 (cast), both condylar facets are somewhat concave; when viewed from behind, the medial facet lies slightly above the level of the lateral facet. In all of these tibial specimens, KNM-KP 29285A included, the medial margin of the shaft flares out toward the proximal articular region below which the profile actually swells (either slightly as in KNM-KP 292895A, AL 288-1am AL 129-1b, and *H. sapiens* or noticeably as KNM-ER 1481 and AL 333x-26). Also in these specimens, with the notable exception of *H. sapiens*, the lateral border of the shaft flares out slightly before terminating below the proximodistally relatively tall, somewhat squared-off overhang of the lateral portion of the proximal articular region with which the fibula articulates (Fig. 8). Interesting, in *H. sapiens*, the medial and lateral borders of the shaft fan out more or less symmetrically as they approach the proximal end with greater swelling occurring on the lateral rather than the medial side.

As is evident even from this small tibial sample, the possession of a concave lateral femoral condylar facet that lies level with the medial facet, a pair of apically distinct tubercles, and a more symmetrically flared proximal shaft does not fully characterize *Homo sapiens* (and *H. neanderthalensis*), and they certainly do not a hominid make. Indeed, the only tibial feature Leakey et al. (1995) discussed that could distinguish a hominid from an ape is the flaring and swelling of the medial profile of the shaft as it converges upon the proximal articular region – which, in its more swollen state would represent a more derived configuration. Features of the proximal tibia not detailed here (e.g., symmetry/asymmetry of condylar facet shape, orientation of condylar facets, configurations of intercondylar facet depressions, height of tubercular region) are also consistent with the picture of nonuniformity not only among this sample of "australopiths" but also among specimens from Hadar, among which the distinctiveness of AL 333x-26 alone makes clear that "australopith" systematics is far from being resolved (for another perspective, see chapter "▶ The Species and Diversity of Australopiths," Vol. 3). Further, proximal tibial as well as femoral morphology (see above) confirms observations based on dental morphology (Schwartz and Tattersall 2005), namely, that the Hadar specimens encompass more than one taxon. At a higher taxonomic level, since various "australopiths" retain primitive tibial features – e.g., convex medial condylar facet, medial facet higher than lateral facet, indistinct tibial tubercles, and asymmetrically flared proximal shaft – features Leakey et al. put forward as defining hominids appear instead to unite a subclade or subclades within it.

Since tibial and femoral morphologies reflect aspects of locomotion, the differences noted here between specimens suggests, as pedal morphology has begun to indicate, that "bipedalism" was enacted differently among different species or subclades of hominid (see also chapter "▶ Origin of Bipedal Locomotion," Vol. 3). Since no Hadar specimen is dentally comparable to the type specimen of *Au. afarensis*, Laetoli hominid (LH) 4, and all Laetoli specimens can reasonably be allocated to the same dental morph (Schwartz and Tattersall 2005), it would be interesting to know the postcranial morphology of the hominid – that is, of *Au. afarensis* – that left the footprints. Further, the singular degree to which the tibial condylar facets of AL 333x-26 are depressed and cuplike not only reflects a uniquely derived configuration but also likely a unique type of hominid locomotion.

In their description of the Lukeino proximal femur (BAR 1002'00), Pickford et al. (2002) commented on how slight the linea aspera is compared to specimens of australopiths and *Homo* (because the spiral line of BAR 1002'00 does not meet the gluteal/3rd trochanteric line to form a linea aspera of high relief). I agree with this general description (personal observation; Fig. 7). They (p. 202) then suggested, because apes do not present a muscle scar descending from the region of the gluteal tuberosity, that such "a precursor of the *linea aspera*" is a hominid-identifying feature related to bipedalism. A review of casts of some femora identified as australopith or *Homo* reveals, however, a more complex picture (Table 2). For instance, KNM-WT 15000, the supposedly first humanlike striding biped, lacks a spiral line altogether. Other specimens differ in presence and degree of expression of a gluteal line (Table 2), as well as in where each line, if it is identifiable, emerges relative to the associated trochanter and side of shaft; how and where they converge to form/not form a linea aspera; the shape and surface morphology of any supra-linea aspera triangle these lines might delineate between them; where on the shaft their merging produces a linea aspera; and the degree of development and distal course of the linea aspera (personal observation).

Pickford et al. (2002) also mentioned that in BAR 1002'00 the lesser trochanter is medially projecting and, as in humans, gorillas, and *Pongo*, also well separated from the femoral neck. Regarding the latter feature, images in Pickford et al. as well as, for instance, in Robinson (1972), Day (1986), Johanson et al. (1982), and Walker and Leakey (1993) illustrate that while notable separation of lesser trochanter and femoral neck may describe specimens such as SK 82 and 97, Sts 14, AL 288-1, OH 62, KNM-WT 15000, and KNM-ER 738, 1503, and 1547, this configuration does not characterize *Homo sapiens* (or, e.g., *Pan*). Perhaps this disparity is due to differences in femoral neck length – which might imply that separation of lesser trochanter and femoral neck is phylogenetically significant not for, but within, the clade Hominidae. As discussed above, the medial orientation in BAR 1002'00 of the lesser trochanter, although similar to *Homo sapiens*, is also broadly descriptive characteristic of primates (Swindler and Wood 1973) (personal observation; see above). In contrast, in specimens such as AL 128-1, 288-1, AL 333-95, AL 333-3, Maka VP 1/1, SK 82 and 97, OH 62, KNM-WT 15000, and KNM-ER 738 and 1547, the lesser trochanter is more posteriorly than medially if not strongly posteriorly directed (Table 2).

As contemplated above, interpretation of these different configurations is not straightforward. For instance, most mammals present a medially or more medially-than-posteriorly (i.e. medioposterior to posteromedial) oriented lesser trochanter. Based on commonality, the possession of this in apes and *Homo sapiens* could reasonably be interpreted as a primitive retention – in which case configurations to the contrary would be derived and thus potentially reflect a hominid subclade. On other hand, albeit less parsimoniously (but why should parsimony always dictate interpretation?), the apparent widespread distribution among possible hominids of a posteriorly oriented lesser trochanter (and other features as well) might be primitive within a hominid clade – which implies an "independent" development of the primitive mammalian condition in *H. sapiens*. Since, however, postcrania definitively associated with crania and teeth are rare indeed, the former interpretation might be the more likely.

Another feature that Pickford et al (2002; also Galik et al. 2004) suggested unites *Orrorin* via BAR 1002'00 with australopiths and at least *Homo sapiens* is differential distribution of femoral neck cortical bone, being thinner superiorly and thicker inferiorly (Ohman et al. 1997). Taxically broader study is required.

Non-postcranial Features of "Erect Posture"

Although other postcranial features might delineate clade Hominidae, I will turn now to another skeletal region from which "erect posture" or "bipedal locomotion" has been inferred: the cranial base. For ever since Dart's (1925) discussion of the Taung child, an anteriorly placed foramen magnum with attendant occipital condyles has been central to the identification of hominoids as bipedal hominids. With *Ardipithecus ramidus* (White et al. 1994) and *Sahelanthropus tchadensis* (Brunet et al. 2002) being promoted as potential hominids, attention to basicranial morphology is crucial.

Interpretation of *Ardipithecus* (White et al. 1994) and *Sahelanthropus* (Brunet et al. 2002) as "hominid" was in part based on White et al.'s inference of bipedalism from the intersection of the bicarotid (foramen) chord and basion (=the anthropometric landmark in the midline of the anteriormost margin of the foramen magnum). The published photograph of the crushed and distorted basicranium of *Sahelanthropus* reveals, however, that what appears to be the anterior margin of the foramen magnum lies posterior to the bicarotid chord. It is obvious that in the undistorted state, the preserved left petrosal and thus the bicarotid chord were situated more anteriorly. Consequently, a forward position of the foramen magnum is not indicated.

Although not demonstrated, White et al.'s claim of an association between basion (i.e., the anterior margin of the foramen magnum) and the bicarotid chord, an anteriorly placed foramen magnum, and erect posture and bipedalism would seem intuitively reasonable. However, comparison of other potential fossil hominids, extant large-bodied hominoids, and various extant New and Old World monkeys, reveals a more complex picture (Schwartz 2004b). In juvenile anthropoids, including humans, basion, the bicarotid chord and the biporionic chord are essentially in alignment. This relationship is retained into adulthood in some anthropoid taxa, but, in others, during growth, the positions of basion and/or the bicarotid chord may change position relative to the biporionic chord. Consequently, it is the biporionic and not the bicarotid chord that better reflects the position of the foramen magnum. The alignment of basion and the two chords in the adult is, therefore, a neotenic feature that, while not defining clade Hominidae (Schwartz 2004b; Schwartz and Tattersall 2005), may be relevant to delineating relationships within it. More recently, in the context of comparison between an unspecified sample of extant catarrhines and extant *sapiens*, Kimbel et al. (2013) argued the hominid status of *Ar. ramidus* on the basis of reconstructing cranial base width and anterior foramen magnum position from missing basicranial elements in ARA-VP/500. Nevertheless, until the ontogeny of this general region in a diversity of anthropoids is understood, comparisons only between adult specimens are – as demonstrated above vis-à-vis ontogenetic changes – uninformative.

Proposed Craniodental Features of Being Hominid

Based on isolated teeth attributed to *Ardipithecus*, White et al. (1994) suggested that, in lateral profile, a hominid's permanent upper canine should present subequally long and quite divergent mesial and distal edges terminating in "shoulder-like" basal swellings that create the impression of a superoinferiorly short crown. This does not, however, describe the permanent upper canine ($C^{\backslash}$) of *Sahelanthropus* (Brunet et al. 2002) or the majority of C^1s of traditionally accepted Plio-Pleistocene and later hominids, including *Homo sapiens* (Schwartz and Tattersall 2005). Rather, White et al.'s description better captures the morphology of the $C^{\backslash}$s of adult female orangutans and the deciduous upper canines of juvenile orangutans and chimpanzees (Swarts 1988).

White et al. (1994; also Suwa et al. 2009) also described *Ardipithecus*' C^1 as "incisiform" but from the belief, also shared by Brunet et al. (2002), that a C_1-C^1-P_1 honing complex had been lost in hominids via a decrease in size and projection of these teeth (particularly the canines) in concert with closure of presumed attendant diastema. According to this scenario, as canines became less caniniform, they became associated functionally with the incisors, ultimately assuming the morphology and function of these spatulate anterior teeth. Yet, both the right C^1 allocated to *Ardipithecus* and the C^1 in the skull of *Sahelanthropus*, although differing in buccal profile triangularity, are apically pointed. Indeed, *Sahelanthropus*' trenchant C^1 would likely have occluded with a much more "caniniform"-looking C_1 than the very unprimatelike isolated element identified as this tooth (Schwartz 2004b). Although it appears from teeth in situ that *Sahelanthropus* lacked upper diastema, their absence is only inferred for *Ardipithecus* from isolated teeth. Nevertheless, if *Ardipithecus* did not have diastema, both it and *Sahelanthropus* would be more derived than geologically younger (and supposedly descendent) specimens with diastema [e.g., AL 200-1a and StW 252 (Schwartz and Tattersall 2005)] as well as the maxilla from Bouri Hata allocated to *Australopithecus garhi* [see photographs in Asfaw et al. (1999)]. Consequently, features associated with "reduction of a canine-premolar honing complex," while not defining clade Hominidae, may delineate subclades within it.

Another approach to defining Hominidae is predicated on an a priori assumption of a human-chimpanzee relationship, which immediately constrains the hominid "out-group" to this single large-bodied hominoid. Thus, although White et al. (1994, p. 306) describe the dm_1 of *Ardipithecus* as "apelike," the only ape in their comparison is *Pan*. Yet, *Hylobates* and *Gorilla* dm_1s are also very similar to *Pan* dm_1s, while *Pongo* dm_1s are most similar to those of traditionally accepted hominids, the major difference being more talonid cusp compression in the orangutan (Schwartz 2004b; Swarts 1988). Thus, *Pongo*, "australopiths," and *Homo* dm_1s conform best to White et al.'s (1994, p. 307) depiction of "apparently derived hominid features," i.e., "buccolingual crown expansion, mesiolingually prominent metaconid, well-defined anterior fovea, and large talonid with well differentiated cusps" (White et al. 1994). In fact, the dm_1s of *Pongo* and hominids[1] are similarly derived relative to other extant hominoids (Schwartz 2007b; Schwartz and Tattersall 2002, 2003, 2005): e.g., the protoconid is more mesially situated; the less vertical and lingually facing anterior fovea (= trigonid basin) is noticeably smaller than the talonid basin and is enclosed by a distinct paracristid that courses somewhat mesially and then turns toward the lingual side; and the more horizontally oriented talonid basin is enclosed by a distinct hypocristid (Swarts 1988) (personal observation).

Only if *Pongo* (and members of its clade for which dm_1s are currently unknown but for which this description would be predicted as applicable) is not the sister taxon of a potential hominid clade would these dental features be relevant to defining only clade Hominidae.

More broadly, Irish and Guatelli-Steinberg (2003) claim to have delineated features characteristic and also distinctive of the last common ancestor of clade Hominidae and also demonstrated that recent sub-Saharan Africans most closely resemble various Plio-Pleistocene hominids in these features. Their study is based on the ASU dental trait scoring system established decades ago by Turner et al. (1991) (see chapter "▶ The Dentition of American Indians: Evolutionary Results and Demographic Implications Following Colonization from Siberia," Vol. 3). Although seemingly objective (e.g., in matching individual dental features of a specimen with plaques of dental casts varying degrees of expression of that trait), the Turner scoring system has no relation to the terms and descriptive protocol that inform the study and systematic interpretation of mammalian teeth. Rather, Turner's system focuses instead on predefined minutiae and often idiosyncratically defined variation. Thus, although hominids are toothed mammals, Turner and scions have so ignored the

---

[1] Comparison comprises juvenile *Homo*, including Melka Konturé MK81 GAR IV (2), and "australopiths" (e.g., Hadar AL 333-43b; Koobi Fora KNM-ER 820, 1477, and 1507; Laetoli LH2 and 3q; Omo 22_7; Taung; Swartkrans SK 47; Kromdraai TM1536, TM1601a, and TM1604; KB5503 and KB5223; and Sterkfontein Sts24 and StW 104 and 151).

conventions of mammalian dental terminology and description that a mammalian systematist cannot understand or even divine the morphology of the teeth subjected to the ASU scoring system. Indeed, terms such as "lower molar deflecting wrinkle" and "lower molar seventh cusp" or referring to a (huge) protostyle as an element of a "twinned hypocone" demonstrate just how far from biological/systematic practice paleoanthropology is. In short, coding for one trait after another and their presumed degrees of expression informs neither about the relations of structures to one another nor, more importantly, about the shape of a tooth and the relative expressions of as well as the spatial relationships of the details of occlusal morphology. Further, rather than testing hypotheses of which specimens might represent which morph/taxon, these analyses begin by accepting prior taxonomic allocation of specimens [e.g., (Bailey 2002, 2004; Bailey and Wu 2010; Trinkaus et al. 2000)].

Unfortunately, the emphasis of the ASU approach on scoring individual traits with a focus on degrees of trait expression (e.g., larger, larger, small, smaller; distinct, more distinct, less distinct) rather than on their relationships informed the dental "study" of specimens identified as *Australopithecus sediba* (Irish et al. 2013). Although rooting their analysis in a gorilla out-group – without understanding that gorillas are unique among large-bodied hominoids in aspects dental morphology (Schwartz 1986) – Irish et al. (Irish et al. 2013) conclude that *Au. sediba* is dentally distinct from other "hominids" but similar in a phylogenetically meaningful way to their sample of *Au. africanus* and an assumed *Homo habilis/heidelbergensis* + *H. erectus* group. The latter larger grouping is based on four features, including the vague "identical LM1 cusp 7 expression." Their conclusion, in conformity with interpretation of cranial and postcranial morphology, is that its "mosaic" of presumed primitive australopith and derived *Homo* features makes *Au. sediba* a good ancestor of genus *Homo*.

Although the taxonomic distinctiveness of *Au. sediba* has been challenged on the grounds that the skull upon which the species was based is that of subadult – and thus its adult morphology could be comparable to known specimens of australopith (Strauss et al. 2012, 2013) – tooth and mandibular morphology provide less speculative clues to understanding this hominid. Indeed, comparison with all known australopiths demonstrates that *Au. sediba* is remarkably similar to Kromdraai TM1517b, the mandibular holotype of *Paranthropus robustus* (Fig. 9).

For example, although the mandibular corpus of MH1 (UW-88-8) is more gracile, shorter superoinferiorly, and more swollen below the alveolar region – which may be because of its being subadult – both it and TM1571b are otherwise similar, including presenting two (top and bottom) mental foramina below P_1. Further, in both specimens, the anterior root of the ramus originates below the region of $M_{1\text{-}2}$, masking M_3 entirely, and then swells only modestly before becoming crest-like as it ascends, inclining a bit backward. UW-88-129 presents a moderately steep postincisal plane, as also seen in TM1517b. Damage and incomplete restoration of TM1517b preclude assessing C_1 orientation, but this tooth in UW-88-8 was relatively larger. Preserved alveoli in UW-88-8 suggest that the missing $P_{1\text{-}2}$ were similar to TM1517b in shape: i.e., P_2 was larger, especially in a distended hypocone region such that the buccal side of the tooth was mesiodistally

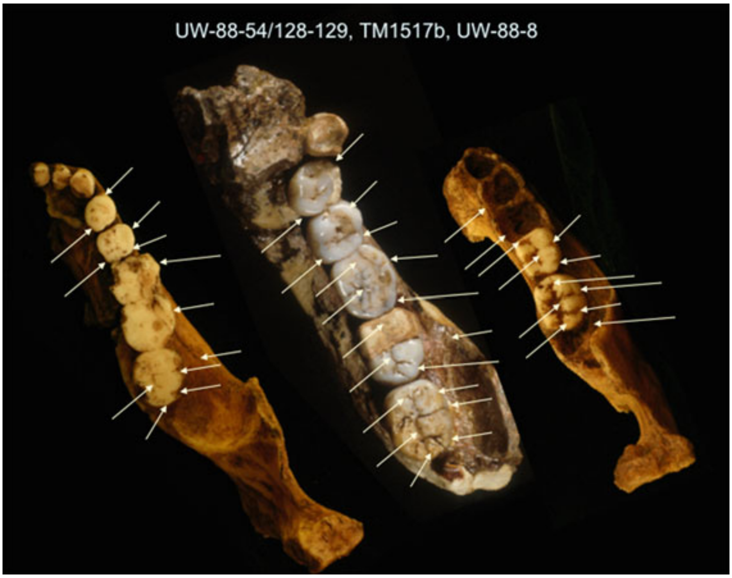

Fig. 9 Occlusal views (*left* to *right*) of right mandibles of Malapa hominid MH 2 (UW-88-54-128-129), Kromdraai TM1517b (type, *Paranthropus robustus*), and MH 1 (UW-88-8), illustrating numerous dental similarities, size being the major difference. See text for further discussion; not to scale but to relative size (Casts of MH 1 and MH 2 courtesy of the American Museum of Natural History)

somewhat shorter, while the buccal side of P_1 was marginally but still visibly longer than the lingual side. The P_2 of UW-88-129, although also smaller, is morphologically comparable to TM1517b. The M_1s of the smaller UW-88-8 and TM1517b are otherwise distinctively similar, especially in the oblique orientation of the distal part of the crown, the presence of notches between buccal cusps, and a buccal cingulid on the protoconid. Further, for example, in both UW-88-8 and the TM1517b, $M_{1\text{-}2}$ the hypoconids are compressed, they bear hypocristids, and their bases extend lingually across the midline of the crown, terminating approximately in the midline in a mesiodistally relatively long and internally squared-off end; also, small hypoconulids angle in toward the middle of the tooth, following the generally oblique orientation of their distal sides of the crowns. A groove on the internal face of the M_1 metaconid base of TM1517b produces a "pillar-like" feature, which is seen on UW-88-8's M_2. Although the mesial part of TM1517b's M_2 is partially reconstructed, the distal extremity of a definitive protoconid buccal cingulid is clearly evident abutting the mesial side of this tooth's hypoconid even in the presence of a notch between these two cusps. Similar morphological detail is noted in UW-88-8. Further, the M_3s of TM1517b and UW-88-8 are generally similar in size and shape and also in presenting buccal cusp notches (also in UW-88-55a), distinct buccal cingulids on the distal part of the protoconid, a slight buccal enamel swelling below the hypoconulid, a distobuccally obliquely oriented

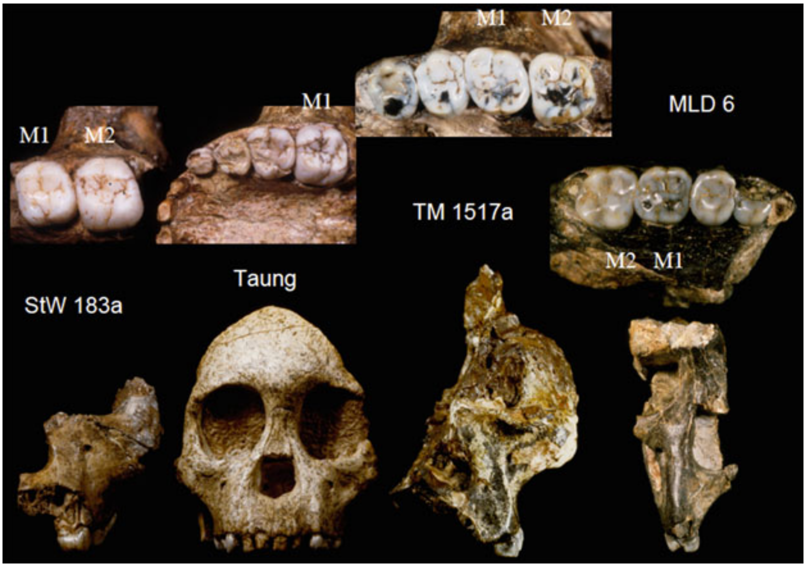

Fig. 10 Comparison of the Taung child specimen, the type of *Australopithecus africanus*, and a few other South African specimens that present similar facial and dental features of as well as variation within the Taung morph. Note that TM 1517a, which Broom referred to the holotype of *Paranthropus robustus*, compares favorably with this morph. Not to scale (Copyright © J. H. Schwartz)

metaconid base, and mesiodistally short trigonid basins confined to the inner portions of protoconid and metaconid bases.

If, as appears to be the case, these specimens represent the same hominid, they should be regarded as *Paranthropus robustus*, with the Malapa specimens' smaller size likely reflecting sexual dimorphism: i.e., MH1 was female, not male (Berger et al. 2010). Since, however, dentally and even in bony morphology the partial face TM 1517a is relatable to a morph that includes the Taung child, and which therefore must regarded as *Australopithecus africanus* (Schwartz and Tattersall 2005; Fig. 10), only the lower jaw from Kromdraai TM1517b represents the holotype of *P. robustus*. In this regard, future comparisons of the upper dentition of MH1 with those of other "australopiths" should prove enlightening in sorting out which specimens actually do represent this taxon. Certainly, we now know a lot about the postcranial skeleton of this hominid.

Additional Defining Characters of Hominidae

Although some obviously derived features when considered in isolation might delineate clade Hominidae, they are also shared with *Pongo* and its potential extinct relatives. Consequently, in order to claim them as strictly hominid apomorphies, and their presence in an orangutan clade as autapomorphic for it and non-synapomorphic with hominids (i.e., features seen in hominid and orangutan clades are homoplastic), one must first embrace another theory of extant large-bodied hominoid relationship and then "explain away" the phylogenetic significance of the similarities between humans and orangutans, which is often done merely by declaring them homoplastic (e.g., Collard and Wood 2000, 2007; Diogo and Wood 2011; Lockwood and Fleagle 1999; Wood and Harrison 2011) as if homoplasy were identifiable without first presuming a theory of relationship based on characters deemed synapomorphic for other taxa (see discussion in Schwartz 2008; see also chapter "▶ Homology: A Philosophical and Biological Perspective," Vol. 1).

This, of course, is the current state of affairs in paleoanthropology, wherein the molecular similarities between *Pan* and *Homo* are taken as evidence of their close relationship (e.g., see Lockwood et al. 2004; Pilbeam 1986, 2000; Gibbs et al. 2000, 2002; Wood and Harrison 2011), even though most of the "favorable" comparisons involve only small portions of the 2–3 % coding (i.e., metabolically, not developmentally relevant) region of the genome and rarely include the orangutan and an array of other catarrhines (e.g., Grehan and Schwartz 2009; Grehan and Schwartz 2011; Schwartz 2009, 2011, 2012; Schwartz and Maresca 2006). Although Wood and Harrison (2011) assert there is also "overwhelming. . .morphological evidence for a ((*Pan*, *Homo*) *Gorilla*) *Pongo*) pattern of relationships" and that features suggesting a *Pongo*-*Homo* sister group were "selected" to do so (p. 470), neither of these statements is correct, especially, "overwhelming-morphological evidence for with regard to a ((*Pan*, *Homo*) *Gorilla*) *Pongo*) pattern of relationships." Although Groves (1986) is consistently cited as having demonstrated a close human-chimpanzee relationship, scrutiny of his data demonstrates not only that most of the features he presented in support of this contention are not synapomorphic because they are found in other primates listed (Grehan and Schwartz 2009; Groves 1986; Schwartz 1988, 2005) but, more importantly, that numerous features are either ambiguously or incorrectly reported (Grehan and Schwartz 2009).

Unfortunately, Groves' work has been reiterated without question in subsequent publications claiming demonstration of a *Homo*-*Pan* relationship (e.g., see especially Lehtonen et al. 2011; Strait and Grine 2004; Collard and Wood 2000; Gibbs et al. 2000, 2002). Further, in light of Wood and Harrison's claim of "overwhelming. . .morphological evidence for a ((*Pan*, *Homo*) *Gorilla*) *Pongo*) pattern of relationships," Wood's own work (Collard and Wood 2000; Gibbs et al. 2000, 2002), which was based in large part on Groves (1986), delineated essentially no hard-tissue and only a handful of soft-tissue features in support of a human-chimpanzee sister group. With regard to the criticism that features in support of a human-orangutan sister group were selected to demonstrate this, scrutiny of the relevant publications reveals that in all cases the comparative morphological, physiological, and developmental data cited was available in the literature (Grehan and Schwartz 2009; Schwartz 1983, 1988, 2004a, 2005). When new data was introduced, it was spelled out and, as with all data, presented for an array of primates, not just humans and large-bodied hominoids (Grehan and Schwartz 2009; Schwartz 1983, 1988, 2004a, 2005). In contrast to Groves' claiming

Homo-Pan synapomorphy not only in the rare instances when only these two hominoids shared features but more frequently when other primates shared features present in humans and chimpanzees, I hypothesized synapomorphy only when two taxa exclusively shared a feature. Consequently, in every publication, I presented all alternative theories of relationship, including *Homo-Pan*, even though they differed significantly in degree of robustness (= corroboration). The fact of the matter is, even if one used Groves' data without eliminating ambiguous or incorrect data, and hypothesized synapomorphy on the basis of exclusivity of shared features, *Homo-Pan* emerges as the least and *Homo-Pongo* as the most highly supported theory of relationship (Schwartz 1988). With the addition of more features to the data base, and in the context of a broad comparison among primates, the same pattern of relationship emerges (Grehan and Schwartz 2011). If one were to cast the stone of "selectively" choosing features to support a particular human-ape theory of relationship, it would have to be toward those who maintain a *Homo-Pan* sister group through reiteration of faulty morphological datasets and ignore additional data that might lead to a conclusion other than their preferred conclusion.

Nevertheless, even if the latter phylogenetic hypothesis were true, this does not justify using *Pan* alone as the referent for defining clade Hominidae or for determining character polarity within this clade (e.g., see Asfaw et al. 1999; Brunet et al. 2002; Guy et al. 2005; Lovejoy et al. 2009b, c; Suwa et al. 2009; White et al. 1994, 2006; Wood and Harrison 2011). Rather, the broad comparative approach that Le Gros Clark might have pursued remains the more reliable way in which to hypothesize features that could distinguish a hominid from other primate clades and also determine character polarity within it. And, in doing so, one must also confront instances when humans, or hominids in general, compare more favorably with primates other than *Pan*, as, indeed, they often do with *Pongo*.

Pongo-like Dental and Palatal Features of Potential Hominids

An interesting case of "interpreter's bias" lies in analyses of molar enamel thickness. For example, although Martin (1985) has been cited as demonstrating that the last common ancestor of large-bodied hominoids had thick molar enamel (which was retained in orangutan and hominid clades but secondarily reduced in African apes), he merely interpreted enamel thickness data in the context of an [orangutan (human-African ape)] theory of relatedness (Schwartz 1987). Otherwise he should, or at least could, have concluded that thick molar enamel united human and orangutan clades. Kelley and Pilbeam (1986) also interpreted molar enamel thickness in the context of an [orangutan (human-African ape)] theory of relatedness but presented two scenarios: Martin's and one in which the last common ancestors of separate human and orangutan clades independently developed thick molar enamel. In the latter case, thick molar enamel would be a defining feature of Hominidae. In contrast, but embracing first a human-chimpanzee relationship, Suwa et al. (2009) could claim that thin enamel was secondarily derived in *Pan*.

More recently, Schwartz (2000) found that, while humans and orangutans both have thick molar enamel, humans have thicker enamel in some areas of their occlusal surfaces. He suggested that thick molar enamel had evolved independently in humans and orangutans (and, by implication, in the last common ancestors of separate human and orangutan clades) because of the demands of different diets. A more straightforward interpretation of G. Schwartz's data is that human and orangutan clades shared a thick-molar-enameled common ancestor and that, within this clade, humans (and perhaps other hominids) are more derived. Only by accepting thick molar enamel as synapomorphic of traditionally accepted hominids can one embrace thin-enameled *Ardipithecus* as a sister of this clade (assuming that this relationship is based on synapomorphy). Of course, Brunet et al.'s (2002) suggestion that the thicker enameled *Sahelanthropus* is ancestral to *Ardipithecus*, and Suwa et al.'s (2009) argument based on a presumed hominid-*Pan* sister group that thin enamel in the latter must be secondarily derived, underscores the need for systematic rigor in paleoanthropology. For, indeed, explaining the distribution of morphology based on an already accepted theory of relationship does not substitute for the generation of that theory.

If thick molar enamel does not contribute to defining Hominidae, does dental morphology? Some aspects of it might (e.g., see discussion above on dm_1 morphology) but, at present, delineating more than a handful of features would be a Herculean task. This difficulty derives from the longstanding notion of the Miocene being a time of an "ape radiation," after which "hominids" emerged. Guided by this scenario, paleoanthropologists typically identified post-5.5 ma specimens with thick-enameled cheek teeth as "hominid" and pre-5.5 ma specimens as orangutan relatives. Nevertheless, study of fossils identified as hominid reveals that *Pongo*-like teeth have often been referred to species of *Homo* and *Australopithecus* (Grine and Franzen 1994; Schwartz 2004a; Schwartz and Tattersall 1996). Teeth allocated to *Orrorin tugenensis* (Senut et al. 2001), if truly thick-enameled, reinforce the question of how many Miocene "apes" are actually hominids and how many Plio-Pleistocene "hominids" are not. In addition, since "hominid" teeth are often worn flat, little attention has been paid to details of occlusal morphology. Thus, although most of the human fossil record has now been scrutinized at the level of morphs (Schwartz and Tattersall 2002, 2003, 2005), much work on testing these hypotheses remains before assigning specimens (other than, of course named type specimens) to specific genera and species.

Were it not for their presence in, for instance, *Pongo*, *Sivapithecus*, and *Ankarapithecus*, other features that could "define" Hominidae are the development of a single incisive foramen (Schwartz 1983, 1997) and a posteriorly thickened palate (as seen in midline cross section) (Schwartz 2004a). With regard to the palate, if the Hadar broken palate AL 200-1a does thin posteriorly, it would be the outlier among "accepted" hominids (Schwartz 2004a; Schwartz and Tattersall 2002, 2003, 2005). As with thick molar enamel and the morphological details of dm_1, the simplest phylogenetic interpretation of these features is that they characterized the last common ancestor of human and orangutan clades.

Pongo-Like Features of "Australopiths": Implications for Defining Hominidae

Another stumbling block to defining Hominidae is the degree to which "australopiths" and specimens traditionally allocated to *Homo* differ from one another, especially in craniofacial morphology, e.g., in orbital and nasal aperture outline as well as in the configuration of the supra- and infraorbital regions; elevation of the nasoalveolar clivus above the floor of the nasal cavity; height and orientation of the subnasal region; orientation, flatness, and height of the zygomatic region; development of a "snout" with/without facial pillars (vertical or medially inclined); and a canine fossa, and in the development and configuration of a mastoid process. Thus, while one might unite all of these potential hominids via various postcranial features, craniofacial morphology seems only to delineate possible hominid subclades. This may in part explain why one approach to associating living humans with *Pan* is to try first to link the latter with australopiths and then to assert, since australopiths and *Homo* form a clade, that humans and chimpanzees are closely related (Begun 1994; Begun et al. 1997). In the latter case, the primary feature of supposed synapomorphy between (an undefined) *Australopithecus* and *Pan* – bar-like supraorbital torus with sulcus behind – describes no "australopith" (e.g., Figs. 10 and 11) and only some specimens of *Homo* (e.g., Fig. 13; Clarke 1987; Schwartz and Tattersall 2002, 2003, 2005). In addition, not only is the markedly inferosuperiorly tall supraorbital region of *Sahelanthropus* not bar-like as in African apes [i.e., it is not both superiorly and slightly anteriorly projecting and bound posteriorly by a distinct posttoral sulcus; see Schwartz (1997) for discussion], it is so unusually tall that it must represent a derived, not primitive, configuration – which, together with its distinct dental morphology and not very thick molar enamel, makes determining its relationship to any hominid (or ape) difficult indeed (Schwartz 2004b).

While seeking connections between fossil hominids and African apes (especially *Pan*) has historical precedent (Johanson and White 1979), the most favorable comparisons are actually between *Pongo* (and its fossil relatives) and australopiths and some specimens attributed to *Homo* (Grehan and Schwartz 2009; Schwartz 2004a, 2005), e.g., rim-like superior orbital margins with a rather smooth transition into the frontal plane; often ovoid orbits; and forwardly facing, tall, and often vertical zygomatic regions (a further derived configuration, e.g., as in KNM-WT 17000, is a posteriorly tilted zygoma) (Figs. 10, 11, 12, and 13). Since the faces of *Pongo*, *Sivapithecus*, and *Ankarapithecus* as well as of most specimens taken as being hominid are relatively tall superoinferiorly and, even with anteriorly oriented zygomas, relatively narrow from side to side, those specimens with broad and short faces (in the orangutan clade, *Lufengpithecus* and among hominids, e.g., AL 444-1, SK 48, KNM-ER 406, KNM-WT 17000, KNM-ER 3883) emerge as potentially derived, which for hominids may reflect relatedness among some, if not all of them (see also Schwartz and Tattersall 2005; Fig. 14). Many australopiths are also similar to *Pongo* in having distinct facial pillars that emerge just above the canines and, together with a variably developed canine fossa, delineate a "snout" [Figs. 10 and 11; see also

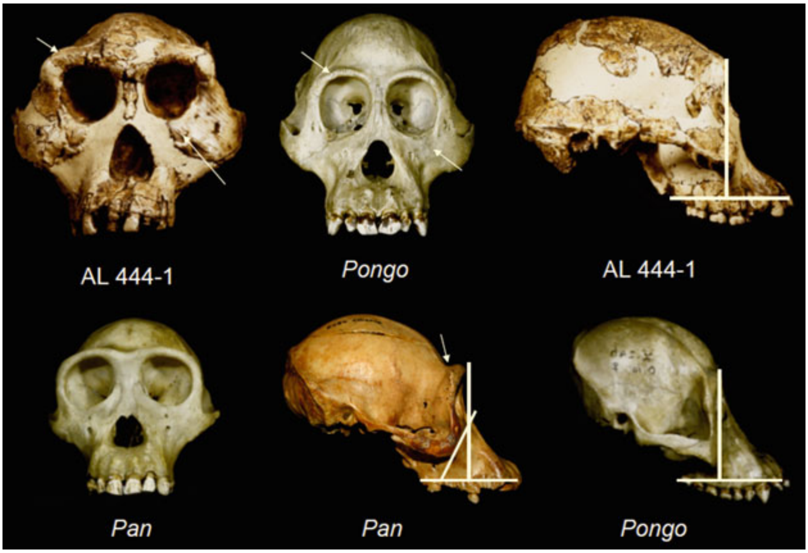

Fig. 11 Comparison of AL 444-1 (cast of reconstruction) with *Pongo* and *Pan* illustrating lack of *Pan*-like supraorbital, lower facial, and zygomatic morphology, but orangutan-specific features in the hominid. See text for further discussion; not to scale (Copyright © J. H. Schwartz)

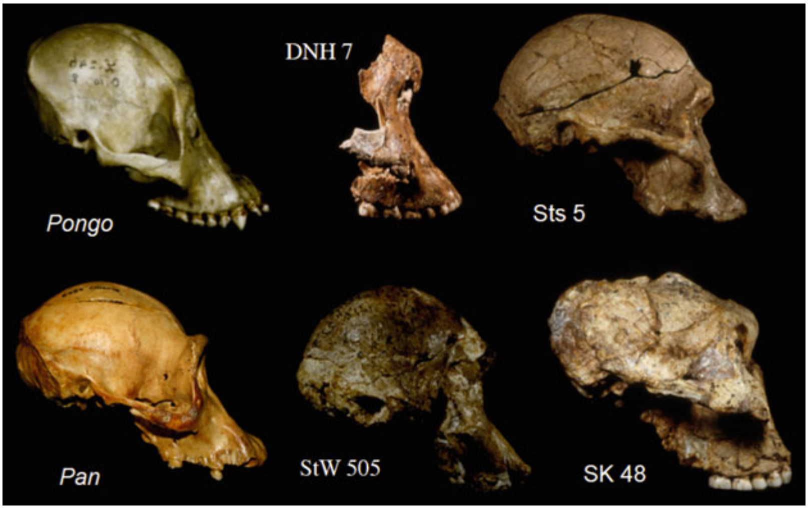

Fig. 12 Right lateral views of *Pongo*, Drimolen DNH 7, and Sts 5 (*top row*) and *Pan*, StW 505, and SK 48 (*bottom row*) illustrating, e.g., lack of *Pan*-like supraorbital, lower facial, and zygomatic morphology but orangutan-specific features in the hominids. See text for further discussion; not to scale (Copyright © J. H. Schwartz)

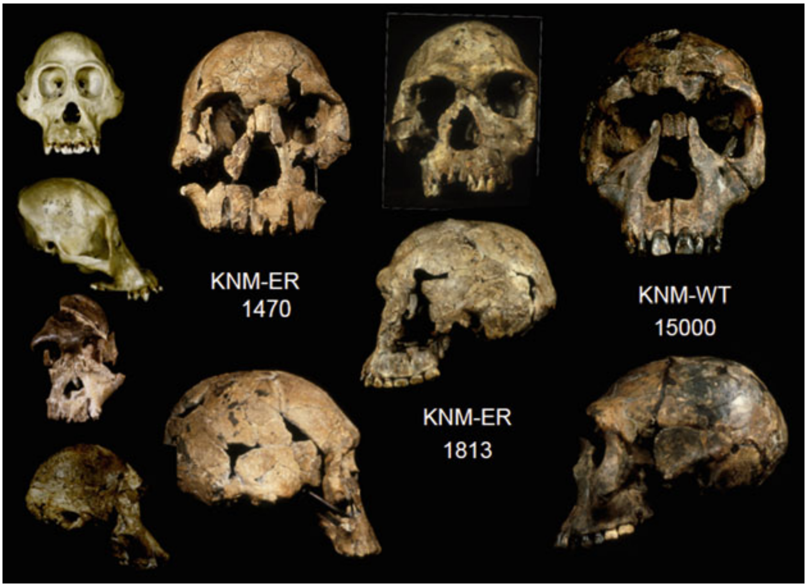

Fig. 13 Comparison of (*left column*) *Pongo* and StW 505 with various specimens allocated to *Homo* illustrating especially orangutan-like facial features. See text for further discussion; not to scale (Copyright © J. H. Schwartz)

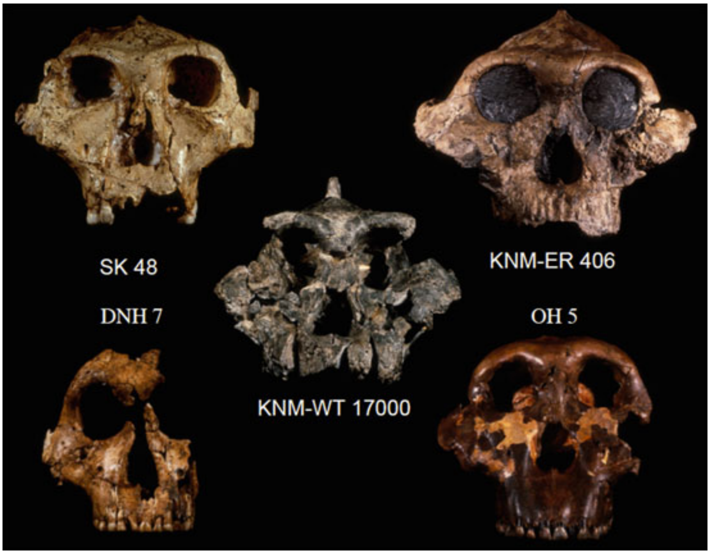

Fig. 14 Comparison of various specimens of "robust australopith" to illustrate similarly derived laterally broad and superoinferiorly short faces in SK 48, KNM-ER 406, and KNM-WT 17000, which might reflect their membership in a hominid subclade that does not include specimens such as DNH 7 and OH 5. See text for further discussion; not to scale (Copyright © J. H. Schwartz)

illustrations in Schwartz and Tattersall (2005)]. Interestingly, the Taung specimen has the long, slit-like single incisive foramen seen in *Pongo* and also preserved in *Sivapithecus* and *Ankarapithecus* (Schwartz 2005). While I am not advocating a special relationship between a *Pongo* clade and some or all australopiths, attention to these apparent synapomorphies is more relevant to the task of defining Hominidae, its subclades, and sister taxa than is currently appreciated.

Indisputable similarities between *Pongo* and australopiths exist (Schwartz and Tattersall 2005) and they should be accounted for in any critical evaluation of human-ape and within-hominid relationship. Further, these similarities make even more critical for defining a hominid clade and relationships within it broadening comparisons from solely between hominids and *Pan* alone, or between hominids and both African apes, to include as many catarrhine taxa as possible in order to provide the best foundation for delineating shared character similarity and determining character polarity – which are critical to phylogenetic reconstruction.

Conclusions

When comparing extant taxa, defining Hominidae is a simple matter. Through a curious historical twist, *Homo sapiens* is the only survivor of a clade whose dimensions we will never fully know. Take, for instance, the discovery of an apparent hominid from the late Pleistocene of Flores, Indonesia, best seen in LB1 (Brown et al. 2004). Its combination of morphologies would be unexpected no matter what its age.

LB1 has or had a moderately globular cranium (as in some hominids); somewhat thickened and anteriorly (but not superiorly) protruding but rim-like supraorbital margins with no sulcus behind (australopiths in part and orangutans and their relatives); tall, ovoid orbits (*Pongo*, *Sivapithecus*, some “australopiths”); flat nasal bones (most hominoids, including some *Homo*); forwardly facing and vertical yet superoinferiorly short zygomas (australopiths and orangutans and their relatives); well-developed mastoid processes (some “australopiths” and some *Homo*); a thick frontal with thick diploe (autapomorphic or pathological); no frontal sinuses (most primates, including bonobos); an anterior cranial fossa that does not extend fully over the orbital cones (most primates, including some *Homo*); a clivus that slopes gently away from the dorsum sellae (most primates, including some *Homo*); basion and bicarotid and biporionic chords in alignment (juvenile anthropoids, some adults); a broad incisive foramen that proceeds anteriorly as a expanding groove (a few “australopiths,” e.g., OH 5); marked separation of the nasoalveolar clivus and an anteriorly thin palate (African apes, some Miocene hominoids, some “australopiths”); a smoothly but narrowly curved mandibular symphyseal region (many anthropoids); a long retromolar space (various *Homo*); a broadly and smoothly rounded but somewhat truncated gonial angle (some *Homo*); a very anteroposteriorly long sigmoid notch (some *Homo*); a sigmoid notch crest that is deepest near the coronoid process (autapomorphic); very large cheek teeth and apparently relatively small anterior teeth (some “australopiths”); unusually mesiodistally short upper and lower molars with large mesial and truncated distal cusps (autapomorphic); a relatively long ilium (e.g., SK 50) with a beaklike anterior superior iliac spine (great apes, SK 50, MLD 7 and 25); a poorly defined iliac pillar (australopiths); a knoblike anterior inferior iliac spine that lies noticeably superior to above and somewhat back over the supra-acetabular rim (hominids as discussed here); an arcuate line that descends well before reaching the region of the acetabulum (some hominids); no ischial spine (most primates); posterior iliac expansion that defines a greater sciatic notch (hominids as used here); a "V"-shaped greater sciatic notch (most hominids, but not Neanderthals); a large femoral head (most primates); a long and anteroposteriorly compressed femoral neck (*Orrorin*, "australopiths" including BOU-VP-12/1, and some *Homo*, e.g., OH 62, KNM-WT 15000, D4167); a well-defined intertrochanteric crest (most primates, but not KNM-WT 15000, *Orrorin*, and most if not all "australopiths" or OH 62); a medially facing lesser trochanter (most primates, not "australopiths" or various *Homo*, e.g., OH 62, KNM-WT 15000, D4167); a weakly developed linea aspera (*Orrorin* and various "australopiths"); a femoral "carrying angle" ("australopiths" and *Homo*); a tibia that is much shorter than the femur (at least apes); poorly differentiated tibial tubercles (most primates); a medial tibial condylar facet that is situated higher than the lateral (at least apes); and a convex medial tibial facet (apes and some "australopiths," e.g., AL 288-1a, AL 129-1b) (see Brown et al. 2004).

Is this Flores specimen – if the cranial and postcranial remains represent a single individual – a hominid? A gut reaction based on the external morphology of the skull is "yes," but the internal morphologies are odd. The teeth are not necessarily hominid, the humeral shaft lacks the torque or "twist" characteristic of large-bodied hominoids (Morwood et al. 2005) and the morphology of the distal articular region is clearly not hominoid (Morwood et al. 2005; Schwartz 1986), the tibia is definitely not hominid, the femur is *Orrorin*-like, and the partial os coxa is somewhat "australopith"-like. So why is the composite Flores specimen considered a species of *Homo* when its affinities to a clade Hominidae are not entirely clear? Largely because there has been a history of allocating specimens to taxa based more on their geological age than on their morphology – which, in turn, has led to the general practice of trying to explain away "anomalous" morphologies in terms of variation (see also chapter "▶ General Principles of Evolutionary Morphology," Vol. 1). Methodologically, however, before one even contemplates referring a specimen to a genus and species, one should have to defend first why any specimen is a hominid and then a member of the nested subclades that subsume that species (see also chapter "▶ Principles of Taxonomy and Classification: Current Proce dures for Naming and Classifying Organisms," Vol. 1). But in order to do so, we must have a working definition of this potential clade that is open to criticism, testing, and revision, rather than constructed in the context of a presumed theory of hominid-ape and then hominid-subclade relationship, wherein primitive features dominate the description and homoplasy assumed demonstrable (Lovejoy et al. 2009a; Wood and Harrison 2011). In this regard, there is still much work to be done.

persistent debates – on the issue of environmental linkages to hominin adaptation. Current hypotheses which link physical change, adaptation, and speciation in general and in hominins in particular are discussed (including hypotheses on the role of ecological specialization and generalization, the coordinated stasis and variability selection hypotheses, habitat theory, and the turnover pulse hypothesis). Some persistent debates are revisited (such as on the current status of the savanna hypothesis and on whether or not there was mammalian species' turnover in the Turkana Basin during the Plio-Pleistocene). The relation of hominin evolution to the recent finding of several turnover pulses coincident with global cooling trends in the 10 Ma to recent record of all African larger mammals is considered. One example of hypotheses which address issues of environmental stimuli of ontogenetic evolution is the heterochrony pulse hypothesis: the generative properties shared among lineages can result not only in coherence of morphological changes but also in a strongly nonrandom timing of heterochrony events, as diverse lineages respond in parallel by similar kinds of heterochrony to the same environmental changes. The discussion includes cases in hominins and other mammals of evolutionary increase in body size by prolongation of growth and attendant "shuffling" of body proportions including relative increase in brain volume, namely, encephalization.

Introduction

It is a truism that environmental stimuli have influenced the evolution of hominins and all other life forms. The challenge is to understand the causal subcategories: what are the hypotheses and predictions that should be tested and what kinds of data can be used to best effect. This approach is based on three premises: (1) one needs to study not only the hominins but also their wider biotic and environmental contexts. (2) Given the aim of understanding hominin evolution, the theory of evolution should be accorded more prominence than has been the norm, and an expanded theoretical framework is needed. A focus on the dynamics that link the environment to selection and adaptation at the organismal level is insufficient. One also needs to consider the causal linkages from the environment to dynamics at lower and higher levels – from morphogenesis during organismal ontogeny to the macroevolutionary level of species turnover (speciation and extinction) – and investigate the separate and combined roles in the origins of new phenotypes and species. (3) The direct influence of physical environmental stimuli on evolution at each level deserves more intensive study than it has been accorded traditionally. For much of the century following Darwin (1859), the research disciplines of geology (including climatology) and paleobiology were conducted separately. Speculations abounded on how they might link, but analyses directly integrating data from both areas remained sparse. This changed over the past decades as more refined methods led to discovery of new patterns and causal principles in paleoclimatology (e.g., the astronomical climatic cycles, Hays et al. 1976) and in the fossil record (e.g., rigorous phylogenetic hypotheses, geochemical inference of past diet, etc.). Proposals that hominins, the beginning of bipedalism, and other important human adaptations occurred in the African savanna, in response to the new selection pressures in such more open environments, are often loosely grouped under the term "savanna hypothesis." The first such proposal is often attributed to Dart (1925) who wrote (pp. 198–199), for example, that in the ancestral forest,

> Nature was supplying with profligate and lavish hand an easy and sluggish solution....For the production of man a different apprenticeship was needed to sharpen the wits and quicken the higher manifestations of intellect – a more open veldt country where competition was keener between swiftness and stealth, and where adroitness of thinking and movement played a preponderant role in the preservation of the species.

Later notable examples include the dietary hypotheses of Robinson (1963) and Jolly (1970). In his insightful review, Potts (1998b:107) considered that "Washburn's [1960 and other publications] influence and interest in intrinsic accounts (as opposed to extrinsic accounts, which interpreted evolutionary events in relation to environmental change) may explain why many paleoanthropologists in the 1950s–1970s paid little attention to environmental context." Early papers proposing physical change as a direct cause of hominin evolution concerned particular stratigraphic sequences in East and southern Africa (respectively, Coppens 1975; Vrba 1974, 1975; both compared climatic indications from mammalian change with the hominin record), the circum-Mediterranean area (Hsu et al. 1977 implicated the Messinian Salinity Crisis in hominin origin), and comparison of global climatic data with the hominin record (Brain 1981a).

Darwin (1859) argued that the initiating causes of phenotypic change and speciation are located at the level of organisms, namely, natural selection, particularly arising from competition: ".... each new species is produced . . . by having some advantage over those with which it comes into competition . . ." (p. 320). He stressed climatic effects on competition rather than on population structure: "in so far as climate chiefly acts in reducing food, it brings on the most severe struggle between the individuals...." (p. 68). Darwin thought that an understanding of organismal selection and adaptation will also answer the question of species' origins. Most later evolutionary studies, including those in paleoanthropology, have continued in this tradition. (See Tattersall 1997a who argued that "paleoanthropology fell completely under the sway of the evolutionary views of the [neoDarwinian] Synthesis – where it remains, for the most part, today.") The questions which will be addressed, using theory and evidence, include how physical dynamics have influenced species' structure and speciation, organismal ontogenetic systems, and selection and adaptation. I also consider some of the interactions among these levels.

Hominini means the evolutionary group of species which are considered by most to be more closely related to humans than to chimpanzees. The term "species" is used for a sexually reproducing lineage, the members of which share a common fertilization system, and "speciation" for the divergence of the fertilization system in a daughter population to reproductive isolation from the parent species

(Paterson 1982), with awareness of the difficulties involved in applying such concepts to the fossil record (Kimbel 1991; Vrba 1995a). The terms "habitat," "specific habitat," and "habitat specificity" of an organism or species refer to the set of resources that are necessary for life; resources are any components of the environment that can be used by an organism in its metabolism and activities, including ranges of temperature, relative humidity and water availability, substrate characteristics, places for living and sheltering, and all kinds of organic foods such as plants and prey, mates, and other mutualist organisms in the same or different species (Vrba 1992). An organism's biotic environment derives from other organisms and biotic interactions such as competition, parasitism, predation, and mutualism. "Physical change" refers to the global and local effects from extraterrestrial sources, including the astronomical climatic cycles, and from dynamics in the earth's crust and deeper layers as manifested by topographic changes such as rifting, uplift, sea level change, and volcanism. The use of the term "savanna" follows Ratnam et al. (2011) and Cerling et al. (2011:53): "a modern ecological definition of the term savannah is comprehensive and includes structural, functional and evolutionary aspects, Ratnam et al. 2011. Because our focus is on reconstructing the physiognomic structure of palaeo-vegetation, we use a purely structural definition of savannah [quoting Ratnam et al. 2011]: "mixed tree-grass systems characterized by a discontinuous tree canopy in a conspicuous grass layer.""

Physical Change, Adaptation, and Speciation: Some Current Hypotheses

The traditional hypothesis follows Darwin closely and has often been called neoDarwinian. In its most conservative form, it assumes that adaptation and speciation are always driven by natural selection. The particular causes of selection are seen as very diverse, the most important being organismal interactions – such as competition and predation – that can act alone, or in combination with physical change, to initiate and complete speciation (and extinction). Under this null hypothesis, H_0, selection pressures that cause speciation, differs from group to group and from one local area to the next. To explore how this model's predictions differ from others, let us ask: what rhythm of speciation events would one expect if we could see all the events in the real world across the entire area under study (e.g., Africa) and if we plotted their frequencies against time? H_0 predicts that the pattern of origination frequencies for large areas, over long time, is a random walk in time with an averagely constant probability of origination. Examples of such arguments are found in Van Valen (1973), Hoffman (1989), McKee (1993), and Foley (1994). In contrast, a number of hypotheses share the argument that physical change has an important causal role in initiating the evolution of novel adaptations and species turnover, with the consequent prediction that such evolutionary events should be nonrandomly distributed in time and in association with episodes of physical change. Several such hypotheses will be discussed after introducing some relevant theory.

Allopatric Speciation

Allopatric speciation occurs in isolated populations that have been separated by vicariance or dispersal over barriers. (Vicariance is the fragmentation of a formerly continuous species' distribution into separated populations.) Gulick (1872), who studied the Hawaiian fauna, was the first to argue that the causes of speciation are not well explained by selection among competitors, but that vicariance brought about by physical changes was seminal in initiating speciation. Mayr's (1942, 1963) comprehensive arguments for allopatric speciation eventually resulted in widespread agreement that this mode predominates. Although there continue to appear claims of sympatric speciation, mainly in herbivorous insects and fishes, most recent such reports acknowledge that the best evidence remains circumstantial (review in Vrba 2005). It is fair to say that an expectation of predominant allopatric speciation, particularly in hominins and other large mammals, is consistent with the weight of available evidence and enjoys widespread consensus. In terms of earlier concepts of hominin phylogeny, which accepted a progression from the earliest biped to *Homo sapiens* with minimal branching from that lineage, one might wonder whether it is worthwhile to test causal hypotheses of hominin speciation, but recent finds indicate that "any accurate view of ourselves requires recognizing *Homo sapiens* as merely one more twig on a great branching bush of evolutionary experimentation" (Tattersall 1999:25, 2000). That is, we need to consider seriously the question of what caused lineage branching in the hominin tree.

Physical Change as the Driver of Vicariance, Selection, and Speciation

If allopatric speciation predominates, then so also must physical initiation of speciation predominate. Vicariance is nearly always produced by tectonic and climatic change. Incipient speciation initiated by dispersal over barriers also in most cases implies the causal influence of physical change (e.g., chance *Drosophila* fly dispersals over the ocean always occur, whether there are islands within reach or not; it took the production of the precursor islands of the Hawaiian Archipelago for the founding of those first allopatric populations of Hawaiian drosophilids, Carson et al. 1970). Thus, the chief causes of population size reduction and allopatry in the history of life have probably derived from physical changes. Although the relationship of punctuated equilibria to physical change was not explored in Eldredge and Gould (1972), the pattern they argued for implies independently that the initiation of speciation mostly comes about through physical change (Vrba 1980): if species are in equilibrium for most of their durations, what causal agency of the punctuation can one invoke other than physical change? The general consensus on the importance of allopatric speciation, together with the implications of punctuated equilibria and Paterson's (1978) "recognition concept" of species, led to the proposal that physical change is required for most speciation (Vrba 1980). Paterson (1978, 1982) argued that change in the fertilization system, the critical evolutionary change in sexual speciation, is most likely to occur in small, isolated populations that are under selection pressure from new environmental conditions.

Ecological Specialists and Generalists

This contrast is of general evolutionary interest (Stebbins 1950; Simpson 1953; Eldredge 1979; Vrba 1980, 1992) and particularly germane to mammalian evolution during the climatic instability of the late Neogene (Vrba 1987a). It has been discussed using various terminologies, such as stenotopy and eurytopy (e.g., Eldredge 1979), niche breadth (e.g., Futuyma 1979), and breadth of habitat specificity or resource use (Vrba 1987a). Specialist and generalist adaptation can be expressed in relation to different kinds of environmental variables, e.g., with respect to food intake, temperature, vegetation cover, light intensity, etc. Given the effects of the late Neogene climatic and tectonic changes in Africa (see sections "Physical Background: Climatic Change" and "Physical Background: Tectonism"), the distinction between species which are stenobiomic (restricted to a particular biome) and eurybiomic (ranging across biomes) is particularly relevant. As populations of a species encounter a new environment, beyond the ancestral biome range, they could in principle either diverge from their adaptation to the ancestral biome to become specialized on the new one or become more eurybiomic by broadening their resource use to include the new biome alongside the ancestral one (e.g., Vrba 1987a, 1989a). Evolution toward eurybiomy, which is very rare (e.g., Hernández Fernández and Vrba 2005 found a large preponderance of biome specialists in living African mammals), is of special interest as it applies to *Homo* (Vrba 1985a, 1989a; Pickford 1991; Potts 1998a; Wood and Strait 2003). Proposals that temporal and/or spatial environmental variability, namely, life in fluctuating or unpredictable environments, can promote generalist adaptations have a long history of extensive discussion (e.g., Stevens 1989 reviewed the evolution of broad climatic tolerance in high-latitude environments which have a greater range of annual and longer-term variation). Adaptations to strong seasonality range across life forms, from diatoms and other photosynthetic groups in polar waters (which each winter form resting spores in response to darkening and sink down dormant out of the plankton environment to germinate again when light returns, Kitchell et al. 1986) to the deciduous habit of many plants and hibernation and long-distance migration in animals. In advanced vertebrates, complex behaviors form an important category of such adaptations, ranging from the behavioral adjustments of animals to changing temperature and aridity (Maloyi 1972) to hominine culture.

The notion of a "biome generalist species" can be subdivided as follows. The eurybiomic phenotypes can be either (A) heritable, namely, genetically based and fixed, or (B) expressed as ecophenotypes, within a broad norm of reaction, in response to varying environments (Hall 2001; West-Eberhard 2003). Case (A) has two subcases. A1: Each organism can live in more than one biome, either because each organism has the needed biomic flexibility or because each organism is a specialist on resource patches which occur across biomes. An example of the latter is the aardvark, *Orycteropus afer*, which is stenophagous (it eats only ants and termites), a substrate specialist (it digs burrows in sandy or clay soil), and stenophotic (it is nocturnal). Yet *O. afer* is eurybiomic: its specialized “resource patches” range from semidesert to dense, moist woodland across Africa. A2: There are intraspecific differences in resource use among organisms and populations; i.e., polymorphism in resource use allows the species to respond to environmental fluctuations by shifting relative abundances of the variants. An example is the African buffalo (Sinclair 1977): *Syncerus caffer caffer* differs in phenotype and resource use from (and lives at higher latitudes and/or altitudes with more grassland present than) the smaller, plesiomorphic phenotype *S. c. nanus* (in warm, forested regions). This species appears to have “rolled with the punches” of large and frequent climatic changes since the late Pliocene mainly by changes in polymorphic frequencies. All generalist adaptations first evolve in populations, thus rendering the species polymorphic. Intraspecific adaptations and polymorphisms, which become more elaborate with repeated climatic shifting, are likely to be the most frequent responses to climatic extremes (see Vrba 1992: Fig. 4c) with speciation and extinction being rarer outcomes.

Habitat Theory and the Turnover-Pulse Hypothesis

The turnover-pulse hypothesis is a part of the broader “habitat theory” which focuses on species’ habitats and on the dynamic relationships between physical change, habitats, and species (Vrba 1985b, 1992). It uses the predominance of allopatric speciation and the consequence that physical change is required for most speciation. Climatic changes (from global or/and local tectonic sources) result in removal of resources from parts of the species’ former geographic distributions and therefore in vicariance. Vicariance on its own is insufficient for speciation. Many species underwent repeated episodes of geographic shifting, vicariance, and reunion of their distributions in response to the astronomical climatic oscillations, without speciation although intraspecific adaptive changes may have accumulated (Vrba 1992, 2005). For speciation to occur, physical change must be strong enough to produce population isolation, but not so severe as to result in extinction, and the isolated phase must be of sufficiently long duration for the changes which define speciation (divergence of the fertilization system) to occur. It has been suggested that most speciation requires sustained isolation or near isolation, without rapid reintegration on the Milankovitch timescale, and that shrinking populations are important in which habitat resources are dwindling and competition increases, with consequent strong selection from the changing environment (Vrba 1995b). In the absence of physical change of appropriate kind and duration, although species may accumulate new adaptations, they are buffered against speciation at several levels (review in Vrba 2005).

One prediction is that most lineage turnover, speciation and extinction, has occurred in pulses, varying from tiny to massive in scale, across disparate groups of organisms, and in predictable temporal association with changes in the physical environment (Vrba 1985b, 2005). If we think of origination, several possible patterns of origination frequency could result, all different from the temporally random pattern predicted under H_0: (1) origination could in principle be confined to rare, large pulses in response to the largest environmental changes. Such large pulses may resemble jagged mountain crests, or dissected high plateaus, rather than simple, single peaks because the timing of turnover responses to climatic or tectonic episodes will differ among organismal groups and local areas. (2) Many, frequent, small pulses, such as in response to the 100 Ka astronomical cycle, interspersed by the less frequent, larger ones described under (1). (3) Combinations of the random null model and the turnover-pulse hypothesis suggest additional predictions such as a random background of turnover frequency punctuated by rare pulses. A comparison among turnover pulses is expected to show much heterogeneity – or "mosaic" differences. The environmental changes that trigger turnover are diverse. They vary in nature, intensity, timing – how long they endure, how much fluctuation occurs, and steepness of component changes and net trends – and in geographic emphasis and extent, from very localized to present in many parts of the earth. Topographic and latitudinal factors contribute to geographic variation in the turnover responses to a major global change. Also, the different organismal groups differ sharply in how they are affected by climatic variables (see Andrews and O'Brien 2000 for mammals). They differ in response (by speciation, extinction, intraspecific evolution, or no response at all). Lineages which do undergo turnover initiated by a given physical change may do so with different timing (in "relays," see examples in Vrba 1995b, 1995c). Thus if a turnover pulse is detected in a data set, it is desirable to study subdivisions of those data to understand the detailed taxonomic, geographic, and temporal patterns.

Additional hypotheses: (1) Under habitat theory and other concepts which invoke predominant allopatric speciation, the species should generally "start small," namely, in geographic distributions that are more restricted than those they attain later on (Vrba and DeGusta 2004). H_0 does not predict this. (2) Of two areas of similar large size, both subject over the same time to climatic cyclic extremes that remain habitable for organisms; the area that is more diverse in topography will have higher incidences of selection pressures and vicariance per species. The prediction is that the topographically more diverse area has higher rates of vicariance, speciation, and extinction (Vrba 1992). (3) During periods of strong latitudinal thermal contrasts, with ice caps on one or both poles, biomes closest to the equator are predicted to have higher speciation and extinction rates than biomes at adjacent, higher latitudes (e.g., this bias may have contributed to the high species richness in the tropics today, Vrba 1985b, 1992.). (4) Biome generalists are expected to have lower rates of vicariance, speciation, and extinction than biome specialists (Vrba 1980, 1987a, 1992). Because habitat theory stresses physically initiated vicariance and selection pressure, changes in amplitude and mean of the climatic cycles, and in which cycle predominates, are expected to affect the evolutionary outcome. The larger the amplitude, the higher the incidence of vicariance and selection pressure at any cyclic extreme, accelerating the rates of intraspecific adaptation, speciation, and extinction. Changes in cyclic dominance can affect the frequency and duration of vicariance. Large translations in the climatic mean and envelope may be especially significant for speciation and extinction (Vrba 1995b: Figs. 3.2, 3.3).

The Coordinated Stasis Hypothesis

Brett and Baird's (1995) hypothesis of coordinated stasis is Darwinian in a focus on organismal interactions in a community as a source of stasis. It proposes that the coevolutionary bonds during stasis are so strong that physical change is needed to disrupt them to result in turnover. Thus this model is "community based" in its theoretical assumptions (see also the hypothesis of coevolutionary disequilibrium of Graham and Lundelius 1984 and reviews in Barnosky 2001; Vrba 2005). Brett and Baird's (1995) model predicts stasis of species, interrupted by pulses of speciation and extinction, across all communities in which a set of species occurs. Thus, their predictions are closely comparable with those of the turnover-pulse hypothesis, as acknowledged by Brett and Baird (1995:287): "The same term [coordinated stasis] could be used for the blocks of stability in Vrba's (1985b) 'stability-pulse' hypothesis."

The Variability Selection Hypothesis

This hypothesis was proposed and applied to hominin evolution by Potts (1998a, 1998b, 2012; pages quoted are from the 1998a paper unless otherwise noted). It is about (1) a particular category of adaptations which he calls "variability selection adaptations" (VSAs), (2) their initial appearance and establishment, (3) their fate in the face of long-term climatic cycles, and (4) an interpretation of the theoretical implications of their evolution:

1. VSAs are "structures and behaviors responsive to complex environmental change" (p. 81), which are uniform within species "yet able to mediate secondary phenotypic traits that vary. . ." (p. 85). His examples include a locomotor system allowing a wide repertoire of movement and "a large brain or specific neurological structure that is effective in processing external data and generating complex cognitive responses" (p. 85).
2. VSAs arise first in isolated populations. Intraspecific polymorphism results with VSAs in some populations and not in others. Organismal selection from short-term variability during organismal lifetimes initially promotes such VSAs (or at least allows them to persist).
3. The long-term evolutionary outcome at Milankovitch and longer timescales is that organisms with VSAs survive climatic extremes. Therefore species, which include at least one VSA-carrying population, survive. Over time the VSAs can become more elaborate as climatic extremes recur. Thus, high climatic amplitude at timescales longer than organismal life times, notably at Milankovitch and longer timescales, causally influences the evolutionary outcome.

4. Climatic variability at the longer timescales is a selective agent of VSAs, which are "designed [by selection] to respond to novel and unpredictable adaptive settings" (p. 85). That is, these organismal adaptations are shaped by selection for the function of flexible responses to future climatic excursions of the Milankovitch cycles, and this is a new kind of selection: "variability selection" (VS).

Potts regards his concept as distinct from previous concepts, notably from the (p. 82) "savanna hypothesis" and other "environmental hypotheses of hominin evolution [which focused] on a specific type of habitat." Proposals (1), (2), and (3) are severally and jointly consistent with previous theoretical proposals (see section "Ecological Specialists and Generalists"). The sole departure is proposal (4) of a distinct type of selection, which is commented on next.

The special effects which the high amplitude of climatic cycles since the late Pliocene had on the biota (e.g., that species, in which generalist adaptations for climatic tolerance evolved, survived disproportionately) has been much discussed (e.g., Stanley 1985; Vrba 1985a, 1992, 2000). No one doubts that strong Milankovitch excursions can selectively remove some populations and species whose organisms are unfit under those conditions, nor that generalist adaptations of survivors can sequentially be elaborated during recurrent such episodes. But this would not be a new kind of selection. *Organismal selection* cannot promote adaptations to future Milankovitch extremes, although *inter-demic selection* (Wright 1932, 1967) or *species selection* (review in Vrba 1989b) could in principle occur at those longer timescales. (In fact, Potts did at one stage wonder whether his notion might represent a form of lineage or species selection, R. Potts pers. comm.). The problem is that the concept of selection and adaptation at levels higher than that of organisms is onerous (Williams 1966; Maynard Smith 1987; Vrba and Gould 1986; Vrba 1989b). Maynard Smith (1987) discussed this as follows (p. 121): "We are asking whether there are entities other than [organisms] with the properties of multiplication, heredity, and variation, and that therefore evolve adaptations by natural selection." Considering the nature of the adaptations Potts (1998a) had in mind, one probably does not need to invoke higher level selection. Such issues on levels of selection have been extensively debated and with respect to diverse organismal case histories. An example which is of interest here, in spite of (and perhaps because of) being far removed from hominins on the tree of life, is the case in diatoms of the resting stage adaptation to polar conditions of long winter darkness (Kitchell et al. 1986): The fossil record shows that diatoms living in Arctic waters just before the Cretaceous/Tertiary (K/T) boundary already had this life cycle adaptation. Kitchell et al. (1986) documented that during the K/T mass extinction (which involved long-term global darkening), diatoms and other photosynthetic planktonic groups with resting stages had markedly lower extinction rates than groups which lacked this seasonal adaptation. They argued (correctly in my view) that these life history features, which arose by selection at the organismal level as adaptations to seasonal variability, were also fortuitously (by sheer luck) available and useful during the K/T event for weathering much longer intervals of darkness. They concluded that this sorting among species, although nonrandom, does not represent species selection but species sorting according to the effect hypothesis (Vrba 1980). The adaptation is this case could not have been selected at the organismal level for climatic variability at the timescale of mass extinction. The selective forces and character complexes which contributed to the survival of hominins and other mammals in the face of increasing climatic amplitude during the late Neogene may in principle fall into the same category.

Additional Comments on Environmental Hypotheses of Hominin Evolution

In the current spirited and exciting debate on the various hypotheses (savanna, variability selection, turnover pulse, habitat theory, and more), some confusion has crept in, which is affecting the debate in a negative way to the point where sometimes the discussants are talking past each other. While Potts (2012:154) wrote that "Regarding the external drivers of human evolution, the primary alternative to Vrba's TPH [turnover pulse hypothesis] has been the variability selection hypothesis," the points raised here are relevant to all the hypotheses and all parts of the debate. Three such issues will be mentioned here.

1. **Specific Habitats, Species-Specific Habitats, and Other Specific Notions.** Consider these quotations: "The VS [variability selection] hypothesis differs from prior views of hominin evolution, which stress the consistent selective effects associated with specific habitats or directional trends (e.g., woodland, savanna expansion, cooling)" Potts (1998a:81). "Habitat-specific adaptations may entail a more limited responsiveness to environmental perturbation..." (Potts 1998a:155). "Over the past three decades, the environmental study of human evolution has been dominated by the search for the preferred [i.e., specific] habitat of each hominin species. This approach has led to a far more static concept of early hominin adaptation..." (Potts 1998a:161). This pits "consistent selective effects," "specific habitats" and "habitat-specific adaptations" of "limited responsiveness," and directional climatic trends (the not-so-good "static concept") against variable selective effects, variable habitats, and "variability selection adaptations" and pervasive climatic oscillations and environmental complexity (the good, dynamic concept). But is this a substantive dichotomy with correct characterization of both sides? It is not, and one "culprit" is the interpretation of the word "specific."

   In the present context, "specific" simply means "relating to, characterizing, or distinguishing a species," thus neutral on breadth and changeability of adaptation, habitat, or environment in this case. The definition of the specific habitat of a species (see third paragraph in introduction of this review, which describes how many including the present author have used it) is indeed neutral on degree of variability, referring only to a list of resources and their ranges which describes where and how the species can live. In principle, the resource ranges of the specific habitat can be extremely broad. Consider an extreme and hypothetical example of a land species which can live everywhere within a temperature range of 0–100 °C. Its specific habitat with respect to temperature is the range 0–100 °C. A related point: the notion that each species is "specific for a particular *habitat*" does not equate with specificity for a particular – or single – type of *environment*. For example, the aardvark, while a specialist in terms of food and substrate, ranges widely across Africa from semidesert to dense, moist woodland. A species' habitat may remain intact although it lives in strongly fluctuating environments over long time, such as the aardvark whose habitat and resources persisted as widely varying environments swept over the areas in which it lived. In other cases, habitat variability – such as variable use of food and substrate – is an integral part of the habitat specificity of the species (see 2).

Unfortunately, such simple misunderstandings can spread and eventually harden. For example, deMenocal (2004:4) stated that "most environmental hypotheses of African faunal evolution are 'habitat-specific' (Potts 1998b) in that they consider faunal adaptations to a specific environment, most commonly the emergence of grassland savannah…"

2. **Adaptation to Variability.** Potts (1998a, 1998b, 2012) regards the VSA (variability selection adaptation) concept as distinct from previous concepts of adaptation, such as the generalist adaptations which confer eurytopy (Eldredge 1979), broad habitat specificity (Vrba 1987a), and broad climatic tolerance (Stevens 1989). He considers "habitat-specific" adaptations (e.g., Vrba 1987a) and selection pressures as different from VSAs and VS because the former in his view narrowly refer to a particular kind of environment and not to variable environments. He is wrong in these claims.

   Structures and behaviors that confer flexibility in the face of – and are usually ecophenotypic or genetically based adaptations to – climatic variations, and that may arise and exist as polymorphic variants in species, are well known (e.g., the resting/vegetative life cycle in diatoms noted above, hibernation, etc.) including complex behaviors in primates (e.g., the presence in some Japanese macaque populations of grass-washing behavior, Nakamishi et al. 1998). Concerning human evolution, as reviewed below, many have written about adaptation to variability (including environmental heterogeneity at any one time) and the effects of climatic cycles. As Potts (2012:154) considers habitat theory and the VS hypothesis as "primary alternatives," any impression that previous discussions of human evolution in the light of habitat theory (e.g., Vrba 1985a, 1989a) have ignored hominin adaptation to climatic variability needs to be corrected. One hypothesis (Vrba 1989a:30) concerns culture in general:

   > *The culture of the genus* Homo *is a generalist adaptation.* Hominine culture is an extension of the common phenomenon in other animals that use behaviour to cope with climatic conditions. … a special case among animal behaviors that confers an expanded use of environmental resources. In contrast, robust australopithecines were more specialized on open, arid habitats. . . .[and in *Homo* occurred] a switch to the crucial generalist adaptations of brain and culture that have made us the least environment-dependent species on earth today.

It turns out that Vrba's (1989a) hypothesis that the robust australopithecines "were more specialized on open, arid habitats" is probably wrong (see review below). However, it now seems likely that the masticatory features of *Paranthropus*, while adaptations for consuming tough or gritty foods, had the effect of broadening, not narrowing, the range of food items consumed and allowed these forms to subsist in varied environments (Wood and Strait 2003).

One hypothesis on hominin adaptation to climatic variability, which is plausible and deserving of testing, is that humans descend from deep nomadic (migratory) ancestry, at least since the onset of advanced bipedalism in *Homo* ca. 1.6 Ma, which falls during a time of change to more open and seasonally arid landscapes:

> As Baker (1978) observed, most animals are 'migratory' to some extent. But it is undeniable that those living in open, arid habitats, where resources tend to be patchy in space and/or time, invariably have a greater tendency to seasonal and more extensive movement... Did one or both of the hominin lineages that diverged during the Pliocene migrate seasonally across ecotonal margins? (Vrba 1985a:70).

If evidence of hominid nomadism in the Early Pleistocene were to be found (as it might be, for instance, by isotopic analysis of diet in conspecific hominins), one would still need to ask whether that nomadic potential was there previously or whether it evolved de novo by genetically based broadening of the norm of reaction to allow both nonmigratory and migratory behavior depending on seasonality. If the latter is true, then migratory behavior by *Homo* could surely be termed a good habitat-specific adaptation and a good variability selection adaptation. The use of different wording does not change the logic of that.

3. **Climatic Variability.** Potts (1998a, 1998b, 2012) concluded that others with versions of the savanna hypothesis that were articulated previous to his VS hypothesis, which includes me, were focusing narrowly on long-term cooling trends and failed to incorporate observations about patterns of African paleoclimatic variability from deep-sea cores and recently also from coring on the African continent (Scholz et al. 2007; Cohen et al. 2007; reviewed below). Again, the issue must be taken with this. First of all, the focus on long-term trends (e.g., Vrba 1995b) is a necessary part of the study of climatic variability in mammalian evolution: the shorter-period Milankovitch cycles modulate each other which gives rise to cycles of longer periods (and therefore to long-term cooling and warming trends) which are associated with ice sheet expansion and cooling and turn out to be important triggers of mammalian speciation and extinction (e.g., cycles with periods of ca. 1 Ma and ca. 2.4–2.5 Ma; see van Dam et al. 2006). More generally, it was the realization of the potentially enormous implications of the climatic oscillations for evolution of new form, function, and species in hominins and other mammals – of the fact that the "species specific for these . . . biomes are riding along on their 'habitat plates', that drift back and forth rapidly . . . over the tectonic plates that drift more slowly beneath" (Vrba 1992:11) – that prompted the organization of an interdisciplinary conference to explore those implications (Vrba et al. 1995). It was argued then

(Vrba 1995a:33) that "if prolonged vicariance is important for turnover and especially for speciation, then major shifts in the *mode*, or periodicity pattern, of the astronomical cycles should be examined for associated turnover" (see also Vrba 1992), and a model was illustrated (Vrba 1995a:30–33), using Shackleton's (1995: Fig. 17.3) data which records delta^{18}O variation at 0.003 Ma interval steps for the past 6 Ma, for measuring climatic variability. Because this way of measuring climatic variability monitors the outer envelope of climate curves step by small step, it is expected to detect major changes in climatic mode such as documented by deMenocal and Bloemendal (1995): a shift from dominant climatic influence occurring at 23–19 Ka periodicity prior to ca. 2.8 Ma to one at 41 Ka variance thereafter, with further increases in 100 Ka variance after 0.9 Ma (see also Ruddiman and Raymo 1988). (Some results will be compared in section "Physical Background: Climatic Change" with those of others who have measured variability in climatic curves, including Potts 1998a.)

In sum, how do the turnover-pulse hypothesis (within in more general habitat theory which includes responses to climatic variability of generalists and specialists) and the variability hypothesis compare in terms of content? Readers will make up their own minds. My conclusion is that they do not differ substantively in terms of the basic processes implied. There are differences in emphasis, in terms used, and in how the terms they have in common are interpreted (particularly the term "specific habitat" of species).

Is the early savanna hypothesis still alive and well? Yes, the basic hypothesis – that climatic change has caused reductions in wood: grass cover proportions which affected hominin populations and evolution – remains a good one, although it has evolved and branched out into more sophisticated versions. Cerling et al. (2011) showed that the fraction of woody cover in tropical ecosystems can be quantified using stable carbon isotopes in soils and applied the method to fossil soils from hominin sites in the Awash and Omo-Turkana basins. They concluded (p. 55) that "the combined results from two of the most significant hominid-bearing regions in eastern Africa leave the savanna hypothesis as a viable scenario for explaining the context of earliest bipedalism, as well as potentially later evolutionary innovations within the hominin clade."

Tests Based on the Temporal Distribution of Newly Appearing Phenotypes and Species

The models above all predict significant concentration in time of particular newly appearing morphologies and in the case of the coordinated stasis and turnover-pulse hypotheses also of speciation and extinction events. All of them predict that such events in the fossil record should associate significantly with climatic change. Most difficulties in testing such hypotheses have to do with errors in the chronological, physical, and biotic data and with testing at inappropriate temporal, geographic, and taxonomic scales (Barnosky 2001). There are two types of errors in such tests:

inferring fossil events that are not there (i.e., erroneous rejection of H_0, Type I error) and failure to detect real events (Type II error) as exemplified by Signor and Lipps (1982). Take, for example, a Type II error under the turnover-pulse or coordinated stasis hypotheses, the attempt to distinguish between H_0, and real small speciation pulses that occurred at the Milankovitch timescale. Such a test using first appearance data with lower time resolution (e.g., the data for 0.5 Ma-long intervals length in Vrba and DeGusta's 2004 study of African mammals) will fail, although major pulses might be detectable. The main bias that leads to Type I error, seeing pulses that are not there, arises from unequal fossil preservation between time intervals, areas, and groups of organisms, the "gap bias" (Vrba 2005): any given species' fossil FAD (first appearance datum) may postdate its true, or cladistic, FAD (Kimbel 1995). Gaps have the effect that, for instance, a count of FADs in an interval is erroneously inflated by FADs of species which in reality originated (but were not detected) previously. An early version of a test that corrects for the "gap bias," thus allowing a rigorous test of the pulse hypothesis, was applied to the African larger mammals of the past 20 Ma divided into 1 Ma-long intervals (Vrba 2000). More recently, a second, updated form was applied to the nearly 500 African species recorded over the past 10 Ma divided into 0.5 Ma-long intervals (Vrba and DeGusta 2004; Vrba 2005). Time resolution in this record is sufficiently good, with more than 70 % of the site records dated by radiometric or paleomagnetic means, that any large speciation (or extinction) pulses spaced sufficiently far apart in time should be detectable. Some results will be mentioned in section "The Record of First Appearances of Mammalian Species."

Physical Change, Adaptation, Speciation: Evidence from the African Neogene

Physical Background: Climatic Change

Following the definitive documentation of the astronomical cycles (Hays et al. 1976), it was thought that they may have had little effect on the tropics in general (review in Burckle 1995) and on African hominin-associated environments in particular. For example, Hill (1995:187) considered that "it may be that African terrestrial vertebrate habitats were to some extent buffered from climatic changes seen elsewhere." Hill's caution is well taken that specific areas may "march to a local drummer" especially if that drumbeat derives from tectogenesis (see below). It now appears that much of Africa participated in global as well as more localized climatic changes over the time period of interest, namely, the late Miocene-Recent record, as the earliest hominin fossils currently date to ca.7 Ma ago (Brunet et al. 2004). For much of this time Africa has been influenced by two separate processes (deMenocal 2011): forcing from the orbital precession cycle has brought about monsoonal cycles that alternated between wet and dry conditions, and superimposed on these was a long-term trend toward increasingly more arid and more variable conditions.

The Late Miocene. Changes in polar ice volume and sea level have greatly influenced African climate and human evolution as cited variously below. By the time hominins evolved, there had been large ice sheets in Antarctica since 33 Ma (following a previous time of ephemeral ice sheets), while the earliest extensive Arctic glaciation was established much later, by 2.7 Ma and contemporaneously with the first appearance of *Paranthropus*, the robust australopithecines, and probably also of the lineage to modern humans. Miller et al. (2005) discussed the relations of ice sheets, global climate, and sea level and considered that sea level mirrors oxygen isotope variations, reflecting ice-volume change and thus global climate on the 10,000 year–1,000,000 year timescale which applies to human evolution. They found prominent sea level falls and thus global climatic events, at 8.2 Ma, 5.7 Ma, 4.9 Ma, 4.0 Ma, 3.3 Ma, and 2.5 Ma. There was ice buildup on West Antarctica and general increase in delta^{18}O values 7.0–5.0 Ma ago (Kennett 1995). A major cooling which started before 6 Ma and peaked shortly thereafter contributed to isolation and desiccation of the Mediterranean Basin during the Messinian low-sea level event and salinity crisis dated ca. 5.8–5.3 Ma (Haq et al. 1980; Hodell et al. 1994; Bernor and Lipscomb 1995; Aifa et al. 2003; Garcia et al. 2004). This major cooling coincides with a strong vegetation change ca. 6.3–6 Ma, with a large decrease in tree cover and increased aridity in both West and East Africa, according to Bonnefille's (2010) overview of macrobotanical (fossil wood, leaves, and fruits) and microbotanical (mainly pollen) evidence for the past 10 Ma in tropical Africa with special reference to the hominin sites. After the Messinian followed warming and a transgressive phase started before 5 Ma and reached a maximum in the 5–4 Ma interval, according to Haq et al. (1987).

Questions remain on the African effects of these late Miocene climatic events. Kingston et al. (1994) found that, in the Kenyan Tugen Hills area, a heterogeneous environment with a mix of C_3 and C_4 plants – and without grassland dominance – persisted over the entire past 15 Ma without any apparent local influence from global climatic change. Yet evidence from Lothagam indicates that this part of Kenya experienced strong environmental changes over the latest Miocene (Leakey et al. 1996; Leakey and Harris 2003). Further evidence comes from analyses of carbon isotope ratios in soils and fossil tooth enamel. Cerling et al. (1997) studied fossil herbivores ranging over the past 22 Ma from several continents. Using the fact that low delta^{13}C values in herbivore teeth reflect a diet of mainly C_3 plants, while high values indicate feeding on C_4 plants, they found that up to 8 Ma ago, mammals in Pakistan, Africa, and South and North America had C_3 diets or C_3-dominated diets. By the late to latest Miocene, C_4 plants came to dominate the diets. In Kenya, representing the lowest latitude in the sample, the transition was complete by between 8 and 6.5 Ma and in Pakistan by ca. 5 Ma. Cerling et al. (1997) interpreted their results as showing a global increase in the biomass of C_4 plants 8–6 Ma ago which resulted from a decrease in atmospheric CO_2.

The Plio-Pleistocene. Interest in African hominin-associated climatic changes has burgeoned greatly over the past decade. Here, only a few examples are given from the large volume of evidence for the Plio-Pleistocene, from research on broader regional climatic variability, to illustrate some of the basic lines of enquiry and the diversity of approaches. Additional evidence more directly focused on hominin environments will follow below. Clemens et al. (1996) discussed how monsoon variability and evolution respond to external forcing (orbitally driven changes in solar radiation) and internal forcing (interaction among the atmosphere, oceans, land surface, and ice sheets). They examined a deep-sea sediment record spanning the past 3.5 Ma from the northwest Arabian Sea and compared diverse proxies, including abundances of *Globigerina bulloides*, biogenic opal content which indicates radiolaria and diatom production, and lithogenic grain size of the deep-sea sediments, all of which in this area can indicate the strength of the Asian monsoon. Clemens et al. (1996) argued that the growth of Northern Hemisphere ice sheets over the past 3.5 Ma weakened the Asian summer monsoon and increased the aridity of subtropical Asia and eastern Africa. They demonstrated that the phase relationships between the African monsoon and the glacial cycles were shifting continuously over the past 2.6 Ma, explaining why indicators of surface water such as lake levels and of vegetation, such as dust spikes, often do not covary. The authors found significant shifts in the intensity and phase of the Indian monsoon at ca. 2.6 Ma, 1.7 Ma, 1.2 Ma, and 0.6 Ma. deMenocal (2008, 2011:541) discussed the large amplitude of the African wet-dry monsoon cycles using the example of changes in the Sahara and pointed out the usefulness of sapropel layers as proxies (see also Rossignol-Strick 1985; Rossignol-Strick et al. 1998) for detecting the intensity and phase of the monsoon cycles:

> From 15,000 to 5,000 years ago, the modern Saharan Desert was nearly completely vegetated, with large, permanent lakes and abundant fauna. Precessional increases in summer radiation invigorated the monsoon, delivering more rainfall deeper into Africa, and enhanced Nile river runoff flooded into the eastern Mediterranean Sea. The resulting freshwater stratification created anoxic conditions and led to deposition of organic-rich sediments (sapropels) on the seafloor.

Similarly, Cole et al. (2009, 2012) found evidence for the prevalence of extensive paleolakes in the Sahara during the African humid period.

The opposite extreme, “megadrought,” has also been documented. In companion papers, Scholz et al. (2007) and Cohen et al. (2007) presented results from drill cores from Lake Malawi and point out that by 2007, these were the first long and continuous, high-fidelity records of tropical climate change from the African continent itself. Their record documents periods of severe aridity between 135 Ka and 75 Ka ago, when the lake’s water volume was reduced by at least 95 %. Scholz et al. (2007:16416) wrote, “Surprisingly, these intervals of pronounced tropical African aridity in the early late-Pleistocene were much more severe than the Last Glacial Maximum, the period previously recognized as one of the most arid of the Quaternary.” According to Cohen et al. (2007:16422), “Fossil and sedimentological data show that Lake Malawi itself, currently 706 m deep, was reduced to a ca. 125 m deep saline, alkaline, well mixed lake.”

Among Plio-Pleistocene records that demonstrate the large effects of global climatic change on Africa, many are based on signatures from plants, algae, or other indicators of overall plant cover such as dust. Pollen cores off West Africa record the shifting of the Sahara-Sahel boundary and the earliest extensive spread of the Sahara desert ca. 2.8–2.7 Ma ago (Dupont and Leroy 1995). One of the two strongest vegetation changes found by Bonnefille (2010) across tropical Africa over the past 10 Ma occurred at 2.7 Ma (p. 391): "abrupt decline of forest pollen accompanied by an increase in grass pollen was found at 2.7 Ma, . . . accompanied by a significant increase in C-4 grass proportions, well indicated in the Turkana region and likely explained by an increase in dry season length." Marlow et al. (2000) used an index based on the ratio of two types of alkenones (chemical compounds produced by specific species of haptophyte algae) to measure sea surface temperature (SST) in a marine core off Namibia. They presented their continuous time series of changing SST for the past 4.5 Ma, as well as estimates of paleoproductivity from the mass accumulation rates of organic carbon, diatom abundances, and diatom assemblages. Marlow et al. (2000) interpreted decreased upwelling to represent warmer conditions with wetter, more mesic periods in southern Africa and concluded that SSTs decreased markedly, in association with intensified Benguela upwelling, after 3.2 Ma, with subsequent periods of marked SST decrease and upwelling intensification near 2.0 Ma and 0.6 Ma. Another marine record from southwestern Africa, off Angola, derived from carbon isotope analyses of wind-transported terrigenous plant waxes, indicated African C_4 plant abundances 1.2–0.45 Ma (Schefuss et al. 2003). The evidence showed that the African vegetation changes are linked to SST in the tropical Atlantic Ocean and that changes in atmospheric moisture content due to tropical SST changes and the strength of the African monsoon controlled African aridity and vegetation changes. Marine records off West Africa and from the Gulf of Aden have documented delta^{18}O variations and also dust influxes from the Sahara and Sahel regions in the West and from Arabian and northeastern African areas in the Gulf of Aden (deMenocal and Bloemendal 1995; deMenocal 2004). The latter paper reported steplike shifts in the amplitude and period of eolian variability at 2.8 (±0.2) Ma, 1.7 (±0.1) Ma, and 1.0 (±0.2) Ma.

As one method to use climatic records to predict over which time intervals vicariance (population fragmentation) should be particularly concentrated, the following hypothesis was introduced with discussion on how to test it: "*long-term, continuous vicariance*, and long-term increases and decreases in the minimum- and maximum-value envelopes of the astronomical climatic cycles, are the kinds of allopatry and climatic change that are particularly important for speciation" (Vrba 1995b:27 and following pages). Shackleton's (1995: Fig. 17.3) data were used, which record delta^{18}O variation at 0.003 Ma interval steps for the past 6 Ma, to identify periods over which the largest net cooling or warming trends occurred. (Vrba 2004: take an interval t_x of length x Ka, for example, t_{100} for $x = 100$ Ka, and move it step by step along the time axis from early to late. At each interval step, mark the interval along the time axis if either of conditions C, for cooling, or W, for warming, is true. C: the upper [warm] envelope of the climatic curve remained continuously below the running mean of the previous 300 Ka, i.e., the interval is a $t_{100,C}$, or an interval of length 100 Ka with marked cooling. W is the corresponding condition for a warming trend. A pattern of $t_{100,C}$ and $t_{100,W}$ distribution in time results, with data clusters for the most sustained trends. I here report results for separate assessments using interval lengths in Ka of x = 40, 65, 100, and 140.) The following approximate intervals (in chronological sequence) emerged as times of sustained net cooling ($t_{40,C}$, $t_{65,C}$, $t_{100,C}$, and $t_{140,C}$ are respectively labelled as *, **, ***, and ****, from least to most severe; time ranges in ca. Ma): 6–5.7****, 5.1–4.9*, 4.2–3.9*, 3.4–3.2***, 2.9–2.3 especially 2.7–2.5****, 2.1–2.0*, 1.8–1.65**, 0.95–0.85**, and 0.8–0.65** (and 0.8–0.6*). Intervals of net warming (similar notation as for cooling): 5.6–5.35****, 4.5–4.4*, 3.1–2.9*, 1.65–1.6*, and 0.85*. Because this method of measuring changes in climatic variability, in this case in delta^{18}O variability, monitors the outer envelope step by small step, it is expected to detect major changes in climatic mode such as documented by deMenocal and Bloemendal (1995): a shift from dominant climatic influence occurring at 23–19 Ka periodicity prior to ca. 2.8 Ma to one at 41 Ka variance thereafter, with further increases in 100 Ka variance after 0.9 Ma (see also Ruddiman and Raymo 1988). Comparison with the results in the previous paragraph shows that this way of measuring change does succeed in detecting the major dominance shifts. There are now several such approaches. For example, Potts (1998a) subtracted the lowest from highest value for each unit million year as a measure of total climatic variability for that unit year. He found that variation of 0.3–0.5 parts per million (ppm) is obtained for most of the Neogene until the 6.0–5.0 Ma interval, during which variability rose sharply. After a minor decrease during 5 to 4 Ma, there were increases during every succeeding interval with the highest one, to 1.9 ppm, during the past 1 Ma (Potts 1998a:83, Fig. 1). Donges et al. (2011) applied a nonlinear method of time series analysis, recurrence network, to records of dust flux. They found (p. 20422) three “transitions between qualitatively different types of environmental variability in North and East Africa during the (i) Middle Pliocene (3.35–3.15 Ma B. P.), (ii) Early Pleistocene (2.25–1.6 Ma B. P.), and (iii) Middle Pleistocene (1.1–0.7 Ma B. P.),” which approximately also appear among my results, as does the mode change 6.0–5.0 Ma ago found by Potts (1998a).

It is worth noting the major climatic changes, including some with rough consensus on when they occurred, from the diverse sources cited above: 8.2 Ma, 7–6 Ma, and associated with the Messinian ca. 5.8–5.3 Ma, ca. 5 Ma, 4.2–3.9 Ma, 3.5–3.2 Ma, 2.9–2.3 Ma, 1.8–1.6 Ma, 1.2 Ma, and 1.0–0.6 Ma.

Physical Background: Tectonism

Tectogenesis has featured less prominently than climate change in discussions of evolution, perhaps because it is mostly a slow process and the date limits for events tend to be wide. Yet it has had a primary influence on landscape and biotic evolution. This includes hominin evolution especially in rift-associated environments as recognized long ago by Coppens (1988–1989). Crustal changes influenced climate on a grand scale, e.g., the late Pliocene closure of the Isthmus of Panama may have led to the start of the modern ice age (Maier-Reimer et al. 1990; Haug et al. 2001). The uplift of western North America, the Himalayas, and the Tibetan

Plateau possibly influenced the Pleistocene cooling intensification ca. 1 Ma ago (Ruddiman et al. 1986). Northward drift of Africa during the Neogene led to southward displacement and areal decrease of tropical African forests and contributed to long-term aridification (Brown 1995). Episodes of intensified African uplift since ca. 30 Ma ago, which raised the entire eastern surface higher than in the West, greatly affected the African climate (Burke 1996). Apart from the numerous localized climatic effects of tectogenesis (e.g., Feibel 1997), the *topographic diversity* it generates *together with the superimposed climatic cycles* constitutes a prime cause of spatial and temporal environmental heterogeneity, changing selection pressures, and speciation (Vrba 1992). Thus evolution of the African Rift had an especial role in some evolutionary events in hominins (Coppens 1988–1989) and other mammals (e.g., Denys et al. 1987). The present episode of rifting began in the Early Miocene (Frostick et al. 1986). Ca. 8–6 Ma ago, a general increase in African tectonic activity led to formation of the Western Rift (Ebinger 1989). A major episode of uplift coincided with the climatic changes ca. 2.5 Ma ago (Partridge and Maud 1987). After 6 Ma ago, the rift system continued to propagate to the southwest toward the Kalahari Craton (Summerfield 1996). One incipient zone of rifting, trending southwest from Lake Tanganyika, terminates in central Botswana, where faulting and tilting of the zonal margins have resulted in damming of the Okavango River to spread out as the extensive inland Okavango Delta (Scholz et al. 1976).

I suggest that the dynamics of the hydrological features associated with rifting – rivers redirected, lakes forming and disappearing, and especially the inland deltas spreading at the margins of incipient rift zones – have had a particular impact on the evolution of hominins and other biota. All early hominins required permanent water, and many of the eastern African hominin sequences reflect riverine and rift margin associated deltaic and lake environments (e.g., Harris et al. 1988; Brown and Feibel 1991). The significance of inland deltas is that they can form vicariated "islands" of mesic conditions – or refugia – throughout periods of aridification and even in the absence of topographic heterogeneity. The edges of such a refugium are ecologically heterogeneous with intrusions of the arid surrounding environment. ("Refugium" here means a biome refugium, e.g., a forest refugium preserves the characteristic forest vegetation physiognomy, although its detailed taxonomic composition may differ from that of the parent forest community.) The Okavango Delta provides a good example: it is a vicariant island – despite the very low relief of the area (Scholz et al. 1976) – of woodland savanna and water almost entirely surrounded by semidesert. Many of the hominin-bearing strata represent times when the areas were such inland deltaic-riverine-lacustrine refugia (Vrba 1988). This poses problems for our ability to recognize times of widespread climatic change across the larger areas because "climatic change in the larger region is recorded in a refugium only close to its ecotonal limits, by the new appearances (or disappearances) of peripheral taxa . . . that represent occasional intrusive elements from the alternative biome" (p. 410). An important implication from the evolutionary perspective is this: as climatic changes were sweeping across much of Africa at the Milankovitch scale, such inland deltas were recurrently isolated and reconnected as parts of larger continuous biomes. During the reconnected phases, migration and gene flow occurred. During the vicariant phases, there was enhanced incidence of gene pool divergence among populations, selection pressures at the refugial margins, intraspecific phenotypic diversification, and speciation. If it is true that inland deltas can in this way act as centers of phenotypic diversity and speciation and that they are particularly prevalent at the tilting margins of incipient rift zones, this would predict a late Neogene propagation of centers of increased speciation in a South-southwesterly direction as the rift evolved.

The Record of First Appearances of Mammalian Species

All Larger Mammals. As noted above, a method which corrects for the "gap bias" was applied to the African larger mammal record of the past 10 Ma. Such correction is especially important in the late Neogene climatic context because open, mesic to arid areas tend to preserve vertebrate fossils better than do the more forested, wetter ones (Hare 1980). The following results emerged (largely agreeing with those in Vrba 1995c, 2000, in so far as they are comparable): over the past 8 Ma, the strongest turnover pulses, involving both origination and extinction, occurred in the 5.5–5.0 Ma and 3.0–2.5 Ma intervals. (The dating of the earlier pulse is tentative as there are no physical dates, and this event may belong to the 6.0–5.5 Ma interval; I will refer to the 5.5 Ma event.) Each of the intervals 7–6.5 Ma and 3.5–3.0 Ma had an origination pulse without an extinction pulse and 1.0–0.5 Ma ago an extinction pulse without an origination pulse. Where one can compare this set of turnover events with the strongest cooling trends, the coincidence in time and intensity is strikingly close: the strongest climatic event, cooling toward ~2.5 Ma ago, coincides with the strongest turnover pulse, while lesser cooling and turnover events are present in the intervals 3.5–3.0 Ma and 1.0–0.5 Ma. The results also showed intervals of significantly low origination and extinction, some of which overlapped with periods of high sea level with low polar ice on a warmer earth (Haq et al. 1987; Hodell and Warnke 1991).

The African mammalian record and the bias-correction model which was used continue to be updated. The results do give preliminary support to the hypothesis that at least a substantial part of turnover in African mammals was initiated by climatic change and that global cooling with increased aridity and increased seasonality was a more important stimulus of turnover than was global warming (Vrba 2000, 2005). Of the cooling trends, the one toward 2.5 Ma was the strongest, followed by a lesser trend starting ca. 1 Ma ago. Yet individual glacial maxima became colder after 2.5 Ma, especially after 1 Ma (Shackleton 1995). The fact that there were no further major origination pulses after 2.5 Ma suggests that most of the lineages present then were either species that had evolved during the start of the modern ice age with adaptations to the new environments or long-lasting biome generalists that survived right through that cooling trend.

A related result is that of Vrba and DeGusta (2004). We studied the question of whether most species "start small," namely, in geographic distributions that are more restricted than those they attain later on. We used the same 10 Ma-long record of the African larger mammals and the correction for the "gap bias." The number of fossil site records from which each species is known in an interval was taken as a proxy for the magnitude of its living geographic range and abundance in that interval. We then tested H_0 that the geographic spread of species remained averagely constant across successive survivorship categories, namely, from the first appearance (FAD) interval to the immediately following one, and so on. We found that the mean number of site records increased strongly from the FAD interval to the following survivorship interval, followed by a less marked although still significant increase to the next interval, with no significant changes thereafter. Thus we concluded that the average large African mammal species has indeed started its life in a relatively small population and thereafter increased in geographic range to reach its long-term equilibrium abundance by ca. 1 Ma after origin. This supports hypotheses of speciation that accord a major role to the formation of isolated populations of reduced size initiated by physical change.

Not everyone has agreed that global change was a driver of evolutionary change and speciation in African hominins and other mammals. For instance, one aim of Behrensmeyer et al. (1997) was to test Vrba's (1995c) finding of a turnover pulse in African mammals between ca. 2.8 and 2.5 Ma by examining the past 4.5 Ma in the Turkana Basin (including the northern Shungura Formation, Ethiopia, and the southwestern Nachukui and southeastern Koobi Fora Formations in Kenya). They concluded that there was "no major turnover event between 3.0 and 2.5 Ma" (p. 1591) and that this "weakens the case for rapid climatic forcing of continent-scale … faunal turnover" (p. 1593). I have reservations about their methods and assumptions which differed substantially from mine (Vrba 2005). A reexamination of Turkana Basin evolution over 4.0–1.0 Ma divided into 0.5 Ma-long intervals, using my African mammal database and the statistical "gap bias" model outlined above, showed a single significant origination pulse in the 3.0–2.5 Ma interval and no extinction pulses (Vrba 2005). Separate examination of the northern and two southern areas of the Turkana Basin indicated a strong speciation (and extinction) pulse in the North 3.0–2.5 Ma ago, but none in the combined or separate southern areas. This result is consistent with the southward spread of the Sahara Desert in the latest Pliocene (Dupont and Leroy 1995), which affected the northern basin more strongly, eliciting significant turnover, while the southern deltaic-lacustrine areas may have behaved more nearly like biome refugia. More recently, Bobé and Behrensmeyer (2004:399) found that between 4 and 1 Ma in the Turkana Basin, "episodes of relatively high faunal turnover occurred in the intervals 3.4–3.2, 2.8–2.6, 2.4–2.2, and 2.0–1.8 Ma. *Paranthropus* and *Homo* appear in the Turkana Basin during successive intervals of high turnover at 2.8–2.6 and at 2.4–2.2 Ma, while the appearance of *Homo erectus* is coupled to a major episode of turnover and grassland expansion after 2 Ma." (See also Bobé's 2011, comprehensive overview.)

At least some studies show that the larger mammalian turnover pattern is also reflected in small mammals. Among micromammals of the Shungura Formation, Ethiopia (Wesselman 1995), at 2.9 Ma woodland taxa predominated and even rainforest taxa were present (e.g., the bush baby *Galago demidovii*, a rainforest species today). These forms were displaced by new grassland-to-semidesert species by 2.4 Ma. The turnover includes terminal extinctions, immigrants from Eurasia such as a hare, *Lepus*, and global first appearances of species, such as a new species of *Heterocephalus*, the genus of desert-adapted naked mole rats, and a new species of the ground squirrel genus *Xerus* (Wesselman 1995). This time also marks the first African and global debuts in the record of several species of bipedal, steppe-, and desert-adapted rodents, such as the genus *Jaculus* of desert gerboas (Wesselman 1995) and a new springhare species, *Pedetes*, in South Africa.

Evidence for turnover pulses has by now been found in many records from different continents and time intervals and in diverse taxa, from marine invertebrates (e.g., Lieberman 1999) to mammals in areas beyond Africa (e.g., Azanza et al. 2000; Raia et al. 2005; van Dam et al. 2006). The last study, of a dense, long (24.5–2.5 Ma) record of rodent lineages from Spain, adds an intriguing element. It showed the existence of turnover cycles with periods of 2.4–2.5 and 1.0 Ma, which van Dam et al. (2006) linked to low-frequency modulations of Milankovitch oscillations. Specifically, the pulses of turnover occur at minima of the 2.37 Ma eccentricity cycle and nodes of the 1.2 Ma yr obliquity cycle. Obliquity nodes and eccentricity minima are associated with ice sheet expansion and cooling and affect regional precipitation. As the average duration of African larger mammal species over the past 20 Ma is close to the period of the eccentricity cycle (2.33 Ma, Vrba and DeGusta 2004), the question arises: did a substantial proportion of those species originate at one eccentricity minimum, and become extinct at the next, and could hominins have been a part of that?

The Hominin Record. The hominid sample is too small (15 to more than 20 species depending on which sources are consulted) to test whether most hominin species "started small" and to test for turnover pulses using the statistical methods which were applied to all larger mammals. Nevertheless it is of interest to compare the known hominin FAD record with the timing of major climatic trends and speciation pulses in all larger African mammals. The earliest appearance of hominins, *Sahelanthropus* from Chad (Brunet et al. 2004), is ca. 7.2–6.8 Ma according to Lebatard et al. (2008). The hominin clade originated 8–5 Ma ago based on molecular estimates (Ruvolo 1997). Thus, the first appearance of hominins in the record participates in the elevated mammalian origination toward 6.5 Ma ago, in an interval marked by increased African tectonic activity (Ebinger 1989), and ice buildup in West Antarctica with global cooling (Kennett 1995). The FAD of *Orrorin tugenensis* ca. 6 Ma (Senut et al. 2001; Sawada et al. 2002) occurs near the end of the strong and widespread decrease in tree cover and increased aridity over ca. 6.3 and 6 Ma reported by Bonnefille's (2010). The genus *Ardipithecus* from the Middle Awash area, Ethiopia, includes two species to date: *A. kadabba* from the western margin in 5.7–5.2 Ma-old strata (Haile-Selassie 2001; Haile-Selassie et al. 2009) and *A. ramidus* dated 4.4–4.2 Ma at Aramis (White et al. 1994; WoldeGabriel et al. 1994; White, Asfaw et al. 2009) and with a similar date at Gona Western Margin (bracketed 4.51–4.32 Ma, Semaw et al. 2005). Thus, the FAD of *Ardipithecus* is associated temporally (and possibly also causally) with the major climatic changes which accompanied the Messinian ca. 5.8–5.3 Ma ago and with the ca. 5.5 Ma turnover event in African mammals.

Most African FADs of hominin species are mid-Pliocene to mid-Pleistocene in age, during which time the intervals of strongest climatic change were (see review above) 4.2–3.9 Ma, 3.5–3.2 Ma, 2.9–2.3 Ma, 1.8–1.6 Ma, 1.2 Ma, and 1.0–0.6 Ma and possibly also near 2 Ma and 4 Ma. Together, these episodes occupy ca. 40 % of the past 5 Ma. Yet most, and possibly all, of the hominin FADs either coincide with or fall very close to one of these events (chronology mostly after Wood and Richmond 2000; Wood and Leakey 2011): *Australopithecus anamensis* first appears at ca. 4.2 Ma and *A. afarensis* ca. 4.0 Ma (3.8 Ma or possibly 4 Ma according to Wood and Leakey 2011); FADs of *A. bahrelghazali*, *Kenyanthropus platyops* and possibly also *A. africanus* are a part of the mammalian origination pulse in the 3.5–3.0 Ma interval which may be a response to the cooling trend ca. 3.5–3.2 Ma; *Australopithecus garhi*, *Paranthropus aethiopicus*, *P. boisei*, and possibly also *Homo habilis* and *H. rudolfensis* have FADs in the 2.8–2.3 Ma interval. The FADs of *Australopithecus sediba* (Berger et al. 2010; Pickering et al. 2011), *H. ergaster*, and *H. erectus* (and its migration to Eurasia) between 2.0 and 1.8 Ma may also be associated with major climatic change. While taphonomic factors and chance may have contributed to this pattern, it does leave intact the hypothesis of climatic cause of at least most hominin speciation. An important splitting event in the hominin clade was the one that led to *Paranthropus* on the one hand and *Homo* on the other. Several systematic studies have concluded that the characters of *A. afarensis* are consistent with it being the common ancestor of *Paranthropus* and *Homo* and possibly also of one or more additional lineages (e.g., Kimbel 1995; Asfaw et al. 1999). After enduring in apparent equilibrium since ca. 4 Ma, *A. afarensis* is last recorded just after 3.0 Ma (Kimbel et al. 1994), while its descendants appear variously between 2.7 Ma and 2.3 Ma. Kimbel (1995:435) concluded: “regardless of which phylogenetic hypothesis is more accurate, it is clear that a pulse of speciation occurred in the hominin lineage between 3.0 and ca. 2.7 Ma, producing at least three lineages.” The phylogenetic pattern, of an inferred ancestor ending after 2.9, with new descendants branching off between 2.9 and 2.3 Ma ago, is common in bovids (e.g., Vrba 1995c, 1998a). These concordant genealogical patterns among different mammalian groups strongly suggest the causal influence of the start of the modern ice age, namely, that common causal rules connect the climate system with evolution of different biotic groups. It remains to be seen whether additional information in the future will support these preliminary indications that major changes in the mode of the climatic pattern and the concomitant changes in African environments were important causal influences on speciation in hominins, just as they were in many other mammalian lineages.

Climate in Relation to Habitats and Adaptations of Hominins

Bonnefille’s (2010) review of African vegetational evolution provides a particularly good context for this section because of its broad temporal and geographic scope, which encompasses the Cenozoic with focus on the past 10 Ma, includes the recent vegetation, and ranges right across the African tropics with emphasis on areas and sites which have yielded hominins. She discussed both the macrobotanical and the microbotanical evidence and its relationship to results from recent isotopic studies and from Atlantic and Indian Ocean deep-sea cores. Her conclusions include the following (Bonnefille 2010:409):

> the palaeontological hominid record so far documented appears embedded within a long evolution of tropical vegetation bracketed between two main events. These two events are the most pronounced among all of the many that occurred during the last 10 Ma. They had the strongest impact on past vegetation, at the continental scale, both in west central and eastern Africa..... The first event was a strong shift from an important forest expansion (7.5–7 Ma) to an abrupt retreat with minimum tree proportion (6.5–6 Ma) concerning the whole tropical region, half a million years before the Messinian salinity crisis. . . . The second event (2.7–2.5 Ma) was the arid shift, from forest to savanna expansion, corresponding to maximum expansion of the northern hemisphere glaciation. . . . [It involved] greater and more widespread aridity, increase in C_4 grass abundance in lowlands savanna and steppe, and the relative expansions of mountain forests coincide with the appearance of the genus *Homo* and stone tools registered simultaneously at different sites in East Africa.

Her summation stresses how pervasive mixed vegetation types are in tropical Africa, namely, areas which include both wooded and open habitat in close geographic proximity (p. 409): "*Mixed tree and grass cover* are among the widely spread vegetation conditions [and have] *persisted throughout the last 10 Ma*."

I have added the italic emphasis in the last sentence because it reflects a convergent theme in early hominin environmental research over the past decade, as apparent in the following discussion of the hominin species in terms of their natural surroundings, adaptations, and habits: the vegetational and other local conditions surrounding each of the early hominin species were heterogeneous and mosaic.

The earliest known hominins (or presumed members of the hominin clade; not all agree) are *Sahelanthropus tchadensis* (Brunet et al. 2002), ca. 7 Ma old, and *Orrorin tugenensis* (Senut et al. 2001) from Lukeino, Kenya, ca. 6–5.7 Ma (Sawada et al. 2002). The associated fauna of *Sahelanthropus* according to Brunet et al. (2005:753) "indicates a mosaic of landscapes probably resembling that of the present-day Okavango Delta (Botswana)." The Okavango Delta today "is an interlocking mosaic of habitat types" (Paterson 1976:55). These range from permanent swamp, wetlands, and seasonally inundated open areas, through higher-lying grasslands, dry scrub, woodland, to very dense woodland with high and nearly closed tree canopy and water margin forest, and many of the mammal species are virtually confined to particular parts of this mosaic (Ramberg et al. 2006).

The environment of *Orrorin* was initially described as follows by Senut (2006:89): "It has been widely accepted that hominins (and thus bipedalism) emerged in a savannah environment. However, it is now clear that the earliest bipeds are associated with forested environments as proved by the flora and the fauna of the Lukeino Formation (Kenya, 6 Ma)." But detailed studies of the mammals indicated a more heterogeneous environment (Mein and Pickford's 2006:183 micromammal study):

> The presence of galagids, fruit bats and the diversity of dendromurines (3 species) and some probably arboreal murids (possibly ancestral to *Thallomys* or *Grammomys*) indicates the presence of trees in the vicinity of the site, but some of the taxa suggest the presence of

> relatively open environments in the vicinity of Kapsomin at the time of deposition. A similar mixture of vegetation types is indicated by the large mammals from Lukeino.

Bonnefille (2010) linked the strong decrease in tree cover in both East and West Africa after 7 Ma to the earliest hominins as follows (p. 390):

> At that time, very arid conditions shown by scarce tree cover occurred over the whole tropical region. … Generally arid conditions coincide with the accepted timing for the chimpanzee/hominid split, and record of *Sahelanthropus tchadensis* in Chad and *Orrorin tugenensis* in Kenya, although these fossils were found under locally wooded environment.

This underlines the important point that patterns and causal actions at different hierarchical levels should not be conflated, because they are to some extent decoupled and relate only indirectly and in subtle ways: at the more inclusive climatic level "very arid conditions" and "scarce tree cover [spread] over the whole tropical region," just as at the higher phylogenetic level of species, there were changes in population structure toward vicariance that in some cases resulted in speciation and extinction. At the more local scale were those "habitat islands," each with its "interlocking mosaic of habitat types," in Paterson's (1976) words, and buffered to some extent from the larger geographic pattern of aridity and low wood cover, with the hominins and other organisms adapting to those local conditions. We still know very little about what the earliest hominids were doing. Bipedal locomotion of some kind has been claimed for both *Sahelanthropus* (Brunet et al. 2002) and *Orrorin* (Pickford et al. 2002), although doubts on that have been expressed, for example, by Harcourt-Smith and Aiello (2004), who considered that the earliest evidence for bipedalism is only arguably from *Sahelanthropus*, *Orrorin*, and the next taxon discussed here, *Ardipithecus*.

Ever since the announcement of *Ardipithecus ramidus* as a candidate for the "long-sought potential root species for the Hominidae" (White et al. 1994:306, who described it as *Australopithecus ramidus*), there has been a debate about its morphology, phylogenetic position, and its habitat 4.4 Ma ago at the source site Aramis. Some of the unexpected and astonishing features and implications of this taxon, especially after subsequent discovery that more than 110 additional specimens from 4.4 Ma stratum include a partial skeleton with much of the skull, hands, feet, limbs, and pelvis, are reflected by the following statements by White, Asfaw et al. (2009:75):

> This hominid combined arboreal palmigrade clambering and careful climbing with a form of terrestrial bipedality more primitive than that of *Australopithecus*. *Ar. ramidus* had a reduced canine/premolar complex and a little-derived cranial morphology and consumed a predominantly C_3 plant-based diet (plants using the C_3 photosynthetic pathway). Its ecological habitat appears to have been largely woodland-focused. *Ar. ramidus* lacks any characters typical of suspension, vertical climbing, or knuckle-walking. *Ar. ramidus* indicates that despite the genetic similarities of living humans and chimpanzees, the ancestor we last shared probably differed substantially from any extant African ape. Hominins and extant African apes have each become highly specialized through very different evolutionary pathways.

Concerning the Aramis habitat, White, Ambrose et al. (2009) wrote (p. 87):

> Assessment of dental mesowear, microwear, and stable isotopes from these and a wider range of abundant associated larger mammals indicates that the local habitat at Aramis was

> predominantly woodland. The *Ar. ramidus* enamel isotope values indicate a minimal C_4 vegetation component in its diet (plants using the C_4 photosynthetic pathway), which is consistent with predominantly forest/woodland feeding. Although the Early Pliocene Afar included a range of environments, and the local environment at Aramis and its vicinity ranged from forests to wooded grasslands, the integration of available physical and biological evidence establishes *Ar. ramidus* as a denizen of the closed habitats along this continuum.

In their response to White, Ambrose et al. (2009) and also to companion papers by WoldeGabriel et al. (2009) and Louchart et al. (2009), Cerling et al. (2010) disagreed and stated that from their analysis of the stable isotopic record (p. 1105d): "we find the environmental context of *Ar. ramidus* at Aramis to be represented by what is commonly referred to as tree-or bush-savanna, with 25 % or less woody canopy cover," and that "although we do not judge the validity of the savanna hypothesis, we note that from the stable isotopic record, the connection between bipedalism and C_4 grass expansion starting in the late Miocene and continuing into the Pliocene remains a viable idea." White et al. (2010) replied that Cerling et al.'s (2010) reconstruction of a predominantly open grassland environment with riparian woodland is inconsistent with a wealth of fossil, geological, and geochemical evidence. While they acknowledged that the local environment in the vicinity of Aramis ranged from dense woodland/forest to wooded grassland, White et al. (2010:1105) held firm that "in the Middle Awash, *Ar. ramidus* fossils are confined to the western portion of the sampled Pliocene landscape where the species is associated with woodland to grassy woodland habitat indicators." More recently, Cerling et al. (2011) investigated the percentages of woody cover, using stable carbon isotopes, in fossil soils from hominin sites in the Awash and Omo-Turkana basins. They concluded (p. 55) that "the combined results from two of the most significant hominid-bearing regions in eastern Africa leave the savanna hypothesis as a viable scenario for explaining the context of earliest bipedalism, as well as potentially later evolutionary innovations within the hominin clade."

As coauthors of White, Ambrose et al. (2009), David DeGusta and I contributed inference of the paleohabitat based on bovid astragali (DeGusta and Vrba 2003), especially of the overwhelmingly most common species which is a tragelaphine antelope, namely, that 4 Ma ago in Aramis, *A. ramidus* lived in (or at least spent a lot of time in) a woodland habitat. Additional inferences from the bovids suggest that there were wetlands and water bodies nearby (thus, Louchart et al.'s 2009:66e1, conclusion that the woodlands were "distant from large water bodies" is not one I share) and that there were also grassland areas in the vicinity. Namely, the notion that the Aramis environment was a mosaic of habitats among which *A. ramidus* preferred the dense woodlands seemed (and still seems) reasonable to me. I wonder whether we may find future support for the hypothesis that, since ape ancestry, *Ardipithecus* had already diverged toward a measure of broader use of environmental resources and the more generalized ability to live within a vegetationally mosaic environment. The results of Levin et al. (2008) give encouragement to consider this possibility seriously. They concluded (Levin et al. 2008:215) that

> the spectra of isotopic results from herbivores found in late Miocene *Ar. kadabba* and early Pliocene *Ar. ramidus* sites at Gona are most similar to isotopic values from extant herbivores living in bushland and grassland regions and dissimilar to those from herbivores living in closed-canopy forests, montane forests, and high-elevation grasslands. The tooth enamel isotopic data from fossil herbivores make it clear that *Ardipithecus* at Gona lived among a guild of animals whose diet was dominated by C_4 grass, and where there is no record of closed-canopy vegetation.

However, the notion that *A. ramidus* at Aramis was tied to – or at least strongly preferred – woodlands (albeit situated in a mosaic of habitats) seems to be compatible with what Semaw et al. (2005:301) reported for *Ardipithecus ramidus* from As Duma, Gona, Ethiopia, that "the Early Pliocene As Duma sediments sample a moderate rainfall woodland and woodland/grassland."

Kimbel et al. (2006) argued persuasively that *A. anamensis* and *A. afarensis* represent parts of an anagenetically evolving lineage or evolutionary species. In Bonnefille's (2010) broad overview of the large-scale African changes which led to the origin and establishment of this lineage, she noted that the period from 6 to 4 Ma was marked by a progressive increase in tree cover that culminated at 3.9 Ma, during *A. anamensis* time and before the first appearance of *A. afarensis*. From their stable isotope-based diet reconstructions of Turkana Basin hominins, Cerling et al. (2013:10501) concluded that "*Australopithecus anamensis* derived nearly all of its diet from C_3 resources . . . [while] by ca. 3.3 Ma, the later *Kenyanthropus platyops* had a very wide dietary range-from virtually a purely C_3 resource-based diet to one dominated by C_4 resources."

Bedaso et al. (2013) used carbon and oxygen isotopes of mammalian tooth enamel to reconstruct paleoenvironments of *A. afarensis* from the Basal Member (ca. 3.8–3.42 Ma) and the Sidi Hakoma Member (3.42–3.24 Ma) of the Hadar Formation in the Middle Pliocene locality of Dikika, Ethiopia. Their results indicate a wide range of foraging strategies, characterized by mixed C_3/C_4 to C_4-dominated diets in wooded grasslands to open woodlands and that (2013)

> the middle Pliocene habitat structure at Dikika could be as diverse as open grassland and wooded grassland, and woodland to forest in the Sidi Hakoma Member while wooded grassland, woodland to grassland are evident in the Basal Member. All habitats except closed woodland and forest are persistent through both members; however, the relative proportion of individual habitats changed through time. . . . Thus, the existence of *A. afarensis* throughout the middle Pliocene indicates either this species might have adapted to a wide range of habitats, or its preferred habitat was not affected by the observed environmental changes.

Kingston and Harrison (2006) used similar methods and reached similar conclusions on a heterogeneous environment for *A. afarensis* from the Laetoli Beds in Tanzania, much further south. While over the long term many African records show that cooling was accompanied by aridification, it is by no means an invariable association, as expected from the shifting phase relationship between the monsoon and glacial cycles. For example, pollen data from Hadar, Ethiopia, show that "*Australopithecus afarensis* accommodated to substantial environmental variability between 3.4 and 2.9 Ma ago. A large biome shift, up to 5 °C cooling, and a 200- to

300-mm/year rainfall increase occurred just before 3.3 Ma ago, which is consistent with a global marine delta^{18}O isotopic shift" (Bonnefille et al. 2004:12125).

Wood and Richmond (2000) considered the tibia of *Australopithecus anamensis* (ca. 4.2 Ma; Leakey et al. 1995) the earliest undisputed evidence of bipedalism and in thinking about the ecology of the *anamensis-afarensis* lineage, recall the debate on selective factors which might have promoted the inception and advancement of bipedalism. Much new evidence now clearly indicates that the relevant lineages since the late Miocene were probably all living in patchy environments, mosaics of habitat types, with patches of dense woodland and forest, light woodland, grassland, and interrupted by barriers such as volcanic deposits and watered areas including seasonally flooded wetlands. Selection pressure for traversing the barriers to reach resources on the other side (which may have been what the *A. afarensis* individuals who formed the Laetoli footprints were doing; Leakey and Hay 1979), or for foraging in these areas (as in a shallow delta or wetland) might have promoted the onset or, later on, elaboration of bipedality. The notion that wading in shallow water played a part (Niemitz 2000; Verhaegen et al. 2002) seems reasonable given what we know about the palaeoenvironments of many early hominid species. In such a mosaic context some additional previous hypotheses of what caused the adoption of upright posture may apply: carrying, display or warning, new feeding adaptations, control of body temperature, tools, and stone throwing. Reviews are given by McHenry (1982), who thought that hominin bipedalism "could have arisen as an energetically efficient mode of terrestrial locomotion for a small_bodied hominoid moving between arboreal feeding sites" (p. 163), and by Preuschoft (2004).

Whatever the combination of selective forces, there is much healthy debate on how the postcranial anatomy of early hominins should be interpreted in terms of function, habitat use, and phylogenetic relationships. Harcourt-Smith and Aiello (2004)) reviewed some of the evidence (including the Laetoli footprints, the AL 288-1 *A. afarensis* skeleton, postcranial material from Koobi Fora, the Nariokotome *H. ergaster* skeleton, "Little Foot" [StW 573] from Sterkfontein, South Africa, fossils of *Orrorin*, *Ardipithecus*, and *Sahelanthropus*) and pointed out the greater diversity in bipedalism (or putative bipedalism) in earlier hominins than previously suspected. In each of their three phylogenetic scenarios (Harcourt-Smith and Aiello 2004: Fig. 4), the postcranial diversification coincides broadly with the 3.0–2.3 Ma period of the largest Pliocene climatic trend. More recently, Haile-Selassie et al. (2012) reported a new hominin foot from a new site Woranso-Mille in the central Afar, Ethiopia, which further increases the diversity of Pliocene bipedal adaptations. They wrote (p. 565):

> Here we show that new pedal elements, dated to about 3.4 Ma ago, belong to a species that does not match the contemporaneous *Australopithecus afarensis* in its morphology and inferred locomotor adaptations, but instead are more similar to the earlier *Ardipithecus ramidus* in possessing an opposable great toe. This not only indicates the presence of more than one hominin species at the beginning of the Late Pliocene of eastern Africa, but also indicates the persistence of a species with *Ar. ramidus*-like locomotor adaptation into the Late Pliocene.

There has also been input from South Africa into the debate on diversity and environmental associations of hominin locomotion. Clarke and Tobias (1995) proposed that the foot bones from Sterkfontein Member 2 (StW 573, Little Foot, dated ca. 4 Ma, Partridge et al. 2003, see below) reflect a foot that had not sacrificed arboreal competence or hallucial opposability and that this suggests dense tree cover in the environment. Based on fossil pollen, it has been suggested that the preferred habitat of *A. africanus* at Makapansgat was subtropical forest and that selective pressures associated with densely vegetated environments played a role in the evolution of bipedalism (Cadman and Rayner 1989; Rayner et al. 1993). Potts (1998a) dubbed this the "forest hypothesis" of bipedal origin. The fossil bovids associated with *A. africanus* at Makapansgat and Sterkfontein do not suggest a uniform forest, although a mosaic in the greater area which includes dense and open woodland patches, as well as grassy patches and permanent water, could be consistent (Vrba 1974, 1980, 1987b), which agrees with Reed's (1997) conclusions. A related insight comes from Lee-Thorp et al.'s (2010) analysis of stable isotopes in the tooth enamel of more than 40 hominin specimens, including *A. africanus* from Makapansgat and Sterkfontein and *Paranthropus robustus* from Swartkrans and Kromdraai together spanning ca. 3–1.5 Ma. They concluded (p. 3389) that among all these South African australopithecines including *A. africanus* and persisting over the entire time range, "these data demonstrate significant contributions to the diet of carbon originally fixed by C_4 photosynthesis, consisting of C_4 tropical/savannah grasses and certain sedges, and/or animals eating C_4 foods. Moreover, high-resolution analysis of tooth enamel reveals strong intra-tooth variability in many cases, suggesting seasonal-scale dietary shifts." (See also Sponheimer et al. 2013.) These results suggest spatial variability in vegetation cover and also seasonal variability, rather than predominant forest.

Australopithecus afarensis, which persisted in place through major climatic and vegetational variability (e.g., at Hadar, Bonnefille et al. 2004; Bedaso et al. 2013), appears to have been the most generalist of all hominin species up to the Middle Pliocene. It was geographically so widespread that in the past one wondered why it was not also found among the South African hominins. The findings of Partridge et al. (2003) suggested that the *anamensis-afarensis* lineage may well have been present there as well: based on cosmogenic aluminum-26 and beryllium-10 burial dates of low-lying fossiliferous breccia in the Sterkfontein caves, associated hominin fossils such as skeleton StW 573 date to ca. 4 Ma, the time of the *anamensis-afarensis* transition in East Africa.

An important splitting event in the hominin clade was the one that led to *Paranthropus* on the one hand and *Homo* on the other. Several systematic studies have concluded that the characters of *A. afarensis* are consistent with it being the common ancestor of *Paranthropus* and *Homo* and possibly also of one or more additional lineages (e.g., Kimbel 1995; Asfaw et al. 1999). After enduring in apparent equilibrium since ca. 4 Ma, *A. afarensis* is last recorded just after 3.0 Ma (Kimbel et al. 1994), while its descendants appear variously between 2.7 Ma and 2.3 Ma. Kimbel (1995:435) concluded that "regardless of which phylogenetic hypothesis is more accurate, it is clear that a pulse of speciation occurred in the hominin lineage between 3.0 and ca. 2.7 Ma, producing at least three lineages." The phylogenetic pattern, of an inferred ancestor ending after 3.0 Ma, with new descendants branching off between that and 2.3 Ma ago, is common in bovids (e.g., Vrba 1995c, 1998a).

According to Wood (1995), the first signs of the "hypermasticatory trend" occurred with an advent of *Paranthropus aethiopicus* ca. 2.6 Ma ago, followed by exaggeration in this trend ca. 2.3 Ma with the FAD of *P. boisei*, and further lesser modifications to the dentition of this species between 1.9 and 1.7 Ma. Efforts to find out what the robust australopithecines were eating, and where they lived, have been ongoing for a long time. A study which uses functional morphology of mammalian assemblages associated with early hominins to reconstruct their environs by Reed (1997) is particularly useful because it treats the East and South African Plio-Pleistocene fossil assemblages in the same analysis, comparing them with each other and with extant mammalian communities from different habitat types. Reed (1997) concluded that *Paranthropus* species in East and South Africa lived in both wooded and more open environments, always in habitats that include wetlands. This is compatible with our earlier findings for the relevant South African sites, based on bovid abundances (Vrba 1975) and also on the assemblages as a whole (Brain 1981b), which indicated environs of *P. robustus* including substantial grassland with wooded patches and permanent water indicated by water-dependent fauna.

The notion that robust australopithecines, *Paranthropus*, were in certain senses specialists was originally proposed by Robinson (1963) based on the dentition of *P. robustus*. He suggested that the "crushing, grinding" robust vegetarian specialist lived in a somewhat wetter and more luxuriant environment than did the earlier gracile omnivore *A. africanus*. Prompted by the bovid evidence of change to more open vegetation in the *Paranthropus*- and *Homo*-bearing strata, compared to the earlier South African ones with only *A. africanus*, the question arose whether the musculature of *P. robustus* was massive and the molars proportionally so large "because their 'vegetables' were of the tough grassland type" (Vrba 1975:302) and whether, in contrast to the more generalized *Homo*, robust australopithecines may have been more specialized on open and relatively more arid habitats. Based on comparisons of the dental microwear of *A. africanus* and *P. robustus*, Grine (1981, 1986) concluded that the latter had probably processed tougher food items. Wood and Strait (2003) did a thorough analysis of the proposal that *Paranthropus* species were feeding specialists. They concluded that *Paranthropus* species were most likely ecological generalists (i.e., eurybiomic in being able to make a living in varied environments) and made the novel proposal that (p. 149) "… although the masticatory features of *Paranthropus* are most likely adaptations for consuming hard or gritty foods, they had the effect of broadening, not narrowing, the range of food items consumed." I accepted their arguments because the acquisition, in response to newly encountered environments, of morphology which can perform a new specialized function but which at the same time permits the retention of functions evolved in the ancestral more uniform environment, is a recurrent theme in the evolution of generalist mammals (e.g., the impala *Aepyceros melampus* which, from a browsing ancestry, Vrba and Schaller 2000, evolved cranial and dental features which allow mastication of grass and other tough plant matter and also a stomach structure which undergoes reversible seasonal changes, Hofmann 1973, a rare adaptation to varied vegetational environments. As a consequence of these dental and digestive evolutionary advances, the impala is today a consummate herbivore generalist which can subsist in different environments by switching its dietary intake).

A number of isotopic analyses of diet and environment have since contributed to illuminating such questions. van der Merwe et al. (2008) did isotopic dietary studies of *H. habilis* and *P. boisei* teeth from Olduvai, Tanzania, and discussed how the results compare with previous ones for the South African hominins (see citation of Lee-Thorp et al. 2010, above). They found that the two Olduvai species had very different diets, while, in contrast, the isotopic analyses of the three South African species of early hominins, *A. africanus*, *P. robustus*, and *Homo* sp., showed considerable variation in individual diets but no marked differences between species. For two Olduvai specimens of *P. boisei*, van der Merwe et al. (2008) found C_4 dietary components (77 % and 81 %) that far exceeded those of the South African taxa, including *P. robustus*, and indeed of all other early hominins for which carbon isotope values were available by that time. They pointed out that the C_4 input could come from consuming grasses, some sedges and forbs, and a variety of animals which eat C_4 plants and suggested that *P. boisei* may have fed on papyrus or other C_4 species of Cyperaceae which are perennially available near water. A similar study by Cerling et al. (2013) on hominins in the Turkana Basin showed comparable results: by ca. 2 Ma, specimens attributable to the genus *Homo* provide evidence for a diet with a ca. 65/35 ratio of C_3- to C_4-based resources, whereas *P. boisei* had a higher fraction of C_4-based diet (ca. 25/75 ratio). Thereafter *Homo* sp. increased the fraction of C_4-based resources in the diet through ca. 1.5 Ma, whereas *P. boisei* maintained its high dependency on C_4-derived resources. Sponheimer et al. (2013:10513) summarized their overview of isotopic evidence of early hominin diet as follows:

> Before 4 Ma, hominins had diets that were dominated by C_3 resources and were, in that sense, similar to extant chimpanzees. By about 3.5 Ma, multiple hominin taxa began incorporating ^{13}C-enriched [C_4 or crassulacean acid metabolism (CAM)] foods in their diets and had highly variable carbon isotope compositions which are atypical for African mammals. By about 2.5 Ma, *Paranthropus* in eastern Africa diverged toward C_4/CAM specialization and occupied an isotopic niche unknown in catarrhine primates, except in the fossil relations of grass-eating geladas (*Theropithecus gelada*). At the same time, other taxa (e. g., *Australopithecus africanus*) continued to have highly mixed and varied C_4 diets.

Together all the available lines of evidence for species of *Paranthropus* support a degree of generalism in terms of the patchiness, from open to more wooded, of vegetational environments they inhabited and dietary specialization in the east African species yet not in the southern *P. robustus* which evidently maintained a more mixed diet in terms of the range of C_3- to C_4-based resources. All these leave intact the possibility raised by Wood and Strait (2003) that the evolution of the masticatory features of *Paranthropus*, while allowing consumption of hard or gritty foods, may have broadened their options in the soft-to-hard-and-gritty spectrum of foods, perhaps remaining within the C_4/CAM range of plants in the case of *P. boisei* while ranging across both C_3 and C_4 resources in the case of the southern *P. robustus*.

There are two species with first appearances after the last record of *A. afarensis* which have been assigned to *Australopithecus*. The specific name *Australopithecus garhi* reflects well the reactions of many ("garhi" means "surprise" in the Afar language) when they found out about the mosaic combination of its anatomical features relative to previously known hominins and the tantalizing associated evidence of cultural advances (which may or may not be the handiwork of this species), all at the hitherto under-represented age of 2.5 Ma (Asfaw et al. 1999; de Heinzelin et al. 1999). The cranial and dental remains, from the Hata beds, Bouri Formation, of Ethiopia's Middle Awash, led Asfaw et al. to conclude that (p. 629) *A. garhi* "is descended from *Australopithecus afarensis* and is a candidate ancestor for early *Homo*. Contemporary postcranial remains feature a derived humanlike humeral/femoral ratio and an apelike upper arm-to-lower arm ratio." The abundant vertebrate remains together with the sedimentology indicate an environment (de Heinzelin et al. 1999:626) that was "primarily lake marginal. Alcelaphine bovids are abundant and diverse. All indicators point to a broad featureless margin of a freshwater lake. Minor changes in lake level, which were brought about by fluctuating water input, would probably have maintained broad grassy plains leading to the water's edge." With *A. garhi* are found some of the earliest made stone tools with earliest evidence of the their use to butcher large mammals (p. 625):

> Spatially associated zooarchaeological remains show that hominins acquired meat and marrow by 2.5 Ma ago and that they are the near contemporary of Oldowan artifacts at nearby Gona. The combined evidence suggests that behavioral changes associated with Lithic technology and enhanced carnivory may have been coincident with the emergence of the *Homo* clade from *Australopithecus afarensis* in eastern Africa.

One of the specimens on which unambiguous cutmarks are visible, perhaps made during tongue removal, was identifiable to a new genus and species of a medium-sized bovid (of body size comparable to living hartebeests) in the tribe Alcelaphini, a tribe and bovid size class which are very abundant not only in this Hata Member but also were appearing in greater numbers than before all over Africa near 2.5 Ma. Looking at this earliest evidence of cutmarks made by hominins, in its faunal and environmental context, prompts one to think about the arguments of Owen-Smith (2013) who contrasted the Pleistocene large herbivore faunas of the southern continents and argued (p. 1215) that it was the African "abundance and diversity of medium-sized grazing ruminants unrivalled elsewhere ... that facilitated the adaptive transition by early hominins from plant-gatherers to meat-scavengers."

Only a few years ago, another new species of hominin was announced, *Australopithecus sediba*, based on two partial skeletons dated 2.0 Ma (by uranium-lead dating combined with paleomagnetic and stratigraphic analysis) from cave deposits at the Malapa site in South Africa (Berger et al. 2010; Dirks et al. 2010; Pickering et al. 2011). Berger et al. (2010:195) argue that *A. sediba* "is probably descended from *Australopithecus africanus*. Combined craniodental and postcranial evidence demonstrates that this new species shares more derived features with early *Homo* than any other australopith species and thus might help reveal the ancestor of that genus." The faunal fossils associated with *A. sediba* are as yet few, but consistent in chronological and environmental implications with what was found at the other hominin-associated sites thought to date near 2 Ma in the Sterkfontein area.

Near the end of the large late Pliocene cooling trend, by ca. 2.6–2.5 Ma, stone tools appeared in several other places (e.g., Semaw et al. 1997) besides the finds from Bouri, together with evidence of butchery already mentioned (de Heinzelin et al. 1999). Hatley and Kappelman (1980) proposed that the climatic change led to this behavioral advance. They showed that a high belowground plant biomass is characteristic of xeric open areas and argued that digging out of such foods, first by hand and later by digging sticks and other tools, evolved as an important feeding strategy of early hominins when the African savanna became more open and arid. Leakey (1971) noted early on that the onset of more expanded tool kits appears to overlap with the climatic change ca. 1.8–1.6 Ma ago. Another milestone dating to this time was proposed by Wood and Richmond (2000): the fact that the mandible and postcanine tooth crowns of *H. ergaster* (dated ca. 1.9–1.5 Ma) when scaled to body mass are no larger than those of modern humans may reflect the earliest cooking.

The late Pliocene and Pleistocene behavioral and cultural advances presumably reflect reorganization and expansion of the brain. The available evidence indicates significant increase in EQ (encephalization quotient) in *Homo* only over the past 2 Ma, with the largest EQ increase occurring ca. 600–150 Ka ago, according to Holloway (1970, 1972, 1978) and McHenry (1982). Shultz et al. (2012) found punctuated changes in encephalization at approximately 1.8 Ma, 1 Ma, and 100 Ka, noting that brain size change at ca. 100 Ka is coincident with demographic change and the appearance of fully modern language. Holloway et al. (2003) presented evidence that brain reorganization predated brain expansion in hominin evolution. I previously suggested that the encephalization trend in *Homo* "evolved by progressive prolongation of ancestral, fast, early brain growth phases. It started with the modern ice age, and was fuelled by progressive intensification of cooling minima since then" (Vrba 1996:15). I suspect that we may find future indications that some of the brain modifications which came to characterize *Homo* – perhaps not increase in EQ but brain reorganization – were promoted by the start of the modern ice age, which would be consistent with the proliferation of stone tool finds in the record by 2.6–2.5 Ma.

If the largest EQ increase did occur ca. 600–150 Ka ago (as cited above), it could be related to the end of the mid-Pleistocene strong climatic events ca. 1.0–0.6 Ma ago. Many selective scenarios for encephalization in *Homo* have been proposed. Falk's (1980) review included warfare, language, tools and labor, hunting, and heat stress. Gabow (1977) emphasized population structure and culture, McHenry (1982) language, and Brain (2001) our predatory past. Vrba (1985a, 1988, 1989a) proposed that major selection pressures that led to brain and cultural evolution derived from the large-scale changes in climatic mean and amplitude during the Plio-Pleistocene and that culture and the underlying brain modifications in *Homo* represent adaptation to eurybiomy or "generalist adaptation. Hominine culture is an extension of the common phenomenon in other animals that use behaviour to cope with climatic conditions . . . a special case among animal behaviors that confers an expanded use of environmental resources" (Vrba 1989a:30). As cited above, Potts (1998a) made a similar proposal to explain the brain and behavioral adaptations of *Homo*. Others have also argued that *Homo* evolved toward biome generalization (e.g., Wood and Strait 2003).

Morphological evidence of a commitment to long-range bipedalism (e.g., long legs, large femoral head) appeared much later, ca. 1.6 Ma, in the postcranial skeleton KNM-WT 15000 from Nariokotome, West Turkana (Brown et al. 1985, who assigned it to *H. erectus*; Wood and Richmond 2000 included it in *H. ergaster*). There is some agreement that the onset of advanced bipedalism in *Homo* ca. 1.6 Ma ago not only falls during a time of change to more open and seasonally arid landscapes (and near the advent of other novelties in hominin evolution, as noted above) but also makes sense as a selective response to these changes. Potts (1998a) pointed out that the latest Pliocene populations of *Homo* were increasingly mobile, for example, tool-making behavior involved long-distance transport of stones as far as 10 km. Increased mobility is reflected by the migration out of Africa by 1.8 Ma of a lineage of *Homo* (if the early date for *H. erectus* in Java, Indonesia, is correct, Swisher et al. 1994), the first of many subsequent migrations out of Africa which were associated with physical changes (Stringer 1995; Tattersall 1997b; Klein and Edgar 2002; see also Abbate and Sagri 2012, who found that the early to Middle Pleistocene *Homo* dispersals from Africa to Eurasia were temporally arranged into cycles of four major exodus waves (2.0–1.6 Ma, 1.4–1.2 Ma, 1.0–0.8 Ma, and 0.6–0.1 Ma) controlled by climatic and environmental changes).

Climate in Relation to the Evolution of Ontogeny

Heterochrony Pulses: Parallel Developmental Responses to Common Environmental Causes

The term heterochrony has been applied to both ecophenotypic and evolutionary changes in the rates and timing of ontogenetic events (Gould 1977). The same kind of heterochronic phenotype, *H*, commonly appears independently in different parts of a given monophyletic group in association with the same kind of environmental condition, *E*, and variously as an ecophenotype (i.e., reversible in later generations not faced by *E*) or as a phenotype, the expression of which is genetically fixed (or at least more constrained under varying conditions). An example is relative reduction of limb length in colder environments, an aspect of Allen's Rule (Allen 1877: mammalian extremities are reduced relative to body size in cooler climates). Not only the environmental association with *E* but also the growth patterns tend to be similar between the independent occurrences of such a phenotype *H* in a clade (e.g., Gould 1977a; Wake and Larson 1987; Vrba 1998b). It appears that certain kinds of heterochrony are more likely than others under particular environmental changes. Each heterochrony response starts off from the ancestral ontogenetic trajectory for that character, and this inheritance imparts limits and direction on what can grow and evolve. To the extent that aspects of ontogeny are shared by common inheritance between related species and across larger taxonomic groups, similar kinds of heterochrony will evolve independently in related lineages faced by the same environmental change. A summary and extension of the above is given in the following two statements (Vrba 2004, 2005):

1. Similar environmental changes elicit similar heterochronies in parallel, potentially in numerous lineages across large phylogenetic groups. Such heterochrony often involves change in body size and may be accompanied by large-scale phenotypic reorganization (Arnold et al. 1989; Vrba 1998b), such that the parallel heterochronies involve concerted evolution of suites of linked characters and "shuffling" among body proportions.
2. At times of widespread climatic change, diverse lineages may show parallel changes in size and in similar kinds of heterochrony associated in time and consistently with the climatic change – a "heterochrony pulse." "Pulse" here does not imply that the lineages responded in unison in a short time, but only that the events are significantly concentrated in time.

I will mention one particular category of heterochrony, which is associated with body size increase by prolongation of growth and which is a common mammalian response to colder temperatures. It is of special interest in the Plio-Pleistocene context of net global cooling, and it appears to have affected many African mammals including some evolutionary changes in *Homo*.

Cooling and Body Size Increase. Many species with FADs during times of cooling and aridification were larger than their ancestral phenotypes (as cladistically inferred). For example, Vrba (2004) tested H_0 that size changes across lineages are randomly distributed in time in the Alcelaphini (wildebeests, etc.) and Reduncini (waterbuck, etc.), which together comprise 63 recorded species over the past 5 Ma with a body weight range of ca. 20–250 kg. The result of significant peaks in size increase 3.0–2.5 Ma and 1.0–0.5 Ma ago, two periods with strong cooling, is consistent with Bergmann's Rule (1846: larger bodies are associated with colder temperature). While exceptions have been noted, in general, the predictions are upheld in living mammals (Ashton et al. 2000; Meiri and Dayan 2003) including in humans (Baker 1988) and in fossil mammals (Davis 1981; Kurten 1959; Heintz and Garutt 1965). To evaluate the claim that climate-associated heterochrony can involve extensive rearrangement – or "shuffling" – among body proportions, with parallel changes across related lineages, consider the example of Bergmann's Rule. Bodies can become enlarged by faster growth relative to the plesiomorphic (or directly ancestral) ontogeny, by prolongation of growth time, or by a combination of both, and the influential factors may include temperature change itself or one of the attendant environmental changes (such as seasonal changes in food and water availability, e.g., Guthrie 1984; Barnosky 1986). Such changes in growth mode are expected to result in rearrangement of body proportions. This is especially true of growth prolongation which is prevalent among Bergmann cases for which there are growth studies. For instance, many African tropical ungulates have shorter growth periods to smaller size in warm lowlands, while their close relatives at higher altitudes and/or latitudes grow for longer and become larger. The example of polymorphism in the African buffalo was noted earlier: *Syncerus caffer caffer* is much larger (up to 810 kg), grows for longer, and lives at higher latitudes and/or altitudes always near grassland, while the smaller and plesiomorphic phenotype *S. c. nanus* (up to 320 kg) with a shorter growth period lives in warmer, more forested regions.

Body Size Increase and "Shuffling" Among Body Proportions. Consider what is expected under the simplest way in which growth prolongation could occur: namely, if all ancestral growth phases for a character become proportionally prolonged (or extended in time by a constant factor) while maintaining the ancestral number of growth phases and the ancestral growth rates for respective phases (Vrba 1998b: Fig. 1). Let us call that simple proportional growth prolongation. Characters in the same organism have differing growth profiles, in terms of growth timing and rate in relation to age and body weight (e.g., Falkner and Tanner 1986), and character growth typically occurs in distinct phases in each of which character change is nonlinear with respect to age (Koops 1986). We can distinguish two major types of heterochrony and associated allometric growth under growth prolongation: (A) in type A heterochrony, characters which grow with net negative allometry with respect to age and body size will become reduced relative to body size in the adult stage of the prolonged descendant ontogeny (even if no other growth parameter changes) and paedomorphic in that the descendant adult resembles the ancestral juvenile. A probable example is the character evolution by Allen's Rule (Vrba 1998b, 2004) which is upheld in modern humans (Baker 1988). The persistence of Allen's Rule in modern biology supports the general hypothesis of similar changes in body proportions across lineages, which share inherited developmental responses to common environmental causes. (B) In type B heterochrony, characters which grow with net positive allometry become relatively enlarged. This mode, particularly by prolongation of a positively allometric late growth phase, may be how the hypermorphosed antlers of the giant Irish elk evolved (Gould 1974) and how exaggerated secondary sexual characters in enlarged bodies commonly evolve (Vrba 1998b). As growth trajectories become prolonged, some characters become relatively reduced and others enlarged, with potentially extensive rearrangement among body proportions and substantial evolutionary novelty (Vrba 1998b: Fig. 1). Type B heterochrony can also result from prolongation of positively allometric *early* growth, in which case the descendant structure is relatively enlarged and paedomorphic. An example is provided by the enlarged hind-feet of the bipedal, saltatory rodents during times of cooling (section "Climate in Relation to Habitats and Adaptations of Hominins"). If the growth of rodents, the juveniles of which in general have relatively large hind-feet

(Hafner and Hafner 1988), is prolonged, a descendant adult with enlarged hind-feet is predicted. Evidence for at least some taxa is consistent with this; e.g., bipedal Kangaroo rats, *Dipodomys*, which inhabit semiarid to arid regions in North America, have longer growth periods and are hypermorphosed in some characters – yet paedomorphosed in others – relative to the ancestral ontogeny (Hafner and Hafner 1988). As noted earlier, the bipedal forms share suites of characters in a characteristic body plan that is today strongly associated with open, arid habitats and has appeared independently in 24 genera in 8 families (Hafner and Hafner 1988). I do not know how many of the 24 instances of parallel evolution involved growth prolongation. But I suggest that at least some of these appearances of suites of integrated character complexes exemplify coordinated morphological changes, by growth prolongation, within and between lineages in response to a common climatic cause. This case illustrates that evolution by growth prolongation, as it acts on characters with different nonlinear growth profiles in the same body plan, can result in a "shuffling" of body proportions. Substantial novelty in form can result and also in function as in these rodents which can jump to a height that is from 4 to 25 times their body length. I next discuss another example of type B heterochrony with prolongation of positively allometric early growth, namely, encephalization.

Heterochrony and Brain Evolution. I applied statistical models for multiphasic growth to data on living human and common chimpanzee brain weights at ages since conception to test the hypothesis that encephalization of the human brain occurred by simple proportional growth prolongation (Vrba 1998b). Specifically, I wanted to know whether prolongation of the fetal growth phases, with strongly positive allometric growth, could account for most of the observed EQ increase. The results supported the hypothesis and imply that gross brain weight increase toward humans required change in only one growth parameter: prolongation of the nonlinear ancestral growth phases. In mammals, in general, simple growth prolongation is predicted to result in encephalization, as all mammalian brains complete a large proportion of their total growth rapidly early in ontogeny (Count 1947; Holt et al. 1975). A positive correlation of EQ with more open, seasonally cooler and drier environments has been noted in diverse mammals (Vrba 2004; e.g., in living African bovids this association is supported by comparison of the habitat preferences of the species with Oboussier's 1979 results for their EQ variation). This raises the hypothesis that there were past "encephalization pulses," across many mammalian lineages, in response to cooling over particular intervals (Vrba 1998b).

Conclusion

Environmental stimuli have influenced the evolution of hominins and other mammals at the levels of ontogeny, organismal adaptation, and speciation. From a time a few decades ago, when any proposal that climatic change is causally linked to speciation of hominins and other mammals was subjected to much doubt and even derision, there is now substantial convergence of opinion that such a linkage is real.

The climatic influence on hominin adaptation has received most attention, and some agreement has also emerged in this area: successive cooling trends since the late Pliocene were associated with the earliest evidence of – and probably initiated – the "hypermasticatory trend" in *Paranthropus* (ca. 2.6 Ma) and its later exaggeration ca 2.3 Ma, stone tools and their use to butcher carcasses (ca. 2.6–2.5 Ma), the Early Pleistocene expansion of tool kits, increased mobility by the Plio-Pleistocene interface and commitment to long-range bipedalism (ca. 1.6 Ma) in *Homo*, and significant brain expansion near 2 Ma and also since 600 Ka ago. There is some consensus that encephalization and culture in *Homo* represent generalist adaptations which conferred a more flexible and expanded use of resources (Vrba 1985a, 1988, 1989a; Potts 1998a; Wood and Strait 2003). It now seems likely that the masticatory features of *Paranthropus*, while adaptations for consuming tough or gritty foods, had the effect of broadening, not narrowing, the range of food items consumed and allowed these forms to subsist in varied environments (Wood and Strait 2003). There is less agreement on environmental stimuli of the onset of bipedalism, particularly on whether the vegetational habitats of the earliest bipedal hominins were forest to dense woodland or more open. I discussed why, even if the hominin ancestor and its bipedal descendant species both live(d) in forest, this does not necessarily mean that climatic change did not bring about speciation.

Far less work has been done on the issue of environmental causes of hominin speciation. A brief summary of the current status is as follows: in terms of theory, the expectation that allopatric speciation predominates, particularly in hominins and other large mammals, is consistent with the weight of available evidence. It would take special pleading to argue that hominins are exceptions. If allopatric speciation predominates, then so must physical initiation of speciation predominate. Most, and possibly all, of the hominin FADs either coincide with or fall very close to one of the major cooling trends. While taphonomic factors and chance may have contributed to this pattern, it does leave intact the hypothesis of climatic cause of hominin speciation. Also, on cladistic grounds, some speciation events must be closely associated with climatic change in hominins (Kimbel 1995) and other African mammals (Vrba 1995c).

Environmental stimuli of ontogenetic evolution have hardly been studied in our field. I discussed the "heterochrony pulse hypothesis": the generative properties shared among lineages can result not only in coherence of morphological changes but also in a strongly nonrandom timing of heterochrony events, as diverse lineages respond in parallel by similar kinds of heterochrony to the same environmental changes. This has not yet been tested. Of particular interest in the present Late Neogene climatic context is heterochrony involving body enlargement by prolongation of growth, because it is associated with colder (at least seasonally colder) temperatures (Bergmann's Rule, upheld in modern humans, Baker 1988). I have discussed some examples, including encephalization as a result of growth prolongation, in hominins and other mammals, and suggested that there were past "encephalization pulses," across many mammalian lineages, in response to cooling trends over particular intervals, such as during the onset and later intensification of the modern ice age.

In our field, one sometimes regrets (at least I do) that conclusive answers, such as those that emerge from some experiments of physical scientists, are so difficult to achieve. Hypotheses on the subject of environmental causes of hominin and other biotic evolution are difficult to test because the data come from different subdisciplines, each with its own set of biases, errors, and ambiguities. As a result, debates tend to continue interminably. While we have a long way to go, on the positive side, we can take heart in the simple fact that we are, so to speak, in a "growth industry": while many aspects of life are deteriorating, the fossil record with its associated geological information is constantly improving. Thus, there is an excellent expectation of decisive future progress on some of the unresolved issues. In my view, the results to date already offer support for the notion that common rules give qualitative and temporal coherence to the evolutionary responses across many mammalian – including hominin – lineages. These common rules arise from the regularities of physical change and from attributes of organismal ontogenies and phenotypes and species that are widely shared by common inheritance. The evidence implies closer linkages between the physical and biotic dynamics on earth than has traditionally been acknowledged. This perspective contrasts with the neoDarwinian view that selection of small-step random mutations is the vastly predominant evolutionary cause, with the implication that each evolutionary advance is to a larger extent an independent piece of history. Evolution is more rule bound than that, and our evolution is no exception.

Origins of Homininae and Putative Selection Pressures Acting on the Early Hominins

Bogusław Pawłowski and Wioletta Nowaczewska

Contents

Abstract

One of the biggest mysteries of human evolution is the divergence of the hominin lineage from the other hominoids. This chapter addresses the problem of the selective forces that might have been behind hominin emergence and that shaped this evolutionary lineage in its early stages. To establish the selection pressures that led to hominin emergence, the following issues will be discussed: (1) The time when the human–chimpanzee split could have taken place according to paleoanthropological and molecular data. (2) The putative traits of the last common ancestor (LCA) of Hominini and extant Panini. The models for the LCA can be constructed only on the basis of the fragmentary fossils of the earliest hominins (ErH) and on the basis of the morphology and behavior of

extant apes. (3) The environment in which the ErH lived and could have been exposed to some specific selection pressures. (4) The hypotheses for the selection pressures for bipedality (SPfB), which is the main diagnostic trait of the hominin clade. Some arguments for and against suggested SPfB according to different hypotheses will be presented. (5) The putative selection pressures related to the dental features of ErH. A much more difficult task is inferring behavior (including the social structure) of ErH. Since the fossils of the earliest hominins are so scarce, inferences as to their behavior are possible mainly on the basis of some features of *Ardipithecus ramidus* (*Ar. ramidus*) representatives, i.e., their overall body size, sexual dimorphism in body size, and sexual dimorphism of the canines. Finally, the future perspective (e.g., through closer integration of paleoanthropology and genetics) for determining the first appearance of derived hominin traits and the selection pressures that acted upon them is discussed.

Introduction

The theory of evolution with its central tenet of Darwinian natural selection provides the scientific framework that gives the opportunity to understand the evolution of all life-forms including the hominins. Some lineage-specific phenotypic traits that can be observed in the fossil record or in living organisms ought to be explicable by certain selection forces. It is assumed that the traits that appeared and were perpetuated in some lineages were adaptive, i.e., were related to an improvement in relative reproductive success or in overall biological fitness, in relation to the specific physical or social environment. The factors that contributed to higher reproductive success of organisms that had some novel phenotypic feature are called selection pressures, and they can act either on morphology, physiology, or behavior. Natural selection is a process by which new adaptive traits (e.g., morphological, physiological, or behavioral) evolve and persist. In a population with heritable variation of traits, this can lead to phenotypic changes over consecutive generations. Although such processes as genetic drift or any other nonselective (random) forces may act on organisms and cause some lasting effects, it is mainly natural selection that produces long-term directional change (Ward 2002).

In the Late Pliocene, when hominins developed Paleolithic technology and became to some extent dependent on culture, they were released from some previously effective selection pressures (e.g., stone tools and the ability to control fire could have dramatically weakened the effect of predation pressure). However, before these inventions, i.e., in the Late Miocene and for most of the Pliocene, hominins were exposed to natural selection factors in the same way as other organisms. This means that for a large part of our evolution, human ancestors were constrained and directed by similar natural pressures to those acting on other organisms. The main types of selection pressures acting on the ErH might have been related to variability in climatic conditions and change in habitat, which can be driven by climate change and is usually strongly related to the types of food available, to predation or sociosexual factors (including sexual selection), and to biomechanical or energetic constraints.

In the early stages of hominin evolution, some specific features emerged that demand evolutionary explanation (e.g., bipedalism and certain dental features). There are, however, a few serious difficulties with the reconstruction of the selection pressures for hominin emergence. Reconstruction of the selection pressures that triggered the Panini–Hominini (P-H) split is today a somewhat more difficult task than it was only 15–20 years ago. This is because in the last two decades, we have gained new fossils that make the picture of human evolutionary tree more difficult to determine. What is more, some fossils attributed by their discoverers to the hominin clade are controversial in terms of the interpretation of features that may be homoplasies or retained hominoid primitive features (Wood and Harrison 2011). The most controversial of these is *Sahelanthropus tchadensis*, dated at over 6 Ma (Brunet et al. 2005), for which we have only craniodental material that was found ca 2,500 km west of the African Great Rift Valley (traditionally seen as the cradle of the hominins). This form exhibited small upper canines (worn at the tip) and the position of the foramen magnum suggests that this form was bipedal. These two traits were recognized as principal indicators of its hominin status (Brunet et al. 2005). Some authors, however, disagree that this form is a hominin and contest the inference, made on the basis of the position of the foramen magnum, that it was bipedal (Wolpoff et al. 2002). Less controversial the earliest hominin is *Orrorin tugenensis* from Lukeino Formation, dated to between 6.2 and 5.6 Ma (Senut et al. 2001; Pickford et al. 2002). Its remains include 13 specimens (fragments of hand, arm, and lower limb). The discoverers of *Orrorin* argued that the dental morphology of this form was "apelike" (its upper canine resembles that of a female chimpanzee) (Pickford et al. 2002). Based on morphology of its femur (BAR 1002'00), humerus, and manual phalanx, it is claimed that *Orrorin* possessed the adaptations both for bipedal locomotion and arboreal climbing (Senut et al. 2001; Pickford and Senut 2001; Richmond and Jungers 2008). Another genus widely attributed to the earliest hominins is *Ardipithecus*, containing two species: *Ardipithecus kadabba* (Haile-Selassie et al. 2004) from Central Awash Complex and the Western Margin, Middle Awash in Ethiopia, dated between 5.8 and 5.2 Ma, and the better-known *Ar. ramidus* dated to 4.4 Ma from the Afar Rift region (northeastern Ethiopia) (White et al. 2009). A relatively complete skeleton of the latter species (ARA-VP-6/500 – Ardi) provides data for the reconstruction of the earliest stages of human evolution and allows suggesting the putative traits of LCA of the Hominini and Panini clades (White et al. 2009). The preservation state of Ardi makes possible the comprehensive study of locomotion, morphology of the teeth, body size, and even sexual dimorphism of the earliest hominins.

The presence of the small canines and the lack of the C/P3 honing complex (characteristic of chimpanzees) in *Sahelanthropus* and *Ardipithecus* are traits they share with later hominins and are described as most indicative of their hominin status (Wood and Harrison 2011). However, as noted by Wood and Harrison (2011), the traits mentioned above are also visible in a number of Late Miocene

Eurasian hominids, and they probably developed in response to dietary behavior changes, induced by ecological conditions. We cannot then reject the possibility that a similar evolutionary response also took place in African Late Miocene hominids. There is similar problem with postcranial evidence for bipedalism in the earliest hominins and in European Late Miocene *Oreopithecus bambolii* (Wood and Harrison 2011). All these observations indicate that recognition of the earliest unquestionable hominins is still a difficult task. One cannot exclude the possibility that the currently ascribed traits to the earliest hominins will appear to be also the features of other members of hominid lineage (e.g., chimpanzee). Only new discoveries of more complete skeletons of Miocene African hominids would help to resolve this issue.

Another problem with the early stage of hominin evolution concerns methodology. Each new trait that appeared in ErH could be a real adaptation that emerged under some specific selection pressure, or it could be a trait that appeared as a side effect of some other functionally adaptive trait. If a new trait that was not under direct selection pressure later acquired some new function, it is called an exaptation. An exaptation – the term was coined by Gould and Vrba (1982) – is thus a trait that was not designed by selection. The appearance of such new by-products, nonadaptive traits, could be due to the effects of pleiotropy. When strong selection acts on a feature determined by a particular gene and if this gene is also responsible for some other feature, the latter feature can emerge irrespective of its adaptiveness and without any specific selection pressure on that particular trait. Thus, the presumption that all anatomical or behavioral traits are adaptively informative (Hlusko 2004) does not always need to be true. This also means that some morphological traits are not independent and should be analyzed as if they were dependent (Hlusko 2004) and not the effect of different selection pressures on each of the new features. We must then be aware that, the case of some derived hominin traits, one can be faced with side effects that were only later co-opted for a new function and which at the time of their evolutionary appearance were not selected specifically for the function they later acquired.

All this makes the reconstruction of the selection forces that triggered the P-H split a very difficult task. To try to decipher the selection pressures that led to hominin emergence on the basis of our present knowledge, the following problems will be addressed in this chapter:

1. The time when the P-H split could have taken place.
2. The putative traits of the last common ancestor of hominins and chimpanzee.
3. The environment in which the ErH lived and was exposed to specific selection pressures.
4. Possible hypotheses for selection pressures for bipedality, the main diagnostic trait of the hominin clade.
5. The putative selection pressures related to the dental features of ErH.
6. Whether on the bases of paleoevidence and socioecological rules, we can infer something about the behavior and social structure of the ErH (inferences from body size, sexual dimorphism in body size, and from canine size in ErH).

This chapter concerns the problem of selective forces that might have been related to hominin emergence and that could have shaped this evolutionary lineage at the stage of the early hominins, i.e., before 3.0 Ma. The selection pressures for the traits that appeared in the genus *Homo* at the end of Pliocene or in Pleistocene will be not analyzed here (e.g., brain size increase, rate of enamel formation, longer development and growth time span, language or cultural inventions, including stone technology, for which the oldest evidence we have comes from ca. 2.5 to 2.9 Ma).

When Did the Hominin Lineage Diverge from the African Extant Hominoids?

Early in the second half of the twentieth century, it was thought that the human lineage diverged from the lineage of living apes sometime between 10 and 15 Ma. This very early date for the origins of hominins was set in view of the strong peculiarities of humans, which were then seen as needing a long time to evolve, and because of the mistaken inclusion of the thick-enameled Miocene Asian ape *Ramapithecus* in the human evolutionary tree. Only in the late 1960s did pioneering molecular analyses (Wilson and Sarich 1969) reveal that the human–great ape split must have taken place at a much later date. The reassessment of *Ramapithecus* taxonomy and a stricter approach to all Miocene and Pliocene hominoid fossils from Africa confirmed that in fact there is no good fossil evidence of hominins before 7–5 Ma. Fossils found later and many new molecular results confirmed that dating. It now seems that there is a quite high concordance between the two kinds of evidence. Although in a range of molecular analyses the split was assessed from 3.6 (Easteal and Herbert 1997) to 13 Ma (Arnason et al. 1998), the bulk of analyses indicated either 7–5 Ma (Glazko and Nei 2003) or more extent 4–8 Ma (Wood and Harrison 2011). It is now generally held that for calculating the time of the human–great ape divergence, nuclear genes are a better guide than mtDNA. The evolutionary changes in mtDNA over time vary among different lineages, and for time estimation, we should use genes that follow a global molecular clock (Glazko and Nei 2003).

Based on the results encompassing the comparison of the genome sequence of the western lowland gorilla with the genomes of the extant hominoids (including *Homo sapiens*), Scally et al. (2012) considered the variation in past mutation rates (10^{-9} mutations per bp per year in the common ancestor of great apes and possibly $0.5\text{-}0.6*10^{-9}$ afterwards) and suggested that the human–chimpanzee split was between 5.5 and 7 Ma and human–chimpanzee–gorilla speciation between 8.5 and 12 Ma.

The majority of paleoanthropologists now agree that hominins appeared between 5.4 and 7.0 Ma. If the controversial Miocene taxa *Sahelanthropus* and *Orrorin* are unambiguous hominins, then this divergence would have taken place closer to 7 Ma than to 5 Ma.

Molecular data also bring an interesting perspective to selection intensity in the hominin and panin clades. The hominin lineage very likely underwent a reduction in effective population size after the divergence from the chimpanzee clade (Chen and Li 2001). This would indicate that our lineage was exposed to more intensive selection pressures than other hominoids. Furthermore, comparative genetic studies also indicate that the speciation event that gave rise to hominins and chimpanzees did not involve an extended period of gene flow between the emerging species (Wakeley 2008). Thus, it is very likely that this speciation was allopatric, i.e., related to geographic isolation of these two clades. This is in contradiction to Navarro and Barton (2003), who suggested that there was a relatively long period of gene flow in collinear chromosomes and therefore hybridization between ErH and its closest contemporary African ape (the ancestral chimpanzee). The long period of genetic exchange between these lineages was also suggested by Patterson et al. (2006), who estimated that human–chimpanzee speciation occurred before 6.3 Ma. These results were, however, later contested by Wakeley (2008).

We can tentatively conclude that knowing the estimated time of hominin emergence and the ecological circumstances of its occurrence in Africa allows reconstructing and perhaps identifying a small pool of possible selective factors that could have driven the P-H evolutionary split.

Last Common Ancestor

One way to infer the nature of the selective forces that were the main causes of the emergence of the hominin lineage from the species described as the "last common ancestor" (LCA) of humans and chimpanzees would be on the basis of the best available knowledge about the morphology of LCA, about the first derived traits that appeared in the earliest hominins, and about the place and environment in which the earliest hominins and the earliest representative of the chimpanzee lineage appeared. Unfortunately, at present, remains of African Late Miocene great apes among which LCA could be found are scarce (Suwa et al. 2007). This means that it is possible to construct models for the LCA on the basis of the fragmentary ErH fossils and on the basis of behavioral ecology of extant apes. It is also possible to infer the nature of the selective forces that existed at that time, because we have some information on the biotopes in which the ErH lived. However, one must be aware that there is no certainty that ErH really emerged in the areas and in the habitats from which we have fossil evidence of these forms.

Previously it was assumed that in cranial capacity, facial or dental features, as well as in postural ability, the LCA generally resembled the extant African apes. This form was described as living and foraging in the African tropical rainforest and using knuckle-walking locomotion on the ground (Richmond et al. 2001). The new specimens of the *Ar. ramidus* changed the views on the morphology and behavior of the LCA of human and chimpanzee lineages. The morphology of the skeleton of *Ar. ramidus* was not transitional between *Australopithecus* and its hypothetical apelike ancestor (earlier considered as similar to chimpanzee) (Lovejoy 2009; White et al. 2009). The traits exhibited by *Ardipithecus* indicate that the LCA probably had a low degree of sexual dimorphism, lacked specializations for knuckle-walking and suspension, had relatively thin enamel in the postcanine teeth, and had an omnivorous/frugivorous diet (Lovejoy 2009; White et al. 2009).

Although currently there are more remains of *Ardipithecus*, there is still an inadequate number of fossils and an absence of an archaeological record which would allow scientists to determine the social structure of the LCA. To reconstruct the behavior and reproductive strategies of the LCA, both parsimony and known socioecological rules are usually used for different behavioral traits present in the extant hominoids. Some scientists claim that the LCA and ErH were behaviorally most similar to the extant chimpanzees (McGrew 2010), but others contest this assumption (Sayers et al. 2012). Taking into account *Ardipithecus* body size and canine size dimorphism, the chimpanzee model might not be the best for inferring the LCA social structure. In order to infer social system of LCA and to avoid the chimpanzee referential doctrine, one should consider the characteristics, present in all extant African hominoids, such as:

- Male philopatry and female exogamy
- Male kin bonding social groups and coalitionary behavior
- Relatively complex interpersonal interactions
- Polygamy

These forms were also relatively intelligent and might have even used some rudimentary tools (view strongly supported by McGrew 2010). If the earliest hominins were sexually dimorphic in body size, the dinichism of LCA could be also inferred. Females could have had smaller home ranges and a somewhat different diet, e.g., as a smaller form, they could have more frequently used trees not only to escape from predators but also as a source of food and shelter.

Knowing the main evolutionary morphological adaptations that appeared in hominin evolution allows scientists to concentrate on the features that are distinctive of our close living relatives (the great apes). On the basis of this knowledge, modern Darwinian theory allows to make intriguing inferences about the selective pressures that could well have been responsible for the new (i.e., derived) traits that characterized the emergence of hominins.

Climate and Environment at the Time of Hominins' Emergence

There is a general premise that shifts in climate alter habitats and thus constitute selection pressures leading to speciation (DeMenocal 2004). It is known from many evolutionary lineages for different animals that key turnover events took place during times of climatic and ecological change (for more detail about climate influences on hominin evolution, see Vrba, chapter "▶ Role of Environmental Stimuli in Hominid Origins," Vol. 3). Until the late 1980s, it was assumed that the earliest hominins lived in open savanna environments and that the biotope they inhabited was a principal factor in the emergence of the hominins. The change of the east Africa environment to a more open, drier, and cooler habitat has been proposed as a main cause for the most important adaptive changes in hominins' evolution during the Plio-Pleistocene ("savanna hypothesis") (Vrba et al. 1989). However, with the addition of new paleoecological data from hominin fossil sites dating from the Late Miocene to the Early Pliocene, this hypothesis has been seriously undermined. We realize now that ErH lived in more mixed or wooded settings (Cerling et al. 1997; Brunet et al. 2005; Le Fur et al. 2009; WoldeGabriel et al. 2009; Blondel et al. 2010) and that the widespread expansion of more open environments in Eastern and Southern Africa took place a few million years after the emergence of bipedality (e.g., DeMenocal 2004, 2011).

Between 4 and 1 Ma, the main faunal turnover in the Turkana Basin occurred at four main periods: 3.4–3.2, 2.8–2.6, 2.4–2.2, and 2.0–1.8 Ma (Bobé and Behrensmeyer 2004). The second and third intervals seem to coincide with the presence of *Paranthropus*, and the last one with grassland expansion and the first appearance of *Homo ergaster*. Pollen analysis also indicates that it was only after ca. 3 Ma that expansion of xeric vegetation took place (Dupont and Leroy 1995). Also, stable isotopic analyses of pedogenic carbonates from Turkana and Olduvai indicate a step-like increase in open habitats ca. 1.8 Ma (Cerling 1992). There is evidence that climatic and habitat changes triggered selection pressures that resulted in the emergence of *Paranthropus* and *Homo* and that they also triggered selection for the origin of other hominins (DeMenocal 2011).

Reed (1997) reconstructed Plio-Pleistocene habitats on the basis of the analysis of mammalian fossil assemblages. She compared eight vegetative habitat types in order of tree density forests: closed woodland, woodland bushland transition, medium density woodland and bushland, open woodlands, shrubland, grasslands, and desert. It is not surprising that the percentage of arboreal locomotion decreases as these habitats progress from forest to desert. Using fossil mammals from different African sites, Reed (1997) showed the relationship between habitat type and two ecovariables (locomotor and trophic). These two variables proved to be better indicators for habit differentiation than body size. According to her analysis, the percentage of arboreality and frugivory between 3.6 and 1.8 Ma in East Africa demonstrates closed to open woodland habitats. Only later does it drop to percentages indicative of shrub and grassland. All this means that there is more evidence that climatic and habitat changes triggered selection pressures that resulted in the emergence of *Paranthropus* and *Homo* than that they triggered selection for the origin of earlier hominins.

Paleobotanical and faunal evidence clearly indicate that the sites bearing fossils of *Orrorin* (Pickford et al. 2002), *Ardipithecus* (WoldeGabriel et al. 2009), *Au. anamensis* (White et al. 2006), and *Au. afarensis* represent mainly tree-dominated habitats (predominantly closed woodland). Although *Au. anamensis* (Leakey et al. 1995) and *Sahelanthropus* (Vignaud et al. 2002; Le Fur et al. 2009; Blondel et al. 2010) probably lived in more mosaic environments (gallery forests at the edge of lakes and savanna and grassland away from lakes), the places where they were found are related to a lacustrine type of gallery forest. These new data displace the long-held idea that bipedalism first emerged when climate change forced our ancestors to live in open environments. The "savanna hypothesis" gained a serious opponent called the "forest hypothesis" (Rayner et al. 1993), which states that it was dense vegetation that played an important role in the evolution of early hominins. It is the forest hypothesis that explains why ErH retained upper limb morphology with the functional capacity to climb trees (see next section). Data from western and southern Africa clearly indicate that the savanna hypothesis may instead be applicable to the emergence of the *Paranthropus* and *Homo* genera and not to the divergence of hominins from other hominoids (Bobé and Behrensmeyer 2004; DeMenocal 2011).

The change to more open habitat cannot, however, be completely excluded as a possible factor that triggered the acquisition of upright posture and the appearance of hominin lineage. It is possible that this bipedality emerged in the open environment in another region of Africa that is a still unknown cradle of hominin origin. Although the distribution of grassland before the Pliocene remains unclear, open habitats were present in Africa from the Middle Miocene (Retallack et al. 1990). Paleobotanical studies show that grass-dominated savanna became widespread both in west and east tropical Africa in the Late Miocene (ca. 8 Ma) (Jacobs 2004). This is documented by pollen and carbon isotopes. In the Late Miocene, Asian monsoons also influenced North and East Africa (Griffin 2002), and there was substantial environmental change from dense woodlands to grasslands or open woodlands in Asia (Barry 1995). Increased aridity around the Mediterranean and North Africa could also have led to the regional differentiation of apes. It is quite likely that such changes were not just coincidental with the rise of the hominins. Furthermore, if, as some claim (Rook et al. 1999; Wood and Harrison 2011), *Oreopithecus bambolii* in Europe was a biped and if this trait evolved in an open environment, then there is a strong argument that open habitat could be related to selection pressure that could have led to upright posture. All this means that there is no certainty whether the discovered fossil sites really represent the hominin cradle. They might just reflect later expansion of hominins from places with more open habitats.

New studies on the stable carbon isotopes in fossil soils from hominin sites in eastern Africa (Awash and Omo-Turkana basins) showed that since ca. 7 Ma woody cover was less than 40 % at most hominin sites examined (Cerling et al. 2011). This would mean that over the past six million years in eastern Africa, open habitats predominated. This result is surprising because the carbon isotopes analysis from the teeth of several *Ar. ramidus* individuals showed that they consumed C3 plants in woodlands or in patches of forests (Louchart et al. 2009; White et al. 2009). Furthermore, these hominins' bearing sites were rich in fragments of fossilized wood, and the analyses of the isotopic paleosol compositions indicate wooded conditions (WoldeGabriel et al. 2009). This might, however, be reconciled with time-frame results obtained by Cerling et al. (2011). They found that from Late Miocene to Early Pliocene (about 5.7–4.4. Ma) in Awash Valley and between 7.4 and 5.7 Ma in Omo-Turkana Basin, there was sparse wood cover. They also indicate that in this region of Africa, there was expansion of woody vegetation during the middle Pliocene. The same authors suggest that open habitats were associated with presence of the earliest hominins and that *Australopithecus* lived in more wooded environments. If they are right, it means that the emergence of the hominin clade could be associated with the significant shift in habitat conditions occupied by ancestors of the first hominins and that the "savanna hypothesis" may be reinstated as a potential hypothesis explaining the appearance of the bipedality. Further data are needed to resolve this problem.

Apart from two "habitat selection" hypotheses, there is also the "variability selection" hypothesis (Potts 1998), which is discussed in detail by Vrba. This hypothesis says that climate-driven habitat fluctuations over the last 6 Ma in Africa created disparity in adaptive conditions and caused habitat-specific adaptations to be replaced by morphological and behavioral adaptations to complex environmental changes (Potts 1998, 2012; Donges et al. 2011). It points to environmental instability as a main factor of selection among hominins for higher plasticity and new "multihabitat" adaptations. The crucial adaptations of the hominins seem to confirm that this group became adapted to variable environments. Bipedal locomotion and the retained tree climbing ability of the australopithecines made it easier to move relatively effectively both in densely forested and in open habitats. Dental traits adapted to hard and soft food, large brain volume, complex social behavior, and cultural adaptations in *Homo* permitted flexible responses to quite a wide diversity of climatic and habitat conditions.

Although the variability hypothesis is very attractive and seems to explain the high plasticity of early hominin morphology adapted to different habitats, behavior, and later technological inventions, it is not in line with the basic selection mechanisms working in relation to the acting present environmental and social conditions. Unless environmental changes happened really fast, it is hard to believe that for organisms with a generation time of 16–20 years (and for early hominins even less: 10–14), in a period of 40–100 thousand-year cyclicity, selection would keep costly adaptations for conditions prevailing in the distant future. One could also ask how the proposed frequent periodicity worked in the lineages of any other extant taxa.

Bipedal Locomotion as the Most Difficult Trait to Explain for the Early Hominins

There are many long-standing questions in paleoanthropology, but one of the most fundamental is why, in one lineage of hominids (but controversial *Oreopithecus*), selection promoted a new form of locomotion. Bipedalism is the hallmark trait for hominin evolution and its evolution poses a great conundrum for paleoanthropologists. The explanation of the emergence of this trait in human earliest ancestors is important, because this new locomotor pattern probably made possible (i.e., was a preadaptation to) the next great evolutionary jump, the emergence of the genus *Homo*, with its relatively bigger brain and with a postcranial anatomy almost indistinguishable from ours.

We neither want to address here the morphological and biomechanical aspects of bipedality nor to discuss the debate on the differences in bipedal locomotion between different forms of Hominini. What we want to touch on in this chapter are the putative selection pressures for the emergence of this unusual, for primates, way of locomotion and the putative pressures for enhancing the effectiveness of this locomotion in early *Homo*.

Many hypotheses have been put forward to explain bipedality. The first one came from Darwin, who suggested that it was the pressure for freeing the hands for the use of tools or weapons (Darwin 1871, p. 80). The problem with this, and with several later hypotheses, is that the proposed selective force could have been the consequence and not the cause of this evolutionary trait. Darwin himself was already aware of the risk of feedback loops between causes and consequences and recognized the difficulties of trying to disentangle them.

To think about the possible selection pressures for a new way of locomotion, it should first be considered what is already known about:

1. Locomotion of our pre-bipedal ancestors
2. Time and possible place where bipedality could have emerged
3. Climate and habitat in the areas where bipedality could have arisen

(Ad 1) Two main hypotheses have been proposed earlier on the prevailing locomotion of our pre-bipedal ancestors: brachiation (hylobatid-like) and terrestrial knuckle-walking (chimpanzee-like). The newly discovered fossils of *Ar. ramidus* throw a new light on the problem of origin of the bipedality in the hominin clade. According to the discoverers of *Ar. ramidus*, these hominins moved in the trees using palmigrade clambering and walked upright on the ground in woodland habitat, but their terrestrial bipedality was more primitive than that of *Australopithecus* (Lovejoy 2009). *Ar. ramidus* skeletons lacked any traits characteristic of knuckle-walking, suspension, or vertical climbing (e.g., the hand exhibited short bones of the palm and lack of the stiff wrist joints) (Lovejoy et al. 2009a). The pelvis of "Ardi" was useful for climbing and walking (e.g., upper blades were shorter and broader than in extant apes) (Lovejoy et al. 2009c). The foot of these hominins with opposable big toe exhibited the traits useful for upright walking both on the ground and on branches in the trees (Lovejoy et al. 2009b). *Ar. ramidus* remains indicate, then, that the LCA was probably not chimpanzee-like and that *Ar. ramidus* inherited arboreal capabilities from the LCA (White et al. 2009). The primitive traits of the *Ar. ramidus* skeleton provide a new perspective on the derived postcranial characters of *Australopithecus*. Relative to *Ar. ramidus*, *Au. afarensis* exhibited specializations visible in hand, foot, and pelvis, indicating that this hominin abandoned locomotion in the trees probably due to the emergence of new feeding patterns.

(Ad 2) There is direct evidence of bipedality from 4.4. Ma in *Ar. ramidus* and also from 4.2 Ma in *Au. anamensis*. As far as older hominins are concerned, there is still some disagreement. The foot bones fossils belonging to *Ardipithecus kadabba* (Haile-Selassie 2001) show mosaic morphology, and the position of the foramen magnum in *Sahelanthropus* is only indirect and weak evidence for bipedalism. Wolpoff et al. (2002) claim that the position of the foramen magnum excludes an upright position of the head and therefore made bipedality obligate in this form.

More certain diagnostic features for habitual bipedal locomotion are found in fragments of three femora of *Orrorin* (Pickford et al. 2002). If the earliest known hominin forms were really bipedal, this mode of locomotion, and therefore hominins themselves, must have appeared before 6 Ma. From a more conservative point of view, it might have appeared only between 5 and 4 Ma. Fortunately, accepting the first or the second date does not greatly influence our further analysis of the putative selection forces. This is because the habitats in which all ErH were found seem to be quite similar and therefore do not greatly change the inferences about the possible natural selection factors on the emergence of bipedality.

(Ad 3) The majority of the hypotheses on the SPfB are in a direct or indirect way related to the habitat in which the ErH lived. Thus, to verify all these hypotheses, we need to reconstruct the climate and habitats in which the ErH lived. On the basis of new data, some suggest that early stages of hominin evolution in Africa were related to open environments – a hypothesis that also predominated in the twentieth century. Since most evidence indicates that all forms older than 4 Ma lived in wooded habitats, currently the "woodland hypothesis" still dominates. Although those few fossil sites with Miocene and Early Pliocene forms for which there is paleoecological evidence provide quite a strong argument for a habitat in which bipedality could have emerged, this is nonetheless not unquestionable proof that bipedality and hominins evolved in such a habitat. The other problem is the question of how many times could bipedality have arisen among hominoids? The majority claim that this happened only once, but there are also proponents of more than one emergence of bipedality in hominoids (Rook et al. 1999; Wood and Harrison 2011). If *Oreopithecus bambolii* was also a biped (as Rook et al. 1999 claim) and if this form had nothing to do with the later hominins, this would mean an independent evolution of bipedality.

Having knowledge about these three points allows to narrow down the possible scenarios of selection pressures that could have been the cause of bipedality and most likely the evolution of the hominins.

Putative Selection Primers for Bipedal Locomotion

We know much more about the evolutionary stages of morphological adaptation to bipedal locomotion (see chapter "▶ Origin of Bipedal Locomotion," Vol. 3) than about the selection pressures involved in this process. The first difficulty is related to the uniqueness of this adaptation among primates. There is no living nonhuman species that could be used for comparison to allow distinguishing some potential selection factors promoting such a type of locomotion. The second problem lies in the fact that *Homo*-type bipedality emerged not in a short period of time or as an effect of one sudden event, but rather as a more gradual process (or rather with two evolutionary steps) over a long period of time. As far as postcranial anatomy is concerned, in all pre-*Homo ergaster* forms of Hominini, there is some combination of human and ape features (Wood and Lonergan 2008; Pickering et al. 2011).

This implies some degree of locomotor diversity and that at different stages of the elaboration of bipedal locomotion, different selection factors might have been involved. There are more plausible hypotheses regarding the pressures resulting in the changes related to the last stage of bipedalism that appeared in *H. ergaster* than regarding those related to the first stage. Furthermore, different selection pressures can be inferred, depending on whether all australopithecines were habitual bipeds or if they were only facultative bipeds.

The evolution of bipedalism requires adaptive explanation, not only because it is unique among primates but also because in comparison to quadrupeds this mode of locomotion has certain disadvantages (e.g., reduced speed and agility) and was related to the effective enforcement of some costly but necessary morphological changes. The question "why, then, did bipedalism evolve at all?" is crucial because it is very closely related to the answer to the question of what selection process caused the evolutionary appearance of hominins.

Many hypotheses have been advanced to explain the diagnostic and fundamental hominin trait of bipedality. So many concepts have been suggested that they can be divided into a few categories (Rose 1991; Niemitz 2010). Due to the limited space, and the limited plausibility of many of them, we are not going to describe all of them in detail. Some hypotheses violate the presently known temporal sequence of adaptations that appeared in our evolution; some seem to take consequences for causes; some suggest behavioral activity that can be performed as effectively when using, for instance, knuckle-walking locomotion; and still others are based on wrong presumptions about the habitat in which the earliest hominins lived. Furthermore, some hypotheses are very speculative, i.e., with no paleoanthropological evidence to support them, and some are very unlikely, e.g., due to the very weak or only very temporarily acting suggested selective pressure.

The majority of ideas are related to various behavioral pressures, e.g.:

a. Increasing viewing distance above tall grass (Oakley 1954; Dart and Dennis 1959)
b. Grass seed eating (Jolly 1970)
c. Freeing hands for using tools or weapons (Etkin 1954; Washburn 1967)
d. Load carrying (Preuschoft 2004) – but the same selector is also suggested only for the later *Homo* body proportions (Wang and Crompton 2004) – or more specifically carrying food (Hewes 1961; Isaac 1978; and in the sexual and reproductive strategy model of Lovejoy 1981) or tools and other valuable objects (e.g., unpredictably available food) Carvalho et al. 2012
e. Hunting or scavenging (Rodman and McHenry 1980)
f. Bipedal threat display (Livingstone 1962; Jablonski and Chaplin 1993) or "fighting from a bipedal posture" (Carrier 2011)
g. Terrestrial feeding postures when harvesting on small fruits of low, open-forest trees (Hunt 1994)
h. Walking and running (Jungers 1988; Bramble and Lieberman 2004)
i. Stone throwing (Fifer 1987; Dunsworth et al. 2003)

On the base of current knowledge, some of these hypotheses can be excluded (or treated as only of historical interest). This is because bipedality predated the use and manufacturing of stone tools (argument against c) and probably did not evolve in an open environment as was once assumed (a, b), and it predated robust hominin dental complex (b), predated hunting (e) and social structure changes, which could be related to provisioning females with meat food (d). Because of the high energetic cost of load carriage, infant carrying was also unlikely as precursor to bipedal locomotion (Watson et al. 2008). The hunting hypothesis (Brain 1981) can be applied as a selection force only for Late Pliocene hominins. ErH were rather the hunted than the hunters, and this also means that predation pressure on ErH in Late Miocene and in most of the Pliocene could have been quite strong and therefore could have influenced hominin evolution. The main predators of our ancestors were probably the leopard (*Panthera pardus*), saber-tooth felids, and possibly hyenids. Only very rarely in extant apes are such behaviors as throwing objects manifest (i) or bipedal display (f); thus, these factors are a very unlikely selection pressure to posture habitual bipedalism (against (i) and (f)). Although aggressive behavior can be associated with locomotor bipedalism, it is observed mainly in male chimpanzees in captivity (Thorpe et al. 2002). The other argument against this hypothesis (f) is small dimorphism in the body size of the *Ar. ramidus* and therefore probably low intermale aggression in the early hominins.

The cost of running for the type of bipedality used by ErH was probably higher than the cost of walking; therefore, possible selection for *Homo*, such as bipedal running, was rather an unlikely pressure for the emergence of bipedality. Biomechanical and energy saving hypotheses are usually proposed for the more humanlike bipedalism in *Homo* (Preuschoft 2004; Ruxton and Wilkinson 2011a).

The analysis of relative thumb length in *Au. afarensis* (Alba et al. 2003), however, reveals a similar proportion to that in present-day humans. This would mean a high precision grip capability in *Australopithecus* and would therefore be a strong argument for the hypothesis of the evolutionary causes of bipedality under the selection for manipulative skills in these hominins. Although this would support Darwin’s proposal (c) or others related to freeing the hands (b, d, e, i), one should remember that with these particular hypotheses, there is also the problem of the possible reciprocal causation of causes and consequences.

The second group of hypotheses is related to morphological, biomechanical, and/or physiological response to the physical environmental influences. One theory that in the 1980s seemed quite probable was the hypothesis of the avoidance of thermal stress (by decreasing body surface exposed to the direct overhead sunlight during midday, which allowed increased daytime foraging) in open environments where there is a strong diurnal insolation. This was first suggested in 1984 and later elaborated by Peter Wheeler. Since this hypothesis is inextricably related to open habitats, it is rather unlikely explanation for the origin of bipedality in ErH (Ruxton and Wilkinson 2011a). It would rather be applicable to the new adaptations that probably appeared only in the genus *Homo*, e.g., fur loss and elaborate thermoregulation by eccrine glands or endurance running (Ruxton and Wilkinson 2011b).

Another hypothesis is the very controversial idea of the aquatic or semiaquatic ape (Hardy 1960; Veerhaegen 1985; Morgan 1997), which states that upright posture appeared as an effect of selection for breathing air and for streamlined body shape in hominins who spent a lot of time in sea water, where they had to dive for food. This hypothesis also explains loss of body hair, brain size increase, and increase of subcutaneous fat tissue and newborn size (and even long hair on the head) as adaptations to the aquatic environment. It is a very speculative hypothesis, without fossil evidence, any similar reference within the primate order, and knowledge about the long time span sequence in the appearance of all these traits in Hominini. There is, however, also a more likely scenario that is related to littoral wading and is called "shore dweller hypothesis" (Niemitz 2010) and "waterside dweller" (Veerhaegen et al. 2007). These hypotheses are based on suggested advantages that could favor wading behavior and investment in high-quality food collection on shorelines. It also assumes that the ancestor of human clade was ecologically nonspecialized. This hypothesis is interesting and seems to be in accordance with the suggestions about omnivorous diet of LCA (Suwa et al. 2009). But whether wading behavior could stimulate our ancestor to stand up and bipedal walking, as suggested by Niemitz (2010), is still debatable. Although the data on seafood reliance by hominins (Braun et al. 2010; Steele 2010) seems to support this scenario, more evidence to connect the origin of bipedality with wading is needed.

What seems to be a likelier selection force for bipedality is the hypothesis proposed by Hunt (g). Although in nonhuman primates bipedal posture or locomotion accounts only for less than 5 % of total locomotion, the majority of what is observed is related to food acquisition (Rose 1991). Studies by Stanford (2002) also provide new data on relatively frequent arboreal bipedal posture (arm assisted) by chimpanzees when foraging for small fruits (mainly figs). Although an earlier concept by Washburn (1963) was also based on the chimpanzee model and feeding adaptation in bipedal locomotion, it emphasized terrestrial (and not arboreal) bipedal posture as a preadaptation of ErH that emerged in savanna habitats. The new data on the ErH habitats and on arboreal bipedality by chimpanzees support Hunt's hypothesis. Limb-length proportions in australopithecines indicate that their bipedality was rather related to the less energetically costly walking than running. This seems to support the view that the primary pressure could have been related to the postural feeding bipedalism and walking between clumped food sources (Rose 1984; Hunt 1994). On the basis of skeletal biology and ontogeny, it is rather unlikely that bipedality would have evolved only as a result of pressure for stationary bipedal posture. Bipedal walking must have been involved (Ward 2003), for instance, as in chimpanzee who use bipedal locomotion for transporting valuable food and objects (Carvalho et al. 2012).

The other cue for solving the problem of SPfB is the body size of the ErH. The postcranial remains of *Ar. ramidus* indicate that these hominins were relatively small (White et al. 2009); thus, it is possible that bipedalism emerged in relatively small forms that were forced to undertake longer terrestrial or arboreal walking (McHenry 1984). If there was selection pressure for bipedal posture among small-bodied hominins in the food acquisition context, then one can postulate that this pressure must have been the strongest for young (smaller) individuals who had even more difficulties in reaching the food source when it was above their heads. If they very often had to use upright posture while feeding, and if the food was relatively closely clumped (close to each other), frequent raising up of the whole trunk and the arms and stretching of the legs could have been more energetically costly than moving between these closely distributed fruits on two legs. If food acquisition pressure holds true, the costs for the behavior mentioned above must have been higher than for bipedality. Furthermore, when one arm was needed to hold and bend a branch and the second to collect food, the pressure for bipedal postural behavior and slow bipedal movement would have been even stronger. For small infants and young individuals that were already independent from mother's milk, reaching highly positioned food could have been possible only with maximal extension of the body and arms. Together with the need to climb trees, such postural feeding would also explain why arms were not shortened and fingers were still curved at this stage of hominin evolution.

According to fossil data and the molecular clock and considering how much complex rebuilding was needed to walk bipedally efficiently, we can say that natural selection acted really rapidly on the transformation of the hindlimb in the earliest stages of hominins' evolution. The evolution of the upper limb, rib cage, or even vertebral column was, however, much slower. What may be then important in determining putative selection pressures on the bipedality is to determine whether early Hominini, apart from their upright posture, were also effective tree climbers. If arboreality was unimportant in early bipedal forms, one can assume that it was biotope change that could have influenced this dramatic change. In the case of retention of arboreal agility and parallel adaptation to both types of locomotion, i.e., until the appearance of *Homo*, one needs to consider different selection pressures.

Australopithecines retained relatively plesiomorphic upper-limb morphology, but what is hotly debated is the adaptiveness of this ErH trait. Although it is still difficult to explain the retention of this primitive apelike character, there are only a few possible explanations for it: stabilizing selection for skilled arboreality, evolutionary inertia, pressure for a new kind of arboreality, change of diet at the time when bipedality appeared, or some specificity of ErH locomotion.

The arboreal environments in which the earliest hominins lived indicate that they could have spent quite a lot of time as tree dwellers, which would seem to explain the retention of prehensility and primitive upper-limb morphology (Lovejoy et al. 2009a). The *Ar. ramidus* postcranium indicates palmigrade clambering in the trees and more primitive terrestrial bipedality than in *Australopithecus* (White et al. 2009). According to Lovejoy (2009), upright walking probably did not provide energy advantage for *Ar. ramidus*; thus, these hominins lacked many of the adaptations which appeared in *Australopithecus*. White et al. also suggest that the further musculoskeletal adaptations (visible in *Australopithecus*) associated with more advanced terrestrial bipedality might have been the response to carry foods, simple tools, and/or offspring.

Using forelimbs for support when feeding could be a possible selection for the upright stature, as Hunt (1994) suggests. Similar to apes, an upwardly directed shoulder joint in *Au. afarensis* indicates that this form could have frequently directed its arms upwards (Green and Alemseged 2012; Larson 2012). All this might mean that the early hominin morphology, in effect, was a compromise for different locomotor patterns. Living in forested areas is a strong reason to have the possibility of also exploiting arboreal food resources and, therefore, of retaining the capability to climb trees.

According to the basic pattern of the genetic mechanism of limb development, there is strong covariance between the morphology of the upper and lower limb. It might then be that it was strong selection for shorter toes that caused the shortening of the fingers in ErH (Hlusko 2004), and shortened fingers should not be treated as an indication of the lack of selection for arboreality in these hominins. Shortened fingers would be then a side effect for bipedalism and an exaptation for tool using and manufacturing.

Our grasp of the selection mechanisms that were related to the emergence of bipedality and hominins will increase as more new fossils are recovered both from the Late Miocene and Early Pliocene and with the advances in the understanding of developmental and epigenetic processes (Ward 2002; Larson 2012).

Selection Factors Inferred from the Teeth and Masticatory System of Early Hominins

In addition to bipedality, the second important set of traits that seems to be connected with the appearance of the Hominini and that allows us to reconstruct the putative selection pressures that triggered the human–chimpanzee split is found in a number of features of the dentition. Teeth are not only more abundant as fossils than bones are (and especially those bones that directly indicate the mode of locomotion), but they are also easier for inferring the selection pressures which acted directly on them. Current knowledge of the adaptive meaning of relative tooth size and shape, enamel structure and thickness, microwear, and canine size is much better than of bipedality, which is not directly detectable in the earlier-known fossil record. These traits, together with the general robusticity of the masticatory system, are related not only to body size but primarily to diet (Andrews and Martin 1991). Food type and availability, and the locations in which food could have been found, probably constituted strong selection pressures on hominin evolution.

The diet of the ErH can be inferred from the teeth of *Ar. ramidus*, *Ar. kadabba*, *Sahelanthropus*, and *Orrorin*. The morphology of the crown of *Ar. ramidus* molars was not similar to those characteristic of *Pan*, *Gorilla*, and *Pongo*, and the other traits of these hominins' dentition (e.g., the incisors that were not as large as in *Pan* and *Pongo*) imply a diet different from extant apes (Suwa et al. 2009; White et al. 2009). *Ar. ramidus* lacked the enlarged rear teeth of *Australopithecus* that have been interpreted as adaptations to abrasive diet (heavy chewing) in open environments. The co-occurrence of the small canines with small molar crowns in *Ar. ramidus* can suggest that small canines appeared early in hominin evolution within the context of a nonspecialized diet (White et al. 2009).

All hominins living before 3.5 Ma had teeth with thicker enamel than chimpanzees. From the functional point of view, this means that EH were better adapted to eat abrasive food than extant apes. The molars' enamel of the *Ar. ramidus* appeared thinner from enamel exhibited by molars of earlier hominins and *Australopithecus*; thus, in comparison to them, *Ar. ramidus* diet was less abrasive. It is worth to note that the Miocene African apes, which gave rise to both living African apes and hominins, had relatively thinly enameled teeth (but thicker than in *Pan*) (Suwa et al. 2009). According to Sayers et al. (2012), the dentitions of the extent *Pan* and *Gorilla* are derived from that of their hypothetical LCA – e.g., *Dryopithecus* and all earliest hominins (including *Sahelanthropus*, *Orrorin*, and *Ardipithecus*). They stressed that molars of the *Ar. ramidus* showed some important similarities with those of *Dryopithecus* and *Pierolapithecus* (Miocene taxa of great apes) including bunodont crowns with low cuspal relief and also greater enamel thickness than in chimpanzees (Suwa et al. 2009); thus, *Ar. ramidus* is more similar to ours and *Pan*'s LCA than chimpanzee. The reconstruction of the evolutionary history of enamel thickness in the case of Miocene apes is a very difficult task, because of the uncertainties concerning their phylogeny. Alba et al. (2010) suggest that thin enamel could have independently evolved several times in hominid phylogeny and that thick enamel can be considered as the symplesiomorphy of the great apes and human clades. If they are right, it would mean that LCA had thick teeth enamel.

Macro- and microscopic wear patterns in *Ar. ramidus* molars indicate that these hominins had less abrasive diet and did less masticatory grinding than *Au. afarensis* (Suwa et al. 2009). Recently, the dental microwear texture analyses of hominin cheek teeth in specimens of *Au. anamensis*, *Au. afarensis*, and *Paranthropus* showed that none of the *Australopithecus* and *P. boisei* teeth have surfaces indicating that these hominins were hard-object feeders. Only *P. robustus* had teeth specialized for a diet based on harder items (Ungar et al. 2008, 2010, 2012). The results of these studies were surprising, because although *Au. anamensis* and *Au. afarensis* were from different habitats, their teeth show similar pattern of microwear complexity. The structure (including the thickness of the enamel) and the pattern of wear of the crowns of *Ar. ramidus* teeth indicate that this hominin's diet was not specialized and was less abrasive than that of later hominins (Suwa et al. 2009). It is probable that the LCA of human and chimpanzee lineages had the same nonspecialized diet as suggested for *Ar. ramidus*, i.e., omnivory and frugivory.

The results of the isotopic analysis of *Ar. ramidus* tooth enamel indicate that these hominins consumed mainly C3 plants (~85–90 %) in woodland habitats and small patches of forest. Savanna woodland-dwelling chimpanzees' intake was more than 90 % C3 plants, and *Australopithecus* (robust and nonrobust) consumed more than 30 % C4 plants (Suwa et al. 2009; White et al. 2009). Carbon isotope analyses, including those of hominin teeth from 4.4 to about 0.8 Ma, indicate dietary diversity and complexity. *Ar. ramidus* had C3 diet similar to chimpanzees and *Au. africanus*, *P. robustus*, and early *Homo* consumed more than 50 % C3 plants and also nearly similar quantity of C4 foods (Ungar and Sponheimer 2011). Thus, earlier ideas about the increasing dominance of hard objects in the diet of early hominins have been challenged (Ungar and Sponheimer 2011). The shift from C3-dominated diet to more middling diet (nearly the same proportions of the C3 and C4 food in diet) observed from *Ar. ramidus* to later hominins suggests the expansion of the *Australopithecus* into more open habitats. Taking into account the recent discovery at Dikika (Ethiopia) of the stone-tool-inflicted marks on animal bones older than 3.39 Ma, one cannot exclude the possibility that some species of *Australopithecus* (e.g., *Au. afarensis*) used stone tools for meat and marrow consumption (McPherron et al. 2010) and that these forms had a more expanded geographical range than the EH.

The paleofauna, plant fossils, isotopic composition of soil samples and teeth all indicate that *Ar. ramidus* lived in woodland with patches of forest (WoldeGabriel et al. 2009). It is supposed that *Ar. ramidus* relied on a wider range of woodland foods than chimpanzees but did not like *Australopithecus* rely on open-biotope foods (White et al. 2009). All this seems clear when one look at the available fossils of *Australopithecus*, but inferring the putative dietary selection pressure acting on the P-H split is somewhat more complicated. *Ardipithecus* had still relatively thin enamel (White et al. 2009) and was forest dwelling, and these lines of evidence are against the prime-mover strong selection for a dietary change that might have triggered a P-H split. If, however, either *Sahelanthropus* or *Orrorin* was the first hominin, and both had relatively small canines and thicker enamel than *Ardipithecus*, then the possibility that the selection for a dietary shift was one of the causes for hominin emergence cannot be excluded. In that case, dental features would show the influence of dietary selection pressures from the very point of origin of the hominins.

According to the present knowledge of the dental features of ErH and the suggested hypotheses of selection pressure for upright posture, the most likely scenario for the selection pressure that triggered the P-H split would be adaptation to more variable food, including some clumped and small fruits that were easier for ErH to reach via an upright body position in the trees (Hunt 1994) or possibly from the ground. This scenario can also be inferred on the basis of the relatively small incisors in ErH (Suwa et al. 2009). This is because primates eating smaller fruits ingest them without extensive incisor preparation (Ungar 1994). Relatively longer thumbs in australopithecines (Alba et al. 2003) would support this hypothesis. However, unless more certain fossils of the ErH are found, to fully answer the question of whether selection for new diet was intimately connected with the P-H separation will not be possible.

Inferences About Behavior and Social Structure of the Early Hominins

Fossil evidence provides scientists with information about the skeletal or dental morphological features that appeared in the early hominins. A much more difficult task is inferring behavior (including species-specific social or mating structures) from these very scarce fossils. This is much easier for later forms of hominins (e.g., *Homo*) for which there are more fossils and such archaeological records as stone tools or animal bones with cutmarks. In general, paleoanthropologists have almost the same idea about the behavior of the earliest hominins as about the behavior of the LCA. Nonetheless, they try to use all possible hints to reconstruct the behavior and social structure of the ErH. With no direct evidence of early hominin social structure and behavior, one can only propose some models that are not in disagreement with the fossils. Apart from features of locomotion and diet that probably modified ErH behavior in relation to the ancestor, other aspects of behavior and social structure do not seem to be very different. What can be inferred about behavior or the mating system of the ErH is based mainly on overall body size, sexual dimorphism in body size, and sexual dimorphism of the canines.

Since fossils of the earliest hominins are so scarce, one can only infer their behavior on the basis of some features of new remains of *Ar. ramidus* and later *Au. afarensis*. Recently it was shown that *Ar. ramidus* exhibited less dimorphic skeletal body size than *Australopithecus* (White et al. 2009). This, similar to *Pan*, sexual dimorphism in size (SDS) in *Ar. ramidus* suggests a male-bonded social system. According to Sayers et al. (2012), the morphological traits of the "Ardi" skeleton indicate that the LCA was anatomically and behaviorally different from chimpanzees. In contrast, McGrew (2010) asserts that based on the current knowledge on chimpanzee behavior, one should infer the trait of our LCA. Below are putative selection pressures and behavioral consequences of body size and sexual dimorphism of the ErH.

Were There Any Selection Pressures on Body Size of Early Hominins?

Body size is very informative about animal socioecology, life history (see Zimmermann and Radespiel chapter "▶ Primate Life Histories," Vol. 2), and possible selection pressures that can act on differently sized animals. For example, smaller forms have more predators, smaller ranges, and less protection against hypothermia. The advantages of having a bigger body size are manifold: a lower predation risk, better control over the environment, higher mobility, bigger brain, longer infancy, and therefore longer time for learning and a longer lifespan. Disadvantageous consequences, however, are also present: longer gestation and infancy means longer maternal dependence, and more food and a bigger foraging area (home range size) are needed (Clutton-Brock and Harvey 1980). Without knowing the size of the LCA, it is difficult to speculate about any selection pressure for body-size change in the ErH. If they lived in a forested environment as their ancestors did, then it is rather unlikely that there was any pressure for changing body size that was independent from the pressure for greater bipedal biomechanical efficiency. What is known for sure is that a change in size did take place in the Late Pliocene, when *Homo* emerged.

Until the relatively recent discovery of "Ardi," early hominin body size and sexual size dimorphism were inferred from *Au. afarensis*, and the main reference fossil specimen was "Lucy" (AL-288), which had preserved ca. 40 % of the skeleton. Now these inferences can be made on the basis of most complete skeleton of the earlier and relatively small "Ardi." Only minimal dimorphism in size probably characterized "Ardi" and indicates that the common ancestor of human and chimpanzee presumably also exhibited the same trait. If this assumption is proper, the specific selection pressures that could have acted on body size and sexual dimorphism at this stage of hominin evolution cannot be suggested.

Sexual Dimorphism and Social Structure

Sexually dimorphic traits specific to hominins should also have been selected for in response to certain selection pressures. Analysis of SDS, and its changes in the hominin lineage, might then give some insight into the mating system and social structure of these forms. It is known from living primates that SDS reflects male–male competition for monopolizing the reproductive potential of females. Higher SDS is usually related to more intense male intrasexual aggression. Male body size is an investment in fighting abilities, and this investment is inversely related to the mating opportunities (Trivers 1972). Species living in a one-male group (e.g., gorilla) have the largest SDS, monogamous species (like gibbons) are monomorphic, and species living in multi-male groups (like chimpanzee) have moderate SDS. The difficulty with reconstructing the mating system in the earliest hominins is related to the lack of sufficient fossil data for the size of both sexes. Fragmentary fossils mean that sex assignment is made frequently only on the basis of size (and not on pelvic or cranial morphology). This may lead to overestimation of SDS.

The problem with inferring social structure, however, becomes complicated when one also takes into consideration dimorphism in canine size (CD). This feature can also be useful for reconstructing mating systems, as CD is often positively related to SDS and therefore might also indicate a higher level of intra-male competition. If SDS and CD were both large in ErH, behavioral inferences would be relatively consistent, indicating a polygynous reproductive system in these forms. The problem appears when, contrary to SDS which suggests a high intensity of competition, CD in hypothetical ErH is small and therefore contradicts a high male–male competition for females. To solve this problem, Plavcan and van Schaik (1992) distinguished four types of male–male competition that are connected with different SDS. In order of increasing SDS: (1) low frequency and low intensity (as in monogamous gibbons), (2) high frequency and low intensity (as in chimpanzees), (3) low frequency and high intensity (as in *Saimiri*), and (4) high frequency and high intensity (as in *Macaca mulatta*, *Papio hamadryas*). These authors claim that the SDS of ErH hominins fits well with type 2 here.

The best present model for SDS and CD and therefore social structure in the earliest hominins is *Ar. ramidus*. The lack of a projecting, daggerlike upper canine crown and absence of an apelike honing C/P3 complex (characteristic for chimpanzees), together with reduced canine size in *Ardipithecus* males, indicates a lower intensity of male–male aggression in this species than in extant chimpanzees. Although the canines of the earliest known hominins at about 6 Ma were slightly more primitive, they were similar in size to those of *Ar. ramidus* (Suwa et al. 2009). This indicates that male canine size was reduced by 6–4.4. Ma from an ancestral apelike condition which probably exhibited a honing C/P3 complex and a moderate chimpanzee-like difference in size between male and female canines (Suwa et al. 2009). Among other features, the big size of the upper canines is important in territorial defense and in male agonistic behavior. The "feminized" shape of the male canines in *Ar. ramidus* and in other early hominins has been interpreted as the result of sexual selection and an occurrence of the reproductive and social behavioral changes in hominin evolution long before brain enlargement and stone tool use (Suwa et al. 2009).

The dental traits and small SDS of *Ar. ramidus* justify ascribing to LCA minimal skull and body size dimorphism and moderate canine dimorphism, indicating male philopatry, weak competition between males, and probable male–female codominance (as in the case of *P. paniscus* and ateline species) (Suwa et al. 2009). The intense intermale aggression characteristics of *Pan troglodytes* or social structure of gorillas are then rather unlikely social models for the LCA (Lovejoy 2009; Suwa et al. 2009; White et al. 2009).

High variation in body size in *Australopithecus* within a single site indicates high SDS and strongly undermines the hypothesis of a monogamous mating system in these forms (e.g., as suggested by Lovejoy 1981) and its possible influences on the evolution of bipedality. Gordon et al. (2008) also demonstrated that *Au. afarensis* showed substantial level of sexual dimorphism (most consistent with that present in gorillas and orangutans), which is in contrast with human or chimpanzee-like level of SDS in this species, as earlier suggested by some authors (e.g., Reno et al. 2005). SDS in *Australopithecus* was also larger than in *Ar. ramidus* (White et al. 2009).

If the driving force behind SDS in anthropoids is sexual selection (Lindenfors and Tullberg 1998), it can be inferred on this basis that the social structure in the earliest *australopithecines* was not monogamous. Although smaller canines in male in these forms might indicate a lower selection pressure for fighting ability, they lived probably in multimale/multifemale groups. A new skeleton of a large-bodied *Au. afarensis* male (dated to 3.38 Ma) discovered in Ethiopia indicates sophisticated terrestrial bipedality (Haile-Selassie et al. 2010). It is then possible that the reduction of body size in *Australopithecus* females was the result of enhancing their cooperation, but male size could have increased in response to predation pressure, which became higher in more open habitats invaded by these hominins (White et al. 2009).

All presented evidence and inferences about social structure face also the problem of great variation in SDS or CD within one competition type. There are a number of polygynous species with a very slight degree of dimorphism both in body and canine tooth size (Plavcan 2000). Thus, inferring social behavior from sexual dimorphism in primates has proved to be ambiguous, and this means that all speculations on the ErH social structure based on SDS or CD should be treated with caution. It cannot be also excluded that the mixture of high SDS and low CD was a consequence of male predator defense and not strong male–male competition.

The primate species with higher frequency of conciliatory behavior (e.g., Tonkean macaques or bonobos in comparison to chimpanzees) have lower CD (Plavcan and van Schaik 1992). There is also a possibility that the lack of concurrence of marked SDS and CD implies a unique social system that is unknown among living primates.

One possible explanation of the canine reduction observed in ErH (*Ar. ramidus* and *Australopithecus*) is the relaxation of the selection pressure favoring canine use as a weapon in an intrasexual and/or antipredatory context. Furthermore, the selective forces responsible for canine reduction probably had nothing to do with their dietary function. The later possibility of using them as functionally equivalent to incisors could have been a by-product of canine reduction selected for other reasons (Plavcan and Kelley 1996). In the opinion of Leutenegger and Shell (1987), however, the lack of CD in australopithecines could have produced the effect of "dental crowding," which resulted from the selection for the increase of premolar and molar chewing surface area, and SDS was a result of relatively high intrasexual male competition. Unfortunately, past behaviors do not fossilize, and therefore, one cannot be certain about the mating system within the early Hominini.

Small-bodied hominins disappear from the fossil record ca. 1.7 Ma (McHenry 1994). This suggests that there was strong selection pressure for both female and male body size to increase. However, this increase was much larger for females (McHenry 1994). Thus, it is unlikely that it was sexual selection, for example, for monogamy, that caused the decrease in SDS. If the decrease of SDS had been related to selection for monogamy, one would have expected a reduction in male–male competition and thus male body-size decrease (Lindenfors and Tullberg 1998) rather than a large increase in female body size. It is more likely, therefore, that selection pressures could have been related to locomotion efficiency (longer legs enabled walking for longer distances, which was adaptive for both sexes) or to an antipredatory strategy, thermoregulatory demands (Ruff 1991; Wheeler 1992), or to giving birth to bigger and fatter newborns (Pawlowski 1998) with larger brains.

Future Perspectives for Determining the First Appearance of Derived Hominin Traits and the Selection Pressures Acting on Them

There is no doubt that the closer integration of paleoanthropology and genetics will in the future markedly advance our knowledge of the mechanism of hominin evolution. It is worth to note that the phenotypic traits described as unique to human lineage are commonly considered as the results of the selective pressures acting on human genome and the unique demographic history since the time of the divergence of the human and chimpanzee lineages (O'Bleness et al. 2012). Currently the rapid comparison of the numerous genomes within and between species is possible, and there are data on the draft genomes of several primate species including chimpanzees (*Pan troglodytes*), bonobo (*Pan paniscus*) (Prüfer et al. 2012), gorillas (Scally et al. 2012), and orangutans (Locke et al. 2011). It was, for instance, determined that 25 % of human genes contain parts that appeared closely related only to one of the two *Pan* species (bonobo or chimpanzee). The examination of these regions can help to determine the genetic background of the phenotypic similarities between humans and *Pan* and to assess the time of their evolutionary appearance. There is also the genetic evidence that LCA of human and *Pan* lineages possessed a mosaic of the traits specific to human, chimpanzee, and bonobo (Prüfer et al. 2012).

We are now in the "golden age" of exploration of the genetic changes and between-species differences that might contribute to the search for the emergence of the specific traits for human lineage. On the basis of the sequence changes that occurred at the rate greater than the rate of the neutral mutations, we are able to identify hypothetical evolutionary pressures. There are, however, still many challenges we face with (O'Bleness et al. 2012). Most problematic is difficulty in linking human-specific genomic change to human phenotype features. This is because to understand the genomic changes, one has mainly to rely on the observation of the variation and diseases that occur in modern humans (O'Bleness et al. 2012), although recently applied heterologous expression of human regulatory regions in mice allows detecting functions of genetic changes specific to human lineage (Prabhakar et al. 2008; McLean et al. 2011). An interesting example of using this method is the study of human accelerated noncoding region 1 (HACNS1) enhancer. This noncoding region is expressed in the anterior developing limbs of the mouse embryo, which could mean that HACNS1 might have contributed to the emergence of human bipedalism (Prabhakar et al. 2008; O'Bleness et al. 2012).

It can be supposed that identification of the genes or genomic regions more directly responsible for the traits that emerged in our lineage than those suggested now will be in the future easier and much more helpful for reconstructing the fine details of our evolutionary past. Finding the time of the appearance of different gene changes will allow to put a date to the emergence of given traits and to identify the particular selection pressures that were responsible for the appearance of different traits in hominin evolution. A good example of this issue is the assessment of the appearance time of the FOXP2 gene in human evolution. FOXP2 has been described as helping in learning the complex muscle movements important to speech and language in human (Enard et al. 2009), and it was suggested that the human version of this gene appeared about 500,000 years ago (Krause et al. 2007).

What is abundantly clear at the beginning of the twenty-first century is that in combination with these genetic approaches, our grasp of the mechanisms of hominin evolution will radically improve through the discovery and interpretation of hominin fossils uncovered in strata of Late Miocene and Early Pliocene ages.

Conclusion

The main focus of this chapter was the consideration of the main adaptive traits that appeared in the early hominins, paying particular attention to the putative selection pressures that could have triggered the hominin–chimpanzee split and then acted on the early hominins prior to the appearance of genus *Homo*. This task, however,

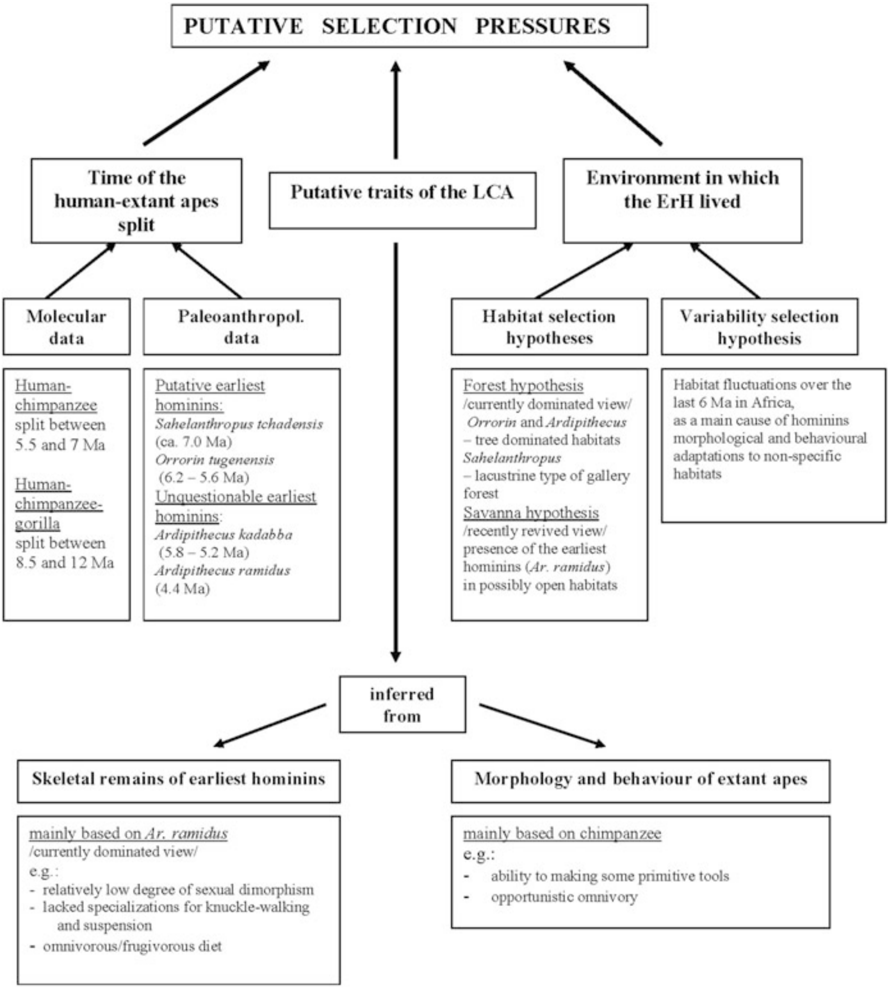

Fig. 1 The main types of data helpful in inferring the putative selection pressures acting on the early hominins. *LCA* last common ancestor, *ErH* the earliest hominins

is not easy. Although there is some general idea about the chronological sequence of the appearance in hominins of new (derived) morphological traits, the typically very fragmentary nature of the pre-hominin and early hominins' fossil record limits our ability to fully account for both the selection pressures acting on derived morphological traits and even more so for behavior of the earliest hominins (Fig. 1). It is obvious that the availability of only hard-tissue fossils restricts our possible understanding of the whole biology of these extinct forms. But paleoanthropologists can also have problems with determining the evolutionary mechanisms that were responsible for the appearance of main morphological hominins' features.

There is not even a clear pattern of the main changes in the earliest stages of hominins' evolution. The most certain trait, diagnostic for this clade, is bipedal locomotion, and this is certainly the trait for which a clear evolutionary explanation is really needed. Since it is the defining hominin trait, it is almost certain that explaining selection pressures for bipedality is concomitant with explaining the causes of the hominin–chimpanzee divergence. But unless the chronological order of the ErH is determined, the reconstruction of the main selection forces that led to the hominin–chimpanzee split will remain unclear.

The reconstruction of selection pressures responsible for hominin emergence would be easier if paleoanthropologists were dealing with a complex of traits that appeared at the same time than if the derived traits appeared at different times and were independent of each other. In the latter case we would need to analyze each trait separately, and there are possibly more selective pressures to be taken into consideration. When a few traits appear at the same time, it is usually much easier to propose a selective factor (the pool of such factors would be restricted) for a complex set of dependent traits. For instance, if the ErH became bipedal and at the same time acquired new masticatory adaptations to feed on abrasive food, then the habitat change hypothesis for bipedalism would be more likely as a putative selection pressure for hominin appearance. If *Orrorin* and *Sahelanthropus* were the earliest hominins, it could be inferred that bipedality could have arisen concomitantly with a dietary shift towards more variable diet, including more abrasive foods. Since they lived in a mosaic environment, and *Sahelanthropus* lived far from East Africa, one cannot exclude the possibility that the cradle of the hominins was much farther to the north that was originally thought and that it was in a more open environment in which bipedality and thus the hominins first emerged.

The knowledge of the sequence in which the different traits emerged is, however, not enough to exclude one selection factor for different traits. This is because the appearance of new traits can be related to a different speed of evolutionary response for the same selection pressure or can be related to different strength of the same pressure at different times. It seems unlikely that such a fundamental hominin trait as bipedality emerged a number of times independently. Other traits, such as size and body proportions, or bone and enamel thickness, seem to respond much faster to environmental selection pressure, so in our family tree, these traits might have changed in a different way in a few evolutionary lines. This notion is important because it is usually presumed that the evolutionary processes are parsimonious, which means that traits are difficult to change and evolve, and therefore, it is unlikely that one trait evolved independently in different lineages. However, such an easily evolvable trait as enamel thickening appeared under similar selection pressures, probably independently in the evolutionary lineages of at least a few Miocene hominoids.

When speculating about putative selection pressures, one should also remember to distinguish causes from consequences. It is easily possible to construct scenarios which confuse them. The problem is that in many cases, they are then difficult to disentangle.

The earliest stage of hominin evolution seems to be the biggest mystery and challenge of our entire evolutionary clade, and therefore, it should be no surprise that the theories of the selection pressures presented here are in part inherently speculative and highly vulnerable to adjustment in the light of new evidence. There is no doubt we need more ErH remains to find out whether some ErH skeleton traits were homoplasies or symplesiomorphies. This would allow to acquire much better knowledge about the traits of LCA (Wood and Harrison 2011). We can only hope that some fresh evidence will be gained soon and that it will allow to exclude some of the more unlikely selection pressure scenarios, thereby both narrowing the debate and at the same time making it more substantial.

Origin of Bipedal Locomotion

William E. H. Harcourt-Smith

Contents

Abstract

Bipedalism is a highly specialized and unusual form of primate locomotion that is found today only in modern humans. The majority of extinct taxa within the Hominini were bipedal, but the degree to which they were bipedal remains the subject of considerable debate. The significant discoveries of fossil hominin that remains in the last 40 years have resulted in this debate becoming

increasingly focused on how bipedal certain fossil taxa were, rather than on the overall process. Although the early hominin fossil record remains poor, evidence points to at least two distinct adaptive shifts. First, there was a shift to habitual bipedalism, as typified by certain members of *Australopithecus*, but possibly including earlier genera such as *Ardipithecus* and *Orrorin*. Such taxa were bipedal, but also retained a number of significant adaptations to arboreal climbing. The second shift was to fully obligate bipedalism and coincides with the emergence of the genus *Homo*. By the Early Pleistocene, certain members of *Homo* had acquired a postcranial skeleton indicating fully humanlike striding bipedalism. The final part of this chapter reviews why bipedalism was selected for. There have been many theoretical explanations, and the most robust remain those linked to the emergence of more varied habitats. Such an environmental shift would have involved strong selection for new behavioral strategies most likely linked to the efficient procurement of food.

Introduction

Bipedal locomotion sets modern humans apart from all other living primates. We are the only obligate bipeds among well over 200 extant primate species. It therefore stands to reason that this unusual and highly derived form of locomotion has attracted much attention from those who study human evolution. Current evidence points to anatomical traits strongly associated with bipedalism relatively deep in the hominin lineage (Ward et al. 2001) and well before the advent of other “traditional” human traits such as larger brains and tool use. This chapter reviews the current state of thinking on this unique form of primate locomotion.

In order to understand the origins of hominin bipedalism, one first has to understand the mechanisms that make it such an efficient form of locomotion in modern humans. In the first section of this chapter, I will briefly explore the nature of the modern human walking cycle and the associated anatomical traits that facilitate it. I will then explore the fossil evidence for the origins of bipedalism and speculate on the likely locomotor behaviors that preceded it. Finally I will discuss some of the theories surrounding why bipedal locomotion was selected for.

Locomotor Differences Between Modern Humans and Great Apes

Modern humans are fully obligate bipeds. After the first few years of life, bipedality is the sole form of locomotion in all healthy individuals. By comparison, the great apes do not have any one form of specialized locomotion. *Pongo* is almost exclusively arboreal, but its locomotor behavior is taken up by clambering, vertical climbing, brachiation, terrestrial fist-walking, arboreal quadrupedalism, and even some above-branch assisted bipedalism, although orangutans are best known to have a predilection for suspensory postures (Tuttle 1968; Thorpe and

Crompton 2005; Thorpe et al. 2007). Clambering, which accounts for over 50 % of observed locomotor behavior, mainly consists of forelimb suspension and hindlimb support and suspension (Tuttle 1968; Cant 1987). In nearly all respects *Pongo* can be considered to be an arboreal specialist.

The most important aspect of the African apes is that, unlike *Pongo* and modern humans, their specialization lies not in their tendency to be *either* arboreal or terrestrial specialists but rather on having a mosaic of different locomotor modes that suit different environments and situations. Field observations have shown that all three African ape taxa spend considerable time in both the trees and on the ground. The principal form of terrestrial locomotion is fast and slow knuckle-walking, where the legs do most of the propulsive work but a significant degree of body weight is borne by the upper limbs through the knuckles (Tuttle 1970). African apes spend a small degree of time walking bipedally, but only for relatively short periods of time (Tuttle 1970; Hunt 1994). *Pan* also spends a proportion of its time standing bipedally, mainly to collect fruit in tall bushes, but it is important to note that, even when doing so, individuals are partially supporting themselves with their upper limbs, which are grasping onto branches (Hunt 1994; Doran and Hunt 1995). When in the trees, *Pan troglodytes* has a particular predilection for using knuckle-walking to move along large branches (Tuttle 1970).

The Walking Cycle

The modern human walking cycle is characterized by two distinct phases: the *stance phase*, when the leg is on the ground, and the *swing phase*, when it is off the ground. The stance phase begins with the foot striking the ground, known as *heel-strike*. The knee is fully extended and the foot dorsiflexed, which results in the heel-striking the ground well before the rest of the foot. The foot then plantar flexes, and typically force is transmitted through to the substrate along its lateral border. The point when the body is directly over the weight-bearing foot is known as the *midstance phase*. The body then carries its forward momentum over the leg, at which point force moves medially over to the ball of the foot. At this point, strong muscular contraction of the plantar-flexors results in the ball of the foot pushing against the ground and eventually lifting away from it as the body continues to move forward. This action finishes with a final push-off of the big toe, known as *toe-off*. The leg is now off the ground and in the swing phase, with the knee and hip both bent so as to keep the leg off the ground as it swings forward to make the next heel-strike.

When chimpanzees walk bipedally, there are considerable differences (Aiello and Dean 1990). The knees and hips remain bent throughout the stance phase, and the foot is less dorsiflexed at heel-strike. This results in a gait that is an awkward “shuffling” movement, with marked mediolateral swaying of the body from step to step, that is often referred to as a “bent-knee, bent-hip” (BKBH) gait. Heel-strike itself is at best weak and is often almost immediately followed by much of the rest of the foot making contact with the ground. There is little in the way of the lateral to medial shift in force transmission to the substrate during the late stance phase, and often three or more toes leave the ground at the same time (Elftman and Manter 1935).

Associated Anatomical Differences Between Humans and Great Apes

A large number of anatomical traits are functionally related to bipedal locomotion, and it is the combination of these traits that allows this to be the sole form of locomotion in modern humans. Naturally it is sometimes hard to determine which traits specifically *facilitate* bipedal locomotion and which are more a *result* of it, but in terms of determining the locomotor affinities of fossil remains, it is fair to assume that, either way, many of these traits certainly *indicate* bipedal locomotion to a lesser or greater degree. Table 1 summarizes the major anatomical features associated with human bipedal locomotion, but a number of them warrant further discussion. In some cases, where particular traits relate to particular fossil specimens, there is further discussion in section "Fossil Evidence."

Some of the most radical morphological adaptations in the human skeleton that relate to bipedalism are found within the pelvis and lower limb. Compared to apes, the entire lower limb complex in humans has become highly remodeled to cope with the intricate dynamics of balancing an upright trunk while efficiently moving the body forward (Schultz 1930). Balance is a particularly important factor as at any point during the walking cycle, only one limb is actually in contact with the ground and has to bear the entire weight of the body and balance it accordingly. The minimizing of mediolateral swaying of the body during walking is therefore critical, as it acts to stabilize the body over the supporting leg and to reduce energy expenditure. Consequently, many of the traits associated with bipedal locomotion relate to two major factors: balancing the body as a whole and keeping the downward transmission of force as close to the midline of the body as possible.

In the skull there are two main osteological features related to bipedalism in modern humans. The semicircular canals have a larger vertical canal, which is thought to relate to more complex bipedal behaviors such as running (Spoor et al. 1994). The foramen magnum is also more anteriorly situated and horizontally orientated. This is a reflection of the more vertical positioning of the spine. Anterior positioning of the foramen magnum has recently been shown to relate to bipedalism in several lineages of mammals that have independently become bipedal (Russo and Kirk 2013). Below the neck, the spine of modern humans has a distinct "S" shape, caused by marked lordosis in the lumbar region, which helps to bring the center of the trunk's mass anteriorly (Aiello and Dean 1990; Fleagle 1999). The lower limb is considerably longer in modern humans than in great apes. *H. sapiens* has a low intermembral index (~72), whereas for *Pan* (103–106), *Gorilla* (~115), and *Pongo* (~139) it is far higher, reflecting their relatively shorter lower limbs and longer upper limbs. The longer lower limb in humans directly facilitates a longer stride length.

Table 1 Some of the important anatomical features specifically related to bipedal locomotion in modern humans. Some descriptions adapted from Aiello and Dean (1990)

Trait	*Homo sapiens*	African apes	Functional significance in *H. sapiens*
Foramen magnum orientation	Perpendicular to orbital plane	More vertically inclined	Related to vertical positioning of spine
Shape of spine	S curve with lumbar lordosis	C curve with no lumbar lordosis	More efficient balance and support of upright trunk
Intermembral index	Low (~72)	High (103–115)	Longer stride lengths
Size of vertebral bodies	Larger, especially L1-5	Smaller	Increased load of vertical trunk
Shape of iliac blades	Short, wide, and curved	Long, narrow, and flat	Support for vertical trunk
Orientation of iliac blades	Mediolaterally	Anteroposteriorly	Support for vertical trunk
Relative distance from hip to sacroiliac joints	Small	Large	More efficient transfer of weight from spine to hip
Size of acetabulum	Large	Small	Increase in weight transfer through hip joint
Anterior inferior iliac spine (AIIS)	Present	Absent/weak	Attachment site for strong iliofemoral ligament – helps maintain balance by preventing hyperextension of thigh
Femoral head size	Large	Small	Increase in weight transfer through hip joint
Cortical bone distribution in femoral neck	Thicker inferiorly	Even all around	Increase in weight transfer through hip joint
Bicondylar angle of femur	Valgus	Absent/varus	Placement of lower leg closer to midline of body
Relative lengths of articular surfaces of femoral condyles	Similar in length	Lateral condyle shorter	Aids medial rotation of femur and locking of knee joint at heel-strike
Inclination of tibial trochlear surface	Perpendicular to long axis of tibia	More laterally inclined	Allows perpendicular passage of leg over foot
Plantar tuberosity on calcaneus	Two	One	Facilitates stable heel-strike
Longitudinal arches in foot	Two present – one medial and one lateral	Absent	Acts as "shock absorber" and maintains structural rigidity in foot throughout stance phase
Hallux opposability	Absent	Present	Facilitation of efficient toe-off and loss of arboreal grasp
Relative tarsus length	Long	Short	Increases power arm length in foot – leads to more efficient leverage in foot

(*continued*)

Table 1 (continued)

Trait	*Homo sapiens*	African apes	Functional significance in *H. sapiens*
Relative lengths of rays II–V	Short	Long	Decreases level arm length in foot – leads to more efficient leverage in foot
Metatarsal robusticity pattern	1 > 5 > 4 > 3 > 2	1 > 3 > 2 > 4 > 5	Reflects increased transfer of weight along lateral edge of foot
Phalangeal curvature	Flat	Curved	Loss of arboreal grasp

The modern human pelvis is very different in shape to that of all other primates, including the great apes. The iliac blades are short and wide, the ischium extends posteriorly, and the sacrum is relatively wide. These features greatly facilitate support of the upright trunk, place the trunk's center of gravity closer to the hip joint, and allow the lesser gluteal muscles to be positioned at the side of the pelvis (Napier 1967; Rose 1984; Aiello and Dean 1990). This last feature is important, as contraction of these muscles during walking tilts the trunk toward the leg in contact with the ground, providing greater stability and balance. Humans also have a large acetabulum to accommodate a large femoral head, reflecting the relative increase in body weight passing through the hip during locomotion. The modern human femur has a valgus bicondylar angle, resulting in the knee being situated far closer to the midline of the body than the femoral head is. This greatly reduces the lateral deviation of body weight during walking and is argued by many to be an important feature related to habitual bipedal locomotion. However, modern humans who are unable to walk from birth do not develop a valgus bicondylar angle (Tardieu and Trinkaus 1994), and so this trait is best considered as ontogenetic even though its presence indicates habitual bipedal behavior.

The human knee has the unique ability to lock when in full extension, which greatly facilitates upright walking by keeping the leg straight and enabling the efficient downward passage of the body's weight through to the ankle. This locking action is facilitated in humans by having long femoral condyles that are the same length as each other (in *Pan* they are shorter, and lateral condyle is shorter than the medial) and different femoral attachment sites for the posterior cruciate ligament (Aiello and Dean 1990). The distal tibia has a particularly important feature linked to bipedal locomotion worth noting. The talar articular surface is orientated perpendicular to the long axis of the bone, resulting in a less arcuate passage of the leg over the foot (Latimer et al. 1987). This allows more efficient weight transfer through to the foot. The modern human foot is particularly specialized for the requirements of bipedal locomotion. The African ape foot can be considered a grasping organ with some terrestrial adaptations, whereas that of humans is essentially a propulsive platform. Modern humans are the only living primates to have lost the ability to oppose the hallux, which is in line with the remaining toes. Human toes are relatively short and straight, and the tarsus relatively long, with an elongated calcaneal tuberosity. This allows for a more efficient lever-arm to power-arm ratio, which facilitates efficient propulsion during the stance phase. A combination of bony architecture and strong plantar ligaments results in the human foot being arched longitudinally on both the medial and lateral sides. By comparison the ape foot is weight-bearing through the midfoot, and this is reflected in the enlarged medial tuberosity on the navicular. This longitudinal arching combined with strong plantar ligaments and the unique locking morphology of the calcaneocuboid joint allows the human foot to not only act as an efficient shock absorber but also stay rigid during weight transfer to the ground.

Fossil Evidence

The precise number and nature of derived traits characterizing stem hominins is increasingly difficult to determine and likely to remain so. It has recently been pointed out that, in its entirety, bipedality requires a combination of many complex anatomical traits and so cannot necessarily be classed as a dichotomous character (Haile-Selassie et al. 2004). However, it is reasonable to assume that strong evidence of bipedal locomotion is key in determining whether fossil material warrants inclusion within the hominin clade. Perhaps the best way to consider such evidence is to ask whether fossil hominin material indicates *habitual* or *obligate* bipedalism, rather than merely *occasional* bipedalism, which we see in most extant species of great apes (see Rose 1991). Clear evidence of a shift from occasional to habitual bipedalism is important when considering early hominin remains, as is the shift from habitual to obligate bipedalism when considering later hominin remains. In that context, when considering the hominin fossil record, this chapter will consider *occasional* bipeds as those animals with a bipedal component of their locomotor repertoire similar to that of modern-day chimpanzees. By contrast, *habitual* bipeds are considered those taxa that had a significantly increased bipedal component but were by no means exclusively bipedal and would have retained an arboreal component to their locomotor repertoire. *Obligate* bipeds are taxa that were exclusively bipedal and had lost all other forms of terrestrial and arboreal locomotor behaviors.

Precursors of Bipedalism

There is a significant literature on the likely locomotor mode that directly preceded hominin bipedalism (see reviews by Richmond et al. 2001; Harcourt-Smith and Aiello 2004). Early models, in the absence of fossil evidence, relied heavily on observed extant primate locomotor behaviors and phylogenetic hypotheses. Arguably, the prevailing view was that a brachiating, hylobatid-like ancestor evolved into a larger-bodied African apelike ancestor capable of orthograde climbing and terrestrial knuckle-walking, which in turn evolved into a bipedal hominin (e.g. Keith 1903, 1923; Gregory 1916, 1928; Morton 1924, 1935). Minor variants of these models existed between authors, with Morton (1924, 1935) arguing for a more terrestrial "gorilloid" prehuman locomotor mode, while Gregory (1916, 1927) and Keith (1903, 1923) favored a more "troglodytian" hominin precursor. Others argued for a very deep tarsoid ancestry for humans and bipedalism (Wood Jones 1916, 1929) or an arboreal quadruped ancestry of monkey-like above-branch locomotion (Straus 1949).

Despite the elegance of some of these early models, the central factor in understanding the evolution of bipedalism lies in the reconstruction of Late Miocene large hominoid locomotor behaviors. The advent of fossil evidence and molecular dating methods has effectively precluded some of these early theories from being likely. Based on molecular data, the last common ancestor of modern humans and chimpanzees is likely to have lived between 5 and 9 Ma (Gagneux and Varki 2000; Page and Goodman 2001; Springer et al. 2012; Steiper and Seiffert 2012; Schrago and Voloch 2013), and most Miocene hominoid remains do not show a strong adaptation to brachiation (e.g., Napier and Davis 1959; Avis 1962; Rose 1991; Moyà-Solà and Köhler 1996), although the hylobatian model is still argued by some (Tuttle 1974, 1975, 1981). In place of these earlier theories, a number of alternatives can be found in the recent literature. Perhaps the best-known recent theory today is the suggested knuckle-walking ancestry for hominins (Washburn 1967; Richmond and Strait 2000; Richmond et al. 2001), which draws heavily on the specialized knuckle-walking behavior of chimpanzees and gorillas as a model and argues for a retention of traits associated with knuckle-walking in the wrists of *Au. afarensis* and *A. anamensis* (Richmond and Strait 2000). However, this theory is also disputed by others on both paleontological and neontological grounds (e.g., Tuttle and Basmajian 1974; Dainton 2001; Lovejoy et al. 2001; Kivell and Schmitt 2009). While certain Middle and Late Miocene hominoid remains show an increased capacity for terrestriality, no large fossil hominoid taxa from this time-range show adaptations for knuckle-walking behavior (Stringer and Andrews 2005). Recent work on extant primates has also shown that several traditionally accepted knuckle-walking features are not always found in *Pan* and *Gorilla* and that both genera may knuckle-walk in biomechanically distinct ways (Kivell and Schmitt 2009). This leads to the possibility that knuckle-walking may have evolved independently within hominines, although Williams (2010) argues that this may have been unlikely due to the lack of highly integrated knuckle-walking morphologies in *Pan* and *Gorilla*.

Alternate contemporary theories include those suggesting an arboreal climbing ancestor (either large bodied or small bodied) (e.g., Fleagle et al. 1981; Tuttle and Basmajian 1974; Tuttle 1975, 1981; Stern 1975; Prost 1980; Hunt 1996), a terrestrial quadruped ancestor (Gebo 1992, 1996; Sarmiento 1994, 1998), a *Pongo*-like pronograde clambering ancestor (Crompton et al. 2003; Thorpe and Crompton 2005; Thorpe et al. 2007), and even an ancestor that practiced a type of terrestrial "tripedalism" with one limb always free to carry objects (Kelly 2001).

A universal theme that links both the older and the more recent hypotheses is the choice of a single specific locomotor mode as the dominant "precursor" to hominin bipedalism. As Rose (1991) points out, most primates apart from humans usually use several different types of locomotor activity as part of their daily locomotor repertoire. Within the hominoid clade, *Pongo* and particularly *Hylobates* are traditionally considered rather derived and specialized in their locomotor behavior, while *Pan* and *Gorilla* are considered more generalized. However, the great specialization of *Pan* and *Gorilla* in fact lies in that they have a particularly mosaic and versatile locomotor repertoire, especially in the case of the smaller-bodied *Pan*. Both genera regularly engage in terrestrial knuckle-walking, occasional bipedalism, vertical climbing, and orthograde clambering as part of their daily activities. It is quite possible that some of these behaviors, for instance, knuckle-walking, may have been independently acquired in *Pan* and *Gorilla* (e.g., Begun 2004; Kivell and Schmitt 2009). Their locomotor behavior and associated anatomy, however, combined with our current knowledge of the Middle to Late Miocene fossil record, suggest that the immediate precursors to the very first hominins are likely to have been rather generalized hominoids (McHenry 2002) capable of a suite of different locomotor behaviors, although perhaps with an emphasis on arboreal, predominantly orthograde locomotion (Almécija et al. 2013). In that context, it is perhaps rather limited to single out one particular locomotor mode as the likely "precursor" to habitual hominin bipedalism.

Evidence for Habitual Bipedalism Outside the Hominin Clade

Although there is little current evidence to suggest that fossil hominoid taxa existing prior to the Hominini–Panini split had any significant degree of bipedalism in their locomotor repertoires, the possible locomotor affinities of one specific taxon are worth noting. There has been the suggestion that the late Miocene European hominoid, *Oreopithecus bambolii*, was partially bipedal (e.g., Straus 1957, 1962; Kummer 1965; Hürzeler 1968; Köhler and Moyà Solà 1997; Rook et al. 1999). However, that assertion remains highly controversial. Although the iliac blades of *Oreopithecus* are reduced in length, it also has a suite of postcranial features that indicate adaptations to vertical climbing and forelimb suspension, including longer forelimbs than hindlimbs, a flexible shoulder joint, a strong grasping foot, and a lumbosacral region that is incompatible with bipedality (Harrison 1987, 1991; Russo and Shapiro 2013).

Earliest Hominin Evidence

The earliest fossil evidence for potential hominin bipedalism comes from recently discovered Late Miocene cranial remains from Chad, dated to almost 7 Ma and assigned to *Sahelanthropus tchadensis* (Brunet et al. 2002). Virtual reconstruction of the distorted TM266 cranium is argued to show a foramen magnum that is more anteriorly positioned than in *Pan* and *Gorilla* and, more importantly, orientated almost perpendicular to the orbital plane (Zollikofer et al. 2005). This is a trait shared by modern humans and australopiths and indicates a more vertically orientated spinal column that is associated with bipedal locomotion. Currently there are no known postcranial remains of *S. tchadensis*, precluding any further speculation on its locomotor behavior.

Fossil remains from the Lukeino formation in Kenya currently assigned to the putative hominin taxon *Orrorin tugenensis* (Senut et al. 2001) are also argued to indicate bipedality. The material is dated to between 5.7 and 6 Ma (Pickford and Senut 2001; Sawada et al. 2002), and it is reported that there are anatomical features on the BAR 1002’00 proximal femur that indicate habitual bipedal locomotion. The cortical bone of the inferior section of the femoral neck is argued to be relatively thick, and there is an “intertrochanteric groove” for the tendon of the *obturator externus* muscle on the posterior surface (Pickford et al. 2002; Galik et al. 2004). Thick cortical bone on the inferior section of the femoral neck is argued by some to imply habitual bipedalism (e.g., Pauwels 1980; Lovejoy 1988; Ohman et al. 1997), but others have noted that similar patterns of cortical distribution are found in many other primate species and that only apes and atelines differ in having relatively even distribution around the whole neck (Stern and Susman 1991; Rafferty 1998; Stern 2000). There is also debate as to whether the presence of the *obturator externus* tendon groove is reliable in inferring bipedalism. This feature, originally described by Day (1969), is argued to imply regular full extension of the thigh during bipedal locomotion (Day 1969; Robinson 1972; Lovejoy 1978). Others argue that it is not a diagnostic trait of habitual bipedalism (e.g., Stern and Susman 1991) and that it can even be found in quadrupedal cercopithecoids (Bacon 1997). Most recently Lovejoy et al. (2002) posit that while the trait is completely absent in large samples of *Pan* and *Gorilla* and present in australopiths and 60 % of modern humans, it does not specifically imply bipedality, but merely habitual extension of the femur. Despite these somewhat contradictory lines of evidence, more recent metrical analyses of BAR 1002’00 (Richmond and Jungers 2008; Almécija et al. 2013) seem to confirm its hominin status. These studies have found that the femur is strikingly similar to that of later australopiths such as *Au. afarensis*, indicating that *Orrorin* was well adapted to habitual (but not obligate) bipedalism. However, it is also clear that this taxon retained adaptations consistent with arboreality. The upper limb of *O. tugenensis* includes a curved proximal manual phalanx and a humeral shaft with a straight lateral crest for *m. brachioradialis* (Senut et al. 2001; Richmond and Jungers 2008), which are both seen as adaptations reflecting arboreal locomotor behavior (Senut 1981a, b, 1989; Stern and Susman 1983, 1991).

The best-known hominin remains from the Late Miocene/Early Pliocene that indicate bipedalism belong to the genus *Ardipithecus*, from the Middle Awash region of Ethiopia (White et al. 1994, 1995; White 2002). The oldest *Ardipithecus* remains (5.6–5.8 Ma) are ascribed to *Ar. kadabba* and include one proximal fourth pedal phalanx that is described as having strong plantar curvature, but also a dorsally inclined proximal articular surface similar to that of *Au. afarensis* (Haile-Selassie et al. 2004). This latter trait is argued to show that *Au. afarensis* could dorsiflex its foot in a similar way to modern humans (Latimer and Lovejoy 1990b). However, it has also been argued that this feature in *Au. afarensis* is intermediate between modern humans and great apes (Duncan et al. 1994). Until more postcranial remains of *Ar. kadabba* are discovered, its locomotor affinities should be treated with some caution (Haile-Selassie 2001).

The 4.4 Ma *Ardipithecus ramidus* remains are, however, far more comprehensive. Based on a partial cranial base, this taxon was originally reported to have had an anteriorly positioned foramen magnum (White et al. 1994). Following the 2009 announcement of a partial *Ar. ramidus* skeleton (ARA-VP-6/500) with associated cranial and postcranial remains (White et al. 2009), this finding has been confirmed by several studies (Suwa et al. 2009; Kimbel et al. 2014). The rest of the skeleton possesses traits associated with both bipedalism and arboreal locomotor behaviors. The best evidence for bipedality rests with the pelvis. Although the original fossil is damaged and distorted, there is a prominent anterior inferior iliac spine (AIIS), and computerized reconstruction of the iliac blades suggests that they are mediolaterally flared (Lovejoy et al. 2009d). These are features found in later australopiths and indicate bipedality. However, other aspects of the pelvis are more African apelike (such as the elongated superior ischial ramus), and there is no sacrum preserved. In contrast, the relatively long upper limb of *Ar. ramidus* is well adapted for arboreality (Lovejoy et al. 2009b), with curved manual phalanges and a more palmarly orientated capitate head. It is important to note that the hand and wrist of ARA-VP-6/500 do not have any knuckle-walking features (Lovejoy et al. 2009b). The foot also indicates arboreality, as it has a markedly convex and abducted hallucial articular surface on the medial cuneiform, indicating a grasping hallux. Conversely, it is argued that the rather wide lateral side of the cuboid implies the presence of an *os peroneum*, a small sesamoid bone indicative of a powerful *fibularis longus* muscle that would have helped stiffen the lateral foot during the stance phase of upright walking (Lovejoy et al. 2009a).

In a summary paper Lovejoy and colleagues (2009c) have interpreted *Ar. ramidus* as having had a locomotor repertoire made up of bipedalism on the ground and a combination of careful climbing and above-branch, pronograde quadrupedalism when in the trees. Orthograde suspensory behaviors and terrestrial knuckle-walking were definitively ruled out, and the arboreal locomotor component was argued to be somewhat similar to that suggested for the Early Miocene stem hominoid, *Proconsul* (Lovejoy et al. 2009c). It should be noticed that the hominin status of *Ar. ramidus* and its bipedality have been challenged (Harrison 2010; Sarmiento 2010; Wood and Harrison 2011) on the basis that some of the derived features reported in the taxon are found in several, non-bipedal Miocene hominoids. This has been challenged by White and colleagues, who argue that given the particular combination of features found in *Ar. ramidus*, the most parsimonious approach is to class it as a bipedal hominin (White et al. 2010). A preliminary morphometric analysis of the *Ar. ramidus* reconstructed innominate confirms the original suggestion of a derived pelvis partially adapted to bipedality, but also suggests that, when in the trees, *Ar. ramidus* was likely more similar to orthograde suspensory apes such as *Pan* and *Gorilla* (Webb et al. 2013).

In summary, the rather fragmentary fossil record for early hominins allows a degree of speculation as to how bipedal these taxa were. The horizontal orientation of the *Sahelanthropus tchadensis* foramen magnum does certainly indicate that this taxon was likely to have spent more time engaging in bipedal behaviors than either *Pan* or *Gorilla* do, but only the discovery of postcranial remains will further strengthen this argument. The femur of *O. tugenensis* indicates that it was also likely to have been a biped, but its upper limb implies strong climbing. The comparatively extensive remains of *Ardipithecus ramidus* undoubtedly provide the best insight into the locomotion of early hominins and indicate an animal with a pelvis partially adapted to bipedalism, but a foot and upper limb clearly adapted to arboreal climbing behaviors.

The First Habitual Bipeds

Perhaps the first concrete evidence for habitual bipedalism comes with the earliest *Australopithecus* remains from the Kanapoi and Alia Bay localities at Lake Turkana, Kenya. Assigned to *Au. anamensis*, the remains include a large and well-preserved distal and proximal tibia of one individual and are dated to between 3.9 and 4.2 Ma (Leakey et al. 1995, 1998). Crucially, the distal end of the tibia has a horizontal talar surface relative to the long axis of the shaft, implying that the *Au. anamensis* knee would have passed directly over the foot, as in later hominins and modern humans (Ward et al. 1999, 2001). In *Pan* and *Gorilla*, the talar surface is sharply inclined, which results in the knee passing over the foot more laterally during plantigrade locomotion (Latimer et al. 1987).

There are significant australopith postcranial fossil remains from the site of Woranso-Mille, Ethiopia, that at 3.8–3.6 Ma are just slightly younger than the youngest *Au. anamensis* specimens. They include a partial skeleton with an almost complete scapula, a partial pelvis, ribs, and well-preserved upper and lower limb bones. Overall, these remains are argued to strongly imply committed bipedalism with little in the way of arboreal specialties (Haile-Selassie et al. 2010). As they are currently assigned to *Au. afarensis*, see section “Locomotion in Australopiths” for more discussion concerning this taxon.

Following the *Au. anamensis* and Woranso-Mille remains the, record becomes richer and starts with what is arguably one of the best-known and strongest lines of evidence for early hominin bipedalism: the Laetoli footprint trail. Laetoli, Tanzania, is the type locality for *Au. afarensis* (see below) and has produced a number of hominin fossils assigned to this taxon. However, it is perhaps best known for its extraordinary series of preserved animal tracks, first discovered in 1976. Excavation through 1977–1979 revealed at least two (and probably three) trails of unmistakably bipedal hominin footprints preserved in a volcanic ash-fall layer that had become wet from rainfall (Leakey and Hay 1979; Leakey and Harris 1987; White and Suwa 1987). The footprints are dated between 3.5 and 3.7 Ma (Hay and Leakey 1982; Drake and Curtis 1987). The most distinctly hominid tracks are those from Site G, where there are two trails (and a possible third overprinted on the larger G-2 tracks). There is also a putative hominin track at Site A, but that has been argued by Tuttle et al. (see 1991) to have probably belonged to an ursid.

Most researchers agree that the G-1 and G-2 series of tracks are very humanlike, with no evidence of any type of forelimb support. The best preserved prints show a strong heel-strike and toe-off and indicate a transmission of body weight through the stance phase of walking similar to that of modern humans. In accordance with this, there is evidence of longitudinal arching, and the hallux is in line with the remaining toes (Day and Wickens 1980; Robbins 1987; Tuttle 1987; White and Suwa 1987). Stern and Susman (1983) do argue that the footprints show a "transitional" morphology between apes and modern humans, but the prevailing view remains that they are very humanlike. Schmid (2004) has argued that although the prints were made by habitual bipeds, there is some evidence of increased rotational movement of the upper body reflecting a more apelike morphology of the trunk. This in turn implies an "ambling" gait-pattern inconsistent with the ability to run. More recent analyses of the prints using three-dimensional analytical techniques (e.g., Raichlen et al. 2010) have confirmed that the Laetoli hominins had a very humanlike weight transfer pattern during walking.

There is much more debate over the taxonomic assignation of these trails. Most researchers accept that *Au. afarensis* is likely to have made them, given that the type specimen for that taxon comes from Laetoli and is roughly contemporary with the footprints. Others, principally (Tuttle 1981, 1987; Tuttle and colleagues 1990, 1991), have argued that the prints are so humanlike that they are incompatible with the known *Au. afarensis* remains from Hadar, which have long and curved pedal phalanges. They argue that another, as yet undiscovered, hominin must have made the tracks, which would have had feet far more humanlike than the Hadar *Au. afarensis* specimens. White and Suwa (1987) addressed this issue with a large study in which they reconstructed a hypothetical *Au. afarensis* foot using an amalgam of Hadar bones and the *Homo habilis* foot complex from Olduvai, OH 8 (Day and Wood 1968). They argued that this reconstruction perfectly matched the Site G footprints. However, at 1.76 Ma, OH 8 is almost 2 younger million years than the Laetoli trails and has a very different combination of morphologies to the Hadar remains (Day and Napier 1964; Kidd et al. 1996; Harcourt-Smith 2002), while a number of studies have shown that the Hadar *Au. afarensis* are unlikely to have had longitudinal arching in the foot, as seen in the Laetoli prints (Berillon 2000, 2003; Harcourt-Smith 2002; Harcourt-Smith and Hilton 2005; DeSilva and Throckmorton 2010). There are also a number of Hadar tarsal remains, including calcanei, two naviculars, and two tali that would be better suited to making a reconstruction of the *Au. afarensis* foot. Despite all this debate, what is certain is that the footprints provide an excellent temporal benchmark in terms of the origins of bipedalism. They mark a distinct behavioral event in time, which fossils can never do. In that context we can be sure that at least one line of hominins were practicing habitual bipedalism by at least 3.6 Ma, which implies that the shift from occasional to habitual bipedalism occurred sometime well before that and probably well before 4 Ma.

Locomotion in Australopiths

There has probably been more debate over the locomotor affinities of members of the genus *Australopithecus* than over any other taxa. This is partially due to the fact that there is a relatively rich postcranial record for this genus. However, the main reason is that these remains show intriguing combinations of primitive and derived traits relating to both terrestrial and arboreal locomotor behaviors. Historically the South African *Au. africanus* remains provided the major focus of work through to the early 1970s, perhaps culminating in Robinson's seminal treatise "Early Hominid Posture and Locomotion" in 1972. Between the 1970s and the 1990s, the discovery in Ethiopia of extensive postcranial remains assigned to *Au. afarensis*, including the famous "Lucy" skeleton, has shifted the debate to East Africa and back as far as 3.4 Ma. The *Au. afarensis* remains are considerably older than those of *Au. africanus* and along with Laetoli confirm that bipedal locomotion was likely to have been selected for well before brain expansion and tool-making behavior. Most recently the exciting new *Au. sediba* remains from South Africa have considerably added to the locomotor variation we see within the genus. In this section we will review the morphology and associated locomotor behavior of *Au. afarensis*, *Au. africanus*, and *Au. sediba* in turn.

Au. afarensis

This taxon provides the first direct anatomical evidence of a true shift from occasional to habitual bipedalism. However, there has been much disagreement over the precise locomotor affinities of this taxon, most of which falls into two distinct camps. Some researchers argue that *Au. afarensis* was almost as proficient a biped as modern humans (e.g. Latimer 1991; Lovejoy et al. 2002; Ward 2002). Others argue that in fact this taxon had a significant number of primitive postcranial traits that must have implied an important arboreal component to its locomotor repertoire (e.g., Susman et al. 1984; Stern 2000). These views are rather polarized, and it is best to consider *Au. afarensis* as highly mosaic in its adaptations (see McHenry 1991, for a comprehensive review of primitive and derived traits in the Hadar hominins).

The first specimen of *Au. afarensis* to be discovered showing evidence for bipedality was the AL 129 knee, discovered at Hadar, Ethiopia, and consisting of a well-preserved distal femur and associated proximal tibia (Taieb et al. 1974). Crucially, the morphology of the distal femur indicated a bicondylar angle even higher than that of modern humans (Johanson et al. 1976). This implied that the leg of *Au. afarensis* would have passed close to the midline of the body as in humans, which is an important adaptation to bipedal locomotion. Subsequent discoveries at Hadar, including the AL 288 partial skeleton ("Lucy") and the extensive AL 333 assemblage, provided further evidence of a strong selection for bipedality. The AL 288 skeleton, approximately 40 % complete, included a well-preserved pelvis, ribs, vertebrae, and representative pieces of all major limb elements. In overall morphology, the pelvis of "Lucy" is far more similar to that of modern humans. The iliac blades are short and wide, which would have allowed the lesser gluteal muscles to be situated laterally and act as pelvic abductors. The wide sacrum, situated behind the hip joint, would also have kept the center of mass of the trunk close to the hip, allowing efficient transfer of the weight to the lower limb during walking. Finally, there is a prominent anterior inferior iliac spine, indicating the importance of the knee extensor, *rectus femoris*, and a strong attachment for the iliofemoral ligament which helps maintain balance by preventing hyperextension of the thigh (Aiello and Dean 1990). It is worth noting that the pelvis of AL 288 is also unique in being markedly wide, more so than in modern humans, and that its iliac blades are not orientated as anteriorly–posteriorly as they are in humans. This considerable width may well be functionally linked to the more funnel-shaped rib cage of *Au. afarensis* (Schmid 1983, 1991). Such a rib cage would have been relatively wider inferiorly than in humans, therefore requiring a wider pelvis to support the resulting wider trunk. However, overall the anatomy of the *Au. afarensis* pelvis implies that it was well suited to two of the major requirements of bipedalism: maintaining balance and efficiently transferring weight from the trunk to the leg during walking.

Apart from the high bicondylar angle in *Au. afarensis*, it has been argued that its long femoral neck is especially adapted to bipedality. This feature may in fact have made abduction of the hip biomechanically easier than in modern humans (Lovejoy 1973; Lovejoy et al. 1973). However, it is also possible that this feature is a reflection of the wider thorax and pelvis in *Au. afarensis*. There are a number of other traits in the lower limb that unequivocally imply habitual bipedality. The mediolateral orientation of the talar surface of the distal tibia is horizontal relative to the long axis of the shaft. As discussed in section “Associated Anatomical Differences Between Humans and Great Apes,” this is an important feature unique to later bipedal hominins that facilitates efficient transfer of weight from the leg to the foot. In the *Au. afarensis* foot, the talus is very humanlike, particularly with respect to the trochlear surface (Latimer et al. 1987). The calcaneus has a lateral plantar process on the tuberosity, which greatly helps dissipate stress produced by ground reaction forces at heel-strike (Latimer and Lovejoy 1989). In general the morphology of the ankle joint and heel in *Au. afarensis* is extremely humanlike and would have been well suited to coping with the increased forces through the ankle associated with bipedal locomotion. It is also argued that the *Au. afarensis* foot would not have been capable of opposing its hallux (Latimer and Lovejoy 1990a).

Other features present in the postcranium suggest bipedalism, but are more open to interpretation. The femoral neck in both the AL 128–1 and Maka femora has thicker cortical bone inferiorly than superiorly (Lovejoy et al. 2002). As discussed in section “Earliest Hominin Evidence,” there is disagreement concerning this trait being used to confidently imply bipedality. The femoral condyles of larger-bodied members of *Au. afarensis* are also more humanlike in proportions and symmetry, but this is not the case for smaller members of the species, such as AL 129 (Aiello and Dean 1990). In the foot, it has been argued that *Au. afarensis* had more dorsally orientated proximal articular facets on the proximal pedal phalanges, implying a human-like ability for increased dorsiflexion of this joint in bipedal walking (Latimer and Lovejoy 1990b). However, a subsequent metrical study found that the *Au. afarensis* angle actually falls well outside the human range of variation and between humans and the African apes (Duncan et al. 1994). The foot of *Au.*

afarensis had also been suggested to have had strong longitudinal arching (e.g., Latimer and Lovejoy 1989; Ward et al. 2011). This assertion is partially related to the assumption that the arched footprints from Laetoli were made by *Au. afarensis*. As discussed in section "The First Habitual Bipeds," this may not be the case, and when assessing the degree of arching in this taxon, it is best to assess the fossil remains directly. The markedly enlarged medial tuberosity on two navicular bones from Hadar strongly implies considerable weight-bearing in the midfoot of *Au. afarensis* (Sarmiento 2000; Harcourt-Smith et al. 2002; Harcourt-Smith and Hilton 2005). Such morphology is incompatible with longitudinal arching. A comprehensive architectural analysis of the *Au. afarensis* pedal material by Berillon (2003) also finds that this taxon was unlikely to have had a longitudinal arch, and recent work linking distal tibial morphology and arch height reached similar conclusions (DeSilva and Throckmorton 2010). However, an analysis of a well-preserved fourth metatarsal from Hadar does argue for a longitudinal arch due to humanlike torsion of the metatarsal head relative to the base (Ward et al. 2011). Drapeau and Harmon (2013) challenge these findings and point out that such torsion can only really inform on the presence of a transverse longitudinal arch, a trait many extant primates possess. They note that cercopithecoids and modern humans have similar levels of torsion for this reason, even though cercopithecoids do not have a longitudinal arch.

There are also a number of more apelike traits in the *Au. afarensis* postcranium, some of which suggest a degree of arboreal climbing ability (see Stern 2000). Most noticeably, the manual and pedal proximal phalanges from the AL 288 and AL 333 localities, as well as from the infant Dikika specimen, are markedly curved and long and have prominent flexor ridges (Marzke 1983; Stern and Susman 1983; Susman et al. 1985; Alemseged et al. 2006). These features strongly imply an arboreal proficiency not found in later hominins. In the foot, the morphology of a partial medial cuneiform bone from AL 333 also implies that there may have been a degree of hallucial opposability (Harcourt-Smith et al. 2003), although others assert this to not be the case (Latimer and Lovejoy 1990a). Elsewhere, it has been reported that that the morphology and function of the *Au. afarensis* calcaneocuboid joint may have been apelike (Gomberg and Latimer 1984). Analysis of the limb proportions of the AL 288 skeleton show that the femur was relatively short (Jungers 1982; Jungers and Stern 1983), meaning that "Lucy" would have had much shorter stride lengths than modern humans. The morphology of the tibial plateau indicates that *Au. afarensis* would have had a single attachment for the lateral meniscus, as in apes (Senut and Tardieu 1985), although the phylogenetic relevance of this trait has recently been questioned (Holliday and Dugan 2003). In the upper limb, it has been argued that the distal humerus of smaller-bodied *Au. afarensis* specimens shows a well-developed lateral trochlear crest, an apelike trait that prevents dislocation of the elbow joint during climbing/suspension (Senut 1981a, b; Senut and Tardieu 1985) and a more cranially orientated glenoid in the scapula (Stern and Susman 1983). Both these features could have facilitated the arm's being used in above-branch climbing behaviors. However, more recent finds have added to the debate over *Au. afarensis* shoulder function. The 3.3 Ma Dikika specimen, a presumed

3-year-old female, has a complete scapula that is most similar to its counterpart in *Gorilla*, something that is argued to imply arboreal locomotor behavior (Alemseged et al. 2006). Conversely, the older Woranso-Mille adult partial skeleton KSD-VP-1/1 (3.8–3.6 Ma) is argued to have a scapula with a combination of *Gorilla*-like and *Homo*-like features, but overall a total morphological pattern that was incompatible with suspensory locomotion (Haile-Selassie et al. 2010). In the wrist it has been suggested that *Au. afarensis* retained features consistent with a knuckle-walking ancestry (Richmond and Strait 2000, although the authors do not go so far as suggest that *Au. afarensis* itself had a capacity for knuckle-walking. Others disagree with this assertion (Dainton 2001; Lovejoy et al. 2001), and it is interesting to note that none of the other important morphological traits associated with knuckle-walking (e.g., transverse dorsal ridges and dorsally expanded articular surfaces on the metacarpal heads) are found in *Au. afarensis* specimens (Stern and Susman 1983).

It has also been suggested that there is a significant degree of postcranial variation between larger-bodied and smaller-bodied individuals of *Au. afarensis*, particularly in the knee and elbow joints as discussed above, but also in the ankle (Stern and Susman 1983; Senut and Tardieu 1985). These differences could imply locomotor differences between the sexes, as Stern and Susman have suggested (1983), but have also been interpreted as suggesting that there were two distinct species of hominin at Hadar (e.g., Senut and Tardieu 1985; Tardieu 1981, 1983, 1986, 1993, 1994; Deloison 1999). However, the prevailing view remains that the Hadar material constitutes a single species (Harcourt-Smith and Aiello 2004), although there continues to be disagreement over the degree of sexual dimorphism in *Au. afarensis* (e.g., Plavcan et al. 2005; *contra* Reno et al. 2003).

The considerable debate over the locomotor behavior of *Au. afarensis* ultimately rests on how one views the evolutionary relationship between these traits and the process of selection (Ward 2002; Harcourt-Smith and Aiello 2004). One can argue, as Latimer (1991) does, that the derived anatomical adaptations to bipedalism seen in *Au. afarensis* demonstrate clear evidence of directional selection toward bipedality. Conversely one can also argue that the retention of primitive apelike traits present in *Au. afarensis* indicates a degree of stabilizing selection for arboreal proficiency (e.g., Stern and Susman 1983; Stern 2000), although there have also been suggestions that such features in *Au. afarensis* were reflective of efficient terrestrial quadrupedalism (Sarmiento 1994, 1998). Only a better understanding of the relationship between many of these traits and ontogenetic and/or epigenetic factors may help to resolve this debate (Lovejoy et al. 2002; Harcourt-Smith and Aiello 2004).

Overall, the postcranial skeleton of *Au. afarensis* can be best considered as mosaic showing a combination of derived humanlike bipedal traits, primitive apelike climbing-related traits, and a number of traits that appear to be unique. There is no doubt that *Au. afarensis* was a habitual biped and would have spent a significant amounts of time engaging in bipedal locomotor behaviors, but there are enough arboreal adaptations present to imply a degree of climbing ability, and it is not unreasonable to suggest that *Au. afarensis* could have spent time in trees at night and for predator avoidance.

The Burtele Remains

In contrast to the extensive remains within the *Au. afarensis* hypodigm, there is one new similarly aged (3.4 Ma) partial foot from the site of Burtele in Ethiopia that appears to have been distinct to that of *Au. afarensis*. Although not yet taxonomically assigned, its discoverers argue that it had strong grasping abilities, with an opposable hallux (Haile-Selassie et al. 2012). The only other hominin with such a feature is *Ar. ramidus*, and the authors suggest that the Burtele hominin was similar to that taxon in its locomotor adaptations. If true this would strongly lend support to the hypothesis that multiple forms of bipedalism existed in different hominin lineages from the Late Miocene through to the Pleistocene (Harcourt-Smith and Aiello 2004). However, three-dimensional metrical analyses of the AL 333–54 hallux from Hadar have shown that it is more apelike than humanlike (Proctor et al. 2008), and further work will be needed on the Burtele foot to ascertain that it is distinct from that *Au. afarensis*.

Au. africanus

Until the discovery of the Hadar remains in the 1970s, the South African *Au. africanus* fossils provided the best insight into the locomotor behavior of ancient fossil hominins. This was initiated by the discovery of the Taung Child in the 1920s and Dart's (1925) description of its foramen magnum as being in a more humanlike position, thus implying upright posture and locomotion. Since then a large number of fossils assigned to *Au. africanus* have been discovered, predominantly from the site of Sterkfontein (Partridge et al. 1999). The most diagnostic specimen of bipedality is the partial skeleton, Sts 14, which includes a partial pelvis and femur and vertebral fragments and has been argued to belong to the same individual as the Sts 5 skull (Thackeray et al. 2002). The pelvis is morphologically very similar to AL 288, in having wide and short iliac blades and being predominantly more humanlike than apelike (McHenry 1986). Also like AL 288, the pelvis of *Au. africanus* is very wide, with laterally flaring iliac blades and a relatively smaller acetabulum and iliosacral joint. This high pelvic width is confirmed by other *Au. africanus* pelvic fragments, including the reconstructed StW 431 pelvis from Member 4, Sterkfontein (Kibii and Clarke 2003). As for *Au. afarensis*, this is argued to have provided a distinct advantage in bipedal walking (Lovejoy 1973). Distal femora from Sterkfontein (TM 1513 and Sts 34) also indicate that *Au. africanus* had a high bicondylar angle, as in *Au. afarensis* and modern humans. More recently discovered *Australopithecus* postcranial remains from the Jacovec Cavern at Sterkfontein, which may be as old as 4.0 Ma, include a proximal femur (Stw 598) that has a markedly long neck and short head, as for the *Paranthropus* femora from Swartkrans (see below) (Partridge et al. 2003).

Other aspects of *Au. africanus* locomotor anatomy have been argued to be more mosaic. Analysis of the relative size of the semicircular canals in the inner ear indicates that *Au. africanus* had canals of apelike proportions. The morphology of the semicircular canals is closely linked to locomotor behavior, and while this finding does not preclude *Au. africanus* from having been a biped, it is likely that it would have been less competent at complex bipedal behaviors such as running and jumping (Spoor et al. 1994). McHenry and Berger (1998a, b) argue, mainly based on analysis of the Stw 431 skeleton, that *Au. africanus* had relatively large upper limbs and small lower limbs, implying a more prominent climbing-related component of its locomotor repertoire. However, Stw 431 does not have any lower limb remains, only a partial pelvis with a preserved acetabulum and sacroiliac joint, and this limits the scope of their study. It is important to note that this study is often misinterpreted as stating that the limb proportions (e.g., humerofemoral index) of *Au. africanus* were primitive. In fact the study mainly concentrated on measurements taken from the articular surfaces at the ends of limb elements. It has also been argued that a proximal tibia from Member 4, Stw 514a, is "chimpanzee like," in having a more rounded lateral profile of the lateral condyle, thus inferring an apelike range of motion at the knee joint (Berger and Tobias 1996). This may have been so, but it is premature to describe a structure as complex as the proximal tibia as apelike based on one feature alone, and further analysis is needed.

Finally, full recovery and analysis of the well-preserved Stw 573 "Little Foot" skeleton from Member 2 (Clarke and Tobias 1995; Clarke 1998) may prove vital in helping to resolve debate surrounding the locomotion of *Au. africanus*. Stw 573 promises to one of the most important discoveries in the early hominin fossil record, as it is far more complete than that of "Lucy," with a complete skull, a scapula, arm and hand bones in articulation, leg bones, foot bones, ribs, and fragments of vertebrae and the pelvis (Clarke 1999, 2002, 2013). The date of Stw 573 has been the subject of considerable debate, ranging from almost 4 to 2.2 Ma, although recent advances in dating methods and a better understanding of the complex stratigraphy of Sterkfontein have resulted in a likely range of 2.6–2.2 Ma (Herries et al. 2013). Most of these bones await removal from the breccia, but the foot bones were found separately and were initially described as showing a mosaic of adaptations, with a partially opposable hallux capable of some grasping potential, but a more humanlike ankle joint (Clarke and Tobias 1995). However, metrical analyses of these remains show that while Little Foot could not have opposed its hallux and had a navicular distinct from those at Hadar, it did have a more apelike ankle joint, implying that overall the foot was mosaic, but in a different way to that originally suggested (Harcourt-Smith 2002; Harcourt-Smith et al. 2003; Harcourt-Smith and Aiello 2004; Kidd and Oxnard 2005; McHenry and Jones 2006). It should be noted that while Stw 573 was originally argued to possibly belong to *Au. africanus* (Clarke and Tobias 1995), it has recently been suggested that it might instead belong to a different species of australopith (Clarke 2013).

Au. sediba

The discovery of the *Au. sediba* associated skeletons from Malapa, South Africa (Berger et al. 2010), has provided a fascinating new twist to the debate surrounding the emergence of obligate bipedalism. Dated to 1.95–1.78 Ma (Berger et al. 2010), *Au. sediba* is contemporary with as many as six different hominin taxa across southern and eastern Africa. When considering the locomotion of *Au. sediba*, analysis of the hand bones implies arboreal locomotor capabilities (Kivell et al. 2011). This is not inconsistent with the predicted locomotor behavior for other, earlier species of *Australopithecus*. However, more surprising information comes from the pelvis and foot. Although some features of the pelvis are shared with other species of *Australopithecus*, it has many more derived, *Homo*-like features than not. The iliac blades are more vertically orientated and have a sinusoidal anterior border, the ischia are shortened, and the distance from the sacroiliac joint to the hip joint is reduced (Kibii et al. 2011). Given that *Au. sediba* has a small, australopith-sized brain, the markedly more human-like pelvis implies a level of anatomical remodeling most likely related to locomotion and challenges the hypothesis that pelvic remodeling in Plio-Pleistocene hominins was related to obstetric constraints related to increased brain size (e.g., Lovejoy et al. 1973).

The foot of *Au. sediba* is, conversely, very mosaic. The ankle joint is humanlike, but the medial malleolus of the tibia is markedly thick mediolaterally, and the calcaneus is primitive in lacking a lateral plantar process, unlike *Au. afarensis* and modern humans (Zipfel et al. 2011). Combined with other features in the lower limb, including a very high lateral patella lip on the distal femur, these pedal features are argued to indicate a form of hyperpronating bipedalism in *Au. sediba* entirely distinct from that of other australopiths (DeSilva et al. 2013), providing further evidence of locomotor diversity in early hominins (Harcourt-Smith and Aiello 2004; McHenry and Brown 2008).

Paranthropus

The majority of available postcranial material from the genus *Paranthropus* come from the South African sites of Swartkrans and Kromdraai and are assigned to *Paranthropus robustus*. There are no complete long bones for *P. robustus*, but from Swartkrans there are a partial pelvis (SK 50), two proximal femora (SK 82 and 97), and a number of other postcrania including hand and foot bones, while from Kromdraai there is a partial talus (TM 1517). Two major studies on this postcranial material, by Napier (1964) and Robinson (1972, 1978), argued that *P. robustus* had a slightly less-derived postcranial skeleton than *Au. africanus* and would have had a less efficient type of bipedal gait. The main anatomical arguments for this were a more laterally facing acetabulum and longer ischium in the SK 50 pelvis, smaller femoral heads, and a more medially orientated talar neck and head, which has been sometimes linked to hallux opposability (Broom and Schepers 1946; Napier 1964; Robinson 1972). However, the SK 50 pelvis is severely distorted, and it is questionable whether there is enough well-preserved morphology for serious anatomical analysis. The Kromdraai talus, although apelike in some metrical aspects (Wood 1974), also has a relatively flat humanlike trochlear surface (Robinson 1972), and the significance of talar neck orientation to grasping potential has been brought into question by Lewis (1980, 1989). More recent finds assigned to *P. robustus* suggest that it was, in fact, likely to have been an efficient biped (Susman 1989). In particular, two well-preserved first metatarsals from Swartkrans show that *P. robustus* would have had a strong toe-off during walking, which is in concordance with efficient bipedality (Susman and Brain 1988; Susman and de Ruiter 2004). There is little in the way of confidently assigned postcranial remains of *P. boisei*, though a recently described partial skeleton from Olduvai Gorge, Tanzania (Domínguez-Rodrigo et al. 2013), indicates that this taxon may have had large, powerful forelimbs.

Locomotor Differences and Similarities Among Australopiths

The postcrania of *Au. afarensis*, *Au. africanus*, and *Au. sediba* all show distinct adaptations for bipedal locomotion. Particularly in *Au. afarensis*, however, there is also strong evidence of retained apelike traits indicating a proficiency for arboreal climbing, especially within the upper limb. There is no doubt that all these taxa were habitual bipeds, but at the same time they cannot be considered as obligate bipeds, and it is best to treat them as having had degrees of mosaicism in their locomotor repertoires. A number of studies have suggested that *Au. africanus* and *Au. afarensis* were very similar to each other in their locomotor anatomy (e.g., McHenry 1986; Dobson 2005). However, a number of other studies show that there are in fact morphologically, and this functionally, distinct. In a major analysis of the Stw 431 skeleton, Haeusler (2001) argues that there are a number of subtle but significant anatomical differences between the Stw 431 and Al 288 pelves implying that *Au. africanus* may have had a more humanlike type of bipedalism. Work on the tarsal bones of australopiths also shows that the putative Stw 573 *Au. africanus* foot may well have been mosaic (see above for details) in a different way to that of *Au. afarensis* (Harcourt-Smith 2002; Harcourt-Smith et al. 2003). Finally, it is clear that *Au. sediba* is distinct from other australopiths, especially concerning its far more humanlike pelvis. Given that *Au. sediba* also retained more primitive features in the foot and upper limb that respectively imply a unique form of bipedalism and possibly arboreality, it seems increasingly likely that from the Early Pliocene through to the Early Pleistocene, there was perhaps a significant degree of locomotor diversity within *Australopithecus*. *Au. afarensis*, *Au. sediba*, and *Au. africanus* all show clear adaptations for bipedality, but it is entirely possible that they were achieved through different evolutionary pathways (Harcourt-Smith and Aiello 2004).

The Rise of Obligate Bipedalism

In section “Locomotion in Australopiths,” I discussed locomotor behavior within the genera *Australopithecus and Paranthropus*. While there may well have been some diversity in the way that different species of *Australopithecus* were bipedal, what is certain is that they cannot be considered as fully obligate bipeds in the way that modern humans are. Conversely, later species of *Homo*, such as *H. erectus*, *H. antecessor*, and *H. neanderthalensis* were unequivocally obligate bipeds (see Fig. 1 for a summary of which taxa there is agreement and disagreement over concerning bipedalism). There are some subtle anatomical differences in the postcranial skeletons of these taxa when compared to modern humans, but their overall skeletal biology strongly implies fully humanlike bipedal locomotion (e.g., Trinkaus 1983; Aiello and Dean 1990; Lorenzo et al. 1999). It seems, then, that the emergence of true obligate bipedal locomotor behavior occurred between about 2.5 and 1.8 Ma. This time period is associated with the emergence of the genus *Homo*, with which the emergence of obligate humanlike bipedalism is likely to prove to be strongly associated.

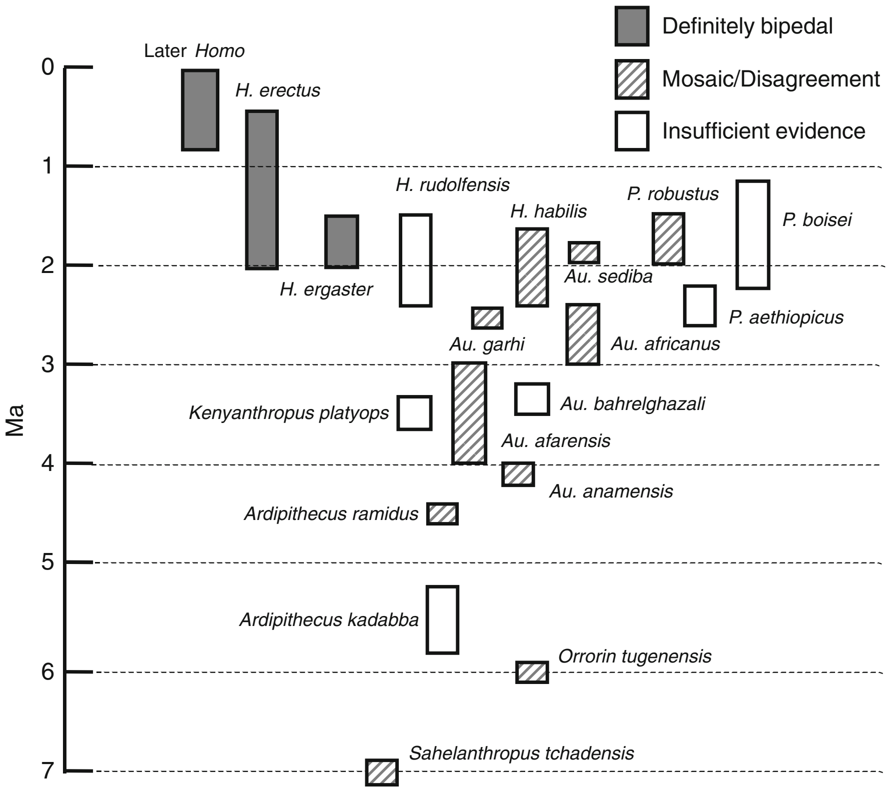

Fig. 1 Temporal ranges of known hominin taxa. Solid shading indicates taxa that were unequivocally obligate bipeds. Cross-hatching indicates taxa where they are mosaic, or there is disagreement over the degree to which they were bipedal. No shading relates to those taxa where there is insufficient evidence (Adapted from Wood (2002))

This period is also extremely complex in terms of hominin evolution and has been the subject of a very diverse range of taxonomic interpretations. At least ten widely accepted hominin species have first or last appearances within this time frame, and the fossil record implies that there was considerable overlap in the temporal and geographical distribution of many of these taxa. Determining which of these species were fully obligate bipeds, and which were not, has been hampered by a number of factors. The principle issue is a meagre postcranial fossil record, but even where there are significant numbers of postcranial elements, as at Koobi Fora (Leakey et al. 1978), there are often problems of reliable taxonomic association. However, the 1.8 Ma juvenile *Homo ergaster* skeleton from Nariokotome, Kenya (KNM-WT 15000), was unequivocally that of a full biped. Its postcranial skeleton is remarkably humanlike, with long legs and short arms and all of the derived postcranial traits associated with obligate bipedal locomotion (Ruff and Walker 1993). With such an advanced body plan, it is reasonable to assume that *H. ergaster* and possibly its direct precursors had developed obligate bipedal behavior before 2 Ma. There are a number of other postcranial remains from Koobi Fora that imply striding bipedalism. In particular the femora KNM-ER 1472 and 1481A are long and extremely humanlike. However, it is difficult to speculate whether these specimens belonged to *H. rudolfensis*, *H. ergaster*, or even *P. boisei*. More recently, 1.5 Ma hominin footprints discovered at Koobi Fora also indicate extremely humanlike bipedalism (Bennett et al. 2009). Study of the prints suggests that they are not only more humanlike than those at Laetoli, (Bennett et al. 2009) but also are compatible with body mass and height estimates for *H. ergaster*. However, as for many other remains at this site, they cannot confidently be assigned to any one taxon.

African Early *Homo*

Most of the debate over the locomotor affinities of early members of *Homo* has concentrated on postcranial remains assigned to *Homo habilis* from Olduvai Gorge, Tanzania. Found at site FLK NN, the holotype for this taxon, OH 7, includes a number of predominantly juvenile hand bones. These bones are argued to be mosaic in their overall morphology. The scaphoid is apelike, the proximal and intermediate phalanges are more curved than in modern humans, and the intermediate phalanges have more apelike attachments for *m. flexor digitorum superficialis*, a muscle associated with climbing and suspensory behavior (Susman and Creel 1979; Aiello and Dean 1990). The OH 8 foot, also found at FLK NN, is included as a paratype of *H. habilis* and provides the best insight into the locomotor behavior of this taxon (Day and Napier 1964; Leakey et al. 1964). Extensive analyses of these bones indicate that the foot had strong longitudinal arches, a locking calcaneocuboid joint, a metatarsal robusticity pattern similar to that of modern humans, and perhaps most importantly a hallux in line with the remaining toes that was wholly incapable of any opposability (Day and Napier 1964; Susman and Stern 1982; Berillon 1999, 2000; Harcourt-Smith and Aiello 1999). The combination of all these features points to an individual capable of efficient bipedal locomotion. However, the talus is less humanlike than the remaining foot and has a trochlea that is strongly grooved and medially sloping. This is a more-apelike morphology and is consistent more laterally arcuate passage of the leg over the foot during the stance phase (Latimer et al. 1987). The implication of this is that although the OH 8 foot is very humanlike in most critical features, its ankle joint implies less efficient weight transfer from the leg during walking. There are also the OH 35 distal tibia and fibula, which were found at site FLK (Davis 1964). These are argued to be humanlike, with a talar facet that is perpendicular to the long axis of the shaft and predominantly humanlike muscle attachments (Davis 1964; Lovejoy 1975; Susman and Stern 1982). It has been argued that OH 35 is likely to have come from the same individual as OH 8 based on morphological similarity (Susman and Stern 1982). Recent metrical comparisons contradict that assertion (Aiello et al. 1998), and it should be noted the two specimens were found 300 yards apart and in different geological horizons (Davis 1964; Dunsworth and Walker 2002).

The other specimen of interest from Olduvai is the more recently discovered partial skeleton OH 62, found at site FLK and assigned to *H. habilis* based on associated craniodental remains (Johanson et al. 1987). Although OH 62 is extremely fragmentary, it has been argued that the intermembral proportions were more apelike and similar to that of *Au. afarensis*. This assertion was based on humerofemoral proportions that relied on the femoral length of OH 62 being estimated as similar to those of the considerably older *Au. afarensis* AL 288 (Johanson et al. 1987; Hartwig-Scherer and Martin 1991). Based on these findings, it has also been suggested that OH 62 has limb proportions as primitive as those of *Au. africanus* (McHenry and Berger 1998a, b). However, the OH 62 femur is incomplete, lacking a considerable part the distal end, and it is impossible to accurately estimate the correct length of this fossil (Korey 1990; Haeusler and McHenry 2004). Furthermore, an alternative reconstruction of the OH 62 femoral length, based on morphological similarity to the younger (1.15–0.8 Ma) and undescribed OH 34 femur from Bed III, yields a far more humanlike value, indicating more humanlike limb proportions (Haeusler and McHenry 2004). Given that OH 34 may have been subjected to a degree of post-depositional erosion that may have compromised its morphology (Day and Molleson 1976), this latter finding must also be treated with caution. However, given that the OH 35 tibia and fibula are also relatively long, it is not unreasonable to assume that the limb proportions of *H. habilis* could have been rather more humanlike than some have suggested. Until further material is uncovered, the evidence is not strong enough to be definitively sure of either scenario. More recently Ruff (2009) has addressed the cross-sectional properties of the OH 62 long bones and concluded that the humeral and femoral strength proportions were outside the modern human range of variation and within that of *Pan*, implying that *H. habilis* was not an obligate biped and retained some arboreal specializations.

There are thus a number of things that can and cannot be said about the locomotor affinities of *H. habilis*. The foot, tibia, and fibula are all very humanlike in most critical aspects. There is some degree of uncertainty concerning whether the limb proportions were more human or apelike, but this issue cannot be currently resolved. The hand bones show a mosaic of humanlike and apelike morphologies that may imply some climbing activity, and this is supported by analyses of the cross-sectional properties of the long bones. Therefore, a conservative estimation of the locomotor behavior of *H. habilis* would place it *between* the habitual bipedalism of the australopiths and the obligate bipedalism of *H. ergaster* and later species of *Homo*. The ambiguity surrounding the locomotor affinities of *H. habilis* has been used by some to add weight to the argument that it should be transferred to the genus *Australopithecus* (e.g., Wood and Collard 1999). There may or may not be the case craniodentally, but it cannot yet be argued postcranially. Further fossil discoveries will undoubtedly help resolve some of these issues, but findings to date imply a type of bipedalism in *H. habilis* more humanlike and more efficient than that of either *Au. afarensis* or *Au. africanus*.

Early *Homo* from Outside Africa

Outside of Africa a number of postcranial remains have been discovered at the 1.8 Ma site of Dmanisi in Georgia (Lordkipanidze et al. 2007). The species-level affinities of the Dmanisi hominins are the subject of some disagreement, but there is little debate that they belong to the genus *Homo*. Descriptions of the material suggest that the Dmanisi hominins had a combination of derived and primitive morphologies in their postcranial skeleton (Lordkipanidze et al. 2007; Pontzer et al. 2010). There is evidence for a longitudinal arch in the foot, a humanlike ankle and an elongated lower limb. However, there is also low humeral and tibial torsion compared to modern humans. In the original description of the material (Lordkipanidze et al. 2007), it was argued that the foot of the Dmanisi hominins would have struck the ground in a more medial orientation, which is often described as being "pigeon toed" in modern humans. However, a reanalysis of the published data has clearly refuted this suggestion and shows that the variables in question fall within the ranges of modern human variation (Wallace et al. 2008).

Early *Homo*: Summary

There is likely to have been some degree of locomotor diversity between different species of early *Homo*. The anatomy of the *Homo ergaster* postcranial skeleton (mainly based on KNM-WT 15000) is extremely humanlike and derived, and it would have been an obligate biped capable of long distance travel (Wang et al. 2004). In fact it has been suggested that this would have included endurance bipedal running, something that earlier hominins are unlikely to have been able to have done (Bramble and Lieberman 2004). On the other hand there is far less certainty concerning *Homo habilis*. Although there is evidence of a distinct shift between the morphology and associated locomotor function of its postcranial remains and those of *Australopithecus*, it would not have been as efficient a biped as *H. ergaster* and is likely to have had a unique pattern of gait. Therefore, while it is certain that by the beginning of the Pleistocene fully obligate bipedalism had developed in at least one lineage of *Homo*, it cannot be argued that this had occurred in *all* species within that genus. This would suggest that different early species of *Homo* were perhaps ecologically distinct from each other, with different locomotor behaviors and activity patterns.

Bipedalism in Later *Homo*

As mentioned above, nearly all later members of the genus *Homo* (e.g., *H. antecessor*, *H. heidelbergensis*, *H. neanderthalensis*) have postcranial skeletons entirely consistent with obligate bipedalism. Differences that do exist between these taxa and *H. sapiens* are small at best, though may have had some subtle effects on locomotor behavior. For instance, it has recently been shown that *H. neanderthalensis* had a slightly longer calcaneal tuber than modern humans, which would have increased its energy expenditure costs during running (Raichlen et al. 2011).

The one exception is the diminutive *H. floresiensis* from the Middle and Late Pleistocene of Flores, Indonesia. A number of metrical analyses of the postcranium show that the wrist retained several primitive, australopith-like features (Tocheri et al. 2007), the shoulder was more like that of *H. ergaster* than *H. sapiens*

(Larson et al. 2007), and the foot was markedly long compared to the leg and was unlikely to have had a longitudinal arch (Jungers et al. 2009). With such a combination of morphologies, while *H. floresiensis* was undoubtedly a biped, it was likely to have had a gait very different to that of modern humans.

Summary of Locomotor Behaviors Within the Hominin Clade

As we have seen, there are varying degrees of fossil evidence for the origins of bipedalism. More often than not, we are faced with the problem of being unable to place skeletal remains diagnostic of bipedality within a particular taxonomic hypodigm, and those fossil specimens which are associated with a particular species often show bewildering combinations of primitive, derived, and unique characteristics. However, on the basis of existing evidence, a number of broad conclusions can be made (Fig. 2). It is possible that the earliest hominins, such as *A. ramidus*,

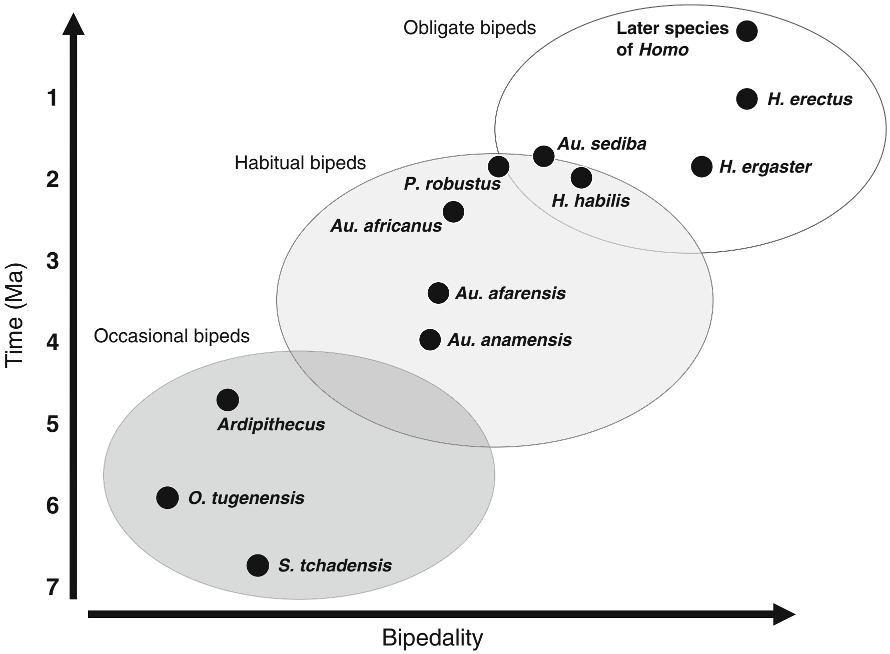

Fig. 2 The degree of bipedality in known fossil hominins relative to time. Only taxa with documented traits relating to bipedal locomotion are included. *Ardipithecus*, *O. tugenensis*, and *S. tchadensis* are classed as occasional bipeds on the basis of having very few or weak traits related to bipedality. *Australopithecus afarensis*, *africanus*, and *sediba* are classed as habitual bipeds on the basis of major anatomical remodeling of structures functionally related to bipedality, but retention of a number of apelike climbing specializations. *H. ergaster*, *H. erectus*, and later species of *Homo* are classed as obligate bipeds, but there is enough debate over *H. habilis* to place it between habitual and obligate bipedalism

O. tugenensis, and *S. tchadensis*, show important enough features to imply a slight shift to increased terrestrial bipedality. However, with the exception of *Ar. ramidus*, the evidence is extremely meagre, and further finds may show that any shift to bipedality could have been more or even less substantial. Following these taxa, there appears to have been at least two distinct shifts in the development of hominin locomotion. Firstly, between 4.5 and 3 Ma, a number of habitually bipedal hominin species emerged, as typified by the Laetoli footprints and the extensive postcranial remains from Hadar. Within this time frame it is possible that different species varied in the way that they became bipedal and that there were several different "types" of bipedalism being practiced (Harcourt-Smith and Aiello 2004; Haile-Selassie et al. 2012). The period between 2.5 and 1.8 million years heralds a second shift to fully obligate bipedalism. This period coincides with the emergence of the genus *Homo*, and by 1.8 Ma at least one member of this genus (*H. ergaster*) was a fully obligate biped with a modern human body plan. Other early species of early *Homo*, like *H. habilis*, may well have had a locomotor repertoire that was transitional between that of *Australopithecus* and *H. ergaster*. Subsequent to the advent of *H. ergaster* and *H. erectus*, all known hominins were fully obligate bipeds, although the enigmatic remains of the Middle-to-Late Pleistocene *Homo floresiensis* retain a number of primitive postcranial traits that would have made their gait, although bipedal, entirely distinct from that of *Homo sapiens* (Jungers et al. 2009).

Why Was Bipedalism Selected for?

As has been discussed, much contemporary debate over the origins of bipedalism rests on the locomotor affinities of particular taxa or individual specimens. This is understandable given that fossils provide concrete evidence. However, it is critical to also ponder why bipedalism was selected for and why it became such a successful form of locomotion for our species. Most early theories as to why humans became bipedal center on the "freeing of the hands" as the principal force of selection. This can be traced back to Darwin, who argued in the *Descent of Man* (1871) that bipedal locomotion must have evolved to allow for the construction and use of hunting weapons. Since that first explanation there has been as abundance of different theoretical explanations, ranging from the plausible to the wholly implausible. When considering these different potential selection pressures, it is important to consider that bipedal locomotion is a highly derived and unique form of primate locomotion. In that context, we have seen that the skeletal modifications associated with bipedality are considerable. It is therefore strong selection pressures that specifically required prolonged periods of upright walking that are likely to provide the key as to why bipedalism evolved (Lovejoy 1981; Rose 1991).

Prior to the discovery of the *Au. afarensis* remains from Hadar, the orthodox view remained that tools and tool use were intrinsically involved with the emergence of habitual bipedalism. Echoing Darwin (1871), some argued that tool use itself explained the selection for bipedalism (e.g., Washburn 1960), while others suggested that behavior was a more likely explanation (e.g., Bartholomew and Birdsell 1953; Washburn 1967). Both these theories are now contradicted by the temporal sequence of events provided by the contemporary fossil and archaeological records (Rose 1991). Evidence of bipedal locomotion currently predates the earliest stone tools by at least 1.5 Myr and probably more, which precludes the involvement of any stone-tool-associated behavior in the origins of bipedality. More recent hypotheses have tended to be strongly linked to paleoenvironmental changes from the end of the Miocene through to the beginning of the Pleistocene. In this respect the traditional view has been that the emergence of bipedalism most likely correlated with generally cooler and dryer global conditions and an associated increase in more open grassland habitats (Van Couvering 2000), often referred to as the "savanna hypothesis." Predominantly forested environments were gradually replaced by more mosaic environments made up of different proportions of open grassland, bushland, and open woodland (Reed 1997). To cope with these environmental changes, it was argued that hominins had to adapt a series of new behavioral strategies. Change in habitat composition would have resulted in a shift in food availability and thus necessitated a shift in food acquisition behaviors (e.g., Rose 1991; Foley and Elton 1998). Hominins would either have to have ranged further to find food or develop strategies to procure new and different types of food. In this scenario, it was therefore very likely that hominins would have had to have engaged in more terrestrial travel over more open habitats, resulting in the emergence of bipedality as an important part of the locomotor repertoire.

However, the discovery of late Miocene hominins (see section "Earliest Hominin Evidence") and the increasing complexity associated with accurately reconstructing hominin paleoenvironments (Behrensmeyer and Reed 2013) has complicated the savanna hypothesis to some degree. The paleoenvironments of the earliest hominins through to late *Australopithecus* have been varyingly reconstructed from very open and dry to relatively closed and forested (Behrensmeyer and Reed 2013). Coupled with recent suggestions that hominin bipedalism originated in arboreal environments (e.g., O'Higgins and Elton 2007; Thorpe et al. 2007; Almécija et al. 2013), it is possible that the classic savanna hypotheses is in need of reevaluation when considering the shift from occasional to habitual bipedalism in early hominins. For the shift from habitual to obligate bipedalism in the early Pleistocene, the hypothesis is on stronger ground, as this period coincides with an unambiguous opening up of hominin habitats (Reed 1997; Van Couvering 2000).

Despite these complexities, a number of theories strongly associated with the savanna hypothesis warrant discussion. Lovejoy (1981) argues that food-carrying and procurement by males was the driving selection pressure. This would tie in with some interpretations of the fossil material from Hadar that suggests that there was a degree of locomotor sexual dimorphism in *Au. afarensis* (Stern and Susman 1983). Recent experimental work also supports Lovejoy's (1980) theory in showing that introducing widely distributed "food piles" leads to an increase in chimpanzee and bonobo locomotor bipedality, mainly associated with food-carrying (Videan and McGrew 2002). Such a situation could be analogous to the more spread-out concentrations of food sources available to hominins in a more open grassland environment. Increased bipedalism in such a setting would greatly increase the ability to carry food to desired locations. Other theories argue for terrestrial food-gathering (Jolly 1970; Wrangham 1980) or even hunting (Carrier 1984; Shipman 1986; Sinclair et al. 1986). Jolly's (1970) model uses the open-savanna gelada baboon as a modern-day analogue to suggest that early hominin bipedalism was linked to rapid seed-collecting behavior. Hunt (1990, 1994, 1996) has argued that chimpanzee postural behaviors may provide the key to our understanding of this issue. Over 80 % of chimpanzee bipedalism is related to postural feeding. Using this as a behavioral analogue, Hunt argues that early hominin postcranial adaptations in *Australopithecus* were related to similar postural feeding behaviors, and that true bipedal locomotion emerged with the advent of *Homo* (see Wood 1993). It is certainly possible that bipedal postural behavior may have preceded bipedal locomotion, but posture alone is likely to be too weak a selection pressure to have resulted in the significant anatomical remodeling seen in the *Au. afarensis* and *Au. africanus* pelvis and lower limb structures (Lovejoy 1981; Rose 1991). It has also been suggested that bipedal threat displays may have been an important selective precursor to bipedal locomotion (Jablonski and Chaplin 1993).

One of the most interesting and widely accepted explanations of why hominins became bipedal is the thermoregulatory hypothesis suggested by Wheeler (1984, 1988, 1991, 1993, 1994). This argument rests on strong physiological explanations related to the reduction of thermal stress and directly relates to the more open habitats that hominins would have become exposed to through the Pliocene. On the open savanna, quadrupedal animals expose considerably more of their body's surface area to the sun. By standing fully upright, Wheeler calculated that a hominin would absorb 60 % less heat at midday. Furthermore, being upright exposes the subject to any potential breeze, which would have a further cooling effect. These factors would greatly reduce the rate at which hominins would have overheated on open ground, meaning that they could have ranged further without having to have increased water intake. In a more open environment, where food sources were likely to have been more spread out, such an advantage would have greatly enhanced the ability of hominins to successfully collect food (Chaplin et al. 1994). One other physiological explanation for the development of bipedalism warrants comment. Rodman and McHenry (1980) have argued that there is a considerable energetic advantage to become bipedal. However, it has been shown that *Pan* and *Gorilla* locomotion is not any less efficient physiologically than that of modern humans (Steudel 1994).

Perhaps the most interesting point relating to all the above theories is that made by Robinson (1972), who states that there is unlikely to have been *one* specific reason why bipedalism was selected for. It was more likely a combination of several selective factors strongly relating to feeding strategies and reproductive behavior that provided the impetus for this shift in the hominin locomotor repertoire. Furthermore, bipedalism would have provided not only the ability to range further for food and other resources; it would have exposed hominins to novel parts of the surrounding landscape, different types of predators, and new food sources. This in turn would have led to new hominin behavioral strategies to cope with such changes. It has also been argued that, on the basis of increasingly variable environmental conditions during the Late Miocene and Pliocene, associated behavioral versatility would have been a critical selective factor for early hominins (Potts 1998). If so, there is little doubt that selection for bipedality would have considerably facilitated such behavioral versatility.

Conclusion

There is no doubt that the evolution of bipedalism is a critical issue in the study of human origins. However, as we have seen, there has often been a considerable degree of rather polarized debate and disagreement as to how, when, why, and in whom hominin bipedalism evolved. In particular, the emergence of so many important fossil finds in the last 40 years has resulted in the literature becoming increasingly "fossil driven" in its concentration on *how* bipedal a particular hominin taxon might have been. This has often clouded our understanding of the larger issues at stake surrounding the emergence of this unique form of primate locomotion. As Rose (1991) has pointed out, selection for bipedality was not an event, but rather a series of processes. In that context, what can be said about these processes? It is certain that the selection pressures for bipedality must have been strongly linked to reproductive success, and it is therefore likely that such pressures would have been related to the efficient gathering and transport of food and other resources across increasingly varied habitats. As discussed earlier in this chapter, the current fossil record points to at least one minor and two major steps in the emergence of obligate, humanlike bipedality. The earliest hominins were little more than occasional bipeds, while the australopiths can certainly be considered as habitual bipeds who still engaged in some arboreal locomotor behaviors. By the emergence of early *Homo*, certain species within that genus were unequivocally obligate bipeds much in the way that we are today. It is perhaps seductive to view such steps as punctuated events, and that may have been the case. But it is also possible that the fragmentary fossil record merely creates the illusion of such steps. Only the recovery and analysis of further fossil remains relating to bipedality, particularly from the Late Miocene hominoid record, will further our understanding of this complex and unique process.

The Evolution of the Hominid Brain

Ralph L. Holloway

Contents

Abstract

The evolution of the human brain has been a combination of reorganization of brain components and increases of brain size through both hyperplasia and hypertrophy during development, underlain by neurogenomic changes that have involved epigenetic changes largely effecting regulation of growth dynamics. While both genomics and comparative neuroanatomical studies are invaluable to understanding how brains and behavior correlate, it is paleoneurology, based on endocast studies (chapter "▶ Virtual Anthropology and Biomechanics," Vol. 1), which are the direct evidence demonstrating volume changes through time. Some convolutional details of the underlying cerebral cortex do appear on

DOI 10.1007/978-3-642-39979-4_81

the endocranial surface. These details allow one to recognize reorganizational changes that include (1) a reduction of primary visual cortex and relative enlargement of posterior association cortex, (2) expanded Broca's regions, and (3) cerebral asymmetries. The size of the hominid brain increased from about 450 ml 3.5 Ma ago to our current average volume of 1,350 ml, with a slight reduction since Neolithic times. Many more data from additional fossils will be necessary to decide how and when these two changes through time occurred and whether these were gradual or punctuated.

Introduction

The evolution of the human brain has largely been a matter of integrating both increases in the size of the brain and the brain's organization through the past 3–4 myr mainly based on species of the genus *Australopithecus* and two of its species, *A. afarensis* and *A. africanus*.[1] Earlier possible hominin forms such as *Sahelanthropus* or *Ardipithecus* in the time range of 3–6 myr do not have sufficient endocranial remains to do more than estimate volumes. Three lines of evidence are used by paleoneurologists to ascertain how these events might have occurred: (a) direct evidence from the brain endocasts of fossil hominids (paleoneurology) and (b) the indirect evidence from comparative neuroscience, where variations in brain structures can be related to variations in behavior and be compared between species. This latter evidence is "indirect" because extant living animals are not ancestral to humans and have undergone their own evolutionary changes. Indeed, the last common ancestor for apes and the hominid line existed some 5–7 Ma ago. (c) Newer neurogenomics evidence also promises to provide important clues to how and when certain aspects of brain changes occurred during human evolution (e.g., Preuss 2012; Zeng et al. 2012).

Our best paleoneurological evidence suggests that the human brain evolved from an early hominid 3–4MY, *A. afarensis*, having a size of roughly 400 ml to our present average of 1,330 ml. These brain size increases, at different taxonomic levels, were mostly allometric, i.e., related to body size, but not always. Integrated with these changes in brain size was reorganization of the cerebral cortex, as well as changes in subcortical structures such as the hippocampus, amygdala, etc., to mention a few important structures that relate to aspects of social behavior but that cannot be seen on endocasts. Reorganization simply refers to both qualitative and quantitative changes through time of neural structures. Endocasts, of course, cannot provide information regarding neural variables such as subcortical volumes, cell densities, dendritic branching and connectivity, or any neurochemical or neurophysiological information. Thus from the point of view of knowing what

---

exactly the data indicate regarding human brain evolution, the direct evidence of endocasts is critically important, however poor the data they contain actually may be.

At least three areas of the reorganization of the cerebral cortex were affected at different times: (a) a relative reduction of primary visual striate cortex (V1, PVC) and an attending relative increase in posterior parietal association cortex; (b) a change in Broca's region, resulting in a more humanlike pattern; and (c) increasing degrees of cortical asymmetry, as well as increases in overall brain size and number of neurons.

How exactly did the human brain evolve, and when did changes in it happen? Obviously, to answer this question fully would require a time machine and thousands of generations of observations to ascertain both the variability and direction of selection pressures in the past. We can, however, flesh out an initial understanding of how we got to be the animal *par excellence* that utilizes its brain for intelligent rationalizations, based largely on the use of arbitrary symbol systems and on behavioral adaptations involving a complementary social existence between males and females permitting prolonged infant growth and nurturance (chapters "▶ Great Ape Social Systems" and "▶ Theory of Mind: A Primatological Perspective," Vol. 2). The evidence consists of two components: (a) the "direct" evidence from the fossil record and (b) the "indirect" evidence of the comparative neuroscientific record of extant living animals, particularly those most closely related to us such as the chimpanzee and bonobo. There is also a third possibility: since the Human Genome Project has sequenced almost all of the genetic code, the future study of evolutionary neurogenomics might provide more data about the actual genetic history of our genus through time, as well as that of the great apes mentioned above (see, e.g., Hernando-Herraez et al. 2013; Gokcumen et al. 2013). As this latter possibility is little more than a gleam in our eye at present, this article will concentrate on the evidence provided by the first two components.

Lines of Evidence

Direct Evidence

The term *paleoneurology* is used to describe evidence relating to the size and morphology of the casts made from the inside of actual fossil cranial remains. Occasionally, the casts are "natural," i.e., where fine sediments have filled the inside of the cranial cavity, becoming infiltrated and compacted through time. These casts sometimes retain some of the morphological details that were imprinted on the internal table of bone of the cranium when the animal was alive. The famous australopith (*A. africanus*) Taung child's skull, described by Dart (1925), is one of the best-known examples, as are Sts 60 and SK 1585, the latter a fine example of *Australopithecus robustus*. Curiously, these "natural" endocasts are only found in the South African australopiths (chapter "▶ Analyzing Hominin Phylogeny: Cladistic Approach," Vol. 3) and date from about 3.0 myr to about 1.5 myr (see Fig. 1). Traditionally, paleoneurologists have made casts of the insides of fossil

Fig. 1 Casts of the Taung (*left*), Sts 60 (*right*), and SK 1585 (*bottom*) "natural" endocasts of Australopithecines

skulls using rubber latex, or silicone rubber, extracting these from the cranial remains. The partial cast is then sometimes reconstructed by adding plasticine (modeling clay) to the missing regions. The whole is then measured by immersion into water, and the amount of water displaced is regarded as the volume of the once-living brain. Other measurements (linear chords and arcs) and observations (convolutions and asymmetries) may be made on the original cast. More recently, "virtual" endocasts have been made from CT scans of intact or partial crania, an approach that has the advantage of being noninvasive (chapter "▶ Virtual Anthropology and Biomechanics," Vol. 1). As it is computer driven, there are various algorithms for deriving the size of the endocast and other metrics (chapter "▶ Virtual Anthropology and Biomechanics," Vol. 1; Weber et al. 2012; see also Zollikofer and Ponce de León 2013). Of course, CT scans (medical and micro) are not continuous, as is the case with actual casting materials such as silicone-based materials that flow into all the cracks, crevices, and convolutional details available.

During life, the brain is surrounded by three dural tissues (the dura mater, the arachnoid tissue and its cerebrospinal fluid, and the pia mater) that interface between the actual brain tissue (cerebral cortex, mostly) and the internal table of bone of the skull. The gyri and sulci (convolutions) of the once-pulsating cerebral cortex are thus imperfectly imprinted on the interior of the skull, and the degree of replication often varies in different regions, e.g., sometimes the frontal lobe imprints more details than the parietal lobe, as well as by age. The degree of replication also varies in different animals. Two extremely important considerations emerge from this: (a) the resulting imprints are never complete and are thus

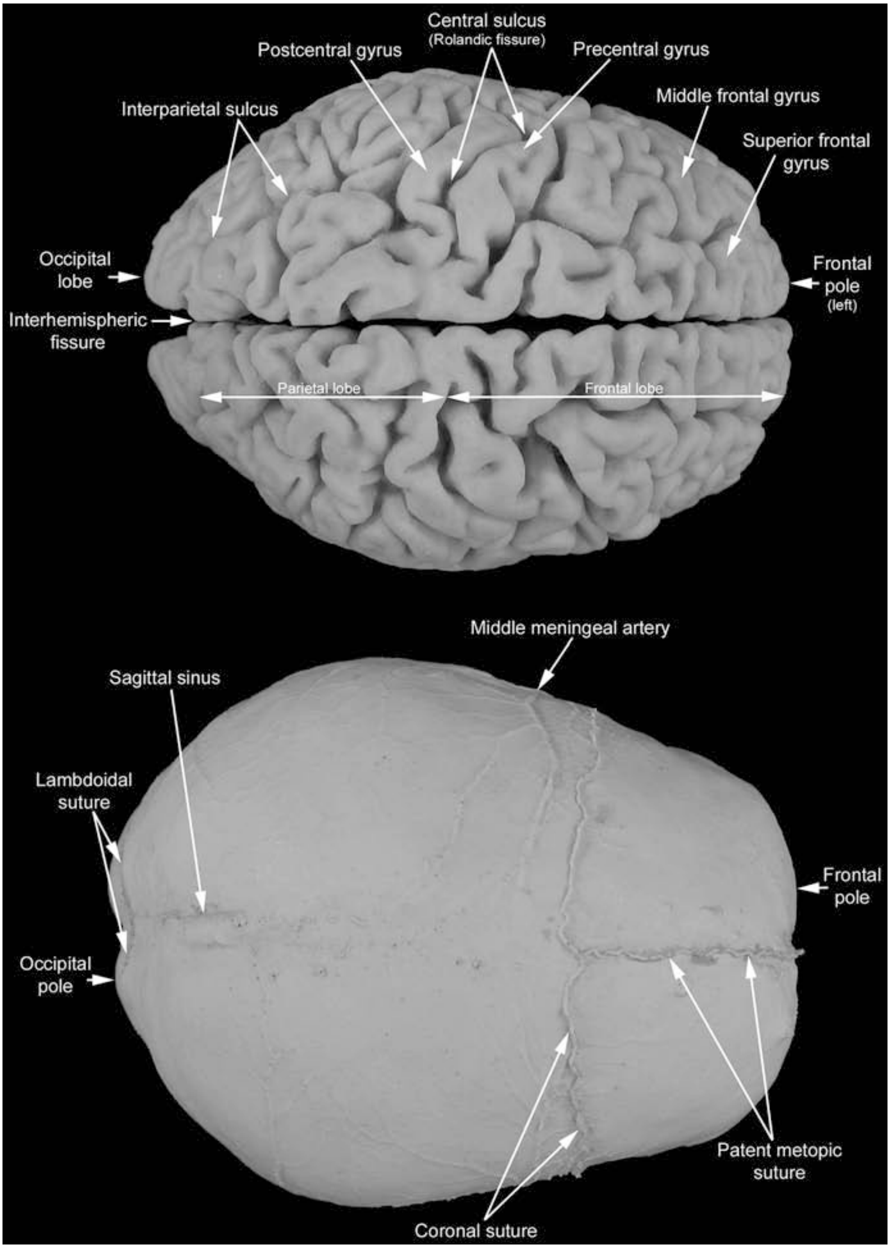

Fig. 2 (continued)

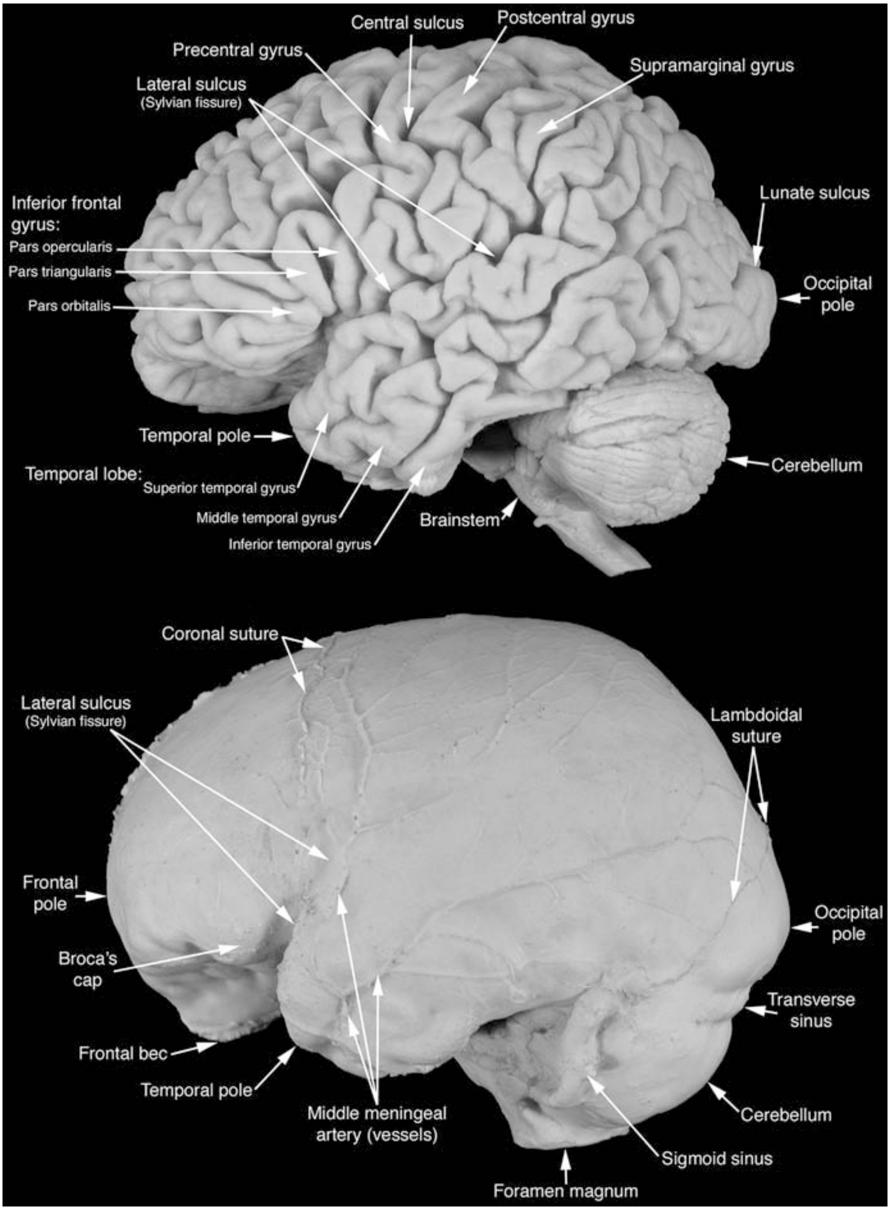

Fig. 2 Dorsal (see *previous page*) and lateral (see *above*) views of a modern human brain and the endocast to demonstrate the loss of detail on the endocast surface

in that sense "data poor," never including subcortical structures, and (b) the controversial interpretations of what the underlying brain once looked like are guaranteed (see Fig. 2). Nevertheless, endocranial casts do provide extremely important information regarding (1) overall size, (2) shape, (3) rough estimates of

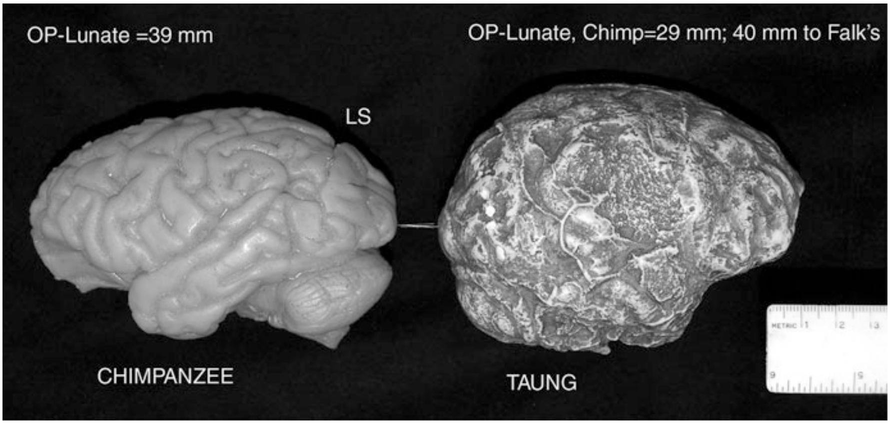

Fig. 3 Lateral view of a chimpanzee brain and the Taung *A. africanus* endocast. The lunate sulcus separates PVC from association cortex and is in an anterior position in apes. The *white dots* on the Taung endocast show where the average chimpanzee lunate sulcus would fall and that location violates the sulcal morphology on Taung. Placing it more anteriorly would be a monkey-like configuration. The Taung lunate sulcus would most probably be posterior, in a humanlike position, which is near the lambdoid suture

the lobal dimensions of the brain, and (4) cortical asymmetries that have relationships to hemispheric specializations and behavioral processes including handedness. In addition (5), if the imprints of the underlying gyri and sulci are available, they can provide important information regarding the organization of the cerebral cortex and whether the patterns of these are the same or different as in known extant primate brains. The infamous "lunate sulcus" is a good example, as it is a demarcation boundary between purely sensory primary visual striate cortex (PVC) and multimodal association cortex in both Old World monkeys and anthropoid apes. When the lunate sulcus appears in an anterior position, it is most similar to the condition known in modern apes. When it is found in a posterior position, it is in a more humanlike condition. Ascertaining its correct position is thus essential in deciding whether or not such a fossil hominid had a brain organized along human or ape lines. In modern humans, the "lunate" is only partially homologous with that found in apes and is usually fragmented (Allen et al. 2006). Hominins such as *Homo erectus*, *H. heidelbergensis*, *H. georgicus*, and *H. neanderthalensis* unfortunately do not have occipital lobes that allow clear-cut identification of the lunate sulcus if it were a singular unfragmented sulcus. Figure 3 shows a comparison between a chimpanzee brain with a lunate sulcus and that of the Taung child, *A. africanus* (See also Holloway 1984, 2000). Finally (6), meningeal arteries and veins that nourished the dura mater also imprint on the internal table of bone and sometimes show patterns that are useful for deciding taxonomic issues; these have no known relationship to behavioral functions of the brain. (See also Grimaud-Hervé in Holloway et al. 2004, for further discussion and illustrations.) Figure 4 shows that a more recent *A. africanus* specimen from Sterkfontein, S. Africa, Stw 505, shows a clear lunate

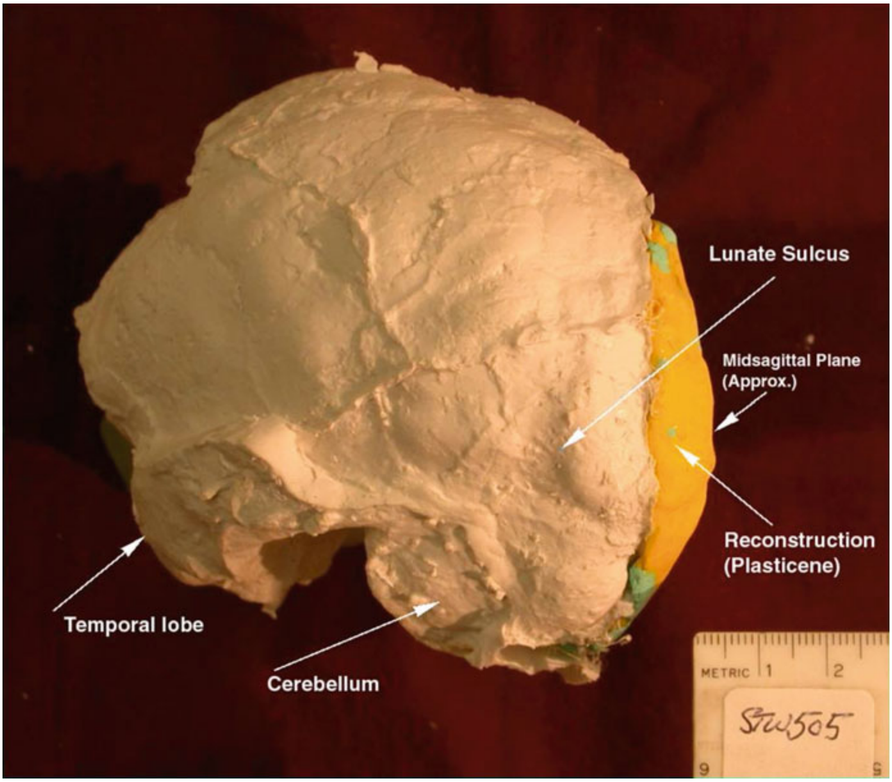

Fig. 4 Oblique view of the Stw 505 *A. africanus* specimen, showing a prominent lunate sulcus in a posterior position. This specimen makes it clear that at least some australopithecines had reduced primary visual cortices and expanded posterior parietal lobes, evidence showing that reorganization probably preceded brain size increases

sulcus in a relatively posterior position compared to chimpanzee brains. Falk (2014) has made the bizarre suggestion that is perfectly crescentic lunate sulcus is the lateral calcarine sulcus, which is not possible given the medially directed curvature of both inferior and superior ends of the depicted lunate sulcus in Stw505. When in the course of subsequent hominin evolution, the lunate sulcus changed into a more fragmented partially homologous structure as found in modern humans is unknown, as neither *Homo erectus* nor Neanderthals show detailed gyri in the occipital region (chapters "▶ Later Middle Pleistocene *Homo*" and "▶ Neanderthals and Their Contemporaries," Vol. 3).

The frontal lobe is of course a major focus of examining endocasts in the hope of understanding the evolutionary trajectories through time of the most crucial part of neuroanatomy underlining our very humanness, intelligence, and social behavior. Here, we are plagued with by the fact that very few sulcal details are available on the endocasts of early hominins, particularly the australopiths. A recent paper by Carlson et al. (2011) describes the frontal portion of an endocast of MH1 (Malapa

Hominin 1) that they have named *Australopithecus sediba* and that shows some possibility of prefrontal organization toward a more human condition.

Indirect Evidence

This line of evidence is “data rich,” providing comparative neurological information on living species, such as brain size (both absolute and relative, i.e., related to body size), the actual makeup of the brain from the gross to microscopic levels, including neural nuclei, fiber systems and interconnections, and distribution of neurotransmitters and neuroreceptors. Additionally, the brain can be studied ontogenetically, and neuroscientists can actually study the relationships between how the brain varies neurologically and how these variations relate to the behavioral variation. Modern examinations including CT, MRI, fMRI, and tensor diffusion techniques can be applied, yielding different kinds of data relevant to different aspects of growth and development, genetic and epigenetic unfolding, and behavioral consequences (chapter “▶ Virtual Anthropology and Biomechanics,” Vol. 1). Neurogenomic information will also add considerable details as to how living brains vary and operate, both within and between different species, and hopefully inform us about selection events in the evolutionary past. This richness is simply lost to the paleoneurologist. However, it is necessary to realize that the extant living species often used as comparisons to humans, e.g., bonobo, chimpanzee, and macaque (chapters “▶ Estimation of Basic Life History Data of Fossil Hominoids,” Vol. 1, “▶ Evolution of the Primate Brain,” and “▶ The Hunting Behavior and Carnivory of Wild Chimpanzees,” Vol. 2), are end points of their own evolutionary lines of development and are not our ancestors, however closely related to us they may be. It is thus the blending and complementation of these two approaches which provide the best set of evidence for when and how our brains evolved. Another aspect of the comparative evidence is the question of how well we can explain species-specific behavior on the basis of what we know from comparative neurology. Considering the behavioral differences between chimpanzees and bonobos and gorillas and orangutans, there are no current explanations to explain these in terms of neuroanatomical detail.

Characteristics of the Human Brain

Brain Size, Absolute and Relative

The human animal is obsessed with size, and those who study the brain comparatively are perhaps more so than average. With a mean brain weight of 1,330 g and a body weight of 65,000 g (Tobias 1971), the human species has the largest absolute brain size within the primate order, but is actually dwarfed by elephants and some of the whales, in which brain weight can exceed 7,500 g. Of course, body weights are also very much higher in elephants and whales. But even for its body weight,

Table 1 Fossil hominid brain volumes

Group	Average Number	Location	Brain volume	Range	Dating (myr)
A. afarensis	3	E. Africa	435	385–500+	3–4

Source: Holloway 1997

Homo sapiens does not have the largest relative brain weight (about 2 % of body weight), being outdone by several monkeys, some rodents, and even some fish. Normal modern human brain size varies between roughly 900 and 2,000 g, although a very small number of exceptions do occur, with sizes in the 750–900 and 2,000–2,200 g range. Human populations vary, as do the sexes. In general, Arctic peoples tend to have larger brains than those living in the tropics, and the smallest brains appear to be found among Ituri forest pygmies who also display small stature. Males in all populations for which good autopsy or cranial data have been gathered show brain sizes on the average of 100–150 g greater than females, an amount roughly the same as the range of modern human racial variation. It should be pointed out that these differences, and their possible relationship to cognitive skills, are highly controversial, and simple correlations are deceptive (Holloway 1996, 2008; Nyborg 2003). Table 1 provides a listing of the major fossil hominid taxa and their respective brain sizes (See Neubauer et al. 2012 for confirmation of my australopithecine volumes). Notice that the range of values

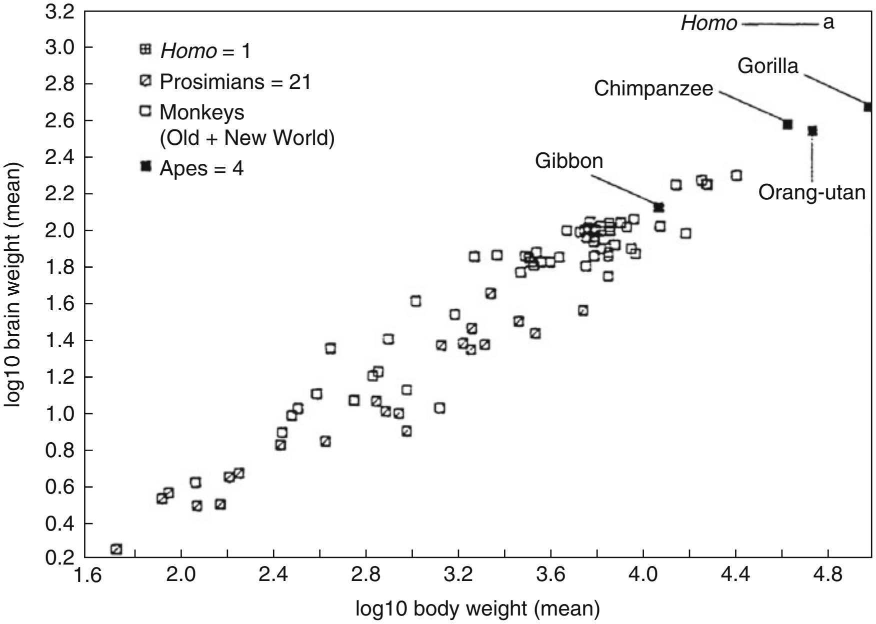

Fig. 5 Graph showing human deviation from a plot of log brain weight against log body weight for primates, with *Homo* at the extreme upper right position

from the earliest australopithecine to modern *Homo* is roughly 1,000 ml or about the same amount as the normal range of variation within our species.

Encephalization (Encephalization Coefficient, EQ)

Nevertheless, the human animal does come out on top of the evolutionary heap when its absolute brain and body weights are considered together. When the log (base 10) of brain weight is plotted against the log10 of body weight for a group of relevant taxa, the result is usually a linear relationship, where (log10) brain weight = a + b (log10) body weight. For a large array of primate data (e.g., Stephan et al. 1981), the slope of the line (b in the equation above) is about 0.76, and the correlation coefficient is 0.98, indicating that the relationship is almost perfect (chapter "▶ Estimation of Basic Life History Data of Fossil Hominoids," Vol. 1). This relationship will naturally vary depending on the databases and the transformations used. This is known as an allometric equation, and these are used frequently in biology to assess the underlying relationships between the size of parts of the body and the whole (see Fig. 5). The slope sometimes has an interpretation suggesting functional relationships between the brain and other variables. For example, in the above example, the slope is 0.76, extremely close to 0.75 or 3/4, which often describes a metabolic relationship (Martin 1983). The slope of 0.66, or

Table 2 Some examples of encephalization quotients

Species	Brain wt. (g)	Body wt. (g)	EQ *Homo*[a]	EQ Jerison[b]	EQ Primates[c]	EQ Stephan[d]
Lemur	23.3	1,400	21	1.56 (22.6)	0.94 (32.7)	5.66 (19.6)
Baboon	201	25,000	28	1.97 (28.5)	0.90 (31.3)	7.94 (27.5)
Gorilla	465	165,000	23	1.56 (22.5)	0.61 (21.2)	6.67 (23.2)

Chimp	420	46,000	39	2.63 (28.1)	1.81 (41.1)	11.3 (39.3)
Human	1,330	65,000	100	6.91 (100)	2.87 (100)	28.8 (100)

Source: Holloway 1997. Note: each formula is based on a different set of data. The EQ *Homo* equation simply uses the average brain and body weight for *Homo sapiens* and assumes an intercept where both brain and body weights are zero. The value of whichever animal is calculated is then given as a direct % of modern *Homo sapiens*. EQ Jerison is based on data for almost 200 mammals, while the EQ Primates is based on Martin's (1983) data set for primates only. The EQ Stephan equation is based on insectivores only. The numbers in the parentheses are the % of the *Homo sapiens* value

[a] Formulae: EQ *Homo* = Brain wt/1.0 Body $\text{wt}^{0.64906}$

[b] EQ Jerison = Brain wt/0.12 Body $\text{wt}^{0.66}$

[c] EQ Primates = Brain wt/0.0991 Body $\text{wt}^{0.76237}$

[d] EQ Stephan = Brain wt/0.0429 Body $\text{wt}^{0.63}$

2/3, has been championed by some (e.g., Jerison 1973) as indicating an important geometric relationship between volume and surface area. It is important to realize that these slopes vary depending on the taxa examined. In general, as the taxa become more similar, the slope decreases. Species within a genus generally have a slope around 0.3; within a species, the slope is smaller yet, being about 0.2, and the correlation coefficient is also reduced (see also Martin and Isler 2010).

Just as the human animal is curious, it is also vainglorious, always trying to find a measure that places it at the top. Thus we can fabricate a device, the *Encephalization Coefficient* or EQ, which shows that relative to any database, the human animal is the most encephalized animal living. The point for *Homo sapiens* shows a clear positive residual above the expected regression line, and in fact the human value is about three times that expected for a primate with its body weight. Table 2 provides a number of different equations based on differing databases, which happily give *H. sapiens* the highest value. (Actually, young immature dolphins will provide a higher number, but when compared to an immature human, the value is higher in the latter.) Two additional points should be made: (a) EQs are relative to the databases used, and thus there is an inherent "relativity" to relative brain sizes; and (b) EQs do not evolve, only brain weight/body weight relationships do, and EQs are simply a heuristic device enabling comparisons between taxa; they have no reality outside of the database chosen, or species within a taxa, and are not designed to discuss within-species variation. For example, female humans are "more" encephalized than males, given their smaller body sizes, more body fat which is not innervated, and smaller brains, but the relationship might be simply a statistical artifact with no known gross behavioral manifestation given the sexes equal overall intelligence. It is more likely that small differences in neural reorganization might be related to behavioral differences such as language ability or math and spatio-visual manipulation rather than brain size or EQ.

I will discuss later how the processes of hypertrophy and hyperplasia have been positively selected for in the course of the last 2–3 myr of hominid evolution. (Hypertrophy refers to increases in size of the neural components, e.g., neurons, dendritic branching, nuclei, and fiber tracts; hyperplasia refers to increased production of cells through mitotic division.) It is most probably the case that these processes are controlled by regulatory genes, and one of the major differences between ourselves and our closest nonhuman primate relative, the chimpanzee (brain size = ca. 385 g), relates to the schedules by which hyperplasia and hypertrophy are turned on and off during ontogenetic development (Holloway 1980, 1995; Miller et al. 2012).

Brain Organization and Reorganization

It is well known that the brains of most animals are extremely similar to each other in terms of their overall organization, by which are meant neural nuclei and fiber systems. The human animal does not appear to show any different structures when compared to Old World monkeys such as the macaque or the great apes, including bonobo, chimpanzee, gorilla, and orangutan. Even the neural fiber tracts that are involved in human language appear in these primates (Deacon 1997). One might ask, then, given the obvious species-specific repertoires that exist in all animals, how can these behaviors differ without differences in the underlying nervous systems? This is one of the major challenges of studying brain evolution and in particular understanding what neural organizations account for the specificity of, say, human behavior, the ability to use language composed of arbitrary symbols. In other words, all mammals have a cerebral cortex, a thalamus, cerebellum, hypothalamus, etc., and basically these structures possess almost identical divisions of nuclei and do the same neural tasks. Clearly, brain size alone will never explain species-specific behavior, and the relationships between neural nuclei and fiber tracts will only go so far in explaining behavioral differences.

Allometric equations showing the relationship between individual bodily components and the whole are instructive here. If we were to plot the logs (base 10) of primary visual cortex (PVC) against brain volume, we would find that the human PVC is 121 *% less* than predicted, and similarly, the lateral geniculate nucleus of the thalamus is about 144 *% less* than expected for a primate of our brain size (see Fig. 6). In contrast, if one plots the amount of cerebral cortex against brain weight the result is a straight line, and the human point lies almost exactly on the line. In short, the human cerebral cortex is as large as would be expected for a primate of its brain size. But do portions of the cerebral cortex vary in size between different primates? In humans, the residuals mentioned above suggest that compared to chimpanzees, the amount of PVC is significantly smaller in humans, or alternatively put, the posterior association cortex of the parietal and temporal lobes is relatively larger in humans. Since there are no essential differences between

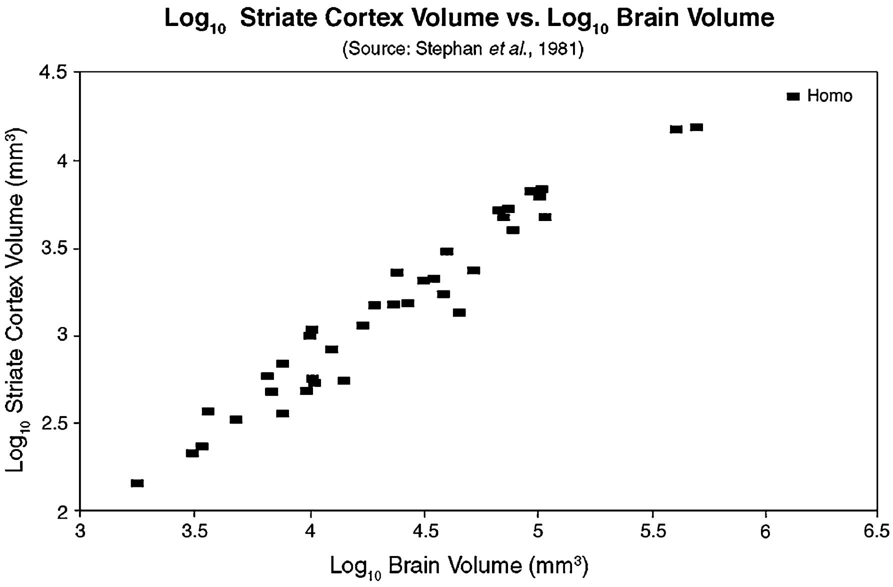

Fig. 6 Graph showing log striate cortex (area 17) versus log brain volume, where the value for *Homo sapiens* (*upper right*) is 121% less than expected from the log-log regression (see also Table 3, which shows other departures between actual and predicted values for different brain structures)

Table 3 Human brain structure residuals[a]

Dependent variable	Independent variable	Number species	Correl. coeff. (R)	Actual value (A)	Expected value (E)	(A)/ (E) ratio	%Diff. (A)/ (E) homo

[a] Based on Stephan et al. (1981) data

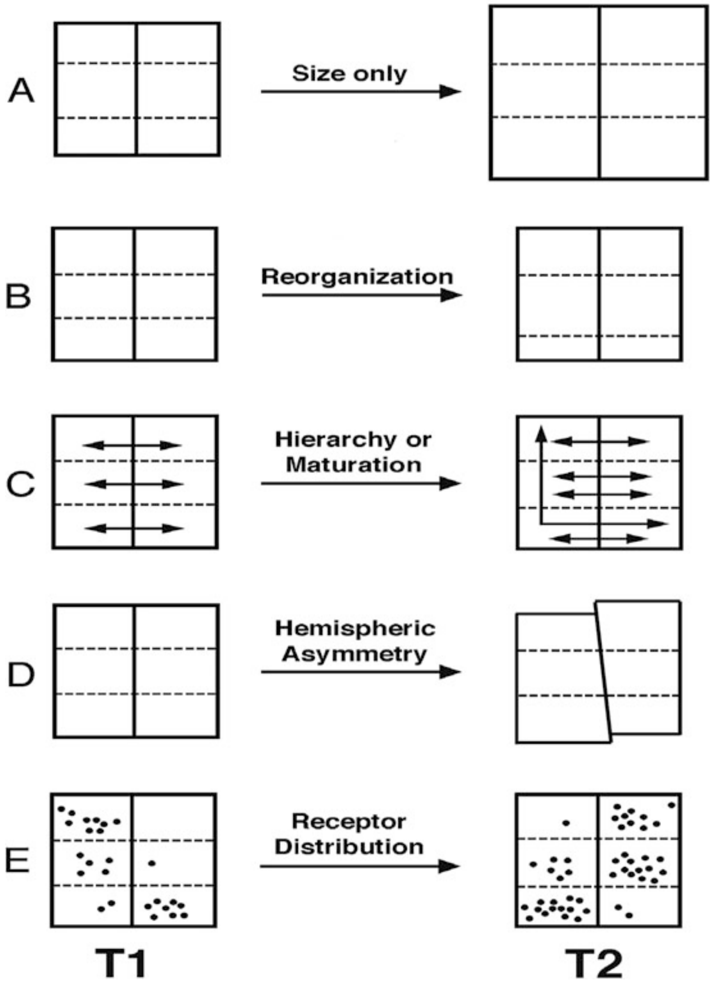

Fig. 7 Types of reorganization without necessary brain size increase. The *dashed lines* represent boundaries between frontal, parietal, and occipital lobes, which if changed in relative positions from T1 to T2 would suggest reorganization

chimpanzees and humans in their visual abilities and competencies, these differences most probably reflect selection for expanded functioning of the association cortex in humans. This is precisely what is meant by "reorganization" (Table 3).

When used in a comparative or evolutionary context, reorganization means changes in the sizes and proportions thereof of neural nuclei and their fiber tracts (see Fig. 7). Given that chimpanzees and hominids had a last common ancestor some 5–7 myr and that chimpanzees appear to have large PVC cortices, we infer that one aspect of human brain evolution has been some reorganization of the cerebral cortex, namely, an increase in posterior association cortex (or, equally, a reduction in PVC) involved in polymodal cognitive tasks, where visual, auditory, and motor information are brought together in a synthetic whole. The trick, of course, is to demonstrate objectively when, where, and why these changes took place. This example of PVC has been purposefully chosen because one of the sulcal landmarks of the cortex that defines the anterior border of PVC is the “lunate” sulcus, named for its crescentic shape, and there is some hope of identifying its position on some of the early hominid brain endocasts. In this regard, endocasts are most often frustratingly mute on other convolutional details.

Neuroanatomists have been trying for many decades to demonstrate the major differences between us and other primates, and aside from gross brain size, very little else of significance has been shown as most of the differences can be explained as allometric scaling. The frontal lobe, and particularly its prefrontal portion, has been a favorite target, and indeed, Brodmann (1909) claimed it was proportionally larger in humans, a view most recently championed by Deacon (1997). Unfortunately, other work has shown that the human brain has just as much frontal lobe as would be expected for a primate of its brain weight (von Bonin 1937, 1948; Semendeferi et al. 1997; Uylings and van Eden 1990), although the picture regarding prefrontal cortex has yet to be determined objectively using cytoarchitectonic criteria, which is how prefrontal cortex is differentiated from the pure motor cortex behind it (Schenker et al. 2010; Sherwood et al. 2003; Rilling et al. 2008). Hominid brain endocasts do not, alas, provide any sulcal landmarks with enough reliability to determine the boundaries of prefrontal cortex, which is so important to impulse control, and higher cognitive functions such as planning and abstraction and recognition of social actors and behavioral elements suggesting “theory of mind” abilities. Thus, these regions cannot be accurately measured in a phylogenetic sequence. However, given the apparent closeness between us and the great apes in terms of percentage of prefrontal cortex, it strikes this writer as extremely doubtful that there could be any major quantitative differences in prefrontal relative volume among the various hominin taxa. The Neanderthals, living from about 300,000 to about 28,000 years ago, have frequently been described as having smaller frontal lobes; this is not based on objective measurements, but rather a perception that the large brow ridges on these humans were constraining frontal lobe development. Studying the Neanderthal brain endocasts and comparing them to modern humans, I have failed to see any significant difference between these two groups, and Bookstein et al. (1999) showed that their prefrontal profiles were practically indistinguishable. More recently, Pearce et al. (2013) have suggested that Neanderthal orbital size meant they had larger visual cortices and thus less parietotemporal association cortex and were thus less intelligent than modern *H. sapiens*. Unfortunately, these authors did not control for facial size which is larger in Neanderthals, nor did they bother to take into account the large degree of occipital lobe variation in those Neanderthal endocasts providing such details. There is nothing in the external morphology of Neanderthal endocasts that can pinpoint any primitive characteristics in cortical morphology; and yes, their brains *were* on average larger than ours today, but not necessarily than Upper Pleistocene

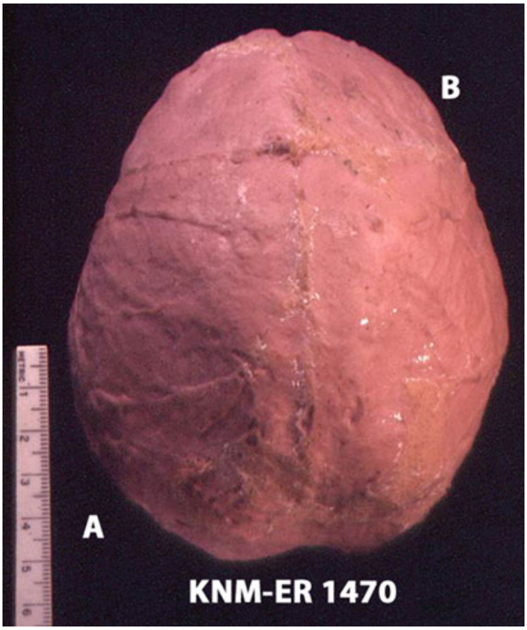

Fig. 8 Dorsal view of KNM-ER 1470, *Homo rudolfensis* (1.8 myr), showing a typical *Homo* pattern of petalias, the left occipital projecting more posterior and being wider than the right side (*A*) and the right frontal being wider than the left (*B*)

Fig. 9 Neanderthal cerebral asymmetries. *Left* is Monte Circeo and *right* is La Ferrassie. Both show a larger width of the right-frontal lobe and a larger left-occipital region (as in Fig. 8)

anatomical modern humans. Their bodies, being larger in terms of lean body mass, might have required larger brains.

Similarly, regions such as "Broca's and Wernicke's areas," anterior and posterior association cortical regions involved in motor (Broca's) and receptive (Wernicke's) aspects of speech, are determinable on most fossil endocasts, and we can determine, for example, that Broca's region is more humanlike on one brain cast of an early *Homo*, some 1.8 Ma. This is the famous KNM-ER 1470 endocast of *Homo rudolfensis* from Kenya, which had a brain volume of 752 ml. It may not be a direct ancestor to our own line of *Homo*, but it does show cerebral asymmetries similar to those found in modern *Homo* (Fig. 8, KNM-ER 1470). We know that Broca's regions in modern *Homo* are asymmetrical both in overall size and cytoarchitectonic divisions between areas 44, 45, and 47 of Brodmann (Amunts et al. 2010; Schenker et al. 2010). Interestingly, Neanderthal endocasts show similar asymmetry to modern humans in Broca's region (Fig. 9).

While the concept of reorganization has a heuristic value in directing our attention to changing quantitative relationships between different neural nuclei and fiber tracts, we cannot yet ascribe behavioral differences between closely related animals such as chimpanzee, gorilla, and orangutans or different species of the genus *Macaca* or indeed different breeds of dogs or cats with their different temperaments, aptitudes, and sociality to particular brain conformations. We simply do not know what magic level of neural description is necessary to describe species-specific behavior. Recent research on prairie and mountain voles suggests that the difference in the females' ability to retrieve pups back to the nest depends on the distribution and number of neuroreceptors for the hormone oxytocin found in several nuclei of the brain, particularly the thalamus. Otherwise, their brains appear identical (Insel and Shapiro 1992). In addition, it is necessary to remember that the brain possesses aspects of plasticity that we did not appreciate except within the past decade and that as the brain's organization unfolds ontogenetically, interactions with environmental stimuli are always occurring, and the brain builds its organization partly through its plasticity. It is difficult enough to study and understand such patterns in laboratory animals, let alone in our fossil ancestors! While the above suggests a somewhat pessimistic tone, we should remember that advances in noninvasive technology such as MRI, fMRI, PET, and tensor diffusion scanning have enormously increased our understanding of how the brain works and how neural systems integrate and dissect data from the environment, always providing us with newer paradigms for further exploration about our brains and behavior. In time, they will do the same for those of our closest relatives, the apes, in particular the bonobo and chimpanzee (see in particular Semendeferi et al. 2010).

Human Brain Asymmetry

The cerebral cortices of the human brain are usually asymmetrical and tend to grow in a torqued manner, reflecting minor differences in maturation rates. The hemispheres are seldom, if ever, equipotential in terms of functioning. Our left hemisphere is often characterized as "analytic" and involved with language tasks, while our right hemisphere appears most competent in visuospatial integration and is often thought of as the "intuitive" or "gestalt" hemisphere. These characterizations, while crude, hold up fairly accurately for right-handers and many ambidextrals. From radiographic studies, it was possible for LeMay (1976) to ascertain different petalia patterns for right- and left-handed humans with a high degree of precision. These petalias are small extensions of cerebral cortex that extend farther in one part of a hemisphere than on the other side. For example, we speak of a left-occipital right-frontal torque pattern of petalias as occurring with high frequency in right-handed individuals. This means that the left-occipital lobe bulges somewhat more posteriorly on the left hemisphere, while the right hemisphere is somewhat broader in width in the frontal lobe. In true left-handers, who make up about 8–10 % of human populations, the pattern is reversed, meaning they exhibit a right-occipital left-frontal pattern. Petalia patterns for a large collection of apes indicated that while chimpanzees, gorillas, and orangutans sometimes demonstrated asymmetries, they did not show the particular torque pattern described above *as frequently*. The gorilla, incidentally, was the most asymmetrical of the apes (Holloway and de LaCoste-Lareymondie 1982). On the other hand, brain asymmetries, particularly in the planum temporale (temporal cortex) of the chimpanzee, show a strong left-hemispheric size difference compared to the right (Gannon et al. 1998). This is simply puzzling as we do not have any evidence that chimpanzees use this structure in communication as do humans, and the fact that we share this difference with chimpanzees suggests that brain organizational features relating to complex cognitive functioning has been around for at least 5–7 myr. As our noninvasive scanning techniques become more sophisticated, we can expect to learn how these asymmetries function in animals other than ourselves. In fact, asymmetries appear in many animals and are hardly unique to primates (Hopkins and his colleagues have been in the forefront in demonstrating chimpanzee asymmetries and possible handedness: Hopkins and Nir 2010, Gomez-Robles et al. 2013, and references). It is probably the degree of asymmetry which is important in distinguishing humans from other primates (Balzeau and Gilissen 2010; Balzeau et al. 2012). Wey et al. (2013) have recently shown that intrinsic connectivity networks are more complex with regard to asymmetry of frontoparietal connectivity in humans compared to nonhuman primates. These connections probably, in part at least, account for the usual petalial asymmetries that appear more frequently in human brains.

Hominid brain endocasts, when complete for both sides (unfortunately, this is very rare), allow the paleoneurologist to assess the cerebral asymmetries, and indeed, even australopithecines appear to show beginnings of the right-handed torque pattern found in humans, and, as one progresses through time, the petalia patterns become more accentuated in the modern human direction. If we add to these observations those of Toth's (1985) studies on the early stone tools (chapters "▶ Overview of Paleolithic Archaeology," Vol. 3 and "▶ Modeling the Past: Archaeology," Vol. 1) of about 2 myr, which strongly suggest right-handedness, this underlines the fact that our early ancestors' brains, despite their small sizes (sometimes within extant apes ranges), were reorganized and that they probably had some modes of cognition very similar to our own (chapters "▶ Overview of Paleolithic Archaeology," Vol. 3 and "▶ Modeling the Past: Archaeology," Vol. 1).

Synthesis: Putting Together Size, Organization, and Asymmetry During Human Evolution

As mentioned earlier, human brain evolution has clearly been a process of integrating neurogenomic processes that led to increased size of the brain (hyperplasia and hypertrophy), and these neurogenomic changes also played roles in the reorganization (quantitative shifts) of neural nuclei, fiber tracts, and cortical cytoarchitectonics. In addition, it is probable that other changes occurred at the neurochemical level, involving neurotransmitters and receptor sites, but these are not well known from the comparative record, let alone the fossil one. This integration was sometimes gradual, sometimes "punctuated," at least based on the fossil hominid record currently available. The only reliable evidence from paleoneurology suggests that Brodmann area 17 (PVC) was reduced early in hominid evolution, signs of the reduction being clear in *A. afarensis* some 3–3.5 myr. While this would have meant a relative increase in posterior parietal cortex (area 39) and peri- and parastriate cortex (areas 18 and 19, respectively), the faithfulness of sulcal impressions does not allow for unambiguous definition of these areas. Similarly, it is not possible at this time to measure and delineate remaining areas of the temporal cortex and superior parietal lobule unambiguously. What is suggested, however, is that visuospatial abilities were most probably cognitively enhanced early in hominid evolution. It is not until we come to *H. rudolfensis* ca. 1.8 Ma that a case can be made for some frontal lobe reorganization in the third inferior frontal convolution, Broca's area. Thus, it would appear there was a gradient of cerebral reorganizational changes starting posteriorly and progressing anteriorly. Table 4 outlines these changes.

More recently, Falk et al. (2012) have argued that the Taung *A. africanus* specimen possessed an open metopic suture that allowed the prefrontal lobe to expand and widen despite the pelvic constraints thought to exist for this species in relation to bipedal locomotion. These authors then expanded this idea to several of

Table 4 Summary of reorganizational changes in the evolution of the human brain

Brain changes, reorganizational	Taxon
1. Reduction of primary visual striate cortex, area 17, and a relative increase in posterior parietal and temporal cortex, Brodmann areas 37, 39, 40, as well as 5 and 7	*Australopithecus afarensis* and *Australopithecus africanus*
2. Reorganization of frontal lobe (3rd inferior frontal convolution, Broca's areas 44,45, 47)	*Homo rudolfensis* and early *Homo*
3. Cerebral asymmetries, left-occipital right-frontal petalias	Australopithecines and early *Homo*
4. Refinements in cortical organization to a modern *Homo sapiens* pattern	*Homo erectus* to present

Source: Holloway 1997. Note: (4) is inferred, as brain endocasts cannot provide that level of detail necessary to demonstrate the refinements in cortical organization from surface features alone. Areas 18 and 19 are peri- and parastriate cortex just anterior to area 17 and are included in posterior association cortex here

Table 5 Brain size changes in hominid evolution

Brain changes	Taxon	Time (myr)	Evidence
1. Small increase, allometric[a]	*A. afarensis* to *A. africanus*	3.5–2.5	Brain endocast increase from ca. 400 to 450 + ml
2. Major increase, rapid, both allometric and non-allometric	*A. africanus* to *H. habilis*, *H. rudolfensis*	2.5–1.8	KNM–1470, 752 ml (300 ml increase)
3. Modest allometric increase in brain size to 800–1,000 ml	*H. habilis* to *H. erectus*	1.8–0.5	*H. erectus* brain endocasts and postcranial bones
4. Gradual and modest size increase to archaic non-allometric FOXP2	*H. erectus* to *H. sapiens neanderthalensis*	0.5–0.075	Archaic *H. sapiens*, Neanderthal endocasts 1,200–1,700 + ml
5. Small reduction in brain size among modern allometric	*H. sapiens* *H. sapiens sapiens*	0.015–present	Modern endocranial volumes

Source: Holloway 1997 and more recent endocast data Holloway et al. 2004
[a]Related to increase in body size only

the specimens regarded as early *Homo*, without providing any detailed evidence. Unfortunately, a newer study using micro-CT scanning (rather than medical CT scans) failed to show any evidence of a metopic suture except for a possible small portion just superior to nasion (Holloway et al. 2013), strongly suggesting that the infant metopic suture had already fused from nasion to bregma.

Table 5 outlines the major size changes in the human brain during its evolutionary odyssey. Paleoneurological data simply are not detailed enough to integrate the two tables of size and reorganizational changes into one holistic sequence of events. Basically, the paleontological record supports an early reorganizational change resulting in an increase in posterior cortex associated with visuospatial processing, perhaps accompanied by a relative small allometric increase in brain size from *A. afarensis* to *A. africanus*. This would correlate well with geological and paleontological evidence that shows that early hominids were expanding their ecological niches (chapter "▶ The Paleoclimatic Record and Plio-Pleistocene Paleoenvironments," Vol. 1) and becoming more diverse in their subsistence patterns in mixed habitats. We know this based on the fact that stone tool types are becoming standardized in form, tool inventories grow larger, and right-handedness is highly probable. With the advent of *Homo*, we find strong evidence for a major increase in brain size, both allometric (related to body size) and non-allometric, and a reorganized frontal lobe, broader and showing a more modern humanlike Broca's area. This suggests that there had indeed been some strong and dramatic selection pressures for a somewhat different style of sociality, one perhaps based on a primitive proto-language that had some arbitrary symboling elements, as suggested by the standardization of stone tools (e.g., Acheulean hand axes) (chapter "▶ Dispersals of Early Humans: Adaptations, Frontiers, and New Territories," Vol. 3) that suggest social cohesion and control mediated through symbolically based communication (Holloway 1981). Needless to say, this is only one speculative account of the evidence. But from about 1.8 to roughly 0.5 myr, we think there were minor allometric brain size increases to the earliest *Homo erectus* hominids of Indonesia and China, where brain sizes ranged from 750 to 1,250 ml in volume. We have very little evidence for body sizes, but we believe, on the basis of the KNM-WT 15,000 Nariokotome youth from Kenya at ca. 1.6 myr, that these did not differ significantly from our own.

This is also a time during which cerebral asymmetries are becoming more strongly pronounced. With the advent of Archaic *H. sapiens*, about 0.15–0.2 myr, we find brain sizes well within modern human values and no evidence for further allometric increases, except possibly for the Neanderthals, in which it can be argued that larger brain and body sizes (lean body mass: bone and muscle) were adaptations to colder conditions. If further changes took place in cerebral and/or subcortical organization, they are simply not apparent from a paleoneurological perspective. Yet the Upper Paleolithic is the time when cave art makes its appearance, and one cannot help but wonder whether the explicit use of art involving symbolization might not also have been the time for the emergence of full language (see, e.g., Klein 2009). However, there is nothing in the direct fossil evidence, and in particular paleoneurology, to provide any evidence for such views. Claims for a single mutation are extremely speculative, and while some genes have been identified (chapters "▶ Genetics and Paleoanthropology," Vol. 1 and "▶ *Homo ergaster* and Its Contemporaries," Vol. 3) such as the FOXP2 (also in Neanderthals), these also involve more general aspects of cognition. It is more likely that stone tool making and its underlying cognitive elements are very similar to language, if not partially homologous (Holloway 1969, 1981, 2012; Stout 2006). Finally, it would appear that there has actually been a small reduction in brain size, probably allometric in nature, from about 0.015 myr to the present (Henneberg 1988; Hawks 2012).

The totality of evidence shows that the brain has always been evolving during our evolutionary journey, with myriad changes taking place at different tempos during different times. As suggested recently (Holloway 1997, p. 200):

> In sum, the major underlying selectional pressures for the evolution of the human brain were mostly social. It was an extraordinary evolutionary 'decision' to go with an animal that would take longer to mature, reach sexual maturity later, and be dependent for its food and safety upon its caretakers (parents?) for a longer period of time. The benefits for the animal were many, including a longer learning period, a more advanced, larger, and longer-growing brain, and an increasing dependence on social cohesion and tool making and tool using to cope with the environments that they encountered. Needless to say, language abilities using arbitrary symbol systems were an important ingredient in this evolution.
>
> The fossil record shows us that there was a feedback between the complexity of stone tools (which must be seen as a part of social behavior) and increasing brain size and the expansion of ecological niches. The 'initial kick,' however, the process that got the ball rolling, was a neuroendocrinological change affecting regulatory genes and target tissue-hormonal interactions that caused delayed maturation of the brain and a longer growing period, during which learning became one of our most important adaptations.

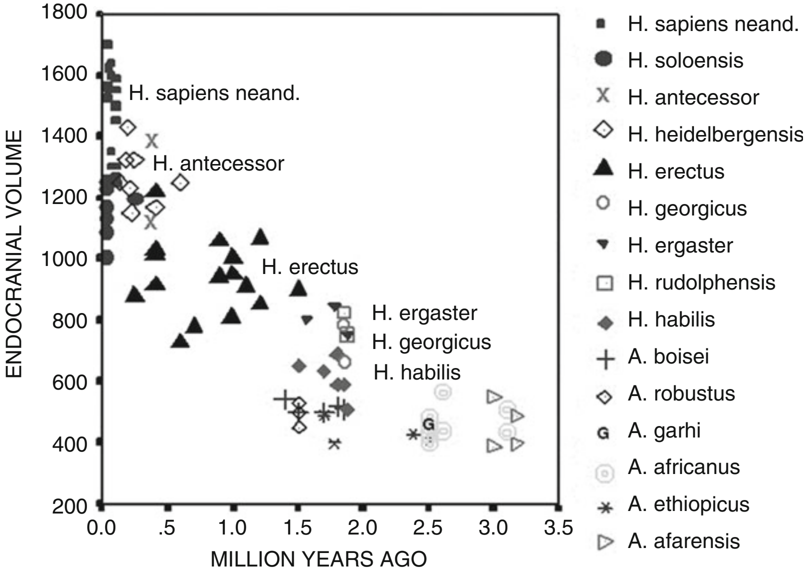

Fig. 10 Endocranial volume plotted against time, showing an accelerated change in volume from *Homo erectus* on to anatomically modern *Homo* in the late Pleistocene. This figure cannot include times of reorganization events, changes in neurogenomic elements, or any of the finer-grained differences in morphology of the endocasts. It is important to observe overlap of endocranial volumes, as well as their variation within taxa

These ideas have been detailed elsewhere (Holloway 1967, 1969, 1980, 1996, 2010), where more details may be found.

Finally, Fig. 10 provides the often-seen relationship between time and endocranial volume, and as should be apparent, there is considerable overlap between fossil groups and considerable variation within each taxon (e.g., *H. erectus*). Needless to say, such depictions cannot reveal the complex interactions between phases of reorganization, size increases through hypertrophy and hyperplasia, asymmetries in between left and right sides, different distributions of neuroreceptors and neurotransmitters, and the intricate interactions between natural selection, environmental challenges, mutation, drift, sensorimotor adaptations (think of the challenges of becoming fully bipedal), social behavior, communication skills, emotions, etc., all of which were operating during the whole of hominid brain evolution, each having some necessary relationship to neural reorganization, both cortical and subcortical. I hope the point is obvious that while we have learned much over the last century from the fossil, comparative, and neurogenomic evidence, we remain almost totally ignorant of how it really happened.

And to the Future?

There appear to be two common presumptions about our future brain evolution. One is that our biological evolution has stopped. The second is that our brains will continue to grow in size, with bulging frontal lobes, to handle our growing dependence on technology. What we have witnessed from the past fossil record is that our brains and bodies work largely in allometric fashion, and given the high metabolic cost of operating bigger brains (about 20–25 % of our metabolic resources go to supporting our brains, which constitute only 2 % of our total body weight), the second scenario seems highly unlikely. To demonstrate the first scenario would require vast amounts of information from each generation of many living populations: feasible perhaps, but not currently being collected. Furthermore, it is quite controversial whether brain size has any close relationship to intelligence; however, intelligence is actually defined and measured. Recent research based on MRI determinations of brain volume and selected batteries of cognitive tests have shown correlations between test scores and brain volume ranging from 0.4 to 0.6 (Andreasen et al. 1993; Anderson 2003; Davies et al. 2011). Most recently, Burgaleta et al. (2013) have found significant relationships between Full Scale, Performance, and Verbal IQ scores and cortical thickness in their study of cortical thickness development in children and adolescents. As more sophisticated imaging and neurogenomic advances are made, it would appear that our genes and epigenomic processes have much to do with brain biology and function. But if protein resources were to nosedive throughout the world for a significant period of time, selection would probably favor smaller body sizes in our species, and that could result in smaller brains, given an allometric relationship of roughly 0.3 between stature and brain size, at least in males (Holloway 1980). While genetic engineering may well provide some respite from the correlation between the ever-increasing mass of humanity and ecological and nutritive degradation, this too is likely to be nothing more than short-term fending off of the unstoppable future. These degradations are part and parcel of the human brain's capacity to ignore warnings that should properly curtail greed and stupidity. The paleontological record for most mammals suggests that genera (such as *Pan*, *Homo*, *Canis*, *Notocherus*, etc.) typically span approximately 5–10 Ma. Our genus has thus far a duration of about 2 myr. We, as a genus, despite our largish highly encephalized brains, have another 3 myr to go if we wish to be as successful in the paleontological longevity game.

Conclusions

Minor controversies notwithstanding, the evolution of the human brain has been an intermingled composite of allometric and non-allometric increases of brain volume and reorganizational events such as the reduction of primary visual cortex and a relative increase in both posterior association and (most probably) prefrontal cortex, as well as increased cerebral asymmetries, including Broca's and Wernicke's regions, with some of these changes already occurring in australopithecine times. As outlined in Holloway (1967), positive feedback (amplification deviation) has been a major mechanism in size increases. Exactly how this mélange of organs evolved will require many more paleontological discoveries with relatively intact crania, an unraveling of the genetic bases for both brain structures and their relationship to behaviors, and a far more complete picture of how the brain varies between male and female and among different populations throughout the world. After all, the human brain is still evolving, but for how long is quite uncertain.

Abstract

An understanding of the phylogenetic relationships among organisms is critical for evaluating the evolutionary history of their adaptations and biogeography as well as forming the basis for systematics. As the numbers of hominin fossils and hominin taxa have increased over the past 40 years, controversies over phylogeny have expanded and have become a hallmark of paleoanthropology. Concordant with the rise in taxonomic diversity, the increased use of phylogenetic systematics, or cladistics, has provided a valuable tool for reconstructing hominin phylogeny. Despite the widespread view that hominin phylogeny is a source of endless debate, there is a broad consensus regarding many aspects of hominin phylogeny.

Introduction

Phylogeny is central to our understanding of virtually any aspect of an organism's biology. An appreciation of the phylogenetic relationships of an organism not only provides a perspective on its place in the history of life and a basis for taxonomy but is also critical for evaluating biogeography as well as ecology and behavior. The adaptations of all organisms, even those as adaptively flexible as primates, are inherited, and thus any proper statistical analysis of physiological adaptations requires a consideration of phylogeny (Harvey and Pagel 1991; Purvis and Webster 1999).

In paleoanthropology at the beginning of the twenty-first century, the study of phylogeny hardly needs to be justified. The first questions that are asked about any new fossil discovery are "How is it related to us?" and "What does it tell us about our evolutionary past?" Paleoanthropology has a reputation in the popular press as a discipline characterized by disagreements over phylogeny, and this is perhaps not unfair if one considers the seemingly diverse array of phylogenetic hypotheses that have been proposed in the last two decades (Delson 1986; Walker et al. 1986; Chamberlain and Wood 1987; Grine 1988; Kimbel et al. 1988, 2004; Wood 1988, 1991, 1992; Skelton and McHenry 1992, 1998; White et al. 1994; Leakey et al. 1995, 2001; Brunet et al. 1996, 2002; Lieberman et al. 1996; Strait et al. 1997; Strait and Grine 1998, 1999, 2001, 2004; Asfaw et al. 1999; Senut et al. 2001; Martinón-Torres et al. 2007; Berger et al. 2010; Organ et al. 2011). Certainly much of the current interest in hominin phylogeny has been fueled by new paleontological discoveries. Nine new early hominid species have been described in the decades between 1994 and 2014 (White et al. 1994; Leakey et al. 1995, 2001; Brunet et al. 1996, 2002; Asfaw et al. 1999; Senut et al. 2001; Haile-Selassie et al. 2004; Berger et al. 2010). Many of these discoveries have been accompanied by phylogenetic hypotheses, not all of which are compatible with each other. However, the current importance of phylogeny in paleoanthropology and the current understanding of hominin phylogeny are not just the result of new fossil discoveries. They also reflect major theoretical and methodological advances in the discipline during recent decades (Tattersall 1999). Thus, before discussing current views on hominin phylogeny, a brief history of this endeavor during the last century is provided. The term hominin is used to mean taxa that are more closely related to humans than to any other primate.

Phylogenetic Diversity in Hominin Evolution

As numerous authors have emphasized, theoretical approaches to hominin phylogeny changed considerably through the course of the twentieth century (Fleagle and Jungers 1982; Tattersall 1999; Gundling 2005). In the early decades, discussions of hominin phylogeny were largely limited to evaluating whether the few fossil taxa that were known at the time – *Pithecanthropus erectus* from Java, *Cyphanthropus rhodesiensis*, or Rhodesian Man from Africa, Piltdown (*Eoanthropus dawsoni*) from England, Neanderthals from Europe, and, after 1925, *Australopithecus* and allied forms from Africa – were ancestral to living humans in their various forms. Two distinct issues dominated the literature. First, were any of the various fossil forms directly in the lineage leading to modern humans? As noted by Dobzhansky in 1944, most authorities found that all fossils had features which precluded placing them directly in human ancestry so that phylogenetic trees generally show a main trunk leading from somewhere in the primate past to modern humans, with each fossil taxon occupying a side branch leading to extinction (Fig. 1; Dobzhansky 1944; Tattersall 1999). Despite the lack of reliable estimates of the geological age of any extinct taxa, they were generally suggested to have branched from the (main) human lineage at different times, such that each documented some aspect of human ancestry. However, all discussion concerned the relationship of the extinct taxa to the main human lineage, with little discussion of the relationships among the extinct taxa themselves. The notable exception to this was Weidenreich's trellis model of hominin evolution in which all living and extinct taxa were interconnected but with temporal and geographic differentiation (Weidenreich 1946; Smith 1997). To a large degree, these trees showing humans at the crown just reflect the fact that in the early part of the twentieth century, as today, paleoanthropology was different from other aspects of zoology in being by definition focused primarily on tracing the history of a single organism, humans, rather than on the interrelationships of a large group of more or less equally important taxa. After all, it is the human species that writes the books.

However, as Gundling (2005) has argued, a related but distinct and in many cases more important issue in the first half of the twentieth century was the taxonomic issue of whether the various extinct species were hominins or apes. That is, where should the ape-human boundary be drawn? In most cases, these two approaches yielded concordant views. Fossils that were placed on the ape lineage were clearly not hominins. However, in some cases fossil taxa might be considered offshoots of the main human stem but still considered apes because they lacked the critical hominin character. This was at the heart of much of the debate regarding the place of Piltdown and *Australopithecus* in hominin phylogeny during the early part of the twentieth century. In general, most researchers limited the human family to modern people.

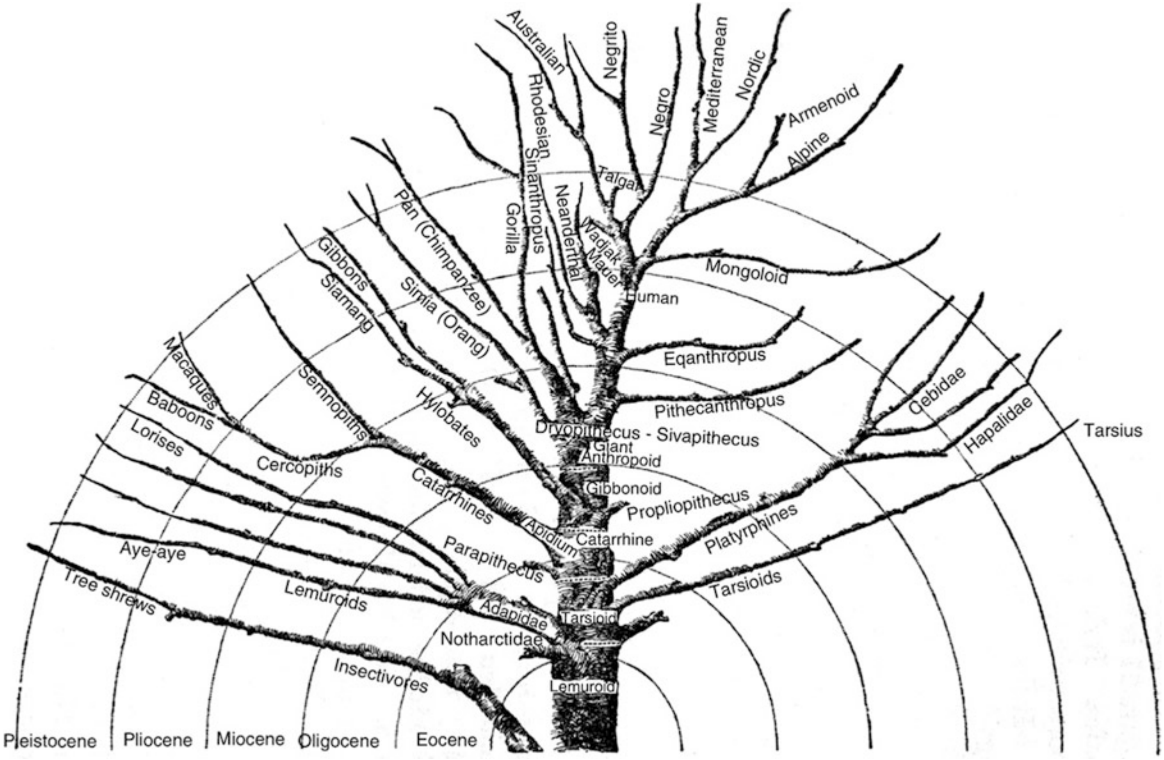

Fig. 1 A phylogeny of Primates from Hooton (1931) showing a tree with human races at the crown and the few known fossil taxa as long side branches from the main stem

As Tattersall (1999) has so eloquently discussed, all of this changed in mid-century as paleoanthropologists began, however slowly, to adopt the tenets of the New Darwinian Synthesis. Despite a growing record of new fossils, human evolution was increasingly seen as a unilinear progression through time, with all morphological diversity consigned to intraspecific variation due to geography or sexual dimorphism (Buettner-Janusch 1966; Brace 1967). All of the divergent branches from earlier in the century were incorporated into the main stem, and human evolution was seen as one continuous chain of forms separated mainly by time. The most extreme expression of this approach was Mayr's (1950) inclusion of all fossil hominins (including "robust" and "gracile australopithecines") into a single genus, *Homo*, with three species. Certainly there were other views, for example, Robinson, following Broom, repeatedly argued that *Paranthropus* was a separate lineage of hominin from *Australopithecus* and *Homo*, and Louis Leakey argued from time to time that the ancestry of the human lineage was not to be found among known fossils of the time. However, for much of the discipline, there was little appreciation of phyletic diversity in human evolution (Fig. 2). This view of limited phyletic diversity was very compelling. It was supported by the leading authorities on evolutionary biology at the time, such as Mayr and Dobzhansky; it brought paleoanthropology in line with the rest of evolutionary biology; and it conformed well with what is seen in the world today: a single species of humans with considerable intraspecific variation. Moreover, there were theoretical reasons offered to justify a lack of phyletic diversity in a culture-bearing creature (Mayr 1950; Wolpoff 1971). And while extrapolating human behavior backward into the fossil record may not be totally justified, especially for the Pliocene, it is not totally unreasonable.

However, by the 1970s the unilinear view of human evolution was being seriously challenged on several fronts and had become increasingly difficult or even impossible to support. There were clearly two distinct hominin lineages present in the Late Pliocene and Early Pleistocene at Olduvai Gorge and Koobi Fora (Leakey and Walker 1976), and there was increasing evidence that in other parts of the world modern humans had preceded or were contemporary with European Neanderthals (Leakey 1969; Stringer 1974, 1978; Howells 1975; Bräuer 1982). Likewise, "new" analytical approaches emphasized the view that morphological changes over the past 3 Myr or so did not follow a simple temporal pattern of increasingly modern features through time (Eldredge and Tattersall 1975). With an increasing number of contemporaneous taxa, the potential phylogenetic complexity of the hominin fossil record continued to grow and came to a head with the description of *Australopithecus afarensis* (hereafter called *Praeanthropus afarensis*) in 1978 and the ensuing debate over taxonomic diversity and phylogenetic relationships in early hominin evolution (Johanson et al. 1978; Johanson and White 1979; Tobias 1980; Olson 1981, 1985; White et al. 1981; Rak 1983; Kimbel et al. 1984; Skelton et al. 1986). The level of debate over early hominin diversity and phylogeny was heightened even further with the discovery in Kenya of the Black Skull (KNM-WT 17000) several years later (Delson 1986; Walker et al. 1986; Grine 1988; Kimbel et al. 1988; Wood 1988). Similarly, the debate

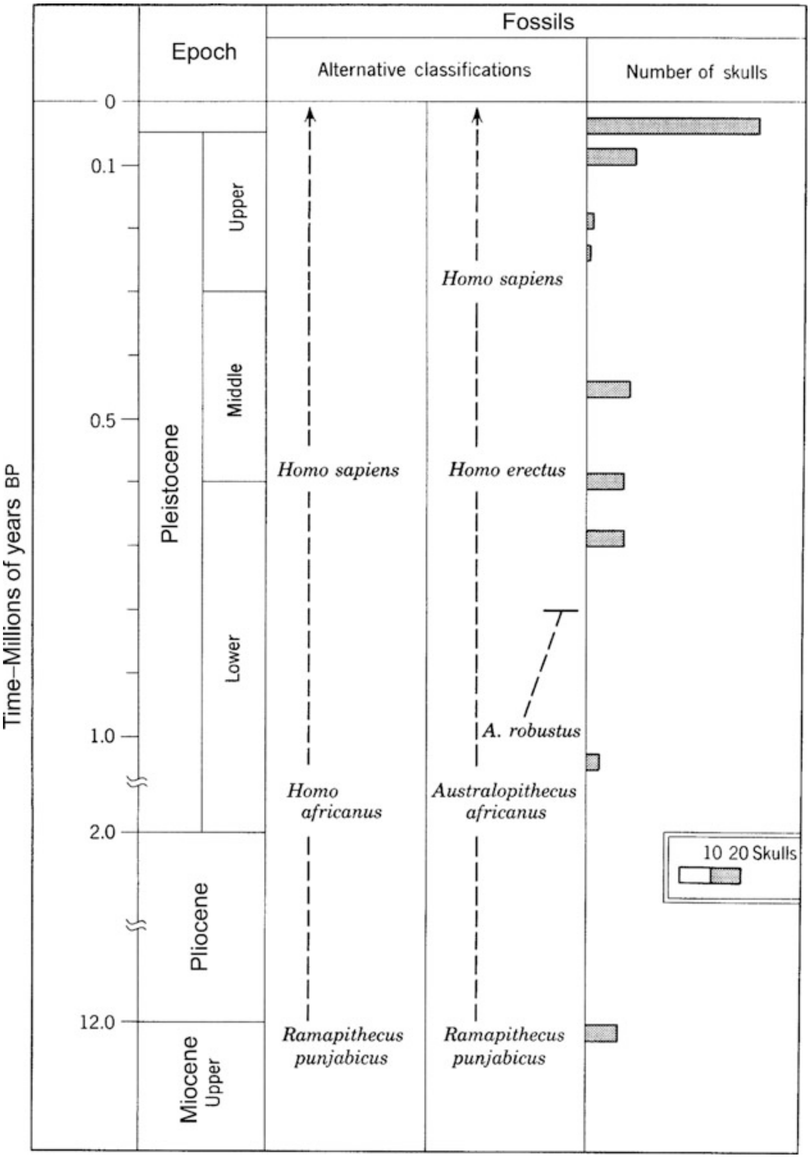

Fig. 2 A chart of hominin evolution from a major textbook from 1966 (Buettner-Janusch 1966) showing the conservative lumper's view on the *left* and the extreme splitter's view on the *right*

over the timing and geography of modern human origins and the relationship between *Homo sapiens*, Neanderthals, and *Homo erectus* expanded in the 1980s and has yet to abate (Smith and Spencer 1982; Mellars and Stringer 1989; Trinkaus 1989; Stringer 2002, 2012a).

Reconstructing Phylogeny: The Rise of Cladistics

The increasing evidence of taxonomic and phyletic diversity in hominin evolution during the 1970s and 1980s coincided with the increasing prominence of phylogenetic systematics or cladistics in paleoanthropology (Eldredge and Tattersall 1975; Luckett and Szalay 1975; Delson et al. 1977; Tattersall and Eldredge 1977; Delson 1985; Skelton et al. 1986; Wood et al. 1986; Grine et al. 1987; Grine 1988). The methods of phylogenetic systematics, or cladistics, were developed by the German entomologist Willi Hennig in 1950, but it was only with their publication in an English translation (Hennig 1966) that his methods became widely known and applied in morphological studies to understanding the phylogeny of all sorts of organisms.

Cladistics is a method of phylogenetic reconstruction premised on the notion that not all morphological similarities are indicative of phylogeny. Rather, only those similarities that are derived (i.e., novel) and inherited from a recent common ancestor should be indicative of patterns of relatedness. In practice, it is difficult (if not impossible) to discern, a priori, such features (called synapomorphies) from other types of similarities such as primitive retentions (symplesiomorphies) or traits that have evolved convergently or in parallel (homoplasies). Thus, cladistics relies on the principle of parsimony to identify synapomorphies and, hence, to reconstruct phylogeny. In a general sense, parsimony is the idea that the simplest explanation is the best one because it makes the fewest assumptions. As applied to cladistics, parsimony dictates that the best cladogram is the one that requires the fewest number of homoplasies or independent appearances of the same feature. Parsimony analysis is conventional in evolutionary biology (Kitching et al. 1998) but is viewed with skepticism by some paleoanthropologists (Trinkaus 1990; Asfaw et al. 1999; Hawks 2005). This skepticism is misplaced because, at its core, the logic of parsimony is intuitive and not too dissimilar from that of “traditional” evolutionary systematics (e.g., Olson 1981). More significantly, it provides a replicable criterion for evaluating alternative hypotheses beyond preconceived notions of how things should be (Tattersall 1996).

Consider an example in which a phylogenetic analysis is being performed on the living hominoids (*Hylobates*, *Pongo*, *Gorilla*, *Pan*, and *Homo*) and a fossil hominin (*Australopithecus*). Now consider a character with two states (knee joint valgus or varus). The nonhuman apes and various outgroup taxa (other Old World higher primates) have a varus knee, while *Homo* and *Australopithecus* have a valgus knee. Given a cladogram in which *Australopithecus* and *Homo* are sister taxa (Fig. 3a), what can be concluded about the evolution of the knee joint? There are actually many ways in which the knee joint might have evolved. It is possible that a valgus knee joint was present in all of the ancestors represented by the internal nodes of the cladogram (Fig. 3b). Such a reconstruction requires that a varus knee joint evolved in parallel in each nonhuman ape lineage. Alternatively, it is possible that a varus knee joint was present at all of the nodes of the cladogram, including the one representing the last common ancestor of hominins (Fig. 3c). This reconstruction requires that a valgus knee joint would have evolved in parallel in *Homo* and *Australopithecus*. Neither of these reconstructions is satisfying because both are

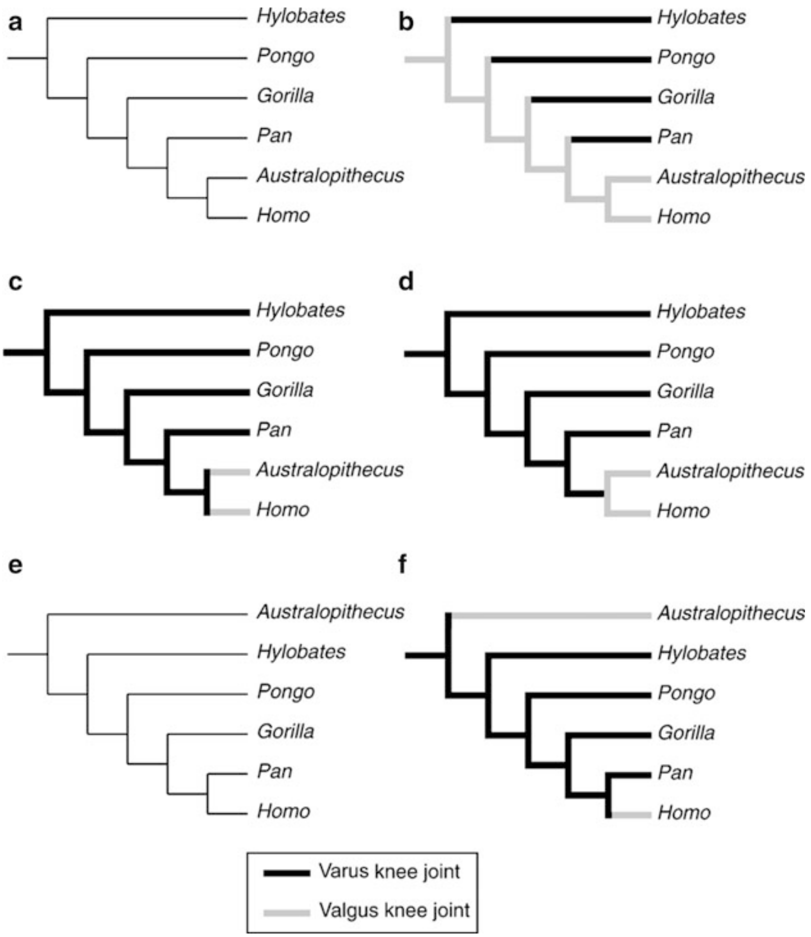

Fig. 3 Principles of cladistics. (**a**) Cladogram depicting possible phylogenetic relationships among hominoids. (**b**) Pattern of character evolution in which a varus knee evolves many times in parallel in each of the nonhuman hominoids. (**c**) Valgus knee evolves in parallel in *Homo* and *Australopithecus*. (**d**) Most parsimonious pattern of character evolution in which a valgus knee evolves once in the last common ancestor of *Australopithecus* and *Homo*. (**e**) Cladogram depicting an alternative phylogeny. (**f**) Most parsimonious pattern of character evolution in the alternative cladogram. a(=d) is preferred over (**e**) because it involves fewer changes, and it is therefore the most parsimonious

needlessly complex. There is instead a much simpler (i.e., more parsimonious) explanation for the evolution of the knee joint, namely, that a valgus knee joint evolved once in the last common ancestor of the hominins *Australopithecus* and *Homo*, who subsequently passed that trait onto its descendants (Fig. 3d). Such a reconstruction does not require any homoplasy.

Now consider an alternative cladogram in which *Australopithecus* is the sister taxon of all of the living hominoids (Fig. 3e). In this tree, the most parsimonious reconstruction of the evolution of the knee joint is one in which a valgus knee evolved in parallel in *Australopithecus* and *Homo* (Fig. 3f). No other possible reconstruction of character evolution in the knee joint requires fewer character state changes or steps. Now consider that the two cladograms presented here (Fig. 3a and e) represent alternative interpretations of hominoid phylogeny. How can these cladograms be compared so as to select one of them as the better hypothesis of phylogeny? Parsimony states that the preferred cladogram is the one that is simplest, namely, the one that minimizes the number of homoplasies required. Fewer homoplasies are required in Fig. 3d than in Fig. 3f, so the preferred cladogram is the one in which *Australopithecus* and *H. sapiens* are sister taxa (Fig. 3a). There is nothing controversial about this example, and both cladists and noncladists would agree with the result. The only difference between this example and an actual cladistic analysis is that most analyses would examine many characters at once. This is a great advantage of numerical cladistic analysis over “traditional” evolutionary systematics in which only a handful of characters tends to strongly influence the shape of phylogenetic trees. Even more significant is the fact that cladistic studies make explicit assumptions and predictions so that analyses are replicable, and the results are testable.

Cladistic Analyses of Hominin Phylogeny

Early Studies

The first cladistic analysis of hominin evolution was by Eldredge and Tattersall (1975) who also coauthored a series of papers delineating various levels of phylogeny reconstruction from producing a cladogram, to creating a phylogenetic tree, and finally an evolutionary scenario (Delson et al. 1977; Tattersall and Eldredge 1977). In the late 1970s and early 1980s, cladistic analyses in paleoanthropology were relatively simple and often consisted of little more than producing a cladogram and identifying a few shared derived characters at each node (Olson 1978; Andrews 1984; papers in Luckett and Szalay 1975; Delson 1985; Wood et al. 1986; Grine et al. 1987). Nevertheless, this was major advance from much previous work in primate phylogeny in that there was a clear effort to distinguish shared derived features from shared primitive ones, and authors provided explicit morphological justification for phylogenetic grouping at every level. Falsifying a set of relationships based on a cladistic analysis generally requires identification of additional morphological features that produce a different cladogram when analyzed. As Tattersall (1999) has pointed out, the rise of cladistics has led to a tremendous increase in the detailed documentation and analysis of hominin morphology.

The mid-1980s saw the first use of quantitative cladistic analyses in hominin evolution. By using computer algorithms researchers were able to evaluate dozens of characters and compare thousands of trees (or more), tasks that were simply unfeasible otherwise. The first efforts to evaluate hominin phylogeny using numerical methods were in an analysis of early hominin phylogeny by

Chamberlain and Wood (1987) and a study of the genus *Homo* by Stringer (1987). Numerous subsequent analyses of the phylogeny of hominins and many other groups of primates have used essentially the same methods (Fleagle and Kay 1987; Kay et al. 1997; Strait et al. 1997; Ross et al. 1998).

Moving Toward a Rough Consensus

The 1987 study of early hominin phylogeny by Chamberlain and Wood did not include *Paranthropus aethiopicus*, which subsequently became the linchpin of early hominin phylogeny. The first study to include this species was that of Wood (1988), who examined the trait list provided by Walker et al. (1986) in their description of KNM-WT 17000. Wood (1988) found that *Paranthropus robustus* and *Paranthropus boisei* are sister taxa, that *Homo* is the sister taxon of this clade, and that *Pr. afarensis*, *P. aethiopicus*, and *Australopithecus africanus* branch off in sequence from the base of the hominin tree (Fig. 4a). Notably, the three "robust" species are paraphyletic. A subsequent study by Skelton and McHenry (1992),

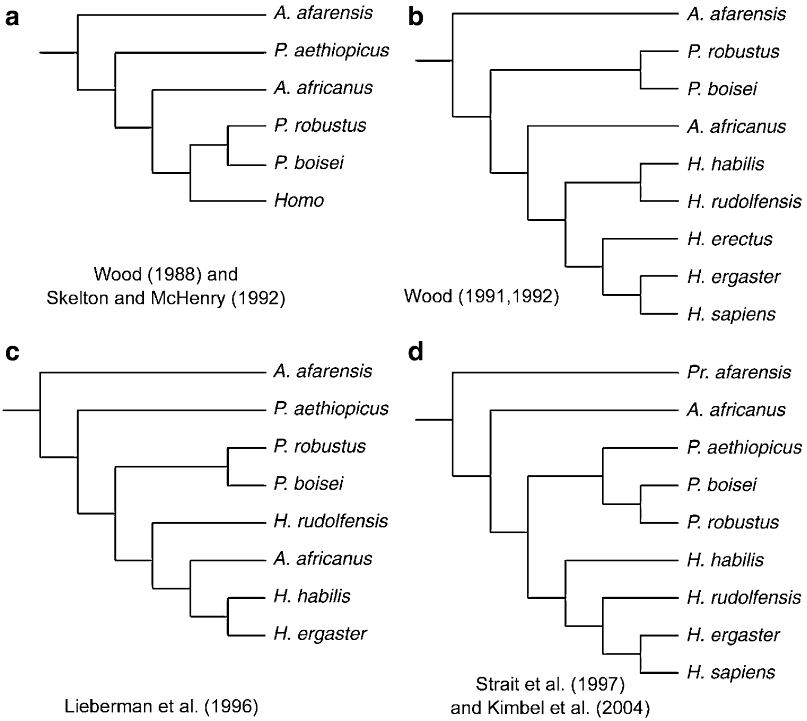

Fig. 4 Cladistic analyses of early hominins from various studies. (**a**) Cladogram of Wood (1988) and Skelton and McHenry (1992). (**b**) Cladogram of Wood (1991, 1992). (**c**) Cladogram of Lieberman et al. (1996). (**d**) Cladogram of Strait et al. (1997) and Kimbel et al. (2004)

using a more extensive trait list, found an identical cladogram. Wood (1991, 1992), using a data set composed entirely of craniometric measurements, found a most parsimonious cladogram in which *A. africanus* is the sister taxon of *Homo*, *H. habilis sensu stricto* and *H. rudolfensis* are sister taxa, and *P. boisei* and *P. robustus* are monophyletic (Fig. 4b). Technically, Wood's (1991, 1992) cladogram does not include *P. aethiopicus*, but it is reported in the text of his analysis that this species is the sister taxon of *P. boisei*. Lieberman et al. (1996) found a most parsimonious tree (Fig. 4c) in which *Paranthropus* is paraphyletic, *P. robustus* and *P. boisei* are sister taxa, and *A. africanus* is nested within the *Homo* clade. Subsequently, Strait et al. (1997) found a cladogram in which *Paranthropus* is monophyletic and the sister taxon of *Homo* (Fig. 4d). Recently, an independent analysis by Kimbel et al. (2004) has largely corroborated Strait et al.'s (1997) results. Kimbel et al. (2004) found two equally parsimonious trees: one is equivalent to those of Strait et al. (1997) and the other differs only in placing *A. africanus* as the sister taxon of the *Paranthropus* clade.

The analyses noted above appear to differ from each other, but in fact they are similar to a much greater degree than is generally acknowledged. The results of Strait et al. (1997) and Kimbel et al. (2004) differ from those of Wood (1988) and Skelton and McHenry (1992) only with respect to the relationships of *P. aethiopicus*. They differ from those of Wood (1991, 1992) principally with respect to the relationships of *A. africanus*. The most parsimonious tree of Lieberman et al. (1996) differs from that of Wood (1988) and Skelton and McHenry (1992) only with respect to *A. africanus*. Thus, these cladograms disagree primarily with respect to only two taxa, *A. africanus* and *P. aethiopicus*. There are also disagreements concerning the exact relationships of *H. habilis* and *H. rudolfensis*, but all analyses that include these taxa place them at the base of the *Homo* clade. In short, it appears as if cladistic analyses of early hominins are converging on a common set of relationships. It would be an overstatement to claim that the pattern of early hominin phylogeny is known, but insofar as repeatability is a key component of any scientific result, it would appear that the broad strokes of early hominin phylogeny are perhaps better understood than commonly acknowledged.

Phylogenetic Implications of a "Golden Age" of Discovery (1994–2004)

There were many discoveries of new fossil hominin species in the decade between 1994 and 2004 (White et al. 1994; Leakey et al. 1995, 2001; Brunet et al. 1996, 2002; Asfaw et al. 1999; Senut et al. 2001; Ward et al. 2001; Haile-Selassie et al. 2004). Despite the common refrain that phylogenetic debates can be resolved by the discovery of new fossils, many of these new finds raised rather than resolved phylogenetic questions. Although most of the new discoveries were accompanied by a phylogenetic hypothesis, those hypotheses often only addressed the relationships among a few hominin taxa. Moreover, these hypotheses were potentially difficult to test using cladistic analysis because they specified ancestor-descendant relationships without specifying sister-group relationships. At the time, the remains of many of these new hominin taxa were not yet thoroughly published, and further documentation of their morphology will doubtless permit more complete analyses. However, on the basis of information available so far, one can use cladistic analysis to test many of the initial hypotheses that have been proposed because phyletic relationships imply sister-group relationships. In particular, it is an accepted principle that a species can only be an ancestor of another taxon if it is the sister species of that taxon and if its character states resemble those reconstructed as being present in the relevant internal node of a cladogram (Szalay 1977; Smith 1994; Wagner and Erwin 1995; O'Keefe and Sander 1999). Accordingly, the phyletic hypotheses that have been proposed for many recent fossil discoveries in hominin evolution can be evaluated through reconstruction of sister-group relationships (Fig. 5).

Strait and Grine (2004) tested many of the hypotheses generated by these new taxa. They found that the pattern of hominin phylogeny is unbalanced such that many species branch off by themselves from the base of the tree, while the top of the tree is dominated by two multispecies clades, *Homo* and *Paranthropus* (Fig. 6). *Sahelanthropus* and *Ardipithecus* are, respectively, the first two branches of the tree, with subsequent branches successively represented by *Australopithecus anamensis*, *Pr. afarensis*, *Australopithecus garhi*, and *A. africanus*. If *Kenyanthropus platyops* is a valid species, then its position within the *Homo* + *Paranthropus* clade is unresolved; it is either the sister taxon of the rest of the clade or of *Paranthropus*. Relationships within *Paranthropus* are also unresolved, with *P. boisei* being the sister taxon of either *P. aethiopicus* or *P. robustus*. The position of *H. habilis* relative to *H. rudolfensis* is unresolved, but it is clear that one or the other is the basal branch of the *Homo* clade. *Homo ergaster* and *H. sapiens* are sister taxa. These results are consistent with certain of the hypotheses offered in the original descriptions and inconsistent with others.

Ardipithecus ramidus

At the time of its description (White et al. 1994), *Ardipithecus ramidus* was the oldest and most morphologically primitive hominin species then known. White et al. (1994) suggested that *Ar. ramidus* lies near the ancestry of all other hominins and that it may be the actual ancestor of those species. A cladogram consistent with this hypothesis would place *Ar. ramidus* as the sister taxon of a clade that includes all other hominin species (Fig. 5a). Strait and Grine (2004) found that *Ar. ramidus* is the sister taxon of all hominins except *Sahelanthropus* (Fig. 6). These results support the hypothesis of White et al. in a general sense insofar as *Ar. ramidus* branches off near the base of the hominin tree, if not necessarily at the basal node.

Australopithecus anamensis

The following year, Leakey et al. (1995) described *Australopithecus anamensis* as a species intermediate both chronologically and morphologically between *Ar. ramidus* and *Pr. afarensis*. Leakey et al. (1995) and Ward et al. (2001) have suggested that

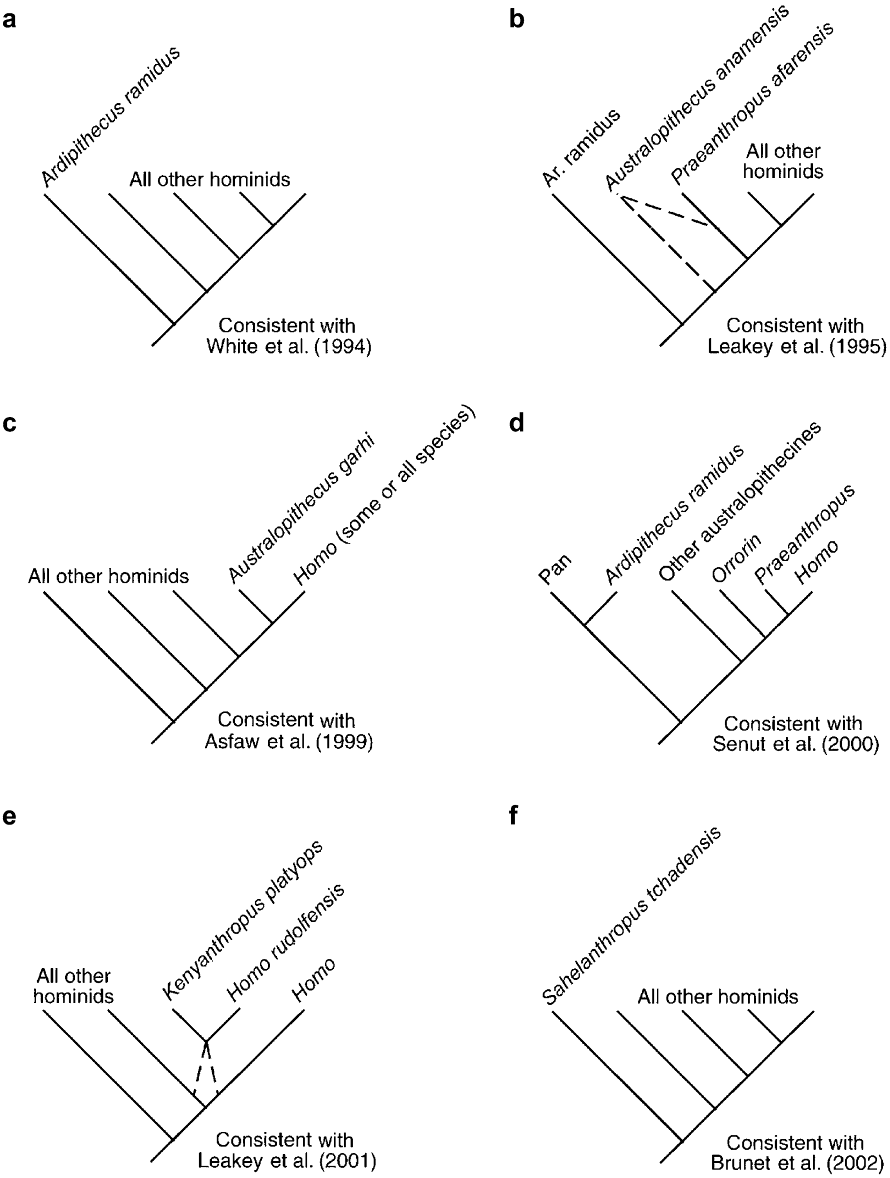

Fig. 5 Phylogenetic hypotheses associated with recently discovered hominins

A. anamensis is more closely related to later hominins than is *Ar. ramidus* and may be directly ancestral to *Pr. afarensis* (Kimbel et al., 2006). A cladogram consistent with this hypothesis would depict *A. anamensis* as diverging from a higher node on the hominin tree than *Ar. ramidus* and as the sister taxon of all later hominins (Fig. 5b). An alternative topology that might also be consistent with the phyletic hypothesis

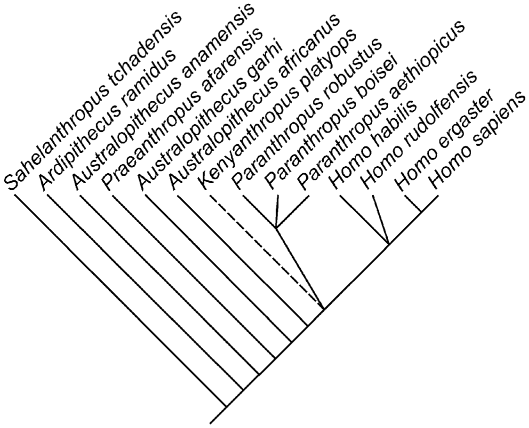

Fig. 6 Early hominin cladistic relationships found by Strait and Grine (2004)

would make *A. anamensis* the sister taxon of *Pr. afarensis*. Strait and Grine's (2004) results (Fig. 6) are consistent with the hypothesis that *A. anamensis* is the sister taxon of all hominins except *Ardipithecus* (and, presumably, *Sahelanthropus*).

Australopithecus bahrelghazali

The discovery of *Australopithecus bahrelghazali* was notable primarily because it represented the first early hominin species found in central Africa. Brunet et al. (1996) did not offer a detailed phylogenetic hypothesis for *A. bahrelghazali* but rather noted merely that the species is more derived than the contemporaneous *Pr. afarensis*. Not all workers accept that *A. bahrelghazali* and *Pr. afarensis* are distinct species (Kimbel et al. 2004). This species was not included in the analysis by Strait and Grine because it is known from only a few remains.

Australopithecus garhi

As described by Asfaw et al. (1999), *Australopithecus garhi* preserves an unexpected combination of cranial and dental characteristics. In particular, it has megadont molars and premolars but a relatively primitive-appearing face and neurocranium. Asfaw et al. (1999) implied that *A. garhi* could be a suitable ancestor for *Homo*, although they noted that the exact phylogenetic relationships of this species remained unresolved. They presented a cladogram in which *A. garhi*, *A. africanus*, *P. robustus*, *P. boisei*, *P. aethiopicus*, and *Homo* form a clade but in which relationships within that clade were left unresolved. However, they presented four phyletic trees, and in three of those, *A. garhi* was posited to be an ancestor of at least some members of the genus *Homo*. Moreover, they (Asfaw et al. 1999, p. 632) state that "If *A. garhi* proves to be the exclusive ancestor of the *Homo* clade, a cladistic classification would assign it to genus *Homo*." Such a classification would only be valid if *A. garhi* and at least some of the *Homo* species form a monophyletic group, as in Fig. 5c. Furthermore, in reference to the morphology of *A. garhi*, Asfaw et al. (1999, p. 634) state that "its lack of derived robust characters leaves it as a sister taxon to *Homo* but absent many derived *Homo* characters."

Strait and Grine's (2004) results are consistent with the hypothesis that *A. garhi* belongs to a clade that also includes *A. africanus*, *Paranthropus*, and *Homo*, insofar as *A. garhi* is reconstructed as the sister taxon of a clade comprising those taxa (Fig. 4). In addition, the relationships of *Ardipithecus ramidus*, *A. anamensis*, and *Pr. afarensis* are equivalent to those proposed by Asfaw et al. (1999). However, Asfaw et al. (1999) also suggested that *A. garhi* may be ancestral to all or part of the genus *Homo*. Cladistic analysis fails to find a sister-group relationship between *Homo* and *A. garhi* (Fig. 6). Moreover, *A. garhi* is excluded from a clade that includes only *Homo*, *Paranthropus*, *A. africanus*, and *K. platyops*. Thus, there is no support for the hypothesis that *A. garhi* and *Homo* are sister taxa, so *A. garhi* is unlikely to be the direct ancestor of *Homo*.

Orrorin tugenensis

Found in Late Miocene deposits (Senut et al. 2001), *Orrorin tugenensis* supplanted *Ar. ramidus* as the oldest known fossil hominin. Senut et al. (2001) claim that on the basis of dental and postcranial characters, *O. tugenensis* is the basal member of the *Homo* clade, to the exclusion of australopiths. Moreover, they suggest that *Ar. ramidus* is not a hominin but an ancestor of *Pan*. A cladogram consistent with these hypotheses (Fig. 5d) would have *Orrorin* and *Homo* as sister taxa, a clade of all australopithecines except *Ardipithecus* being the sister taxon of the *Orrorin* + *Praeanthropus* + *Homo* clade, and *Ardipithecus* as the sister taxon of *Pan*.

Strait and Grine's (2004) analysis did not include *Orrorin* because too few characters are preserved in that species. However, their data set can be used to examine the effect of making *Ardipithecus* the sister of *Pan* and the other australopiths monophyletic (Senut et al. 2001). The most parsimonious tree found by Strait and Grine's data set for the hypothesis that *Ardipithecus* in the sister taxon of *Pan* is 30 steps longer than that shown in Fig. 6. Considering that Senut et al.'s (2001) hypothesis is based on only a few characters (e.g., molar size, enamel thickness, details of the proximal femur), which cannot account for so many steps, it is fair to conclude that this hypothesis is not favored by cladistic analysis.

Kenyanthropus platyops

The discovery of *Kenyanthropus platyops* was notable because it demonstrated the existence of multiple hominin lineages in the Middle Pliocene. Leakey et al. (2001) noted that *Kenyanthropus platyops* appeared to share several derived character states exclusively with *H. rudolfensis*. They posited (Lieberman 2001) that this might imply that these two species had a particularly close relationship. A cladogram consistent with this hypothesis (Fig. 5e) would have *K. platyops* and *H. rudolfensis* as sister taxa. Although the validity of the species diagnosis of *Kenyanthropus platyops* has been questioned by White (2003), who has implied that many of the defining features of the type specimen are artifacts of postdepositional distortion, others have found no reason to doubt its validity.

The results of the analysis by Strait and Grine (2004) are inconsistent with the hypothesis that *K. platyops* shares especially close affinities with *H. rudolfensis* even to the point of removing the latter from the *Homo* clade. Rather, *Kenyanthropus* is the sister taxon of either *Paranthropus* or the *Homo* + *Paranthropus* clade (Fig. 6). There is no strong evidence supporting the hypothesis that *H. rudolfensis* and *K. platyops* are sister taxa, and thus the transfer of *H. rudolfensis* to the genus *Kenyanthropus* is at present unwarranted. One implication of these results is that some of the facial features shared between *H. rudolfensis* and *K. platyops* may be primitive for the *Homo* + *Paranthropus* clade, while others may be convergent. Another implication concerns the timing of early hominin cladogenic events. If *K. platyops* is a valid species, then its age (3.3–3.5 Ma) and cladistic relationships suggest that *Homo* and *Paranthropus* may have diverged from other hominin taxa up to 700 kyr prior to the earliest known specimens currently attributed to those genera (Suwa et al. 1996). It follows, therefore, that this divergence would not be explained by the Turnover Pulse Hypothesis (Vrba 1988) because the divergence would have predated the desiccations event that she postulates to have occurred in Africa between 2.7 and 2.3 Ma. These two clades may have each diversified during this period, but their origins are likely to have been earlier in the fossil record.

Sahelanthropus tchadensis

The title of "oldest hominin" now belongs to *Sahelanthropus tchadensis* (Brunet et al. 2002). Brunet et al. (2002, p. 151) note that *S. tchadensis* appears to be "the oldest and most primitive member of the hominin clade, close to the divergence of hominins and chimpanzees." The authors are cautious about the precise phylogenetic relationships of the species, but note the possibility that *Sahelanthropus* is the sister taxon of all other hominins, including *Ardipithecus*. A cladogram consistent with this hypothesis would have *Sahelanthropus* as the basal branch of the hominin clade (Fig. 5f).

Brunet et al. (2002) discuss the possibility that *Sahelanthropus* is the sister taxon of all known hominin species, including *Ardipithecus*. The Strait and Grine study is consistent with this hypothesis insofar as *Sahelanthropus* was found to be the basal branch of the hominin clade (Fig. 6). It also does not group with African apes as suggested by Wolpoff et al. (2002).

Ardipithecus kadabba

Fossils attributed to *Ardipithecus kadabba* were first assigned to a subspecies of *Ardipithecus ramidus* (Haile-Selassie 2001), but subsequent discoveries led to the elevation of this assemblage to species status (Haile-Selassie et al. 2004). The species is notable for its extremely primitive canine-premolar honing complex. Its describers imply that it is the best candidate to be the sister taxon or ancestor of all other hominins and that fossils of the other two known Miocene species, *O. tugenensis* and *S. tchadensis*, are in fact representatives of *Ar. kadabba*. This species was not included in the analysis of Strait and Grine (2004) because it is currently known from only a few body parts.

Discoveries Since 2004 and Implications for Early Hominin Relationships

The phylogenetic relationships described above collectively represent a reasonable working hypothesis of early hominin phylogeny, but more recent discoveries and descriptions of hominin fossils may necessitate important revisions in the near future. In 2009, a relatively complete skeleton of *Ar. ramidus* and other fossils from this species were comprehensively described (e.g., White et al. 2009). These descriptions confirm that *Ar. ramidus* possesses a small number of derived cranial traits that seem to place it within and near the base of the hominin clade. However, as described, the species also seems to lack nearly all of the postcranial traits traditionally associated with bipedal locomotion, as well as most of the traits seen in living apes that are functional related to suspensory locomotion. The describers of *Ar. ramidus* interpret this suite of characters to mean that the earliest hominins were not descended from an ancestor possessing suspensory traits. While possible, this hypothesis appears to be wildly unparsimonious, because it also implies that many suspensory traits must have evolved in parallel in multiple ape lineages. It is difficult to imagine cladistic analysis supporting this hypothesis but formal study is needed. Indeed, in light of the new postcranial evidence, the possibility that *Ar. ramidus* is not a hominin warrants further investigation, even if its hominin status is ultimately upheld.

In 2010, partial skeletons of a new hominin species, *Australopithecus sediba*, were discovered in southern Africa that similarly possess an unexpected mosaic of primitive and derived traits. The species exhibits craniodental traits that may align it with early *Homo*, but has postcranial characters (especially in the foot) that appear to be more primitive than those in *Pr. afarensis* (Berger et al. 2010; Zipfel et al. 2011). It has been hypothesized that it lies near the ancestry of *Homo*, but such a position might imply extensive homoplasy in hominin postcranial traits.

A difficulty in assessing the phylogenetic significance of these new data is that cladistic analyses of early hominins have traditional been based on cranial rather than postcranial characters because several early hominin species lack well-associated postcranial remains. Thus, it is difficult to quantitatively evaluate how the new postcranial data will affect parsimony-based assessments of early hominin phylogeny. Clearly, a research priority of the next decade will be to formally incorporate postcranial data into cladistic analyses of early hominins.

Phylogenetic Relationships Within the Genus *Homo*

Compared with studies of early hominin evolution in the Late Miocene and Pliocene, research on the phylogeny of Pleistocene hominins (Fig. 7) is complicated by ongoing debates on the number of species involved. The extremes range from those who, like Mayr in 1950, have argued for a single species in the genus

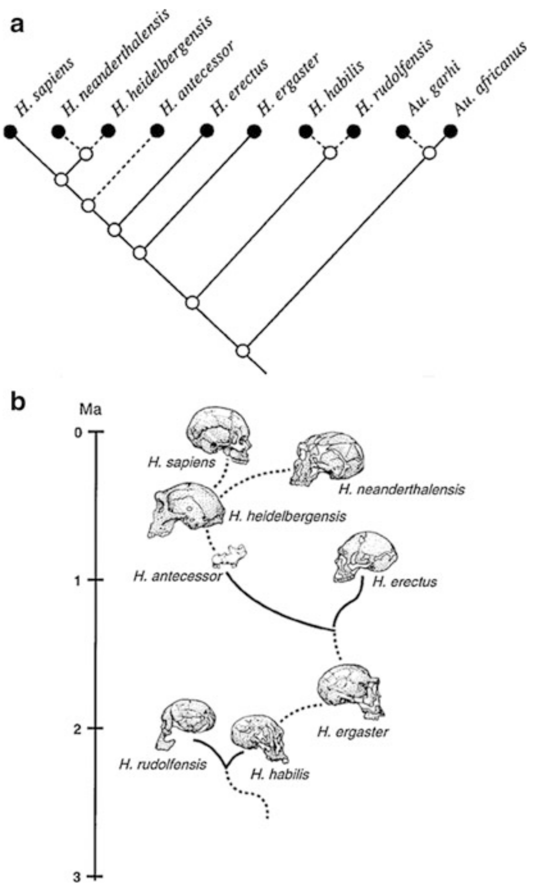

Fig. 7 Hypothetical cladogram (**a**) and phylogenetic tree (**b**) of evolution within the genus *Homo* (Modified from Tattersall 1999)

Homo (Wolpoff et al. 1994) – thus precluding any phylogeny within the genus – to others who suggest the presence of more than 15 species (Tattersall 1999). However, the majority of researchers recognize, at least for the purposes of discussion, between seven and nine species. *Homo habilis*, *Homo rudolfensis*, *Homo ergaster*, *Homo erectus*, *Homo heidelbergensis*, *Homo neanderthalensis*, and *Homo sapiens* are widely recognized, with *Homo antecessor* and *Homo floresiensis* more poorly known and/or less widely accepted.

As noted above, the relationships of *H. habilis* and *H. rudolfensis* are poorly resolved. On the basis of an assessment of adaptive differences between *Homo* and *Australopithecus*, Wood and Collard (1999a, b) have argued that these taxa should be removed from the genus *Homo*, although their suggestion has yet to be widely adopted. Among other early Pleistocene species, there are ongoing debates over whether *Homo ergaster* from Africa is more closely related to later species of *Homo* than is the mostly Asian *Homo erectus* (e.g., Fig. 4b) or whether any of the early species of the genus *Homo* can be distinguished at all (e.g., Wood 1994; Bräuer 1994; Rightmire 1992; Lordkipanidze et al., 2013).

Like studies of early *Homo*, studies of phylogenetic relationships among later species of the genus *Homo* are bedeviled by problems of proper taxonomic allocation of fossils to be included in any analysis. Many researchers agree that the descendant of the Early Pleistocene *H. erectus* (or *H. ergaster*?) is a Middle Pleistocene taxon usually referred to as *H. heidelbergensis* (Rightmire 1998), which in turn may have given rise to both Neanderthals and modern humans (Fig. 7b). However, it has also been suggested that the immediate ancestor of *H. heidelbergensis* is not *H. erectus*, but the poorly known *H. antecessor* from the latest Early Pleistocene of Atapuerca, Spain (Bermudez de Castro et al. 2004), and possibly Italy as well (Manzi 2004). The relationships between *H. heidelbergensis*, *H. neanderthalensis*, and *H. sapiens* are also uncertain. Although Neanderthals have traditionally been viewed as either a subspecies or sister taxon of *H. sapiens*, many authorities now argue that *H. heidelbergensis* and *H. neanderthalensis* are sister taxa or even a single anagenetic lineage with no clear break (Arsuaga et al. 1997; Hublin 1998). From this perspective, *H. sapiens* is the sister taxon of a *H. heidelbergensis* and *H. neanderthalensis* clade (Fig. 7a). In this scheme *H. sapiens* is the descendant of a distinct early Middle Pleistocene taxon from Africa, usually given the name *Homo rhodesiensis*. Stringer (2012b) has recently argued that reconstructions of the population history of Middle Pleistocene humans might be clarified by removing the hominins from Sima de los Huesos out of *H. heidelbergensis* and instead grouping them with Neanderthals.

An interesting recent debate concerns the phylogenetic relationships of *H. floresiensis*. Although once considered to be a dwarf descendant of *Homo erectus*, there is tantalizing evidence from both cranial and postcranial anatomy suggesting that it may, in fact, represent a *H. habilis*-like hominin whose lineage pre-dates the appearance of *H. erectus* (Argue et al. 2009; Jungers et al. 2009). More study is needed, however, and this, again, speaks of the need to incorporate postcranial characters into cladistic analyses of hominins.

Conclusions

It is too soon to say whether a consensus will emerge concerning the phylogenetic relationships of the hominin species described over the last two decades, not to mention those likely to be discovered in the coming years. Strait and Grine's (2004) results on early hominin phylogeny need to be tested by other, independent cladistic analyses, and a comprehensive phylogenetic analysis of the genus *Homo* is long overdue. Postcranial characters need to be incorporated into future studies. New fossils of almost all of these species are badly needed in order to provide a better representation of characters and a better understanding of intraspecific variation. Improvements in techniques to assess character independence, morphological integration, and developmental modularity (McCollum 1999; Ackermann and Cheverud 2000; Strait 2001) will also greatly improve the accuracy of cladistic analysis. At the heart of all attempts to understand hominin phylogeny are unresolved issues regarding the identification of species in the fossil record (Tattersall 1986, 1992, 1996;

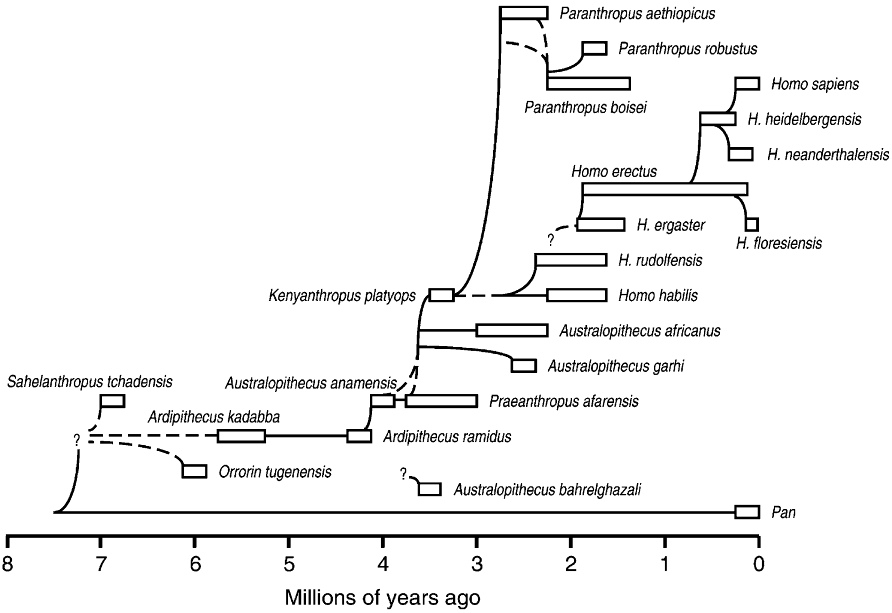

Fig. 8 A summary of the temporal span and phylogenetic relationships among fossil hominins

Kimbel and Rak 1993; Plavcan and Cope 2001). This is especially critical within the genus *Homo*, in which genetic evidence has demonstrated that population history is perhaps more complicated than might have been expected based on a consideration of the fossil record alone (Green et al. 2010; Reich et al. 2010).

Despite these caveats, a broad consensus regarding the phylogenetic relationships of many hominin taxa has emerged (Fig. 8). It is likely that disagreement will persist as to the exact relationships among *S. tchadensis*, *Ar. kadabba*, and *O. tugenensis* until they are known by more body parts that can be directly compared, but most workers accept that these species all lie somewhere near the base of the hominin tree. The greatest disagreement will probably focus on *A. garhi* and *K. platyops* and the relationships of these species to the genus *Homo*, as well as whether or not *Ar. ramidus* is a hominin. While there is broad general agreement about overall phylogenetic relationships in later hominin evolution, there is less consensus about the number of taxa that should be identified. The number and relationships of the early species of the genus *Homo* remain a source of ongoing debate (Wood and Collard 1999a, b; Wood and Lonergan 2008; Henke and Hardt 2011; Stringer 2012a), and there are various alternative interpretations concerning the few fossils from the Early and Middle Pleistocene (Tattersall 1986; Rightmire 1998; Bermudez de Castro et al. 2004; Manzi 2004).

Some have argued that hominin phylogeny will never be resolved in a timely fashion because of the many gaps in the fossil record (White 2002). That view is unduly pessimistic. Of course there are gaps in the fossil record! Despite the fact that knowledge of that record is constantly expanding, it will never be complete. That is not an excuse for failing to do the best one can with the material that is available in order to evaluate phylogenetic hypotheses. There is no doubt that the fossil record samples only a portion of the organisms, including hominins, that have ever lived and that new discoveries always document new, unanticipated aspects of evolutionary diversity. This is why paleontology is such an exciting and rewarding field of study. Despite this serendipitous sampling of the history of life, and ongoing uncertainties regarding some taxa, cladistic analysis has led researchers toward a general consensus of the phylogenetic relationship of many of the hominin taxa that can be documented and remains the best hope for resolving future questions about hominin phylogeny.

Phylogenetic Relationships of Hominids: Biomolecular Approach

Todd R. Disotell

Contents

Abstract

Biomolecules, in particular DNA, assist us in generating and testing hypotheses about human evolutionary history. Molecular analyses testing for and then utilizing a local molecular clock can inform us as to the timing of the split between different lineages or populations. When applied to the split between hominins and chimpanzees, for instance, the molecular clock estimates of their divergence date place constraints on interpretations of the growing fossil record from the Late Miocene and Early Pliocene. The pattern and distribution of modern human variation can be used to extrapolate back in time to infer when and where the modern human gene pool arose. Mitochondrial DNA and Y chromosome sequences and markers have been extensively surveyed in populations from around the world. Numerous nuclear loci and other markers, such as microsatellites and *Alu* insertions, have similarly been sampled and analyzed. More recently, high-throughput massively parallel sequencing technologies have allowed for the characterization of hundreds of human and

nonhuman primate complete genomes. The majority of such analyses point toward a relatively recent origin for modern human diversity from a small population in Africa within the last 200 Ka, with a subsequent dispersal into Eurasia less than 100 Ka though there is some debate as to the timing of these events. While analyses of ancient mitochondrial sequences from archaic hominins strongly suggest that archaic females did not contribute to the modern human mitochondrial gene pool, whole-genome sequences of two archaic populations suggest limited interbreeding with modern humans in Eurasia but not Africa. Analyses of modern African genomes suggest that some populations also interbred with an as yet unknown archaic population or populations. Thus, while a complete replacement of archaic populations by African-derived modern humans is no longer fully tenable, only a limited amount interbreeding between anatomically modern human populations and archaic forebears is likely to have taken place.

Introduction

Over 100 years ago, George Nuttall (1862–1937) began his book, *Blood Immunity and Blood Relationship*, with a discussion of the classification of the order Primates stating, “The persistence of the chemical blood-relationship between the various groups of animals serves to carry us back into geological times, and I believe that we have but begun the work along these lines, and that it will lead to valuable results in the study of various problems of evolution” (Nuttall 1904, p. 4).

We now know that biomolecules, in particular DNA, can inform us about phylogeny and population history, selection, and perhaps even taxonomy. Inferences drawn from molecular analyses can provide insights into at least three areas of hominin history. The first is the timing of the hominin–chimpanzee split, which in turn may provide a background for interpreting the growing Late Miocene–Early Pliocene hominin and hominid fossil record. The second is the origins of modern human populations by extrapolating into the past by examining the pattern of modern human molecular variation. Finally, Middle to Late Pleistocene fossils such as the Neanderthals and Denisovans have now successfully yielded DNA sequence information which allows us to draw inferences back to the point at which the modern and archaic lineages originated (see Fig. 1).

History

Nuttall’s research, carried out shortly after the discovery of blood groups in 1901, was based on qualitative and quantitative measures of the immunological reactions of various proteins in the blood. Immunological approaches were improved and systematically applied to questions about primate evolutionary history extensively in the 1960s through the works of Goodman (1961, 1963) and Sarich and Wilson (1966, 1967). It was also during this period that the concept of the molecular clock

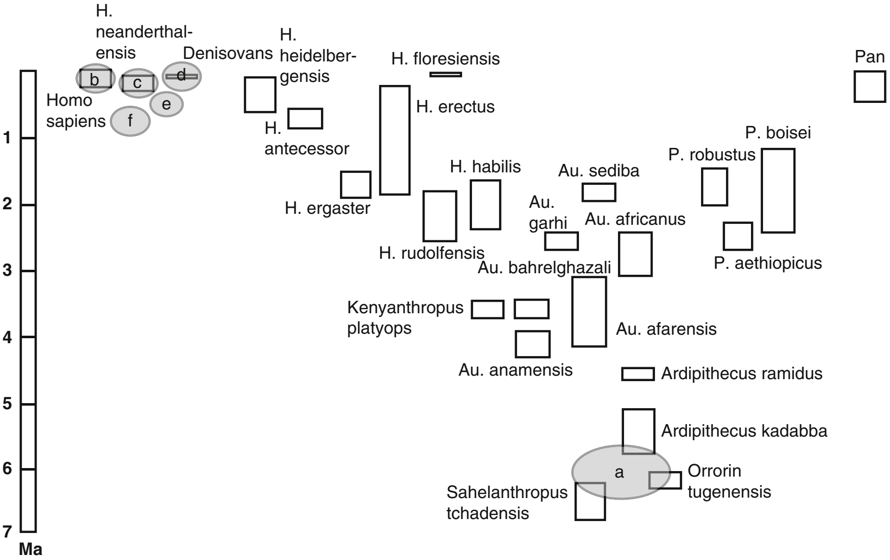

Fig. 1 Time ranges of hominin species (After Wood 2010). *Gray ovals* represent the six places where molecular information may be informative. (*a*) The timing of the split between hominins and chimpanzees, (*b*) the origins of the modern human gene pool, (*c*) the diversity and origin of the Neanderthal gene pool, (*d*) the diversity and origin of the Denisovan gene pool, (*e*) the time of divergence between Neanderthals and Denisovans, and (*f*) the time of divergence between the common ancestor of Neanderthals and Denisovans and that of modern humans

was first proposed (Zuckerkandl and Pauling 1962). By the 1970s, research increased directly at the DNA level, though only using approximate methods such as DNA–DNA hybridization and restriction mapping to measure the differences between species, populations, and individuals. This time period also saw the development of chromosomal banding techniques for evolutionary analysis (Chiarelli 1966; Dutrillaux 1979; Yunis and Prakash 1982). These techniques have been further developed and have helped us understand the rearrangements that are both shared and differ between humans and other primates using fluorescence in situ hybridization (FISH) and reciprocal chromosomal painting (Weinberg and Stanyon 1998). Chromosomal techniques are generally only used clinically within modern humans as our level of chromosomal variation is extremely low.

Techniques that directly measure differences at the DNA sequence level have advanced greatly in the last three decades. Earlier studies of species and population differences utilized restriction endonucleases, enzymes that cut a strand of DNA at a particular short sequence pattern, to estimate either genetic distances or to provide phylogenetically informative characters between individuals in the sample. Until 2005, the majority of molecular information was derived using a variety of manual to semiautomated technologies that allowed DNA sequences or microsatellite allele sizes to be relatively rapidly determined. The use of the variants of the polymerase chain reaction (PCR) allowed for minute samples from a variety of biomaterials including blood, saliva, hair, feces, bones, teeth, and other biological materials to be amplified and/or sequenced from only a few molecules of DNA. Amplification was generally followed by gel or capillary electrophoresis to determine sequences or allele sizes.

Practical constraints required the use of either relatively short sequences (hundreds to tens of thousands of bases) or variable markers such as retroelements, microsatellites, and SNPs. One popular class of molecular markers consists of retrotransposable elements, including short interspersed elements (SINEs) and long interspersed elements (LINEs). SINEs, particularly the *Alu* family, which exists in over 500,000 copies in human genomes, can vary in number and location between individuals and populations (Batzer et al. 1996). Because the absence of an *Alu* element at a particular location in the genome is the ancestral condition, the shared presence of an element is most likely indicative of common descent. Similarly, the longer LINE elements, which make up over 15 % of human genomes, can be used as markers of common evolutionary descent (Sheen et al. 2000; Boissinot and Furano 2005). Extremely variable short tandem repeats (STRs), also known as microsatellites, have also proven useful in individual identification and parentage assessment and to infer population relationships based on the analysis of the frequencies of different allele sizes (Bowcock et al. 1994). SNPs continue to be used to infer population relationships and evolutionary history (Yu et al. 2002).

Another class of genomic DNA elements is the endogenous retroviruses, which make up a surprisingly large portion of the human genome. Their type, copy number, and positions within the genome vary between populations, so they can provide useful evolutionary markers in the same way as the retrotransposable elements mentioned above (Turner et al. 2001). Extragenomic molecular data from pathogenic and commensal organisms can also be useful in inferring human evolutionary history. Tapeworm, lice, and stomach bacteria sequences have all been used to generate and test hypotheses about human population relationships and migrations (Hoberg et al. 2001; Disotell 2003; Leo and Barker 2005).

Single-nucleotide polymorphisms (SNPs) are typically characterized using DNA microarrays in which DNA probes for variants that are to be identified are usually attached to a solid surface. A DNA sample is then passed over the microarray to allow for hybridization of the source DNA to the probes which are then detected by fluorescence or chemiluminescence indicating a match. Current DNA microarrays can detect up to nearly two million SNPs, copy number variants, or other markers at once.

Beginning in 2005, several new sequencing platforms were developed that generate several orders of magnitude more data than previous methods, at dramatically reduced cost (Mardis 2013). Often referred to as Next Generation (NextGen) technologies, Second Generation (2ndGen) is probably a better term as there will always be a next generation. Though multiple platforms and methods are used, they all basically share several commonalities. First, rather than cloning or amplifying the DNA in advance, different synthetic adapters are added to the source DNA depending upon the platform used, and the fragments are amplified on a solid surface, either glass or a tiny bead, to which the adapters bind. Then the bound amplified fragments are sequenced by adding nucleotides that are detected one at a time as they are incorporated into the amplified clusters. The sequencing and detection step is carried out in a massively parallel manner so that hundreds of thousands to millions of DNA fragments are sequenced simultaneously. One downside to these techniques is that they generate relatively short sequences (from 50 to 60 to a few hundred bases long), with a relatively high error rate. These then need to be assembled into a genome or portion of a genome usually be comparing them to a closely related reference genome.

The completion of the first human genomes in 2001 by Lander et al. (2001) and Venter et al. (2001) was followed in 2005 by a complete draft of the chimpanzee and, in 2007, the macaque genomes, using conventional sequencing approaches allowing for even more sophisticated comparative analyses (Chimpanzee Sequencing and Analysis Consortium 2005; Rhesus Macaque Genome Sequencing and Analysis Consortium 2007). Second-Generation technologies were used to sequence the orangutan (Locke et al. 2011), gorilla (Scally et al. 2012), and bonobo (Prüfer et al. 2012) genomes. These genomes have not only allowed for far more in-depth analyses of the similarities and differences among the various ape lineages but provide information useful in inferring the polarities of molecular characters that vary among humans.

Finally, molecular data are being used to investigate the differences between humans and our primate relatives through studies of copy number variation, gene expression, epigenetics, and other underlying molecular and developmental processes; but these issues are beyond the scope of this review (e.g., Enard et al. 2002; Cheng et al. 2005; Eckhardt et al. 2006; Sudmant et al. 2013; Pääbo 2014).

Hominin Origins

Molecular studies have been used to draw inferences about the possible Eurasian origin of the African hominids including the ancestor of hominins, though not without controversy (Miyamoto et al. 1998; Stewart and Disotell 1998; Moyà-Solà et al. 1999; Heizmann and Begun 2001; Begun et al. 2012). However, until the discoveries of the Late Miocene hominids and/or hominins including *Ardipithecus*, *Orrorin*, and *Sahelanthropus* (Haile-Selassie 2001; Senut et al. 2001; Brunet et al. 2002), little could be said about origin of the hominin lineage itself. In fact, only its date, approximately 6 Ma, inferred from molecular clock estimates was available (Chen and Li 2001; Wildman et al. 2003). This date estimate is also not without controversy, though significantly older dates put forth by Arnason et al. (1996, 1998) and supported by Tavare et al. (2002) do not appear to be supported by more detailed molecular analyses (Raaum et al. 2005).

Recently a new debate has broken out over estimating divergence dates with molecular data. Typically, comparisons between two lineages for which good fossil evidence provides the age of at least one of them are converted into rates of change per year. This is of course dependent not only on proper placement of a fossil but also its appearance in the record near the point of divergence. Nevertheless, multiple estimates within the catarrhines have relatively consistently suggested a rate of approximately 1.0×10^{-9} bp^{-1} $year^{-1}$ (Takahata and Satta 1997; Green et al. 2010). With whole-genome analyses now common and relatively inexpensive, a direct estimation of the human mutation rate can be estimated by examining parent–offspring triads across the whole genome. With a known mutation rate and an estimate of the generation time for the taxa being investigated, divergence dates can be estimated. Coupled with new estimates of generation times for human, chimpanzees, and gorillas (Langergraber et al. 2012), an overall rate of approximately 0.5×10^{-9} bp^{-1} $year^{-1}$ or about half the previous rate has been estimated (Roach et al. 2010; 1000 Genomes Project Consortium 2010; Scally and Durbin 2012). However O'Roak et al. (2012) do not find such a slow rate in their whole-genome family triad study. Ho et al. (2011) provide an excellent discussion of the discrepancy in rates of evolution determined at different timescales, at both the morphological and molecular levels.

Fu et al. (2013) provide a third way of estimating molecular rates of evolution, at least for the mitochondrial genome. By sequencing mtDNA in fossils dated to within the last 40,000 years (the reliable range of radiocarbon dating), they can measure the effect of "branch shortening" in which fossil lineages are missing the substitutions that would have occurred had they survived to the present. The number of missing substitutions coupled with the dates of the samples provided remarkably consistent rates. These rates when applied to mitochondrial trees provide divergence estimates that fall within the range of the classically accepted dates discussed below. When high enough quality whole-genome data become available, this technique will be applied to nuclear DNA as well (Green and Shapiro 2013).

It should not come as a surprise that, with whole genomes of the apes available, the interpretation of when speciation occurred has become more complex. For instance, 15 % of the sequences in the western lowland gorilla genome are most similar to those in humans, and 15 % are most similar to those in chimpanzees despite the overall closer relationship of chimpanzees to humans (Scally et al. 2012). Furthermore, 3 % of the human genome is more closely related to chimpanzees or bonobos than they are to each other (Prüfer et al. 2012). These differences in gene lineages from the overall pattern of speciation may be due to several phenomena. In incomplete lineage sorting, ancestral polymorphism or variation in the common ancestral population may be partitioned into descendent populations and ultimately descendent species such that individual genes do not match the species phylogeny. If there is gene flow between the ancestral populations or the incipient species, the gene phylogeny may similarly differ from the species phylogeny. Thus, care must be taken in interpreting molecular divergence dates, especially those derived from concatenated datasets and whole genomes.

With the discovery of these Late Miocene fossils, numerous phylogenetic hypotheses were put forth suggesting their hominin status (Haile-Selassie 2001; Brunet et al. 2002) or that only one was an early hominin and the others were either fossil chimpanzees or gorillas or broadly ancestral to both the human and chimpanzee lineages (Senut et al. 2001). Given the vast amount of molecular data

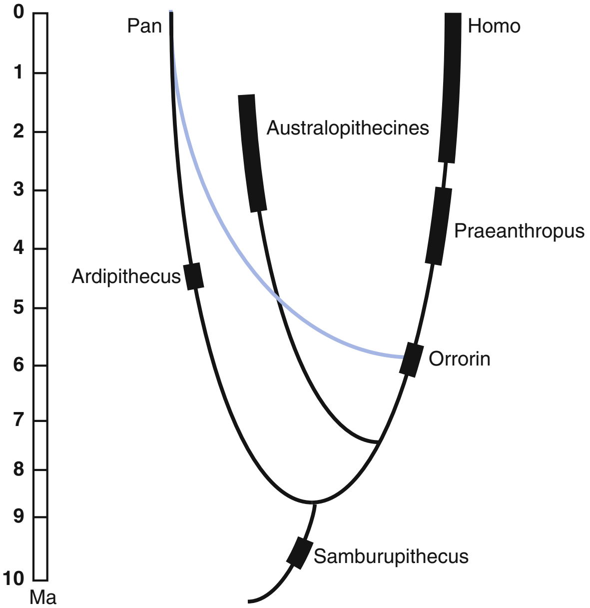

Fig. 2 Potential phylogenetic relationships of Late Miocene and Early Pliocene hominins and hominids. *Black lines* and ranges after Senut et al. (2001); *gray line* represents the molecular clock estimate of the divergence of hominins and chimpanzees (Chen and Li 2001; Wildman et al. 2003)

collected to assess the relationships among African apes including humans, "… genetic data can also give us trees that are well enough proportioned to be useful to us as paleontologists and that can provide constraints on our 'flights of fancy,' when calibrated by plausible paleontological or other historical data" (Pilbeam 1995). An approximately 6 Ma split between humans and chimpanzees (see Fig. 2), for instance, makes untenable the phylogenetic proposal put forth by Senut et al. (2001), in which *Ardipithecus* falls along the chimpanzee lineage and *Orrorin* falls well within the hominin lineage more than 2.5 Ma after a human–chimpanzee divergence (assumed by Senut et al. to have occurred around 8.5 Ma). On the other hand, if the purported much slower rate of evolution is applied, the human–chimpanzee split (and all others) becomes much older. Hawks (2012) points out that if older divergence dates are accepted, then fossils such as *Chororapithecus* at 10.5 million years old could indeed fall along the gorilla lineage as claimed by Suwa et al. (2007). The gorilla affinities of *Chororapithecus* have, however, been disputed by others (Gibbons 2007). Overall, given that the phylogenetic approach to estimating divergence dates and the method using missing substitutions from fossils concur and the whole-genome family triad methods give suspiciously ancient divergence estimates for many primate lineages, it is probably best to continue to use the faster rate estimates when inferring dates.

An interesting proposal put forth by Wildman et al. (2003) using a combination of lineage divergence estimates based both on molecular and fossil data would substantially revise the taxonomy of all hominins and our close relatives, the chimpanzees. They propose a time-based phylogenetic classification/taxonomy linking the timing of the origin of a clade to its taxonomic level for most catarrhines. In their scheme, because chimpanzees and humans share a recent common ancestor at only 6 Ma, chimpanzees would be classified within the genus *Homo* as *Homo* (*Pan*) *troglodytes* and *Homo* (*Pan*) *paniscus*. Consequently, all genera of hominins, including *Australopithecus*, *Paranthropus*, and *Kenyanthropus*, would necessarily be sunk into the genus *Homo*. Depending on their phylogenetic positions and divergence dates, *Sahelanthropus*, *Orrorin*, and *Ardipithecus* might similarly be included within *Homo*. While the chaos and difficulty of adopting this strategy are apparent, the underlying phylogenetic logic is appealing.

Modern Human Origins

Most studies of blood group allele frequencies and protein polymorphisms carried out in the 1960s and early 1970s that presented their findings in the form of a phylogenetic tree posited a basal split between Asians and an Afro-European cluster. In 1974, Nei and Roychoudury (1974) analyzed 21 blood group systems and 35 polymorphic proteins from which they inferred an initial African versus European–Asian split. In this rather prescient chapter, they extrapolated from estimated amino acid replacement rates and inferred that the basal split between Africans and Eurasians occurred approximately 120 Ka and that Europeans and Asians split around 55 Ka. Few additional studies attempting to infer modern human origins were carried out until the late 1980s.

Two seminal papers published in the late 1980s by Cann et al. (1987) and Vigilant et al. (1989), both working in Allan Wilson's laboratory at the University of California at Berkeley, inferred a less than 200 Ka African origin for all human mitochondrial DNA (mtDNA) and, by extrapolation, perhaps for all modern populations. Known by various names, the "Mitochondrial Eve" or "Out-of-Africa" hypothesis, will hereafter be referred to as the Recent African Origin (RAO) model. This model stands in contrast to the regional continuity or multiregional (MRE) model in which local populations are thought to derive from the original groups that migrated into the various regions of the Old World over 1 Ma from Africa, with various amounts of gene flow between the different regions ever since (Wolpoff et al. 2000). Cann et al.'s (1987) study was based on phylogenetic inferences drawn from parsimony analysis of high-resolution restriction mapping of the whole mtDNA genome. To counter criticisms of the precision of restriction mapping, the geographical sampling, and the lack of an outgroup in Cann et al.'s original analysis, Vigilant et al. (1989) employed one of the first uses of PCR utilizing hair samples to generate nucleotide sequences in a phylogenetic analysis, followed by a sequence-based analysis with a much larger sample size (Vigilant et al. 1991). Through sequencing the D-loop or control region of the mtDNA genome, they were able to align human sequences with those of a chimpanzee in order to carry out a parsimony analysis rooted by an outgroup. The results were remarkably congruent with those of Cann et al. (1987), in inferring a similar timing and location for the origin of all contemporary human mtDNA: approximately 200 Ka in Africa.

The initial papers of Cann et al. (1987) and Vigilant et al. (1989, 1991) came under criticism for an important analytical flaw. Their parsimony trees suggesting a recent African ancestry for all modern mtDNA were derived from heuristic search strategies that did not find the most parsimonious trees for their respective data sets. Other researchers were able to infer trees without African roots that were more parsimonious (Maddison et al. 1992; Templeton et al. 1992). Since no search strategy is available to guarantee the most parsimonious tree is found for such large data sets, alternative strategies were utilized to infer the root of the modern human mtDNA tree. However, Stoneking et al. (1992) and Sherry et al. (1994) demonstrated that the much greater amount of mtDNA diversity found within Africa compared to outside of it was best explained by a longer period of time for it to accumulate within Africa. Additional smaller data sets chosen to represent the most diverse human sequences possible were also analyzed, and an African origin for modern mtDNA types was inferred (Kocher and Wilson 1991). Additional molecular dating inferences also supported the approximately 200 Kyr time frame inferred to explain human mtDNA diversity (Ruvolo et al. 1994).

A huge number of human complete mitochondrial genome sequences has been collected and subjected to phylogenetic and population genetic analyses. Due to the rapid rate of evolution of the mtDNA genome, short sequences such as those found in the D-loop or control region are not always useful over long timescales and may show spurious clustering due to homoplasy or multiple substitutions at the same site, including saturation of substitutions at a site. One solution when available is to characterize both the fast-evolving control region and several more slowly evolving region of the mtDNA genome to define haplogroups or related lineages of mtDNA haplotypes. In fact, sequencing the complete 16.5 kb mtDNA genome has become commonplace (Ingman et al. 2000; Herrnstadt et al. 2002). By the end of 2013, more than 20,000 complete human mitochondrial genomes had been deposited in GenBank. Such analyses show more geographic partitioning of mtDNA sequences than previous studies based on much shorter sequences revealed.

Unfortunately, the nomenclature for major mtDNA lineages has developed haphazardly, mostly by time of definition and not with phylogenetic relationships in mind. In fact, most haplogroups are defined by the number of substitutions that they differ from the first complete human mtDNA sequence (a European) published (Anderson et al. 1981). A recent proposal has been put forth to redefine the mtDNA tree from its root, by inferring the common ancestral human mtDNA haplotype through analyzing 8,216 modern mitogenomes along with those from six Neanderthals (Behar et al. 2012). Seven major lineages (L0–6) have been defined for African mtDNA haplotypes, while two macro-haplogroups (M and N) contain all Eurasian lineages which are derived from African L3 (Kivisild et al. 1999; Herrnstadt et al. 2002). Sub-haplogroups of macro-haplogroup M are almost exclusively found among contemporary Asians along with a small number of individuals in Africa presumably due to back migrations (Gonzalez et al. 2007). Macro-haplogroup N contains around a dozen sub-haplogroups that are found predominantly in Europe with another seven that are found in Asia and the Americas (see Fig. 3).

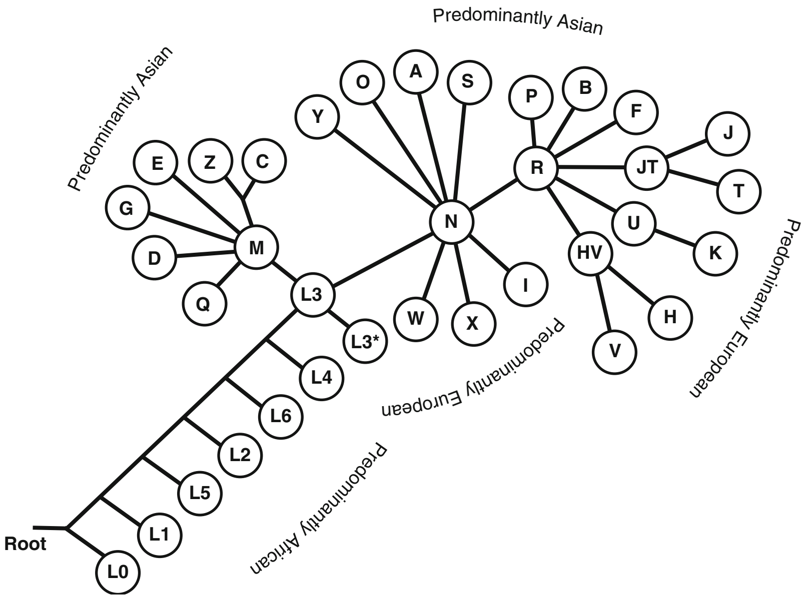

Fig. 3 Mitochondrial DNA haplogroup phylogeny with arbitrary branch lengths (Modified from Ruiz-Pesini et al. 2007 and Behar et al. 2012)

Various criticisms of using mtDNA sequence data that have been put forth include the possibility of nonmaternal inheritance, selection skewing inferences of geographic structure and rates of evolution, and the presence of recombination. To date, no firm evidence of paternal inheritance has been demonstrated in humans (Bandelt et al. 2005). Furthermore, a mechanism that destroys sperm mtDNA has been discovered, making paternal inheritance even more unlikely (Nishimura et al. 2006). Claims for selection acting strongly upon some human mtDNA lineages, especially related to humans' entry into colder climates, have been put forth (Mishmar et al. 2003; Ruiz-Pesini et al. 2004). Others interpret the evidence for selection as mainly for purifying selection with only a restricted amount of positive selection in a small portion of the mtDNA genome (Elson et al. 2004). Eyre-Walker and Smith (1999) suggested that mtDNA genomes undergo recombination making inferences about their evolutionary history much less straightforward. The suggestion that mtDNA undergoes recombination has been amply countered by further analyses (Macaulay et al. 1999).

All in all, mtDNA analyses provide a very powerful tool for inferring the evolutionary history of humans and provide a remarkably consistent story as additional data and techniques are brought to bear. Mitochondria, however, only yield a maternal history of the organisms under study. To better understand the overall evolutionary history of any group, both male-specific and biparentally inherited loci are also needed.
