Preface to the Second Edition

Knowledge is advancing rapidly in all areas of science, and the science of paleoanthropology is certainly no exception. Yet, it was still a surprise, a mere 4 years after the *Handbook of Paleoanthropology* first appeared, to hear from Mrs. Susanne Friedrichsen, senior editor at Springer and our editor for the first edition, that she and Mrs. Hanna Hensler-Fritton, editorial director of life sciences and biomedicine at Springer and successor to Dr. Dieter Czeschlik, who had initiated and enthusiastically supported the project, were already thinking about an updated and possibly even enlarged new edition.

Naturally enough, we were a little hesitant. Of course, we were happy to hear that the handbook had been sufficiently successful for the publisher to contemplate a new edition. But, on the other hand, both of us had recently retired and were looking forward to the tranquil pursuit of pet projects that had previously had to be put on the back burner. What's more, we knew from experience how huge a commitment would be involved. And then, there was the indefatigable multivolume encyclopedist Bernard Wood's comment in a review of our first edition: "The timelessness of the research problems means that from time to time folks will always want to take stock of what progress, if any, we have made toward solving these problems, but I fancy it will be brave ones who try to do this in the future in the form of three printed volumes. My prediction is that the *Handbook of Paleoanthropology* will suffer the same fate as the Neanderthals" (*Evolutionary Anthropology* 17: 119–122, 2008).

Should we be brave, and did we even want to be? During a meeting in Heidelberg, Germany, one of us (WH) was introduced to the new workflow system SpringerReference.com by Mrs. Hensler-Fritton and Mrs. Friedrichsen, who expressed boundless and infectious enthusiasm for the new facility. We learned that the handbook would be available online as well as in hard copy and that the system was sufficiently flexible for authors to make their own updates directly online. With this option for continuous updating, the attractiveness of the project increased.

So in the end, we decided to leave the decision to our contributors. If they were ready to proceed and to update and expand their contributions, then we were prepared to go ahead and edit a new edition. Quite frankly, we had no idea how they would react. As a first step in assessing the willingness of our contributors to proceed, we wrote in January 2012 to all of our original authors inviting them to cooperate once more and telling them of the new game plan. The feedback was overwhelming. Fewer than one-tenth of our 67 contributors declined, though many, predictably enough, requested extended deadlines. And everyone we subsequently approached agreed to write replacement chapters. With such a response, we had no choice but to press ahead. In the process, we added new material with the benefit of the input, especially from reviews, that the first edition had generated.

By Easter 2014, 76 articles had been submitted, and we hope that the thoroughly revised, enlarged, and updated second edition adequately reflects the many changes that have impacted the sciences of human evolution since the first edition appeared. We are pleased to make it available to all those students and professionals who are interested in paleoanthropology defined in its broadest sense and in its principles, methods, and approaches.

The concept of the first edition has not been changed, and, as then, we have not tried to impose any uniformity of viewpoint on our authors. Indeed, we have welcomed heterogeneity of opinion and have had the luxury of giving authors sufficient space to lay out all the evidence they consider relevant to allow every reader to reach his or her own conclusions. In addition, the online version allows the inclusion of unlimited colored figures: a welcome improvement and an aesthetic delight especially in those contributions that discuss glorious fossils and marvellous artifacts. As we expect most readers to use the easily searchable SpringerReference.com version and not the hardcover publication, we have reduced the basic index to keywords indicated by the authors. For the same reason, the taxonomic index is restricted to genera and species only.

That we are in the happy position of writing this preface exactly 3 years after we began negotiations on this second revised and enlarged edition is due to the contributors who worked so diligently on the updates of their chapters (only four survive intact from the first edition). Some topics needed more input than others, but we thank all authors equally. It has been a pleasure working with them. We additionally extend special thanks to those colleagues who took on the task of writing (with an entirely free hand) replacement versions of old chapters and chapters on themes that were not addressed in the original edition. It has been great working with you all.

On the editorial side, we are especially grateful to Mrs. Hanna Hensler-Fritton and Mrs. Susanne Friedrichsen, already mentioned, whose enthusiastic support for the project and for integrating the handbook in the live reference system (Springer-Reference.com) was crucial for its realization. During the first stage of the project, the coaching of the authors in its technicalities was done with patience and commitment by Ms. Swati Sharma, previously associate editor, MRW, Springer, New Delhi. When Ms. Sharma's functions were handed over to Ms. Audrey Wong, associate editor, MRW, Springer Science+Business Media, Singapore, at the end of 2012, we were again in highly professional hands. The continuous dialogue with Ms. Wong and later on with Ms. Meetu Lall and subsequently Ms. Sunali Mull greatly facilitated the shepherding of the submissions through the initial production process. We are grateful to all of these dedicated people. At SPI Technologies, we also thank Mrs. Christine Bartels for her extraordinary copyediting expertise and Ms. Anitha Rajasekaran, Project Manager, SPi Technologies India Private Ltd, for deft assistance in the later stages of the production process.

Preface to Volume 1, Second Edition

Principles, Methods, and Approaches

Although in the 7 years since the appearance of the first edition of the *Handbook of Paleoanthropology* there have been no paradigmatic changes in paleoanthropological thinking, the field has been energized by numerous theoretical developments (e.g., epigenetics, symbolism), methodological innovations (e.g., virtual anthropology, paleogenetics), and highly innovative collaborative approaches to paleoanthropological research (e.g., NESPOS, EVAN). There have additionally been exciting new paleogenetic (e.g., the Neanderthal genome, Denisovans), fossil (e.g., *Australopithecus sediba*) and artifactual (e.g., Swabian Venus of Hohle Fels) findings that provide more than enough reason for an update. This second edition has also given us the chance to integrate additional contributions too (e.g., on Charles Darwin, paleoanthropology, and the modern synthesis; the relationship of paleoanthropology and genetics; the evolution of speech and language; virtual anthropology and biomechanics; the investigation of human fossils using medical technologies; and facial reconstruction in paleoanthropology).

2009 marked the bicentennial of Charles Darwin's birth and the 150th anniversary of his seminal *On the Origins of Species by Means of Natural Selection* that gave biology its most important unifying concept. This double anniversary was celebrated by innumerable events and gave rise to intense biographical research and reflection on the state of evolutionary biology. In the opening chapter, **Winfried Henke** tries to integrate some of this introspection in a detailed update of his "Historical Overview of Paleoanthropological Research." He demonstrates that a historiographical glance backward, even as we move forward, will be helpful in making us more critical about the reliability and validity of our theoretical concepts, methodological approaches, and empirical bases. It is obvious that the change from monocausal explanations to a more complex and multifaceted thinking (e.g., biomechanical and energetic aspects as well as such things as ecological and nutritional prerequisites) has led to better explanations of the process by which we became human – but he warns that we still should not expect too much of models! Many problems remain unsolved and pose challenges for future research.

As a belated tribute to Darwin's double anniversary, we asked **Franz M. Wuketits**, evolutionary biologist and philosopher of science, to focus on the role paleoanthropology played in Charles Darwin's views of evolution and later on in the formation of the synthetic theory or modern synthesis. His essay "Charles Darwin, Paleoanthropology, and the Modern Synthesis" is a critical review of Darwin's concepts of human evolution as developed in *The Descent of Man*. He analyzes the role of Darwin's thoughts in establishing the synthetic theory in the 1930s and 1940s, although only later were most leading proponents of this theory explicitly concerned with paleoanthropological issues. His chapter also recalls some historical examples showing how paleoanthropologists have sometimes been misled by ideology (*Weltanschauungsfragen*). Wuketits brings methodological issues to the fore and rightly emphasizes that these matters deeply affect the status of a discipline that is of crucial importance for understanding the human condition, past and present. **Philippe Huneman's** contribution on "Evolutionary Theory in Philosophical Focus" has been wholly rewritten. This critical essay from the perspective of a philosopher is now more accessible to those who are unfamiliar with philosophical methods. The survey focuses on the philosophical problems raised by two of Darwin's claims: the existence of a tree of life and the explanatory power of natural selection. Huneman's overview illustrates that evolutionary theory is replete with theoretical problems over such basic concepts as selection, fitness, and adaptation. His perspective that "those problems are at the same time philosophical since they involve conceptual matters that imply epistemological and metaphysical options" is a challenge to all those who wish to escape the generally reductionist views of biology, and it may have relevance to such long-standing puzzles as the origin of language, maternal attachment, morality, and cultural evolution. **Peter Menke** has produced a slightly enlarged update of his contribution "The Ontogeny-Phylogeny Nexus in a Nutshell: Implications for Primatology and Paleoanthropology" in which he explains via the example of the cranial base how ontogeny can help illuminate the processes of human evolution. **Michael Ohl's** excellent contribution on "Principles of Taxonomy and Classification: Current Procedures for Naming and Classifying Organisms," commended as "a jewel" by a reviewer of the first edition, has remained unchanged. **Colin Groves** has contributed a minor update to his chapter on species and speciation (previously in Volume 3). **Kaila Folinsbee** and coauthors' contribution on "Quantitative Approaches to Phylogenetics" has been expanded by the integration of numerous new references, while **Oliver Rieppel's** article on "Homology: A Philosophical and Biological Perspective" has also retained its structure from the first edition.

The last few decades have seen ongoing developments and methodological progress in the field of chronometric dating, and we are very grateful to **Daniel Richter**, who took over the task of extensively updating **Günther Wagner's** "Chronometric Methods in Paleoanthropology." This comprehensive contribution introduces the reader to the principles of radiometric dating and to the most frequently applied dating methods such as argon/–argon, uranium series, luminescence, electron spin resonance, and radiocarbon. Their potential for paleoanthropology is illustrated using various examples covering the entire period since hominins first entered the scene several million years ago. Of special interest is a new section on the cosmogenic ^{26}Al/^{10}Be technique successfully applied at such sites as Sterkfontein, Atapuerca/Sima del Elefante, and the Lower Cave at Zhoukoudian. This article impressively illustrates how paleoanthropological knowledge and concepts have benefited from these methodological advances. **Walter Etter** provides a broad view of "Patterns of Diversification and Extinction," and his meticulously rewritten history of life on Earth reaches back to the beginning of organic life. This places human evolution in an extremely broad perspective. Etter points out "that each extinction event had its own signature, and no common cause has been found." The Phanerozoic has seen 5 major and more than 15 smaller mass extinctions that disrupted the diversification of life and sometimes drastically altered the path of evolution, and Etter expresses concern "that we are currently entering a 'Sixth' major extinction, caused by human impact on nature."

Taphonomic processes lead to a stepwise loss of information about formerly living organisms, so understanding the transition of organic remains from the biosphere to the lithosphere is essential. **Gisela Grupe's** update coauthored by **Michaela Harbeck** on "Taphonomic and Diagenetic Processes" therefore gives a comprehensive and up-to-date overview of the successive steps of necrology, biostratinomy, burial, and diagenesis. The revised chapter contains additional sections dealing with mineral changes, e.g., the recrystallization and/or the preferential loss of smaller crystallites in the course of mineral dissolution leading to an increase in bone crystallinity, a most fundamental aspect of bone diagenesis. She further covers the preservation of biomolecules, an increasingly important topic. Stable light isotopes allow us to detect linkages between hominin evolution and environmental changes, and **Julia Lee-Thorp** and **Matt Sponheimer's** updated "Contribution of Stable Light Isotopes to Paleoenvironmental Reconstruction" integrates many recent studies. The authors convincingly demonstrate that "carbon isotope ratios of pedogenic carbonates and faunal enamel have pushed back the emergence of C_4 grasses, and thus more open environments, to ca. 9 Ma," and as a further remarkable result, they cite isotopic evidence from East and South Africa that "suggests a significant change to more open, grassy ecosystems ca. 1.8 Ma, broadly concordant with the emergence of *Homo ergaster*." These and many other results demonstrate the great importance of isotopic approaches to understanding paleoenvironments. **John Rowan** and **Kaye E. Reed** have provided a new contribution on "The Paleoclimatic Record and Plio-Pleistocene Paleoenvironments." Their concisely written overview of various paleoecological methods summarizes recent results on the paleoecology of hominins from the late Miocene to the early Pleistocene, ~2.0 Ma. For habitat reconstruction bases on fauna, the use of taxon-free methods (e.g., enamel isotopes) is preferred over taxon-based methods (e.g., tribal relative abundance) because the latter involves considerable assumptions, e.g., sites containing *Australopithecus* are often reconstructed as "mosaics." The authors note that this could be due to time averaging or depositional processes or might actually represent various habitats across the landscape.

There is no doubt that Africa is the "cradle of human origins," and it is highly likely that many fossils still await unearthing. **Ottmar Kullmer** asserts in his contribution on the "Geological Background of Hominid Sites in Africa" that "the types of sediments and the geological contexts likely to yield hominid fossils are known. We just have to look for the right deposits." His contribution adds recent literature and gives us a comprehensive overview of the topic. Kullmer advises all "fossil-hunters" to look not only at those sites and regions that yielded hominin fossils in the past but encourages them to "discover new fossiliferous localities in smaller-scaled graben and basin structures at places in central, western or southwestern Africa." As an experienced field paleontologist, he is convinced that ". . .it is just a matter of time until the first early hominid is reported from the other side of the African continent." Let us hope he is right! Soils are "products of environmental factors such as climate, vegetation, topographic setting, parent material, and time for formation," so that "paleosols, or fossil soils," give us the chance to reconstruct changing environments in the past. **Gregory Retallack's** contribution on "Paleosols" does not support the traditional narrative of human evolution in a single transition from primeval forest to dry climate and open grassland. Research on paleosols indicates climatic oscillations between wet and dry and alternating expansion of woodland and grassland since at least 18 Ma (million years ago). Since paleosols do not reproduce well in black and white, it is a great improvement to see the figures in color in the online version. **John A. Van Couvering's** new article on "Quaternary Geology and Paleoenvironments" characterizes the late Neogene in environmental terms both globally and as it applies to African and Eurasian environments. Topics include the chronostratigraphic divisions of the Quaternary, the cause and timing of the climatic cycles, the development of grasslands and deserts, sea-level changes and their effects on human migration, and the apparent synchronicity of hominin evolutionary steps and major climate shifts. Van Couvering emphasizes that "the appearance of *Homo* just as climate changes became significantly more extreme with the beginning of the Quaternary cannot be a meaningless coincidence" and avers that ". . .if we accept that natural selection is driven primarily by environmental change, we cannot avoid a very strange and simple conclusion: that the breakthrough into sentience that makes us able to read and write these words about the Quaternary would not exist, but for the existence of the Quaternary itself." **Klaus-Dieter Jäger's** contribution on "Quaternary Deposits and Paleosites" has been updated and deals mainly with European paleosites of the Pleistocene and Holocene epochs. Though the Quaternary, characterized by a series of significant long- and short-term climatic fluctuations, is comparatively short, it is of special paleoanthropological interest because it saw the origin and expansion of the genus *Homo* and the rise of anatomically modern *Homo sapiens*. **Thorolf Hardt** has slightly updated his coauthored contribution on "Paleoecology: An Adequate Window on the Past?" and we hope that the view through the "window" is a bit clearer now. Sadly, **Alan Turner**, world authority on the evolution of mammalian faunas of Africa and Europe, passed away in January 2012. But his coauthor, **Hannah O'Regan**, took on the task of updating their joint and content-rich overview of "Zoogeography: Primate and Early Hominin Distribution and Migration Patterns." Putting paleoanthropology into paleoecological focus, the new version integrates essential new literature on this challenging issue. Even more difficult is "The Paleodemography of Extinct Hominin Populations" treated by **Alan Mann** and **Janet Monge**. As demographic structures are both the outcome of evolutionary processes operating on groups of individuals and the basis on which future evolutionary forces can potentially operate, it is of great interest to have this topic overviewed. However, Mann and Monge find little prospect that our methods and approaches will soon deliver reliable results as “the paleodemography of extinct hominin taxa has not produced a corpus of dependable data, and it remains possible that reasonable population-based demographic parameters from fossil assemblages will remain unattainable into the foreseeable future.” The authors offer some hope, however, in stating that “the use of modeling from archaeological samples holds more promise in an application to the more distant past to capture demographic parameters in long extinct populations in the hominin lineage.” In contrast, isotope research is a highly dynamic and promising field, and the extensive update of **Matt Sponheimer** and **Julia Lee-Thorp’s** contribution on “Hominin Paleodiets: The Contribution of Stable Isotopes” is excellent proof of this. These authors present new data justifying the assumption that the earliest australopiths had nearly pure C_3 diets, whereas later australopiths, living around 2 Ma, show a predominantly C_4 signal. There is further indication that increased masticatory robusticity in the australopiths is associated with greater C_4 consumption; however, given *Paranthropus boisei*’s thick, robust mandibles, low-cusped cheek teeth, and diminutive incisors and canines, the authors believe it improbable that its major C_4 dietary input was meat, and they regard it most parsimonious to ascribe the preponderance of its C_4 signal to the direct consumption of C_4 plant foods like grasses or sedges.

Helmut Hemmer’s article on “Estimation of Basic Life History Data of Fossil Hominids” remains highly useful and informative, whereas **Jonathan Marks** kindly agreed to write a new replacement chapter on “Genetics and Paleoanthropology.” In a dense historical review, he shows that scholars trained in genetics and in anatomy often see evolutionary comparisons in quite different ways, and he demonstrates that their training and the nature of their data often lead geneticists and paleontologists to conceptualize evolution itself differently. Marks elegantly dissects the pros and cons of the various ways in which the two disciplines invoke adaptation, natural selection, and speciation; he points out that morphological and genetic techniques each have their own set of strengths and weaknesses and that there is a need to integrate both into the deciphering of human origins and evolution. **Susanne Hummel** has thoroughly updated her valuable contribution on “Ancient DNA,” which describes the field’s long trajectory from a “highly skeptical accompanied technical approach revealing spectacular results to a sound practice giving access to biological data helping to explain the past.” Her chapter helps us to understand the complexity of the methods involved and their inherent pitfalls and shows how next-generation sequencing gives access to information on entire genomes. While some practitioners believe that new approaches will replace traditional ones completely, it is likely that complete modeling of the past will only be attained in the context of a multifaceted and integrated science.

In the realm of comparative primatology, **Robert W. Sussman** and **Donna Hart’s** update of “Modeling the Past: The Primatological Approach” is an excellent demonstration that reconstructing the evolution of early human behavior from a primatological perspective is much more than mere storytelling. Instead, it is based on the integration of models of several types: first, the referential model (which uses a living species as literal models for particular extinct species); second, the conceptual model (in which a mosaic of morphological or behavioral traits is seen as a broad analogue for reconstructing early hominin species); and finally, the strategic model (which assumes that species in the past were subject to the same fundamental evolutionary laws and ecological forces as species are today). The update of this paper is a highly informative clarification of the authors' exhortation "to use all of the above in what is considered a logical and appropriate manner but always taking into account whether any particular aspect of our model is inconsistent with the evidence presented in the fossil record." "Modeling the Past: The Paleoethnological Approach" by **Paolo Biagi** uses archaeological legacies in an analogous way. His updated contribution considers current evidence (occupation surfaces, structural remains, hunting weapons, fire) from the earliest Paleolithic (Oldowan, Mode 1) in Africa and continues through early sites beyond that continent, maintaining a paleoethnological perspective. **Miriam Haidle's** detailed update of her contribution on "Modeling the Past: Archaeology" impressively demonstrates the recent progress made in a field of research that has undergone a fundamental change from a descriptive-typological discipline to a highly cross-disciplinary one that integrates the humanities and the sciences. Haidle's chapter focuses on the potential explanatory power of archaeology in paleoanthropology, and she draws her conclusions from a diachronic comparison of the typological, technological, functional, contextual, and cognitive facets of archaeological knowledge. This sophisticated approach allows her to answer questions of how prehistoric populations used their cognitive potential and cultural capacities as determined by biological, historical-social, and individual dimensions and limited by environmental constraints.

What makes us unique? **Phillip Lieberman** and **Robert C. McCarthy's** new contribution on "The Evolution of Speech and Language" gives a possible answer to this fundamental question. Their position is that language did not suddenly arise 50,000–100,000 years ago through a mutation that yielded an innate "faculty of language." Further, they are convinced that human speech, language, and cognition derive from anatomy and neural mechanisms that were shaped by Darwinian processes of natural selection but that are shared with other living species. Their contribution ranges from the neuronal anatomy and neurophysiology of the brain to the larynx and the tongue to findings of neuroimaging techniques such as functional magnetic resonance imaging (fMRI) and diffusion tensor analysis (DTI) to the linguistic capacities of living nonhuman species, syntax, and semantics and further to the fossil record as well as to paleogenomic findings (FOXP2). In the process, it touches on many controversial issues.

Gabriele Macho's update of her contribution on "General Principles of Evolutionary Morphology" illuminates how fossil hard tissue remains such as bones and teeth provide a wealth of information for evolutionary biologists aiming to reconstruct the phylogenetic histories and functional adaptations of extinct species. She demonstrates that it is not an easy task to decipher the constraints acting on morphology, and describes the limitations we are faced with when interpreting form/function and behavior from morphology. Macho's advice is to carefully choose the appropriate research tools, bearing in mind the limitations specific to each approach, and she recommends a periodic change of perspective by turning around the fundamental questions about the form, function, and behaviors of extinct hominins. "Virtual Anthropology and Biomechanics" is a replacement chapter written by **Gerhard W. Weber,** whose lucid writing and brilliant illustrations convey the author's enthusiasm for his discipline. Weber explains the six main areas of virtual anthropology – digitize, expose, compare, reconstruct, materialize, and share – and conveys the impression of a highly innovative and dynamic subdiscipline of paleoanthropology. The same holds true of "Biomechanics," which allows us to infer certain aspects of function via the study of structural loading. Weber suggests that in spite of the absence of a formal bridge between those two domains of inquiry, there are many areas of overlap and potential cross-fertilization between them. In three linked short chapters, **Michael Schultz** and **Tyede Schmidt-Schultz** describe and illustrate new methods and approaches of investigating human fossils via medical technologies. Their first describes "Paleopathology: Vestiges of Pathological Conditions in Fossil Human Bone" and briefly illustrates the methods and techniques of paleopathology, exemplifying how this discipline can shed valuable light on the reconstruction of the lives of fossil humans by providing information on how afflictions and illnesses affected the daily lives of ancient hominids. This contribution is a plea "to start comparative work in this innovative field, which will allow us to recognize certain tentative aspects which will, in turn, help to significantly enlarge our knowledge on the living conditions of human antecessors." The second, "Microscopic Research on Fossil Human Bone," deals with the methods and techniques of light microscopy, scanning electron microscopy, and the advantages of polarization microscopy. Schultz and Schmidt-Schultz present selected histomorphological findings on fossilized human bones of different taxa (e.g., *Australopithecus*, *Homo erectus*, *Homo neanderthalensis*, and Paleolithic *Homo sapiens*) examined using plain and polarized light. Their special focus is on those morphological features that give clues to the taxonomy and the functional anatomy of early hominids as well as on those which originated during the lifetime of the individual (e.g., individual age at death, physical strain, and diseases). Their third contribution concerns a highly innovative field of biomedical research, namely, the "Investigation on Extracellular Matrix Proteins in Fossil Bone: Facts and Perspectives." For several years now, it has been possible to detect typical extracellular matrix proteins (ECMs), e.g., osteopontin, osteonectin, and osteocalcin, in archaeological bone. Further, it has recently become possible to detect growth factors and hormones (e.g., TGF-β, BMP-2, gonadotropin), bone matrix proteins of the immune system (e.g., IgG, IgA, interleukin), and biomarkers for diseases such as tumor markers (e.g., PSA, PSA/ACT). Finally, typical molecules characteristic of nonspecific infectious diseases (e.g., TNF-α, IFN-γ) and specific infectious diseases (e.g., from *Mycobacterium tuberculosis*, Ag 85) have been isolated from macerated bone, opening the prospect of detecting these ECMs in fossil bone as well. The authors briefly outline the future possibilities of such studies in understanding fossil human species and express their hope of attracting interest in these innovative biochemical methods and in particular in proteomic research among paleoanthropologists

As we said earlier, paleoanthropology is a subject of great public interest and is therefore in large part a media-driven science – as evidenced, for example, by the fact that the covers of *Nature* and *Science* are regularly illustrated not only by hominid fossils but also by facial reconstructions of our extinct relatives. This by itself is sufficient reason to examine the methods by which these images are derived. "Images in Paleoanthropology: Facing Our Ancestors" is **Stefan Schlager** and **Ursula Wittwer-Backofen's** valuable contribution on this topic. Images and visualizations in paleoanthropology have a curiously persuasive power, so we have to ask: What about them is science, and what is fiction? How objective, reliable, and valid are the various methods of reconstructing the faces and bodies of our ancestors? The authors thoroughly decipher the contextual limits and pitfalls of the various approaches available as "on the one hand evolutionary theories and contemporary social ideas influence and shape the view on our ancestors; on the other hand, hominid reconstructions themselves have a high impact on shaping our view." Their chapter gives a critical overview from the earliest facial reconstructions of early humans up to the most recent "virtual" 3D reconstructions. The last entry in this updated and enlarged first volume of the second edition of the *Handbook of Paleoanthropology* is **Jean-Jacques Hublin's** "Prospects and Pitfalls." Hublin discusses the various challenges of access to original fossil materials and to field sites of special interest as well as to metrical and virtual morphological data, biophysical and biochemical data sets, and tissue samples for paleogenomic and other research. Paleoanthropology has never been easy in these respects, and as an experienced field and laboratory researcher, Hublin makes valuable observations and practical suggestions.

Finally, we hope that our 35 updated and newly integrated contributions adequately cover most of the principles, methods, and approaches of paleoanthropology and that they will supply the readers with the basics of this wide-ranging discipline in accessible form. We are deeply grateful to all the contributors for their time and commitment, and any deficiencies remain entirely our own.

Preface to Volume 2, Second Edition

Primate Evolution and Human Origins

Human beings' place in nature can only be properly understood against the general background of primate evolution. For this reason, the second volume of the *Handbook of Paleoanthropology* deals with the earliest origins and evolution of our closest mammalian relatives. It features contributions on the wide diversity of fossil and extant nonhuman primates, summarizing the latest comparative primatological research by taking morphological, molecular, ecological, behavioral, and neurological perspectives with the aim of helping reconstruct our deepest primate roots and explaining what makes us human.

Mary T. Silcox and coauthors have updated and expanded their contribution on "Primate Origins and Supraordinal Relationships: Morphological Evidence," showing that during the last decade, much progress has been made in understanding the supraordinal relationships of primates, their ecological niches and diversification, and their pattern of trait acquisition through time. Significant open questions still remain, however, due to wide gaps in the fossil record. **Ryan Raaum** kindly agreed to write a replacement contribution on "Molecular Evidence of Primate Origins and Evolution": an important component of the volume as molecular data have become an important source of evidence on primate evolutionary history especially when primate fossil data are deficient. Raaum reports on current molecular evidence for the branching pattern among the primates, colugos, and tree shrews, touches on the problem of tarsier affinities. He further discusses the insufficiently resolved relationships among *Aotus*, the cebines, and the callitrichines, and in the case of the strepsirhines states that "excluding the early diverging *Daubentonia* lineage, the relationship of the remaining four lemur families almost certainly includes a cheirogaleid-lepilemurid clade but is otherwise poorly resolved by molecular data." He criticizes "absurdly early estimates for the crown primate radiation" and mentions methodological progress in "mostly or completely fossil calibration free divergence date estimation." Another replacement chapter is **Marc Godinot's** "Fossil Record of the Primates from the Paleocene to the Oligocene." His exhaustive article reviews the Paleogene primate fossil record according to higher systematic categories. Godinot masterfully overviews the radiations and Eocene dispersal pattern of the fossil strepsirhines in North America (Notharctinae) and

Europe (Cercamoniinae, Adapinae), tries to disentangle the role of the poorly understood diversification of the Asian Sivaladapidae, and deciphers the African origin of living Lemuriformes in the late Eocene. Further, he documents the Eocene florescence of Omomyiformes in North America (Anaptomorphinae, Omomyinae) and in Europe (Microchoeridae) and discusses the role of Asian middle Eocene Tarsiidae relative to the character-based definition of Haplorhini. His journey through the Eocene-Oligocene primate taxa begins with the enigmatic Eocene South-Asian Amphipithecidae and ends by characterizing the Anthropoidea, or Simiiformes, documented in the late Eocene and Oligocene of Africa (Parapithecidae, Proteopithecidae, Oligopithecidae, Propliopithecidae). Godinot's contribution ranges over about 20 million years of primate evolution and includes many other relevant aspects of anthropoid origins including locomotion, diet, vision and other sensory capacities, brain evolution, and social structure via sexual dimorphism. Hominoids, or taxa identified as hominoids, are known from much of Africa, Asia, and Europe following the Late Oligocene. The earliest such taxa from Africa resemble extant hominoids but share with them mainly primitive characters. Middle and late Miocene taxa are clearly hominoids, and by the end of the middle Miocene, most can be attributed to either the pongine (*Pongo*) or hominine (African ape and human) clade. Interestingly, there is no definitive fossil record of the hylobatid clade (gibbons and siamangs) though some candidates have been proposed. Miocene hominoids experienced a series of dispersals between Africa, Europe, and Asia that mirror those of many other contemporaneous land mammals. These intercontinental movements were made possible by the appearance of land bridges, changes in regional and global climatic conditions, and evolutionary innovations. Most of the attributes that define the hominids evolved in the expansive subtropical zone that was much of Eurasia. Hominines and pongines diverged from each other in Eurasia, and the final Miocene dispersal brought the hominine clade to Africa and the pongine clade to Southeast Asia. Having moved south with the retreating subtropics, hominines and pongines finally diverged *in situ* into their individual extant lineages.

David R. Begun's carefully updated contribution on the "Fossil Record of Miocene Hominoids" directly connects with Godinot's and discusses the adaptive radiations of hominoids and hominoid-like primates. The author describes this period as the "golden age of the Hominoidea" (re his definition of this taxon, see our comment in the preface of the first edition), when some basic attributes of our forerunners appeared, e.g., the absence of a tail, a somewhat extended life history, a slightly enlarged level of encephalization, and hints of powerful hand and foot grips and a propensity for more vertical climbing. Begun presents the latest data on the split between the hominines in the west and the pongines in the east and describes the evolution of the African apes and humans and the appearance of the *Pongo* clade. Of special paleoanthropological interest is that shortly after their dispersal into Africa, hominines diverged probably relatively quickly into their respective clades. Begun's review of the fossil record of hominoid evolution suggests to him "that humans evolved from a knuckle-walking, forest-dwelling soft fruit frugivore/omnivore. Not a chimpanzee in the modern sense, but more chimp-like than anything else nonetheless." **Jordi Augustí's** slightly updated article on "The Biotic Environments of the Late Miocene Hominids" gives a vivid impression of the Middle Miocene terrestrial ecosystems with their wide mammalian diversity of taxa chronologically followed by drier conditions and increasing seasonality in some parts of the Old World and a worldwide extension of grasses at 7–8 Ma. Augustí concludes that "at this moment an extension to the south of the Greek-Iranian Province can be recognized, which led to the Plio-Pleistocene savanna biome, characterized by a high diversity of hypsodont bovids, large grazers like rhinoceroses and giraffids and, most probably, the hominoids that led to the first hominins in Africa." However, the question remains open whether hominin ancestors were part of the "Greek-Iranian province" at all. **Carol Ward** has added some current literature and new critical commentary to her valuable review on "Postcranial and Locomotor Adaptations of Hominoids." She sees increasing evidence for "…the hypothesis that homoplasy…has possibly occurred multiple times within the Hominoidea." In contrast to David Begun, she is unconvinced that *Australopithecus* evolved from a highly derived African apelike ancestor adapted to knuckle-walking. Rather, "mounting evidence from the Miocene suggests that the australopith ancestor was orthograde, not a terrestrial quadruped." If this holds true, paleoanthropologists should no longer ask why hominins were selected to stand up on two legs from all fours but change the question to "Why did early hominins remain orthograde when they began exploiting terrestrial niches?"

Ward's discussion provides excellent background to **Alan Bilsborough** and **Todd C. Rae's** extensive contribution on "Hominoid Cranial Diversity and Adaptation," which has been thoroughly updated. Their detailed review of the extraordinary diversity of hominoid craniomorphological structures allows the formulation of hypotheses about the feeding adaptations of earlier hominoids although more detailed analyses fail to show an exact correspondence. In part, this is a consequence of dietary variability and, in part, of cranial variation. Further, just as in Carol Ward's contribution, the homoplasy problem constantly looms because the cranium represents a tightly constrained, functionally and developmentally integrated structure that is subject to multiple selective influences. It is thus not surprising that none of the potential Miocene candidates can be convincingly ascertained as forerunner to any modern ape. This chapter serves as an excellent example of the diverse possibilities as well as the limitations of comparative morphology.

While there are broad associations between African ape diet and cranial form, evidence suggests that cranial features are less closely determined by diet than are characteristics of dentition. **Mark S. Teaford** and **Peter S. Ungar's** dentomorphological approach helps clarify this. Their update of "Dental Adaptations of African Apes" shows how new high-tech methods can help us generate increasing knowledge of the dietary patterns of fossil apes. However, the authors are careful not to overestimate the reliability of such findings since our descriptions of primate diets are invariably oversimplified. Teaford and Ungar emphasize that the key to valid and reliable findings "…lies in the collaborative use of as many lines of evidence as possible, on samples that are as large as possible." They plead for combining dental microwear analyses and other paleobiological indicators to gain new perspectives on the dietary capabilities of the earliest hominins. Future research in this field is very promising as “… the bottom line is that researchers have only begun to tap into a wealth of data from innumerable sources, ranging from laser scanning and dental microtextures to finite element modeling and nanoindentation.”

Dean Falk’s review of “Evolution of the Primate Brain” has been slightly revised and remains a highly informative introduction to this field. She presents general methods for the macromorphological study of primate brain evolution, describes the evolution of the brain size and the cranial capacities of various adult hominins, and discusses the evolution of general neurological reorganization as well as reorganization related to language, handedness, and music. She also reports exciting new results from a comparative analysis of the spacing of neurons in the frontopolar region of apes and hominins. The horizontal spacing distance (HSD) between neurons increased in hominins after they split from chimpanzees, and this is “…interpreted as facilitating complex interconnectivity, which contributes to information processing related to anticipating future events, multitasking, and integrating limbic input to arousal, motivation and intentions, among other functions.” **Elke Zimmermann** and **Ute Radespiel** integrated numerous new findings, data, and literature into their updated contribution on “Primate Life Histories.” Their article is a very useful treatise on our current knowledge on the diversity of primate life histories and current hypotheses on the evolutionary forces that underlie them. **Angela Meder** has integrated the results of several dozen new studies into her discussion of “Great Ape Social Systems.” These deal with such issues as fission-fusion social systems as a strategy for coping with ecological constraints; foraging and ranging behavior during fallback episodes; cooperative breeding and the evolution of our unique features; maternal support, dominance status, and mating success in male bonobos; and lethal intergroup aggression and its impact on territorial expansion in chimpanzees. In spite of the fact that great ape populations have been studied for decades, ape social systems are not yet completely understood and have not so far contributed much to the issue of what the “natural” human mating system is. In pursuit of the central, stable component of human social systems, Meder absorbingly discusses “How Our Ancestors Broke through the Gray Ceiling” (*sensu* Isler & van Schaik).

Joanna E. Lambert surveys the extraordinary diversity of feeding- and foraging-related adaptations among primates. Her expanded title, “Evolutionary Biology of Ape and Monkey Feeding and Nutrition,” reflects the broadening of her focus to include the results of numerous nutritional studies. Indeed, the chapter was partly rewritten to suggest the evolutionary underpinnings and ecological implications of feeding adaptations and to thoroughly demonstrate evolutionary correlations of large brains, trichromatic color vision, and tool use. Furthermore, Lambert stresses the problems involved in fermenting fibers and detoxifying plant chemicals and discusses their implications for primate adaptation since the Miocene. Finally, focusing on hominoid feeding biology, she evaluates our own lineage and critically reviews relevant energetic trade-off hypotheses such as the “social brain hypothesis" and the "expensive-tissue hypothesis" as well as the recently proposed broader "energy-based hypothesis." The similarly enlarged title of **Nicholas E. Newton-Fisher's** contribution on "The Hunting Behavior and Carnivory of Wild Chimpanzees" points to equally extensive revision. It has been known for a long time that chimpanzees are not the only primates that hunt vertebrate prey, but interestingly enough, except for the bonobos, *Pan troglodytes* is the only hunting great ape; vertebrate predation appears to be rare or absent among both gorillas and orangutans. Until now, hunting has seemed to be a ubiquitous aspect of male chimpanzee behavior though there is obvious diversity, i.e., the intensity and frequency of hunting varies between populations as well as chronically and regionally. The value of meat is obvious, providing a compact nutritional package; however, the adaptive question of *why* chimpanzees hunt is still controversial. Current studies increasingly shed doubt on the "meat-for-sex" hypothesis, while the "show-off" and the "hunting-as-a-risk-assessment" hypotheses are gaining increasing support. Newton-Fisher convincingly refutes the notion that chimpanzees switch to hunting to compensate for energy shortfalls and provides arguments in support of the "meat-scrap" hypothesis, which assumes that chimpanzees gain essential micronutrients from small amounts of meat ("scraps") without having to consume vast quantities of plant material. Newton-Fisher empathically stresses the significance of this kind of field research for clarifying "both why chimpanzees hunt and the importance of this behavior for the study of human evolution."

Charlotte K. Hemelrijk, **Ivan Puga-Gonzalez**, and **Jutta Steinhauser's** updated contribution deals with "Cooperation, Coalition, and Alliances" and continues to express severe doubts about the evidence for cooperative altruism and kin selection. These authors continue to believe that a great deal more detailed observation of primates will be needed to evaluate the cognitive complexity inherent in apparent coalition-building behaviors and go a step further with the statement that "behavioral acts, such as grooming, coalition formation, and tolerance during feeding, have originally been considered as 'altruistic' but are presently often considered advantageous for both parties, the actor and receiver." They propose to regard reciprocity as "emotional bookkeeping," which "suggests that the frequency and quality of previous and present social interactions with a particular partner elicits a specific emotional state. This emotional state may lead to reciprocation and interchange of beneficial acts without relying on high cognitive mechanisms." Further, they reassess patterns of reconciliation and consolation that have hitherto been considered to reflect sophisticated cognition. The authors are increasingly convinced "that these patterns may also arise from simple behavioral rules." In 2007, we endorsed **Richard W. Byrne's** prognosis that we would soon approach a possible paradigm change in the study of primate intelligence and cognition, and this seems to be coming about. Byrne's significant contribution on "Primate Intelligence" continues to insist that "…intelligence is not a single 'thing' but rather a mixed bag of devices and processes, endowments, and aptitudes." This conglomerate of separate facets of intelligence makes it extremely difficult to answer key questions like: What triggered the brain size in primate evolution? What pushed the hominins and especially our species into another league? The author sees two separate changes in intellectual potential with concomitant brain changes. Coping with and succeeding within larger groups induced the enhancement of social perception and memory, but "impressive-seeming tactics of behavior such as deception and cooperation," did not allow a "deep understanding of the mechanism of these social tactics" or "show insight into causal relationships in the physical sphere." In Byrne's view, there was a second evolutionary event by which ancestral great apes acquired extra skills "based on their ability to learn novel routines of skilled, bimanually coordinated manual action, sometimes involving tool use, sometimes involving locomotion, and reliant on imitation by behavior parsing as well as exploration." This may have been the basis for understanding the intentions of other individuals and of a rudimentary grasp of the causal logic of physical events. Since there is much debate whether comparative psychology can decipher the evolutionary roots of the "mind-reading" capabilities traditionally regarded as uniquely human, we asked **Juliane Kaminski** to write a contribution on this specific issue. "Theory of Mind: A Primatological Perspective" poses the question of whether nonhuman primates have the ability to attribute mental states to others. Kaminski explains that "members of different primate species seem to follow other individuals' gazes and are sensitive to others' attentional states; there is as yet evidence in only a few species for an understanding of others' visual perspectives, knowledge states, or intentions." The current consensus is that nonhuman primate species don't have the capacity to truly attribute mental states to others. Will further research validate or close the gap?

We are aware that the selected chapters in this volume give only a restricted view on the wide field of primatology, a dynamically expanding evolutionary discipline that is indispensable for an evolutionary understanding of human origins. But we nonetheless hope that the combination presented here of updated, replacement, and new chapters will provide readers with a reasonably comprehensive introduction to the underpinnings of this fascinating subject area. If we have succeeded in doing this, the credit goes entirely to our authors.

Preface to Volume 3, Second Edition

Phylogeny of Hominins

In this third volume of the *Handbook of Paleoanthropology,* our contributors cover the evolutionary record of Homininae in a roughly chronological sequence, with chapters on various methodological approaches interpolated. As always, we have encouraged authors to emphasize their own points of view while paying due notice to competing ones; and in cases where the field is polarized or highly divided, some chapters deliberately overlap in their coverage. In this second edition, almost all chapters have been replaced or extensively updated, and some additions have been made, as with the chapters on the odd hominid from Flores and on human brain evolution.

George Koufos, in "Potential Hominoid Ancestors for Hominidae," opens the volume with a review of Miocene hominoid taxa that are putatively close to the hominin stem and finds the European record particularly instructive in this regard. Asian Miocene hominoids, on the other hand, group into a pongine clade. **Jeffrey Schwartz** ("Defining Hominidae") follows with a bracing and wide-ranging review of the concept of Homininae (for which he prefers the family rank Hominidae, giving flexibility in the recognition of subclades). He notes a variety of current deficiencies in both the definition and the recognition of the group and suggests a variety of potential postcranial synapomorphies. In contrast, he finds that derived dental features also unite the clade with pongines. In "Role of Environmental Stimuli in Hominid Origins," **Elisabeth Vrba** reviews how external environmental stimuli appear to have influenced hominin evolutionary history and provisionally identifies successive cooling trends over the Plio-Pleistocene as initiators of the *Paranthropus* "hypermasticatory" tendency and the tradition of stone–tool-making at around 2.5 Ma, the adoption of obligate bipedality at around 1.6 Ma, and significant expansions of the brain at around both 2 Ma and 600 Ka. She also emphasizes the implications of climatic oscillation for speciation in the hominin clade. From a more internal viewpoint, **Bogusław Pawłowski** and **Wioletta Nowaczewska** ("Origins of Homininae and Putative Selection Pressures Acting on the Early Hominins") then look more generally at the putative selective pressures that might have shaped the divergence of the hominin lineage from more generalized hominoid trends both in the locomotory and masticatory systems.

The next few chapters are similarly thematic. In a stimulating overview, **Will Harcourt-Smith** ("Origin of Bipedal Locomotion") looks at bipedal locomotion and its anatomical correlates and traces the successive appearances in the hominoid/hominin clades of facultative, habitual, and finally obligate bipedality. He concludes that the most robust explanations for hominin adoption of this unusual locomotor mode lie in external environmental shifts. **Ralph Holloway's** "The Evolution of the Hominid Brain" addresses the evolution of hominin brains and introduces the underlying neurogenomics. Holloway charts the unique hominin history of brain size increase, and in terms of gross morphology takes particular note of the primary visual cortex, the posterior association cortex, cerebral asymmetries, and Broca's area. **David Strait**, **Fred Grine,** and **John Fleagle** ("Analyzing Hominin Phylogeny: Cladistic Approach") next usefully review concepts of phylogeny reconstruction and the various numerical approaches currently employed in this area. They point to an emerging consensus in at least the broader outlines of hominin phylogeny. **Todd Disotell's** "Phylogenetic Relationships of Hominids: Biomolecular Approach" addresses hominin phylogeny in molecular perspective with a wide-ranging review of methods and results that also emphasizes a developing consensus.

With **Brigitte Senut's** "The Miocene Hominoids and the Earliest Putative Hominids," we return to the fossil record. Senut reviews the African Upper Miocene record, concluding that chimpanzees are a poor model for early hominins and that among all putative "earliest hominin" candidates, only *Orrorin tugenensis* shows unequivocal evidence of bipedality. She emphasizes that this form of locomotion arose in mixed rather than open habitats, and suggests based on new fossil finds that the split between African apes and hominins could have occurred much earlier than usually thought. **Bill Kimbel** ("The Species and Diversity of Australopiths") follows with an overview of the australopiths, providing individual portraits of each of the species currently recognized. He warns that the australopith fossil record is as yet too spotty to allow a clear view of evolutionary pattern in this group of early hominins, but nonetheless emphasizes its diversity. **Mark Collard** and **Bernard Wood** ("Defining the Genus *Homo*") then turn our attention to the genus *Homo*, and how it should be defined and recognized. They point out the *ad hoc* way in which this genus has been accreted, and suggest that its growth has got out of hand. They advocate a more compact concept of *Homo* that excludes the species *habilis*, *rudolfensis*, and *floresiensis*. **Friedemann Schrenk**, **Ottmar Kullmer**, and **Tim Bromage** follow up on this in "The Earliest Putative *Homo* Fossils," overviewing the various fossils that have been attributed to "early *Homo*." They are prepared to accept a more comprehensive concept of the genus than Collard and Wood's, and correlate the appearance of this implicitly paraphyletic taxon with that of material culture, at about 2.5 Ma. They believe that the megadont early *Homo* species were adapted to the more arid conditions that began to prevail at this inflexion point of the paleoclimatic curve.

Ian Tattersall ("*Homo ergaster* and Its Contemporaries") points out that the fossils often attributed to "early African *Homo erectus*" exhibit no convincing synapomorphies with the eastern Asian materials that define this species. He further points to a morphological variety in the African record that will have to be addressed systematically at some point. Provisionally, he accepts the name *Homo ergaster* for the African fossils but finds that this species cannot reasonably accommodate the hominin fossils from Dmanisi in the Caucasus, which may themselves not be homogeneous. A completely different interpretation in respect to the systematics and classification of *H. erectus* is presented by **Karen Baab** in her replacement chapter on "Defining *Homo erectus*." She belongs to the group of paleoanthropologists who advocate a *sensu lato* definition for *Homo erectus*, interpreting the considerable morphological and geographic variation within Early and Middle Pleistocene *Homo* fossils as indicating an Old World-wide polytypic species. Her interpretation of the morphological features of the skull leads her to believe that the fossils assigned to *Homo erectus s.l.* maintain "a broadly homogenous cranial and postcranial *Bauplan* across an impressive geographic and temporal range," and she is convinced that the "single species model for *H. erectus* cannot be rejected on the basis of cranial morphology." Readers are encouraged to draw their own conclusions about the "Muddle in the Middle." Not too long ago, many paleoanthropologists still regarded *Homo erectus* as a valid European taxon as well, but **Philip Rightmire** updates this view of "Later Middle Pleistocene *Homo*." He compares and interprets the hominin fossil specimens known from Middle Pleistocene localities in Africa, Europe, South Asia and the Far East, and argues that fossils such as those from Bodo, Kabwe, Arago, Petralona, and Dali retain many plesiomorphic *erectus*-like characters but had undergone a speciation event in which *H. erectus* gave rise to a daughter lineage. Rightmire favors anagenetic change here, asserting that "differences between the Middle Pleistocene hominins can be attributed to geography, time, or intragroup variation. Many, if not all, of the European and African specimens can be accommodated in one species distinct from Neanderthals and modern humans." While he advocates for *Homo heidelbergensis* as the appropriate name of the taxon, which is "probably ancestral to both the Neanderthals in Europe and the earliest representatives of *H. sapiens* in Africa," he cites new craniodental research on the Sima de los Huesos sample suggesting that this population "…may constitute a source population for Neanderthals, while Mauer and Arago document the presence of a morphologically distinct lineage."

Katarina Harvati's extensively updated review of "Neanderthals and Their Contemporaries" forcefully shows that even the longest-running debate in paleoanthropology, namely, the status of the Neanderthals, can still trigger vivid controversies. The current debate partly concerns whether the Sima de los Huesos hominins should be considered early (Pre-)Neanderthals, instead of *H. heidelbergensis* as the discoverers have inexplicably proposed. Her conclusion is that if "the European *H. heidelbergensis* was exclusively ancestral to Neanderthals, this sample could be placed within the Neanderthal lineage and within the taxon *H. neanderthalensis*.... Alternatively, the European lineage could be arbitrarily split into two paleospecies, the earlier segment retaining the nomen *H. heidelbergensis* and the later *H. neanderthalensis*." Harvati also reports and discusses the newest results on Neanderthal genomics, and considers the unprecedented case of the Siberian Denisovans, in which a distinct hominin lineage has been recognized on genomic criteria alone. Just as unusual as the Denisovans was the discovery of a late surviving hominin population in the Liang Bua cave on Flores (Indonesia). **Leslie Aiello** has kindly contributed a chapter on "*Homo floresiensis*" as this population was called by its discoverers. Extremely small-bodied and small-brained, the Flores hominids, dated between 74 Ka and 17 Ka, have been energetically debated. Many are convinced that these fossils are pathological versions of *Homo erectus* or *Homo sapiens*, while others conclude that they represent a distinctive hominid lineage. Aiello thoroughly reviews the various hypotheses about the unique morphology and the relationships of *H. floresiensis* and concludes that the "new species" hypothesis is much more convincing. As to its relationships, she judiciously concludes that "until conclusive evidence appears in the form of additional fossil material, analytical advances, and ideally ancient DNA evidence, [w]e have not heard the end of the *H. floresiensis* story."

Günter Bräuer's updated contribution on "Origin of Modern Humans" overlaps in many respects with issues raised in the preceding chapters as his "Out-of-Africa and Hybridization" model is deeply rooted in Africa. He meticulously analyzes the fossil record and concludes that there was a long-lasting, mosaic-like transition or modernization process in Africa. Participants ranged from 600 Ka-year old fossils like Bodo, classified as "archaic *Homo sapiens*" (grade 1), through an intermediate "late Archaic *Homo sapiens*" (grade 2), to "anatomically modern *Homo sapiens*" (grade 3). This last species replaced archaic populations in other places of the Old World with only slight admixture. Bräuer sees support for his view in recent comparative morphological research and new absolute dates for several hominin specimens, and welcomes current paleogenomic findings such as those from nuclear DNA analyses suggesting widespread if minor archaic-modern hybridization. Bräuer finds these largely in accordance with a lengthy process of modern human origins, without any speciation events. This specifically means we should "regard the European Preneanderthals/Neanderthals and the African Middle Pleistocene lineage to modern humans and the late archaic group in China as belonging to one polytypic species *H. sapiens*." In "Population Biology and Population Genetics of Pleistocene Hominins," **Alan R. Templeton** discusses three types of molecular data analysis: "coalescent processes and haplotype trees estimated from surveys of genetic variation in present-day human populations, haplotypes inferred from ancient DNA extracted from fossils, and overlays of current quantitative genetic variance/covariance matrices upon hominin fossils." He discusses with admirable clarity the complex issues involved, such as nested clade phylogeographic analyses, demographic inferences from coalescent analyses; demic diffusion; admixture; isolation by distance; positive selection. In spite of much progress in paleogenomics, Templeton finds himself able to maintain the basic conclusions presented in the earlier edition.

Michael Bolus asks: What does the archaeological record contribute to our knowledge of dispersal patterns? Reviewing "Dispersals of Early Humans: Adaptations, Frontiers, and New Territories," Bolus traces assumed dispersal routes by analyzing the diverse artifact assemblages and reconstructs the different waves "out of Africa" to Eurasia, Eastern and Southeastern Asia, and finally to Sahul and Europe. Up to now, the 1.8 Ma Dmanisi hominids are the earliest outside Africa, and Bolus suggests that slightly younger evidence from Southeastern and eastern Asia also traces to the same first wave of expansion. He sees the Levantine Corridor is regarded as one of the major dispersal routes for early humans, although a southern route through the Arabian Peninsula seems possible. Bolus describes the dispersal of the Oldowan and reports that the late occurrence of this techno-complex at Atapuerca (Spain) is probably due to a later expansion wave. The Acheulean started in Africa some 1.8 myr ago, and reached southern Asia much earlier than Europe, where the earliest secure appearances are not older than 700–600 Ka. Bolus also looks at the techno-complexes of the Neanderthals and their apparent overlaps in the Near East with those of anatomically-modern *Homo*.

In July of last year, we received the sad news of the passing of our friend **Christy G. Turner II**, "father of dental anthropology" and a prolific and influential anthropological researcher. We are happy that Christy's coauthor, **G. Richard Scott**, agreed to update their joint contribution on "Dentition of American Indians: Evolutionary Results and Demographic Implications Following Colonization from Siberia." The earliest colonization of the Americas is still intensively debated, and, despite its title, this updated review also integrates biological data including nuclear markers, mtDNA, Y-chromosome, and craniometrical sources, that bear on the peopling of the Americas. Significantly, "the homogeneity among American Indians indicated by dental morphology is paralleled by mtDNA and Y chromosome haplogroup data and single-nucleotide polymorphism (SNP) arrays."

Nick Toth and **Kathy Schick's** valuable and compact "Overview of Paleolithic Archaeology" has been updated by integrating much new evidence on technological change and cognitive complexity from paleoanthropology and primatology into their archaeological perspective. They summarize archaeological advances from the earliest, ca. 2.6 Ma evidence of hominin technology in the Ethiopian Rift Valley, to early occupation of the Americas by at least 15 Ka. They conclude that "the human lineage is a product of its Paleolithic past, and that the modern human condition, characterized by industrialization, farming, urban life, and ever-increasing networks of communication and globalization, is firmly rooted in its Stone Age past." **Nicholas Conard's** chapter on "Cultural Evolution During the Middle and Late Pleistocene in Africa and Eurasia" connects to this same issue, especially in focusing on the "large-scale patterns of behavioral change that are often viewed as indicators for the advent of cultural modernity and developed symbolic communication." His update, including several amazing new figures, uses examples from Africa and Eurasia to review patterns of lithic and organic technology, subsistence, and settlement as potential indicators of modern behavior. In discussing hypotheses for the development and spread of cultural modernity, he rejects a strict monogenetic model in favor of a pattern of mosaic polycentric development. This chapter highlights the need for new refutable, regional and superregional hypotheses for the advent and spread of behavioral modernity.

The final two chapters deal with entirely different aspects of the unique modern human behavioral pattern. Every human society practices religion, and there is consensus that religiousness is part of the canon of transcultural human universals (which, though descriptive, are not definitional). This is reason enough to inquire into whether religiosity might have any evolutionary implications and/or adaptive value. **Matthias Herrgen**, philosopher and anthropologist, contributes reviews of "Evolution of Religion" that aims to provide a naturalistic foundation for religious behavior. Herrgen's focus is on emergent features of cultural evolution, e.g., on mysticism, ethics, myth, and ritual as domains of religion. He assumes that these domains describe a modular structure of cognitive skills in a network of brain, body, language, and culture that provides an architecture underlying the human capacity for religion. He concludes that "the vast bio-cultural complexity must be the key aspect in any theory of the evolution of religion. Concepts like the (cognitive) niche construction offer new perspectives in the gene-culture-coevolution for further approaches to the study of religion." The final contribution to this new edition of the *Handbook of Paleoanthropology* is an extended update of **Mathias Gutmann** and **Michael Weingarten**'s contribution on "Paleoanthropology and the Foundation of Ethics: Methodological Remarks on the Problem of Criteriology." Inspired by the vivid interdisciplinary discussion stimulated by the 200th anniversary of Charles Darwin's birth, Gutmann and Weingarten have framed their essay to explain, within a criteriological framework, which traits should be considered "typically human." With this approach, "the difference between human and nonhuman beings is expressed in terms of an animal-human comparison." The authors' mediation-oriented perspective assumes "that the nonhuman-human transformation takes place not within (first) nature but within culture," which has "consequences for empirical research as well as for ethical judgment." Their considerations confront us with the dilemma that paleoanthropology as a biological discipline cannot provide us with an adequate basis for ethical reasoning, while "on the other hand those ethical approaches, which depend immanently on criteriological descriptions of humanity, show serious methodological deficiencies."

As with the other volumes of the *Handbook*, we hope that the reader will find in these pages a useful and reasonably comprehensive resource for understanding the current state of knowledge and debate in the area it covers of the multifaceted study of paleoanthropology. Once again, we thank our contributors and emphasize that any deficiencies the reader may find are ours.

Winfried Henke is retired Academic Director and apl. Professor of Anthropology at the Johannes Gutenberg University of Mainz. He was born in 1944 in Pomerania, Germany, and studied biology, anthropology, geosciences, as well as philosophy and pedagogy in Kiel and Braunschweig. In 1971, he received his Ph.D. (Dr. rer. nat.) from the University of Kiel, his thesis focusing on a prehistoric anthropological topic and multivariate statistical analysis in skeletal biology. Since 1971, Henke conducted research and taught at the Faculty of Biology of the Johannes Gutenberg University of Mainz in paleoanthropology, primatology, prehistoric anthropology, comparative morphology, systematics, demography, sociobiology, and scientific history. He had research activities in various countries (Iceland, Israel, Jordan, US, Greece), and in 1990, he habilitated with a monograph on the "Anthropology of Upper Paleolithics and Mesolithics of Europe and the Mediterranean Basin." In the scope of the ERASMUS docent exchange program, intensive lecturing at numerous European Universities followed. Henke acted as elected anthropology referee for the German Research Foundation (DFG) and still serves at the advisory boards of scientific journals (e.g., *Interdisziplinäre Anthropologie*, published at Springer-Verlag); further, he was book review editor and advisory consultant to museums, e.g., the Neanderthal Museum (Germany). He published approximately 200 original papers in scientific journals and anthologies and several hundreds of book reviews and supervised more than 100 diplomas and Ph.D. theses in biological anthropology. He is author, coauthor (together with H. Rothe), and editor of several books including such standard works as *Paläoanthropologie*, *Stammesgeschichte des Menschen*, and *Phylogenetische Systematik* (published at Springer-Verlag). In 2006, he was awarded the honorary doctorate of the National and Kapodistrian University of Athens; he is an elected member of the German National Academy of Sciences *Leopoldina* and Academician of the *Leibniz-Sozietaet of Sciences.*

Ian Tattersall is Curator Emeritus in the Division of Anthropology of the American Museum of Natural History in New York City. Trained in archaeology and anthropology at Cambridge and in geology and vertebrate paleontology at Yale, he has worked on lemur systematics and ecology as well as in paleoanthropology, where his special interest has been in hominid diversity and cognitive evolution. Most recently, he has been concerned with trying to understand how a nonlinguistic and nonsymbolic ancestor gave rise to the cognitively unprecedented *Homo sapiens* and what drove the exceptionally fast evolution of the human lineage over the course of the Pleistocene. He has done both primatological and paleontological fieldwork in countries as diverse as Madagascar, Vietnam, Surinam, Yemen, and Mauritius. In collaboration with Jeffrey Schwartz, he wrote three volumes of *The Hominid Fossil Record* (2002–2005), a documentation in standardized descriptive and illustrative format of a large proportion of the most significant fossils that tell the human evolutionary story. Ian is also a prominent interpreter of human paleontology to the public with several trade books to his credit, among them *The Brain: Big Bangs, Behaviors, and Beliefs* (2012, with Rob DeSalle), *Masters of the Planet* (2012), *Race? Debunking a Scientific Myth* (2011, with Rob DeSalle), *The World from Beginnings to 4000 BCE* (2008), *Becoming Human: Evolution and Human Uniqueness* (1998), and *The Fossil Trail: How We Know What We Think We Know About Human Evolution* (1995, 2nd ed. 2009), as well as many articles in *Scientific American* and *Natural History* and the coeditorship of the definitive *Encyclopedia of Human Evolution and Prehistory*. He lectures widely and, as curator, has also been responsible for several major exhibits at the American Museum of Natural History including *Ancestors: Four Million Years of Humanity* (1984); *Dark Caves, Bright Visions: Life In Ice Age Europe* (1986); *Madagascar: Island of the Ancestors* (1989); *The First Europeans: Treasures from the Hills of Atapuerca* (2003); and the highly acclaimed *Hall of Human Biology and Evolution* (1993) and its successor, *Hall of Human Origins* (2007).

Abstract

This chapter provides a comprehensive scientific historical overview of paleoanthropology as a multifaceted biological discipline. A brief summary of pre-Darwinian theories of evolution is followed by a historical report of the paradigmatic change wrought by Darwin's perspective on life processes, from a teleological to a teleonomic view. Focusing on the fossil discoveries in Europe and later on in Asia and Africa, and on various methodological approaches, it becomes obvious that, as opposed to other biological disciplines, paleoanthropology remained until post-World War II first and foremost a narrative discipline, with widespread contemporary preconceptions (e.g., Eurocentrism, ethnocentrism) as well as erroneous conceptualizations (e.g., typological approach, orthogenism) that set it in many ways apart from the mainstream of biological thinking. Paleoanthropology is widely believed to have maintained this "iridescent image," wrongly, as I will hopefully show. However, there remains skepticism that current theories of human origins are free of narrative components. Since Sherwood L. Washburn provided his innovative conceptual outline for physical anthropology, a theoretical and methodological change has arisen in the understanding of human evolution, focusing on evolutionary adaptations within the order Primates. The anthropological subdiscipline of paleoanthropology profited tremendously from this new approach – albeit with some delay, maybe caused by problems with the "Modern Synthesis" (e.g., the "single species hypothesis"). Intensified exploitation of old and new sites, the improvement of excavation techniques, and complex laboratory research on hominid fossils, on the one hand, and comparative research on living primates (e.g., taxonomy, biomechanics, behavioral psychology, ethology, molecular genetics, and genomics), on the other, constituted paleoanthropology as a highly innovative subdiscipline within the evolutionary sciences seeking to explain the processes of hominization, including our evolution, by concise hypothesis testing. A profound historiographical look back, as we move forward, seems helpful for different reasons: In this way, perhaps we will become more critical about the reliability and validity of our theoretical concepts, methodological approaches, and empirical basis. The history of paleoanthropology could thus help to increase the credibility of ideas about our evolutionary origins.

Introduction

Historical Research: More than Looking into a Mirror!

"Does disciplinary history matter?" This question was asked by Corbey and Roebroeks (2001a, p. 1) at the eponymous congress focusing on the history of paleoanthropology and archaeology. A negative answer assumes that studying the history of these scientific fields is an unsuitable job, at best a nice leisure time activity for retired colleagues. And since Landau (1991) implies in her book on

Narratives of Human Evolution that modern paleoanthropologists are still only "storytellers," a history of paleoanthropology faces a double-sided problem: We have to ask whether there is really any need for a dubious historical approach to a biological discipline that only alleges to be doing science.

The allegation that paleoanthropology is not a serious and respectable field of research is unacceptable, as I hope that the broad spectrum of genuine research presented in the diverse contributions of this handbook of paleoanthropology is proof of this, although this anthropological subdiscipline may have its discreditable aspects (White 2000; Kalb 2001; Stoczkowski 2002; Henke 2010a, b; Reader 2011; more on this later).

In addition, what should one say about the history of science in general? Is disciplinary history no more than a waste of time for practitioners, as well as historians of science? Experience shows that there is no uniform answer to this question. Willoughby (2005) mentions correctly that the historical sciences are different from the so-called hard sciences in which assumptions can be tested experimentally; but even biology is no physics. Popper described evolutionary biology as a "metaphysical research program" and "a possible framework for testable scientific hypotheses" as Tattersall (2002, p. 14) mentions in his sophisticated essay "The Monkey in the Mirror." Though the distinction between the so-called hard and soft sciences has been made for a long time, and anthropology is positioned on the soft side, we have become increasingly aware from recent epigenetic findings (Jobling et al. 2004; Sassone-Corsi and Christen 2012) that the "white coat group" has similar epistemological problems (Oeser 2004). Obviously, scientists need support from philosophers. In his essay *Über die Unvermeidlichkeit der Geisteswissenschaften*, the German philosopher Odo Marquard (1987) emphasized the compensatory function of the cultural sciences and pleaded for the "*Inkompetenzkompensationskompetenz*" [I confess I like this term] of his discipline (Marquard 1974). It think it's a gross error in European curricula of the biological sciences to have marginalized a *propaedeuticum logicum* as merely soft skills.

Let's come back to the historical sciences and their relevance for paleoanthropology. Willoughby (2005, p. 60) summarizes: "Rather than worrying about 'physics envy' (Gould 1981 (sic!), p. 113), some historical sciences are beginning to learn how to live within these restrictions." And this seems to be right for the following reasons: If paleoanthropologists and historians of science can provide good suggestions for the improvement of the discipline, why should one give up studying the history of sciences or look on this discipline as an insignificant one? Goodrum (2009, p. 349) concludes in his valuable contribution to *The History of Human Origins Research*: "Historians, philosophers, and sociologists of science have a great deal to contribute to a better understanding of the development of palaeoanthropology as a science and to the impact it has had on modern culture and society."

Ernst Mayr (1904–2005) – an outstanding modern Darwinist – gave a reasonable, albeit not exhaustive, classification of the various relevant historical approaches: (1) elaborated lexicographic histories, (2) chronological histories,

(3) biographical histories, (4) cultural and sociological histories, and (5) problematic histories (Mayr 1982). The essential point of all these is that the historicist approach may give rise to reflection, as Bowler (1976, 1988, 1996, 1997, 2001), Wolpoff and Caspari (1997), Spencer (1997), Theunissen (2001), Stoczkowski (2002), Delisle (2007), Goodrum (2009, 2013), and Gundling (2005) emphasize.

Although some may doubt whether the various approaches they suggest (heuristics, source criticism, interpretation, hermeneutics, and analytics) will improve paleoanthropology, Corbey and Roebroeks (2001a) emphasize the heuristic value of historical studies. Dennell sees two further lessons from science history: awareness of the dangers of fragmentation and complacency. He considers the lack of dialogue and understanding between the anthropological disciplines as a fatal risk and warns that “There is still excessive specialisation and insufficient dialogue across the disciplines, especially where the terminology and techniques are unfamiliar” (Dennell 2001, p. 66). Concerning the aspect of complacency, he explains that “It is always much easier to see the danger in retrospect, but perhaps one of the main lessons to absorb from the history of science is the danger of too many people becoming too comfortable for too long with an idea, just because so many agree with it, and have agreed with it so often in the past” (Dennell 2001, p. 66). Stoczkowski (2002, p. 197) insists that “we must not forget that the past, remote as it may be, acts on us with a force no less powerful than that of the present. [. . .] Acknowledging that historical processes can be slow and protracted, that timelags due to the force of inertia are omnipresent, that the ideas of yesterday and the day before weigh on those of the present, does in fact offer a few practical consequences, not only on the historian but also to any scientists who seek a better mastery of their conceptual tools.” And Goodrum (2009, p. 338) touches on another relevant aspect when expressing the hope that historiographical studies “can help bridge the gap that sometimes appears to exist between the history of natural sciences and the history of the human sciences.”

I am convinced that a view across the fence between natural and cultural sciences is both necessary and long overdue (see Riedl 1985, 2003; Sarasin and Sommer 2010). The above severe arguments for the improvement of science by disciplinary history are valid for every field of study or “area of intellectual endeavour that holds a common set of concerns, theories, and procedures or techniques that are intended to address a closely connected web of problems” (Shipman and Storm 2002, p. 108). The Darwin anniversary in 2009, with innumerable interdisciplinary colloquia on evolutionary biology and a flood of “Darwinia,” demonstrated that there is an ongoing dialogue which longs for “a cross-fertilization of the various theoretical approaches” as “the crucial step towards a thorough understanding the evolutionary history of our science” (Destro-Bisol and Paine 2011; further Delisle 2007; Henke 2010a, b; Henke and Herrgen 2012; Begun 2013; Goodrum 2013).

A major aspect of biological anthropology is that the present is inevitably rooted in the past. For this reason, Dennell (2001, p. 65) sees the study of human origins as “a search for windows that should give us access to the past through fossil specimens, stratigraphic and climatic changes, inferences from the world

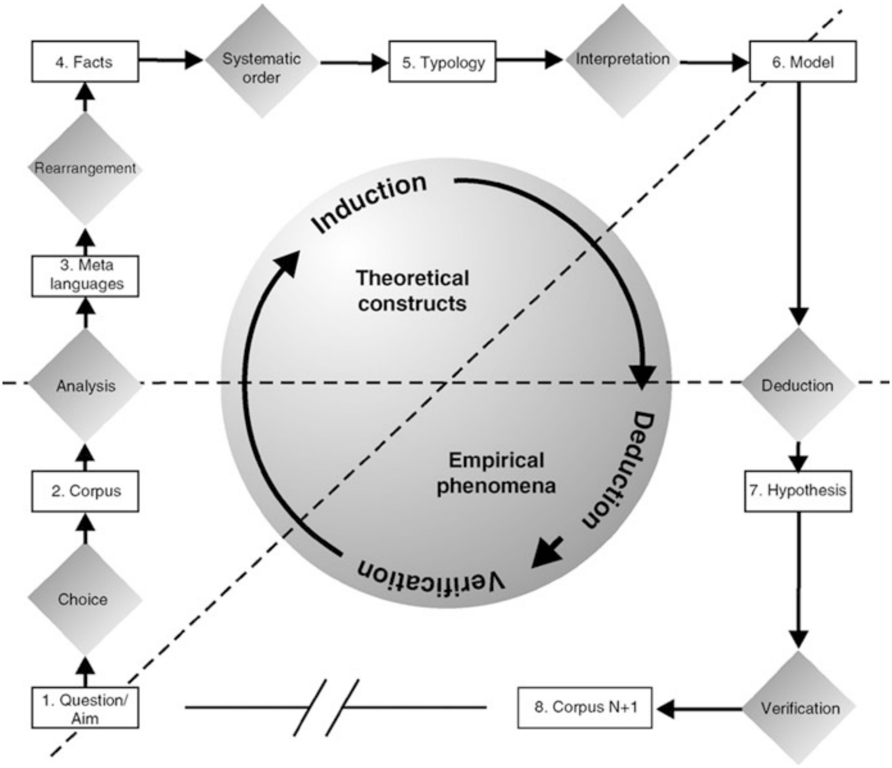

Fig. 1 Diagrammatic relationships between inductive and deductive scientific approaches (After Galley 1978, modified, see Henke and Rothe (1994))

around us, and the like." Paleoanthropologists and prehistorians and archaeologists seek windows to the past but use different sets of keys. A fatal danger is, however, that we may mistake a mirror for a window and simply extrapolate our own views and prejudices about the present onto the past. The important point here is, as L.P. Hartley put it: "the past is a foreign country, they do things differently there" (Foley 1987, p. 78). For this reason, Foley maintains that "The past cannot just be invented or imagined, nor reconstructed solely from observations of the way the world is at the present." This brings both the task and the challenge of paleoanthropological research and other evolutionary sciences to the fore: We are creating essential models (Foley 1987; Henke and Rothe 1994; McHenry 1996; Delson et al. 2000; Stoczkowski 2002; Gutmann et al. 2010; Henke 2003a, b, 2004, 2005, 2007a, b, 2009, 2010a, b, c; Henke and Hardt 2011; Henke and Herrgen 2012). This kind of approach (Figs. 1 and 2) is by no means simply narrative; it is rather contextual hypothesis testing; and even if in some cases it involves scientific speculation, the accent is still on science (White 1988; Henke and Rothe 1994; Henke 2003a). Every scientist needs to arrive at innovative solutions within a channeled imagination. Tattersall (2002, p. 3) stresses in this context: "Indeed,

	Skeletal	*Contextual*	*Speculation*
Anatomy	Ontogeny Body size Sexual dimorphism		Soft tissue
Ecology	Diet	Distribution Habitat	Home range Territoriality Core area
Demography	Disease Longevity	Predation Relative abundance Population density	Natality Mortality Group size Group composition
Behavior	Locomotion	Sleeping habitats Material culture	Communication Mating Parenting Cognition Foraging Social structure Interspecific relations
Phylogeny	Number of species Relationships between species	Appearance Extinction	

Fig. 2 An illustration of how skeletal and contextual data from the fossil records might be used to understand five broad overlapping categories of early hominins (After White 1988, redrawn)

there *is* no single scientific method. Scientific methods of course there are, in abundance; and methodologies lie at the heart of the immense variety of different things that scientists do [but] there is no particular method that will give you the key to all types of scientific inquiry."

The gift of Darwin's theory is "that there was no blueprint to be followed, only unfoldings of opportunity," as Howells (1993, p. 14) put it. If the magnificent panoply of life today is the outcome of a real historical-genetic process without a plan, how do we explain the patterns and processes? Darwin's theory is uncontested as the center of the whole science of biology. In *Darwin's Dangerous Idea*, Dennett (1995, blurb) compares the theory of evolution to a universal acid, an imaginary "liquid that is so corrosive that it will eat through anything!" and asks

"Is nothing sacred?" Every traditional concept that tries to explain our existence has to compete with Darwin's revolutionized worldview. As a consequence of Darwin's theory of life, even human beings can no longer be explained in a teleological way, as expressed by Dobzhansky (1973, p. 125) in his famous dictum: "Nothing in biology makes sense except in the light of evolution".

Common sense mainly considers paleoanthropology as the study of human fossils and a descriptive and broadly narrative discipline that is dominated by poorly researched and media-friendly fossils and findings that cause changing views on the process of human evolution. Particularly, popular science media convey the impression that paleoanthropology is scarcely more than storytelling, labeling every human fossil as spectacular despite the fact that, when viewed soberly, most of the fossils and findings are just as expected. And empirical studies show that the public interest mostly fades very soon or bursts like a soap bubble. But is the history of paleoanthropology in fact something more than the demonstration of "a road full of errors, freak opinions and bizarre concepts finally discarded?" (Corbey and Roebroeks 2001a, p. 1) Or, as Stoczkowski (2002, p. 2) comments: "The problems of origins of humanity and culture, constantly pondered over millennia, provides a convenient opportunity for reconstructing a naive anthropology widely accepted in western culture. This may enable us to retrace the influence exerted by this shadowy knowledge on present day scholarly thought." Given that we are in a dilemma of subject-object identity, we should be conscious of the baggage we carry over from "various 'social' factors, such as fashionable theories, paradigms, ideologies and power relations within the scientific community" (Stroczkowski 2010, p. 1). Are most anthropologists even aware of these obstacles? Apparently not. Most paleoanthropologists are largely concerned with "pure facts." Most anthropologists today agree that paleoanthropology is, like other categories of evolutionary biology, a serious subject involving hypothesis testing and scientific modeling (Wuketits 1978; Foley 1987; White 2000; Wood and Richmond 2000; Wood and Lonergan 2008; Cartmill and Smith 2011; Begun 2013). They are aware that data ascertained from fossils do not speak for themselves and that for this reason the scientific approach involves the creation and testing of hypotheses and theories (Fig. 3). It is by doubting theoretical insights that we come to questioning; and by questioning, we may perceive the truth – or what we think to be the truth (Popper 1959a, b, 1968, 1983; Foley 1987; Mahner and Bunge 2000; Vollmer 2003; Oeser 2004). Stronger theories are those that are optimally corroborated; however, even well-tested general theories may conceivably be refuted (overview in Sarasin and Sommer 2010; Toepfer 2011; Wood 2011). Paleoanthropology is not, like physics, empirical science sensu stricto; but this does not mean at all that it is a narrative subject; storytelling is frowned upon in every science, and I agree with Kroeber (1953, p. 358) who stressed that "there exists basically only one kind of fundamental science. All genuine science aims at the comprehension of reality, and it uses both theory and evidence, in combination, to achieve this comprehension."

In history varying answers have been given to the question "What is the meaning of man?" However, in post-Darwinian times, there is no consensus on how we got

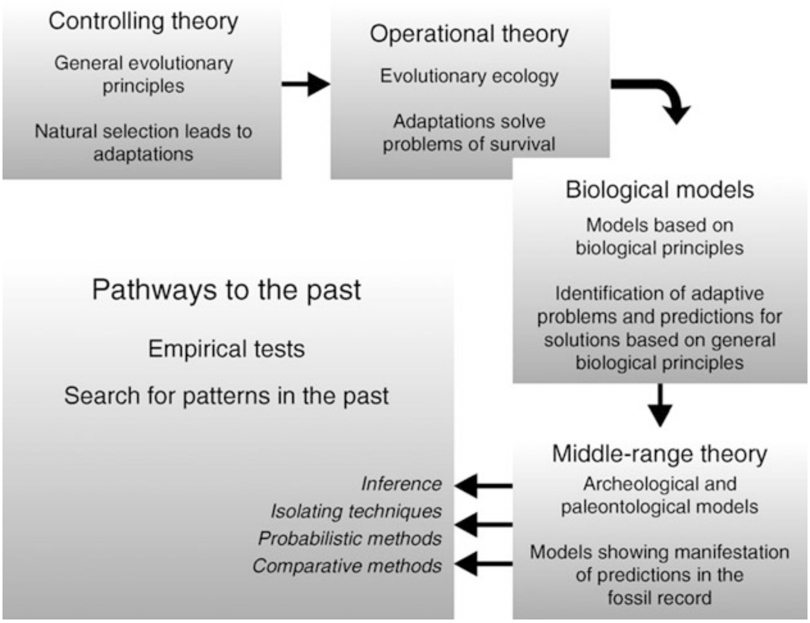

Fig. 3 Pathways to the past; ways of investigating hominid evolution (After Foley 1987, modified)

here (overview in Eldredge and Tattersall 1982; Tattersall 1995, 1998, 2002; Corbey and Theunissen 1995; Antweiler 2009; Bohlken and Thies 2009; Bayertz 2012). Like all other anthropological scientists, paleoanthropologists are only able to establish a reductionistic view of our *conditio humana* (Henke and Herrgen 2012). Heberer (1968a) used the terms "Jetztbild" and "Jeweilsbild" (meaning status quo) to intimate the changeability of our knowledge and the fact that every paleoanthropological report will be out of date very soon after it is published (Hoßfeld 1997, 2005a, b; Schwartz and Tattersall 2002, 2003, 2005). In spite of the multiple schemes in hominin taxonomy and the irritating – not only for laymen and outsiders but for undergraduate students too – various interpretations of the hominid/hominin fossil record (see, e.g., Wood 2000; Wood and Lonergan 2008), there is no doubt that biologists are *in principle* on the right track when evaluating human fossil finds and reconstructing human origin in evolutionary terms (Tattersall 1998, 2002; Delson et al. 2000; Levinton 2001; Grupe and Peters 2003; Cartmill and Smith 2009; Begun 2013).

One word concerning alternative nonbiological explanations of human origin: It is wasting time to discuss pseudoscientific theories of intelligent design proponents at eye level; I am tempted to quote Berthold Brecht: "*Wie kommt die Dummheit in die Intelligenz*?." Biologists have first and foremost to keep their own house clean; however, there is a great interest on the part of historians of science to decipher the reasons and the underlying social and political structures that have recently promoted the renaissance of creationism (Graf 2007, 2010; Graf and Soran 2010; Meyer (2006) for an excellent review and critics, see Neukamm 2009).

Darwin's Perspective on Life Processes

The paradigmatic change from a traditional static view to a dynamic evolutionary concept at the beginning of the second half of the last century resulted in the recognition that humans are an integrated part of a historical process. The so-called Darwinian Revolution, triggered by Darwin's masterpiece from 1859, long remained in a state of confusion. As Bowler (1988) demonstrates in his historiography *The Non-Darwinian Revolution*, Darwin's ideas were fundamentally misunderstood. In his judgment, the impact of evolutionism on late nineteenth-century thought has been greatly overestimated by historiographers (Hull 1973; Moore 1981; Desmond and Moore 1991; Engels 1995; Bowler 1996, 1997, 2001, 2009; Hemleben 1996; Ruse 2005; Goodrum 2004, 2009, 2013; Wuketits and Ayala 2005; Engels and Glick 2008).

Traditionally, it has been assumed that the Darwinian Revolution in biology provided the impetus for a new evaluation of human origins, and Bowler claims that this assumption is valid up to a point. "Because of religious concerns, Darwin and his followers knew that they would have to explain how higher human faculties had emerged in the course of mankind's evolution from the apes" (Bowler 1988, p. 141). The complex scientific answers within the frame of ever-increasing biological facts and the "disciplinary matrix" sensu Kuhn (Chamberlain and Hartwig 1999) essentially reflected our self-image and orientation. An argument often given for the scientific necessity of paleoanthropological research is that humans have to know where they come from to decide where to go; but "How [do] we know what we think we know?" to borrow a phrase from Tattersall's (1995) eponymous book.

Today's paleoanthropology is a subdiscipline of evolutionary biology that aims to describe, analyze, and interpret the process of human evolution, mainly through a vast set of inductive approaches and deductive hypothesis testing (Foley 1987; Henke and Rothe 1994; Wolpoff 1999; Tattersall and Schwartz 2000; Begun 2013). If we want to know more about our origins, there are three basic approaches available to reconstruct our evolutionary history (Washburn 1953; Henke and Rothe 1994, 1999a; Cartmill and Smith 2009):

- First, the primatological approach: One can study the closest living relatives to understand the evolutionary context. Such work includes field and laboratory research on behavior and cognition and comparative morphological, physiological, serological, cytogenetical, molecular biological, and genetic studies (e.g., Goodall 1986; Martin 1990; Jones et al. 1992; Tomasello and Call 1997; Tomasello 1999, 2008; de Waal 2000; Dunbar et al. 2010).
- Second, the paleoanthropological or human paleontological and paleogenetic approach: One can reconstruct our evolutionary history from the recovery and analysis of any relevant fossil evidence, macro- and micromorphological,

histological, and biophysical (e.g., isotopes), and by paleogenetic approaches: ancient mtDNA and genomicDNA (e.g., Aiello and Dean 1990; Herrmann 1986, 1994; Henke and Rothe 1994, 1999a, 2003; Henke 2005; 2010a; Hartwig 2002; Schwartz and Tattersall 2002, 2003, 2005; Hummel 2003; Jobling et al. 2004; Burger 2007; Wagner 2007).

- Third, the population genetic approach: One can study the phenetic and genetic intergroup and intragroup variation of recent human populations to provide clues about geographical samples and their evolutionary histories (e.g., Jones et al. 1992; Freeman and Herron 1998; Jobling et al. 2004; Crawford 2006).
- Finally, there is additional information on prehistoric human activities, mind reading, and symbolism from cultural findings, i.e., the archaeological record, and behavioral fossils (e.g., Haidle 2006; Gamble 1999; Klein 2009; Dunbar et al. 2010; Haidle and Conard 2011; Půtová and Soukup 2015 in press).

Current paleoanthropological research asks not only what our forerunners looked like and when, where, and how they evolved, but also specifically asks, for example, why humans evolved while other primate species died out (White 1988; Tattersall and Schwartz 2000). We have to reconstruct the ecological niches of fossil humans to define the determinants that caused adaptation in human evolution, a process sometimes defined as hominization, although some anthropologists argue that this term is misleading as it sounds teleological (Delisle 2001). Hence, when using this concept, we should be aware that it describes a teleonomic process sensu Pittendrigh (1958). In paleoanthropology – as in other life sciences with a chronological perspective – the experiment is in the historical process of nature itself. We have correspondingly to interpret this process within the general principles of evolutionary theory ex post-factum, and we have to take into account all the problems that arise from the epistemological difficulty known as subject-object identity (Riedl 1975; Mahner and Bunge 2000; Vogel 2000; Vollmer 2003).

Why a Scientific Historical Approach to Paleoanthropology?

The present review of the historical development of paleoanthropology as a multifaceted biological subject is intended to focus on its cultural and social background and on its many problematic time-specific aspects. This historical point of view promises to clarify the following questions:

- Which paradigmatic changes in evolutionary thinking have guided the field of paleoanthropological research?
- Which cultural, social, and scientific factors have decelerated or accelerated the progress of paleoanthropology?
- Which outstanding scientists, and which ideas, brought about the integration of biological, geological, and archaeological research?
- What underlies the successive development, respectively, from Darwinism to neo-Darwinism and from the Synthetic Theory and “Modern Synthesis” to the

System Theory of Evolution as the concept and strategy of paleoanthropological research?
- What were country-specific impacts on the orientation of paleoanthropological research?
- What influence of political ideologies and systems (e.g., radical authoritarian nationalism, communism, colonialism) can be noted on paleoanthropological thoughts and research?
- How was paleoanthropological thought on sex-specific roles in human evolution influenced by the fact that this subdiscipline was for long male dominated?
- What is the impact on current paleoanthropology and its image of innovative biological techniques in these multimedia times?
- Is paleoanthropology a fossil- and/or media-driven science, triggered by the discovery of and publicity about exceptional hominin fossils?
- If the accusation is correct that paleoanthropologists offer mainly shallow but media-friendly "findings" (White 2000) that contribute only very little to a proper understanding of the pattern and process of human evolution (following Shakespeare: "Much Ado About Nothing"), how can historic studies on paleoanthropology contribute to new educational strategies to survive antievolutionary thinking?

Paradigmatic Change in the Nineteenth Century: Step by Step

Darwin's Forerunners, Especially in France and England

The biblical view of the permanence of species expressed by Linnaeus' sentence "*Species tot sunt diversae*, *quot diversas formas ab initio creavit infinitum ens*" was the underlying dogma of Genesis and the Judeo-Christian tradition. Although animal fossils had been described long before Darwin's theory was published, they were interpreted as witnesses of "lost worlds" within cataclysm models, and not as evidence of a real historical-genetic process (for contemporary views, see, e.g., Paley 1860; Zöckler 1860, 1876; for recent literature on pre-Darwinian thinking, see, e.g., Nebelsick 1985; Corbey and Theunissen 1995; Livingstone 2008; Bayertz 2012; Schwarz 2012; Ingensiep 2013).

Georges Cuvier (1769–1832), the outstanding French comparative anatomist, did pioneering research on mammalian fossils and contributed to the self-consciously new science of geology. He began to understand that fossils truly represent remains of once-living organisms and argued for the reality of extinction caused by sudden physical events, so-called catastrophes. Cuvier first opened up the geohistorical perspective that is now appreciated as his most important legacy to science (Rudwick 1997). Besides this, he adamantly rejected "transformist" explanations. Although he was doubly on the wrong track, and his remark "*l'homme fossile n'existe pas*" slowed the development of thinking on human evolution, Rudwick's interpretation of the primary texts demystified Cuvier, who was one of the first to professionally plan his research. His approach had an important influence on scientists of his time.

One of the outstanding opponents of catastrophism was Sir Charles Lyell (1797–1875), British geologist and popularizer of uniformitarianism. He defended one of the most basic principles of modern geology, the belief that fundamentally the same geological processes that operated in the distant past also operate today. *Principles of Geology*, his specific work in the field of stratigraphy, was the most influential geological work of the middle of the nineteenth century and did much to put geology on a modern footing (Bynum 1984; Wilson 1998).

In spite of much progress in natural scientific thinking, the early explanatory approaches of evolutionary theorists were not able to replace traditional views. All pre-Darwinian explanations of diversity and variability are regarded as just another story of natural history, because they failed to explain the driving force of evolution. This holds true for such outstanding naturalists of the eighteenth century as Georges-Louis Leclec, Comte de Buffon (1707–1788); Erasmus Darwin (1731–1802), grandfather of Charles R. Darwin; and William Paley (1743–1805), whose *Natural Theology*, *or Evidences of the Existence and Attributes of the Deity Collected from the Appearances of Nature* was a best seller of which the 20th edition was published in 1820. Paley tried to prove that the world has been created by a designer. Charles Darwin had studied Paley's "long argumentations" carefully, as he noted in his *Autobiography*, before he wrote "I think" in his *First Notebook on Transmutation of Species* (1837) (for concise information on the dispute between theology and natural sciences during the last four centuries, see Schwarz 2012).

The evolutionary theory of Jean Baptiste de Lamarck (1744–1829) proved to be a nonvalid explanation for transformation. However, Charles Darwin (1809–1882) looked upon this retrospectively as an "eminent service of arousing attention to the probability of all changes in the organic, as well as in the inorganic world, being the result of law, and not of miraculous interposition" (Darwin 1861, preface). For a revised assessment of Lamarck's merits, see Wuketits (2009a).

Lamarck's theory triggered Darwin's evolutionary thinking on "transmutation" of species; Darwin himself regarded his Lamarckianistic *pangenesis theory* in retrospect as "stillbirth" (see Wuketits 2009b, p. 626). However, it was foremost Lyell's *Principles of Geology* and Thomas Malthus' essay on the *Principle of Population* (which stated that the population size is limited by the food resources available) that inspired Darwin to his multifaceted approach toward deciphering the biological principles of evolution. He defined the fundamentals and described evolution as a self-organizing process by a mutation-selection mechanism without the necessity of a creator or deus ex machina. The driving force of this event, natural selection (codiscovered by Alfred Russell Wallace, 1823–1913), is the central explanation of the evolutionary process (Glaubrecht 2008a, b).

Darwin's and Wallace's legacy, the theory of natural selection, ultimately led to a paradigmatic change, a totally new view of the development of life systems including human origins. The vintage philosophical questions "Who are we?" "Where do we come from?" and "Where are we going?" were transferred from the metaphysical and the philosophical to a biological focus. They created new and important existential questions. Kuhn (1962) saw the truly revolutionary aspect of

Darwin's theory, not as lying in its evolutionism, but in its powerful rejection of the traditional, teleological view of nature. How explosive Darwin's evolutionary theory was, and how conscious Darwin was of this, is reflected in the fact that he hesitated to deal with the questions of human evolution. The first edition of his classical opus *On the Origin of Species by Means of Natural Selection*, or *the Preservation of Favoured Races in the Struggle for Life* (Darwin 1859), provides proof of this feeling of insecurity. It then took him 12 years to publish his ideas in *The Descent of Man and Selection in Relation to Sex* (Darwin 1871). His innovative focus on human origins set the context for many of the themes of paleoanthropology during the following century. The anthropological challenge within the dynamic evolutionary concept was how to explain ourselves without compromising our posture. Altner (1981a, p. 3) verbalizes the existential problem as follows: "*Der neuzeitliche Mensch ist aus allen ihn übergreifenden Sinnbezügen herausgefallen und auf sich selbst und sein Werden zurückgeworfen*." (For more recent literature on the impact of Darwinism to contemporary and current philosophical thoughts, see Becker et al. 2009; Bohlken and Thies 2009; Engels 2009.)

Evolutionary thinking was widespread during the nineteenth century as various science historians have shown. Bowler (1988, p. 5) suggests in this context "that Darwin's theory should be seen not as the central theme in the nineteenth-century evolutionism but as a catalyst that helped to bring about the transition to an evolutionary viewpoint within an essentially non-Darwinian conceptual framework."

Nowadays we know that most late nineteenth-century evolutionism was non-Darwinian as "it succeeded in preserving and modernizing the old teleological view of things"; however, it was a revolution "in the sense that it required the rejection of certain key aspects of creationism," as Bowler (1988, p. 5) says (see also Moore 1981; Desmond and Moore 1991). The heart of Darwin's materialism, the theory of natural selection, had little impact until the twentieth century. For this reason, the Darwinian Revolution did not take place in the second half of the nineteenth century and remained incomplete until the synthesis with genetics in the twenties and thirties of the last century. But even after this breakthrough, there was no straightforward scientific approach in paleoanthropology until anthropologists appreciated the essential corollary of Darwin's theory, that we are only "another unique species" (Foley 1987).

In retrospect it becomes obvious that the earliest "evidence" for human evolution was disregarded and misinterpreted. Fossils do not speak, but the dictum in paleontology is that they give silent witness. One can only get morphological, ecological, or taxonomical information within a concise methodological approach. Apparently easy paleoanthropological questions about the space and place of human origins do not necessarily have easy answers, so it requires rigorous efforts to establish a sophisticated research design and an adequate methodology to find solutions for the key questions given earlier (see section on "Why a Scientific Historical Approach to Paleoanthropology?").

As there was no evolutionary context at the time when William Buckland (1784–1856), professor at the University of Oxford, discovered the first human fossil, the "Red Lady of Paviland" at Goat's Hole in South Wales in 1823, he totally misinterpreted this 26-ka-old find (Sommer 2004, 2006, 2007a). Buckland considered the find as of postdiluvian age and was unwilling to attribute any great antiquity to this Upper Paleolithic fossil skeleton.

"For most of the nineteenth century, no one believed or anticipated discoveries that would demonstrate a history of humans and their ancestors stretching back over more than a few thousand years," wrote Trinkaus and Shipman (1993, p. 9). Although savants struggled with evolutionary ideas for decades, the belief persisted that the human past differed from the present only in the "primitiveness" of the ancient peoples, not in their very essence and being. Starting in the twenties of the nineteenth century, there sprang up one local natural history society after another. The Red Lady inspired the hunt for human fossils and artifacts (Sommer 2004, 2006, 2007a; Delisle 2007). Kent's Cavern in Torquay, Devon, today recognized as one of the most important archaeological sites in the British Isles, was excavated by John MacEnery and William Pengelly (1812–1894) (Sackett 2000). They discovered an Upper Paleolithic skeleton in association with flaked stone tools. John Lubbock (1834–1913), the foremost British archaeologist at that time, refused the report on "modern savages" written by Godwin-Austin and considered the findings as "improbable" (Trinkaus and Shipman 1993). Lubbock divided the Stone Age into two distinct periods, the Paleolithic and the Neolithic, based on the presence of crudely shipped flint tools versus more subtly made tools. Goodrum (2009, p. 341) mentions Lubbock's *Prehistoric Times* (1865) and Daniel Wilson's (1816–1892) work on *Prehistoric Man* (1865) as landmark in "the emergence of a new discipline, prehistoric archaeology, and the use of the term 'prehistory' in English" (overviews in Sackett 2000; Goodrum 2009, 2013).

Phillipe-Charles Schmerling (1791–1836), a Belgian physician and anatomist, unearthed an infant skull in 1829/1830 at Engis near Liège, which was diagnosed later as a Neanderthal fossil. The Engis child was the first specimen of this kind to be discovered (Schmerling 1833). During the same period, Casimir Picard (1806–1841), a physician and avid archaeologist, was excavating prehistoric stone tools in France. His passion was in taking an experimental approach to archaeology, and he attempted to make and use stone artifacts like those that were being found in excavations. Due to inadequate chronology of the artifact-bearing horizons, he was not able to calibrate some of his stone tools as Neolithic. But his experiments led him to conclusions about how the tools were manufactured. Picard developed, for the first time, both systematic excavation techniques and a stratigraphic approach. While his innovative research was without wider impact on archaeological progress, he impressed his friend Boucher de Perthes (1788–1868). This influential aristocrat, who combined his romantic views on human origins with archaeological fieldwork, argued for the existence of Pleistocene – or, as he said, pre-Celtic-humans; but his findings were at first disregarded by the scientific community. When, in 1864, some of his findings were published in *The Anthropological Review*, the comment of the scientific board was downright British: “We abstain at the present from offering any comment on the above” (Trinkaus and Shipman 1993, p. 44). Although Boucher de Perthes could not avoid the image of flamboyant enthusiast and “madman,” there was finally a change in the assessment of the hand axes as genuine tools. The careful excavation of the gravel beds of the Somme at St Acheul by the French amateur naturalist Marcel-Jérôme Rigollot (1786–1854) impressed a group of outstanding British colleagues, among them Charles Lyell (Fritzsche 1997), and led to the acceptance of the claim that the hand axes were associated with extinct mammal bones – but where did this leave the human fossils? (See Klein and Edgar 2002; Goodrum 2009; Wuketits 2009a)

Neanderthal Case: “Neanderthals Without Honor”

The Neanderthal man from the Kleine Feldhofer Grotte in the Neander Valley near Düsseldorf was found by limestone workers in 1856 and described by the local teacher Johann Carl Fuhlrott (1803–1877). The fossil was the first early human specimen to be recognized as such. The discoveries from Engis (found 1829) and Gibraltar (found before 1848) were made sooner, but their nature became evident much later. Fuhlrott’s merit was that he realized the significance of the fossils, which the limestone workers took for animal bones. Luckily, the owner of the excavation site saved them at the last moment (Schmitz and Thissen 2000). Fuhlrott fought, together with the anatomist Hermann Schaaffhausen (1816–1893) who taught at the University of Bonn, for their acceptance as ancient remains from the diluvial age. Both were convinced that the morphological structure of the bones indicated a high-diluvial age. Since the discovery of the fossil bones antedated the publication of Darwin’s *Origin of Species*, this specimen has often been termed as first proof for human evolution. A deeper analysis of the Fuhlrott/Schaaffhausen contribution demonstrates that both protagonists of paleoanthropological research in Germany were far from an evolutionary interpretation, although they looked upon their fossils as diluvial forerunner of recent *Homo sapiens* (Zängl-Kumpf 1990).

A contemporary of Fuhlrott and Schaaffhausen was Thomas Henry Huxley (1825–1895), the famous British zoologist often referred to as “Darwin’s Bulldog” (Desmond 1997). However, Huxley was no Darwinian. Historians know the difficulties of accurate definition, and Hull (1985, 1988) gets to the heart of this problem in suggesting “that Darwinians are simply those scientists who expressed loyalty to Darwin as the founder of evolutionism, whatever their beliefs about how evolution actually works” (Bowler 1988, p. 73). Although Huxley was highly committed by Darwin’s theory, it is well known that he had essential problems with the selection theory. Further, he was strongly tempted by non-Darwinian ideas, e.g., internal factors that would produce changes independent of the environment. Not being really interested in adaptation, Huxley speculated that evolution might sometimes work in a saltatory manner (Bowler 1988; Desmond 1997). His position was that the continuity between humans and other animals does not detract from the inherent specialness of humans. Similarly, other contemporary so-called proponents of Darwinism were not at all Darwinian evolutionists. In his famous papers on *Evidences as to Man's Place in Nature*, Huxley (1863) gave morphological arguments for our relationship with recent primates and pointed to the scant fossil record known in his time. In spite of contrary statements by many historians, Huxley said virtually nothing about human origins, but concentrated exclusively on demonstrating the physical resemblances of humans and apes. Concerning the Neanderthal man from Germany, Huxley conducted a sophisticated comparison with anatomically modern skulls from Australian Aborigines and other aboriginal relicts, pioneering new ways of orienting and measuring skulls for easier comparison (Desmond 1997). His conclusion was that the Neanderthal skull emerged as an exaggerated modification of the lowest of the Australian skulls. Huxley stated that the brain of the Neanderthal man was of normal size for an ancient savage, and its stout limbs suggested to him a cold adaptation to glacial Europe. However, in no sense was this specimen "intermediate between man and apes." He viewed the Neanderthals as a very "primitive race" of humans, "the most pithecoid of human crania yet discovered" (Huxley 1863, p. 205). The Huxley biographer Desmond (1997) illustrates this by reference to Huxley's diary entries: "Where, then must we look for primeval Man? Was the oldest *Homo sapiens* pliocene or miocene, or yet more 'ancient'? How much further back must we go to find the 'fossilized bones of an ape more anthropoid, or a man more pithekoid' (sic!)?" Desmond concludes that Huxley was preparing the world for ancient semihumans. How misleading the effects of the concept of "semihumans" were becomes evident from the popular scientific literature and illustrations (see Corbey and Theunissen 1995; Kort and Hollein 2009, herein especially Jane Goodall's article; Ingensiep 2013).

The Irish zoologist William King (1809–1886) proposed in 1864 the name *Homo neanderthalensis*, although his arguments for a separate species in the genus *Homo* were inadequate, not to say absurd. Since then, opinion has fluctuated as to whether the fossils should be considered as a separate species, *H. neanderthalensis* or *H. sapiens neanderthalensis* (a subspecies of *H. sapiens*). The "fate of the Neanderthals" is the trickiest controversy in paleoanthropology (e.g., Henke and Rothe 1999b; Stringer and Gamble 1993; Tattersall 1999; Krings et al. 1997; Wolpoff 1999; Henke 2003a, b, 2005; Finlayson 2004; Green et al. 2008, Green et al. 2010a, b; Condemi and Weniger 2011; Stringer 2012). The question of whether some or all of these fossils deserve a place in our direct ancestry or whether they can be viewed as a single lineage leading to and culminating in the classic Neanderthals of the last Ice Age is the longest-running taxonomic problem in paleoanthropology (Schmitz 2006; Uelsberg and Lötters 2006; Harvati and Harrison 2006; Cartmill and Smith 2009). What very soon became apparent with Huxley's *Evidences* was the tremendous need for an extension of the fossil record and for an improved comparative methodology to analyze and interpret the fossils of recent primates. The starting signal for the search of the so-called missing link was given.

Theoretical and Methodological Progress in Paleoanthropology Since Darwin Till Mid-twentieth Century

Successive Discovery of the Paleoanthropological Background

In Darwin's time, it was already evident that the scant evidence of hominin life in the past does not allow us to neglect any clues. We need all available sources to reconstruct our evolutionary history, and to do this we rely overwhelmingly on fossils. No wonder the mantra of paleoanthropologist's of the first hour was "We Need More Fossils!" – and this call has never faded. However, there arose a paradox: the more fossils, the more complex the phylogenetic interpretations of the material became. Begun (2004) even wondered "Is Less More?" The answer must be an improvement of the epistemological and methodological bases of paleoanthropological inquiry, to ensure the trustworthiness of the investigation of fossils. These latter are obviously mute; and for this reason, one has to formulate hypotheses about the biological and phylogenetic roles of the extinct taxa. The only reliable approach to increasing our knowledge of the lost worlds is to compare them with recent sets of well-known phenomena (Foley 1987; Henke and Rothe 1994).

This scientific process started very soon after the creative flash (fulguration sensu Popper) of the pre-Darwinian interpretation of fossil specimens as documents of species of former times and of their relevance to Darwin's evolutionary theory. It was in this context that the systematic search for phylogenetic forerunners of recent taxa began. The most dramatic part of the Darwinian paradigm focused on the question of how humans evolved from archaic primates. What did the hypothetical species transitional between apes and man look like? When, where, and how did the "missing link" live? (The origin of this term is contested. Some claim it was created in 1861 by Asa Gray (Shipman and Storm 2002), while other sources say it was coined by Lyell in 1837). Like the term "semihumans," just mentioned, this concept caused a lot of misunderstandings (Goodall 2009; Ingensiep 2013), and for this reason it should be abandoned as inadequate for modern evolutionary thinking. However, John Reader's (2011) *Missing Links*, an enthralling story of fossil hunting, stuffed with eccentrics and enthusiasts, and even some frauds in the search for humanity's origins, demonstrates the hold this expression has had on the popular scientific media since Herbert Wendt's (1953) best seller *Ich suchte Adam*. Fortunately, controversial book titles don't implicitly match with a book's contents; reader's advanced and ambitious storytelling is as diverting as Wendt's publication which first aroused my interest in the subject. Darwin's evolutionary theory of natural selection did not automatically provide an answer to the question of human ancestors, and Darwin himself was cautious enough not to give a premature answer. But he had provided a new framework in which all these questions could be answered. While the public longed for strong proof of human evolution, Darwin gathered all available arguments for more than 10 years before finally publishing his brilliant anthropological volumes *The Descent of Man and Selection in Relation to Sex* (1871) and *The Expression of Emotions in Animals* *and Man* (1872). Both books deal with human evolution, and particularly with sexual selection, whose enormous evolutionary impact was first understood only around 100 years later, when the sociobiological paradigm emerged (Wilson 1975; Vogel 1982; Miller 1998; Voland and Grammer 2002; Voland 2000a; 2009).

During the 1860s, Darwin's ideas were widely popularized. However, there was still much scientific skepticism since the laws of heredity worked out by Gregor Mendel (1822–1884) in 1865 remained unknown until the twentieth century. Beside Darwin's British supporters, especially Thomas H. Huxley and Charles Lyell, it was the German geologist and paleontologist Friedrich Rolle (1827–1887) and the zoologist Carl Vogt (1817–1895) who advocated Darwin's theory (Rolle 1863; Vogt 1863; for more details, see Bowler 1988; Junker and Hoßfeld 2002; Hoßfeld 2005a, b; Rupke 2005; Ruse 2005).

Even more committed and sarcastic than the "Affenvogt" was Ernst Haeckel (1834–1919), an outstanding German biologist who sagaciously fought against the "ape complex." He is best known for his *recapitulation law* (ontogeny recapitulates phylogeny), a highly controversial assumption. After reading *The Origin*, he became a powerful and eloquent supporter of evolution. Although Haeckel admired Darwin's theory, he remained an orthogradualist and a Lamarckian concerning the concept of the "survival of the fittest." Haeckel was not really supportive of natural selection as the basic principle of evolution, and his interest in fossils and paleoanthropology was small. He was convinced that due to the intertwining of phylogeny and ontogeny, ontogenetic structures were sufficient evidence for evolution (Haeckel 1898, 1902, 1905, 1922; Heberer 1965b, 1968b, 1981; Hoßfeld and Breidbach 2005; Kleeberg see www; Preuß et al. 2006; Henke und Rothe 2006; Sarasin and Sommer 2010).

Despite misunderstanding many of Darwin's ideas, Haeckel inspired the public and colleagues with his enthusiasm for evolution and animated the debate. As he was highly motivated by his anti-Christian attitude, his influence in science faded, especially after he had created his monistic theories and dabbled in esoteric fields (Hoßfeld 2005b; Kleeberg see www; Richards 2005). Still, he gave paleoanthropology an essential impulse by publishing the first phylogenetic tree (Fig. 4) that included humankind. Darwin's comment on this was "Your boldness, however, sometimes make me tremble, but as Huxley remarked, some one must be bold enough to make the beginning in drawing up tables of descent" (German translation "Ihre Kühnheit läßt mich jedoch zuweilen erbeben, aber, wie Huxley bemerkte, irgend jemand muß eben kühn genug sein und einen Anfang machen, indem er Stammbäume entwirft") (Darwin's letter to Haeckel, November 12, 1868) (Schmitz 1982). As the limited fossil record only allowed a very hypothetical pedigree, there was much courage needed indeed. Haeckel postulated a forerunner species *Pithecanthropus alalus* – a speechless ape-man – a missing link, which he believed lived during the Pliocene in Southeast Asia or Africa. Within an orthogenetic pedigree, he posited a primitive species – which he named *Homo stupidus* – between this "ape-man" and the recent *H. sapiens*. Around 30 years later, fossils were found

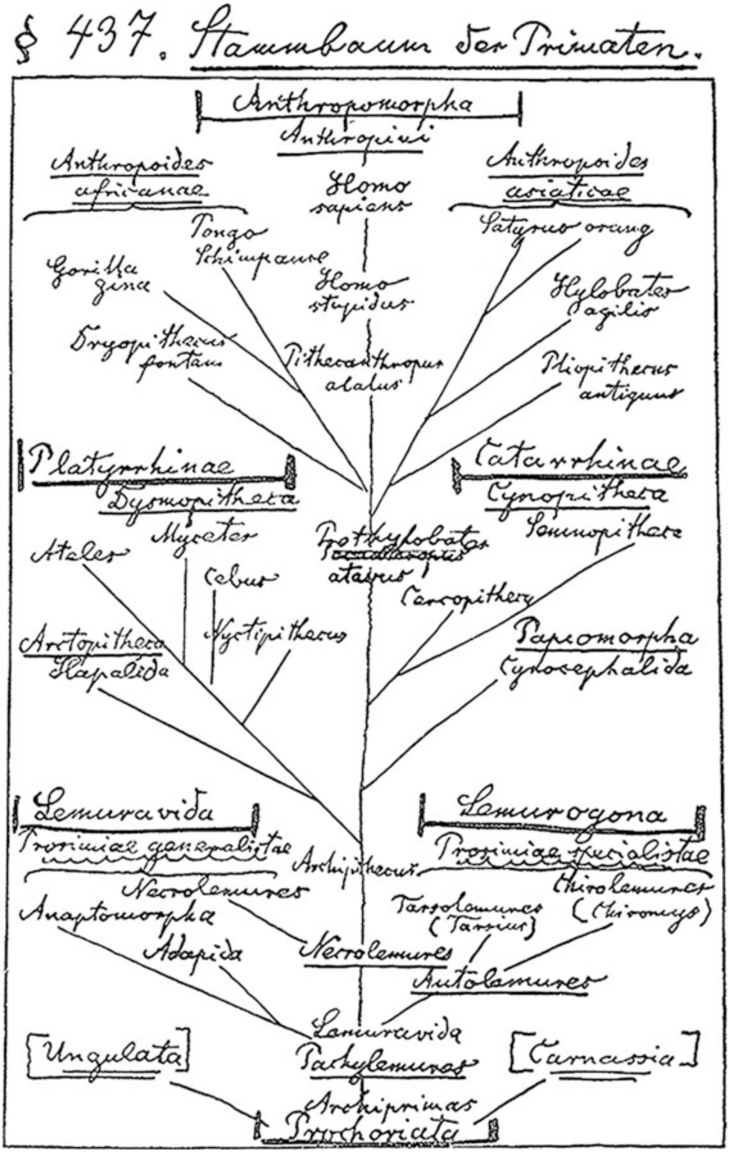

Fig. 4 Hand-drawn sketch of the family tree of primates by Ernst Haeckel; published in Herbert Wendt: *Ich suchte Adam*, 2nd ed. 1954 (Grote Verlag, Hamm). The artwork is part of the estate of Gerhard Heberer, and currently in the possession of Uwe Hoßfeld (Jena). Due to a detailed recherche by David Morrison (see Morrison et al. (2013), www), it was detected that contrary to earlier claims, this is *not* the first primate pedigree from Haeckel; there is evidence to suppose that the sketch was designed around 1895

in the postulated Asian region by the Dutch physician Eugene Dubois (1858–1940), which roughly fitted the expectation of a *Pithecanthropus* (Bergner 1965).

Meanwhile a focus of research was the phenomenon of the Ice Ages and the discovery of Upper Paleolithic man and Ice Age cultures (Trinkaus and Shipman 1993; Sackett 2000). Although human fossils were rare at the time of Darwin's revolutionary discovery, there was much evidence from animal bones, mollusks, sediments, and other materials to give insight into ancient populations. Further, there were ever-increasing indications of long-term fluctuations in the earth's climate. Geologists, like Agassiz, Geike, and Lyell as well as Brückner and Penck, established a Pleistocene framework of successive glaciations (Gräslund 1987), and archaeologists strove to establish the antiquity of human ancestry through the association of stone tools with extinct animals. The geological research resulted in the Alpine model, a chronological system of glaciations that gave a framework for the ongoing discovery of Neanderthal fossils.

As biological, anthropological, paleontological, geological, and archaeological data came together within the framework of the evolutionary theory during the second half of the nineteenth century, many scientific societies were founded, which supported all kinds of scientific research.

Rudolf L.C. Virchow (1821–1902), a famous German physician and anthropologist sensu lato, best known for his guiding research in cellular pathology and comparative pathology, was a universal scientist and liberal politician who founded the German Society of Anthropology, Ethnology, and Prehistory in 1869 (Degen 1968; Andree 1976; Schipperges 1994; Goschler 2002; Saherwala 2002; Trümper 2004). He included humankind in the historicization of nature and came to the conclusion that *H. sapiens* was "post-history" (Goschler 2002, p. 322). For that reason, he was highly skeptical about the validity of Darwinian theory as regards our own species and doubted the phylogenetic classification of the species *H. neanderthalensis*, as the Irish zoologist William King had dubbed the skeleton from the Kleine Feldhofer Grotte (Stringer and Gamble 1993; Trinkaus and Shipman 1993; Schmitz and Thissen 2000). Due to his "pathologist view," he interpreted the Neanderthals' derived features, or apomorphies, as pathological features resulting from arthritis; further, from the erroneous information that the skeletal remains were associated with polished stone tools (an indicator for the Neolithic), he concluded that the Neanderthal specimen must have lived in recent times (Schott 1979). Thus, not all human fossils known at that time were accepted as convincing evidence of our ancestry, especially given their uncertain dating.

Neither Virchow nor Haeckel pushed paleoanthropological research, the former from misinterpretation of the facts and skepticism on Darwin, the latter from his conviction that ontogenetic research delivers sufficient information to demonstrate phylogenetic evolution. Virchow's interest was much more in prehistoric anthropology and ethnology, from the point of view of the decoupling of natural and cultural evolution. The retrograde view that the assumed "missing link" does not exist was admired by the Christian church, and when *Pithecanthropus erectus*, the so-called Java man, was described, he thought that the bones represented a giant gibbon. However, Haeckel's interpretation was not in accordance with the results of the discoverer. Dubois was convinced “that his famous specimens from Trinil represented a true human ancestor, while other fossils from Sangiran and Zhoukoudian in China were too derived to have been ancestral to later humans. His theories, however, were widely misunderstood at the time” (Durband 2009, p. 10). As an excellent proof that in science history really matters, it can be noted that his “somewhat bizarre” reading of the evidence was roundly chastised by anatomists of the time (e.g., Le Gros Clark 1934; Weidenreich 1946) and generally dismissed by the scientific community as a whole. Only decades later, through the efforts of Theunissen (1989) and later Shipman (2001), were Dubois’ motives for this stance made clear (Durband 2009, p. 10; see too Theunissen 1989; and Shipman 2001).

Virchow’s skeptical attitude concerning *Pithecanthropus* as well as his critical interpretation of the Neanderthal fossil as a pathological individual lessened the biological impact of a premature “paleoanthropology” in Germany during the second half of the nineteenth century (Trümper 2004). This holds true for the English and French scientific scenes as well. Although the physician Paul Pierre Broca (1824–1880), the founder of the Société d’Anthropologie de Paris in 1859, was a pioneer of comparative anatomy and anthropology, he never accepted the Neanderthals as fossil documents. His interest was in understanding patterns of variation in order to understand the significance of anatomical differences. For this reason, he became one of the first to use statistical concepts in establishing anthropology as a scientific discipline in contrast to medical science. In 1882, his French colleagues Quatrefages and Hamy published *Crania ethnica*, a monograph which exemplifies the huge interest in recent cranial variation that dominated the anthropological discipline.

Édouard Lartet (1801–1871) was the first to describe the primate genera *Dryopithecus* and *Pliopithecus*, but much more important was his discovery of signs of prehistoric art made by early humans (Lartet and Christy 1865–1875). The fossil ivory carving of La Madeleine, found in 1864, was presented at the world exhibition in Paris 1867 and raised tremendous interest.

In the following period, neither the discoveries of human fossils from La Naulette in Belgium nor those of Pontnewydd (Wales), Rievaulx (Southern France), Šipka, Mladeč (see Teschler-Nicola 2006), and Brno (Čzech Republic) were able to convince the European scientific community of great human antiquity. Even the analysis of the Spy fossils, which had been discovered in Belgium in 1886, did not slow the rejection of evolutionary ideas. Trinkaus and Shipman (1993, p. 132) summarized: “The man of the Neander Valley remained without honour, even in his own country.”

In the motherlands of evolutionary thinking, France and England, Paleolithic archaeology dominated paleoanthropological discussion as it began taking shape as an organized scientific field of research in the 1860s. Sackett (2000, p. 38) put it this way: “discovering the Paleolithic became a matter of empirically demonstrating that human remains and artifacts could be found in association with the remains of extinct animals belonging to the deep time of earth history.”

Progress was for the first time possible through the geological recognition of the Pleistocene epoch, making the interpretation of fossils possible within a solid geological background. Although Cuvier and Lyell had done indispensable scientific work in understanding the past, the first assumed that the changes came about by a series of revolutions, while the second, although he had major objections to Cuvier's theory of catastrophism, was no evolutionist either. The challenging question for the evolutionists was how to provide empirical data on the existence of "diluvial" and "antediluvial" early human populations. As these workers had to rely on the research of the paleontologists and the archaeologists, paleoanthropological science was becoming multidisciplinary even at this early stage. The evidence from the Paleolithic record was mainly from data from stream gravel terraces, rock shelters, and bone caves. As Sackett (2000, p. 42) mentions, from the 1820s until 1859, there was a series of discoveries in France (especially in the Perigord), England (Paviland bone cave near Swansea, Wales; Kent's Cavern, near Torquay, Devonshire), and Belgium (Engis near Liège). The research resulted in the assignment of Pleistocene faunas to deep geological times, but it did not support evolutionary thinking due to the many alternative explanations available. The consequent question was whether actual human remains existed in association with Pleistocene animal fossils and undoubted artifacts. The immediate question of human antiquity came up with the discussion of the fossils from the Neanderthal in Germany and Darwin's evolutionary theory. Most of the geologists and paleontologists remained skeptical; they saw no proof of a high antiquity of humankind from evidence from the bone caves or gravel terraces. One reason for their skepticism resulted from the archaeological work of Jacques Boucher de Perthes, director of customs at Abbeville, France, whose empirical evidence was much doubted. As consequence of his having "found much too much," as Sackett (2000, p. 45) put it, the Bible continued to dominate everyday metaphor; and ironically enough, the successful archaeological research in the Near East, Egypt, and Palestine solidified the traditional view that humankind was unique and doubtless recent. In spite of many convincing facts – as retrospectively gauged – from archaeology, the social establishment of the mid-nineteenth century maintained the older view.

An opportunity for change came in 1858, when Brixham Cave near Torquay on the Devon Coast was discovered, and outstanding scientists like Hugh Falconer (1808–1865), Charles Lyell, Richard Owen (1804–1892) supervised excavations there. William Pengelly (1812–1894), a local schoolteacher and geologist, was able to gather, by a new method of layer-by-layer excavation, thousands of animal bones including those of hyena, cave bear, rhinoceros, and reindeer. The impact of these fossils on the question of human antiquity would have been zero if Pengelly had not found undeniable artifacts, which he described as "knives." These chipped stones from Brixham Cave challenged the received opinion about human antiquity in 1859. While the belief in human antiquity of the excavator and some colleagues was confirmed by the association of fossil bones and the hand axes, others like Owen did not agree and thought that the animals had not become extinct until geologically modern times.

New aspects came into the stagnating discussion when the implements of the Brixham Cave were compared to the finds at Abbeville and Amiens excavated by Boucher de Perthes. The ultimate convincing facts came when the English team, digging in the Somme terraces, was able to document a hand axe in place in a fossil-bearing stratum at St Acheul. This was the turning point as Pengelly, Prestwich, and Lyell were then able to convince the British establishment of the antiquity of humankind. The French scientific community, which had contradicted Boucher de Perthes' interpretations for many years, now no longer rejected the idea of human antiquity. Some French scientists like the zoologist Isodore Geoffrey St Hilaire (1805–1861) and Édouard Lartet had been more or less convinced about human antiquity before, but the discovery of human teeth intermixed with fossils of cave bear and hyena in a cave near Massat in southern France brought about final acceptance. Lartet published the ultimate proof in 1860. He described cut marks on fossil bones that had been made by stone tools when the bones were still fresh. This was the essential evidence of contemporaneity of humans and extinct animals, and it signaled the start of intensified geological research. The glaciological research aimed at structuring the Pleistocene epoch that helped to put the human antiquity into a chronological frame; and the amalgamation of archaeological and geological facts brought up a new era that started with Lyell's first edition of his famous *Geological Evidences for the Antiquity of Man* (Lyell 1863). The coming together of diverse aspects of the cultural and natural sciences ultimately yielded an innovative conception of man and his origin (Daniel 1959, 1975; Trinkaus and Shipman 1993; Sackett 2000; Murray 2001; Sommer 2004, 2007a; Delisle 2007).

Southeast Asia as Supposed Cradle of Humankind

If paleoanthropologists had to answer the question of which fossils had the most exceptional influence on human evolutionary thinking, they would, of course, include the *Homo erectus* fossils from Java alongside those from the Neander Valley (Theunissen 1989; Durband 2009). The assessment is very easy to understand: first, there is a hero, a young, enthusiastic physician from the Netherlands, Eugène Dubois, who feels inspired by Darwin's theory and Haeckel's preliminary draft of a link between the lesser apes and earliest human populations; he joins the army as military surgeon and embarks for Indonesia. Besides his service in the army, he is looking for the so-called missing link, *P. alalus*, as Haeckel had dubbed the speechless and small-brained human species (Shipman 2001; Shipman and Storm 2002). Second, this paleontological amateur is successful in discovering a fossil human tooth and then a skullcap in the gravels of the Solo River. He proposes at first the name *Anthropopithecus* and then changes it to *Pithecanthropus*, the name given by Haeckel. Finally, a stroke of good fortune leads to the discovery of a human femur, which seems to belong to the *Pithecanthropus* fossils, and causes the species to be named *erectus*. Third, Dubois, the man who found the posited "missing link," gets into more and more trouble with his critics and, due to severe personal problems, the end of his career is tragic. Since Dubois was neither an accidental discoverer nor a paranoid eccentric person, as science historians and colleagues (v. Koenigswald 1971) have sometimes characterized him, the reinvestigation of his lifework yields a less discreditable view (Theunissen 1989; Shipman 2001; Shipman and Storm 2002; Durband 2009).

If one takes all aspects of this story together, it shows the main characteristics of a myth. On the one hand, his unbelievable luck and, on the other hand, his unyielding, difficult character and his stubborn nature made Dubois an interesting public figure. While some historians like Erickson (1976) look upon Dubois as an unimportant figure in paleoanthropology, others like Haddon (1910), Theunissen (1989), and Shipman (2001) see him as one of the founding fathers of paleoanthropology (Shipman and Storm 2002).

Did Dubois' essential discovery coincide with a paradigm shift in paleoanthropology? While Howell (1996, p. 4) stated that the entire field of paleoanthropology is "close to a paradigm state without yet having achieved it," Chamberlain and Hartwig (1999, p. 42) suggest "that the validity and promotion of knowledge claims in palaeoanthropology are explicitly Kuhnian and that future epistemological progress depends on acceptance of both Kuhnian and positivist approaches to knowledge-building."

In opposition to Chamberlain and Hartwig's opinion, Cartmill (1999, p. 46) stated that "Whatever a paradigm is, normal science consists of attempts to 'articulate' a paradigm by answering questions, verifying predictions, and solving sticky problems in paradigmatic terms." He continues: "Conceptual change in science is perpetually going on at all levels, and is not ordinarily concentrated in punctuational events that can be distinguished as 'revolutions'."

Whatever position one adopts, there are obviously good reasons to regard Dubois as a founder of paleoanthropology. According to Shipman and Storm (2002, p. 109), founders must have special qualifications, e.g.:

- A pivotal discovery of fossils or artifacts
- Development of an innovative technique for the description and analysis of discoveries
- A new framing of the problems or questions of the fledgling field
- A broad dissemination of information or debate about the subject, which serves to make it a matter of wide concern
- The provocation of a general reaction or response from potential colleagues

The last point fits with the Machiavellian fact that an invention needs the attention of the scientific community to become common currency. One may ask what would have happened to Dubois' discovery in modern times. The rules of "The Economy of Attention," formulated by Georg Franck (1998a, b), list the following stepwise pattern: "Attention by other people is the most irresistible of drugs. To receive it outshines receiving any other kind of income. This is why glory surpasses power and why wealth is overshadowed by prominence."

While Haeckel, Broca, and other scientists focused on the comparative anatomy and embryology as proof of human evolution, Dubois was the first who implemented a new strategy. Since he realized that human evolution is a chronological process, which must have happened in preferred localities with specific ecological niches, he set out for Southeast Asia, promised by Haeckel's fictional pedigrees as a possible "cradle of mankind" where the mysterious so-called missing link should have lived.

Dubois was the first to write a detailed monograph on a hominin fossil, and he applied for the first time metrical and mathematical procedures for the calculation of brain volumes and stature heights to a human fossil. A critical evaluation of his work by Shipman (2001) shows that his scientific work was innovative and erudite, contrary to reports circulated by paleoanthropologists and science historians. The contemporary reviews of his 1895 monograph by, e.g., the German anatomist Wilhelm Krause and the multitalented scientist Rudolf Virchow were scathing, just as were those of British, French, and Swiss scientists. On the other hand, it was no surprise that Haeckel's comment was positive. The skepticism of part of the scientific community incited him to tremendous activity, and there resulted a flow of papers on *Pithecanthropus*. It is thanks to Dubois that the focus on human fossils increased (Shipman and Storm 2002). The marketplace for human fossils and paleoanthropological discussions was open (Sander 1976).

Among the scientific activities at the turn of the penultimate century of anthropological organizations in different European countries, e.g., the Gesellschaft für Anthropologie, Ethnologie und Urgeschichte in Berlin or the Société d'Anthropologie de Paris as well as the Royal Anthropological Society of Great Britain, interest in the diversity of recent humankind was paramount. While many activities were concentrated on the typological classification of recent populations as well as prehistorical and archaeological research, paleoanthropological problems and fossils played only a minor role. Dennell (2001, p. 52) designates the period from ca. 1870 to 1930 as the "Age of Prejudice so far as European (and North American) perceptions of non-whites is concerned." The dominating theme was the racial prejudice of fixity and inequality of races. While this attitude did not change when the first non-European fossil caught the interest of scientists and the public in general, it introduced a new aspect of human evolution: the confrontation of Eurocentric typological views with paleoanthropological facts (Hoßfeld 2005a, b; Henke 2010a, b; Henke and Hardt 2011; Henke and Herrgen 2012).

In the light of the *Pithecanthropus* fossils, the Neanderthal problem reached a new dimension. Virchow's diagnosis implied that the Neanderthal man was diseased with rickets as a child and arthritis as an adult. To many, this explanation of the special bony features of Neanderthals sounded farfetched (Trinkaus and Shipman 1993). There was a fundamental need for appropriate comparative biological research and a reasonable taxonomic approach. With the benefit of the hindsight, one can see that in those times there was no theoretical basis for paleoanthropological research, since the anatomists as well as the archaeologists were concentrating on case studies, while zoologists, like Haeckel (1866), were focusing on other topics than merely paleoanthropology. The end of the nineteenth and the beginning of twentieth century yielded exciting discoveries of human fossils (Table 1). The obvious lack of a sophisticated theoretical basis and elaborate methodological skills in paleoanthropological research gradually led to the development of a new field of evolutionary biology.

Table 1 Timetable of the unearthing and interpretation of human fossil remains and relevant breakpoints of paleoanthropological research before 1930

Year	Place and site	Specimens, taxon, pathbreaking finding	Aspects and comments
1830	Engis, Belgium	First Neanderthal fossil, Mousterian culture	Described much later as such
1848	Forbes' Quarry, Gibraltar	Neanderthal calvarium	Described much later as such
1856	Kleine Feldhofer Grotte (Neanderthal, Germany)	Calotte and postcranial skeleton, no archaeological remains	First human fossil remains which have been attributed by Fuhlrott and Schaaffhausen in 1857 as diluvial remains, detailed description by Fuhlrott in 1859
1859	London (UK)	Charles Darwin publishes his "Origin of Species by Means of Natural Selection . . ."	Darwin's descent theory and his explanatory theory of selection induced a paradigmatic change
1866	La Naulette (Belgium)	Mandible, Würm I	Further indication for the existence of fossil man
1868	Cro-Magnon (France)	Fossil remains of several individuals, best known as "Le Villard" (Cro-Magnon 1), type specimen of a so-called Cro-Magnon race within contemporary typological classifications of those times	The fossils have been described by Vacher de Lapouge as *H. spelaeus* but are fully modern Upper Paleolithic humans. The association of the "Cro-Magnon" type with an (evolved) Aurignacian and an extinct Pleistocene fauna was essential for the acceptance of a human antiquity
1880	Šipka (Czech Republic)	Fragmentary mandible of a child, Mousterian, Würm I/II	The Neanderthal mandible did not convince the critics of the evolutionary theory
1886	Spy (near Namur, Belgium)	Two skulls and postcranial remains	The morphology of the bones disproved any doubt on the existence of Neanderthal man in Europe
1887–1892	Taubach (Germany)	Isolated teeth, Mousterian culture	"Pre"-Neanderthal remains
1891–1898	Trinil (Central Java, Indonesia)	Calotte and complete femur, partial femur, teeth	The discovery of the Trinil fossils by Eugène Dubois (*Pithecanthropus erectus*) was essential for the discussion of the "missing link" and displaced the focus on human origins from Europe to Asia

(*continued*)

Table 1 (continued)

Year	Place and site	Specimens, taxon, pathbreaking finding	Aspects and comments
1899–1905	Krapina (Croatia)	>670 cranial remains, Riss-Würm Interglacial, cannibalism, burnt bones, Mousterian culture	The "*H. primigenius*" (later on *H. neanderthalensis*) was excellently described and analyzed by Gorjanović-Kramberger (1906)
1907	Mauer (near Heidelberg, Germany)	Fossil mandible, dated to the middle Pleistocene, between the Cromerian and Holsteinian interglacials, ca. 500 ka	Schoetensack (1908) described the Mauer jaw as a new species, *H. heidelbergensis*. Some regard the fossil as *H. erectus* or classify the specimen as archaic *H. sapiens*
1908	La Chapelle-aux-Saints (France)	Well-preserved Neanderthal skeleton with a lot of pathologies, Charentian, Mousterian, Würm II	Boule's description of the fossil (1911–1913) was a milestone of research of the Neanderthals and "established" them as a separate species of their own; long time regarded as "archetype" of the classic Neanderthals of western Europe
1908	La Quina (France)	Remains of a total of 27 hominin individuals, highly fragmentary, including an infant skull (H 18); Quina variant of the Mousterian, traces of fire	Louis Henry-Martin described the fossil material in 1908 and in the following years as classic Würm Neanderthal remains
1908/1914	Le Moustier (France)	Adolescent and infantile skeleton, associated with Mousterian culture and overlying Châtelperronian assemblage	Described by Klaatsch and Hauser (1910) as the type specimen of the species *H. mousteriensis*, although the Neanderthal affinity of the specimens has never been disputed
1908–1915	Piltdown (Sussex, England)	From "Pleistocene gravels" "unearthed" specimen, a chimera of an intentionally manipulated mandible of a juvenile orangutan and portions of the skull of an anatomically modern man	The specimen was named *Eoanthropus dawsoni* and caused a lot of trouble in paleoanthropology as most of the leading British paleoanthropologists regarded the fossils authentic

(*continued*)

Table 1 (continued)

Year	Place and site	Specimens, taxon, pathbreaking finding	Aspects and comments
1908–1913 and 1914/ 1916/1925	Weimar-Ehringsdorf (Germany)	Calvaria, parietal, mandible, teeth, older than the classical Neanderthal man, Mousterian culture	“Pre”-Neanderthal remains
1909–1912 1920–1921	La Ferrassie (France)	Fossil material of two adult and several highly incomplete and poorly preserved immature individuals, crouched burials	Field descriptions by Capitan and Peyrony (1909, 1911–1912) and detailed analysis by Boule (1911–1913)
1918 f.	Zhoukoudian (near Beijing, China)	Zdansky collected in the large karst cave human teeth and Bohlin started the excavation campaign 1928–1929 followed by further excavations	The successful excavation of the site shifted the focus of paleoanthropological research and the origin of mankind entirely to Asia. Black’s description of *Sinanthropus pekinensis* established a species very similar to *P. erectus*
1921	Broken Hill (newly Kabwe; near Lusaka) Zambia (formerly Rhodesia)	The well-preserved calvarium is associated with an African MSA, dated to 200–125 ka	Woodward (1921) classified the “Rhodesian Man” as a new species *H. rhodesiensis* and Pycraft (1928) opted for a new genus *Cyphanthropus rhodesiensis*, while Mourant (1928) saw Neanderthal affinities. Actually the specimen is mostly attributed to *H. heidelbergensis*
1924	Taung (North West Province, South Africa)	The skull and hemiendocast of a child have been described by Raymond Dart (1925) in a *Nature* article as species nova *Australopithecus africanus*	The characters in Dart’s *A. africanus* were diametrically opposed to those expected; for this reason his classification was highly criticized by Woodward and Keith, the contemporary leading British paleoanthropologists
1924–1926	Kiik-Koba (Crimea, Ukraine)	Hominid remains including an adult male and an infant (possible burials) assigned to *H. neanderthalensis*, Mousterian occupation level, Würm I	Extension of the distribution map of Neanderthal sites to eastern Europe

(*continued*)

Table 1 (continued)

Year	Place and site	Specimens, taxon, pathbreaking finding	Aspects and comments
1926	Gánovce, Slovakia	Cranial and postcranial remains, Riss-Würm Interglacial, Mousterian culture	“Pre-Neanderthal” remains
1927	Mugharet el-Zuttiyeh, near Lake Galilee, Levante (today Israel)	Frontal skull fragment with an intermediate morphology, neither modern nor Neanderthal	First human fossil remain from the crossroads of the Middle East Corridor
1929	Saccopastore near Roma (Italy)	Clavarium (Saccopastore 1), skull fragments, upper jaw, Riss-Würm Interglacial	“Pre”-Neanderthal remains from stage 5e (130–120 ka)

Compiled from Henke and Rothe (1994, 1999a, references given there)

The best basis for such a development existed in France, where Pierre Marcelin Boule (1861–1942), a qualified geologist, paleontologist, and archaeologist, unified all necessary attributes to establish a program for paleoanthropology. His classical description of the Neanderthal skeletons from La Chapelle-aux-Saints (Boule 1911–1913) was a landmark in the history of human paleontology (Heberer 1955a). Contemporaneously, the German anatomist Gustav Schwalbe (1844–1916) analyzed a skull fragment from Eguisheim as well as the famous Javanese *Pithecanthropus erectus* (Schwalbe 1906; Fischer 1917): research that is regarded as critical to the founding of paleoanthropology as a research field of its own. Heberer (1955b, p. 298) comments on this: “An die Stelle ungenügend fundierten Theoretisierens tritt jetzt in der menschlichen Fossilforschung die exakte Empirie.” Albeit this sounds somewhat effusive, the empirical approach to the morphological and metrical analysis of the fossils allowed an independent development separate from geology and archaeology. This view characterizes, on the one hand, the poor cooperation of paleoanthropology, as a biological field of research, with the geosciences as well as with archaeology/prehistory and, on the other hand, the overestimation of the scientific importance of quantifying morphological methods (Chaoui 2004; Hoßfeld 2005b). Both of these aspects hampered any essential progress in paleoanthropology for decades, the subject remaining mainly narrative and descriptive (see Hoßfeld 2005a, b; Henke 2006a, b, 2010a, b; Blanchard 2010).

Development of Principles and Methodical Skills in Paleoanthropology

Neither Haeckel nor Virchow regarded paleoanthropology as a particularly important subject, and even anthropology itself was not a discipline of great significance in their times. The reason for the late establishment of anthropology as a separate

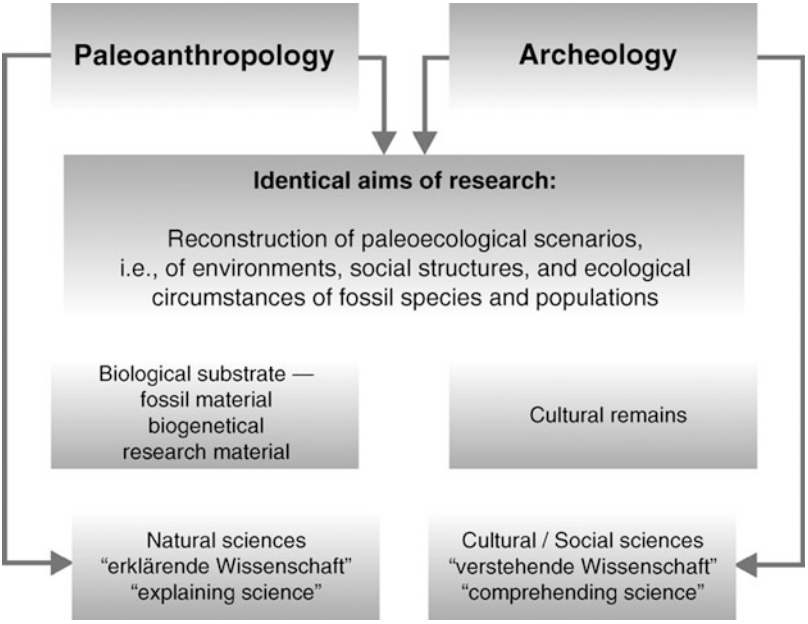

Fig. 5 Paleoanthropology versus archaeology – identical aims but different approaches (Henke and Rothe 2006)

biological discipline is, as Grimm (1961, p. 1) suggested, that "der Anthropologe viel weniger als der Zoologe oder der Prähistoriker oder der Anatom in der Lage schien, die Grenzen seines Faches zu bestimmen."

In the first half of the twentieth century, paleoanthropology remained uncentered as physicians, anatomists, biologists, archaeologists, and ethnographers from different viewpoints and with different intentions and aims all practiced anthropology (Henke 2010a, b). This becomes especially obvious if one looks from the more zoological fields of research across to archaeology. The division of so-called explanatory natural sciences (erklärende Naturwissenschaften) from the comprehending humanities (verstehende Geisteswissenschaften) sensu Dilthey 1883 (Groethuysen 1990) was completed at the beginning of the twentieth century, contingent on the obvious consciousness of superiority of natural sciences (Fig. 5).

The rediscovery of Gregor Mendel's laws in 1900 by Carl Correns, Erich von Tschermak-Seysenegg, and Hugo de Vries gave a push to evolutionary thinking. Around 1930, protagonists of neo-Darwinism like Ronald A. Fisher, John B. S. Haldane, and Sewall Wright developed the basic principles of population genetics and induced a fruitful diversification of natural sciences. In the following period, the Russian-American geneticist and evolutionary biologist Theodosius Dobzhansky (1900–1975), the American paleontologist George Gaylord Simpson (1902–1984), the German evolutionary taxonomist Ernst Mayr (1904–2005), and finally the British biologist Julian Huxley (1887–1975) founded the Synthetic Theory of

Evolution, integrating additionally quite a number of neighboring disciplines to reconstruct the phylogenetic process of our own origin (Jahn et al. 1982; Jahn 2000; Junker 2004; Wuketits and Ayala 2005; Hoßfeld 2005a, b). The major principles of the "Synthesis" itself were subsequently enunciated between 1937 and 1944 in three seminal books. While Dobzhansky (1937) focused on the gene, Mayr's (1942) vantage point was the species and Simpson's (1944) perspective was on the higher taxa. Tattersall's (2000a, p. 2) assertion that "the Synthesis was doomed to harden, much like a religion," is controversial (see, e.g., Foley 2001). However, before we discuss the consequences of the "Synthesis" (for alternative terms, see Junker 2004), we shall have a closer look at paleoanthropology.

Fossils: Hypotheses, Controversies, and Approaches

In the early days of paleoanthropology, the main question was quite simple: Is there a fossil record that proves the existence of our ancestors from ancient times? The protagonists of paleoanthropology soon recognized the need for a more sophisticated empirical approach. The best basis for such a development existed in France, where Pierre Marcelin Boule, just mentioned, unified *in persona* all necessary attributes to establish a qualified paleoanthropology. His classic study of the Neanderthal skeleton from La Chapelle-aux-Saints (Boule 1911–1913) became a landmark in the history of human paleontology (Heberer 1955a). He aimed to understand the patterns of variation and the significance of anatomical differences. For this reason, Boule invented special instruments for quantification and simple statistical concepts to analyze the variation in human skeletons (Boule 1921, 1923; Boule and Vallois 1946, 1952). Boule established a paleontology of humans, later on called paleoanthropology, as a scientific discipline; but as evolution itself was still regarded as a widely speculative myth, the debate on human evolution "rose and fell like a tide in France, Germany, England, and the United States," as Trinkaus and Shipman (1993, p. 154) described the situation.

During the late nineteenth and the early twentieth centuries, an overemphasis quantifying procedures strongly affected the anthropological research, starting with the first occupants of anthropological chairs, Jean Louis Armand de Quatrefages de Breau (1855, Paris) and Marcelin Boule (1867, Paris), as well as Johannes Ranke (1886, Munich) and Felix v. Luschan (1900, Berlin). While Ranke was deeply opposed to the idea of human evolution, with Otto Schwalbe, just mentioned, Theodor Mollison (München), Felix v. Luschan (Berlin), Rudolf Martin (München), and Otto Schlaginhaufen (Zürich) successively advocated measuring techniques of every conceivable kind (Keller 1995; Chaoui 2004; Junker 2004; Hoßfeld 2005b). While Schwalbe was convinced that information on evolutionary history could only be gained from neo- and paleozoology, others focused predominantly on typological classification of prehistorical populations and neglected broader paleoanthropological questions. This can only be understood by the fact that the conventional wisdom of that time was that modern "races" arose from types that were already separate in the early Pleistocene. For this reason, there was a big problem when Gorjanović-Kramberger (1906) described the fossils from Krapina, excavated in 1899–1905, in a voluminous monograph as belonging to a "man-eating" population (Radovčić et al. 1988). As this thesis was accepted by one of the most outstanding anthropologists of the time, Aleč Hřdlicka (Prague, later on Washington), who pushed paleoanthropological research using his influential position at the Smithsonian Institution, Krapina became a big challenge to the scientific community (Henke 2006a). Notwithstanding the problem that the assumed anthropophagy/cannibalism of the Neanderthals remained controversial (see, e.g., Ullrich 1978, 1995, 2005a; Orschiedt 2008), it must be emphasized that Gorjanović-Kramberger (1856–1936) did excellent geological, paleontological, paleoanthropological, and archaeological research far ahead of the standards of his time (Frayer 2006; Henke 2006a). Tim White (2006, preface) lauded him in the centennial bibliography, edited by Frayer, thus: "His osteological and archaeological skills brought the valuable Krapina remains and their contexts to light. His paleoanthropological insights are embedded in a body of scholarly writings (1899–1929) foundational to modern paleoanthropology." And Frayer (2006, p. 3) refers to the publications of Jakov Radovčić (1988) and Radovčić et al. (1988):

"Gorjanović-Kramberger was first

1. to preserve and map a detailed stratigraphic profile of a Neandertal site,
2. to save virtually every Neandertal fossil he encountered from the four tooth germs to the 16, mostly complete patellas,
3. to number the fossils and record the levels from where they derived,
4. to save most of the faunal remains and all the stone tools,
5. to use the emerging field of radiology for documenting Neandertal morphology,
6. to conduct trace element analysis as a relative dating technique for confirming the contemporaneity of fossil mammals and humans,
7. to publish multiple, quality photographs of the hominin fossils and
8. to propose and document cannibalism in the fossil record based on burned specimens, cut marks and other bone damage."

What might he have done further? I confess that Gorjanović-Kramberger is my favorite as most innovative paleoanthropologist of his time (see Henke 2006a), followed by Gustav Schwalbe, anatomist at the University of Strasbourg, whose comparative morphologic research on fossils (e.g., *Pithecanthropus* from Java, Neanderthal calotte, Eguisheim, Brüx, *Oreopithecus*) was setting standards.

Compared to the two protagonists just mentioned above, the image of Hermann Klaatsch (1863–1916; Breslau) is colorful and iridescent; his research output varies from highly elaborated to suspect. The excavator (together with Otto Hauser [see, e.g., Drößler 1988; Drößler et al. 2006]) and researcher of the fossils from Le Moustier and Combe-Capelle was, e.g., wrong about the "sleeping position" of Le Moustier 1 (see Ullrich 2005a, b; Hoffmann 2003a, b), and his papers on Combe-Capelle are – to say the least – under suspicion, since it became known by the radiocarbon calibration of the newly recovered skull that the icon of the

Aurignacian, the earliest period of the Upper Paleolithic, is not older than late Mesolithic (Hoffmann et al. 2011; Henke 2011). These results are both irritating and suspicious, as Klaatsch "used the fossil record to support his polygenist view, and one way he could do so was to show that the Neandertals and Aurignacians (races he believed had separate origins) coexisted" (Wolpoff and Caspari 1997, p. 127; for more details, see Henke 2011).

Further controversies were born when descriptions of the Upper Paleolithic skeletons from, e.g., Chancelade, Grimaldi, Combe-Capelle, and Oberkassel, and also Neanderthals such as Le Moustier, La Chapelle-aux-Saints, La Ferrassie, and La Quina were excavated and published (Henke et al. 2006). There was special interest in the mandible from Mauer that was described in 1908 by Otto Schoettensack (1850–1912) as *Homo heidelbergensis* (Adam 1997; Wagner and Beinhauer 1997; Hardt and Henke 2007; Wagner et al. 2007; Henke and Hardt 2011).

In England, the motherland of Darwinism, there was for a long time little progress in paleoanthropology since the alleged Darwinists were obviously "no Darwinians in the modern sense" (Bowler 2001, p. 14). During the period from 1860 to 1940, a Darwinian style of explanation began to replace non-Darwinian developmental models stepwise, but a real breakthrough or turnover did not occur before World War II, largely due to the overwhelming influence of the paleontologist and geologist Arthur Smith Woodward (1864–1944) and the zoologist Sir Arthur Keith (1866–1955) as the leading authorities on human remains. Keith published *An Introduction to the Study of Anthropoid Apes* in 1896 (see also Keith 1911), followed by a monograph, *The Antiquity of Man*, which appeared in 1915. This publication on all-important fossil human remains founded his worldwide reputation and appeared in an enlarged edition in 1925. As can be seen from his textbook *Concerning Man's Origin* (Keith 1927), he was at that time less convinced than he had been 10 years before that modern humans and extinct "primitive" types had lived contemporaneously. In his volume *New Discoveries*, Keith (1931) rejected this interpretation given the strength of the arguments for an evolutionary branching of hominins. From the viewpoint of history of science, we have to ask why the leading "anthropologist" as well as his compatriot Sir Grafton Elliot-Smith (1871–1937) retained this view for so long in the face of compelling contrary arguments from paleoanthropological discoveries in Europe, Asia, and after 1925 in South Africa too.

One plausible explanation is that theories are the filters through which facts are interpreted as Popper (1959b) said. The reason why the English authorities adhered to wrong models combines the fatal misinterpretation of the Piltdown hoax with wishful thinking and cultural bias (Spencer 1990a).

The background of the Piltdown forgery has been analyzed and described many times (Spencer 1990a, b). The most plausible explanation why the *Eoanthropus dawsoni* hoax was so successful is that it seemed to provide proof for a missing link between apes and humans, using a mix of plesio- and apomorphic characters. Especially, the primitive jaw and dentition made *Eoanthropus* a more suitable intermediate candidate than *Pithecanthropus*. Even after the discovery of *Australopithecus* at Taung in 1924, and the excavation of the first *Sinanthropus* skull from

Zhoukoudian (Chou-kou-tien) shortly thereafter, Keith (1931) hypothesized that the Piltdown type arose from the main ancestral stem of modern humanity.

At that time, prominent British anthropologists such as Smith Woodward, Keith, and Elliot Smith were fixed on a European origin of humankind and absolutely in opposition to models of Asian and African origin. The expected phylogenetic sequence was that the cerebralization antedated the changes of the viscerocranium. As the plesiomorphic jaw and the apomorph brain of *Eoanthropus* complied with this expectation, it fitted perfectly into a scheme that was in fact wrong. One could comment on this "credibility of the plausible" in Plato's (The Republic, 382d) word: "And also in the fables of which we were just now speaking, owing to our ignorance of the truth about antiquity, we liken the false to the true as far as we may" (see Stoczkowski 2002, p. 168).

It took more than 40 years before Joseph S. Weiner (1915–1982), Sir Kenneth P. Oakley (1911–1985), and Sir Wilfrid Le Gros Clark (1895–1971) jointly exposed the hoax, although there was much skepticism and rumor earlier. Whoever the players were in this black mark in science, they were aware of the attractiveness and fascination of fossils, the rare resources that help to decipher our place in nature, and they obviously knew about the public appeal (Stringer and Gamble 1993; Walsh 1996; Weiner and Stringer 2003; overview in Harter (1996–1997) www; Turritin (1996–1997) www). The interpretation of the Piltdown fossil as a human precursor was partially responsible for the vehement dismissal of the first *Australopithecus* from South Africa. Dart's interpretation of the Taung child as missing link between ape and man yielded a storm of controversy (Tobias 1984). As Trinkaus and Shipman (1993, p. 206) put it: "The entire scientific coterie of Britain believed in the fossils without hesitation." This is remarkable insofar as Dart's discovery matched the prophecy of Darwin (1871, p. 202): "It is, therefore, probable that Africa was formerly inhabited by extinct apes closely allied to the gorilla and chimpanzee: and, as these two species are now man's nearest allies, it is somewhat more probable that our progenitors lived on the African continent than elsewhere."

To the extent that these and other indications for an extra-European "cradle of humankind" were deliberately ignored, the Piltdown case is a telling example of cut and dried opinions. Are there more self-fulfilling prophecies? It may be that Klaatsch's "contradictions and fanciful reconstructions" (see Zängl-Kumpf 1997, p. 575), and especially his polygenist view, influenced his interpretation of the Le Moustier and Combe-Capelle fossils (Henke 2011). If paleoanthropologists see what they please, small wonder that the scientific output of paleoanthropology during the first decades of the last century was very heterogeneous and confusing and more redolent of stagnation than progress. The evolutionary biology at those times was characterized by Mayr as "chaotic" (Tattersall 2000a, p. 2). But why?

First, even at the beginning of the twentieth century, Darwin's principles were widely misunderstood by anthropologists, who persisted in orthogenetic biological thinking or insisted on the theoretical split between natural sciences and humanities. Paleoanthropological theory and methodology were still in statu nascendi, judging from the literature of the time (Klaatsch 1899; Hrdlička 1914; Werth 1921; Weinert 1928; Wiegers 1928; Abel 1931; Hooton 1931; Keith 1931; Le Gros Clark 1934).

Second, the rediscovery of Mendel's work in 1900 demonstrated that new hereditary variation, i.e., mutation, occurs in every generation and every trait of an organism. The founding of genetics at the beginning of the twentieth century gave tremendous support to Darwin's theory and removed the objections to his postulates. However, the effects of genetics and population genetics were felt less in paleoanthropology than in the biology of recent populations and especially in aberrations like typological social biology, ethnogeny, and race typology. In Germany, social Darwinism and fatal concepts of hereditary and race dominated biological and medical research on living people. Paleoanthropology was of only minor interest, while the aim of anthropology was defined in the national socialist area or "the Third Reich," ". . . der deutschen Volksgemeinschaft zu dienen" (Reche 1937; see further Zmarzlik 1969; Gould 1983; Müller-Hill 1988; Seidler and Rett 1988; Weingart et al. 1988; Zängl-Kumpf 1992; Hoßfeld and Junker 2003; Junker 2004; Hoßfeld 2005a, b; Preuß 2009).

Third, various approaches to explain the process of hominization later on turned out to be politically highly incorrect: e.g., Kollmann created in 1885 the term "neoteny" suggesting that humans evolved from pygmies who had simply retained juvenile features during size increase (Kollmann 1902). The basic idea was that pygmy progenitors probably arose from juvenile apes that had lost the ancestral tendency to regress. Bolk (1926) argued in a long series of papers that man evolved by retaining the juvenile features of his ancestors. His "fetalization hypothesis" influenced evolutionary thinking on human origins and formed expectations of the appearance of transitional species. Bolk's theory was highly criticized and later on rejected by Starck (1962) because it was built on flawed arguments and a misinterpretation of Darwin's principles. Similar questions still resound in the current so-called evo-devo discussion, e.g., the evidence overwhelmingly suggests that neoteny, the retention of juvenile characteristics, was one of the most important processes involved in the origin of *H. sapiens* (Minugh-Purvis and McNamara 2002).

Fourth, the discovery of numerous Neanderthal skeletons (Table 1) caused new arguments in the discussion of gradualism versus continuity. Boule's monograph evicted the Neanderthals from our family tree, although some outstanding early twentieth-century paleoanthropologists like Aleč Hrdlička argued for gradualism, a controversy that continues to this day (overview in Wood and Lonergan 2008; Cartmill and Smith 2009; Henke and Hardt 2011; see also below).

Finally, the non-European fossils from, e.g., Java, China, and South Africa, could have been a strong stimulus for a wider view of human origins (for details on the history of contemporary excavations, see, e.g., fossil catalogues by Schwartz and Tattersall 2002, 2003, 2005; encyclopedia by Delson et al. 2000; and textbooks by Cartmill and Smith 2011). However, the prejudice of the leading British scientists crushed innovative hypotheses, and the critical skepticism on non-European roots of humankind due to Eurocentric perspectives and the fatal misinterpretation of the Piltdown man resulted in a stagnation of paleoanthropological theories. Dennell (2001, p. 51) puts it this way: ". . . it is depressing to realize how much of what was written on human origins before WWII was little more than prejudice masquerading as science, it is impossible to understand the study of human origins without reference to these prejudices" (see also Stoczkowski 2002; Hoßfeld 2005b; Junker 2004; Delisle 2007; Henke 2010a, 2011).

Paleoanthropology, Ideology, and Politics: Symptomatic Events

The misapplication of the Darwinian biological theory known as social Darwinism has been intensively discussed in another context (Mühlmann 1968; Zmarzlik 1969; Altner 1981a, b; Müller-Hill 1988; Weingart 1988; Hofstadter 1995; Hawkins 1997; Dickens 2000; Junker 2004; Hoßfeld 2005b). It is well known that this biological ideology was the "Janus head" of scientific Darwinism (Altner 1981b) from the beginning; however, it became highly influential and threatening after World War I, especially during the period of National Socialism in Germany. That paleoanthropology was no free zone of research stems from different reasons: first, because paleoanthropology was a subdiscipline of the highly politically involved physical anthropology (Weingart et al. 1988; Hoßfeld 2005a, b) and second, because racial thinking and racist theory were interwoven with all aspects of daily life (Bowler 1976; Stepan 1982; Bowler 1986, 1988, 1996, 1997, 2001; Proctor 1988; Weingart et al. 1988; Vogel 1983, 2000; Hoßfeld 2005a; Preuß 2009; Henke 2010b; 2011) – long before the fascistic "Third Reich" in Germany began. The following symptomatic cases are discussed to exemplify pars pro toto and exemplarily the impact of social Darwinism, ethnocentrism, and racism on paleoanthropology.

First Case: Hermann Klaatsch's Iridescent Image

As mentioned above, Hermann Klaatsch, a German comparative anatomist, anthropologist, prehistorian, and ethnologist who headed the Institute of Anthropology and Ethnology in Breslau (today Wrocław) since 1907 till his sudden death in 1916, was one of the most prominent paleoanthropologists in his time. He started an excellent career under the renowned anatomist Karl Gegenbaur (1826–1903; Heidelberg). The young researcher was impressively noticed by the scientific community of physical anthropologists at the Anthropology Congress 1899 at Lindau, where he presented a paper "About man's place among the mammals, especially the primates and the mode of evolution from an earlier form" (Klaatsch 1899, 1900). Advocating for the application of Darwinian principles to humans, Klaatsch received fierce criticisms from the doyens Virchow and Ranke (see Trinkaus and Shipman 1993; Wolpoff and Caspari 1997; Hoßfeld 2005a, b; Weniger and Klaatsch 2005; Henke 2006a, 2011). Evans (2010, p. 81) states that Klaatsch was the only physical anthropologist in German-speaking anthropological circles besides Gustav Schwalbe (and Hermann Schaaffhausen who died 1893) who championed Darwinism at the late 1890s. I would like to add Dragutin (Karl) Gorjanović-Kramberger who was trained in Germany and maintained close contacts to Schwalbe (see Henke 2006a) but was on slippery ground with his colleague from Breslau, after having refused joint research on the Krapina fossils. Trinkaus and Shipman (1993, p. 168) describe Klaatsch's motives for a cooperation as follows: "the fossils were someone's ticket into the brightly lit heart of anthropology, and Klaatsch lusted after them."

Klaatsch had done doubtless excellent innovative comparative research on primates and human fossils, e.g., the Neanderthal calotte (citations see Wegner and Klaatsch 2005); but, he didn't have priority access to human fossils. It has been suggested that this deficit gave the impetus for his Australian expedition from 1903 to 1907; however, there may have been other reasons, including the "*Out-of-Australia*" theory of his close friend Otto Schoetensack (1850–1912) who developed the notion that the human race in fact originated in Australia (Schoetensack 1901, 1904). In this he was influenced by Thomas H. Huxley who had visited Australia earlier, looking for the origin of mankind in the fifth continent. Corinna Erckenbrecht (2010, p. 49) suggests in her biographical-ethnological thesis on Hermann Klaatsch: "As Schoetensack himself was in poor health it was agreed upon that Klaatsch was to make the trip to Australia."

Her conclusions on the "Personality of Klaatsch as a Scientist and His Ethics of Collecting" are complex; on the one hand, she describes Klaatsch as "a very versatile, well educated and trained scientist who thought in major scientific and theoretical contexts on a high level." On the other hand, she reveals: "To enforce his personal research interests he acted in a very energetic, sometimes uncompromising way without respect for the feelings and values of the Aborigines." In contradiction to this attitude, "he publicly stood up for the rights of the indigenous people, criticized their treatment by the white Australian society" (Erckenbrecht 2010, p. 49). Though one may explain his conflicting behavior as compromisingly assertive, on the one hand, and paternalistically protective, on the other hand, as an attitude of social Darwinistic superior-inferior thinking, and typical of a colonialist mentality, it is in modern terms of political correctness simply unethical.

For historiographical reasons, we must ask how this personality may have influenced Klaatsch's paleoanthroplogical research. In 1907 Klaatsch returned to Germany and cooperated highly successfully with the Swiss art dealer and archaeologist Otto Hauser (1874–1932; Drößler 1988; Hoffmann 2003a, b; Drößler et al. 2006), excavating and analyzing the famous skeletons of Le Moustier and Combe-Capelle (Hoffmann 2003a, b; Ullrich 2005a). The French historian Benoit Massin (1996, p. 88) describes that Klaatsch, "previously an advocate of the unity of mankind," made a dramatic about-face at the 1910 meeting. On the basis of comparative morphological study of prehistoric human races, Klaatsch argued that there were two main branches of human evolution: one Western stock from which emerged the gorilla and Neanderthal man and one Eastern stock for the orangutan and the Aurignacian race (Klaatsch 1910a, see pp. 91ff; see further Klaatsch 1911; Henke 2011).

Evans (2010, p. 65) adds: "Klaatsch's polygenist ideas won few adherents, however, and the resistance that he engendered, confirmed the monogenist consensus." From the beginning, Combe-Capelle's high early Aurignacian age was

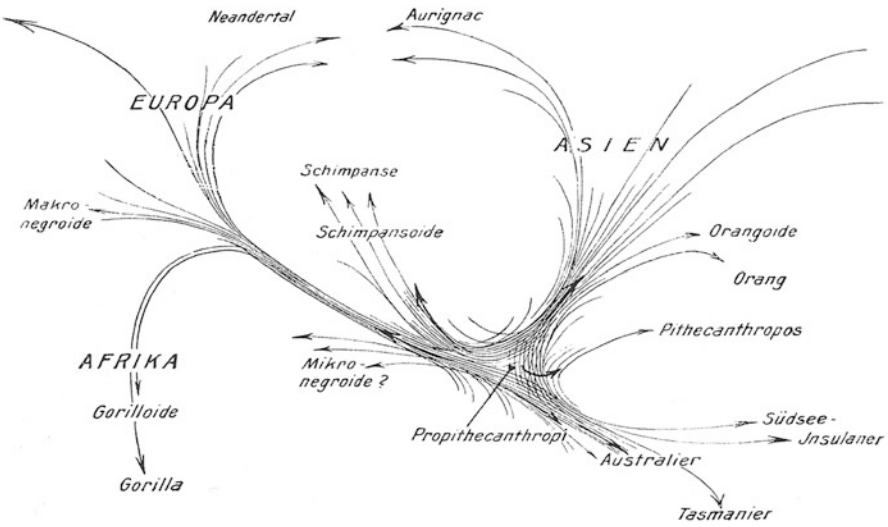

Fig. 6 Klaatsch's polygenist tree, assuming different roots of the Neanderthals and the Aurignac Man (Klaatsch 1911, p. 480)

heavily criticized, though it fitted perfectly in Klaatsch's phylogenetic scheme (Fig. 6). As it recently turned out after the surprising rediscovery of the individual and radiocarbon dating that showed merely an early Holocene age (Hoffmann et al. 2011), there arose many unpleasant questions, e.g., the suspicion that Klaatsch and Hauser might have preferred the greater age for unscientific reasons. Though this isn't proof, there remains a bad aftertaste; however, *in dubio pro reo*! As has been demonstrated by a historical analysis of the literature on Combe-Capelle (Henke 2011), the false calibration of the Upper Paleolithic icon Combe-Capelle had tremendously influenced paleoanthropological theories during the first half of the last century. This is not trivial, insofar as the "Aurignac Man" played a prominent role in the contemporary racial typologies, e.g., the Nordicism, an ideology of racial supremacy and "master race" racism (e.g., Weinert 1941). Apart from this, one might mention that both authors profited – Klaatsch earned scientific praise and Hauser additionally thousands of Reichsmarks because Combe-Capelle was thought to be the oldest anatomically modern human fossil worldwide: *Honi soit qui mal y pense*! Though historians will quite likely not be able to solve the problem of whether the diagnosis was a deliberate move on the part of Klaatsch, or was simply a self-fulfilling prophecy, this case should be a lesson "to see what we are looking at, not to put it in a preferred scheme" (sensu W.W. Howells 1993). Furthermore, this case should make us cautious, as not every scientist knows the guidelines of good and ethical practice (see Wuketits 2010, 2012), and sociobiologists would comment laconically: Never suppose a positive cause, if there could be a negative one.

Second Case: Political Constraints, See What "We" Want

That archaeological and paleoanthropological researches were not spared by the ideology of the national socialists is documented, e.g., by the fact that the Neanderthal Museum, which had been inaugurated on May 1, 1937, was closed by order of the Reichsleiter für Vorgeschichte, Reinertz, on March 3, 1938. The arguments were that the museum, which should demonstrate "Deutsche Urgeschichte, soweit sie mit dem Neandertal in engster Beziehung steht," did not pass the evaluation of an NS commission (Beckmann 1987).

This case may be a warning that (paleo)anthropological exhibitions in museums and all kinds of popular scientific media are interpretatively filtered through ideologies and personal perceptions of the curators and authors (see, e.g., Ickerodt 2005; Sarasin and Sommer 2010). Additionally, one must be aware that this equally applies to all kinds of science and knowledge transfer (Henke 2007a, 2010a).

Third Case: Franz Weidenreich, Politically Unwanted

Even more inimical to the development of paleoanthropology during the Nazi era was the fact that the most outstanding German paleoanthropologist at that time, Franz Weidenreich (1873–1948), lost with effect from December 31, 1935, his *venia legendi* at the Johann Wolfgang Goethe University due to the persecution of the Jewish population (Hertler 2007). His emigration to the USA was an irreplaceable loss for anthropology in Germany.

Exempla docent – after Hubert Markl, former president of the Max Planck Society, we should learn from good *and* bad experiences in our history; in the latter context, history of science plays a most significant role. The well-known biography of most famous scientists, e.g., Albert Einstein, Ernst Mayr, and Erwin Chargaff, is impressive proof that "science serves with heads." Markl's (1988) identical worded article "Wissenschaft dient mit Köpfen" convincingly shows that the scientific community needs internationality: "Wir wissen auch, daß manche dieser Netze buchstäblich zum lebensrettenden Sprungtuch auf der Flucht vor Verfolgung geworden sind und immer wieder werden. Niemand hat diese Weltbürgerschaft des Wissenschaftlers überzeugender deutlich gemacht als Albert Einstein" (Markl 1988, p. 116–119).

Since Franz Weidenreich was involved in research on the largest *H. erectus* sample from a single locality, Zhoukoudian, paleoanthropology in Germany lost a vital contact with the international scientific community. Thanks to Weidenreich (1943), brilliant documentation, casts, and descriptions survived of the "*Sinanthropus*" – skulls which were lost during an attempt to ship them to the USA (Shapiro 1974) – and, equally important, Weidenreich is viewed as the founder of the "multiregional theory of human evolution" (Wolpoff and Caspari 1997; Wolpoff 1999; Hertler 2007; for a popular scientific biography, see Hartkopf 2012). Weidenreich's illustration (see Fig. 7) of the process of human evolution became known as "trellis," a network of populations by gene exchanges. Wolpoff and Caspari (1997, p. 200) explicate the graphic as follows:

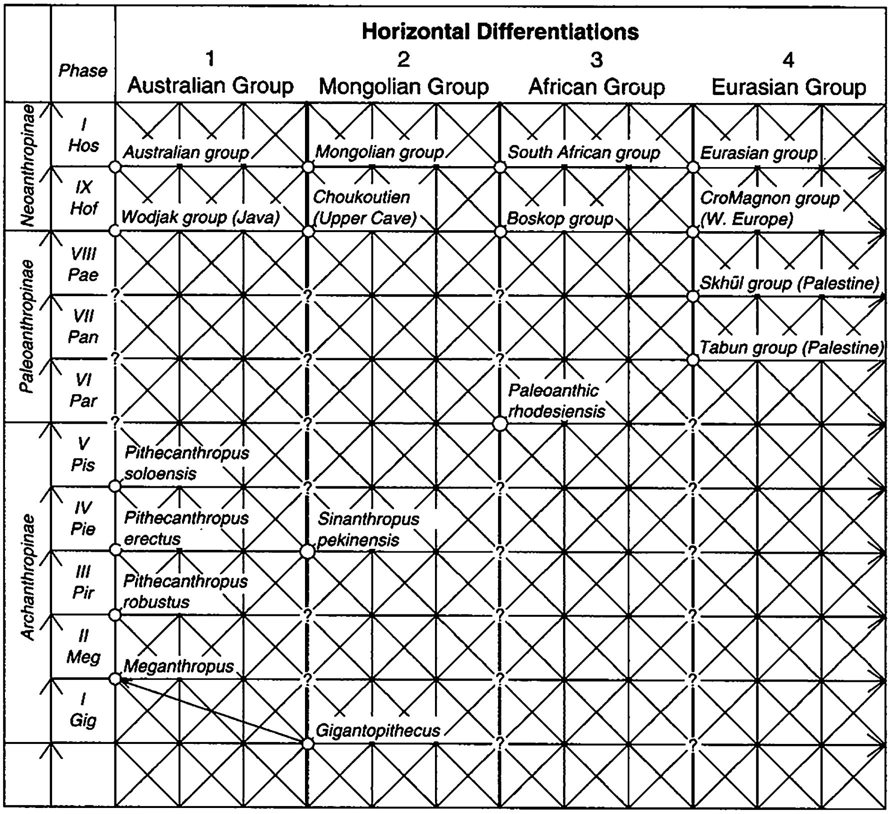

Fig. 7 Pedigree of the Hominidae, so-called trellis, from Weidenreich (1946, p. 30) (Redrawn by Wolpoff and Caspari 1997, p. 201)

"[trellis], a network with vertical lines passing through the main stages of evolution, horizontally separated into the main centers of evolution (distribution and specialization), and the diagonal connections between them reflecting the patterns of genetic exchanges," in Weidenreich's own explanation, "a graphic presentation of the conception of the hominid group as one species" (Weidenreich 1946, p. 30).

This "trellis" or "lattice" expresses Weidenreich's idea that evolution is transformation, in close connection with interbreeding. As the trellis metaphor caused a lot of misinterpretations (e.g., by Howells 1959, 1993) and vehement criticism from cladists and "splitters," we will come back to this controversy later (see below).

Fourth Case: Delayed Awakening

It is widely known that during the Third Reich, German physical anthropologists were strongly involved in the functioning and ideological underpinning of the Nazi

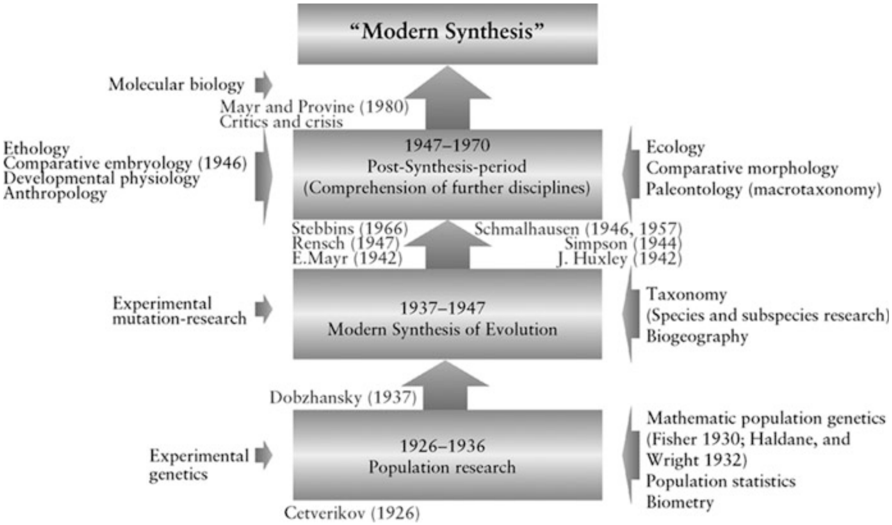

Fig. 8 Development of the theoretical basis of the biological sciences (After Jahn 2000, modified)

regime. In an oppressive manner, e.g., Schafft's (2004) historical analysis "From Racism to Genocide" reveals anthropology's entanglements and unmasks blatant cases of pseudoscience. Therefore, it is not surprising that paleoanthropology was also fraught with racist ideology, though on the international level, there was groundbreaking change in evolutionary thinking (Junker 2004; Hoßfeld 2005b; Mayr 1988). The protagonist of evolutionary thinking, Ernst Mayr (1904–2005), a trained German zoologist, left his homeland in the year 1931 and did his research at the AMNH in New York and after 1953 at the Harvard University in Cambridge. He denied that the "Synthesis" (see Fig. 8) was a revolution; his conclusion was: "It was not so much the discovery of new facts that characterized the synthesis as the removal of misunderstandings. The period from 1859 to 1935 had suffered from being dominated by erroneous conceptualizations, such as essentialism (typology), a belief in an intrinsic tendency toward progress, a misunderstanding of the nature of inheritance and of mutation, a failure to understand the nature of populations and the uniqueness of individuals, and of other erroneous concepts" (Mayr 1988). When misunderstanding of evolutionary principles was commonplace, no wonder German paleoanthropologists didn't conduct acknowledged science. Above all, it must be stressed in this context that the "misunderstandings" mentioned by Mayr in no way equate with wrong conceptions of racial and political ideologies that so horribly became virulent during the era of National Socialism in Germany; there is no excuse for racial discrimination and all kinds of racism from a false understanding of the principles of human evolution. Further, there is absolutely no doubt that a large part of anthropologists and human geneticists were involved in such racist activities, in some cases perhaps only passive, but in many demonstrable cases highly actively, in roles ranging from deskworkers (“Schreibtischtäter”) to racist executioners (Stocking 1988; Proctor 1988; Weingart et al. 1988; Massin 1993, 1996; Hoßfeld 2005b; Schafft 2004).

From the perspectives of paleoanthropology and the history of science, it is noteworthy that during World War II, the first edition of Gerhard Heberer’s compendium “Die Evolution der Organismen” appeared (Heberer 1943). The anthropogenetical contributions of the multifaceted volumes deal, e.g., with comparative anatomy (v. Krogh 1909–1992), paleontology (Gieseler 1900–1976), ethology, and archaeology (Weinert 1887–1967). However, in the view of the scientific historians Hoßfeld and Junker (2003) and Hoßfeld (2005b), the chapter authored by Otto Reche (1879–1966) is the only one that takes the model of synthetic Darwinism into account. I’m in full agreement with the following overall assessment: “. . .[es] handelt sich über weite Strecken um vergleichende Untersuchungen zur Stammesgeschichte der Menschheit, wie sie bereits im 19. Jahrhundert angestellt wurden, ergänzt durch neuere Daten aus Serologie und Paläontologie” (Hoßfeld and Junker 2003, p. 107). Of particular interest, Junker and Hoßfeld (2002, p. 242) mention that the volumes of “Evolution der Organismen” are “with few exceptions – without any reference to national socialist ideas”. The major exception is Heberer’s preface, and the authors assume “that Heberer as editor and the publisher (Gustav Fischer) have demanded ideological neutrality.” The biological impact on paleoanthropology was minor, since in practice fossil discoveries came into the literature through collaboration between the archaeologists who excavated them and the anatomists who described them. Physical anthropologists with a biological background, such as Gerhard Heberer (1901–1973), a convinced national socialist who was induced into the SS by Heinrich Himmler (Deichmann 1995; for biography, see Hoßfeld 1997), were rare (Massin 1993, 1996). These theoretical deficits caused consequences in paleoanthropological thinking, especially concerning Darwinian and Neo-Darwinian thoughts. And I agree with Foley’s (2001, p. 6) statement: “Archaeologists and professors of anatomy seldom made a rich cocktail of Darwinian theory.” In general the descriptive casuistic and more or less narrative approaches in paleoanthropology hold true throughout the period under discussion, and for early postwar times, in Germany as well as in other countries (Tattersall 2000a; Foley 2001; Henke 2010a, b). The period leading up to World War II had seen the emergence of the evolutionary synthesis, but not until the 1950s did innovative biological principles and methods begin to inform paleoanthropological science too (Spencer 1984; Mayr 1988; Delisle 1995; Hoßfeld 1997, 2005b; Jahn 2000; Tattersall 2000a; Foley 2001; Corbey and Roebroeks 2001b; Hoßfeld and Junker 2003; Junker 2004).

What’s the message in all of this? Firstly, research is embedded in an ongoing process of paradigmatic and methodological innovation and needs permanently a critical evaluation. This can most effectively be achieved by international standards. Secondly, physical anthropologists, mainly the negligibly small group of paleoanthropologists in Nazi Germany, missed correctives from outside, or more correctly, many protagonists – like Gerhard Heberer, Wilhelm Gieseler, and Hans Weinert – felt comfortable under a National Socialistic regime in spite of the knowledge of injustice against humanity (e.g., Vogel 1983; Massin 1993, 1996; Hoßfeld 2005a, b). It should also be mentioned that most of them continued their careers in postwar times (Saller 1961; Junker 2004; Preuß et al. 2006; Preuß 2009). Thirdly, every scientist should be aware of the ethical standards of his discipline and should follow ethical rules and the recommendations of good science practice, as personal responsibility will always remain (see Max-Planck-Gesellschaft (1984); AAPA Statement on Biological Aspects of Race (1996) – and ongoing discussion, e.g., Cartmill 1999; Brattain 2007).

Keeping Pace with Other Sciences: Toward a "New Physical Anthropology"

The selected examples given here demonstrate that social and political reasons far removed from paleoanthropology are important; and in this context Dennell (2001, p. 45) reminds us "that paradigmatic shifts in palaeoanthropology occur in response to a wider world, and are not wholly dependent on internal evidence or individual personalities alone."

After World War II, the world opened up, causing drastic changes for paleoanthropology too. Ethnocentricity and old-fashioned typological methodologies of physical anthropology and evolutionary biological thinking were subjected to critical review. The reevaluation of paleoanthropology was mainly carried out by US-American anthropologists like Sherwood Washburn (1911–2000; see Howell 2003; Marks 2000) and especially Francis Clark Howell (1925–2007). His younger colleague Tim White praised him in an obituary (published by Sanders 2007, p. 1, www): "Clark's central importance since the 1950s has been to make paleoanthropology what it is today – that is, the integration of archaeology, geology, biological anthropology, ecology, evolutionary biology, primatology and ethnography." Besides Clark Howell, one must mention the British-born Kenyan Louis S. B. Leakey (1903–1972) (see Isaac and McCown 1976) as a further prominent innovator of the discipline. Desmond Clarke (1976, p. 541) appreciation – by his discoveries, and his brilliant personality, he gained the admiration and captured the imagination of the world – meets it exactly.

In summary, paleoanthropology needs, like all sciences, a properly evaluated underlying theory and methodology (Oeser 2004; Ruse 2005) and can only flourish in open-minded cosmopolitan societies. Furthermore, every discipline needs exceptional personalities too, even if teamwork dominates, and I would like to add, as far as paleoanthropology is concerned, also those with charisma since human evolution is a topic of extreme public interest and with generosity, as "sites" and "nuggets" should be shared according to fair rules (e.g., see EVAN Society, www; NESPOS Organization). These preconditions were developed in the second half of the last century; let's have a closer look at them.

Diversification of Anthropology in the Second Half of the Twentieth Century

Early Post-World War II Period

The principal architects of the evolutionary synthesis mentioned previously gained more and more influence in World War II and postwar times, and their ideas shaped the field of biological anthropology including paleoanthropology (Tattersall 2000a; Foley 2001; Levinton 2001; Mayr 2001; Junker 2004; Hoßfeld 2005b; Wolpoff 2003). Although the fossil record had steadily increased, it was still a challenge to reconstruct the raw outlines of human evolution from the tiny catalog of human skeletal remains. There was tremendous progress as the hominin status (at that time taxonomically termed hominid) of the small-brained, bipedal australopithecines became accepted due to the new finds from fossils from Kromdraai Cave, excavated by Robert Broom (1866–1951) in 1938. The successful excavation of further exciting australopithecine fossils from the cave sites Sterkfontein, Makapansgat, and Swartkrans by Broom and John T. Robinson (1923–2001) after 1947 was the continuation of the success story of human paleontology in South Africa that had started with Dart's description of the Taung child in 1924, had continued with Broom's excavations (Broom and Scheffers 1946), and lasts to the present day (overviews in Grine 1988; Sperber 1990; Partridge et al. 2003; Tobias 2005; Berger et al. 2010; Balter 2011). The diversity of the australopithecine taxa became especially obvious from the megadont *Paranthropus* from Swartkrans, "Another new type of fossil ape-man," as described by Broom (1949, 1952) and Broom and Scheffers (1946). In addition, human origins became even more complex and debatable as the "East Side Story" (sensu Coppens 1994) developed, having started with Wilhelm Kattwinkel's and Hans Reck's explorations in 1911, continued still with scant success by Louis and Mary Leakey in the 1930s, and came into major focus by the discovery of *Zinjanthropus boisei*, a hyperrobust australopithecine (Leakey 1959), and culminated in the successful Afar Research Expedition (Johanson et al. 1978) and many more recent projects.As the dating of known specimens was limited to the relative time scale "older than/younger than," and as the techniques of absolute dating were still unknown (Oakley 1964), there was a lot of uncertainty in the calibrations. The overall picture was a stepwise adaptive evolution from primitiveness to high-order hominids/hominins with modern-shaped bodies and cultural skills. The evolutionary ladder reached from the gracile and robust australopithecines, i.e., very apelike species, to the *Pithecanthropus* and *Sinanthropus* species. These had been lumped with the European *H. heidelbergensis* in a single species, *H. erectus*. This simple gradualistic model regarded the Middle Pleistocene "Java man," "Peking man," and the "Mauer man" as intermediate stages between the early taxa from Africa and the later Neanderthals, a well-documented fossil human group from late Ice Age sites in Europe and western Asia. Little wonder that in this confusion, paleoanthropologists welcomed Mayr's and Dobzhansky's simplifying message that only one kind of hominid (new systematic: hominin) could have existed at any time and that virtually all developments in human evolution since Java man had taken place within the single, albeit variable, species *H. sapiens*. Tattersall (2000a, p. 3) suggests that Dobzhansky was influenced "by his newly arrived New York neighbor Franz Weidenreich, nowadays hailed as the father of 'multiregional continuity'."

Ernst Mayr took the position that at the most three successive species could be discerned within the genus *Homo*: *H. transvaalensis* (the australopithecines), *H. erectus*, and *H. sapiens* (including the Neanderthals). Few paleoanthropologists followed these pronouncements in every detail; however, schemes of hominin evolution routinely came to incorporate the synthesis' basic assumptions, whereby evolutionary change consisted simply of the gradual modification of lineages, usually no more than one, over long spans of time. Human evolution thus became the story of a long, single-minded struggle from primitiveness to perfection which became highly criticized (more later; overview in Tattersall 2000a; see further Foley 2001; Wolpoff 2003). Successively there arose different problems from Mayr's simplified model.

First, the evolutionary model was in contradiction to the mosaic pattern of the erroneously ancient, heavily encephalized Piltdown man. This problem disintegrated when in 1953, Piltdown was declared a hoax by authorities at the British Natural History Museum (Spencer 1990b). Second, paleoanthropological results were severely flawed due to arbitrary taxonomic approaches (see Table 2). For this reason, there was a genuine need for the revision of the overabundance of species and genus names, which had been applied liberally more or less without a taxonomical concept to hominid fossils. The taxonomic revision of the hominid/hominin sample asked for a strict consensus regarding the underlying species concept and how to reconstruct phylogenetic relationships (Washburn 1951, 1953; Hennig 1950, 1966; Remane 1952; Eldredge and Cracraft 1980; Eldredge 1993; Waegele 2000; Gould 2002; Wiesemüller et al. 2003; Lieberman and Vrba 2005; Wood and Lonergan 2008; Henke and Hardt 2011; Willermet 2012). Niles Eldredge's (1993) pressing issue "What, if anything, is a species?" is symptomatic of the need to solve principle taxonomic questions still today (however, this is not an exclusive problem of paleoanthropology; e.g., Hunt 2003). Third, the uncertainty of the temporal allocation of fossils reflected the absence of absolute dating techniques (Oakley 1964; Bishop and Miller 1972). In sum, it became more and more obvious that there was tremendous need for a new and precise strategy of physical anthropology within the frame of a *revised* Synthetic Theory of Evolution (Cartmill 1990a, b; Bowler 1997; Eldredge 1993; Levinton 2001; Tattersall 2000a, b; Lieberman and Vrba 2005; Willermet 2012).

In the immediate postwar period, there arose a body of theory that swept away a host of conflicting notions about the nature of the evolutionary process. The elegantly simple concept stated that all evolutionary phenomena could be ascribed to a single mechanism: the gradual change of genes and gene frequencies within lineages of organisms under the guiding hand of natural selection (Cartmill 1990a, b). Though the innovative population genetic approaches in the 1920s of Ronald A. Fisher (1890–1962), John B. S. Haldane (1892–1964), and Sewall G. Wright (1889–1988) were obviously of great importance for the field of paleoanthropology

Table 2 Hominin taxonomy: Genera and species designations of former and current taxa, temporal and geographical ranges. Except *Homo sapiens*, all the other taxa are extinct (Adapted from Collard (2002), modified and enlarged; see further Groves (2001); Henke (2003b); Wood and Lonergan (2008))

Genus *Homo* Linnaeus, 1758 [including the following genera: *Anthropopithecus* Dubois, 1892, *Pithecanthropus* Dubois, 1894; *Protanthropus* Haeckel, 1895; *Sinanthropus* Black, 1927; *Cyphanthropus* Pycraft, 1928; *Meganthropus* Weidenreich, 1945; *Atlanthropus* Arambourg, 1954; *Telanthropus* Broom and Robinson, 1949; earliest appearance in the Pliocene, worldwide distribution]
Homo sapiens Linnaeus, 1758. Pleistocene to present, worldwide
Homo neanderthalensis King, 1864. Pleistocene, Europe, Western Asia, Siberia, Near East
Homo erectus (Dubois, 1892), Weidenreich, 1940. Pleistocene, Asia, (Europe?, Africa ?)
Homo heidelbergensis Schoetensack, 1908. Pleistocene, Africa and Europe
Homo rhodesiensis (cf. *heidelbergensis*) Woodward 1921. Pleistocene, Africa
Homo helmei Dreyer, 1935. Pleistocene, northern and East Africa
Homo soloensis Dubois, 1940. Middle Pleistocene, Southeast Asia
Homo modjokertensis v. Königswald, 1950. Early Pleistocene, Indonesia
Homo mauritanicus Arambourg, 1963. Middle Pleistocene, Northwest Africa
Homo habilis L.S.B. Leakey et al., 1964. Plio-Pleistocene, Africa
Homo ergaster Groves and Mazák, 1975. Pleistocene, Africa and Eurasia
Homo palaeojavanicus Sartono, 1981. Middle Pleistocene. Southeast Asia
Homo rudolfensis (Alexeev, 1986), Wood 1992. Plio-Pleistocene. East Africa and Malawi
Homo antecessor Bermudez de Castro et al., 1997. Early Pleistocene, Western Europe
Homo georgicus Gabunia et al., 2002. Early Pleistocene, Northwestern Asia
Homo cepranensis Mallegni et al., 2003. Early Pleistocene, Italy
Homo floresiensis Brown et al., 2004. Late Pleistocene–Early Holocene, Indonesia [“Denisova Man,” sometimes designated as “Homo denisovan” is not regarded as a species by Krause et al. (2007, 2010)]
Genus *Australopithecus* Dart, 1925 [includes the genus *Plesianthropus* Broom, 1938]. Pliocene, Africa
Australopithecus africanus Dart, 1925. ca. 3.0–2.5 Ma; South Africa
Australopithecus afarensis s.s. Johanson et al., 1978. ca. 3.7–3.0 Ma; Ethiopia, Tanzania, Kenya
Australopithecus anamensis M.G. Leakey et al., 1995. ca. 4.2–4.0 Ma; Kenya
Australopithecus bahrelghazali Brunet et al., 1996. ca. 3.5–3 Ma; Tchad (North Africa)
Australopithecus garhi Asfaw et al., 1999. ca. 2.5 Ma; Ethiopia
Australopithecus sediba Berger et al., 2010. ca 1.78–1.95; South Africa
Genus *Paranthropus* Broom, 1938 [includes *Zinjanthropus* L.S.B. Leakey 1959, *Paraustralopithecus* Arambourg and Coppens, 1967]. Plio-Pleistocene, Africa
Paranthropus robustus Broom, 1938. ca. 1.5–2.0 Ma; South Africa
Paranthropus boisei L.S.B. Leakey, 1959. ca. 2.3–1.4 Ma; Tanzania, Kenya, Ethiopia, Malawi
Paranthropus aethiopicus Arambourg and Coppens, 1968. ca. 2.7–2.3 Ma; Ethiopia, Kenya, Tanzania (?)
Genus *Ardipithecus* White et al., 1994. Pliocene, East Africa
Ardipithecus ramidus s.s. White et al., 1994. ca. 4.5–4.3 Ma, Ethiopia
Ardipithecus kadabba Haile-Selassi et al., 2004. ca. 5.8–5.2 Ma, Ethiopia
Genus *Kenyanthropus* M.G. Leakey et al., 2001. Pliocene, East Africa
Kenyanthropus platyops M.G. Leakey et al., 2001. ca. 3.5–3.3 Ma, Kenya

(*continued*)

Table 2 (continued)

Genus *Orrorin* Senut et al., 2001. Miocene, East Africa
Orrorin tugenensis Senut et al., 2001. 6.6–5.7 Ma, Tugen Hills, Kenya
Genus *Sahelanthropus* Brunet et al., 2002. Miocene, northern East Africa
Sahelanthropus tchadensis Brunet et al., 2002. ca. 7–6 Ma, Tchad

too, and notwithstanding that the protagonists of the *Synthetic Theory of Evolution* had given special attention to this area at the time when the discipline was absorbing its theoretical underpinnings, there was need for active initiatives by (paleo-) anthropologists themselves. First, the rejection of the typological approach was required before population genetic thinking could board the New Physical Anthropology sensu Washburn in the 1950s. However, many challenges had to be overcome, and some are still waiting to the present day (Vogel 1983; Foley 1987; Martin 1990; Delisle 1995; Wolpoff 1999; Tattersall 1995, 2000a, b; Foley 2001; Levinton 2001; Gould 2002; Jobling et al. 2004; Cartmill and Smith 2009; Fuentes 2010).

New Strategies, Concepts, and Challenges in Physical Anthropology

In the early 1950s, there began an intensive discussion on the strategy of physical anthropology, i.e., the body of scientific theory and techniques with which it attacks its problems. Washburn (1951, 1953) was one of the protagonists of a new conception which was formulated in the new version shown in Fig. 9. The main step was to reduce the speculative and narrative part of physical anthropology in favor of thorough hypothesis testing. Cartmill (1990b, p. 189) puts it this way: “No doubt, people are different from the apes; but it is our job as scientists to explain those differences. Explanation, as opposed to mere storytelling, has to invoke law-like regularities connecting causes and effects.” This then was the challenge facing the evolutionary biological sciences (Popper 1968). Of greatest importance for the renewal of physical anthropology were the rejection of typological concepts and an increased interrelationship between the different parts of anthropology. The change from descriptive studies to the investigation of process and behavior brought about the integration of the problems of human evolution in the vast scientific field of mammalian evolutionary biology. Solutions to problems consequently followed, on the one hand, from paleontology, primatology, genetics, population genetics, ecology, and diverse medical sciences and, on the other hand, from the study of archaeology and ethnology.

The great challenge of human evolutionary biology became the cultural factor, as adaptations, human migrations, mating systems, population densities, diseases, and human ecology all became factors seen as essential to the explanation of our special human way of life (Washburn 1953; Vogel 1966; Osche 1983; Foley 1987, 2010; Tattersall 1995, 1998, 2002, 2012; Wolpoff 1996–97; Cartmill and Smith 2009; Foley and Gamble 2009; overviews in Henke and Rothe 1994;

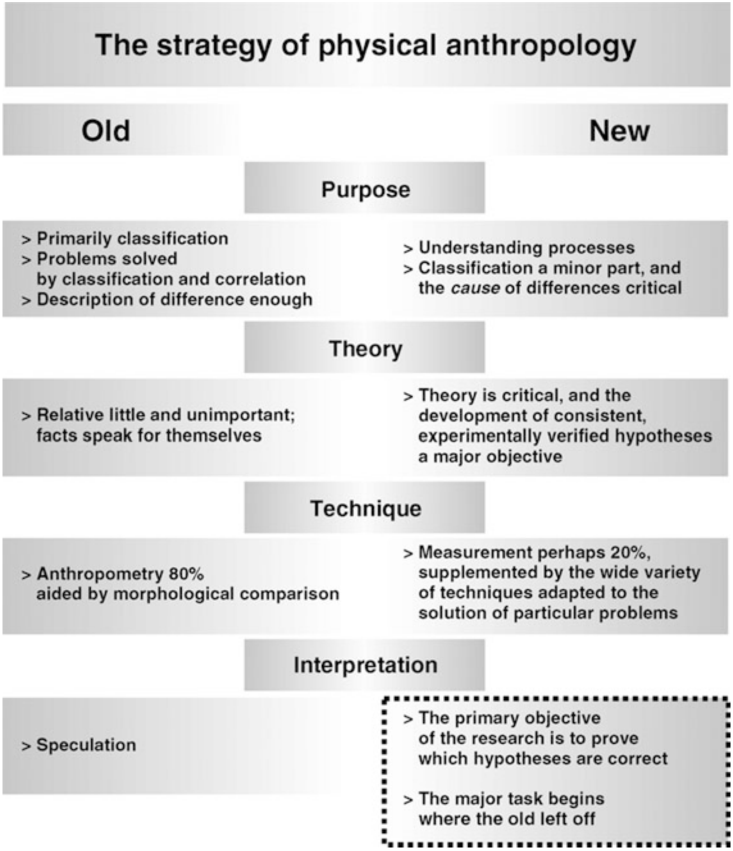

Fig. 9 The strategy of physical anthropology (Redrawn from S.L. Washburn 1953, modified)

Delson et al. 2000; Wood 2011; Begun 2013). Washburn's (1953, p. 726) prognosis was: "If we would understand the process of human evolution, we need a modern dynamic biology and a deep appreciation of the history and functioning of culture. It is this necessity which gives all anthropology unity as a science."

The recognizable post-World War II shape of paleoanthropology resulted from the belated acceptance of neo-Darwinian principles of evolutionary biology, which were successively brought together in the 1930s and 1940s and unified evolutionary biology under a single roof, sweeping away a huge package of mythological narrative thinking (Henke and Rothe 2006; Goodrum 2009). Delisle (1995, p. 217) suggested "that the evolutionary synthesis directly influenced on human paleontology [during the decade 1950–1960] every day practitioners in human paleontology almost solely through the general concepts and methods of the new systematics. Instead of being only a common core shared by a host of disciplines, the evolutionary synthesis should also be defined by the extent to which that core has been guiding current research in any one field."

Washburn's concept of a *New Physical Anthropology* was received with enthusiasm by the scientific community, and the impetus for the development of the individual subdisciplines has been tremendous (see Fuentes 2010; Lille and Kennedy 2010; Larsen 2010), though not by all, e.g., the German anthropologists who slumbered through the theory change (see Vogel 1983; Henke and Rothe 1994, 2006). Despite its generally positive reception, vehement critics have appeared since the 1970s, as it was asked: Was the Modern Synthesis a real step forward in the right direction? The dispute over *evolutionary theory* opened with a stimulating paper on "Punctuated equilibria: an alternative to phyletic gradualism" by Niles Eldredge and Stephen J Gould (1972), originally presented at the *Annual Meeting of the Geological Society of America* in 1971. This was an astonishing contribution, though not entirely unexpected as other evolutionary models, e.g., Weidenreich's "trellis" (Fig. 7), had been under heavy criticism for a long time (see Howells 1959; overviews in Shipman 1994; Wolpoff and Caspari 1997). Gould and Eldredge contrasted the hypothesis of "punctuated equilibria" [which proposes that evolutionary changes occur in geologically rapid events of branching speciation called cladogenesis] against the hypothesis of "phyletic gradualism" [which assumes that evolution generally occurs by anagenesis, uniformly, and by the steady and gradual transformation of whole lineages]. Interesting enough, that research on the evolution of Paleozoic invertebrates had guided Eldredge (1971) to the suggestion that allopatric speciation might be the resolution instead of gradual evolution. His enlightening idea that the pattern of descent is marked by long periods of stasis alternating with rapid changes caused great evolutionary debate (e.g., Wolpoff 1971, 1980, 1996–1997; Eldredge and Gould 1972; Gould and Eldredge 1977; Gould 2007; Tattersall 1994, 1998, 1999, 2000a, 2002; Eldredge 1995; Wolpoff and Caspari 1997; Foley 2001; Cartmill and Smith 2011).

Eldredge's (1995) review of the history of the twentieth-century evolutionary theory is entitled "Reinventing Darwin" and deals from an insider perspective with the confrontation of the "Ultra-Darwinians" and the "naturalists," whose disputes were not always collegial and unpolemic (see, e.g., Wolpoff and Caspari 1997). Those who want to know more about "The Growth of Paleobiology as an Evolutionary Discipline" should read David Sepkoski's (2012) "Rereading the Fossil Record"; we will concentrate here solely on the history of paleoanthropology as a subdiscipline of paleobiology.

Just at the time when the "reinvention" by Gould and Eldredge started, Ian Tattersall had finished his thesis on "Subfossil Lemurs of Madagascar" at Yale University. Inspired by his own research on the vast diversity and variability of the lemurs in combination with the burgeoning (*re*-)evolutionary views in the 1970s, he started an extremely fruitful cooperation with Niles Eldredge, whose colleague he became at the AMNH in New York (e.g., Eldredge and Tattersall 1982). Reviewing the last half-century, Tattersall (2000a, p. 2) reaches the following crushing conclusions about the influence of the Dobzhansky et al.'s "Synthesis": "Sadly, however, the Synthesis was doomed to harden, much like a religion, into a dogma: a dogma whose heavy hand continues to oppress the science of human origins a half-century later." Tattersall (2000a, p. 5) complains that paleoanthropology was laggardly "Slow to absorb the principles of the Synthesis, palaeoanthropology has been equally slow to augment these principles with recognition of the multifarious complexities of the evolutionary process." He gives many convincing arguments for this judgment, e.g., Dobzhansky's lumping of the fossil hominids, with the conclusion "that there existed no more than a single hominid species at any one time level" (Dobzhansky 1944, pp. 261–262). Furthermore, he criticizes Mayr's claim that humans did not speciate (Mayr 1950), a position which opened for Weidenreich and later proponents the so-called single species hypothesis which mainly "rests on the nature of the primary hominid adaptation: culture (structured learned behaviour). Because of cultural adaptation all hominid species occupy the same, extremely broad, adaptive niche. For this reason, allopatric homind species would become sympatric. Thus the competitive exclusion principle can be legitimately applied. The most likely outcome is the continued survival of only one hominid lineage" (Wolpoff 1971, p. 601).

It became very soon evident that the controversial positions of "lumpers" versus "splitters" would lead to sharp disputes in paleoanthropology; and when the long-unsolved Neanderthal problem (overviews in Trinkaus 1989; Vandermeersch 2002; Bar Yosef and Vandermeersch 1991; Stringer and Gamble 1993; Trinkaus and Shipman 1993; Wolpoff 1999; Clark and Willermet 1997; Tattersall 1999; Henke and Rothe 1999b; Harvati and Harrison 2006; Vandermeersch and Maureille 2007; Cartmill and Smith 2009) merged into the controversy of "multiregionalists" versus "replacement proponents," the big paleoanthropological issue of the last four decades was on the floor. An almost endless series of conferences, congresses, scientific papers, proceedings, readers, and last but not least popular science media has addressed this topic.

It was shown above that the controversy of proponents of "unilinearism" versus "multiple species concepts" smoldered long before the 1970s, when William W. Howells (1908–2005) had interpreted Weidenreich's view as the "Candelabra Hypothesis" (Howells 1959). Other prominent anthropologists joined Howells, in spite of the fact that this characterization didn't match Weidenreich's original statement. The hot debate started when the British paleoanthropologist Christopher Stringer (1974) presented the results of his thesis on "Population Relationships in Later Pleistocene Hominids: A Multivariate Study on Available Crania." His *Out of Africa* model claimed – in a late version – a *total replacement* of the non-African archaic populations. Very similar to Stringer's *Recent African Origin* model (RAO I) was Günter Bräuer's "Afro-European *sapiens* hypothesis" (Bräuer 1984; RAO II). The habilitation thesis of the German anthropologist was based on a sophisticated morphological comparison of a broad cranial dataset, taking revised calibrations of the Middle Stone Age in Africa into account. In spite of many similarities between the models, there was a significant difference: Bräuer's hypothesis assumes degrees of "hybridization" between modern and archaic humans (including the Neanderthals). Smith and Cartmill (2009, p. 473) summarize: "Bräuer's model thus has strong flavor of replacement – if not so of species, at least of local populations." The opposing *Multiregional theory* (MRE) by Wolpoff (1971, 2004) was – in some essential aspects – confronted by a further theory within the bundle of continuity and replacement hypotheses in *Homo sapiens* evolution, the so-called Assimilation Model (AM) proposed by Smith et al. (1989). Like the MRE, the AM too recognizes important gene flow between archaic and modern human populations in Eurasia. Concerning the Neanderthals, the AM rejects separate species status, and this is assumed for other Middle and Late Pleistocene populations too (Cartmill and Smith 2009, p. 473).

If we follow the history of the “continuity or replacement” discussion in some prominent contributions, we have to admit that something must have gone wrong (see, e.g., Andrews and Franzen (1984), Smith and Spencer (1984), Wood et al. (1986), Giacobini (1989), Mellars and Stringer (1989), Smith et al. (1989), Trinkaus 1989; Bräuer and Smith (1992), Aitken et al. (1993), Frayer et al. (1993); Meikle et al. (1996), Clark and Willemet (1997), Tobias et al. (2001), Crow (2002), Barham and Mitchell (2008), Condemi and Weniger (2011)). Why was everybody trying to verify their own hypothesis, when falsification should be the method of choice? Why was it apparently so difficult to gain consensus on the underpinning theory and methodology? What made it so difficult to exclude the one or the other model by falsification? Next to these and many other scientific questions, there is a personal one: Why often so emotional? Scientists are not married to their scientific statements; they can “divorce” and admit when they were wrong.

All this begs the question: Is paleoanthropology really a discipline apart from the mainstream of biological thinking, and has the Modern Synthesis really shadowed the scientific work of paleoanthropologists? During the last 50 years, the vestiges of the so-called step ladder model have been successfully refuted [no wonder, when we consider the increased fossil record and the flood of hominin taxa in the Mio-Plio-Pleistocene which can’t be ignored; see Table 2]. While the unilinear and chiefly anagenetic models vanished from the discussion [almost], it became increasingly obvious that the process of human evolution is convincingly represented by multiple species, cladogenesis, and adaptive radiations [when looking at the Mio-Pliocene] as well as by the processes of the punctuated equilibrium model. But, what has happened to the genus *Homo*? (see Henke and Hardt 2011).

However, is this “mainstream” thinking on RAO in current paleoanthropology illusory, insofar as some of the opponents have thrown in the towel? It would be of great interest to know, via a scientific historic approach, which factors have played the decisive role: purely convincing scientific arguments or personal dynamics within the scientific community (coalitions and alliances)? And what about all the publicity and media attention? Paleoanthropology isn’t, and never was, operating in an ivory tower. What is the role of “embedded” scientific journalists in the acceptance or rejection of results of paleoanthropological research? Is anthropology, as a media-friendly subject, particularly at risk? (See Franck 1997, 1998a, b; Stoczkowski 2002; Grim 2009).

Was the Modern Synthesis really an obsolete theory which was uncritically used to give support for unilinearism? (Tattersall 1998, 2000a). Foley’s less negative comment on this centers on the point that paleoanthropology remained “in fact [. . .] blithely innocent of most theoretical issues.” Foley emphasizes that "anthropologists undoubtedly read the modern synthesis as suggesting that there can be no cladogenesis, but rather than seeing the true nature of Darwinian theory they merely saw their own theoretical reflecting" (Foley 2001, p. 5–9).

Foley's opinion that anthropology of the last half-century had many theoretical deficits agrees with that of my academic supervisor Christian Vogel (1933–1994), the former head of the Institute of Anthropology in Göttingen. Vogel had formulated the "biological perspectives of anthropology and the so-called theory-deficit of the physical anthropology in Germany," quoting Washburn (1953), who pleaded that the "application of a constituent, experimentally verified, evolutionary theory is the first task of the physical anthropologist" (Vogel 1983, p. 225). One should remember that Vogel's paper was presented in 1981, reflecting that paleoanthropology, and in a wider sense physical anthropology, remained behind the other evolutionary sciences (Spiegel-Rösing and Schwidetzky 1982). Although paleoanthropology was not the foremost field of anthropological research in Germany, new editions appeared of *Die Evolution der Organismen* (Heberer 1959, 1967–1974) and the textbook *Menschliche Abstammungslehre* (Heberer 1965a). In spite of these and other prominent publications in Germany in the 1960s and 1970s (Kurth 1962, 1968; Heberer 1968b; Hofer and Altner 1972; Kurth and Eibl-Eibesfeldt 1975; overviews in Hoßfeld 1997, 2005a, b; Henke and Rothe 2006), there remained a theoretical vacuum in anthropology, and paleoanthropology seemed here – as well as in other European countries – much more fossil driven than hypothesis guided.

A further appeal came from Cartmill (1990a, b, p. 173) who claimed in the early 1990s that: "Paleoanthropology should aim at increasing its theoretical content by reducing the list of qualitative human uniquenesses-and eliminating it altogether if possible." The evaluation of the scientific reasons that perpetuated inadequate evolutionary approaches in paleoanthropology, and caused complacency with insufficient models, is still incomplete. Whether "the Synthesis was doomed to harden much like a religion, into a dogma", as Tattersall claims (2000a, p. 2; contra Foley 2001), is a continuing issue; but most can agree with the statement that paleoanthropology was not explicitly theoretical, but was descriptive and in part excessively narrative (Bowler 1996, 2001; Foley 2001; Stoczkowski 2002; Ickerodt 2005; Henke 2007b, 2010a; Henke und Herrgen 2012).

In contrast to the European situation, paleoanthropologists in the USA have traditionally been trained as physical and cultural anthropologists (see Lille and Kennedy 2010). This caused a different approach to research in human evolution; in the traditional European system, archaeologists as a rule dug up the fossils, and they or anatomists – not physical anthropologists – described them and perpetuated the problem. The simplicity of narrative approaches also hampered progress. The idea of human uniqueness was emphasized (Cartmill 1990a, b), and hominin fossils were treated casuistically. Foley (2001, p. 7) confesses that it was "frustration with the combination of an absence of evolutionary theory in human evolution and assumptions about human uniqueness that led me to write Another Unique Species (Foley 1987)." His sophisticated approach tries to explain the process of human evolution and the human adaptive strategy as the intersection of the biological categories to which hominins (in Foley's original hominids) belong (Fig. 10).

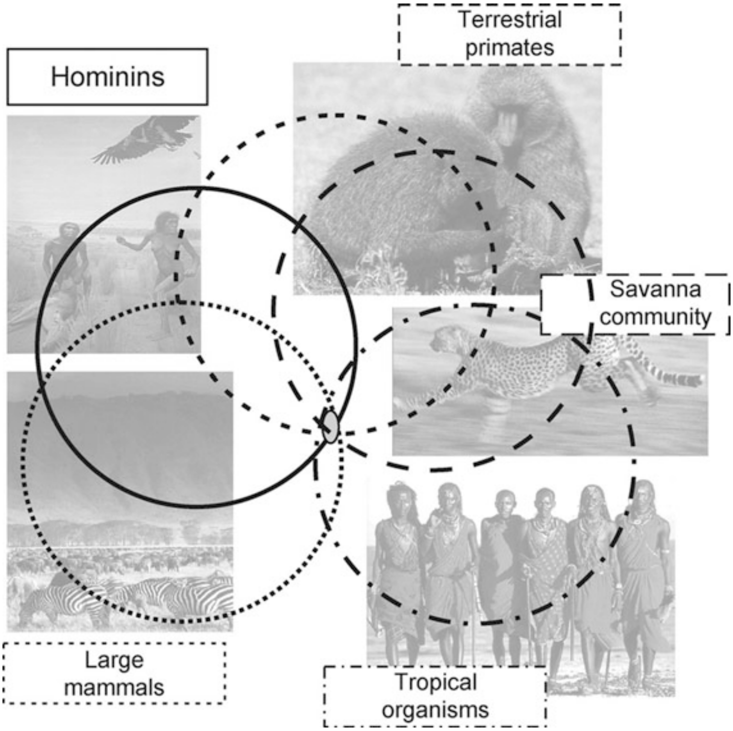

Fig. 10 Venn diagram of human uniqueness and the human adaptive strategy as the intersection of the biological categories to which hominins belong (After Foley 1987, modified)

Although most hominin diversity can be explained by evolutionary changes caused by geographical-climatological factors, there is a vast explanatory field within the life sciences, particularly comparative primatology, sociobiology, paleoecology, and paleogenetics. The multidisciplinarity of paleoanthropology is demonstrated in Fig. 11, but without a detailed special ranking of the importance of the cooperating disciplines. The preference for cooperation naturally depends on the paleoanthropological problems that have to be solved, but it should be remembered that inter-, multi-, and transdisciplinarity is a learning process, and an everlasting challenge for science (Mittelstraß 1989; Drilling 1992; Eggert 1995; Porr 1998; Henke and Rothe 2003; Henke and Herrgen 2012).

The Human Career: Revised

How Many Hominin Species Have There Been?

The last half-century has witnessed a dramatic improvement in our understanding of the process of human evolution, due to new approaches and techniques as well as a tremendous increase in the fossil record (Andrews and Franzen 1984; Franzen 1994;

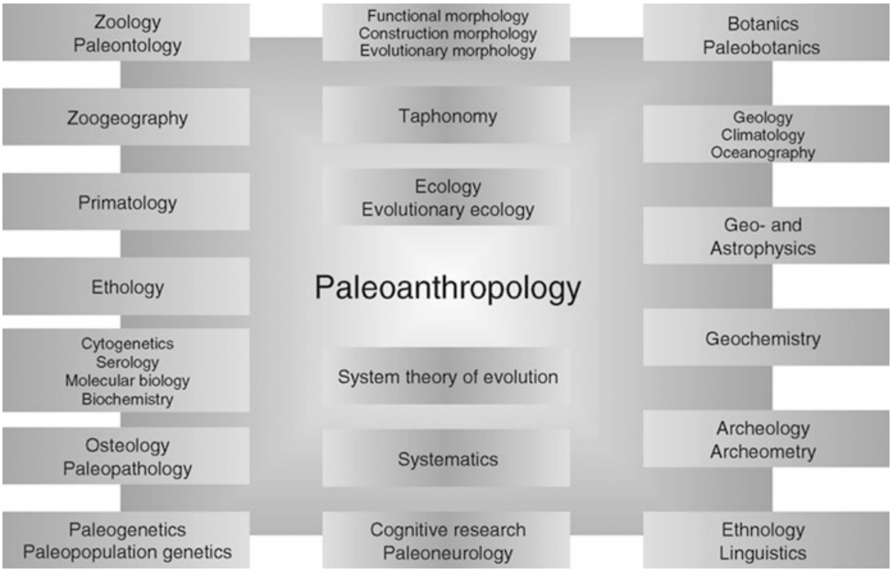

Fig. 11 Scientific disciplines that participate in reconstructing the process of human evolution (After Henke and Rothe 1994)

Henke and Rothe 1994; Ullrich 1995, 1999; Johanson and Edgar 1996; Hartwig 2002; Schwartz and Tattersall 2002, 2003, 2005; Cartmill and Smith 2009; Wood 2011; Begun 2013). Profound knowledge of the relationship between form and function has come from innovations in mechanical engineering, light microscopy and REM, and 2D and 3D tomography, as well as from innovative approaches in geometric morphometrics (Grupe and Peters 2003; Zollikofer and Ponce de León 2005; Bose 2013). Furthermore, evolutionary and developmental morphology (Minugh-Purvis and McNamara 2002) and primate physiology (Martin 1990) have contributed to a better understanding of form-function complexes (Ciochon and Corrucccini 1983; Oxnard 1984; Aiello and Dean 1990; Anapol et al. 2004; Ross and Kay 2004; Slice 2005). Hennig's *Phylogenetic Systematics* (Hennig 1966, 1982, 1984), which was first published in German in 1950 without gaining much attention (Hennig 1950), eventually revolutionized phylogenetic discussion in concert with tremendously increased skills in taxonomy and computer techniques (Rieppel 1999; Waegele 2000; Wiesemüller et al. 2003). In spite of all the positive aspects of innovative methodological approaches, paleoanthropologists shouldn't forget that all sophisticated quantitative approaches in taxonomy are used on extremely small fossil samples and limited datasets. In the context of taxonomy, Tim White (2000, p. 29) warned: "Hennig was not God, and parsimony is not God's truth." Wood and Lonergan (2008, p. 374) put it this way, and advised practitioners of paleoanthropology "to apply a healthy dose of skepticism to pronouncements about the taxonomy and systematics of the human clade." A corrective to the "taxon federation" is Robert B. Eckardt's (2000) textbook

Human Paleobiology. His “attitude to the past” soundly criticizes “splitting” and calls for a check on it. Eckardt’s concept was highly influenced by Paul T. Baker (1927–2007), whose major field of research was human adaptability (“Man Must Adapt, or Be Damned,” Baker 1983). And his paleobiological approach embodies the “endeavor to reconstruct credible impressions of past populations and their members as they were in life: feeding; mating; giving birth to offspring and caring for them; avoiding predators; and enduring vagaries of weather, parasites, and diseases,” (Eckardt 2000, p. 1) a concept very near to Foley’s (1987, 1995a, b) and that of Henke and Rothe (1994, 1999a).

With the improvement of absolute dating techniques (e.g., radiocarbon and other isotopic calibrations) and in relative dating by faunal complexes, the chronological pattern of human evolution was more precisely observed, and it became seen through the application of “molecular clocks” that the branching of the hominin line coincided with the aridification of the East African Rift Valley (Bishop and Miller 1972; Howell 1978; Vrba et al. 1995; Magori et al. 1996; Bromage and Schrenk 1999; Bobé and Behrensmeyer 2004). This allowed for a more effective exploration of hominin sites, increasing the chances of finding fossils of Mio-Plio-Pleistocene faunal complexes. However, as hominins are comparatively rare animals, it still needs much luck to find them. To increase the chances of doing so, taphonomy, the science of decay of organisms and the process of fossilization, first described in 1940 by Efremov, has become an important subdiscipline. Phenomena of biostratinomy, decomposition, and diagenesis are essential for the interpretation of fossils (Behrensmeyer and Hill 1980; Shipman 1981; Etter 1994; Vrba et al. 1995; Martin 1999; Wagner 2007).

The more research on human evolution concentrated on the African continent, the more successful those paleoanthropologists with a licence to dig became, especially as they extended their campaigns into the Miocene as well as to Plio- and Pleistocene strata. Louis Leakey’s good fortune (Cole 1975; Isaac and McCown 1976) at Olduvai Gorge [discovered by the German neurologist Wilhelm Kattwinkel in 1911 (Glowatzki 1979) and successfully explored for the first time in 1913 by Reck (1925)], as well as that of his family members at Koobi Fora and diverse other East African sites, resulted from tremendous efforts (Leakey and Leakey 1978; Grine 1988; Wood 1991; Tobias 1991; Walker and Leakey 1993). Besides the activities of the Leakey family, there should be mentioned the successful expeditions of Francis Clark Howell in Omo, Glynn Isaac in Olorgesailie, and of course the famous Afar Research Expedition (Johanson and Edey 1980; Johanson and Edgar 1996). Finally, the Hominid Corridor Research Project of Timothy Bromage and Friedemann Schrenk in Malawi (Bromage and Schrenk 1999; Schrenk and Bromage 2002) must be alluded to, as well as the activities of Brigitte Senut and Martin Pickford in Tanzania (Pickford and Senut 2001) and Michel Brunet et al. (2002) in Chad. Many findings had to be corrected due to new research, and Pickford’s (1997) “Beyond the Evidence” demonstrates that forcefully.

In the last decades, there have been impressive discoveries of early hominins in South African, at new sites, by Ron Clarke, Lee Berger, and colleagues. Africa has become the “Mecca” of paleoanthropologists. There is no longer any doubt now that Africa was the “cradle of mankind.” The hominin taxonomy presented in Table 2 presents the current list of species recognized by “splitters.”

In spite of the fact that the “fossil hunting” has mostly been done in Africa, many activities in other parts of the Old World allow us to learn more about patterns of hominid migration and development. Exciting new fossils and findings from, e.g., Atapuerca (Spain) (Arsuaga et al. 1999), Apidima (Greece) (Pitsios 1999), Ceprano (Italy) (Ascenzi et al. 2000), Schöningen (Thieme 1996), Dmanisi (Georgia) (Bräuer et al. 1995; Henke et al. 1995; Gabunia et al. 1999a, b, 2000, 2002; Vekua et al. 2002; Lordkipanidze and Vekua 2006), and many non-European and Eurasian sites (Delson 1985; Rightmire 1990; Franzen 1994; Johanson and Edgar 1996; Delson et al. 2000; Brunet et al. 2002; Schwartz and Tattersall 2002; Harvati and Harrison 2006), and the astonishing fossils from Flores (Indonesia) (Brown et al. 2004; Aiello 2010; Falk 2011) demonstrate that paleoanthropology is a field of research with never-ending surprises and new perspectives, albeit with never-ending problems. To say that the sample is too scarce is indeed right when we compare the fossil record with the assumed size of paleopopulations, and how about the number of recognized taxa? Foley asked in 1991, “How many hominid species should there be?” and again 15 years later, when there were claims of 28 hominin species (Foley 1991, 2005). Through highly elaborate comparative modeling, Foley concluded among other things that “it can be seen that the rate of discovery has rapidly increased in the last half-century, and there is no sign of an asymptote. To this extent, it may be proposed that we are still underestimating the number of hominin species” (Foley 2005, p. 69). This may have been a shock for “lumpers,” but some sentences later he says: “In considering the extent to which our knowledge of hominin evolutionary diversity is a challenge to how confident we are that the pattern is ‘real’, we come away with the conclusion of moderate confidence” (Foley 2005, p. 69). While we may underestimate the number of hominin species in the earlier periods, the “full diversity is not yet known even for later periods. What is almost certainly not the case is that we are overestimating diversity” (Foley 2005, p. 70). Good news for excavators and for laboratory scientists too.

However, new fossils are not only solving problems but are raising new questions and providing new answers to that had seemed to have been solved. Here I mention two outstanding cases, both, interestingly enough, from Asia: One of the best illustrations of the phrase “humans are animals who wonder intensively and endlessly about their origin” is partial skeletons of nine hominin fossils (including one complete cranium) from Flores (Indonesia). The “Flores Man” represents a – possible – new species, *Homo floresiensis* (Brown et al. 2004). The most complete individual from the Liang Bua Cave, LB1, was nicknamed the “hobbit” due to its extremely small body size (106 cm) and cranial capacity (380 cc). The unusual anatomy of the fossils caused vehement discussion (e.g., on microcephaly, Laron syndrome, congenital hypothyroidism), and some skeptics regarded LB1 and LB6 as cretins; however, the pathological diagnoses have been largely falsified (Falk et al. 2007; contra, e.g., Martin et al. 2006). Given the case that genetic mutations, diseases, and growth disorders do not apply, the Flores hominins are most reasonably (or better: plausibly) explained as “Late-surviving species of early *Homo*”

(5-year overview of *H. floresiensis* research in Aiello 2010). Public interest was unbelievably intensive due to the striking features of the fossils, and the unusual archaeology of the site, as well as to the diagnostic controversies and claimed skullduggery – a godsend for public media.

Enormous scientific interest, and huge media hype, brought the tiny fossil remains from the Denisova Cave (southern Siberia) to fame. Paleogenetic research using DNA extracted from a finger bone revealed that this individual was from a group (hominin form) that shared a common origin with Neanderthals. Reich et al. (2010, abstract) conclude that "this population was not involved in the putative gene flow from Neanderthals into Eurasians; however, the data suggest that it contributed 4–6 % of the genetic material to the genomes of present-day Melanesians." The authors suggest that the "Denisovans" may have been a widespread hominin population in Asia during the Late Pleistocene. The morphology of a single tooth, whose mitochondrial genome resembles that of the finger bone, suggests an evolutionary history apart from both Neanderthals and modern humans (Gibbons 2011). The floor is wide open for discussion! Or, to put it in Jonathan Marks' words: "Fossil genomics is opening new windows to the past. But the view through them isn't as clear as we like to think" (Marks 2012, p. 1).

Our Ancestors' Great Leap Forward: Changing Explanations

No doubt, the half-life of our theoretical models is very short. But there has undoubtedly been enormous progress, on balance. Besides the paleontological fieldwork, which has also produced valuable data for the reconstruction of the ecological niches of our ancestors (Bromage and Schrenk 1999), research in primatology has become increasingly important for anthropological modeling (Martin 1990; MacPhee 1993; Fleagle 1999; Groves 2001). Thanks to Louis Leakey's encouragement, Jane Goodall, Diane Fossey, and Birute Galdikas started their primatological field researches many decades ago. Their results revolutionized our thinking on primate behavior, and this concept has been enlarged by many other field and laboratory primatologists (see, e.g., research projects of Cheney and Seyfarth; Premack, Fouts, Savage-Rumbough, de Waal, and the working groups of the Max Planck Institute of Evolutionary Anthropology in Leipzig, Germany). The paradigm of behavioral ecology and sociobiology has shaped our hypotheses on food choice, foraging patterns and food detection, as well as on food sharing and intra- and intergroup relations.

It must be mentioned briefly that paleoanthropology as a multidisciplinary research field also brings the major events of primate evolution into focus, to disentangle the evolutionary trends in primate evolution, and to detect our *constitutional preadaptation/predisposition* (see Vogel 1975). Weighty volumes have been edited, e.g., by Fleagle and Kay (1994), Delson et al. (2000), Hartwig (2002), Ross and Kay (2004), Wood (2011), and Begun (2013), proving that "the study of anthropoid origins continues to be a lightning rod for research in paleoanthropology" (Ross and Kay 2004, p. vii). As the focus of this overview is foremost on hominins, let's look briefly at the evolution of bipedal walking as the assumed initial step into humanity. Despite the fact that bipedalism has evolved independently multiple times in primates, and this transition is deeply rooted in the primate behavior, in nonhuman contexts, it is merely facultative, not habitual or obligate.

Since Darwin's (1871) *Freeing of the Hands* hypothesis, the emergence of upright posture and bipedal gait has been discussed in many contexts, proposing alternative triggers and constructing alternative scenarios. Here are some of them: *The Infant Carrying* hypothesis by Etkin (1954); *The Watching Out* hypothesis by Dart (1959); The *Aquatic Ape* hypothesis, initiated by Alister Hardy (1960), presented in detail by Elaine Morgan (see 1997); *The Carrying Food or Provisioning* hypothesis by Hewes (1961); *The Reaching for Food* hypothesis by Jolly (1970); *The Orthograde Scrambling* hypothesis by Sugardijto and van Hoff (1986); *The Display Hypothesis* by Chaplin et al. (1993); The *Scavenging Hypothesis* by Blumenschine and Cavallo 1992 [see earlier untested versions by Eiseley (1953) and Bartholomew and Birdsell (1953)]; *The Thermoregulation* hypothesis (Ward and Underwood 1967; Wheeler 1984, 1991a, b); *The Throwing* hypothesis (Kirschmann 1999; Dunsworth et al. 2003; Young 2003); *The Amphibian Generalist Theory* by Niemitz (2002, 2004, 2010); and *The exploitation of retained locomotor behavior* hypothesis (Thorpe et al. 2007).

While some of the hypotheses/theories are based on monocausal explanations (which shouldn't be regarded per se as most parsimonious solutions), others are more complex and multifaceted, taking into account new paleoanthropological findings and biomechanical and energetic aspects of the anatomy of early hominids, as well as ecological and nutritional prerequisites and evolutionary psychological components. Though some proposals of primary "causes and consequences" seem quite *plausible*, it must be remembered that "plausibility" is an inadequate quality criterion to explain derived features (Foley 1987; Foley and Gamble 2009). The fatiguing, and in retrospect almost absurd, discussion on "facts and fiction" in regard to the *Aquatic Ape Theory* (Roede et al.1991) should remind us that it is not necessary to discuss each conceivable proposal in this field (see Stoczkowski 2002; Henke 2007a, b, 2010a). Scientific explanation, as opposed to mere narration or "just so stories" and myths, has to invoke lawlike regularities connecting causes and effects and to aim to a concise hypothesis testing or at least *quasi*-hypothesis testing (see Vogel 1975; Foley 1987; Henke and Rothe 1994, 1999a, 2005).

Studies on the evolution of social-behavioral systems, kin selection, intersexual and intrasexual selection, cognitive abilities, tool using and tool making, Machiavellian strategies, competition, coalitions, and alliances, which is the total complexity of social systems in primates, especially in apes, have become essential for paleoanthropological modeling (Foley 1987, 1995a, b; Tattersall 1998, 2011; Eckardt 2000; Henke and Rothe 2003; Henke 2003a, 2008; Rothe and Henke 2005; Henke and Herrgen 2012). Besides primatological field studies, which have given us a totally new view on the cultural capabilities of nonhuman primates (Goodall 1986), there is much to learn about our brains and the development of language and our emotions from all kinds of laboratory research [e.g., molecular biology (O'Rourke et al. 2000; Relethford 2001; Enard 2005), psychobiology

(Cartmill 1990a, b; Mithen 1996; Tomasello 1999; Withen 2000; Call and Tomasello 2008; Sommer 2007a, b; Sterelny 2012; Henke and Herrgen 2012)]. There is challenging news from the paleogenetic labs: Various genes are implicated in specifically human capabilities, e.g., language capabilities as indicated by FOXP2 (Enard et al. 2002; Enard 2005); autism (Green et al. 2010a, b); mental capacities (by Human accelerated regions – HAR; on abnormal spindle-like microcephaly-associated protein, ASPM (Pollard et al. 2006; Pollard 2009); on myosin heavy chain 16 (MYH16) which is associated with masticatory structures (Stedman et al. 2005; overview in Jobling et al. (2004). Varki and Altheide (2005) are "Comparing the human and chimpanzee genomes: Searching for needles in a haystack." I'm sure they will find many and inspire the field of human evolution tremendously.

It seems – to say it cautiously – that ancient DNA findings have recently solved one of the "oldest questions" in paleoanthropology that remained unsolved for more than 150 years. After the excavation of the name-giving fossils from the Neander Valley, near Düsseldorf in Germany, the "role of the Neanderthals" is subject to intense discussion (Spencer 1984; Stringer and Gamble 1993; Henke and Rothe 1994, 1999b; Tattersall 1995; Krings et al. 1997; Wolpoff 1999; Relethford 2001; Finlayson 2004; Harvati and Harrison 2006). As has been shown above, also heavily debated are the "Out of Africa" models, with and without hybridization: the *Assimilation model* and the *Multiregional model*. After never-ending and often contradictory discussions on molecular biological results assuming a total replacement of all archaic non-African populations by anatomical-modern *Homo sapiens* dispersing from Africa (see, e.g., Henke 2005; Relethford 2009; Cartmill and Smith 2009), and after many supposedly "infallible" statements that there was no hybridization of Neanderthals and modern humans (e.g., *cell* cover: "Neanderthals Are not Our Ancestors" (Krings et al. 1997), now – what a surprise – the message is that "Neanderthals bred with modern humans" (Green et al. 2010a, b). Paleogeneticists from Harvard and the MPI EVA, Leipzig wrote: "Comparisons of DNA sequences between Neanderthals and present-day humans have shown that Neandertals share more genetic variants with non-Africans than with Africans. This could be due to interbreeding between Neandertals and modern humans when the two groups met subsequent to the emergence of modern humans outside Africa. However, it could also be due to population structure that antedates the origin of Neandertal ancestors in Africa" (Sankararaman et al. 2012, abstract). Here is apparent strong support for the recent interbreeding hypothesis. Will this be the end of discussion? Time will tell!

Behavioral Modernity: What Pushed Us into Another League?

As shown above, the conceptual transition toward the "New Physical Anthropology" sensu Washburn (1951) and the steady optimization and increase of methodological approaches and technical skills during the last 60 years have succeeded in explaining us as "*another unique species*," to repeat Foley's paradox (Howell 2003;

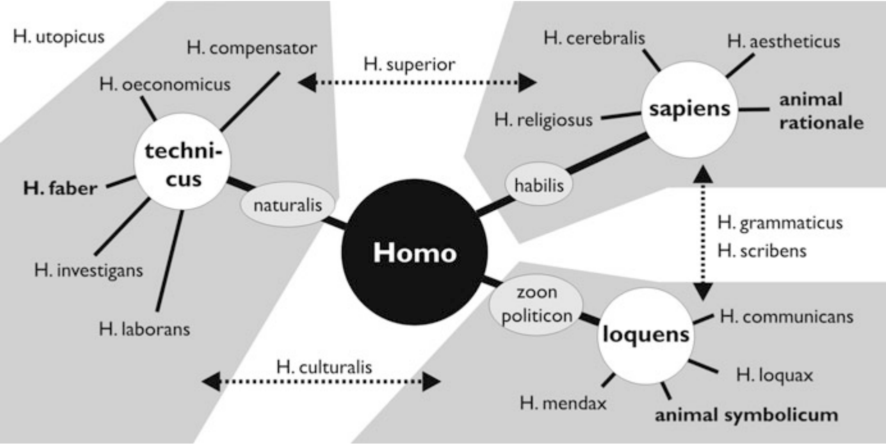

Fig. 12 Conceptions of modern humans as animals which have culture as an evolved constitutional – *tradi*genetical – component (Designed by Herrgen 2008; adapted from Henke and Herrgen 2012)

Fuentes 2010; Larsen 2010; Stini 2010). Paleoanthropologists and their colleagues from neighboring disciplines succeeded in explaining in biological terms the specific morphological and physiological features that set us apart from other primates, e.g., upright bipedal walking, orthognathy, extensive neencephalization, reproductive physiology and biology, loss of body hair, and a wide set of further traits, including skin colors; the latter is insofar important as it breaks racial prejudice (see Jablonski 2012).

Paleobiologists have solved the questions of when, where, and how these specific human patterns evolved, and sometimes "why" too. The most contentious answers are those on causes and consequences; in other words, we have a broad knowledge (or rather think we do) of the selective advantages of the human adaptive morphophysiological pattern. Tattersall (2006, p. 155) stressed wisely, "that the acquisition of novelties cannot be driven by natural selection, which can only favor new structures after the fact," and explains subsequently: "…that any novelty has to rise initially as an exaptation [synonym for preadaptation, add. W.H.], a structure existing independently of any new function for which it might later be co-opted."

Paleoanthropologists have reached wide consensus on the long-term channeling of pathways in primate evolution. They have built up plausible scenarios on the evolution of uprightness and bipedal walking, on the formation of a gracile masticatory apparatus, and on the excessive increase of cranial capacities. So far so good; but evolutionary anthropologists also have to explain our special behavioral pattern (see Fig. 12). They have to elucidate how our specific human information and social systems arose, how humans reached their unique cognitive abilities for name-giving thinking processes, for verbal speech, for extremely complex social traditions, for an extremely complex Machiavellian intelligence, and for the capability of environmental buffering (overviews in Vogel 1975; Withen 2000; de Waal 2001; Rothe and Henke 2005; Gädenfors 2003; Mithen 2005; Tattersall 2006, 2011; Henke 2007a, b, 2008; Klein 2009; Henke and Herrgen 2012; Sterelny 2012; Henke 2015 in print).

The challenge is also to explain the *total pattern* – human biology *and* culture (or better all cultural abilities!) – and to decipher the evolutionary factors and environmental influences that triggered the transitional process. After decades of very successful deciphering of the evolutionary trends within the order of Primates that led to the evolution of our genus *Homo*, we are – after a long "approach-run" – currently faced with the fundamental challenge to reconstruct the evolution of behavioral modernity, sometimes called "humanization," as the last step of the process of "hominization"; both terms sound like a teleological program, what they aren't; evolution has no goal!

During the last decades, there has been done much innovative inter- and multidisciplinary research to get the right answers to ancient anthropological questions: How could an evolutionary process bring about a culturally dependent primate or animal rationale (sensu Artistotle) *rsp*. animal symbolicum (sensu Cassirer 1923–1929)? (See Herrgen 2008; Henke and Herrgen 2012; Henke 2015 in print.) It is becoming significantly evident from primatological research that neither tool using nor tool making, nor hunting, nor food sharing, nor social intelligence and coalitions, nor Machiavellian intelligence, is a unique feature of *Homo sapiens*. So human biologists, cognitive psychologists, and primatologists had to look for other traits which set us apart.

The crucial question is: What pushed us into another league? The explanation has to come by "Darwinian" thinking (Sommer 2007a, b), as evolutionary anthropologists become increasingly critical about those caged in cultural prejudices.

The uniquely human behavioral pattern which made our species so successful, which we call behavioral modernity, is commonly explained as a change in the intrinsic cognitive competence of modern humans. It is described in terms of new capacities for cognitive breakthroughs, like evolution and/or perfection of language, meaning creation (synonyms are theory of mind or mind reading), and symbol use (symbolicity or symbolic thoughts). Kim Sterelny's definition of behavioral modernity is the following: "humans became behaviourally modern when they could reliably transmit accumulated informational capital to the next generation, and transmit it with sufficient precision for innovations to be preserved and accumulated" (Sterelny 2011, p. 809; see also Sterelny 2012; Henke 2015 in print). The last step of becoming human and even *humane*, i.e., an animal with the ability to empathize, to understand the intentions of others, to plan and to deceive, and to use symbols and language, is a recent topic of research. Three abilities of modern human behavior have come under special scrutiny: *language*, *theory of mind*, and *symbolism* (for a more complex approach, see, e.g., Cartmill 1990a, b; Noble and Davidson 1996; Mithen 1996, 1998, 2005; Tattersall 1998, 2002, 2006, 2012; Tomasello 1999; Withen 2000; Crow 2002; Gärdenfors 2003; Henshilwood et al. 2004, 2009; Wuketits and Antweiler 2004; Haidle 2006; Balter 2008;

Cartmill and Smith 2009; Conard 2009, 2010; Klein 2009; Henshilwood and d'Errico 2011; Henke 2015 in print). Cartmill and Smith (2009, p. 416) state: "it seems reasonable to think that language preceded the onset of art, religion, and other sorts of symbolic behavior in the course of human evolution." But how do we know this is fact? Research on paleogenetic features as FOXP2, morphological studies on hyoid bones, and cranial endocasts currently give little hope of proving this. No doubt, we are on very difficult terrain here.

And as regards mind reading and symbolism, there has been much progress from artifacts, mentifacts, and sociofacts (see Posner 1993; Renfrew and Zubrow 1994; Holzmüller 1997; Renfrew 1998; Mithen 1998; Marean and Thompson 2003; Wuketits and Antweiler 2004; Bar-Yosef and Zilhão 2006; Kappeler and Silk 2009; Klein 2009; Conard 2010; Nowell 2010; Sousa and Counha 2012; Sterelny 2012). However, detractors ask how we can reconstruct arbitrary, socially constructed conventions of our ancient Pleistocene antecedents, if understanding of symbols is often restricted to persons sharing a common cultural background, i.e., the same "cognitive map"? Bredholt-Christensen and Warburton (2003, p. 40) caution, referring to the insider/outsider debate, that we run the following risk: "In attempting to understand the people under study we create categories by which we distinguish phenomena of their culture. On this basis (prehistoric "symbols" being "our" interpretation of "*their*" world as "*we*" see it)." The authors emphasize that this doesn't mean that posing questions about prehistoric symbolism and archaeological differentiations are irrelevant and illegitimate; however, such queries can only be answered on an *etic*, not on an *emic* level (Bredholt-Christensen and Warburton 2003, p. 39; for more discussion on more "*Criteria of Symbolicity*," see positions papers of the 9th Annual Meeting of the EAA, 2003; Bouissac 2003). When discussing "how *Homo* became *sapiens*" (see Gärdenfors 2003, book title) and how our ancestor developed full modern behavioral modernity, we are faced with a major problem of anthropology (Marean and Thompson 2003). By an integrated multidisciplinary approach, including paleoanthropology, archaeology, primate ethology, ethnology, cognitive psychology, and evolutionary genetics, we can hope to find answers to the most intriguing question: How could the self-organizing process of hominization bring about a culturally dependent organism that has "*culture as its nature*" (sensu Vogel 2000)?. From a sociobiological perspective, we have to talk about "culture *via* nature" as there are convincing arguments "that culture has been so successful biologically because it gives humans improved possibilities for coping with the perils of life and so increases the chance of survival. [...] Whatever defines culture, it is based on adaptive imitation, or "imitation of the fittest"" (see Voland 2000b, p. 196).

To perform the imperative "*Nosce te ipsum*!" we need a concentrated and concerted approach by all evolutionary biological and cultural sciences, taking a strictly "Darwinian perspective" and with special focus on the "human niche" of *Homo sapiens*. We have to know much more about the totality of the special conditions of early anatomical-modern *Homo sapiens* hunter-gatherers that made their lives – and survival – possible; otherwise, we will never understand the "constitutional preadaptation" affecting the final step to "behavioral modernity" and our specific "design" which evolved *without* a "designer." To prove this Darwinian message is more than enough motivation for future research on the origin of the human mind.

Conclusion

Don't Expect Too Much: We Are Just Modeling!

When we sum up the history of paleoanthropological research, it becomes evident that the paradigmatic change initiated by Darwin's realization of a true historical genetic kinship of all living organisms stimulated enormous interest in questions of human origins. Those research subjects that promised to solve the enigma of anthropogenesis in Darwin's days were the natural sciences (paleontology, geology, comparative anatomy *rsp*. morphology, zoology, and human biology), on the one hand, and the social sciences of prehistory and ethnology, on the other.

The "conglomerate" of natural sciences contributed to a pretty slow formation of "human paleontology" *rsp*. "paleoanthropology" and was joined at its very beginning by the social sciences. However, the segregation of the diverse disciplines in the natural, medical, and social faculties hampered an integrative approach, even apart from the skepticism toward, and even rejection of, Darwinian evolutionary theory by a great part of the scientific community. Rudolf Virchow was by far no exception.

In retrospect, it is apparent that paleoanthropology long failed to adopt a Darwinian evolutionary approach. Its methodology remained – with some commendable exceptions – mainly casuistic, descriptive, and nonanalytical. This didn't even change at the beginning of the twentieth century, when classical genetics began after the rediscovery of the Mendelian laws. Notably, even after the formation of the "Modern Synthesis," (paleo)anthropology perpetuated long-standing erroneous conceptions (i.e., polygenism, orthogenism, Eurocentrism, ethnocentrism, social Darwinism, racism). It can be concluded that paleoanthropology remained "simple minded" until after World War II, without conceptual integration of Darwinian and Neo-Darwinian concepts. However, subsequently, evolutionary biology has become the fundamental superstructure, as already explicitly formulated by the population geneticist Theodosius Dobzhansky (1937) and his outstanding colleagues from other biological sciences.

As a recognizable, valid subject of evolutionary biological science, paleoanthropology was established for the first time in the early 1950s by Sherwood L. Washburn (1951, 1953). The conceptualization and foundation of paleoanthropology/paleobiology as a subdiscipline of the "New Physical Anthropology" was correlated with the adoption of the concepts of Darwinian theory and those of the "Modern Synthesis." This was followed by a period of severe problems in the recognition of taxic diversification and speciation processes when paleoanthropological findings increased exponentially and the fossil record and the "Modern Synthesis" came under critical observation (Eldredge and Gould 1972;

Tattersall 1998, 2000a, b; Foley 2001; see also Wolpoff 1996–1997). Once again, paleoanthropology had a slow start compared to other evolutionary sciences. However, due to crucial conceptual support by outstanding scientists, e.g., Sherwood L. Washburn, F. Clark Howell, Louis S. B. Leakey, Phillip V. Tobias, and many other enthusiastic colleagues, the field was revivified by new fossils and essential findings from field and laboratory research.

Paleoanthropology has now evolved to become a complex research strategy of evolutionary biology that integrates all facets of comparative functional and evolutionary anatomy, primatology, behavioral ecology, cognitive primatology and sociobiology, molecular and population genetics, paleogenetics, as well as earth sciences, archaeology, archaeometry, and ethnology. Since the 1960s and 1970s, there has been developed a large body of empirical knowledge related to international collaborative networks, all underpinned by epistemological discourse. The enhanced armamentarium of perspectives and methodologies was drawn largely from the diverse natural sciences and from conceptual progress in archaeology and ethnology too. Paleoanthropology benefited from the high innovativeness of the natural and associated social sciences and from the increasing complexity of its approaches, as well as from exceptional fossils, surprising findings, and a vast public interest due to new media.

Embedded in evolutionary biology, and adjacent to a broadly based scientific field with theory-guided empirical approaches, paleoanthropology has finally since the 1970s become a mature science. The consistent integration into the wider set of biological sciences underpinned by the revised System Theory of Evolution provides a road map for a successful research design in paleoanthropology. Students should follow this program to achieve reliable and valid findings and to build up reasonable scenarios of the past. However, one should have Robert Foley's four "pathways to the past" always in mind: "Neither theory nor models on their own are sufficient in palaeoanthropology, for they would amount to composing the present on the past. [. . .] Just as the fossils are mute without the frame work of theory, so, too, the theory is self-confirming when not put to empirical tests." He suggests testing the strength of "inferences," using "isolating techniques," and applying "probabilistic" and "comparative biological" tests. Though this seems to be "the appropriate framework for investigating patterns in hominid evolution" (see Foley 1987, p. 90), it's necessary to emphasize that the complexity of human origins can only be understood correctly if we are always aware of our potential prejudices.

Always Being Aware of Biases and Misunderstandings

Paleoanthropologists should always be aware of the principal aims of scientific work (Mahner and Bunge 2000). This allows them to avoid the pitfalls of naïve storytelling and of obscuring their aims with narrative. In spite of the paradigmatic change to a teleonomic explanation of life, there is plenty of evidence that even though "scientific thought is subject not only to the force of empirical knowledge, there doubtlessly is under changing conditions much impact from social constraints" (Stoczkowski 2002, p. 1; Henke 2010a; Sarasin and Sommer 2010). In his "Explaining Human Origins – Myth, Imagination and Conjuncture," the prehistorian and archaeologist Wiktor Stoczkowski (2002) presents a table of distinctive characteristics of humans in general and of primitive humanity in particular, as described in our sample of hominization scenarios. The characteristics most often mentioned as triggering human evolution are ranked by their assumed importance: tools, bipedalism, free hands, language, social life, voluminous brain, superior mental faculties, reduced canines, cooperation, sexual division of labor, food sharing, hunting, perfectibility, family organization, productive success, prolonged childhood, absence of estrus, and carnivorous diet.

Even when neglecting obviously outdated "traditionalist" and "Lamarckian" approaches to explain anthropogenesis in Darwinian terms, Stoczkowski (2002, p. 198) states that "contrary to what is often thought, scientists do not draw their conclusion from empirical data, any more than they rewrite history in terms of prevailing ideology." Since the French original of this work, *Anthropologie naïve, anthropologie savante* was published 20 years ago, in 1994, I am convinced that in saying this, the author has remained in ignorance of much of the theoretical and analytical progress made by current paleoanthropology. Stoczkowski clearly had not considered the more recent phase of "empirical tests" in modeling the past, although it is true that earlier human origin models were one sided and monocausal and missed the required complexity.

This applies, for instance, to the "Man the Hunter" model of Lee and DeVore (1968), the "Food sharing behavior" model of Isaac (1978), the "Hunter-Gatherer" model of Zihlman and Tanner (1978), the "Pair bonding" model of Lovejoy (1981), the "Nutrition strategy" model of Hill (1982), and the "Scavenging" model of Blumenschine and Cavallo (1992). This is not the place to discuss the validity of analogue and concept models or the theoretical patterns of recognition techniques and the appropriateness of optimality principles (overviews in Foley 1987, 1995a, b; Henke and Rothe 1994); but it should be noted that more recent models of human origins, e.g., Aiello and Wheeler's (1995) "Expensive tissue hypothesis," O'Connell et al.'s (1999) "Grandmothering hypothesis," and Wrangham et al.'s (1999) "The Raw and the Stolen; Cooking and the Ecology of Human Origins" model take into account the complexity of the network of causes for social transitions. Further, paying attention to life history, energetic and ecological components of the ecological niche concept have caused much improvement and progress (overviews in Henke 2007a, 2010c; Henke and Herrgen 2012; Kaplan et al. 2000). Foley and Gamble (2009, p. 3267) are aware that "the evolution of 'human society' is underpinned by ecological factors, but these are influenced as much by technological and behavioural innovations as external environmental change."

However, our answers to the why-questions are still contentious and possibly will remain that way. Additionally, what has previously remained unmentioned is that some hominization models were severely flawed by the fact that anthropology was until recently a male-dominated science. The comparison of the prevailing male perspectives with views by feminist researchers demonstrates that paleoanthropology, prehistory, and sociobiology were in particular influenced by androcentrism. Adrienne Zihlman and Nancy Makepeace Tanner were the first (in the 1970s) to complain about androcentric misinterpretations of the female role in human evolutionary history. Their critique of the "Man the Hunter" scenario was a groundbreaking event for feminist anthropology (e.g., Tanner and Zihlman 1976; Zihlman 1978, 1981; Linda Fedigan 1986, 1992; Margaret Ehrenberg 1989; Inge Schröder 1994; Melanie Wiber 1997; Lori Hager 1997; Londa Schiebinger 1999; James M Adavasio et al. 1999; see also Henke et al. 1996; Henke 1997). Linda Fedigan (1992, p. 306) put it this way: "The assumption that females are losers in competition between the sexes, although widespread in sociobiological literature, does not seem to me inherently necessary to evolutionary theories, precisely because it is a cultural assumption rather than a biological given."

In this context, one should also ask: Are there still other biased perspectives that require a closer review by science history? This is quite likely, as some good research work has already been done on the presentation of "lost worlds" and paleoanthropological ideas in print media and movies, as well as in scientific art, popular scientific illustrations, and museum exhibitions (see, e.g., Ickerodt 2005; Kleeberg et al. 2005; Hurel 2006; Crawford 2007; Sommer 2008; Sommer et al. 2008; Goodall 2009; Kort and Hollein 2009; Sarasin and Sommer 2010; Ingensiep 2013).

Furthermore, while it is well known that Christian doctrine and other religious beliefs have demonstrably influenced research on and discussion of human origins in the past, the impact of social and political ideologies on paleoanthropology is a largely unexplored field that offers great possibilities for future historical research. There is, especially, a need to study the impact of sociocentrism, ethnocentrism, and nationalism on interpretations of human origins, as well as national and regional museological conceptions (see, e.g., Schmalzer 2008, Africa; Vickery 2013; Durband (2009) Southeast Asia and Australia; Durband 2009, excellent overviews to the issue in Sarasin and Sommer 2010).

A further issue of historical interest is the relationships of colonialism and paleoanthropology; Goodrum (2009, p. 349) remarks that: "The implications of European and American researchers conducting excavations and removing hominid fossils from Asian and African countries during and following the colonial period is another subject that remains largely unexplored."

And one can bring the same question to recent times: How has the experience of outstanding foreign students trained at American and European universities translated back to their native countries and their subsequent research? Did they bring back new perspectives, and have their researches specially influenced paleoanthropology and their own societies? (See, e.g., Sperber 1990; Lille and Kennedy 2010)

Knowledge Commits to Responsibility!

Besides the diverse "**-***ism*" issues mentioned above, there is a vast "construction site" in paleoanthropology based on transmitting facts – and not fiction – about human evolution to the general public. Paleoanthropologists benefit from enormous public interest in their field; but big problems can arise if the preconceptions of that public are wrong or if their understanding is merely superficial. Transmitting scientific findings to the public is not an easy task and demands great precision; the difficulties involved are proven by the daily experience of lecturers and teachers. Empirical-didactical research by Graf and Soran (2010) provided disillusioning results: Evolution as pattern and process is even today very poorly understood and misinterpreted by the broad public, even though the basic theoretical framework is biologically undisputed. There is a reluctance to understand that there are still unsolved problems out there; science is a process (see Toepfer 2011; Wrede and Wrede 2013). Of greatest relevance is that there is widespread misunderstanding of evolution itself [e.g., that "evolution" aims the preservation of species; evolutionary adaptations are adaptations to recent environments; organisms are perfectly adapted; humans are the crown of evolution; evolution is a simultaneous progress and has an aim; nature is harmony; and nature is "good" and has morality (overview in Henke and Herrgen 2012)]. All this is of relevance for paleoanthropology, since one of the main general insights from the Darwinian paradigm is that we, as modern humans, have to take responsibility ("Das Prinzip Verantwortung," formulated by Hans Jonas; see Altner 1981a), because we are the single organism on earth with morality (Vogel 2000; Cela-Conde and Ayala 2004; Bischof 2012). Washburn (1968, cit. by Fuentes 2010, p. 5) wrote that "human biology has no meaning without society [. . .] the evolution of man can only be understood as a biosocial problem." A proper understanding of evolution is thus essential for modern societies; and when taking responsibility is a social concern, it is clearly necessary to publish scientific results on human evolution not only in scientific journals but also in the public media. Still, while sophisticated popular scientific writing is highly welcome and helpful (see call by Howell 2003; Fuentes 2010, p. 5), superficial and callow fossil – and journalism-driven science initiated by pure sensationalism – is counterproductive. What we need to do in our popular nonfiction is, as Howells (2003, cit. in Fuentes 2010, p. 5) urged, to "adopt modern perspectives of an emergent evolutionary biology, and practice analytical, comparative, and experimental methods, relevant to elucidation of the nature and roots of the Human condition." Howells injunction remains the standard, and fortunately there are currently excellent popular expositions in the bookstores, e.g., Tattersall's (2012) *The Masters of the Planet* and Stringer C (2013) *Origin of our Species*.

Yes, Science History Matters!

With the methodological principles of the biological and neighboring sciences in mind, paleoanthropologists should also be aware of science history. In the words of Theunissen (2001, p. 147): "That 'history matters' is perfectly obvious if it is taken to mean that the present cannot be understood without reference to the past." Although this statement might seem trivial, there is a dilemma, mentioned by Foley (1987); the past is a "foreign country" and our forerunners did things differently there. The challenge of paleoanthropology is to improve our scientific methodology, to learn more about us and our origin, in order to reach a biological and sociobiological self-conception (Vogel 2000). The historicist approach may give rise to reflexive doubt, so don't expect too much. Dennell (2001, p. 64) is regrettably right when saying: "Whilst we might like to think that palaeoanthropology is a discipline that unifies humanity and helps combat racial, sexist, and other types of prejudice simply because of its focus on the origins of humankind, we should not forget it did the opposite for at least the first half of the twentieth century."

The confidence of being on the right road raises the risk of complacency. And therein lies the essential reason why history really matters; one should never be too comfortable for too long with an idea (Dennell 2001). What is needed is a real and intense dialogue between the many disciplines that cooperate to unravel the process of human origin. The history of paleoanthropology teaches us, in all its facets and complex details, quite how great a challenge of evolutionary biology reconstructing our origin is. McHenry (1996, p. 86) has put it neatly: "One needs to make the best of our tiny sample of life in the past, to be open to new discoveries and ideas, and to enjoy the pleasure of learning and changing." No one will explain our human origins, if we don't – and what a fascinating challenge!

Charles Darwin, Paleoanthropology, and the Modern Synthesis

Franz M. Wuketits

Contents

Abstract

The present chapter focuses the role that paleoanthropology played in Charles Darwin's views of evolution and in the formation of the synthetic theory or modern synthesis. It shows the close relationship between these evolutionary conceptions and the central goals of paleontology. Darwin was among the few naturalists in the nineteenth century who fully grasped the importance of fossils for an understanding of evolution. In spite of the incompleteness of the fossil record – and despite opposing views – he referred to paleontology in order to support his theories of common descent and continuous steps in evolutionary history (gradualism) as well as his views on the roots of humans in apelike

mammals. Thus, in his *The Descent of Man* he argued, with some optimism, that the lack of fossil human remains was merely due to the fact that they had not yet been discovered. Indeed, paleoanthropology as a discipline at the interface between paleontology and anthropology was firmly established only in the late nineteenth century. However, up to now it has played a major part in the study of human evolution, and it has also helped in establishing the synthetic theory in the 1940s and 1950s, although only few of the leading proponents of this theory were explicitly concerned with paleoanthropological issues. The synthetic theory has been extraordinary successful as a comprehensive explanation of the mechanisms of evolutionary change of species (mainly variation and natural selection), and it has offered convincing evidence that the very same mechanisms fully apply to human evolution. This chapter also includes some (historical) examples which show how paleoanthropologists were sometimes misguided by ideological questions (*Weltanschauungsfragen*). Moreover, it brings into the focus some methodological issues and the shift of paleoanthropology from mere narrative to a theory-guided science. These issues are serious, since after all they affect the status of a discipline that is of crucial importance for a deep understanding of past and present conditions of humankind. Finally, therefore, the chapter considers the importance of paleoanthropology as the basis for a synthesis of anthropology that is increasingly needed as the latter gets more and more split into a growing number of highly specialized subdisciplines.

Introduction

"Paleoanthropology tries to establish a valid phylogenetic model on the adaptive processes that made us human. As a result of sophisticated planned excavations there has actually been a dramatic increase in fossilized bones and archaeological material, which enables us to unravel our history and its spatial and chronological patterns" (Henke 2005, p. 120). However, there is agreement that fossil and archaeological material is not enough, because any remain of the past requires a theoretical interpretation. The frame for such an interpretation is the theory of evolution. Without this theory, fossils give much room for wild speculations, as can be seen from the role they played – or even still play – in mythology and folklore beliefs (see Thenius and Vavra 1996). The very aim of paleontology is the reconstruction of the history of life on earth (Kuhn-Schnyder and Rieber 1984), and this clearly presupposes that, first, life has a history and, second, that the extant species descended from earlier ones. Hence, paleontology and the theory of evolution are strongly connected with each other.

Evolution is studied in many disciplines and by the means of different tools. Paleontology is one of them, but it is the only field of research that – as a historical science at the intersection between geology and biology (Hölder 1985; Thenius 1972) – offers a direct access to life of the past. "The fossil record provides a powerful basis for analyzing the controlling factors and impact of biological evolution over a wide range of temporal and spatial scales and in the context of an evolving Earth" (Jablonski 1999, p. 2114).

The discovery of a calotte and postcranial skeleton in Neanderthal near Düsseldorf (Germany) in 1856 – 3 years before Darwin's publication of *On the Origin of Species* – was the beginning of paleoanthropology. The Neanderthal man, however, gave rise to many speculations and controversial interpretations, and it took some time to put this discovery – together with other findings documenting the existence of this fossil human species – in the right place. Anyway, soon – and perhaps inevitably – the Neanderthal man was brought into connection with evolution, and it was, hesitantly, concluded that he could be an ancestor of modern humans (Tattersall 1995). Many controversial discussions concerning the evolutionary status of humans followed, and still there are "open" questions regarding the history of the hominin branch. Yet the close connection between paleoanthropological research and findings and conceptions in many other disciplines (recently including molecular biology) gives us today a quite comprehensive understanding of the processes of hominization. The theories underlying this understanding have been Darwin's theory, the synthetic theory and finally an organismic, systemic approach to evolution. The – rather short – history of evolutionary thinking in general can be seen as a process towards an extension of evolutionary theory. Ever since Darwin evolutionary theories have covered more and more empirical data and assembled them to a coherent system of knowledge. Dobzhansky's well-known and frequently cited statement – "Nothing in biology makes sense except in the light of evolution" (Dobzhansky 1973) – has proved to be entirely right.

In what follows, first a brief historical sketch of evolutionary thinking with special reference to Darwin is given. Second, some reflections on the status of paleoanthropology are presented. Third, the formation and implications of the synthetic theory are outlined. Forth and finally, the need of synthesis in anthropology is expressed.

Charles Darwin's Conceptions of Evolution

Darwin and the Emergence of Evolutionary Thinking

The publication of Darwin's monumental *On the Origin of Species* was the climax of a long intellectual development (see, e.g., Bowler 1984; Eiseley 1961; Glass et al. 1959; Junker and Hoßfeld 2001; Oeser 1996; Zimmermann 1953). At the beginning of this development, we find quite cautiously pronounced ideas about the variability of species, speculations concerning a changeable universe, and the place of humans in it. For example, Denis Diderot (1713–1784), one of the chief proponents of the French Enlightenment, stated that "if beings change successively, passing through the most imperceptible nuances, time, which does not stop, must eventually put the greatest difference between forms that existed in ancient times, those which exist today and those that will exist in far-off centuries" (quoted after Crocker 1959, p. 129). And Diderot's compatriot and contemporary, the eminent and celebrated naturalist Georges L. L. Buffon (1707–1788), reasoned as follows: “Though Nature appears always the same, she passes nevertheless through a constant movement of successive variations . . .; she lends herself to new combinations, to mutations of matter and form, so that today she is quite different from what she was at the beginning or even at later periods” (quoted after Lovejoy 1959, p. 104).

Diderot, Buffon, and some other scholars – naturalists and philosophers – of the eighteenth century marked one of the most exciting and momentous transformations in the history of Western thinking: the shift from a static to a dynamic conception of nature. However, they had to meet serious obstacles. For many centuries the only accepted source for an “explanation” of the existence of all things, living and nonliving, was the Old Testament, and it was taken for granted that the Creation story of Genesis reveals the ultimate and unquestionable truth about the origin of the earth and its inhabitants. It was considered as a matter of course that humans are the creation of a benevolent God who had created them in his own image. Natural theology was the most influential and pervasive doctrine in the eighteenth and even in the nineteenth century. Natural theologians, among them – and above all – William Paley (1743–1805), argued that the organization of living beings offered evidence for an omnipotent and omniscient designer and did not leave any space for alternative ideas. Hence, it should not come as a surprise that even when evolutionary thinking in the nineteenth century became more or less popular, many scholars did not abandon theological interpretations of nature and tried to combine evolution with transcendentalism and spiritualism.

The static conception of the world is strongly connected with typological thinking or essentialism (Popper 1960) which is deeply rooted in Western philosophy and still quite influential. In the eyes of a “typologist,” only “ideas” or “essences” are real, while any observed object is just their manifestation; ideas or essences are unchangeable, and they give the observable natural objects their “fixed” character. In a static world the notion of time does not play a significant role, and as long as people believed that the earth and all living beings were created at once some 6,000 years ago, they could neither grasp the variability of species nor the species’ common descent. Some naturalists in the eighteenth century – particularly Buffon – did speculate that the earth could be many thousand or even million years old, but geological time and history were not truly realized before the nineteenth century (Gould 1988).

Anyway, speculations about the possibility of long-term changes in nature and the possible variability of plant and animal species through longer periods of time do not necessarily imply – or lead to – an evolutionary theory in a strict sense. Such a theory has to pose and to answer at least three sets of questions (Wuketits 1988, 2005b):

- Are species changeable? Are the extant species descendants of other, earlier species?
- What are the modes and pathways of evolution? Does evolution occur step by step, by slow gradation, or does it allow discontinuities? To what degree are

species and "categories" of organisms (such as families, orders, or classes) related to each other?
- What are the mechanisms, the "motors" of evolutionary change?

The first question marked the very beginning of evolutionary thinking and is no longer relevant because evolution has turned out to be simply a fact. However, the statement that species are indeed changeable does not yet imply a theory of evolutionary changes and is not a theory by itself. It was common to speak in this context of a "theory," as long as "there was some likelihood that it was incorrect and that evolutionary descent had not occurred" (Ayala and Valentine 1979, p. 1). Any theory of evolution has to answer the second and the third set of questions.

In this strict sense the French naturalist Jean B. de Lamarck (1744–1829) was the first evolutionary theorist (see, e.g., Junker and Hoßfeld 2001; Oeser 1996; Wuketits 1988, 2005b, 2009b). Lamarck was a prolific researcher and contributed to a wide spectrum of scientific disciplines. He did not just speculate about the possibility of evolution, but explicitly stated that complex organisms had evolved from simpler ones. Also, he tried to find out the branching of animal groups and – most important – to specify mechanisms of evolutionary change. In first instance he is – rightly or wrongly – remembered as an advocate of the idea of the "inheritance of acquired characteristics" that is commonly known as Lamarckism.

It is a remarkable historical coincidence that Lamarck published his main methodological work, his *Philosophie zoologique* (*Zoological philosophy*), in Darwin's year of birth and 50 years before the publication of Darwin's *On the Origin of Species*. Although Lamarck did attract the attention of scientists, philosophers, and political commentators throughout the nineteenth and twentieth centuries (Corsi 2011), it was not his but Darwin's work which gave the theory of evolution its final impetus and brought it into the focus of public interest. "No biologist," says Mayr (2000, p. 80), "has been responsible for more – and for more drastic – modifications of the average person's worldview than Charles Darwin." One may doubt that any "average person" in his or her everyday life really bothers about Darwin, but everybody who takes Darwin seriously can no longer adhere to the traditional static worldview (chapter "▶ Evolution of Religion," Vol. 3).

At the beginning of his scientific career, Charles Darwin (1809–1882) believed in creation and was not aware of Lamarck and other scholars who at least tentatively had approached the idea of evolution. He studied theology, learned Paley's doctrine of natural theology by heart, and was prepared for Holy Orders in the Church of England. His *Beagle* voyage (1831–1836) (see Darwin Keynes 1988), however, which gave him many opportunities to observe biological and geological phenomena and to collect a vast number of biological and geological objects, led to dramatic changes in his intellectual life. Sure, already as a theology student (and even earlier), Darwin had been very much fascinated by such objects and attended courses and excursions in botany, zoology, and geology, but since at that time many, if not most, naturalists were Christians or even clergymen, he could not see any contrast between science and the Christian dogma. Besides, he never studied – according to our today's standards – natural sciences at a professional level and represented, in a way, the typical amateur naturalist in nineteenth-century England (Finkelstein 2000).

When Darwin, after his *Beagle* voyage, returned to England, not only his prospects of a parochial life had vanished but his belief in the variability of species had developed. For the next two decades, he was busy studying the collected material and formulating his views of the transmutation of organisms (see, e.g., Ospovat 1981). According to his character – he did not care to hurry either in his private nor in his professional life – he proceeded very cautiously and long hesitated to publish his conclusions. “In June 1842,” he remembered in his *Autobiography* (edited more than 100 years later by his granddaughter Nora Barlow), “I allowed myself the satisfaction of writing a very brief abstract of my theory in pencil in 35 pages” (Darwin 1958, p. 120). But only 17 years later, he published his *On the Origin of Species* that became a landmark in the history of Western thinking. In the mean time, however, he published eight other books, among them a volume on the structure and distribution of coral reefs and – what particularly deserves to be mentioned – a comprehensive monograph in two volumes on a somewhat curious group of crustaceans, the Cirripedia (barnacles). This work can be regarded a “classic” in zoological literature. Thus, when Darwin released the *Origin* he was well established in the scientific community. Thomas H. Huxley (1825–1895), one of Darwin’s chief advocates (“Darwin’s bulldog”), remarked that Darwin “never did a wiser thing than when he devoted himself to the years of patience which the Cirripedia-book cost him” (Darwin 1888, p. 347). While he was thoroughly working on the anatomy and taxonomy of the barnacles for no less than 8 years, he already spent much time thinking about evolution, so that one may argue that this study of a special group of animals served him as a long-term empirical training for the sake of better argumentations in evolutionary thinking. And one can, as Ghiselin (1969) suggests, see connections between Darwin’s ideas on comparative anatomy applied to barnacles and his views of evolution.

Nora Barlow (1885–1989) writes in her introduction to Darwin’s *Autobiography* that “he had to convince himself by accumulated evidence before he could convince others, and his doubts are as freely expressed as his convictions. His books lie like stepping-stones to future knowledge” (Darwin 1958, p. 13). This is particularly true of his *On the Origin of Species*, which is probably best characterized as *One Long Argument* (Mayr 1991). In fact, Darwin intended to offer most convincing evidence for the variability of species and its major mechanism: natural selection (chapter “▶ Evolutionary Theory in Philosophical Focus,” Vol. 1). The *Origin* contains numerous data from different disciplines including geology, biogeography, anatomy, and embryology. Nevertheless, it would be wrong to believe that Darwin collected facts in order to, finally, establish a theory. Rather, his “scientific accomplishment must be attributed . . . to the development of theory” (Ghiselin 1969, p. 4). As he himself put it: “From my early youth I have had the strongest desire to understand or explain whatever I observed, – that is, to group all facts under some general laws” (Darwin 1958, p. 141).

The “law” of natural selection does give a substantial explanation of the variety of organisms, extant and extinct, and their changes through the ages. And it has had significant philosophical implications (chapters "▶ Evolutionary Theory in Philosophical Focus," Vol. 1, "▶ Evolution of Religion," Vol. 3, and "▶ Paleoanthropology and the Foundation of Ethics: Methodological Remarks on the Problem of Criteriology," Vol. 3), for it has made the "intelligent-design argument" obsolete. Darwin replaced the old and venerable concept of (universal) teleology by a very "profane" mechanism that operates on the basis of randomly produced individual varieties in each species and does not entail any plan or purpose in nature. Hence, he concluded that merely "from the war of nature, from famine and death, the most exalted object which we are capable of conceiving, namely, the production of the higher animals, directly follows" (Darwin 1859 [1958], p. 450). The world into which Darwin led us is "a world in which man must rely on himself, in which he is not the darling of the gods but only another, albeit extraordinary aspect of nature" (Simpson 1963, p. 25). Early when he started to reflect on evolution, Darwin must have also human evolution in mind, but in the *Origin* he just – and somewhat cryptically – remarked that "much light will be thrown on the origin of man and his history" (Darwin 1859 [1958], p. 449).

Darwin's Theories and His Credit to the "Great Chain of Being"

However, in fact Darwin established five theories of evolution (Kutschera and Niklas 2004; Mayr 1991, 2000; Wuketits 2005a, b).

- Evolution as such: Species are not constant but variable.
- Common descent: All species are genealogically related and finally to be traced back to one single unique origin in the history of the earth.
- Multiplication of species: One species splits into two or more new species.
- Gradualism: Evolution occurs gradually, step by step, without major discontinuities.
- Natural selection: The very mechanism of evolution is natural selection; it acts on the ground of the abundance of genetic variation in each generation.

Here again a distinction must be made between the fact that species have changed through the ages and theories of the pathways of this change as well as its mechanisms (see also Ayala 2005). Darwin's work addressed all three issues. His well-informed and sympathetic contemporaries noticed that "the two great merits of this work are its bringing together in a condensed form the evidences in favor of the Evolution of Life, and its offering Natural Selection as a cause of this Evolution" (Chapman 1873, pp. 16–17). Since at the beginning of his reflections on the changeability of species Darwin was not aware of his "precursors" (including Lamarck), he discovered evolution once again and, as it were, for himself. Only later he paid tribute to scholars who had speculated on evolution before him and regarded Buffon as the first naturalist who had treated the variability of species in a serious scientific manner.

As is well known, Alfred Russel Wallace (1823–1913) had developed a theory of natural selection very similar to – or almost identical with – Darwin's theory. In June 1858 Darwin received a letter from Wallace and a manuscript in which he indeed found expressed his own ideas. Maybe that, as Ruse (1982, p. 3) speculates, Darwin's "heart started to sink," because for two decades he "had been sitting on a secret: a theory and a mechanism that would explain in a scientific way the organisms we find around us and in the fossil world." Anyway, he felt alarmed and informed his friends, among them Lyell (see section "Darwin and Paleoanthropology") about Wallace's text. Wallace's paper, then, was presented together with an excerpt of Darwin's nascent work at a meeting of the Linnean Society in July 1858, and Darwin felt pushed to complete and to publish his work as quickly as possible. However, what he finally released to the public, the *Origin*, was not what he actually had been preparing, a "big book" on evolution (Ospovat 1981). The "Darwin-Wallace story" still leaves space for speculations among evolutionists and historians of science as well. Here it should be sufficient to note that Wallace – who, by the way, was the founder of biogeography – must not be regarded as "a second Darwin" (Glaubrecht 2013). No matter that he had developed, independently of Darwin, a theory of natural selection (and coined the word "Darwinism" to characterize both, his own and Darwin's selection theory) – the two men disagreed with respect to some crucial implications of evolutionary thinking: Wallace embraced spiritism and was not prepared to fully apply the idea of evolution by natural selection to the emergence and evolutionary history of humans, while Darwin, though due to his personal dispositions, was not determined to become a revolutionary (Wuketits 1987) – revolutionized the Western world view and has been rightly considered one of the leading supporters of scientific materialism (chapters "▶ Historical Overview of Paleoanthropological Research," Vol. 1, "▶ Evolutionary Theory in Philosophical Focus," Vol. 1, and "▶ Evolution of Religion," Vol. 3).

This does not mean that Darwin broke with all traditions of Western thinking. As his views of gradualism show, he adhered to the long-lasting and venerable philosophical tradition, according to which there is continuity in nature: *natura non facit saltus*. Since ancient times the idea of a great chain of being (Lovejoy 1936) was – and to a certain extent still is – compelling. Up to the nineteenth century, scale-of-nature models (*scala naturae*) were very popular. They reflected the assumption that all natural objects – from inorganic compounds to objects of ever-higher complexity, plants and animals, and finally human beings – were arranged in a linear way. But these models were static and implied the conviction that the (linear) arrangement of natural objects represents the divine plan of creation. The natural objects followed, one after the other, but were not linked together by genealogy. Apparently, only the Swiss zoologist Charles Bonnet (1720–1793) approached the perspective that the scale of nature could produce some "branches" and thus, in a way, anticipated the model of a genealogical (phylogenetic) tree which, after all, was introduced by the German physician and zoologist Peter S. Pallas (1741–1811). Pallas replaced the idea of a mere succession in nature by the concept of a genealogical tree or a "net" by which he indicated that living beings are connected like nodes in a network (Oeser 1996; Zimmermann 1953). Hence, he came close to the theory of common descent which, then, in Darwin's work played a central role.

Clearly, in contrast to the scale-of-nature conceptions, Darwin advocated a dynamic and non-typological view of living beings and rejected the belief in a divine plan. His gradualism generally fits the idea of continuity in nature, but it cannot be separated from his theory of natural selection. Darwin (1859 [1958], p. 435) stated: "As natural selection acts solely by accumulating slight, successive, favourable variations, it can produce no great or sudden modifications; it can act only by short and slow steps. Hence, the canon of 'Natura non facit saltum', which every fresh addition to our knowledge tends to confirm, is on this theory intelligible." However, Darwin seriously considered the incompleteness of the fossil record and thus the missing of connecting links. "Why is not every geological formation charged with such links?," he asked, and "Why does not every collection of fossil remains afford plain evidence of the gradation and mutation of the forms of life?" (Darwin 1859 [1958], p. 429). Yet Darwin did not feel that his conceptions of evolution, here particularly gradualism, were weakened by the missing of fossils. Rather, he obviously believed that he had good reasons for some optimism, when he stated the following: "If we look to long enough intervals of time, geology plainly declares that species have all changed; and they have changed in the manner required by the theory, for they have changed slowly and in a graduated manner. We clearly see this in the fossil remains from consecutive formations invariably being much more closely related to each other, than are the fossils from widely separated formations" (Darwin 1859 [1958], p. 431).

It is important to notice that Darwin generally expected strong support for his views from geology and paleontology. This can be seen by the fact that in the *Origin*, he devoted two chapters to the geological and paleontological record. Also, it has to be mentioned that Darwin's notebooks – written in preparation for the "big book" – include material on paleontology and extinction (Ospovat 1981). All things considered, one has good reasons to state that paleontology played an important part not only in Darwin's gradualistic view of evolution but also in the formation of his other four theories. His theories should be seen as a coherent (theoretical) system. As soon as he started to believe that species are changeable, he also began to reflect on possible modes and mechanisms of evolution.

Darwin and Paleoanthropology

In 1871 Darwin published his second major book on evolution, *The Descent of Man*, which maybe more than all his other works "in many ways best manifests the nature of his thought" (Ghiselin 1969, p. 214). Again, he was not the first to treat this issue. In England Thomas H. Huxley (1825–1895) – "evolution's high priest" (Desmond 1997) – in his *Evidence as to Man's Place in Nature* (1863) gave forceful arguments for the descent of humans from apelike creatures and thus put us in our (right) place (Weiss 2004), and simultaneously in Germany Ernst Haeckel

(1834–1919) developed practically the same arguments. Later Haeckel published a massive book in which he extensively treated human ontogeny as well as phylogeny (Haeckel 1891). Both, Huxley and Haeckel, were enthusiastic supporters of Darwin's views from the beginning on and helped popularizing the idea of evolution by natural selection. Unlike Darwin, both were engaged in public discussions and did not avoid controversies. However, paleoanthropology, the study of fossil humans, in the 1860s and 1870s was far from being firmly established as a scientific discipline. To what extent, then, is it justified to connect Darwin with paleoanthropology? And, more generally, which role did the fossil record play in Darwin's evolutionary conceptions?

Fossils had been known already in ancient times, but were constantly interpreted as *ludus naturae* ("play of nature"), as expressions of the Creator's mood or products of the Deluge (see, e.g., Hölder 1960). The Danish physician Niels Stensen (Nicolas Steno) (1638–1687) interpreted, quite correctly, some rock-hard objects as fossil remains of ancient and extinct animals. In a way, this was the beginning of paleontology, but since Steno believed in the Deluge, his intention was to demonstrate the divine plan (Hölder 1960). Remarkably, Lamarck did not at all make use of the fossil record, for he did not believe that species can get extinct, but was rather convinced that all fossils were remnants of organisms still alive somewhere on the earth (Corsi 2011). On the other hand, his compatriot – and chief opponent – Georges Cuvier (1769–1832), who is regarded as the founder of comparative anatomy and paleozoology, did recognize fossils as traces of extinct animals but did not accept the idea of evolutionary change. Instead, he too attempted to prove the reality of the Deluge and of a short history of humans on earth (Haber 1959; Hölder 1960). That a paleontologist did not believe in evolution seems somehow amazing from the today's point of view. But Cuvier was bound to typological thinking, and besides – although he lived in a century of extraordinary paleontological activities, to which he himself contributed so much – paleontology was considered as most valuable by geologists, but its lessons for historians of life were less clear and invited controversies and opposition (Coleman 1977). Moreover, one has to be aware that fossils by themselves do not supply proofs of the evolutionary change anyway. They make plausible that the evolutionary mechanisms of the present also operated in the past (Rieppel 1984) – according to the principle of the "actual causes" that was postulated by Charles Lyell (1797–1875), Darwin's mentor and one of the founding fathers of historical geology who, after all, refuted Cuvier's "catastrophism." Yet paleontology as a historical science relies on a biological understanding of organisms, their structures and functions (Hengsbach 1979). Paleontology – as the reconstruction of extinct species – is a theory-guided discipline; without a theoretical frame the study of fossils would remain to be an art of storytelling, certainly quite entertaining, but scientifically invalid. In particular, paleoanthropologists must carefully separate "paleopoesy" from sound scientific approaches in the study of fossil humans. Their discipline is – as it always was – publicity oriented, and they have to make clear that they try to reconstruct and to conceptualize hypothetically humanity's descent (e.g., Johanson and Edey 1981; Henke 2007, 2009; Tattersall 1995, 1998; Schwartz and Tattersall 2000).

It was said that for Darwin's theoretical conceptions of evolution fossils did not play any part (Rieppel 1984). This is not true, as can be seen from previous remarks in this chapter. It is true that Darwin attained at the theory of natural selection mainly by considering other sources of information – among them and most important domestic breeding of plants and animals that he regarded as an "experiment" from which he could derive the principle of natural selection (Richards 1998) – yet he did not at all neglect the fossil record. During his *Beagle* voyage he was struck – in South America – by fossils, for example, the relics of *Glyptodon*, an extinct giant armadillo. And he collected fossils, whenever the *Beagle* anchored inshore (Huxley and Kettlewell 1965). Unlike Cuvier and Lamarck, Darwin interpreted fossils correctly as evidences for the "evolutionary chain," and his work certainly contributed much to the further development of paleontology (Schmidt 1960). In 1851 he published a monograph on fossil barnacles and in 1854 a second volume on this issue. (Probably, no other naturalist has spent so much time and energy with barnacles, extant and extinct.) This treatise alone offers ample evidence for Darwin's commitment to paleontology (see also Wuketits 2009a).

Sure, in *The Descent of Man* the references to the fossil record are scarce. But one should once again keep in mind that at that time only very few hominin fossils were known – and the few known were still controversially discussed or met with skepticism – and that it took some more years, if not decades, before paleoanthropology was established as a scientific discipline. However, what seems more important, Darwin was convinced that the lack of fossils was just due to the fact that they had not yet been discovered. He, of course, knew Huxley's seminal book *Evidences as to Man's Place in Nature* (1863) where one can find a chapter on fossil remains of humans, namely, the fragmentary skulls from the caves of Engis (Belgium) and the Neanderthal near Düsseldorf (Germany). In retrospect, Darwin had good reasons to be optimistic. In the twentieth century a vast number of fossil humans were discovered, and with their help an ever-better understanding of the evolutionary past of humans could be developed.

Why were hominin fossils at Darwin's and Huxley's time so rare? The answer is quite simple: "All the early human remains that composed [the fossil record] were incidental finds. They had turned up as by-products of quarrying or construction, of fieldworks by geologists, or of the excavations of antiquarians or prehistorians in search of artifacts" (Tattersall 1995, p. 31). Also, as should be added, for ideological reasons there was no systematic attempt to discover fossil humans for the mainstream of naturalists in the nineteenth century did not believe – or did not want to believe – in a long (evolutionary) history of humankind and was convinced of the special status of humans in nature. Thus, for example, Richard Owen (1804–1892) – a most distinguished anatomist and paleontologist and simultaneously a critic of Darwin's *Origin* – "was pulling man and ape apart, showing that moral responsibility and human freedom where altogether higher concerns" (Desmond 1982, p. 74). However, Darwin was on the right track. In his attempt to reconstruct human evolution, he could refer to data from comparative primatology, and it is astonishing how expressively he drew – irrespective of the lack of fossils – a picture of the phylogenetic relationship between humans and apes (Heberer 1960). He might be considered as the first modern anthropologist in a wide sense. His *The Descent of Man* includes full-length chapters on (human) social, moral, and intellectual capacities and outlines, in a way, what is now called evolutionary anthropology.

Paleoanthropology After Darwin: Premises and Expectations

Since in the first chapter of the present work Henke gives a comprehensive account of the history of paleoanthropology (see also Tattersall 1995), this chapter includes only a few – mainly conceptual and methodological – remarks. To begin with, one should keep in mind Tattersall's "warning": "Before you can begin to work out the relationships between extinct species in the human family, you have to have a reliable idea of how many such species there are among the many hundreds of hominid fossils known" (Tattersall 1995, p. 229). Apparently, nobody can really tell how many human species once existed because several of the alleged "species" are under discussion and not unanimously acknowledge as species. The increasing number of fossils does not automatically lead to a deeper understanding of hominization, as can be seen by the recent trend "from trees to bushes" in the representation of hominin branching (Gould 1976; Wood and Collard 1999; Tattersall and Schwartz 2000; Henke 2009). The meaning of theory must be pointed out once more: Fossils as such do not replace theory.

It is clear that the expectation of paleoanthropologists – and of anyone concerned with the evolution of humans and their position in nature – is and has always been to develop an ever-better insight into the pathways of human evolution. But expectations, when too strong, can mislead the human intellect. Like other scientific disciplines, the history of paleoanthropology includes examples for such misguidance.

Again, the Piltdown forgery has to be remembered. "Piltdown man," *Eoanthropus dawsoni* – literally, the human of the aurora – was considered for 40 years as an evidence for the roots of humans in Europe. In a comprehensive paleoanthropological work, Keith (1925) devoted almost 200 pages to the description and explanation of this "fossil document" that, as he enthusiastically stated, "is the most important and instructive of all ancient human documents yet discovered in Europe" (Keith 1925, Vol. 2, p. 486). The interpretations of the Piltdown skull were somehow adventurous but very promising – "the first female intellectual" (Hooton 1947, p. 306) – and were guided, in the last (if not in the first) instance, by ideology. *Eoanthropus* was used to prove the European origin of humans. While already Darwin (1871) had assumed that Africa was the cradle of humankind, all those anthropologists who embraced (almost in a literal sense) the Piltdown skull could not – or did not want to – acquire a taste for an "out-of-Africa hypotheses." Later Darwin's suggestion was substantiated by the fossil record ranging from the Oligocene to the Pleistocene (Leakey 1960), and up to now no unobjectionable support has been found for an opposite view.

"Nebraska man," *Hesperopithecus haroldcookii*, is a story somewhat even more curious than its British counterpart (see Gould 1989). About 10 years after the Piltdown "discovery," a single tooth was found in Nebraska and finally interpreted as the relic of a higher, manlike primate that could demonstrate the early ancestry of humans in North America. This time, however, it did not take long to recover the truth: The tooth turned out to be a remnant of an extinct species of peccaries, piglike animals now around in the south of the United States, in Central America, and in northern regions of South America. Unlike the Piltdown skull this fossil was not a forgery, but as in the former case, it apparently had aroused some ideologically motivated hopes.

Like in any other scientific discipline research work in paleoanthropology leaves some room for speculations, but one must distinguish between wild and sound speculations (Bunge 1983). The discovery of hominin fossils depends on several factors, for example – if not above all – a sophisticated planning of excavations. But sometimes such plans do not really help much; not every excavation brings sensational fossils to light. Sometimes paleoanthropologists have simply good luck, so that it does not come as a surprise that the mass media often treat new discoveries like nuggets. Like all scientists, paleoanthropologists are usually very ambitious, and it is quite natural that they are also driven by emotions. Behind the scenes of the search for human origins, then, they can be found engaged in personal animosities and displaying different typically human patterns of behavior (see Lewin 1987). As the late David L. Hull in a long book on the process of science stated: "The objectivity that matters so much in science is not primarily a characteristic of individual scientists but of scientific communities. Scientists rarely refute their own pet hypothesis" (Hull 1988, pp. 3–4). But Hull (1988, p. 4) also considered that "science is so structured that scientists must, to further their own research, use the work of other scientists. The better they are at evaluating the work of others when it is relevant to their own research, the more successful they will be." This means that, in a sense, scientists are forced to cooperate. With respect to hominin fossils and their interpretations, paleoanthropologists would have hardly attained at the present understanding of human evolution, if all of them would have automatically disagreed with everything and anything that others had achieved, be it at the empirical or at the theoretical level.

But another and somehow sensitive point is to be mentioned here. Certainly, the search for their own ancestry is the most fascinating intellectual adventure that humans can undertake. As history shows, the picture that humans developed about themselves has changed, and it has differed from one culture to another. But everywhere and at any time, one finds some ideas on the origin of humankind. Paleoanthropologists are therefore well advised to consider that they "fulfil needs that are reflected in the fact that all societies have in their culture some form of origin beliefs, that is, some narrative or configurational notion of how the world and humanity began" (Isaac 1983, p. 509). It is therefore important to point out – in the public – that paleoanthropology does not tell just another story about human origins, but that its premises and goals are grounded in a way of thinking which is completely different from that of myths. Moreover, paleoanthropology is not the search for documents that give evidence for the special status of humans in nature that some tried to harden even in the second half of the twentieth century (e.g., Hofer and Altner 1972); its aim is rather (hand in hand with primatology) to close the long supposed gap between humans and other animals.

Unlike paleobotanists and paleozoologists, paleoanthropologists are confronted with a psychological aspect, which means that they are operating with humanity's self-image (Lewin 1987). The broader audience of paleontologists is of course more concerned about the origin and evolutionary history of humans than it is fascinated by fossil rats, dragonflies, or crinoids (dinosaurs and perhaps mammoths and other "giants" are maybe exceptions). Also, paleoanthropologists are challenged by the old question "What is man?" and thus encounter the problem, which of their findings are to be characterized as "human." Where to draw a line between humans and nonhumans? Is it at all possible to draw such a line? (Junker 2006).

One cannot seriously expect that sooner or later paleoanthropologists will have a completed (fossil) record of human evolution. "In fact," says Tattersall (1995, p i), "we will never have a human fossil record that preserves even one thousandth of one percent of all the individuals that have ever lived." But this should not be a reason for discouragement, because, as Tattersall continues, "even now we have a reasonably good sampling of fossil species – even fossil human species – that should allow us, by appropriate analysis, to gain a provisional idea of the major events that led to the emergence of our own kind on Earth." The question only is to which extent we are – and will be – able to arrange this "good sampling" to a coherent picture of our evolutionary past. Again, one comes to the meaning of theory in paleoanthropology. Here – for historical, disciplinary and substantial reasons – one theory deserves particular attention: synthetic theory.

Synthetic Theory or Modern Synthesis

The Rise of an Influential View of Evolution

Synthetic theory or modern synthesis, the "second Darwinian revolution" (Junker 2004), has been one of the most successful theories in the biological sciences, and its formation, influence, and implications have already been subject of numerous historical and methodological studies (see, e.g., Bowler 1984; Junker 2004; Reif et al. 2000; Smocovitis 1992; Wuketits 1984, 1988). The theory grew from Darwin's theory of natural selection and outgrew it with regard to empirical data and explanatory power. Briefly, its main achievements can be summarized as follows:

- The theory is "synthetic" (or pluralistic) in the sense that it offers a multifactor analysis and explanation of evolution combining selection, genetic recombination, mutation, (geographically induced) reproductive isolation, and changes in population size.

- It is a "synthesis," because it refers to findings and concepts in practically all fields of biological research, from anatomy to ecology and biogeography and from genetics to paleontology, and makes also use of data from other disciplines such as geology and oceanography.
- Within the frame of synthetic theory, the factors or mechanisms analyzed at the level of microevolution fully apply to – and sufficiently explain – macroevolutionary processes.

Generally, one can say that synthetic theory has put evolutionary theory in the center of biological sciences – as the theory to which all aspects of the study of organisms have to be referred. In the words of Julian Huxley (1887–1975), one of the founding fathers and chief proponents of synthetic theory: "The evolutionary approach will prompt us to ask the right questions of nature, and, when we have asked them, will help us to find the right answers" (Huxley 1958, p. 23). This might sound somehow prophetic but proved to be completely true.

Huxley's *Evolution, the modern synthesis* (1942 [reissued 2010]) introduced the synthetic theory as a broad concept of evolutionary thinking and is to be regarded as a cornerstone in the history of evolutionary theory. If, however, one wants to understand the rise – and final success – of synthetic theory, one has to take into account that up to the 1930s there was practically no agreement concerning the treatment of evolutionary questions. Therefore, even when in 1947 a conference on evolution was organized by the "Committee on Common Problems of Genetics, Paleontology, and Systematics" of the National Research Council, commentators were astonished that the discrepancies between several fields dealing with evolution that had dominated discussions for several decades had practically vanished (Reif et al. 2000). In fact, the status of evolutionary theory in the first decades of the twentieth century was rather blurred, and issues like genetic mechanisms of evolution were controversially discussed. There were several rival theories, for instance, to mention just two, the "mutation theory" by the Dutch plant physiologist and geneticist Hugo de Vries (1848–1935) and "neo-Lamarckism" (actually a name for a bundle of theoretical conceptions). This is not to say that with the emergence of the synthetic theory, really all controversies came to an end, but this theory was a major contribution to unifying biological concepts.

Progress in any scientific discipline is made if – and only if – more and more separate data and concepts are brought together and combined in a broad theory. In the case of evolutionary biology, Darwin synthesized all biological disciplines that were established at his time, but he had – as should be remembered – only very vague ideas about genetics. In more harsh words: "He knew nothing about the causes of hereditary variation, and his opinions on this subject were neither logical nor consistent" (Stebbins 1971, p. 11). The result of this deficiency was his rather nebulous concept of "pangenesis," which was based on Lamarckian principles. He was unaware of the work of Gregor Mendel (1822–1884) whose discoveries would have been quite important for him, but Mendel generally, for some decades, did not receive any attention. Only at the beginning of the twentieth century his "laws of heredity" were rediscovered (by de Vries and other researchers). More or less simultaneously, the German zoologist August Weismann (1834–1914) embarked upon a synthesis in evolutionary biology. Initially a Lamarckian, he combined cytology, embryology, and (Mendelian) genetics with the theory of natural selection (see Sander 1985). The result was "neo-Darwinism," an expanded version of Darwin's evolutionary conceptions which could be brought to a simple formula: Darwin's theory of natural selection plus classical (Mendelian) genetics. For historical and terminological reasons, it has to be pointed out that neo-Darwinism must not – as frequently happens (see, e.g., Ruse 1982) – be confused with synthetic theory (Reif et al. 2000; Wuketits 1988). The step done by the advocates of synthetic theory was to enhance genetics – from Mendelian genetics to population genetics.

Several authors contributed – at the beginning more or less independently of each other – to the formation of the modern synthesis. As was mentioned above, Julian Huxley published the first full-length book already in its title explicitly referring to a (new) synthetic view of evolution. Remarkable contributions to this view followed.

A leading and ardent proponent of the synthetic theory for some 60 years was Ernst Mayr (1904–2005), who is sometimes called "Darwin of the twentieth century" (see Bock 1994; Greene 1994; Smocovitis 2007). Mayr was a trained ornithologist and systematist, but throughout his career also concerned with history of biology and later with philosophical questions in the life sciences. An indefatigable writer and commentator, he frequently pointed out the importance of historical narratives in biology and used the structure of evolutionary theory to demonstrate the autonomy of biology among the natural sciences (see, e.g., Mayr 2004; Wuketits 2004). Mayr has been criticized, from time to time, as being dogmatic, and it is true that already in the late 1950s he "talked about the Synthetic Theory as something completed" (Reif et al. 2000, p. 47). Since he was lucky to reach a very old age, he watched the evolution controversies – and contributed to them – for many decades. He performed much to popularize Darwin and evolution in general and published, at the age of 97, a fresh and accessible book on major evolutionary issues from the point of view of a Darwinian (Mayr 2001).

From the perspective of genetics, it was Theodosius Dobzhansky (1900–1975) who in his *Genetics and the Origin of Species*, first published in 1937, authoritatively contributed to the formation of the synthetic theory. This work can probably be regarded as the first expressive presentation of the synthetic theory, although its author did not use this word. However, it was not by chance that Huxley in his *Modern Synthesis* frequently referred to it and to other of Dobzhansky's writings. It seems that when Dobzhansky, a born Russian, moved to the United States in 1929, his genetically informed ideas of evolution were already most advanced (Brito da Cunha 1998). Like Mayr, Dobzhansky was interested in philosophical questions, too, but unlike Mayr and the other architects of the synthetic theory, he was – somehow amazingly – a Christian believer.

George G. Simpson (1902–1984), in contrast, bluntly expressed his unbelief and his commitment to rational, scientific thinking. "It is possible," he remarked, "that some children are made happy by a belief in Santa Claus, but adults should prefer to live in a world of reality and reason" (Simpson 1963, p. 25). Simpson was a paleontologist, and his chief contribution to the modern synthesis was *The Major Features of Evolution* (1953), a book that was preceded by numerous of his other writings. It was said that Huxley's *Modern Synthesis* was not just a contribution to evolutionary theory in a strict sense but "was also to act as a remedy for the ills of the modern world" (Smocovitis 1992, p. 33). Similar statements could be made on Simpson's work. The paleontologist was not confined to paleontological data and their arrangement but was also concerned with the destiny of humans. Man is just a species of primate, he said, but "among the myriads forms of matter and of life on the earth, or as far as we know in the universe, man is unique. He happens to represent the highest form of organization of matter and energy that has ever appeared" (Simpson 1958, p. 179). However, he never lost interest in paleontology as a field discipline, and late in his life he published a readable book on fossils in which he also treated fundamental questions of evolution (Simpson 1983).

Like Simpson, Bernhard Rensch (1900–1990), the chief German proponent of the synthetic theory who was internationally recognized, dedicated much time and many of his publications to explain the special status of humans. Rensch was a polymath in biology, and he was also well informed in the fields of history, psychology, and – particularly – philosophy (see Wuketits 2006). His major contribution to the formation of the synthetic theory, *Neuere Probleme der Abstammungslehre* (Rensch 1972), was first published in 1947, revised in 1954 and 1972, and English editions – entitled *Evolution above the Species Level* – were published (1959, 1960) in London and New York, respectively. Mentioning this translation is not unimportant for the publications of some other German representatives of the synthetic theory appeared invariably in German and were not – or only to a minor extent – perceived in the English-speaking world. This applies to Gerhard Heberer (1901–1973) and Walter Zimmermann (1892–1980).

During his lifetime Heberer was, in German speaking countries, probably the best known anthropologist or paleoanthropologist for that matter. This is not the place to discuss his Nazi entanglement, but it should be stressed that Heberer for decades had been engaged in the reconstruction of human history and regularly published provisional pictures (*Jeweilsbilder*) of the understanding of human evolution as documented by the fossil record. Among his last publications are two books (Heberer 1968, 1972), the first a popular account of the evolution of hominids and the second a somewhat more technical, but accessible, small volume. After his death this volume was expanded by Henke and Rothe (1980). Also, Heberer edited a comprehensive book on the evolution of organisms that first appeared in 1943 and later, in the 1960s and early 1970s, in three volumes. The work is to be regarded as a testimony of synthetic theory and of the validity of Darwinian views applied to the reconstruction of evolution and was "the most comprehensive statement of the Synthesis that was published during its formation phase in Germany" (Reif et al. 2000, p. 73). Heberer also edited an extensive volume on the advances in the understanding of human evolution (Heberer 1965).

Zimmermann was a paleobotanist but generally interested in evolutionary questions. He published a well-documented book on the history of evolutionary thinking up to the mid-twentieth century (Zimmermann 1953) and another volume in which he – in a (more or less) truly neo-Darwinian tradition – attempted to refute the Lamarckian assumption of an inheritance of acquired characteristics (Zimmermann 1969). Also, he was concerned with the methodology of phylogenetic reconstructions and the philosophy of evolution, as his – somehow positivist and thus, from today's point of view – obsolete volume on these issues shows (Zimmermann 1968).

Sure, one should mention some other contributors to the synthetic theory – they are named, for example, by Reif et al. (2000) and Smocovitis (1992) (see also Junker 2004, on references to German authors) – but in the present context, the reference to the here mentioned naturalists may suffice. All of them were interested in human evolution and treated philosophical issues on this topic. All of them tried to explain the appearance of humans in a way that Darwin had sketched and were convinced that the previously, from ancient times on formulated enigma of the very human being could be resolved in terms of evolution by natural selection. Nothing can be said here about disagreements among the advocates of the synthetic theory. What is more important in the present context is the general success of the modern synthesis which is also due to the fact that their architects seemed to form something like a phalanx and "seemed tacitly to have agreed to play down their differences and to emphasize their areas of agreement" (Hull 1988, p. 201). The reason for this "agreement about agreement" was maybe a philosophical one: the goal to establish a secular, materialist world view, to give a definitely naturalistic account for the human species, and so finally to dismiss – in Darwin's spirit – the long-lasting idealist tradition. Tattersall (2000, p. 2) wryly remarks that the synthetic theory "was doomed to harden, much like a religion, into a dogma." Especially Mayr has been from time to time accused to be too dogmatic, but he used to say that even he was dogmatic, he did good service to the theory: People frequently react quite sensitively to dogmatically defended positions and try to refute them; this way, a theory can be tested and improved. Sure, no scientific theory should be defended and preached like a dogma. What counts, after all, is its explanatory power. And one must admit that the explanatory power of the modern synthesis has been quite noticeable – and that the advocates of the synthetic theory have stimulated further discussions and opened doors to additional critical studies on the patterns and processes of evolution.

The success of the synthetic theory must not obscure the fact that at least some of its tenets and implications were exposed to criticism "from outside" the theory. Thus, at an international conference on evolution held in Halle an der Saale (Germany, at that time German Democratic Republic) in October 1973 Mayr expressed his conviction that all questions of evolutionary change can be sufficiently resolved within the frame of the synthetic theory, while Remane was much less optimistic and rather critical (Mayr 1975; Remane 1975). Adolf Remane (1898–1976), one of the most influential zoologists for several decades in twentieth-century Germany, opposed to synthetic theory for different – maybe also personal and political – reasons (Junker 2000). It appears that his main drive to resist synthetic theory was his sympathy for the traditional German morphology that – to a certain extent even in the twentieth century – was guided by a typological approach to nature. The same is probably also true to the German paleontologist Otto Heinrich Schindewolf (1896–1971) (see section "Synthetic Theory and Paleontology, Particularly Paleoanthropology").

Despite some disagreements, the architects and early advocates of the synthetic theory had come to terms at least about two aspects. First, they did not see any serious gap between microevolutionary and macroevolutionary processes, and, second, they fostered an adaptationist program, i.e., the view that any trait of organisms in the last instance can be explained in terms of adaptation. How seriously they took this program can be seen from their different books mentioned in this section (e.g., Dobzhansky 1951; Mayr 1963). Therefore, the proponents of the synthetic theory generally rejected – among other conceptions like goal-oriented evolution and types (*Baupläne*) – the notion of an autogenetic, autonomous evolution without interaction with the environment (Reif et al. 2000).

Synthetic Theory and Paleontology, Particularly Paleoanthropology

Few of the leading figures of the synthetic theory were professional paleontologists or paleoanthropologists. Most influential among them was Simpson; less influential were Heberer and Zimmermann. However, already a glance at the major works on synthetic theory in the 1940s and 1950s reveals that their authors paid significant attention to paleontology, although the importance of this discipline is not always explicitly underlined and in some writings said to be quite limited. Huxley (1942, p. 38), for instance, stated that paleontology can only "assert that, as regards the type of organisms which it studies, the evolutionary methods suggested by the geneticists and evolutionists shall not contradict its data." But since the advocates of the synthetic theory anyway did not wish discrepancies between the data of different (biological) disciplines, this statement appears to be trivial.

The main concern on paleontological ground was to refute saltationism, the idea that evolution occurs discontinuously, as was supposed, for example, by Schindewolf who used the term "typostrophe" (in analogy to "catastrophe") to indicate discontinuities in evolutionary change in the case of the emergence of higher taxonomic groups (Schindewolf 1950). Schindewolf stood in an old tradition reaching way back to the nineteenth century when the lack of fossils was received well by all those who generally – and often enough for ideological reasons – opposed to evolutionary thinking. He was definitely not skeptical about evolution as such (see also Schindewolf 1972) but argued against gradualism.

On the other side, Simpson (1953, p. 103) accurately stated: "The paleontological evidence for discontinuity consists of the frequent sudden appearance of new groups in the fossil record, a suddenness common to all taxonomic levels and nearly universal at high levels. Since the record is, and must always remain, incomplete, such evidence can never *prove* the discontinuity to be original."

Yet the controversy "continuity vs. discontinuity" or "gradualism vs. saltationism" endured. The gradualist model implicitly accepted by many advocates of the synthetic theory was challenged in the early 1970s by the concept of "punctuated equilibria" (Eldredge and Gould 1972) that accounts for rapid evolutionary changes. However, it now seems that the case is finished for evolutionists meanwhile tend to agree that evolution occurs at different speeds. The gradualist model still applies to many lineages, and the punctuational model applies to others. In retrospect, the controversy "gradualism vs. punctualism" may seem as an artificially induced debate, because already Simpson (1953, p. 313) clearly had stated that "it is abundantly evident that rates of evolution vary. They vary greatly from group to group, and even among closely related lineages there may be strikingly different rates." In other words, if one wants to find examples for gradualistic change, he or she will easily find them, and the same is true to the punctuational model. Human evolution, by the way, seems to be a good example for the latter, especially if one keeps in mind the comparatively rapid increase in brain size at the level of the genus *Homo*.

Although with the exception of Heberer practically none of the early – and leading – advocates of the modern synthesis was a paleoanthropologist by profession, most of them were, as was already indicated, interested in human evolution and concerned with the place of humans in nature. Dobzhansky published *Evolution, Genetics, and Man* (1957) which includes a long chapter of human evolution, and Rensch (1970) devoted a book explicitly to the pathways leading to *Homo sapiens*. (It is, maybe, worth mentioning that Dobzhansky's book was translated into German and that Rensch's work appeared in English translations in Great Britain as well as in the United States.) Mayr's influential *Animal Species and Evolution* (1963) (which was published in German as well) also includes a chapter of man as a biological species, and Julian Huxley was dealing with human evolution throughout his career anyway. In his later years he was engaged in developing and propagating a secular evolutionary humanism (see, e.g., Huxley 1966). All these works had a common aim: to demonstrate that the paths and mechanisms of evolution reconstructed within the frame of synthetic theory on the basis of Darwinian views fully apply to humankind, albeit their authors presumed the uniqueness of *Homo sapiens*. They referred to paleoanthropological data on a more or less large scale and left no doubt that they – in Thomas Huxley's tradition – considered evidences as to man's place in nature of crucial importance. Also, all of them were attracted by philosophical issues (which is not really surprising because of their classical education).

The Modern Synthesis and Beyond

The mentioned adaptationist paradigm inherent in the synthetic theory has aroused much discomfort and criticism, for one could get the impression that when bringing this paradigm consequently to an end organisms appear to be rather "passive objects" structured merely by their environment(s). Thus, Gould and Lewontin (1978) somehow ironically compared the adaptationist program to a “panglossian paradigm” and pointed to its failure to conceive of evolution as a process with passive organisms instead of seeing living systems as integrated wholes with specific constraints delimiting pathways of (evolutionary) change and therefore being more interesting that environmental selection. In other words, the extent of evolutionary changes, their particular direction, and the degree of adaptation as a result of these changes are largely determined by the organisms themselves. “Selection may supply all immediate direction, but if highly constraining channels are built of nonadaptations, and if evolutionary versatility resides primarily in the nature and extent of nonadaptive pools, ‘internal’ factors of organic design are an equal partner with selection” (Gould 1982b, p. 384).

Such factors were expounded, with some insight, by the Viennese zoologist Rupert Riedl (1925–2005) as integral parts of what is called “systems theory of evolution” (Riedl 1975, 1977; Wagner 1986; Wuketits 1988). It must be pointed out that “internal factors,” as already proposed by Whyte (1965) and before by some other writers, do not resemble the cryptic vital forces that were postulated in earlier times – up to the twentieth century – by advocates of vitalistic doctrines. Rather, within the corpus of systems theory, “internal factors” mean organismic constraints, i.e., the sum total of organizational and functional principles that limit an organism’s adaptability to its outer world. To put it the other way, adaptability is not – and cannot be – defined by the organism’s environment, but by the organism itself. It is not by chance that the systems approach to evolution includes data and conceptions from developmental biology. Ontogenetic constraints have meanwhile received much attention by many evolutionists and have been considered as elements of a new and broader evolutionary synthesis (see, e.g., Müller 2005; Pigliucci and Müller 2010). Generally, one can say that up from the 1970s there have been attempts to establish a broader, organismic view of evolution that somehow transgresses synthetic theory and its explanatory power. This view – without opposing the basic premises of Darwinism and the modern synthesis – lays particular stress to organisms as active systems. For this reason it might be also called “active Darwinism” (Perutz 1986). In retrospect, the question posed by Stebbins and Ayala (1981) whether a new evolutionary synthesis is necessary can be answered by “yes,” but most important steps towards such a synthesis have already be done. Natural selection as external selection has been supplemented by internal selection, and evolution appears to be a complex interaction between inner and outer selective forces. Organisms themselves play a crucial role in their own evolutionary change, and a comprehensive organismic or systems approach to evolution puts living beings in the center of evolutionary thinking.

Remarkably, Darwin was already aware that natural selection, understood as a mere outer factor of evolution, is not enough to explain the existence of particular complex characters of organisms. He deliberately stated: “Naturalists continually refer to external conditions, such as climate, food, etc., as the only possible source of variation. In one limited sense . . . this may be true; but it is preposterous to attribute to mere external conditions, the structure, for instance, of the woodpecker, with its feet, tail, beak, and tongue, so admirably adapted to catch insects under the bark of trees" (Darwin 1859 [1958], p. 28). One can say that Darwin had in mind intraorganismic constraints and that he by no means underestimated the role of the organism in evolution (see also Wuketits 2000).

The estimation of internal selection is of particular importance to paleoanthropology. When reconstructing fossil Hominini, paleoanthropologists must always be aware that the organisms which they are trying to understand within their specific "life worlds" were not just molded or "modeled" by external forces, but rather influencing their own environments to a certain degree. The evolutionary success of the genus *Homo* is to a considerable extent certainly due to the fact that it was more and more able to cope with challenges in its environment(s) and to control "environmental forces." Reconstructing, recognizing, and defining the genus *Homo* have troubled paleoanthropologists for decades (Collard and Wood, this handbook, vol. III; Henke 1981, 2005; Henke and Hardt 2011; Henke and Rothe 1999; Howells 1966; Rothe and Henke 2006), yet there can be hardly any doubt that this genus – now represented by the single species *Homo sapiens* – has been a "careerist," a "born winner," so to speak. Undoubtedly, it is highly adaptable, but many if not most of its achievements are due to its ability to get some control over its environment.

To summarize briefly to this point, evolutionary theory has turned out to be the only serious and reliable explanation of the staggering diversity of life on earth including humans, but it has – as is quite "normal" in the case of scientific theories – undergone some changes. Ever since Darwin new empirical findings have been made and his theories profited from controversies. The synthetic theory or modern synthesis has been a truly multidisciplinary approach to study evolutionary phenomena, and as a pluralistic theory regarding the factors of evolution, it has explained a vast number of details that, when viewed separately, appear somewhat enigmatic in character (e.g., geographical variation, genetic assimilation, and many others). Yet the synthetic theory gave rise to controversies and so an even broader theory of evolution emerged. Advances in evolutionary thinking have had always some (positive) impact on the study of human evolution, as on the other side paleoanthropology has inspired general reflections on evolutionary change. Despite all the open questions concerning many details of life's history, one can now state that the evolution of humans is not to be regarded as a "special case" of evolution, but that it fits into the general principles so far known as "mechanisms of evolution."

Anthropology: The Need for Synthesis

"Anthropology, the study of humankind, seeks to produce useful generalizations about people and their behavior and to arrive at the fullest possible understanding of human diversity" as one reads in the preface of a comprehensive, 700-plus page textbook on anthropology (Haviland 1985, p. 7). This "definition" of anthropology seems trivial – what else could the study of humans be! However, one has to recognize the present status of anthropology: The discipline is split into a vast number of specialized fields that have developed their own methodology and terminology. A synthesis is urgently needed. It can be argued that paleoanthropology is a very good way to establish this synthesis.

Paleoanthropology is part and parcel of evolutionary thinking and has influenced evolutionary theories in different ways. Paleoanthropologists have to take into account not just fossil remains of humans but data and conceptions from different disciplines such as geology, biogeography, primatology, archaeology, and others (see Henke 2005; The history of Paleoanthropology). As a theory-guided discipline, paleoanthropology also fulfills the standards of modern philosophy of science: Single "facts" are not enough; they have to be embedded into a theoretical framework (chapter "▶ Evolutionary Theory in Philosophical Focus," Vol. 1). Unfortunately, as it seems, many anthropologists have abandoned the very goal of their discipline: an understanding of humans, their history, their present status, and their possible future. Sure, for many centuries the study of humans was strongly influenced by idealistic philosophy and by the attempt to demonstrate the special status of humans as creations of God. On the other hand, one should not neglect the efforts of anthropologists during the past 200 years or so – especially after Darwin – that gradually offered a quite profound understanding of our species in the evolutionary process. The advances that paleoanthropology has made more recently can be seen when one compares reviews from the mid-1980s (e.g., Pilbeam 1984) with newer ones (e.g., Tattersall and Schwartz 2000; Henke 2005, 2009).

Despite all the debates about the number of fossil hominin species and problems of systematics, taxonomy, and classification (see, e.g., Cela-Conde 1998), paleoanthropology is unmistakably well established as a scientific discipline. Anthropologists who study very specialized traits of particular (recent) human populations should see good reasons to ask, to which extent such traits could be seen as parts of more general trends in human evolution. Otherwise anthropology runs the risk to come to the level of an aimless collecting of stamps. Stamp collection as such is quite interesting and entertaining, but the "true" collector wants to know something about the origin and meaning of his material and is inclined to study the history of stamps in connection with other historical events. Anthropologists should always keep in mind the two fundamental questions of any evolutionary approach. First, where does a particular trait – be it an anatomical structure, a pattern of behavior or whatever – comes from, i.e., what are its evolutionary origins? Second, what is the biological purpose or advantage of any particular trait? Hence, after all, anthropologists in first and last instance have to refer to evolutionary theory.

The now growing discipline of evolutionary anthropology demonstrates how different aspects of human life can be explained on the ground of evolutionary thinking. Bringing together data and concepts from several disciplines and integrating them into a conceptual scheme, evolutionary anthropology can show the way towards a new anthropological synthesis. Paleoanthropology will be an important part of such a synthesis.

Much light has already been thrown on the origin of humans and their history.

Conclusion

Despite some earlier speculations on the changeability of species (Buffon, Diderot, and others), evolutionary thinking – as theory in a strict sense – was not established before the nineteenth century (Lamarck, Darwin). It replaced a bundle of traditional views of the world that are deeply rooted in Western philosophy: static conceptions of nature, typological thinking, and Act of Creation according to the Old Testament. Among other explanations of the processes of evolution Darwin's theory of natural selection proved to be generally the best approach. However, in the twentieth century is was rectified and extended to a more comprehensive view of evolution, the synthetic theory or modern synthesis which recently was again extended to a broader, organismic conception (systems theory). Some of the crucial problems, particularly whether evolution has occurred by gradation or in a saltationist way, are now practically solved.

From its very beginning on the theory of evolution included statements on the position of humans in nature and their possible descent from other, "lower" creatures. Darwin (1871) argued that there cannot be any doubt that humans carry in themselves traces of their "lower ancestry." The advances of paleoanthropology during the past 100 years or so gave him right. The study of fossil remains of humans – no matter that it is still incomplete (and most probably will remain incomplete in the future) – shows that human evolution can be reconstructed on principle grounds. Most important has been the insight that fossils as such do not tell the story of human evolution. They have to be interpreted, connected with findings in different disciplines, and linked to evolutionary theory. The same is, of course, also true to fossil remnants of all other organisms, be they oak trees, scorpions, sharks, rodents, or elephants. Yet studying the fossil record is indispensible to any attempt to reconstruct the history of life including humans.

"Within a multidisciplinary and multifaceted approach, paleoanthropology tries to decipher the adaptive problems that have been important in human evolution" (Henke 2005, p. 117). "Adaptation" does not, as was mentioned, mean that humans have simply been molded by their respective environments but should be interpreted – to put it briefly – in the following way: In close interaction to their environments, humans have been able to find solutions for their problems of life, i.e., to handle their life's requirements. As the preceding expositions demonstrate, adaptationism in its strict sense has been replaced by a more organism-oriented view that fully – and particularly – applies to humans.

Paleoanthropologists – as far as they take evolutionary thinking really seriously – do no longer try to find out the special status of humans in nature, but apply the methods and principles of reconstructing extinct animals, particularly mammals, fully to the deciphering of fossil humans. They should not, however, pursue their goals monomaniacally, but realize that "improvements in knowledge about human evolution require the acquisition of richly diverse classes of information" (Isaac 1983, p. 538) and that there is an urgent need of synthesis. This need concerns anthropology as a broader field of studying humans. It was one of the targets of this chapter to point to the necessity of synthetic approaches.

Evolutionary Theory in Philosophical Focus

Philippe Huneman

Contents

Abstract

This chapter surveys the philosophical problems raised by two Darwinian claims: the existence of a “tree of life” and the explanatory power of natural selection. The first part explores philosophical issues concerning the process of evolution by natural selection. After laying out the nature of selectionist

explanations, their conditions, and some of their correlated properties such as fitness, we present the epistemic issues raised by such explanations. These include the role of optimality considerations and dynamical modeling, as well as the respective contributions of analytical explanation and historical narratives to evolutionary understanding. Then the metaphysical aspects of natural selection are examined: whether it is a law or supports natural laws; whether it is a cause, and if so, the cause of what. The consequences of the answers to these questions for scientific practice, and especially for current controversies about a possible extension or revision of the Modern Synthesis, are highlighted. The chapter then presents two classical controversies regarding the target and the limits of selective explanations – units of selection, adaptationism – in both cases pointing out the promises of explanatory pluralism. The third section considers issues raised by evolutionary patterns: first, the interpretation of the nodes in the tree of life, where the notion of species is controversial; then, the question of the relationship between macro- and microevolution, and, relatedly, the connection between putative processes and plausible patterns. Consequences for the current controversy about the fate of the Modern Synthesis are also explained. We further explicate issues raised by general features of large-scale phylogenetic patterns, such as increases in complexity, and the question of evolutionary contingency, and discuss the chances of an empirical solution to these longstanding puzzles. The last section considers some consequences of evolutionary theory for philosophical questions about human nature, given the rise of hypotheses on the universality of selectionist explanations; it is mostly concerned with epistemology and psychology.

Introduction

The Darwinian theory of evolution provides a framework of explanatory strategies to explain diversity and adaptation in the living realm. Darwinian science suggested and justified two main claims: first, the existence of a "tree of life," meaning that all extant living species are the historical results of common descent, and second, the *selection hypothesis*, meaning that one of the most important processes to account for those transformations is "natural selection." Hence, Darwin's theory added to the earlier life sciences a new *explanandum* (object to be explained) – phylogenesis – and a new *explanans* (way to explain) – natural selection – the latter of which could also serve as an explanatory device when applied to existing problems in those fields. The concept of evolution, then, having been solidly grounded in that of natural selection, could in turn explain aspects of diversity and adaptation.

Of course, the full consequences of Darwin's two main claims were not recognized immediately; people were too much concerned with the two metaphysical antipodes of evolution versus creationism, and with the animal origins of man. It took almost a century to acquire the historical distance that enables us to fully appreciate the novelty of Darwinism. (On progressive extensions of Darwin's theory, see Ospovat (1981) and Bowler (1989).) In the late nineteenth century

August Weismann, by distinguishing between soma and germ line and postulating that there was no transmission of acquired characters, clarified the difference between Darwinism and Lamarckism and convinced his followers to regard only the germ line as the substrate of evolution, enabling the future integration of genetics with evolutionary biology. Weismann also demonstrated the impossibility of the theories of heredity and variation held by many biologists at the time, including Darwin himself, according to which hereditary traits could arise from within an individual organism's cells and flow continuously from them.

Heredity was a major theoretical problem for Darwinism after Darwin. After 1900, the Mendelians supported "particular" inheritance – i.e., inheritance conceived as the transmission of discrete "determinants" of traits, later to be called genes, which are randomly taken from the two parents in the case of sexual reproduction. This notion contrasted with the traditional concept, shared by Darwin, of a "blending inheritance," according to which the offspring receives a mix of the values of the traits of each parent. Blending inheritance is problematic for Darwinism because it seems that with each generation change, the "best traits" – the ones that give the most advantages to their carriers – are diluted or lost in the mixing (except in the very improbable scenario where these carriers always mate with other carriers of the advantageous traits).

Population genetics was developed in the 1920–1930s, especially by Ronald Fisher, Sewall Wright, J.B. Haldane, and Julian Huxley, as the science of the variation of gene frequencies in a population. Research in this field has shown that in the case of Mendelian inheritance, even a slightly advantageous gene will indeed increase in frequency in a population until its fixation. More generally, population genetics provided biologists with a mathematical model of the process of evolution by natural selection. Whereas previously, the Mendelian vision of organisms as mosaics of traits seemed to contradict the gradualist view of evolution as a kind of "continuous transformation" (Gayon 1998), the population genetic approach was now able to conciliate Mendelian genetic inheritance and Darwinian evolution, resulting in the form of evolutionary theory called the *Modern Synthesis*. (Mayr and Proine 1980)

For this reason, population genetics holds a central status within evolutionary thinking, as indicated by the textbook definition of evolution as the "change of allele frequencies in the gene pool," which clearly pertains to the field of population genetics. This central role of this field is not unanimously accepted today: many biologists, especially some of those working in the tradition of developmental theory and some ecologists, criticize the very framework of the Modern Synthesis, arguing that it leaves aside many important aspects of evolution, in particular developmental processes. Calls are being made for an "extended synthesis" (Müller and Pigliucci 2011) – by which is meant, among other things, that the process of evolution should be assumed to extend beyond the genes themselves (for instance, it should include cases of non-genetic inheritance that have recently been established and studied; e.g., Danchin et al. 2011 or it should include the molding of environments by organism themselves called niche-construction, Odling-Smee et al. 2003). But actually, many proponents of the Modern Synthesis, such as Simpson and Mayr, were not convinced themselves by its narrow definition.

Labels aside, it seems important to ask whether allele frequency change *constitutes* evolution, *causes* evolution, or just *indicates* evolution. This philosophical issue appears to be at the heart of the interpretation of evolutionary theory and the assessment of any alternatives to the Modern Synthesis – which shows that, in the case of evolutionary biology, philosophical aspects are intertwined with contemporary scientific controversies, as this chapter will argue in detail.

In order to grasp the new kinds of epistemological problems brought about by the two Darwinian contentions, it is useful to recall the features of the earlier biological framework that they replaced. The main *explanans* of diversity and adaptation before Darwin was, as we know, the notion of divine design, although alternative hypotheses were increasingly being proposed, especially the transformist theory of Lamarck, which was adopted by Saint Hilaire and many morphologists at the beginning of the nineteenth century. This design was invoked to account for some *prima facie* teleological features of the living world, such as the fine adaptation of organisms to their environment, the fine-tuning of the mechanisms of biological functions, or the proportions of individuals in various species and the geographical relationships between species. Divine design yielded simultaneously the *individual designs* of organisms, unlikely to be produced by the mere laws of physics, and the *design of the entirety of nature* that Linnaeus called the "economy of nature." The selection hypothesis gave a powerful explanation of those two designs, since adaptations of organisms (Gardner 2009) as well as distributions of species in a population were plausible results of the process of natural selection (even if other mechanisms, such as Lamarckian ones, were also used by the first Darwinians).

Selection, unlike divine design, explains adaptation as a fit between organisms and their environment (see below for further explication of this). The diversity of environments in which species find themselves implies a variety of adapted species; therefore, selection explains adaptation through what is called *adaptive radiation*. And finally, the striking similarity of forms between different species of the same genus, or even different genera of the same family, that has been noticed since the eighteenth century by authors like Buffon or Diderot, and then vindicated by, e.g., Geoffroy Saint-Hilaire, and the so-called "transcendental morphologists," is explained by the fact that organisms of different taxa share a common ancestor – a fact that is entailed by the architecture of the tree of life.

However, the rise of Darwinism did not bring about a complete shift in the questions and tools of biology. Rather than wiping out centuries of research in the science of life, Darwinism gave a new and coherent meaning to some accepted facts and descriptions. Instead of rejecting teleology outside science, it provided a way of interpreting teleological phenomena so that they did not depend upon non-naturalistic assumptions, such as hidden intentions on the part of organisms or their creator; it retained the results of traditional taxonomic efforts and conceived of the systematic proximities in the classification of species as historical entities, as Darwin himself noted at the end of *The Origin of Species* (even though, of course, the Darwinian view raised new questions and resulted in new criteria and methods for systematists; cf. Ghiselin 1980).

Thus, evolutionary theory appears to us as the most successful and integrative framework for research strategies in biology generally. Before investigating the details of the philosophical challenges raised by the two Darwinian claims, it is useful to situate the evolutionary approach within the larger endeavor of biology. In this context, Mayr (1961) distinguished between two kinds of causes that can serve as answers to the question *why*. When asked "Why does this bird fly along the seashore to the South?" one can answer by pointing out its physiology, respiratory system, the diverse pressures on its wings, and the streams of air around it: these indicate the *proximate causes* of the bird's flight. But one can also answer by emphasizing that the way the bird chooses to go to the South curiously corresponds to the old demarcation of the continents, implying that the migration trajectory is the result of natural selection acting on this species of bird. This is the *ultimate cause* of the bird's flight towards the South. Notice that the proximate causes concern only *one bird at a time*, and that each bird is affected by them in the same way: they are generic causes. In contrast, the ultimate cause concerns the ancestors of this bird *collectively*, not only the one observed bird. In this respect, the two kinds of causes can be said to correspond to two kinds of biological disciplines. On the one hand, we have the sciences of the proximate causes: molecular biology, cellular biology, genetics, physiology, endocrinology, etc. On the other hand, we have the sciences of the ultimate causes, which are all those disciplines belonging to evolutionary biology: population genetics, quantitative genetics, behavioral ecology, systematics, phylogenetics, paleontology, etc.

Having thus characterized evolutionary theory as a specific set of research programs within biology, and having defined those programs by their use of the hypothesis of natural selection, we can now put evolutionary theory in philosophical focus. This could, in principle, mean two things: either a focus on the philosophical problems raised by evolutionary theory, and on their putative solutions, or alternatively, a focus on philosophical problems that are illuminated by evolutionary theory. It could indeed be argued that the rise of Darwinism has been one of the most significant conceptual shifts in the history of science, and therefore has had tremendous impact on all areas of philosophy. However, most of this chapter will be concerned with the former theme: philosophical problems within the field of evolutionary biology. The last section will briefly sketch a few features of the latter.

Philosophical issues in evolutionary biology can be grouped along two axes: first, in keeping with the distinction between the two main claims of Darwinism, there are issues concerning *patterns* (mostly, patterns captured in the structure of the tree of life) and issues concerning *processes* (mostly, natural selection). Second, philosophical issues may concern, foremost, our way of knowing things, in which case we refer to them as *epistemological* issues; or they may concern the things themselves, as exposed by science, in which case we refer to them as *metaphysical* issues. In the following, we will first address problems related to processes; these will essentially concern the nature and the limits of explanations that rely on natural selection. Some will be more epistemological, while others will be mostly metaphysical. In the second section, we will turn (less extensively) towards some problems regarding patterns; the discussion will be kept brief because many epistemological problems concerning patterns are related to methodological problems concerning proper classification, which are dealt with in other chapters of this book.

Evolutionary Biology: Philosophical Issues Concerning Processes

What is a Selectionist Explanation?

Selection, Population Genetics, and Fitness

Natural selection is a process that is expected to take place in a set of individuals whenever the following requirements are fulfilled: (i) the individuals differ from each other; (ii) the traits that are different are hereditarily transmitted in such a way that the pattern of variation of traits in the new generation is not wholly different from that in the parent generation (e.g., taller parents tend to have tall offspring); (iii) these traits have a causal influence on the reproductive chances of their bearers. After Lewontin (1970) these requirements are often referred to as the condition of variation, the condition of heritability, and the condition of fitness. (It is worth noting that Godfrey-Smith 2009, in describing the various formulations of these conditions, shows that none of these versions can embrace all cases of natural selection.) As a consequence of these conditions, the frequency and the value of heritable traits may vary across generations, until one trait value becomes established in the population, or else an equilibrium between some values is reached. This, then, is evolution by natural selection. It must be kept in mind, as Fisher noted at the outset of his benchmark volume on natural selection (Fisher 1930), that natural selection is not evolution: that is, the changes brought about by natural selection may occur alongside other changes in such a way that in the end no salient change in the population has occurred; conversely, it may happen that evolution occurs, but without natural selection playing a causal role. For example, mere intergenerational random variation (called "drift"; see below) entails evolution.

As they stand, the requirements for natural selection are not restricted to entities – or sets of entities – of a certain type, size, or level of complexity. Anything that meets the requirements is susceptible to the process of natural selection. Thus, researchers have proposed a theory of natural selection of macromolecules, in order to account for the origins of life (Eigen 1983; Maynard-Smith and Szathmary 1995), and – at the other end of the spectrum – theories of natural selection of ideas in order to explain cultural evolution (Cavalli-Sforza and Feldman 1981; Boyd and Richerson 1985; Campbell 1990; see section "Evolutionary Psychology"). By the same token, when one meets a set of individuals which fulfill these requirements, one can assume that those individuals have undergone natural selection, and that some of their current properties present its effects.

Population genetics provides models of biological evolution by natural selection. These models often describe a state of equilibrium expected when no selection occurs, called the Hardy-Weinberg (HW) equilibrium, which is derived from

Mendel's Law in populations with sexual reproduction. (Conditions for this equilibrium include infinite populations and random mixing; these are of course idealizations.) The fact of natural selection means that organisms differ in their chances of reproductive success, which implies departures from HW equilibrium. Population genetic models describe evolutionary dynamics as a function of these chances for different genotypes. Models differ according to the way they present intergenerational change (whether generations overlap or not), population structure, etc.; among the most widely used ones are the Fisher-Wright model, the Moran model, and Kimura's stepping-stone model (Ewens 2004). They generally handle gene frequency change at one locus, and sometimes at two loci, but seldom at more than two loci, because otherwise they would become intractable. One way to think about these models is to say that they take natural selection, mutation, migration, and random genetic drift (that is, stochastic fluctuations correlated to the size of the population) as forces acting on the population of genes and move that population away from its equilibrium, exactly as mechanical forces modify a zero-acceleration state that is the equilibrium state of a mechanical system. In this sense population genetics shares epistemic properties with classical mechanics.

Fitnesses (often notated *w*) are the values of differential chances of being represented at the next generation inherent to different organisms, alleles, or genotypes. Natural selection can be seen as "the survival of the fittest," as Darwin wrote in the last editions of the *Origin*, influenced by Spencer (and concerned by the risk of inducing an erroneous sense of agency with the word "selection"). After Fisher and the Modern Synthesis, "fitness" became a crucial technical term, because it entered as a variable into equations of population change. Controversies still rage about its proper interpretation (e.g., Ariew and Lewontin 2004; Bouchard 2011; Abrams 2007; Ramsey 2013; Sober 2001). For our purposes here, suffice it to say that "fitness" involves a mix of survival and fecundity: what counts for evolution is the chance of having heritable traits represented across generations, which in general is a function of the number of offspring, but may also be attested by an organism's chance of survival. In some population genetic models, however, only viability is taken into account, for purposes of simplicity; whereas in some behavioral ecology models, fitness is represented by a proxy, e.g., energy intake. Either way, the logical form of selection remains the same. In most models, fitness is quantified as the number of representatives of a genotype or a trait in the next generation (or the probability distribution of representatives, given that the models are probabilistic). Often traits are not underpinned by one locus, but by a huge number of loci whose effects are small and additive, as is the case for, e.g., height in humans; often, too, they have continuous values. Quantitative genetics is the study of the evolution of continuous traits (such as size) in the absence of knowledge of their genetic makeup (Falconer 1981). It can also predict how phenotypes will evolve, by modeling their value and frequency as a function of the intensity of selection (formalized as a "selection coefficient") and the value of heritability.

Following Orr (2009) it is useful to distinguish between *individual fitness* – that is, the probability distribution of the offspring of an organism, that many philosophers interpret as a propensity, after Mills and Beatty (1979) – and *trait fitness*, which is a “summary statistic” that denotes the probability distribution resulting from the aggregation of the individual fitnesses of all organisms belonging to the same type (for example, having the same trait value for a given trait, or sharing the same allele). Trait fitness is what enters into the equations of population genetics, and allows researchers to predict evolutionary dynamics.

The Modern Synthesis placed population and quantitative genetics at the heart of the investigation of evolution because they provide a mathematical understanding of the process of natural selection. As modeling practices, these sciences simplify reality. In particular, real organisms have very complex genomes, consisting of thousands of genes (which in aren’t even necessarily physically discrete or continuous units), whereas population genetics models typically model only one locus, or at most two. However, given that each locus occurs against a huge variety of genetic backgrounds, the reasonable assumption is that all the effects that different genetic backgrounds – that is, interaction with other genes within the organism – will have on the phenotypes (and thus reproductive chances) of the alleles for this locus will cancel out. Indeed, population genetic one- or two-locus models do correctly represent and predict the evolution of traits in a given population of organisms (Gillespie 2004), as has been demonstrated many times since the 1930s.

On the basis of this general understanding of evolution, the proponents of the Modern Synthesis made several assumptions that have recently came under criticism, in the light of certain empirical findings. First, they equated inheritance with genes, and variation with recombination and mutation, which was recently challenged by empirical evidence for non-genetic forms of inheritance (Jablonka and Raz 2009). Second, they assumed that development – that is, the process through which a zygote goes from conception to adult or reproductive stage – does not matter to evolution, since what counts evolutionarily are the chances of reproduction of a phenotype. The recent research program of “evo-devo” aims to reintroduce development into evolutionary biology by arguing that differences in development result in important differences in evolution (Raff 1996; Hall 2003). In regards to variation as well, population genetic models make important assumptions that have at times been questioned. Obviously, if variation, for generation after generation, were to focus on the variants that are best adapted to the environment, selection would be superfluous (that is, even without selection the course of variation would lead to the fittest phenotypes). Modern Synthesis theory held that variation, consisting of mutation and recombination, is therefore “random,” in the sense that it is decoupled from the state of the environment – which, empirically, is usually the case. Yet claims that variation is actually not random have arisen on a regular basis since the Modern Synthesis took shape, including the recent revival of “Lamarckism” (though it is not properly called Lamarckism, see Merlin 2010) advocated by Jablonka and Lamb (2005). Indeed, the existence of *some* instances of non-random and beneficial variation need not be a threat to the validity of natural selection in general (Huneman 2014b).

In this picture, each of the three conditions of natural selection exerts an effect on evolution: the more random the *variation*, the more room there is for selection; the greater the differences in *fitness* or selection coefficient, the faster does evolution proceed (fixation of high fitness traits); and of course, a greater degree of *heritability*, for a given selection coefficient, also increases the rate of evolution. Heritability can metaphorically be viewed as the strength of a "memory" that, generation after generation, retains the results of natural selection: if it is very weak, it will be difficult for selection to bring about the highest fitness variants.

Finally, a fourth important variable is the *population size*. For a fixed level of heritability and a fixed selection coefficient (or fitnesses), the size of the population may change the outcome of the evolutionary dynamics, since in small populations stochastic fluctuations are large and may prevent the highest-fitness variants from reaching fixation, that is, having a frequency of 100 % in the population. When population geneticists speak of "random genetic drift," they refer to these stochastic fluctuations, especially emphasized by Sewall Wright (Wright 1932). The content of this concept is still controversial. Biologists have vacillated between seeing drift as a deviant outcome (deviant from what is expected based on fitness values) and as a proper cause of a proper outcome in their models (especially in gamete sampling) (Plutynski 2007). When fitnesses differ, drift and selection drive evolution, but the conceptual interpretation of their combination is problematic, since drift is not a force independent of selection but a stochastic fluctuation occurring during the selection process (see section "Metaphysics of Selection: Causation" below). By contrast, when fitnesses are equal, drift alone drives population changes, and diffusion models can be used to represent such dynamics.

The overall relevance of drift in actual evolution depends upon what the most common population sizes are. In any case, when alleles do not harbor fitness differences, drift may drive some of them to extinction. Kimura used this insight as the basis of his *neutralist theory* of molecular evolution, which argues that large parts of the genome in many species have been shaped by neutral evolution, rather than natural selection (Kimura 1983). The relative amount of neutral evolution has been an important topic of controversy in population genetics since the 1980s (Gillespie 2004), when the huge importance of neutral evolution was first acknowledged; since then, there has been progressively more evidence of "positive selection" (Voight et al. 2006), (i.e., the process by which new advantageous genetic variants sweep a population).

Properties of Selectionist Explanations

Three general features of selectionist explanations should be noted. First, they belong to what Mayr (1959b) called "population thinking"; that is, selection is always understood to apply to a collection of entities, since only *differences* in relative fitness matter. In this respect, explanation by selection might be contrasted with what Sober (1984) called "developmental explanation," namely, an explanation of a property that appeals to the process through which that property was acquired. The developmental explanation of the composition of a football team refers to the sum of the experiences of each of its players; the selectionist explanation refers to the choice of the team by the manager, who set a criterion of competence and then evaluated all available football players by this criterion. What is characteristic for selectionist explanations as instances of population-level thinking is the fact that there are no specified criteria of admission other than reproductive success.

In this view, population genetics appears analogous to statistical mechanics – the science of ensembles of gas molecules, which defines state variables that allow physicists to model coarse-grained descriptions and make predictions for an ensemble's collective evolution. Fisher (1930) proposed such analogy, comparing the mean fitness of populations to the property of entropy.

A second important feature is that two traits can be correlated, either for morphological or for genetic reasons; an illustrative example of this is pleiotropy. The two correlated traits will always be selected together, and the two types of individuals they define will have the same fitness. Elliott Sober (1984) coined the terms "selection-for" and "selection-of" to distinguish between traits that are indeed the targets of natural selection, since their ecological consequences increase reproductive success, and traits that are selected because they are correlated to the former. Conceptually, this distinction involves an appeal to what philosophers call "counterfactual thinking": when there is selection of a trait A, but only as by-product of selection for another trait B, it means that if organisms had A without having B, A would not have increased in frequency. However, population genetics has designed methods to distinguish between selected and correlated traits (Lande and Arnold 1983).

A third important feature is that population and quantitative genetics use fitness values as variables associated with traits and alleles, but do not model the *causes* of fitness values. The latter goal is exogenous to population genetics, since what determines the fitness value of a genotype or a trait is the way it relates to environmental demands. Fitness values only record differential performances of types of individuals (types being defined by shared traits of interest) in the environment.

When applied to extant species, population and quantitative genetic models can identify which traits are expressed (or will go to fixation) due to natural selection just by assessing the fitness values of traits – even without considering the problems associated with estimations of fitness in nature – but they don't offer any explanation of *why* natural selection is taking place. Instead, the causes of fitness or selection are a subject of *ecology* (Wade and Kalisz 1990). Ecology was defined by Haeckel, the most famous Darwinian of the late nineteenth century, as the "science of the struggle for life." Ecological interactions such as competition, predation, or mutualism between organisms of various species explain the differential successes of types of organisms, as well as the extinction and succession of species in a community or an ecosystem.

Ecology studies the causes of fitness, with the fitness values being the variables through which population and quantitative genetics capture evolutionary change. Therefore, evolution by natural selection is the subject of two distinct sciences: population/quantitative genetics and ecology. The latter tries to understand the reasons why natural selection has designed organisms the way they are; in other words, it explains biological traits as adaptations to the environment. For instance, when behavioral ecology studies the mating behavior of gorillas, it asks why strategies such as monogamy or polygamy have emerged in a given species in a specific environment (Dunbar 2001), and then offers answers by demonstrating that one particular strategy optimizes reproductive success in these conditions. (See section "Genes, Dynamics, Optimality, and Strategies" below on optimality.) More generally, several evolutionary disciplines ask why organisms are the way they are, by asking why they have the traits they have. When it comes to species of the past, clearly one should use particular methods because, unlike in behavioral ecology, a straightforward modeling of the parameters is not possible; yet fundamentally, paleontology and behavioral ecology ask the same kinds of functional questions about the presence of traits and the design of organisms.

The conceptual duality of natural selection becomes even more challenging when one considers that ecology is also dual, because it comprises not only the science of ecological interactions affecting individuals, i.e., *behavioral ecology*, but also the science of species interactions, i.e., *community and population ecology*. The latter of course defines the background against which the former takes place (e.g., the behavior of foraging organisms is partly determined by the general competition between species that prey on the same prey). Population genetics models a certain population of a given species, in which alleles are changing because of mutation and migration; in general, the environment is considered to be constant in this. (Sometimes it is variable in time, but nevertheless, its species composition is not part of what the model tries to explain.) In contrast, for community or population ecology the genes are an invariant factor, and the species of interest are what varies.

In sum: the epistemic duality of evolutionary biology – population genetics vs. ecology – makes for a complex structure, which we will explore in more detail below.

Epistemology of Selectionist Explanations

Genes, Dynamics, Optimality, and Strategies

Explanations based on natural selection thus gives rise to two different interpretations. On the one hand, population genetics analyzes the dynamics of alleles or genotypes in a population that contains different fitness values. Natural selection here is a specific feature of the dynamics (i.e., differences in relative fitness); the selectionist explanation therefore shares the epistemological status of a mechanical science. On the other hand, when biologists such as behavioral ecologists investigate, for example, the function of figure-eight-shaped waggle dance of bees, they assume that this behavior is somehow suited to the environment of the bees – in other words, that it is an adaptation. In so doing they assume that the behavior has resulted from natural selection, because it would have been selection that optimized the trait in response to the environment (Mayr 1983; Maynard-Smith 1984). Natural selection here is thus seen as an *optimizing process*: by constantly retaining high-fitness variants it maximizes fitness, and fitness maxima correspond to optimal traits. (When the traits have a fitness value that is frequency dependent, we do not see optima but strategies that are such that when they are generalized, no variant strategy can invade the population.) Epistemologically, the status of such knowledge might be said to correspond to economics as a science of behavior based on the principle of maximization of utility. As a matter of fact. behavioral ecology uses evolutionary game theory (Maynard-Smith 1982), which is mostly an extension of economic game theory – one where the payoffs of the strategies are not defined in terms of utility but of fitness.

Moreover, the two aspects of natural selection differ with respect to the kinds of objects they deal with. In population genetics, selectionist explanations pertain to the dynamics of *allele* frequencies. In behavioral ecology, it seems that entire *organisms* are what is at stake, since natural selection seems to optimize the traits of organisms in the face of environmental conditions. Notably, in this latter context one often does not know anything about the genetic make-up of the traits of organisms. Within evolutionary biology, intense controversy continues over the levels and units of natural selection: does it target mostly genotypes or phenotypes, mostly alleles or organisms? (See section "Targets and Limits of Selection, 1: Levels of Selection" below.) But regardless of this controversy, the levels at which population genetics and behavioral ecology locate their subject are different: for the latter it is organisms, and for the former, genes.

As "Formal Darwinism" (Grafen 2002, 2007) importantly emphasized, these two takes on natural selection do not always concur. In many cases, maximum fitness will not be reached by natural selection. This is especially true in the case of frequency-dependent selection (Moran 1964), but also in the simple case of heterozygote superiority (where for principled reasons, the heterozygote genotype cannot fix in the population). However, behavioral ecologists generally assume that the gene dynamics will match what an optimizing trend would predict and will therefore support their hypotheses. This is what Grafen (1984) called the "phenotypic gambit" – a bet about the relationship between phenotypes and genotypes. Formal Darwinism has shown that there are indeed isomorphisms between descriptions of evolution in terms of changing allele frequencies and descriptions in terms of optimization of organismal traits, so that the phenotypic gambit can be the default position. This formally justifies the intuition behind many proposals in behavioral ecology. Philosophically speaking, it justifies a unification of the two approaches to evolution, as the result of which it is understood as both the object of a kind of mechanics and that of a kind of economics (Huneman 2014a, c).

Epistemology of Selectionist Explanations: Analyticity and Historicity

Analyticity

Population and quantitative genetics is mostly couched in the mathematical language of statistics. In this context, many authors have tried to provide very general formulations of evolution by natural selection. Fisher first forged what he called the "fundamental theorem of natural selection" (FTNS), which states that intergenerational change in the mean fitness of a population equals the additive genetic variance, hence is always positive (i.e., fitness always increases). He saw this as an analytic truth, a priori established, whose status equals the status of the second principle of thermodynamics (for Fisher, both population genetics and thermodynamics were sciences of macroscopic variables defined on the basis of collectives).

Fisher's theorem was controversial, since many authors opposed it on the grounds that population genetics, as indicated, does not always predict fitness maximization. Recent interpretations of the FTNS highlight that the quantity referred to by the theorem is not a global change in mean fitness but, more narrowly, a mean fitness change directly due to natural selection (Ewens 1989; Frank and Slatkin 1992; Edwards 1994). To this extent, the theorem can be made to accommodate empirical cases where mean fitness decreases; in these cases, negative changes in mean fitness due to what Fisher called "environmental deterioration" (a term whose interpretation is debatable) overwhelmed the positive effect of selection.

In any case, the parallels that Fisher drew to statistical mechanics have been seriously considered by several authors, who tried to develop population genetics in a way rigorously analogous to statistical mechanics, viewing the construct of fitness as formally analogous to a kind of entropy (Barton and Coe 2009).

But other general abstract formulations have been proposed as well. George Price suggested that evolutionary change can be captured in a simple quantitative genetics formula that can be analytically derived (Price 1970):

$$\Delta z = \mathrm{Cov}(w_i, z_i)/w + E(w_i \Delta z_i)/w$$

where z (resp. w) is the mean trait value (resp. mean fitness), w_i is the fitness of individuals i, z_i their value of the trait, and Δz_i the change of this value between individual and offspring. This so-called "Price equation" decomposes evolutionary change into the effect of natural selection (captured as covariance between fitnesses and traits) and the transmission biases (the expectation term) (Gardner 2008).

Interestingly, Fisher's FTNS can be derived from the Price equation if "fitness" is taken as the focal trait. But it should be made clear that the variable z, whose change is modeled by the equation, can also mean other properties, such as the frequency of alleles – hence the Price equation is even more general than the principles of quantitative genetics. Moreover, the Price equation, being mathematically true, is a *description* of evolutionary change, but cannot in itself provide *causal* information on evolutionary processes. Grafen's Formal Darwinism (see above) construes its isomorphism between population genetics and optimization on the basis of the Price equation. Other general formulations of evolution have been proposed, some of them in the context of what is called "replicator dynamics," others in the context of "adaptive dynamics" (Metz 2008).

The above discussion of the analytical or formal side of evolutionary theory gives rise to an occasion to mention the so-called *tautology problem*. If natural selection is defined as "survival of the fittest," one could object to Darwin that in the absence of other evidence regarding the capacities of organisms, the "fittest" are precisely those who survive, so the main principle of the theory constitutes a tautology. One response to this is that there are other, independent pieces of evidence for fitness (drawing on physiology, ecology, etc.), or that there are cases where the fittest do not overcome all others evolutionarily (i.e., in the case of drift), demonstrating that the statement is not analytical. But another plausible response consists in accepting the criticisms, and saying that current evolutionary theory has at its core a mathematical theory – mathematics being a system of analytical judgments. This concession does not therefore give up on the scientific validity of the theory (no more so than acknowledging the mathematical nature of modern physics would diminish the validity of physics).

Historical Understanding

As Bock and von Wahlert (1963) wrote, we must distinguish the *processes* of evolution, which involve – but are not to be equated with – natural selection, and the *outcome* of evolution, namely phylogenies and the phylogenetic tree. However, no actual process of evolution could be understood solely through theoretical knowledge of evolutionary mechanisms, in the absence of historical data. For instance, many terrestrial vertebrates are tetrapods: one could imagine a selectionist hypothesis concerning the adaptive origins of their four limbs, since this configuration is obviously adaptive for locomotion. However, there is another reason for those four limbs: marine ancestors of those vertebrates had four fins, so the four limbs are a legacy, resulting from what we might call "phylogenetic inertia." The point is that natural selection often explains the appearance of such traits, but not their appearance in a particular clade. The selectionist explanation has to be historically situated in order to determine what the correct *explanandum* is – the one for which natural selection would be the right *explanans*. Thus, no explanation of the presence of characteristics in the members of a given population or species is available through the sole application of population genetic models of natural selection. The distinctive characteristic of evolutionary theory, if we assume that its explanatory strategies are always related to some use of the selectionist explanation, is that it brings together certain formal models, written in mathematical language in the modality of pure necessity, and certain historical narratives (Gayon 1993; see Richards (1992a) for an argument in favor of evolution as a narrative).

Thus, evolutionary biology is indissolubly both a formal science, to the extent that evolutionary change can be captured through analytic formulae and models, and a historical science, as soon as it comes to understanding actual past and present evolution at any scale. This latter methodological aspect also implies that few empirical inquiries in evolution can be made without *comparative data* (Endler 1986), in order to avoid incorrect, a historical invocation of natural selection mechanisms – such as in the tetrapod example above. Often a divergence of results between studies can be traced back to differences between the sets of comparative data used by the researchers (Sober and Orzack 1994, 2001; Griffiths and Sterelny 1999, pp. 240–250).

This pervasive element of historical narrative in neo-Darwinism accounts for the historical meaning of all biological terms in evolutionary theory. Taxonomies are obviously and easily reinterpreted by history. The concept of homology - initially defined by Owen (1843) as the same organ in different animals under every variety of form and function - that helps systematists build their classifications acquires in the light of evolutionary theory the historical status of “signs of common descent,” as for instance in the case of birds’ and bats’ wings. (See chapter “▶ Homology: A Philosophical and Biological Perspective,” Vol. 1.) Homoplasy, as the other kind of similarity across species, seems less of a historically significant concept at first glance: similar selective pressures gave rise to similar devices, representing similar adaptations to these pressures. But is it really the case that the concept of adaptation lacks any historical dimension?

The question of whether adaptation is a historical concept is widely debated. Philosophers (Burian 1983; Sober 1984; Ruse 1986; Griffiths 1996) concede that “adaptation ascriptions are causal-historical statements” (Brandon 1996), since to say that a trait is an adaptation is to say that it has somehow been selected for some of the advantages it gave to its bearer via differential reproduction. (Note that “adaptation” is a property of *traits*, whereas in a pre-Darwinian context, and often in non-evolutionary biology, “to be adapted” and “adaptation” are features of *organisms*; though many evolutionists as well often use “adaptedness” to refer to this latter kind of adaptation.) It remains to be decided whether this sums up the full meaning of the concept – given that biologists often do not appeal to historical facts in order to describe adaptations, but just forge optimality models with current data, as done in behavioral ecology. Reeve and Sherman (1993, 2001) advanced a powerful “currentist concept” of adaptation, as opposed to the historical concept: “An adaptation is a phenotypic variant that results in the highest fitness among a specified set of variants in a given environment” (1993, p. 9). Having distinguished two goals of evolutionary research – the first being the explanation of the *maintenance* of traits, and the second the reconstitution of a *history* of lineages – they argue that the former essentially needs the currentist concept, whereas the latter is much more closely related to the historical concept. Notwithstanding one’s view on this matter, the fact that there can be a historical component to adaptation ascriptions is important, since it allows biologists to distinguish between the origin of a trait as an adaptation and its current presence and maintenance. A trait that is adaptive might not have emerged as an adaptation, or might have emerged as an adaptation for some other use. This is captured by the concept of “exaptation,” suggested by Gould and Vrba (1982); an example would be insect wings, which probably emerged as thermoregulatory devices (Kingsolver and Koehl 1989). Exaptation has proved to be a useful concept for our understanding of a lot of features that appeared during the evolution of hominids (Tattersall 1998).

However, one should not conflate the two meanings of the historical characterization of adaptation: there is a *definitional* meaning and an *explanatory* meaning. On the one hand, selection *defines* adaptation, since a trait being an adaptation means that it originated through natural selection. But on the other hand, we say that selection *explains* adaptation; this is not contradictory to the definitional meaning, because we now mean that the explanation of a given adaptation may refer to concrete selective pressures in the given environment, which provides an agenda for the experimental testing of hypotheses. An example of such experiments, and of the explanatory use of the historical concept of adaptation in their interpretation, is a study on the differential sensibility of plants to gradients of metal in soils (Antonovics et al. 1971).

Metaphysics of Selectionist Explanations

Laws in Evolutionary Biology

The hybrid epistemic status of evolutionary biology inclined philosophers to enquire about the status of laws in this discipline. Some of them argued that there are no laws in evolutionary biology (Beatty 1997; Rosenberg 2001; Brandon 1997 vs. Sober 1997), or in biology generally (Smart 1959). An analogous controversy occurred among ecologists, with Lawton (1999) doubting that ecological laws exist and other authors (e.g., McGill and Nekola 2010) arguing that ecology does indeed capture specific laws.

Laws of nature are general statements formulated under the modality of necessity. The logical-positivistic account of science viewed explanation as a deductive argument whose conclusion is the *explanans*, and whose premises combine certain laws of nature with particular statements of facts (the so-called “deductive-nomological” account of science; Hempel 1965). Even though the philosophy of science has mostly turned away from positivism since the 1970s, many authors still attribute a crucial explanatory status to laws (e.g., Lange 2009). The usual puzzle in philosophy of science is to find a criterion distinguishing accidental generalities (such as “All mountains are less than 100,000 m high”) from laws (Ayer 1956). As a solution, Dretske (1977) claimed that laws have to be conceived as relationships between “universals” (for instance, the law of gravitation holds between the natural properties mass and distance, which are universals, as opposed to individual bodies, which are particulars). In any case, laws should support counterfactuals; this means that if some variables are changed within them, the results should be affected in a predictable way. The implication is that law-like generalizations can be used in explanations, whereas accidental generalizations seem not to allow such a use, and even less a predictive use.

Yet the very notion of law, as used by biologists, is often ambiguous. Some laws concern the correlation of variables in a given empirical range: for instance, the correlation between body size and latitude (“Bergmann’s rule”); or the species–area relation in ecology. Many laws in paleontology can also be seen as such generalizations: “Dollo’s law” about irreversibility, “Cope’s law,” etc. These laws actually concern patterns, and are mostly established through induction; often they are captured in what physicists call “phenomenological models.” However, one can still wonder why such pattern laws are found, hence investigate the processes supporting them. That then leads to the quest for what scientists often call mechanisms, captured in “mechanistic models.” Philosophers of science would mostly say that the “process laws,” related to the mechanistic model, are the most explanatory and hence have to be called genuine “laws” (whereas they would be content with calling the other laws “rules,” for instance “Bergmann’s rule”).

Many controversies in ecology actually concern these underlying laws. Thus ecologists wonder, for example, whether there is one such underlying law yielding the species–area relationship. Advocates of the absence of laws in ecology argue that given the complexity of ecological systems, there may be many processes accounting for the various patterns of biodiversity we observe, but not a single, overarching mechanistic model likely to capture them all.

Ecology aside, what about other aspects of evolutionary biology? Clearly, in evolutionary theory most generalizations do not seem as robust as typical laws of physics (in fields such as particle physics; though when it comes to cosmology, physics arguably does involve history, and law statements may be traced back to the contingency of primordial history). Most law statements concern species of organisms (e.g., “Bonobos are promiscuous”), and, because of the contingencies of evolution, these species could have been absent or different. They are not “natural kinds” in the metaphysical sense, unlike the chemical elements, of which any chemical substance is made and which can robustyl and a historically be defined in terms of an atomic number - setting aside the complications added by the fact of a cosmological history. Any term in a putative biological law *p* instead seems to be contingent upon the facts of evolution, which makes statement *p* less than a law. As Beatty (1995) argued, Mendelian laws are contingent upon the fact of sexual reproduction, which is a possibly contingent product of evolution on earth. And even the universality of the genetic code is a generalization confined to our planet, where it holds due to the universal descent of life on earth from a contingent fact – a “frozen accident” (Crick 1968); the same correspondence laws between nucleotides and amino acids cannot be expected to hold on other planets. This contingency of generalized propositions affects the whole of the system of supposedly law-like statements in biology.

The only evolutionary statement that could be a law is, thus, the one enunciating the process of natural selection itself, since it specifies no particular entity. And this indeed accounts for the important difference made between pattern laws and process laws. For instance, Bergmann’s rule states a pattern associated with the geographical distribution of clades or species or populations of species: larger ones tend to be found in colder environments (which of course correlate with latitude). This pattern is explained by the fact that larger animals have a lower surface area-to-volume ratio than smaller animals, which implies that they lose less body heat per unit of mass. This, in turn, entails that, the colder the environment in which a species is found, the more likely selection will favor the variants that better resist the cold, which are – everything else being equal – the larger ones. Thus the explanatory core of the process is natural selection: all else being equal, organisms better equipped to face the given environmental conditions (i.e., those having traits that allow them to live longer on average and to produce more offspring) tend to pass on their heritable traits, eventually leading to the dominance of these traits in the species. That adapation-to-temperature process itself could hardly be seen as a law; rather, it is an instance of natural selection. (One would reasonably resist calling a law each case where natural selection yields a specific pattern regarding the distribution of some traits.) It is thus plausible, in our example, that the law underlying Bergmann's rule would be something like "the law of natural selection," a suggestion controversial among philosophers (Bock and von Wahlert 1963; Sober 1984, 1997; Brandon 1996, 1997; Rosenberg 1985, 1995, 2001).

Rosenberg (2001) argued that what Brandon (1996) calls the Principle of Natural Selection (PNS) – briefly summed up as, "When variation is causally connected to differential ability to survive and reproduce, differential reproduction will probably ensue" – is the only law of biology. He relied on Williams' (1970) axiomatization of the theory, which conceives of fitness as an undefined primitive term, e.g., a term for which some definitions, in some contexts, can be given only outside evolutionary theory, in another theory. But, even if by convention we say that the PNS is a law, we still face the question of how it differs from other kinds of law. In effect, unlike physical laws, the PNS does not refer to any natural *kind* of property such as mass, electric charge, etc. The sole property involved in some of its formulations is fitness, which only captures context-dependent consequences of some physical properties evolutionarily relevant in a given setting (for example, the color of moths is a fitness parameter in industrial melanism only because there are predators capable of vision). So the PNS can become the equivalent of a physical law – stated in probabilistic language – only if and when the physical characteristics of the properties contributing to fitness are *specified*, a specification that is always context dependent. For instance, the "optimal shift towards viviparity" in some marine fish described by Williams (1966) results from a kind of rule, since he states the parameters ruling the selection pressures (density of predators, physiological cost of reproduction); these parameters in turn determine a range of relevant physical properties for selection. In this case the PNS becomes predictive, and we can test it by building experiments in which the values of the proper variables vary.

The PNS aside, there surely are a number of genuine laws in evolutionary theory; however, those kinds of propositions are not so much empirical laws as *mathematical laws*. In a way, evolution contains both statements modally stronger than physical laws (since they are purely mathematical statements) and statements nomothetically weaker, such as those derived from the PNS through its empirical instantiation. Rather than being a law, the PNS ultimately proves to be an *explanatory schema*, providing ways of explaining and building models through its more or less empirical instantiations. The least empirically instantiated models are the models of population genetics; the most empirically instantiated are rule-like generalizations, such as paleontological ones.

Metaphysics of Selection: Causation

Philosophers of science have moved away from logical positivism and Carl Hempel's claim that explanation consists in subsuming phenomena under laws. Instead, the view has been on the rise that genuine explanation must be causal – under one of various possible conceptions of causation (probabilistic, physical, counterfactual, Humean, etc.; Tooley and Sosa 1983). Hence, notwithstanding the controversy over the existence and nature of laws in evolutionary biology generally, and over the status as law of the PNS in particular, philosophers are expected now to consider the causal role of selection. Two simple (and related) issues arise: What does natural selection causally explain? And, is it even a cause (vs. some other kind of explanation)?

Attempts to answer the first question generally take one of two views. In the first, selection is a negative, attenuating force: it merely selects, and thus sorts high-fitness traits out from low-fitness ones. In the second view, by contrast, selection assumes a more positive role by being itself *creative*. Thus Mayr (1965) already claimed that selection is not a "purely negative force," since it gradually improves existing traits. Among biologists, this positive view has been widely held: Dobzhansky, Simpson, and Gould shared it. "Creativity" was an important notion for the architects of the Modern Synthesis, since it enabled them to distinguish their view from Mendelian saltationism, which attributed the main evolutionary force to mutation and variation: if selection is creative, then one cannot locate the main reason for evolution at the level of variation (mutations).

In the last decade the debate on the negative vs. positive role of selection has surfaced once more in the field of philosophy of biology. The basic question underlying this ongoing controversy is: what does selection actually explain? It does explain, at a population level, why a trait, *once it had arisen*, pervaded and persisted in a population (1). But is that all? Does selection not, ever, explain why a given individual displays a particular trait? (2) (Should that latter explanation always be given just in terms of developmental effects?) Sober (1984) for one subscribes to the negative view that selection is strictly a population-level explanation, so that the question "Why is trait A present in individual B?" does not fall into its domain.

Neander (1995) challenges this view, in line with Mayr's intuition. Apart from the two questions distinguished above (questions (1) and (2)), there is, according to her, the "creative question," which is: "Why did the genetic and developmental devices underpinning a given trait arise in a population?" Neander contends that natural selection contributes an answer to this creative question, for the following general reason: even if the genotype conditioning a new trait is not created by selection, selection does increase the probability of occurrence of the many alleles composing this genotype.

In a population of diploid organisms, suppose a pool of genotypes of nine loci, and suppose that the genotype G_1-. . .-G_9 has a higher fitness than all the genotypes comprising other alleles G'_i $(1 < i < 9)$, G''_i, G'''_i, etc. Due to selection, organisms with genotype G_1-G_2-. . .-G_9 will have more offspring in subsequent generations than if there had been no selection. Hence, because of selection, the probability that a genotype randomly picked in the next generations comprises one or several G_i will be higher than what it would be without selection (since, without selection, the genotype G_1-. . .-G_9 would have less offspring, thus the alleles G_1, . . . G_9 would be less frequent, and less likely to enter into frequent recombination with other genes into new genotypes). Selection for genotype G_1-. . .-G_9 increases the chances that alleles G_i will be available for variation in subsequent generations, hence genotypic variation at a later generation is different than what it would have been, had there not been genotypic fitness differences (in other words, selection for G_1-. . .-G_9). The thrust of the argument is that genotypic variation at a given stage (i.e., the distribution of genotypes) is not independent from natural selection at an earlier stage, even if allelic variation (as mutation) is not influenced by selection. Hence the claim that only mutation creates the variants (as a sum of mutations) and selection just sorts them is false. To the contrary, *cumulative* selection causally contributes to the appearance (and not only the spread) of traits that are adaptations – assuming that "causation" is broadly understood as a raising of probability or as counterfactual dependence, and not as a mere physical process, as Salmon and other philosophers would have it.

This defense of the positive view of selection can be extended. It has been shown in certain bacteria exposed to stress that selection can increase the mutation rate, providing an advantage in terms of the range of available responses to environmental shifts (Taddei et al. 1995). The notion that the rate of mutation is somehow controlled by selection, while at the same time mutations are the material acted upon by selection, demonstrates a kind of reflexive effect of natural selection on its own parameters. This reflexive structure allows one to say that the traits selected are themselves dependent upon the form of selection pressures, hence are not just sorted but somehow *shaped* by selection. In the case of the stress-exposed bacteria, even if the exact nature of the mutations is prior to selection – that is, not influenced by it – any individual mutation is still counterfactually dependent on selection, since the probability of *its occurrence* is directly dependent on the mutation rate. In conclusion, then, it seems difficult to separate positive causes of the emerging new individual phenotypes ("shaping") from negative causes affecting their spread or extinction ("sorting"). The positive view of selection is likely to prevail.

The second issue that has been hotly debated during this last decade simultaneously concerns the causal status of natural selection and the nature of the relationship between selection and drift: namely, are the latter competing hypotheses? The classical view, stated above, takes drift and selection as two kinds of forces acting (together with the forces of mutation and migration) on an equilibrium model formulated by the HW law. If equilibrium is disturbed, then selection may be at work; and when the fitter allele is not fixed, then random drift must have perturbed selection. Outcomes are the result of the addition of selection and drift, analogously to the summation of forces in Newtonian mechanics. However, this model has been challenged in several papers by Walsh, Ariew, Lewens, and Matthen (Matthen and Ariew 2002, 2009; Walsh et al. 2002; Walsh 2007, 2010). Somewhat deflatingly, these authors claim that selection, migration, mutation, and drift are all not causes, but merely statistical relations resulting from the aggregation of genuine causal processes at the level of single organisms. In population genetic models, these relations are modeled accordingly. These "statisticalists" argue that the individual interactions of the organisms in a population, taken together, in aggregate constitute natural selection; they reject the idea that selection is an additional, exogenous force. Indeed, once all individual-level interactions are specified, all changes in population frequency can be derived: "selection" and "fitness" are just statistical concepts used to describe these population-level changes. Trait fitness is predictive for population genetics, but it is a summation of the fitnesses of many individuals sharing the respective trait and, as a statistical construct, is causally inert.

It has also been claimed by statisticalists that not only is it often difficult to distinguish between selection and drift (Beatty 1994), and not even that drift – far from being another independent process like selection – is something like an error term representing stochastic fluctuations in a directional process that constitutes selection (Brandon and Ramsey 2006) but that fundamentally natural selection and drift are indistinguishably aggregated effects of interactions, so that it is impossible to tell them apart.

Many responses have been elaborated by philosophers. These have ranged from defending selection as a population-level cause (Millstein 2006), to emphasizing the role of individual ecological fitness (Bouchard and Rosenberg 2004), to invoking the causal nature of selection and drift as two variables that can be manipulated through simple intervention (Riesman and Forber 2005), to arguing that even if selection is not another process, the statistical relations at issue can also be expressed by a counterfactual statement of dependence between traits and their frequency change, which amounts to a causal statement (Huneman 2012, 2013). This debate may seem no more than the lofty concern of metaphysicians, but it does have important consequences, as explicated by Walsh (2003, 2013): if natural selection is not a causal explanation, of adaptation the causal explanations must be sought elsewhere, namely, at the level of developmental processes such as organismal activities or physical self-organisation processes.

In general terms, this echoes the way Müller and Pigliucci (2011) present the above-mentioned call for an "extended synthesis" superseding the Modern Synthesis. In the introduction of their volume, they explain that Darwin and the Modern Synthesis biologists did not have any understanding of the mechanisms of variation; whereas we, thanks to molecular biology, are more and more aware of these mechanisms. Lacking a take on the real mechanisms, the Modern Synthesis authors had to model processes in terms of statistics. This explains why population genetics was, for them, at the heart of evolutionary science. But given that we can now grasp the mechanisms of variation directly, we no longer have to ground our evolutionary science on the statistical models of population genetics. Such contrast between "statistical" and "mechanical" understanding is backed up by the statisticalist understanding of selectionist explanations, which sees these explanations as purely statistical and non-causal: hence this view leaves room for other explanations – room to be filled by evo-devo-style explanations, which focus on the inner mechanisms of variation. Inversely, if one is not committed to statisticalism, one may choose to resist Pigliucci and Müller's claim that contemporary evolutionary science should turn to mechanicism and dismiss the Modern Synthesis picture, said by them to be centered on statistics and unable to capture the real causes. We see here how a vivid scientific controversy can hinge on metaphysical issues that revolve around the concepts of causation, explanation, and probability.

Targets and Limits of Selection, 1: Levels of Selection

The PNS is a formal explanatory sketch, but the precise characterization of the process of selection and the entities it involves – the issue of the levels or units of selection – has been one of the hottest controversies in evolutionary biology and philosophy of biology for several decades.

Genic Selectionism

After having studied the collective foraging habits of herds of animals, and found that it appeared as if each animal restricted its own consumption so that resources remained available for subsequent generations, ecologist Wynne-Edwards (1962) claimed that natural selection acts in favor of groups or populations. This claim seemed to contradict the fact that it is individuals who are the entities subsisting and spreading through selection. Against him, Williams (1966) gave a forceful defense of selection – and hence adaptation – applying exclusively to individuals. Since the determinants of heritable variations that are being selected are genes, he concluded that selection acts primarily at the level of the genes. It is worth noting, however, that Williams did not refute the logical possibility of adapted groups, subject to group selection. He merely proved that the examples which had been brought forward as alleged cases of group selection could also be explained by natural selection at the level of genes – the theoretically more parsimonious approach. Along similar lines, Dawkins (1976, 1982) elaborated his view of genic selectionism (the "gene's eye view" of evolution), trying to account for all manifestations of selection. One must distinguish here between genic *selectionism*, which is an assertion about processes of selection, and genic *determinism*, which claims that all phenotypic traits are wholly caused by genes, with no effect of environment or learning. One could perfectly well subscribe to genic selectionism without genic determinism, as did Dawkins himself, as well as Rosenberg (1985) or Dennett (1995). Genic determinism is about development, whereas genic selection is about evolution; the former (which is a straw position now unanimously rejected) claims that the genotype in itself largely controls the construction of an individual's phenotype, whereas the latter takes as central fact that only *differences* in genes matter for the evolutionary dynamics in a population. Thus the genic selectionist concept of a gene only requires that the presence of a gene in a certain environment make a fitness difference, relative to its absence. Commitment to this weaker requisite that genes be "difference makers" (Sterelny and Kitcher 1988) need not be accompanied by any assumption about what it is that genes determine, and through which mechanisms. The genic selectionist view can easily accommodate the massively documented fact that most traits – like human height – are based on a huge number of loci, and that the effects of most alleles vary as a function of environmental parameters (that is, the idea of a "norm of reaction"). Genic selectionism does not rule out the possibility that environment might be as much a determinant in the development of a trait as genes are (Gray 2001).

Hamilton (1963) has been immensely influential in this debate by showing that many apparently altruistic behaviors, i.e., behaviors that are costly (in fitness) for the organism itself, and beneficial for other organisms – such as the sterility of many hymenopteran insects – can be understood at the genic level; this is where the notion of "kin selection" arose (West et al. 2010). At first glance, such behaviors appear rather contradictory to natural selection as a means of enhancing the individual's fitness; hence Wynne-Edwards' appeal to group selection. From a kin selection perspective, altruism has been selected because, although it decreases the fitness of the altruistic individual, it increases the representation of that individual's genes in the next generation, provided that the individual is related closely enough genetically to individuals benefiting from this altruism. This is the case in insect societies, since due to their reproductive structure they are essentially societies of cousins. For example, worker bees are closer to their sisters and queen than to their own putative offspring. Biologists expressed this in a simple rule, "Hamilton's rule," stating that a behavior – or more generally a trait – evolves if and only if $b < cr$, where c is the cost for a given individual, b is the benefit to other(s), and r stands for "relatedness"; the latter is a measure of genic proximity that is often given by kinship relations, but which more generally is rather sophisticated variable, likely to be interpreted in various mathematical ways (Frank 2006; West et al. 2010).

Genic selectionism thus is the claim that natural selection targets the level of the genes; it uses the pervasiveness of kin selection as a key piece of evidence. It has been challenged in several ways by (among others) Gould, Lewontin, Sober, and Brandon. One critical argument is that selection acts only on phenotypes, hence is blind to genotypes. Therefore, the argument goes, the level of genes cannot be relevant for understanding selection. Many genotypes, and therefore many genes, are identical with respect to natural selection, provided that they are genes "for" the same phenotypic trait. Drawing on a notion elaborated by Reichenbach and Salmon in a philosophical debate about probabilities, the argument states that phenotypic interactions *screen off* the efficiency of genotypes and their relationships with the environment. (One says that "A screens off B as a cause of C" if and only if $\Pr(C/A\&B) = \Pr(C/A) \neq \Pr(C/B)$.) It does not deny that genotypes, together with environments, cause phenotypes. Rather, it asserts that this kind of causation does not explain the outcome of selection, since it is both necessary and sufficient for the purpose of explanation to consider the effects of the interaction of the phenotype with its biotic and abiotic environments. The other line of defense, stated by Sober and Lewontin (1982), relies on a *context sensitivity principle* which claims that, since the phenotypic effects of a gene depend on the environmental and *genetic* context of its expression, a single allele cannot be the bearer of the selective causal process. By way of example, the authors cite the case of heterozygote superiority, where it is the diploid genotype (e.g., *AA* or *Aa* or *aa*), and not the single allele (*A* or *a*), that is the genuine entity supporting the selection process (in a classic example of this, only the combination *Aa* confers malaria resistance unaccompanied by sickle cell anemia). It is certainly possible to describe mathematically what happens to a single allele, but this gene's eye view account is not *causally* explanatory, since the real cause resides at the level of the genotype.

Selection: General Formulation and Level-Pluralism

Although biological evolution has been theoretically defined as a change in gene frequencies, the fact that the general model of the process of selection is not committed to any determination of the entities undergoing natural selection implies that these are not necessarily "genes." Thus David Hull (1980) gave a formulation in terms of *replicators* – reproducing entities – and *interactors* – entities whose causal relationships affect the hereditary success of the replicators they are associated with. Selection on this approach is the differential replication of replicators as a function of the interactions of interactors. (It was Dawkins (1976) who first coined the term "replicators," but he opposed it to "vehicles.") In most classic cases of natural selection, the replicators are genes and the interactors are organisms. The gene's eye view claims that genes are the units of selection because they are always the replicators. But of course the formal definitions could be applied to different situations: ones in which replicators could be species or clades, or interactors could be genes themselves or groups. One point of interest of Hull's formulation is that it can handle selection even outside biology – for instance, when we talk about cultural entities. This formal characterization thus offers a more flexible approach to various selection phenomena. For example, in the case of meiotic drive or segregation distorters (cases important to Dawkins' argument) genes are not only the replicators but also the interactors, justifying reference to "genic selection" (Burt and Trivers 2006) – to be distinguished from the stance of *genic selectionism*, which as noted states that *any* selection is in principle taking place at the level of genes.

Concerning genic selectionism, two strong, opposing positions have been put forward among philosophers of biology. The first one, formulated by Brandon (1988), is pluralism: it states that there are several levels of selection (as interactors) and several units of selection (as replicators). On this view it is an open empirical question, in any given case, which are the actual forms of natural selection, although most commonly empirical evidence favors selection at the level of organisms, added to selection at the level of genes and in some cases at the level of groups. The opposite position is defended by Sterelny and Kitcher (1988), who claim that there is always genic-level selection, even if it can often be legitimately captured as a selection process at another level, organismic or supraorganismic. This is so, according to them, even if we cannot have empirical access to this level, and even if it is pragmatically more interesting for biologists to recognize supraorganismic selection processes and treat them as such. The genic level is said to be always the "maximally informative" one.

Those philosophical considerations do not, in fact, impinge on biological investigations. It seems that in practice, biologists are mostly pluralist on this issue (e.g., Williams 1992). However, it is not clear whether the choice between the two contrasting positions could be settled through empirical inquiry alone.

New Group Selection, Kin Selection, and Pluralism

D. S. Wilson and Sober provided new theoretical grounds for the use of group selection (Sober 1988a; Wilson 1992; Sober and Wilson 1994, 1998), postulating what Wilson called "new group selection." Their argument relies on distinguishing and comparing within-group and between-group selection processes. For instance, if "altruism" and "selfishness" are the two traits under focus, selfish individuals do better than altruistic ones in a given group, but the groups that have more altruists generally do better than those that include more selfish individuals (think, for example, of "altruists" as individuals that forage for more resources for the group). The overall number of altruists may therefore increase, if one considers all groups jointly. One consequence is that even kin selection appears as a form of group selection (where the relevant groups are defined by kinship), rather than being genic selection's underpinning of an apparently altruistic phenomenon.

The essence of such approach consists in viewing selection as composed of two selective processes: one at the level of the group, and the other within the group, at the level of individuals (Okasha 2006). Damuth and Heisler (1988) made a useful distinction regarding the concept of multilevel selection, between what they call Multi-Level Selection 1 (MLS1), where the fitness of groups is measured by the number of individuals they comprise in the next generation, and MLS2, where it is measured by the number of daughter groups they can produce at the next generation. The altruism of vervet monkeys warning others about the presence of a predator is an instance of MLS1, whereas species selection pertains to MLS2 (it concerns the greater or lesser ability of a species to speciate).

In the spirit of this multilevel approach, Michod (1999) elaborated a schema accounting for the progressive emergence of new kinds of *units of individuality and fitness*: macromolecules, genes, cells, multicellular organisms, etc. The model relies widely on trade-offs between decreases in fitness at lower levels (for example, the association of individuals creating a common interest, in a way that works against the interest of the individual) and increases in fitness at higher levels (for example, the level of the association itself); this type of trade-off is an exemplary case of multilevel selection. The recurrent problem is, then, to show how, in each case, the tendency for the individual to defect (e.g., by breaking the association), which is an option whenever there is a "common good" (Leigh 1999), can be overcome through this multilevel selection. Michod's approach ignited an important revival of the question of the nature of biological individuality (Bouchard and Huneman 2013), as well as the concept of "organism" – and whether one should accept the existence of "superorganisms" such as ant colonies, or rather talk of degrees of organismality (e.g., Strassmann and Queller 2007).

However, recent developments have shown, first, that kin selection is a very powerful theoretical tool for understanding a great many behaviors and traits, and second, that there are formal equivalences between multilevel selection and kin selection (Kerr and Godfrey-Smith 2002). Moreover, "kin selection" may be understood in a very broad way, where relatedness is not limited to kinship. It then covers many cases where altruistic traits evolve even in the absence of kin groups (West et al. 2007). Kin selection and MLS appear to be two equivalent ways of partitioning the causally relevant factors in a dynamic of evolution: either one defines the various competing *groups* and then expresses selection as the net effect (on the trait under discussion) of intra-group and inter-group competition, or one focuses on the value of *relatedness* and then expresses fitness as the sum of direct (=affecting the relevant individual itself) and indirect (=affecting related individuals, in proportion to their relatedness) fitness benefits (Huneman 2014b) – a measure called *inclusive fitness*. Explanatory pluralism would then consist in allowing for these two approaches to coexist, whereas monism would represent the claim that only one of them really captures the fundamental causal facts. An important argument in favor of kin selection is the empirical fact that it is more widely used than the alternative approach, often because it is more mathematically tractable.

From this perspective, one could argue that inclusive fitness is the most general concept of evolutionary theory, and that evolutionary change can be understood to be directed by maximization of inclusive fitness. This would generalize Fisher's Fundamental Theorem (about natural selection increasing mean fitness) to a yet wider set of cases, including strategic interactions (for which Fisher's Theorem seemed initially problematic; see section "Epistemology of Selectionist Explanations: Analyticity and Historicity" above).

The controversy summarized above bears important consequences for the general scope of the theory of evolution. What is at stake in the discussion of altruism is the possibility of extending selectionist explanations to certain central social phenomena in humans. (See chapters "▶ Great Ape Social Systems" and "▶ Cooperation, Coalition, Alliances," Vol. 2.) If altruism can be explained via kin selection theory, or via Trivers' reciprocal altruism (Trivers 1971) – which holds for populations of nonrelated organisms and is now derived from game theory, particularly from the results of a study of Prisoners' Dilemma by Axelrod (1980) – then the issue of levels of selection entails the issue of the potential appropriateness of an evolutionary approach not only to the emergence of man and human societies, but also to contemporary human psyche and societies. Yet, altruism as studied by biologists is not what vernacular language calls altruism: some very "selfish" person (in ordinary language) who doesn't want to be "burdened" with children would be considered biologically altruistic because of her not having offspring; in contrast, a mother who sacrifices her entire life to her children, even though a paragon of vernacular "altruism," would be typically selfish from a biological point of view, since she is so entirely devoted to entities that share 50 % of her genes. Therefore, regardless of the outcome of the debate about units of selection, any principles extended from evolutionary biology to psychology must be checked as to whether they use vernacular or evolutionary concepts, and whether there is a risk of confusion due to ambiguous terminology.

Targets and Limits of Selection, 2: Limits of Selectionist Explanation: Adaptationism

Darwin stated that the phylogenetic tree life (the first principle of Darwinism) was partly explained by natural selection (the second principle), but that there were other mechanisms at work: "I am convinced that natural selection has been the main but not exclusive means of modification" (1859, p. 6). In this section we will turn to the actual limits of selectionist explanation as understood today in explaining both the form of the phylogenetic tree and the particular features of organisms.

The question of the limits and conditions of selectionist explanation has been central to the controversy about *adaptationism*. In a very influential paper, Gould and Lewontin (1979) described and criticized a pervasive method in evolutionary biology which they called the "adaptationist program." In short, adaptationists are those who think that the majority of important features of the living realm can be explained by natural selection (Sober 1994).

There have been many attempts to clarify the stance of adaptationism (Godfrey-Smith 2001; Lewens 2009). Maynard-Smith (1984) and Dennett (1995) profess adaptationism with some reservations; Gould (1980) and Wake (1991) do not. (Orzack and Sober (2001) present illuminating essays on the testability and the meaning of the adaptationist program.) For Gould and Lewontin (1979), the adaptationist program consists in first disassembling an organism into discrete traits and then building a selective history that establishes how each trait emerged as an adaptation to solve a particular problem. The authors criticize this program, contending that we cannot disassemble an organism any way we want, and that explanations of traits as adaptations are often untestable. Too often, they say, biologists, be they ecologists, paleontologists, or ethologists, create "just-so stories," namely, stories that invent a plausible scenario for the resolution of a hypothesized environmental problem – the trouble being that there is no way to prove that such a problem existed in the first place.

Gould and Lewontin point out that there is always the possibility of constraints on natural selection which prevent an optimal trait from being realized, even though it is also always possible to design models that postulate supposed environmental demands in order to derive as optimum the trait as it actually exists. By "constraint," theorists like them may mean various things (Maynard-Smith et al. 1985), so some clarification is needed. Constraints can be physical, such as the constraint on genome size which entails, e.g., obstacles to rapid metabolism within the cells of salamanders (Wake 1991); or, more obviously, the constraint that an elephant cannot have thin feet. Alternatively, constraints can arise from structural genetic arrangements; for instance, two genes might be too close to each other to be separated by crossover during meiosis. Constraints can be phylogenetic, meaning that selection acts on entities that have been shaped by their history and have inherited features that are difficult to change; for example, selection did not adapt vertebrates to life out of water by creating a perfect respiratory device, but instead modified the pre-existing devices of fish. Phylogenetic constraints become apparent in the course of comparisons across several species or clades: for instance the fact that giraffes, like all other mammals – including mice – have seven neck vertebrae indicates that the number of vertebrae is constrained; if it weren't, we would expect the number of vertebrae to be a function of size, and therefore more adapted. Moreover, phenotypes must be subject to genetic constraints, since there are pleiotropies that entail that a trait will, in any case, be accompanied by another trait that has no adaptive relationship to it.

Not least, constraints can be developmental, in which case they concern the range of variation available to selection. The issue of natural selection (of a given trait) facing constraints of this type is tightly bound up with the other issue raised by Gould and Lewontin, namely the impossibility of deconstructing living beings into discrete traits. The set of developmental constraints provides conditions for a kind of form which in its essence is untouched by selection, though always slightly altered and reshaped by it. Gould and Lewontin, following the German morphologists, of the 19th century call this the *Bauplan*. In this perspective, an organism cannot be seen as a mere bundle of adaptations, and selective explanations of all its traits do not suffice for a complete understanding of it (a claim echoed by a recent call for a "return of the organism" in evolutionary biology; Bateson 2005; Huneman 2010).

However, the emphasis on constraints is best understood in reference to the recently articulated evolutionary theory of development (Raff 1996; Arthur 1997; Gilbert et al. 1996). Selection acts on variants, but not all variants are able to develop from a given gene pool. The evolutionary theory of development unveils constraints on the rise of those variants which selection is about to act upon. For example, Wake (1991, pp. 547–549) showed that in all species of plethodontidae, the feet have got four toes instead of the five exhibited by their common ancestor, from which they derived by miniaturization. This change occurred several times in unrelated lineages, as an alternative state of developmental mechanisms sharply distinguished from the initial five-toes producing state: adaptive processes selected for size, whereas the developmental constraints led to the switch from five to four toes, independent of the lineage. This example has nonetheless been challenged by Reeve and Sherman (1993) in a defense of the adaptationist program. According to them, an appeal to selection is plausible even in Wake's case, since it is possible that there is selection at an embryonic stage that eliminates variants having more than four toes. The example illustrates that claims about developmental constraints may not be so easy to defend in the face of highly elaborated concepts and models of natural selection.

Clarification of this debate has been provided by Amundson (1994), who argues that developmentalists and selectionists simply do not ask the same question. Selection is appealed to in order to explain *why such and such variants arose and spread* in the gene pool among a given set of variants. By contrast, developmentalists try to answer the question of the *nature of this set of variants*: why are there these variants and no other variants, and to what extent is the emergence of certain variants unlikely or impossible? This, in fact, is not exactly a constraint on selection, because selection is an *explanans* to a different *explanandum* than the one developmentalists are interested in.

This acceptance of pluralism within the various explanatory strategies in evolutionary biology is likely to eliminate the false problems created by the adaptationist debates and leaves philosophers and biologists with the task of formulating and evaluating what could count as an adaptationist research program. Following

Godfrey-Smith (2001) and Lewens (2009), it is useful to distinguish between two major types of adaptationism: the *empirical* approach, which makes assertions about the pattern of the phylogenetic tree and the actual mechanisms of evolution, and the *methodological* approach, which contends that biologists must start out assuming the presence of adaptations, even if they recognize later on that in fact the predefined adaptational optima have not been reached and that constraints did exist. Such methodological adaptationism is justified for the same reasons for which the "phenotypic gambit" (cf. section "Genes, Dynamics, Optimality, and Strategies" above) was justified.

However, notwithstanding conclusions about the comparative values of the many adaptationist programs and hypotheses, there is a larger fundamental issue looming in the background to this question: namely, the conditions under which we are likely to recognize the effects of selection and its role in relation to other causes of evolution.

Selection, Drift, and Phylogenetic Inertia

Any model of real phenomena has to state a "null hypothesis," namely, the description of a state in which there is nothing to explain, and relative to which the actual state will have to be explained. (A more precise specification of the notion of a null hypothesis is given in statistics, where it plays a crucial role in hypothesis testing.) Many radical changes in scientific thought over the course of history have consisted in new definitions of a null hypothesis relevant to the subject of inquiry. For instance, Galilean physics began by conceiving of uniform rectilinear motion (as opposed to rest) as the null hypothesis, recasting acceleration or trajectory changes as the proper *explanandum*; the newly defined null hypothesis became known as the "principle of inertia."

By analogy, then, phylogenetic inertia suggests itself as the null hypothesis in evolutionary theory. In any population, traits have to be explained if they are not obviously the result of descent, i.e., if they are not homologous to traits in the ancestor species. Of course, the classification of traits as either homologous or not depends on the set of species under consideration. Thus, a preliminary specification of the set of species to be compared in order to account for traits in a given species is an absolute condition for applying the PNS. If traits are wrongly deemed homologous, due to inadequate specification of the initial set of related species to which the *explanandum* species is to be compared, this immediately entails false results (Orzack and Sober 2001).

However, methodologically, for a set of species, the relationships of homology and homoplasy implied by the statement of a null hypothesis are epistemologically related to the more fundamental *principle of parsimony*. (See chapter "▶ Quantitative Approaches to Phylogenetics," Vol. 1.) It can easily be seen that the more we judge there to be homologies, the fewer evolutionary lineages we need to draw on: this is a kind of parsimony, so Hennig's auxiliary principle – "Always presume homology in the absence of contrary evidence" – can be called upon if one subscribes to epistemological parsimony. But the stronger, ontological claim of parsimony also supposes this way of defining the null hypothesis.

Phylogenetic inertia, however, is not incompatible with selection. We have to distinguish between the question of the origin of traits, on the one hand, and their maintenance, on the other. When traits exist by phylogenetic inheritance but decrease in fitness in the new environment and the new species, selection is likely to suppress them or render them vestigial. In the reptilian family, this was probably what occurred as snakes went from four legs to none. Since origin and maintenance are distinct issues, selection and inertia are not two competing hypotheses but can serve as distinct *explanantia* for distinct *explananda*, and sometimes as complementary explanatory resources.

Proper definition of the null hypothesis is a methodological challenge in population genetics as well: since the Hardy-Weinberg equilibrium defines a kind of rest state of the population against which the effects of selection and other forces are assessed, it could be seen as the null hypothesis. However, it would also make sense to place randomness at the center of the null hypothesis. In that case, the null hypothesis for population change would be stochastic fluctuations, namely "genetic drift," as a consequence of the finite size of populations (drift being stochastic sampling error due to size). By contrast, if the HW equilibrium were the null hypothesis, drift would be a "force" or a "factor" of evolution, along with selection or migration, as the founding fathers of the Modern Synthesis called them.

It seems that the rise of neutralist theory in molecular evolution is leading to a switch in null hypothesis from the HW-based "rest state" to the random drift state (Veuille 2000). Yet, in support of the former hypothesis, one could appeal to Wright's concept of "adaptive landscapes" (see Gilchrist and Kingsolver 2001). The fact is that in a typical gene pool some combinations are local optima, and if a genotype is on the slope of such a local optimum, selection will lead it toward the peak. But there may be a fitness valley that separates it from another, higher fitness peak, so that its fitness will have to decrease first in order for it to reach the slope of that higher fitness peak. Only random drift, provided that the population is small, can lead a genotype through states of decreased fitness, across the fitness valley, toward the beginning of another incline – at which point selection can take over and lead the genotype toward the peak. Then, through migration, the new genotype can spread. In this model, drift helps to increase fitness by moving genotypes to global fitness peaks. Thus, besides natural selection, drift presents the other process accounting for the evolution of species, modeled by the travel of genotypes across fitness valleys and peaks. Wright named this schema the "shifting balance theory"; empirical evidence for its generality is sometimes given but is not always persuasive (Coyne et al. 1997) More recently, Lynch (2007) has argued that drift was a crucial factor in shaping the architecture of the complex genome of metazoans. In short, Lynch's argument is that these organisms, being quite large, lived in small populations, so that drift actually was very intense in the evolution of genomic features – as his models tend to suggest.

Issues Related to Patterns

Patterns: General Metaphysical Issues

There are many epistemological and methodological aspects to the construction of cladograms, and then a phylogenetic tree, presented in other chapters. There are also many issues surrounding the relationship between classification and phylogeny, and the proper understanding of classification: should it be cladist, pheneticist, or something else? The very idea of a phylogenetic tree is now challenged by the overwhelming importance of lateral gene transfer, which prevents systematists from entering conventional branches into trees (since with lateral gene transfer, transmission becomes horizontal; Doolittle and Bapteste 2007). Given the pervasiveness of lateral transfer in prokaryotes, these – as well as the archaea – may not give rise to a tree at all but be better depicted as networks. Lateral transfer aside, the idea of a tree of life raises important metaphysical issues concerning its interpretation. There are general questions about what is represented by the tree – which remain even if tree is not the proper classificatory scheme – and, more precisely, about the meaning of the nodes in the tree.

It is agreed that the nodes of a phylogenetic tree are taxa; authors often think they are species. However, the very meaning of "species" is controversial. Biologists have used different concepts here. Mayr (1970) famously proposed a biological concept of species defined by interbreeding (and non-sterile offspring). However, this definition fails to account for many things, including all prokaryotes and asexual species (which constitute the bulk of all biomass, the majority of living individuals, etc.). Others have proposed ecological concepts, phylogenetic concepts, etc. The metaquestion at issue is whether we should strive for a unique concept of species, or whether we can accommodate some pluralism. A further metaquestion concerns the metaphysical status of species (independently of what is the right concept allowing us to answer the question "Are x and y of the same species?"). Is a species, as traditional logic would have it, a *class*? Or did Hull (1978) come closer to the mark when he famously claimed that a species should be seen as an *individual* instead, made up of all the organisms of this species – an individual that has an outline, is spatiotemporally situated, is somehow integrated even though spatially discontinuous (just as many other individuals, like the USA, consist of spatially disjoint parts). Hull's notion better fits the structure of evolutionary biology. But to the extent that, on this view, species would be treated as genuine individuals, whereas other taxa would remain abstract entities, this discussion pertains to general debates about nominalism vs. realism.

Whatever the metaphysical status of species, the interpretation of phylogenetic trees compels us to make sense of the represented relations between species, and between taxa in general. Given that the relations in a tree reconstructed by systematists are not exactly a genealogy of organisms (Lecointre 2014), what is their logical status? Is it the hierarchical inclusion of species in a clade – and if so, why should this relation involve any diachrony (since inclusion is atemporal)? These are debatable metaphysical issues connected to the proper understanding of classification; it is an open question whether such issues are independent from commitments about the true concept of species, and commitments about the processes of speciation.

Evolutionary Scales, Development, and the Modern Synthesis

All of the issues investigated in section "Evolutionary Biology: Philosophical Issues Concerning Processes" above concerned selectionist explanations in general, whether applied to phenotypic changes in a population over a relatively short time period or to what Mayr (1959a) called the "emergence of evolutionary novelties" (such as the transition from the protostomes to deuterostomes). However, there is a significant difference in scale between those two objects of investigation, which raises another question about the scope of the selectionist explanations under consideration up to now. After Goldschmidt (1940), paleontologists distinguished between micro- and macroevolution: the former includes evolutionary changes in the population of a species, whereas the latter concerns the transformation of species and clades across time (which includes emergence of evolutionary novelties). The criterion for distinction between these two types of phenomena is speciation, which stands at their boundary. Patterns of macroevolution have been very controversial, especially because the Modern Synthesis, after Darwin, claimed that evolution occurred through cumulative selection of small variations, hence is *gradual*. A major issue with patterns is the extent to which gradualism can be said to hold in phylogenies.

This issue is closely intertwined with the question whether microevolutionary processes suffice to account for the attested macroevolutionary patterns. This remains an open question. For instance, it is plausible that Wright's "shifting balance theory" (cf. section 2.4.4 above) accounts for a lot of speciation on small time scales, but that its validity on a wider scale cannot be taken for ganted. Simpson (1944) argued that, even if macroevolution shows very different rhythms in different lineages, it nevertheless arises from the same processes as microevolution. In keeping with this view, Mayr (1965) established that gradualism – meaning that no evolutionary change is due to a single big mutation – is compatible with evolutionary novelties, since any change in function (like the exaptation of insect wings) or intensification of function (as in the evolution of eyes in some lineages) can account for many structural novelties. Yet Simpson felt compelled to introduce the concept of "mega-evolution," i.e., the emergence of new lineages; mega-evolution cannot so easily be characterized as a mere result of microevolution. (See chapter "▶ Patterns of Diversification and Extinction," Vol. 1.)

Eldredge and Gould (1972) were the most convincing proponents of a distinction between macro- and microevolution, which they captured in their paleontological theory of *punctuated equilibria*. This theory is, first of all, a reading of the fossil record that claims that discontinuity – sudden change after a very long period without major transformation – is not a result of geological lacunae (as Darwin tried to establish in Chap. 9 of the *Origin*). Instead, a dual-staged process is proposed to account for the fossil record: for long periods the fine-tuning action of adaptive radiation diversifies the species within a phylum, which is a kind of stasis, and then a quick general transformation of the body plan gives rise to a new phylum. While the first process can be dealt with by selectionist explanations, such as the ones considered up to this point, explanation of the second process – rapid general transformation – at a minimum needs to invoke a change in the conditions under which natural selection can operate, if we assume that no other process is needed.

Even though the idea of discontinuous change had been theorized earlier already as one possible kind of mode of evolution, namely "cladogenesis" (Simpson 1994), punctuated equilibria constituted a deeply challenging theory. The reason was that the configurational differences reflecting continuous vs. discontinuous change in the form of phylogenetic trees cry out for a matching difference in the nature or the conditions of the respective processes. If we subscribe to the idea of *Baupläne* as an integrated set of constraints, as advanced by Gould and Lewontin (1978), then we might think that phases of stasis represent fine adaptive tuning of existing *Baupläne*, whereas quick transformations represent the appearance of new *Baupläne*. The question of the status of macroevolutionary novelties associated with punctuations therefore entails the question of the explanatory sufficiency of the selectionist explanation schemes put forward by the Modern Synthesis.

Nevertheless, the concept of a punctuated equilibrium rests on some orthodox considerations of selection: among the founders of the Synthesis, Mayr (1965) emphasized the stabilizing role of selection, which, in a particular environment, largely eliminates big mutations since they are probably deleterious – given the high degree of integration of most organisms – and likely to threaten functional integrity. Periods of stagnation are, therefore, to be expected. The crucial point is the logical relation between large-scale and small-scale evolution. Fathers of the Synthesis, like Fisher and Wright, focused on microevolution. Yet some assumptions defining microevolution become false when we jump to macroevolution: first, environments are no longer stable and can change quickly and intensively; and second, the order of magnitude of the available phenotypic variation is different, since a much larger range of variation will be available if the time scale is bigger.

This second parameter is connected to evolutionary theories of development, and the focus on heterochronies crucial to Gould's *Ontogeny and Phylogeny*. Even though challenging the ubiquity of the gradual pattern of evolution claimed by Darwin and the Modern Synthesis does not *ipso facto* require challenging the traditional set of explanatory processes, evo-devo theorists assert that changing or extending this set of processes – especially by assigning development a role in evolution – is the necessary next move after acknowledgment of discontinuous patterns of macroevolution. It is these theorists who are mounting the main challenge to Modern Synthesis (Müller and Pigliucci 2011). The question they pose is: what are the constraints on the range of variation, and what constraints are about to change? Developmental constraints are likely to account for the observed limits on available variation, as well as for the restriction of the selection process to fine adaptive tuning and, finally, the puzzling outcome of stagnation in the evolutionary tree. If we want to understand the transformation phase, we have to turn to the modification of available variation and then to a possible change in constraints. Thus, if a modification of developmental mechanisms occurs, then we could expect an enlargement of phenotypic variation, a new field of operation for selection, and new evolutionary possibilities. If we assume that the features yielding this enlargement are deeply entrenched, we can understand that in this case selection will act upon many connected traits, at many levels of the developmental process, so that the result is likely to be a radical change in the existing body plan. This was Gould's (1977) point, following DeBeer (1958) concerning heterochronies: a change in the timing of development, involving many subsequent and connected transformations in the life cycle, is more likely to transform the body plan of a species than is a change in an adult trait. The important discovery of the regulatory developmental homeobox *(Hox)* genes reported in Lewis (1978), which are homologous in arthropods and chordates, supports this thesis: a slight change in expression of such a developmental gene, the Antennapedia gene, can give rise to a leg instead of an antenna in *Drosophila*. Even though genes of this sort (another well-known one is Bithorax) had been known since about 1915, a major stage in the emergence of evo-devo was the molecular characterization of these developmental genes in the 1980s (see Gehring 1998). Sequencing revealed that homeobox genes are homologous across several phyla. Setting aside the complexity of the cascades of interactions associated with these genes, the general idea is that great transformations of a *Bauplan* may be triggered by only slight modifications of some types of genes or of their expression channels (Arthur 1997), because these genes affect development and life cycles at many levels.

This empirical observation has set the agenda for other kinds of evolutionary research, including not only the attempt to construct a taxonomy of different mechanisms able to affect development and thus yield evolutionary novelties, but also the attempt to causally account for them – an agenda which is a part of the evo-devo program. Yet, as emphasized by Newman and Müller (2003), evo-devo does not reduce to an account of the evolution of developmental genes. It also comprises other research programs, ones that insist on sources of variation that may not be wholly genetic. These sources can be located at the level of organisms, as is the case with phenotypic plasticity, which was emphasized by West-Eberhardt (2003), who sees the behavioral plasticity that fits genetically identical organisms to different environments as a leading force in evolutionary change. Alternatively, they can be sought at a basic physical or chemical level, as illustrated by Müller and Newman (2005), who examine the evolutionary role of intrauterine motion in the production of phenotypes and determination of fitness, or by Newman (2013), who investigates the role of a small set of molecules whose combinations constrain possible variation because they include chemical dispositions of these molecules.

These challenges to the Modern Synthesis may concern not only the usual *explanantia* – by assigning to development, via developmental constraints, a major causal role in evolution – but also the *explananda*. For one, many authors characterize the Modern Synthesis vis-a-vis alternative approaches as focus on form vs. focus on genes (Pigliucci 2007), or as focus on structure vs. focus on function, following a traditional divide within biology (Amundson 2005). Yet a closer look at the issue of scale (macro- vs. microevolution) brings to the fore another contrast regarding *explananda*. Some clades are seen to persist for longer evolutionary periods than others; it is as if they had better capacities for evolution. It is often said of such clades that they are highly *evolvable*; the question, then, is what features make them more evolvable than others. At this large evolutionary scale, the issue may no longer be the evolution of adaptations (as responses to one environment at a time), but rather the *evolution of evolvability* itself. Greater variability obviously provides more evolvability; but other features such as modularity (Wagner and Altenberg 1996; Winther 2001) also play a role.

Switching *explananda*, then, could shift interest toward other levels of selection besides genes and individuals – for example, clades and populations – since some population-level traits, such as sex or a high level of polymorphism, quite obviously make a population more evolvable (Williams 1992). Shifting the scale of inquiry in the evolutionary tree expands interest beyond epistemological and methodological issues proper to selection to new objects and concepts – such as evolvability. It also raises genuinely new questions, for instance about the evolutionary origins of those features of traits that make them easily evolvable: should we seek the source of greater evolvability in the physical properties of a gene's DNA string, or in their modularity (Wagner 1995; Sterelny 2004) or redundancy from an information-thoeretic viewpoint?

Time Scales: Metaphysical Issues

The specifics of macroevolutionary patterns raise crucial issues about evolutionary processes and the current assessment of Modern Synthesis, but they also bring up some very general metaphysical themes, such as contingency, complexity, and progress.

Contingency

In *Wonderful Life*, Gould (1989) proposed profound implications for our view of life on earth from the recent findings of the Burgess Shale, analyzed in particular by Withington and Conway Morris. Gould's view was that many phyla appeared in the Cambrian, of which only few survived; thereafter, very few new body plans and phyla were really "invented" through evolution. But this creativity in evolutionary innovation is somewhat puzzling and raises a philosophical concern for the new *explananda* described above. Invoking the famous thought-experiment of the "tape of life" re-play, Gould suggested that the history of life contained an overwhelming number of contingent events, such as the mass extinction that killed more than half of the Burgess phyla (plausibly due to the impact of an asteroid, according to the Alvarez hypothesis).

The punctuated equilibria claim was only a weak challenge to an overall view of selectionism, since it can be reinterpreted as simply suggesting the need to define two regimens of selection – where the second one would include the aforementioned concepts and concerns stemming from developmental theory. By contrast, a view that gives a central role to contingency presents a strong challenge, since selection, and the adaptive capacities of individuals and species, cannot prepare them to withstand mass extinctions caused by excessively strong and rapid changes of environment – too rapid to qualify as what we call "selection pressures." Hence, individuals and species that survived the Cambrian mass extinction did not owe their survival to their higher fitness; the explanatory and predictive power of natural selection is very limited at this level of the history of life. The large, shrimplike *Anomalocaris*, for instance, seemed quite well fitted to its marine environment and was undoubtedly a strong predator – surely no less well adapted than the wormlike *Pikaia*, which seems to belong to the chordate phylum; nevertheless, *Anomalocaris* disappeared. Thus, major events are contingent with regard to the parameters ordinarily involved in natural selection.

However, confirmation of this "contingency thesis" rest on a lot of empirical elements that are not yet available. In particular, the exact interpretation of the Burgess fauna is still debated. Conway-Morris (1998) himself revised his original judgment and proposed that many Burgess phyla are in fact ancestors of already-known lineages. However, as Gould pointed out in his reply (Gould and Conway-Morris 1999), the point is not whether or not there are other mechanisms besides natural selection – a conundrum that we are currently unable to solve – but whether there were many more new phyla in the Cambrian, a great majority of which effectively disappeared. The contingency thesis relies on an affirmative answer to this question, which it should be possible to confirm by paleontological and morphological means. So, notwithstanding the strong challenge to selectionism, in Gould's view the important consequences for the interpretation of the history of life rely on empirical investigations. But the question is likely to be begged by methodological considerations involving *disparity*. If diversity refers to the variety of species, disparity refers to the heterogeneity of the body plans. Gould contends that whereas diversity may have increased in the Cambrian, disparity decreased. But even if we knew what the Cambrian phyla were, this would not entail the ability to measure disparity (Sterelny 2000). Most cladists assume that we can trace the genealogy of phyla but not evaluate the distance or difference between two phyla, because the criteria are always instrumental. In this view, Gould's thesis cannot be tested. The basic question, beyond the measurement of disparity, is the counting of body plans, and hence the definition of body plans. In the absence of any consensus about that issue, the contingency thesis, whether or not it is empirically adequate, is not likely to be tested.

Against Gould, Dawkins (1976, 1982, and elsewhere) has argued time and again, along with Dennett (1995), that even though the history of life is not repeatable exactly, in any "re-play" we would witness an evolution roughly similar to ours: an evolution of more and more complex entities displaying adaptations such as light detectors, motion detectors, energy-storage devices, manipulative strategies, etc. The idea is that even though the details of evolution are contingent, natural selection tends to always find the same kinds of solutions to the problem of living with environmental constraints, accumulating resources, and reproducing. Even if in different situations selection may find very different devices to realize these solutions, the solutions themselves (e.g., tracking prey through sensitivity to light, developing flexible behavior to accommodate variable environments, entering into collectives through kin selection or group selection; see section "Targets and Limits of Selection, 1: Levels of Selection" above) are constant. Contingency may play a huge role when one looks at the details of actual evolution on Earth, but, at a coarse-grained scale, comparing it to other, would-be evolutions would reveal constant "attractors" that organic life always tends to find. Documented instances of adaptive convergences suggest that this is indeed plausible: eyes have been invented 22 times independently, multicellularity has several independent evolutionary origins (Grossberg and Strathmann 2007), etc. But the reasons for convergences may also lie in structural features rather than adaptations (Conway-Morris 2010).

This debate has not arrived at a conclusion yet. But philosophers should emphasize that contingency and necessity may not be incompatible here, since the two theses do not seem to consider evolution at the same level. For this same reason, it is difficult to see what would empirically support one claim against the other in a conclusive way.

Complexity

A second pattern-related issue consists in the claim that evolution represents progress towards complexity. At first glance it does indeed appear true that more recent species are more complex; humans certainly are more complex than stromatolites or amoebas. Darwin himself, though, resisted the idea that evolution is progress: because it is based on natural selection, which is opportunistic and always builds on what already exists, evolution cannot be seen as the fulfillment of a teleological plan that leads to the highest level of perfection. (But see Richards (1992b) about Darwin's latent interest in a progressive view of evolution.)

It may be hard from today's perspective to make sense of the idea that evolution is oriented towards the emergence of mind, as has been often thought in the past, for example by paleontologist Teilhard de Chardin (e.g., de Chardin 1955). Yet even without a view towards a lofty endpoint of this kind, one can still have the intuition that there is some increase in complexity during phylogeny. This intuition is tricky to pin down in the absence of a clear concept of complexity and an operational metric for measuring it. Actually, many definitions of complexity exist, but it is hard to single out the one that would best suit evolution (see Adami (2002) on the variety of concepts of complexity and the lack of agreement). Dan McShea (2005) made some progress on this issue, by assuming a very simple notion of complexity as a measure of the number of distinct cell types, in an organism thereby linking complexity to diversity. Although this forces him to abandon the intuitive association of complexity and functionality – diversity is a purely structural concept – it allows McShea to show, first, that the phylogenetic record does indeed contain some patterns of increase in complexity, and second, that these patterns may occur without being caused by selection; they are simply due to the occurrence of variation (the concept of a "passive trend"). Brandon and McShea (2011) expand the idea into the concept of a "zero force law" in evolution, which states that even without external forces like selection working on it, complexity will tend to increase. When selection does come in, it will limit the observed complexity (and diversity). Whatever the ultimate fate of these proposals may be, they show that on the elusive issues of complexity, progress, etc., which philosophers have debated for centuries, one could in fact come to operational and testable claims in the context of evolutionary theory. This nicely brings us to our last section, about the ways philosophy itself may be affected by evolutionary theory.

An Evolutionary Framework for Philosophical Issues?

A philosophical focus on evolutionary theory cannot ignore the huge consequences that Darwinism had for traditional philosophical discourse, ranging from theological and moral matters to psychology. Conscious of the potentially huge philosophical implications of evolutionary theory's new insights into the descent of man, Darwin famously wrote in a 1838 notebook that "he who understands baboon would do more towards metaphysics than Locke."

Since these implications are as broad in scope as philosophy itself, instead of giving a complete but highly condensed survey this last section will highlight two or three general perspectives on both the fruitfulness and the difficulties associated with the use of evolutionary arguments in philosophical debates on human nature. Evolutionary theory now pervades the entirety of theoretical discourse on mankind: from philosophy of mind and language, to moral and social philosophy (Rosenberg 2003), to epistemology. Two general motivations can be distinguished: on the one hand, the promise of applying the power of selectionist schemes to problems outside biology (see Heams et al. (2014), part III); and on the other, the hope of integrating traditional problems of meaning and culture into an overarching evolutionary framework, which would permit philosophers to freshly approach questions about the origins of certain things (of ethics, of language, etc.) – questions that had been avoided because of the previously assumed non-testability of any hypotheses. This latter project defines a promising path toward naturalization, that is, towards a philosophical program whose goal it is to understand, by way of the natural sciences, objects that are supposedly unique to humanity: intentionality, cognition, ethics, etc.

Biological functions are intrinsically teleological and normative: traits are supposed to fulfill their function and are seen as abnormal when they do not; their reason for existence itself lies in their doing what they do (Millikan 1984). This normativity has often been understood through natural selection: a trait having function Y exists because it has been selected for, and it has been selected for due to its performing Y. Similarly, intentionality – namely, the property that mental states (beliefs, desires, etc.) are "about" something else – has been framed in this way, as having a function of covarying with some states of affairs (Millikan 1984; Dennett 1995; Longy 2014). Even truth itself, as a normative property (in the sense that to be true is a norm for uttering statements), can be understood from an evolutionary perspective: natural selection favors representations and beliefs that fit reality.

Ethical claims as well have been explained in evolutionary terms, by drawing consequences from the fact that altruistic trends may have been favored in humans – something that is even more powerful if the good of the group, having become internalized by individual agents, turns into a selfish motive for further actions

(Richards 1988; Clavien 2014). These and other consequences for intentionality, epistemology, and ethics will not be developed further here (but see chapter "▶ Paleoanthropology and the Foundation of Ethics: Methodological Remarks on the Problem of Criteriology," Vol. 3).

Selectionist Models of Culture and Science

As we have seen, there exists a general formula of selection that does not specify the replicators and interactors. Thus, provided that some cultural or moral entities are heritable, a selectionist scheme could render their initial creation, rise, and fall intelligible. Culture and science (as well as epistemology) are the most important *explananda* for those theories. It was noticed long ago that one human characteristic is culture. Recent research has highlighted forms of culture in many other vertebrate species (Danchin et al. 2011); the definition of "culture" ranges from mere social learning to symbolism, and the extent of the pervasiveness of culture across clades depends upon whether it is narrowly or widely defined. In any case, culture displays another kind of inheritance besides genetic inheritance: individuals learn and transmit what they have learnt, which appears somehow replicated. So, given that the transmitted items are likely to be slightly modified each time they are reproduced, a selectionist evolutionary account of culture might be feasible (Lewens 2008). (See chapter "▶ Cultural Evolution During the Middle and Late Pleistocene in Africa and Eurasia," Vol. 3.) However, an evolutionary account in this realm faces at least two big problems: the first one is the relationship between genetic and cultural inheritance. An entity may have great "cultural" reproductive success even though its bearer leaves no offspring. In that respect there is no necessary genetic basis for cultural traits; but if a cultural trait enhances the biological fitness of its bearer – as in the case of medical devices that cure illnesses – then this enhances the cultural trait's own reproductive success. The other problem is the definition of "success" in this context, given that cultural transmission is not only vertical as in biological heredity, but also horizontal (i.e., directed toward non-offspring); the horizontal dimension is at least as important as the vertical one for the spreading of a trait. Boyd and Richerson (1985) formulated a powerful set of models for cultural evolution. Although they did not make general assumptions concerning the genetic bases of cultural traits, it is clear that cultural evolution, with its vertical and horizontal dimensions of transmission, entails rather complicated relationships with genetic evolution.

Technology is an aspect of culture particularly amenable to an evolutionary approach, because the process of adaptation bears many parallels with technical evolution (Basalla 1988). In considering the rise of a certain technology (for example, photographic cameras), it is even possible to draw an evolutionary tree similar to a branch of the phylogenetic tree, with extinctions, radiations, privileged lines of evolution, and so forth. The growing field of evolutionary archaeology has undertaken such endeavor, showing that prehistoric tools can be arranged in a cladist taxonomy (O'Brien and Lyman 2002). Where technical evolution is concerned, variation is provided by changing fabrication technologies, and selection occurs since the more robust or efficient objects or processes are more likely to be copied. An evolutionary history of recent technology would resemble work in evolutionary economics, a program that applies selectionist schemes to firms and their management and technical "routines" (Nelson and Winter 1982).

Science is a specific area of culture subject to a specific constraint, namely, its aim to accurately represent the world in some way. The foundationalist program for philosophy of science, with its quest for a priori rules and guaranteed truths, declined in the 1960s, following extensive critiques. Philosophers after Quine turned to forms of so-called *naturalized epistemology*, i.e., an epistemology situated at the same empirical level as the sciences, which did away with the need for epistemically relevant norms to be knowable a priori. Evolutionary models of science, insofar as they use selection – in a sense which does not imply a trend among the selected entities toward any particular endpoint – do not presuppose any shared rationality or shared ideals among scientists, nor any special competence to recognize what is true. It is a fact that no definitive formulation of the goal of science – say, "objective truth" and the criteria to recognize it – has ever been reached; thus, we cannot presuppose that all participants in the endeavor of scientific inquiry are oriented toward the same goal. A selectionist process enables the rise of those theories with the tightest match to the real world, whenever theories bear any consequences in practical life; those consequences will be the effects upon which selection acts (Ruse 1986). At the price of giving up the idea that science aims at eternal and ideal truth (Giere 2001), evolutionary epistemology with a strong selectionist commitment, as originally formulated by Campbell and variously advocated by Giere (1990) and Hull (1988), gives a clear picture of the "process of science" that reconciles the lack of an empirically attested "aim" with the cumulative improvement of the fit between theories, data, and applications.

However, the nature of evolutionary units in this process is a confused issue: do these correspond to units of scientific content (suitably defined) and scientists, respectively? The clearest account of science as an evolutionary process is that laid out by Hull (1988). A key challenge lies in the need to prove that where theories are concerned, truth confers a kind of reproductive advantage, which is not obvious if the entities at issue are human beings. Giere's verdict (1990) is that, for the time being, evolutionary epistemology has a similar status as Darwinism did before its synthesis with genetics: it lacks an account of the mechanisms providing heredity and variation across individuals. However, such an account might be now provided by the cognitive sciences.

Like a selectionist theory of culture that is neutral regarding the biological foundations of cultural traits, evolutionary epistemology is not directly committed to any psychological theory about the *acquisition of knowledge*. There are some evolutionary theories using selectionist models that address this point, but these represent "evolutionary epistemology" in another sense: an "evolutionary epistemology of mechanisms" (EEM), distinguished by Bradie (1984) from the "evolutionary epistemology of theories" (EET) of science as a process. The two could be complementary (as in Campbell's Selection Theory of 1990), but they have no logical connection. In general, EEM can nevertheless be understood at an ontogenetic level or at a phylogenetic level. Since the EEM research program relies on an evolutionary representation of mind within nature, in order to figure out the philosophical issues at stake, the next subsection turns to the the strategy of building a continuous evolutionary framework for solving questions concerning the nature of man (see chapter "▶ Defining the Genus *Homo*," Vol. 3).

Evolutionary Psychology

Ever since Darwin's studies on the expression of emotions in humans and animals, evolution has been a resource for theories of mind and brain (Richards 1987). Evolutionary psychology appeared in the 1980s, replacing sociobiology, whose project consisted in applying to human behavior insights from the ecology of social behavior (kin selection etc.). Evolutionary psychology's explanatory strategy is to identify the adaptive value of features of *cognition* (e.g., Barkow et al. 1992). Since Tooby and Cosmides' formulation (e.g., in Tooby and Cosmides 1992), the guiding premise for this program has been, in brief: the human mind is made up of separate cognitive modules that quite unconsciously effectuate successful determinate algorithms that have been constituted through natural selection as adaptations during one of the longest periods of hominization, namely the Pleistocene. One famous example is the hypothesized "cheater-detection" module, whose supposed function it is to discover free-riders in situations of reciprocal altruism – situations that would have been frequent in the Pleistocene environment, and which have been analyzed in evolutionary game theory. Mating behavior and sexual dimorphism (e.g., Buss 1995; Symons 1979) are important subjects of this research program, which has also provided a robust explanation of some social cognition modules (Tooby and Cosmides 1992), such as our computationally amazing capacity to recognize faces, and our ability to represent what others think (called "Theory of Mind" (Chisholm 2003); see chapter "▶ Theory of Mind: A Primatological Perspective," Vol. 2). In linguistics new theories of the origin of language become available when one investigates the adaptive significance of communicating through systems of signs (Pinker and Bloom 1992; Desalles 2014; see chapter "▶ The Evolution of Speech and Language," Vol. 1).

One major assumption of evolutionary psychology is that the mind is at least in significant part composed of "domain-specific" algorithms – as opposed to the pervasive cognitivist hypothesis that the mind is run by generalist algorithms that apply across many domains, in the style of General Problem Solvers. This thesis fits in nicely with the evolutionary framework, because if cognitive competences are being modeled as answers to particular environmental problems, they are necessarily domain specific. Thus, evolutionary theory allows scientists to account for flaws or irrationalities of the mind described in the 1980s by the work of the economists Tversky and Kahneman (see Kahneman (2011) for review) as a lack of adaptation of our cognitive abilities to contemporary needs (since they were initially adapted to a very different environment). Similarly, evolutionary psychology offers a straightforward account for our highly developed ability to execute tasks generally unnoticed by traditional cognitivist psychology (e.g., face recognition). Not least, the claims of evolutionary psychology imply that cultural traits and institutions must be understood from a prior knowledge of psychological cognitive abilities (Tooby and Cosmides 1989a, b).

Evolutionary psychology faces several difficulties: the lack of information concerning the original Pleistocene environment (which leads to the rise of just-so stories), and, more generally, the pervasive invocation of adaptationism and the controversies about the extent of genuine modularity (Buller 2005). Above all, the entire program is in need of clarification of what is to be counted as a *trait*, since this decision affects all subsequent empirical investigations. Suppose that we are investigating the evolutionary significance of aggressive behavior: is aggressive behavior itself the underlying trait? Or is it one observed form of a general disposition that can manifest itself either aggressively or non-aggressively, depending on environmental factors? Or, could the observed behavior arise from a combination of various traits, such as envy, jealousy, territorial ambition, etc.? (Sterelny 2000). Unless this conceptual problem is directly addressed, the agenda of evolutionary psychology is likely to give rise to divergent, incompatible results with no principled way to compare their relative validity.

Conclusions

However interpreted, evolutionary theory is beset with theoretical problems concerning its major concepts (selection, fitness, adaptation). Those problems, while never dissociated from empirical biological issues, are at the same time philosophical, since they involve conceptual matters that imply epistemological and metaphysical choices. Although the problems of evolutionary theory cannot be solved independently of biological results, and above all could not have been formulated without reference to known facts of evolutionary biology, they are not likely to be solved purely within biological science itself. Reciprocally, their insightful articulation and attempts at solutions are of vital interest to the field of philosophy of science in general, as well as to metaphysics.

Surely the most tangible effect of evolutionary theory on philosophy is the opportunity it provides for elaboration of a new framework of inquiry about many philosophical topics – first of all, about the nature of man. This chapter intended to survey the objectives of current research programs in this realm, their variedness, and the difficulties they are facing. No integrative, synthetic knowledge of man, and no methodological framework for philosophical problems, has yet been established within the evolutionary perspective that parallels and is compatible with (and could ultimately be integrated into) the Modern Synthesis. For the moment, we have local results, new challenges, and insightful ways of approaching long-standing puzzles. But in the end, the broad rise of the evolutionary perspective will have profound consequences for the way we conceive of philosophical problems generally and, most of all, for our image of man – who is uniquely able to concern himself with those problems.

The Ontogeny-Phylogeny Nexus in a Nutshell: Implications for Primatology and Paleoanthropology

Peter R. Menke

Contents

Abstract

This chapter aims to review the relevance of ontogenic data in an evolutionary perspective. Phylogenetic investigation through developmental information is one of the most promising avenues to the elucidation of our natural history. First, the problematic integration of biological subdisciplines into the evo-devo synthesis is considered: the homeobox as Pandora's box is discussed and the important role of a comparative morphology program is emphasized. Second, the study of development reveals essential aspects of primate supraordinal relationships and does not support an archontan reality. A special note defines the traditional superorder Archonta as (1) an artifact of the *Scala naturae* concept, since archontans were supreme public servants of the Greek ancient world. On the other hand, it is (2) a vehicle to explain the existence of flying mammals (Chiroptera) via a gliding intermediate stage (Dermoptera). Third, the

impact of neotenic ideas on paleoanthropology is retraced, and current contributions describing the evolution of the human cranial base and bipedalism are presented. Man's domination by neoteny seems to be a *burlesque*, accurately related as pithecocentrism.

Introduction

The polymath Johann Wolfgang von Goethe was fascinated by the anatomical diversity of the animal kingdom and its variability of form. In 1817 (11 years before Karl Ernst von Baer published his embryological manifesto), he wrote:

> Man findet daher in dem Gange der Kunst, des Wissens und der Wissenschaft mehrere Versuche, eine Lehre zu gründen und auszubilden, welche wir die *Morphologie* nennen möchten [. . .] Er abstrahiert bei diesem Ausdruck von dem Beweglichen, er nimmt an, daß ein Zusammengehöriges festgestellt, abgeschlossen und in seinem Character fixiert sei. Betrachten wir aber alles Gestalten, besonders die organischen, so finden wir, daß nirgend ein Bestehendes, nirgend ein Ruhendes, ein Abgeschlossenes vorkommt, sondern daß alles vielmehr in einer steten Bewegung schwanke. . ..[1]

Life is obviously not a static arrangement but the particular result of a dynamic, ongoing process. This phenomenon is nowhere more relevant than for ontogenetic studies.

This review approaches some important aspects of ontogeny and phylogeny by presenting a selection of studies that exemplify this scientific field. Embryology, comparative anatomy, and especially molecular biology demonstrate an amazing unity among organisms, and sometimes, bizarre variations among them stem from a series of basic themes, some of which are common to all living beings (Nielsen 1995). I concentrate here on broader matters, such as (1) comparative embryology, especially with regard to K.E. von Baer and its modern derivative: evolutionary developmental biology. The ancient realm of morphology plays a major role in this context.

---

[1] "It can be observed that in the course of art, knowledge, and science, several efforts are made to create and cultivate a doctrine that we may call *morphology*. . .One abstracts the reality of fluctuation by supposing that a belonging together and a fixation of its character can be fulfilled. Considering all shaping, especially in organic forms, we can state that there is no stability, no resting or completing-but rather a fluctuation of all phenomena" (pp 55, my translation and emphasis).

By the 1980s, molecular biology and paleoanthropology had developed their own concerns and controversies. Yet the significance of studies going beyond the analysis of adult phenotypes was already necessary and self-evident (Howell 2002).

Since hominin fossils, such as those from Dikika, Taung, Mojokerto, Nariokotome, Tešik-Taš, Kiik-Koba, or Le Moustier, represent infantile or juvenile stages, studying our phylogeny via ontogeny should be of particular importance, although, as Krovitz et al. (2003) pointed out, juvenile fossils are lacking for most species in the genus *Homo*. Here, therefore, studies are reviewed that are based on (2) embryological data sets. Generally, the methodological approaches taken to the analysis of the ontogeny of modern individuals and the fossil record differ strongly and accordingly have different meanings for the study of evolution (MacPhee 1981).

Focusing mainly on current primatological and paleoanthropological aspects, the far-reaching influence of (3) Bolk's fetalization hypothesis is retraced. Gould's (1977) interpretation is reconsidered (4), based not only on modern studies but also on traditional work that nowadays maintains only a shadowy existence, although its explanatory power is astonishing. As one may well imagine, any review of the ontogeny-phylogeny question must at present be incomplete. However, *gutta cavat lapidem, non vi sed saepe cadendo* (constant dripping wears away the stone).

Comparative Embryology and Evolutionary Developmental Biology

Karl Ernst von Baer and *Gallus domesticus*: The Beginnings of Comparative Embryology

Nineteenth-century comparative embryology lies at the origin of evolutionary developmental biology or, more briefly, *evo-devo*. Von Baer's and Haeckel's works are the most popular examples of that period, and these authors' "laws" describing the general development of organismic form are of great interest.

Karl Ernst von Baer, a pupil of Ignatius Döllinger, a professor at Würzburg, is known as the founder of embryology as a scientific endeavor. Although representatives of German transcendentalism had provided some insights into the field of embryology, it was only in 1828 that von Baer's *Über die Entwickelungsgeschichte der Thiere: Beobachtung und Reflexion* appeared in print and made even contemporaries recognize him as the founder of embryology. In the first volume of his masterpiece, von Baer concentrated on the development of the chicken (*Gallus domesticus*), but he also bore general laws of development in mind. He worked with dissecting needles and a simple microscope: the "Scholia" describe the deductions he made. The accuracy and minuteness of his fundamental observations is absolutely astonishing. Russell (1982, p. 114) was unable to hide his admiration: "His account of the development of the chicken is a model of what a scientific memoir ought to be...."

Von Baer's ideas incorporate the truly important distinction between the *type* (Wiesemüller et al. 2002) of organization (the structural plan) and the *grade* of differentiation (modifications of this plan). The aim of comparative anatomy to reveal group-specific *Baupläne* now had a prominent new tool by integrating embryological data.

As Charles Darwin was not a professional morphologist, it was others who introduced evolutionary thinking into the realm of comparative embryology. Ernst Haeckel's formulation of the biogenetic law (ontogeny as the short and rapid recapitulation of phylogeny) presents a radicalized phylogenetic approach. Recapitulatory ideas were not new since Müller (Russell 1982) had already supported a similar hypothesis in 1864. Yet Haeckel's verve and passion – very striking in a commemorative speech in 1909 (*Das Weltbild von Darwin und Lamarck*), on the occasion of the 100th birthday of Charles Darwin, favoring Goethe's monistic world view as being the *ultima ratio* – made it famous. The interpretations of *heterochrony* and its implication for paleoanthropology are discussed later on. However, how does today's evolutionary developmental biology reflect the ideas of von Baer and Haeckel?

The Newcomer: Evolutionary Developmental Biology

Von Baer and Haeckel: Outmoded?

The fancy term *evo-devo biology* represents an emerging field (Gould 2002; Carroll 2005) that has been specially featured in semipopular journals such as *PNAS* (2000) or *Nature* (2003). It refers to the quest by evolutionary biologists to understand how organisms change shape and form. Hall (2002, p. 8) explained that "... evolutionary developmental biology is more than a name for an emerging subfield of biology. It is a reflection of a level of analysis, synthesis, and understanding not possible through the study of evolution or development alone."

So how are the laws of von Baer and Haeckel interpreted nowadays? Gould (1977) supported von Baer's explanation and regarded it as being essentially correct while Haeckel's law is incorrect. Arthur (2002, p. 757) disagreed and argued that when comparisons are made between different levels of complexity, a pattern emerges that is broadly (although only in a very imprecise way) recapitulatory. The *déjà vu* occurs by recapitulating levels of complexity rather than precise morphological details. Haeckel and von Baer are both right in assuming that "evolution leads both to embryonic divergence and, in some lineages, to a lengthening of the ontogenetic trajectory leading to more complex adult phenotypes with greater numbers of cells, their embryos passing through simpler, quasi-ancestral forms."

Sander (1983) defined a "phylotypic" stage by describing a point of maximum similarity and a succeeding period of divergence. In this scheme, von Baer's principle of divergence only applies after this stage. Richardson et al. (1997) revealed a phylotypic period, rather than a stage, by screening more vertebrate species: this supports a broader comparative view. The hourglass model of development (Duboule 1994) might prima facie have reduced the explanatory power of von Baer. We should, however, be aware that this is a different kind of hourglass, the point of constriction being close to the beginning (Richardson 1999).

Homeobox: Pandora's Box for the Integration of Biological Subdisciplines?

Lewis (1978), Nüsslein-Volhard and Wieschaus (1980), and others (see also Lemons and McGinnis 2006) have revealed the meaning of *homeobox* genes and their importance for investigating the *Baupläne*. One application of this discovery which causes headaches for many scientists (Kuratani 2003) is the vertebrate cranium: is it a novelty that lies anterior to the head of a prevertebrate organism, or is it homologous to a special region of the amphioxus nerve cord? Holland et al. (1992) recognized a homology based on a comparison of expression patterns of *AmphiHox 3* (an amphioxus *Hox* gene) and *Hox-2.7* (the supposed mammalian homolog) and consequently denied the vertebrate brain as representing a novelty of the animal kingdom.

Hillis and Moritz (1990, p. 502) emphasized that the power and the rapid development of these techniques "has produced an euphoria in evolutionary biology, because so many new problems can be addressed, it is a commonly held misconception that all evolutionary problems are solvable with molecular data...." Nielsen (1995) worried that without morphological characters, the molecular data can produce only "naked" trees. Müller's (2005) review explained inter alia the importance of a comparative morphology program as a prerequisite for an evo-devo synthesis.

Furthermore, Conway Morris (2000, p. 4429) warned about "the risk of losing the overall evolutionary context. [...] Not only that, but there are intriguing mismatches between genomic architecture and bodyplan complexity." He pointed out that in all likelihood, a substantial proportion of the metazoan genome was available well before the Cambrian explosion and that a corresponding genetic architecture of genes and bodyplans is required, although he admits that we are still far from understanding either their interconnections or evolution. Arthur (2002) also met the challenge by demonstrating the change of tendency from general laws to specific pathways. He thus called attention to emerging concepts that integrate the overwhelmingly complex data.

As there is no one-to-one correspondence between genotype and phenotype, another important aspect of the problem lies in the interaction of genetic and nongenetic factors that act in different ways upon gene expression and create phenotypic diversity during development and evolution (Hall 1990, 1998b, 2002). Thus begins an appreciation of epigenetics. Goodwin et al. (1983), Raff (1996), and Hall (1998a, b, c) have called attention to the fact that change in development and evolution must be considered as an interaction of several "biological levels" so that consequently a hierarchical structural analysis is needed.

The timeless stimulus of Carl Gegenbaur – once called the most important morphologist in the world – and his legacy for the twenty-first-century evolutionary developmental biology lies in his methodological reflections about the relationship between embryology and comparative anatomy. Gegenbaur's emphasis of careful and detailed observation over tempting and far-reaching speculation should be the aurea mediocritas (the golden mean) in our fast-moving world. The modern scientific endeavor faces therefore similar challenges to those of the nineteenth-century evolutionary morphologists, "namely to distinguish between several possible phylogenetic scenarios" (Laubichler 2003, p. 29).

As to the formal integration of evo-devo with neo-Darwinian theory, not much progress has yet been made. The way toward a unified theory, however, seems to be open, and the stimulation of the biosciences through evo-devo biology is quite evident (von Dassow and Munro 1999; Müller 2005).

Primates and Supreme Public Servants of the Greek Ancient World

Primates and Their Supraordinal Relationships

Although primate origins and supraordinal relationships are discussed twice in Vol. 2 (chapters "▶ Primate Origins and Supraordinal Relationships: Morphological Evidence" on morphological and "▶ Molecular Evidence on Primate Origins and Evolution" on molecular data), I would like to mention some studies that have used ontogenetic data in this context. According to Hofer, one of the ultimate goals of primatology (Spatz 1964) is the elucidation of the phylogenetic position of primates compared to other mammals. Gregory (1910) formulated the concept of the Archonta, which unites Chiroptera (bats), Dermoptera (colugos), Menotyphla (Macroscelidea, elephant shrews; Scandentia, tree shrews), and Primates into one single superorder. Later on, modified versions of this hypothesis excluded the Macroscelidea (Novacek and Wyss 1986), while Adkins and Honeycutt (1993) surprisingly favored a revival of this grouping based on molecular data (*COII* gene). Even after the Hennigian revolution (1950), many morphologists confirmed the traditional version of primate supraordinal relationships by defining synapomorphies (Hooker 2001). Noncladists, such as Szalay (Szalay and Drawhorn 1980; Szalay and Lucas 1993), supported the evolution and diversification of archontans in an arboreal milieu. The approach is based on the aim of "Darwinian evolutionary classification" to include both adaptive similarity and monophyly sensu Bock and von Wahlert (1965). Critical comments can be found in Grande and Rieppel (1994).

Murphy et al. (2001), however, proposed the new superorder "Euarchontoglires," based on nuclear and mitochondrial gene sequences of 42 placental specimens. This new grouping (Asher et al. 2005; Nishihara et al. 2006) consists of the Euarchonta (= Dermoptera + Primates +Scandentia) and the Glires (= Lagomorpha + Rodentia). Surprisingly, bats are excluded and do not seem to be closely related to primates. MacPhee (1993, p. 372) already noted (based on Adkins and Honeycutt 1993) that ". . . something is pulling the rodents toward the primates in this data set. . .."

These radical changes in primate supraordinal relationships consequently deny the Volitantia hypothesis (Illiger 1811), which favors a sister group relationship of bats and colugos (Leche 1886; Thewissen and Babcock 1991; but see Beard 1993).

Wible and Martin (1993) documented that the ontogeny of the tympanic floor and roof does not provide any characters distinguishing all extant archontans from other eutherians. Actually, Archonta (archontans were supreme public servants of the Greek ancient world) has *Scala naturae* written all over it and represents a vehicle to explain the existence of flying mammals (Chiroptera) via a gliding intermediate stage (Dermoptera) in the absence of appropriate fossils (see also Sears et al. 2006). It should be emphasized that the concept of *Scala naturae* was long developed *before* the theory of natural selection (Martin 1973). Darwin (1859) promoted the view that nature does not make leaps – natura non facit saltum – in order (1) to fill the gaps in the fossil record and (2) to strengthen his intellectual position (Schwartz 2000). Although Darwin's motives are plausible, accepting the Volitantia concept might be an immediate consequence of the emerging battle against supporters of divine creation. Rasmussen (2002, p. 7) specified in a more diplomatic manner: "However, it is fair to say that at this juncture we do really not know if primates are more closely related to Scandentia, Plesiadapiformes, Chiroptera or Dermoptera. These four orders are conveniently lumped together as 'archontan' in what may be a true clade but which for lack of unambiguous evidence is often used as an informal grouping." *Faute de mieux:* chimeric archontans? (see also Hardt et al. 2006; Menke and Henke 2008). In the context of primate evolution, some important examples of cranial and postcranial anatomy are presented here.

The Myth of Primate Entotympanics: Consulting Embryological Data and Its Phylogenetic Implications

It is now more than a century since embryological studies [the Reichert-Gaupp theory, refuted by Otto (1984)] demonstrated the homology of the mammalian malleus and incus with the articular and quadrate bones which formed the ancestral jaw joint of gnathostomes. This tremendous transition can be traced in fossils by comparing basal synapsids through therapsids to early mammals. A fetal mammal shows that the angular (tympanic), articular (malleus), and quadrate (incus) develop in the same positions they occupy in the cynodont skull (Allin 1975; Maier 1987). The importance of new fossils (Rich et al. 2005), however, is demonstrated by Martin and Luo (2005): the separation of the middle ear bones must have evolved independently among the therians and the monotreme mammals. The middle ear and surrounding basicranium have played a decisive part in mammalian systematics over the past years (e.g., Sánchez-Villagra et al. 2002).

In 1979 – 2 years before the *Auditory Regions of Primates and Eutherian Insectivores* was published – R.D.E. MacPhee presented a new interpretation of the disputable issue of "primate entotympanics." Not all mammals show these mysterious skeletal elements. As otic characters are essential for primate taxonomy, this was a potential criterion for distinguishing primates from their relatives [e.g., colugos (Fig. 1) and tree shrews]. Mivart (1881) defined this specific element as "entotympanic," while Wincza (1896) introduced the term "metatympanic" (van Kampen 1905). A few influential morphologists (van Kampen 1905; van der Klaauw 1931) already championed the existence of primate entotympanics.

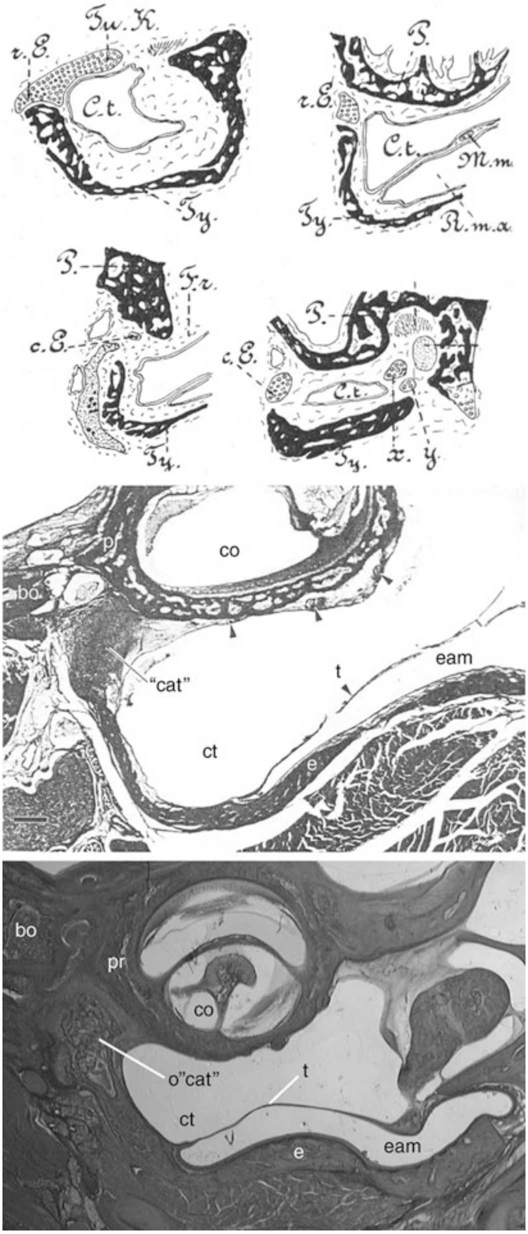

Fig. 1 *Top*: fetal *Cynocephalus volans* (Dermoptera). Cranial length 41 mm, frontal section. Note the entotympanics. *c.E* caudal entotympanic, *C.t.* cavum tympani, *F.r.* fenestra rotunda, *M.m.* manubrium mallei, *P*Petrosal, *R.m.a.* recessus meatus acustici externi, *Tu.K.* tuba auditiva cartilage, *Ty* tympanic, *x,y* cartilage. Sections have a thickness of 25 μm. Not to scale. (Modified from van der Klaauw 1922). *Center*: late-fetal *Cynocephalus variegatus* (DUCEC 806). Crown-rump length 136 mm. It shows a frontal section through the promontorium in front of the tegmen

Van der Klaauw (1922) published an ingenious work (*Über die Entwicklung des Entotympanicums*) in which he made a strong case for two different types of entotympanic, rostral and caudal. Developing in the anteromedial corner of the membranous tympanic floor, the rostral entotympanic grows posteriorly. Unlike the tympanic processes, entotympanics grow and develop within the fibrous membrane of the tympanic cavity (MacPhee 1979).

Starck (1975, p. 143) reported for *Tarsius* that the existence of an entotympanic is not yet proven. In the younger stage, the tympanic region does not show any peculiarities and an entotympanic cannot be detected. However, an older specimen showed a floor of the middle ear cavity that is formed by endochondral bone. It was closely connected with the otic capsule, but it showed a rostral extension near the auditory tube: "The ossified bone still contains some cartilaginous tissue, and this *would indicate the presence of a true entotympanic*, since the petrosal components of the floor are usually formed by periosteal bone. These results are in accordance with the findings of van Kampen (1905)" (my emphasis). According to MacPhee (1979), primate tympanic floor elements do not develop like any known entotympanic but, rather, like other tympanic processes. Prenatal *Microcebus* demonstrates secondary cartilage in the rostral tympanic process of the petrosal, which is interpreted as an embryonic adaptation – the explanation of the primordial fusion of once separate entities is no longer required. The hypothesis of a suppressed entotympanic is made more unlikely by the endochondral development of the caudal tympanic process of the petrosal (contra Starck 1975). To quote MacPhee (1979, p. 43): "Therefore, with regard to the constitution of the primate ventral wall, and with some necessary violence to Newton's quip, *non fingo ossa* – I posit no bones." *Eureka*, a new primate characteristic was identified via the careful interpretation of ontogenetic data.

Postcranial Ontogenetic Data and the Origin of Primates

Stafford and Thorington (1998) and Hamrick (2001) presented important data on the hand proportions in developing and adult mammals. Using a ternary plot (Hamrick 2001), relative metacarpal, proximal, and intermediate phalanx lengths among fossil and extant taxa deliver an elegant possibility of distinguishing primates from other "archontan" mammals. Primates differ from flying and gliding

Fig. 1 (continued) tympani. *Arrowheads point* to branches of the internal carotid nerve running in a transpromontorial position. Scale bar = 0.33 mm. *"Cat"* fused cartilage of the auditory tube and rostral and caudal entotympanics, *bo* basioccipital, *co* cochlea, *ct* cavum tympani, *e* ectotympanic, *eam* external acoustic meatus, *pe*Petrosal, *pr*Promontorium of petrosal, *t* tympanic membrane. (Modified from Wible and Martin 1993, © Plenum Press.) *Bottom*: the next step. Frontal section of a juvenile *Cynocephalus volans* specimen, of 145 mm crown-rump length, from the collection of the Institute of Systematic Zoology in Tübingen. It illustrates the ossification of the fused cartilage of the auditory tube and the rostral and caudal entotympanic (*o"cat"*). Hunt and Korth (1980) reported but they did not illustrate the fate of this important anatomical detail. Sections have a thickness of 40 μm. Not to scale mammals in having much longer proximal phalanges relative to their metacarpals and are unique among the sampled mammals in having elongated proximal phalanges relative to their metacarpals. A comparative analysis of hand development in the mouse lemur *Microcebus murinus* and other meta- and eutherian mammals reveals that "interspecific variation in relative digit and metapodial proportions has high-developmental penetrance; that is, adult differences are observed at early ontogenetic stages" (Richardson 1999, p. 348). Hamrick's (2001) results suggest an evolutionary scenario that describes an "invasion" of the fine branch niche based on a hand with a short palm and long fingers yielded by a change in digital ray patterning and segmentation.

Recent advances in developmental genetics elucidate patterns of postcranial growth in primates. Another study is based on a comparison of developmental data of CD1 mice fetuses and Rhesus macaques: Hallgrímsson et al. (2002) demonstrated the evidence for morphological integration of the limbs as serially homologous structures by reporting the covariation structure of forelimb and hindlimb skeletal elements. This proves that link structures between the limbs are caused by developmental modules, producing the covariation that would be needed to be overcome by selection for divergence in fore- and hindlimb morphology.

Since primates have more distally concentrated limb mass than most other mammals, Raichlen (2005) studied the unique kinematics of primates by testing a longitudinal ontogenetic sample of baboons (*Papio cynocephalus*). He concluded that the evolution of primate quadrupedal kinematics was tied to the evolution of grasping hands and feet.

The Impact on Paleoanthropology

Bolk's Fetalization Hypothesis: Its Successors and Critics

Forever Young?

Many contributions have emphasized the relevance of phylogenetic conclusions from ontogenetic information (Minugh-Purvis and McNamara 2002). One of the most influential books on developmental change and (human) evolution is Stephen Jay Gould's *Ontogeny and Phylogeny* (1977). Tuttle's (1978, p. 287) review of this book was not rhapsodic: "Perhaps the author attempted too much in this chubby volume [. . .] Time will tell whether it is in fact a hemicentennial classic as implied on the dust jacket." Well, in the meantime it has become probably one of the most frequently cited compendiums. Howell (2002, p. xi) commented that "its effect was immediate, substantive and far-reaching." Looking briefly at the bibliographies of modern studies often gives the impression that the consideration of developmental change in human evolution began in 1977 (Coqueuniot et al. 2004). Here, I focus partly on some of the "ancient" morphological studies that negate "essentially neotenous" ideas, to show how profound their explanatory power really is.

Why assume an *impact* on paleoanthropology? The ideas of Louis Bolk, a Dutch anatomist, have in fact had an enormous influence on scientists working in many different fields. The paleontologists Beurlen and Schindewolf (1936, 1950) supported a phenomenon called "proterogenesis" by pointing out that some evolutionary lineages that are present in successive strata may be interpreted as a process of maturing of former embryonic or postembryonic form levels. I mention these thoughts – although they do not deal with anthropological questions – because they show that Bolk's thoughts are part of a greater, speculative construct of evolutionary ideas. Portmann (1960) already assessed the situation by claiming that criticism of Bolk's considerations has to be criticism of the entire construct and argued that it is still in progress and may not be considered completed.

As Starck (1962) argued, Hilzheimer (1926, 1927) and others have pointed to morphological and physiological data to explain the principle of fetalization. Starck (1962) traced the hypothesis of neoteny back to Strickland and Melville (1848), but Bolk was the one who applied it to human evolution. A sequence of papers (the version of 1926 being the most frequently cited) takes us away to a non-Darwinian construct. So which are the essential elements?

Bolk (1926, p. 5) split human characters into (1) primary and (2) consecutive features. Primary characters are those products of developmental factors that caused the origin of human morphology. Consecutive characters, on the other hand, are phenomena of bipedal adaptation. Hence, the primum mobile of human evolution is not bipedalism, the "secondary" characters of which strictly follow functional aspects. Bolk (1926) considered the primary human characters to be the (1) reduction of body hair, (2) form of the external ear, (3) epicanthic eye fold (Mongolian eye fold), (4) loss of pigmentation in skin, (5) orthognathy, (6) foramen magnum in a central position, (7) a long persistence of cranial sutures, (8) subcerebral position of orbits, (9) high relative brain weight, (10) position of the spinal column relative to the cranial cavity, (11) women's labia majora, (12) structure of hand and foot, (13) form of the pelvis, (14) women's sexual canal in a ventral position, (15) multipapillary kidneys, and (16) the branching pattern of the arch of the aorta [the last two characters are not mentioned by Gould (1977)]. What is the common denominator of these characters?

The characters listed by Bolk are phenomena which temporarily appear during primate ontogeny. Although Bolk (1926, p. 44) differentiated the problem by separating (1) the relatives of *Homo sapiens* and (2) the development of human shape, as Slijper (1936, p. 504) explained, he advocated the idea that our ancestor must have been an *extant*Primate species. Characters of human fetalization consequently represent persisting ontogenetic primate characters. Human ontogeny therefore demonstrates conservative traits, while humans' primate ancestors showed "propulsive" (advanced) characters. Bolk's (1926, p. 26) bottom line is *H. sapiens* represents a sexually mature primate fetus. However, how did he explain the inhibitive force that fixes man's physical appearance at a certain point in time?

"The obvious answer is: The slow progress of his life's course" (Bolk 1926, p. 470) and the fact that "human life progresses like a retarded film" (Gould 1977, p. 360). Bolk (1926, p. 38) asserted that the development of dentition, consciousness, and the late closure of cranial sutures act as indicators of a dominant retardation phenomenon. The chain of causes starts with the modification of the endocrine gland function (for a modern hypothesis, see Crockford 2002) by *internal* alteration, not by external factors of the environment (Bolk 1926, p. 22).

Slijper (1936), another Dutch scientist, published an outstanding analysis that considered cetacean relationships, the fetalization hypothesis, and the clarification of fundamental terms. Ironically, Gould (1977, p. 365) called Slijper's criticism "famous," which is quite euphemistic since even the German-speaking Starck (1962) complained about it as not being easy accessible and often ignored. One major problem of Bolk's idea is the *subjective* splitting of primary and consecutive features. Slijper (1936, p. 509) recapitulated Bolk's scientific career and stated: "... we get the impression that Bolk did not present primary characters (mostly human) at first and discovered their fetal character afterwards, but rather observed a contrarian procedure: he discovered fetal characters and defined them subsequently as primary. This explains the remarkable correlation of primary features with fetal phenomena and diminishes its objective value" (my translation). Slijper also denied any general neotenous influence on human ontogeny.

Two prominent morphologists concerned with primordial cranial studies were Benno Kummer and Dietrich Starck. In 1962, they published the first modern study on fetal *Pan troglodytes* (Fig. 2). Starck and Kummer followed Hofer (1958, 1960) in distinguishing basal and prebasal kyphoses. Gould (1977, p. 378) excellently summarized their findings thus: (1) All fetal mammals have a prebasal kyphosis at the junction of the presphenoid and ethmoid bones (a bending with the concave side toward the body, as opposed to a lordosis). (2) This kyphosis decreases during ontogeny, the sphenoethmoidal angle opens out, and the face comes to lie in front of the cranium. (3) While the prebasal kyphosis develops within the basicranial axis during human ontogeny, a different kyphosis develops between the basisphenoid and presphenoid bones at the level of the dorsum sellae. This second kyphosis produces a secondary decrease in the sphenoethmoidal angle following the earlier increase conditioned by straightening of the prebasal kyphosis. (4) The "fetal" value of the sphenoethmoidal angle in human adults does not reflect the retention of a fetal condition but arises from development of the new, sellar kyphosis. It is a new feature – not a paedomorphic retention.

Amazingly, Gould (1977, p. 379) concluded: "These authors have used this single contention as the basis for a campaign against the hypothesis of fetalization..." A single contention? *A campaign*? To be blunt, Gould himself started a campaign. In relation to Bolk's explanation of skull development, Portmann (1960, p. 586) already commented that "... skull development is a complex issue which makes Bolk's solution suspicious" (my translation). Reflecting the development and evolution of the human chin, Vogel (1964) warned against too "localized" a view and called for the consideration of the complexity and interaction of *all* developing skull components. Schwartz and Tattersall (2000) revisited the presence of a chin in hominins and examined the importance of developmental epiphenomena.

Furthermore, Gould (1977, p. 379) claimed that the "... tradition of excellence in descriptive morphology is combined with a general avoidance of quantification,

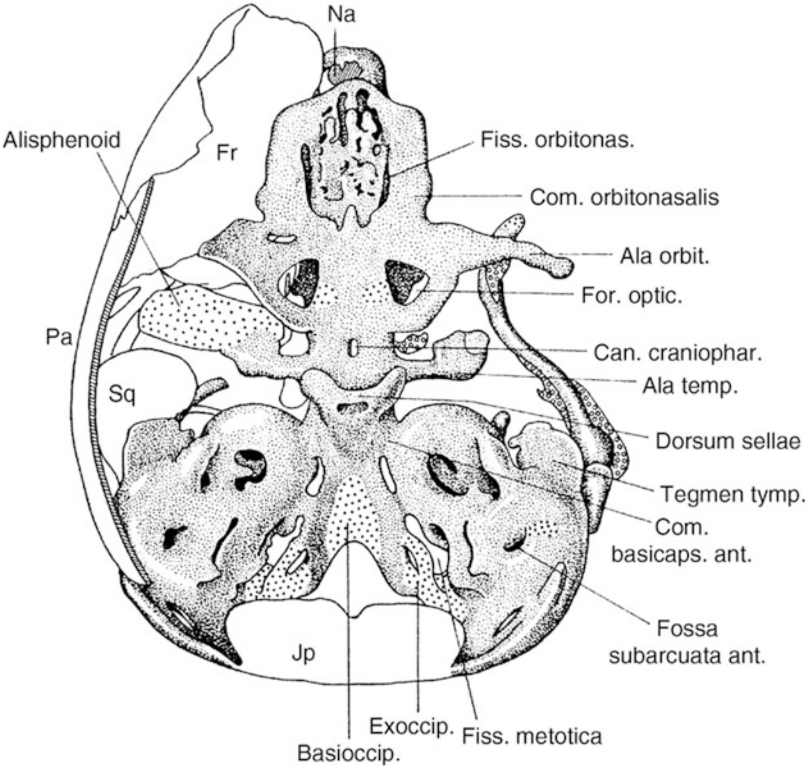

Fig. 2 Dorsal aspect of a fetal cranial model of *Pan troglodytes*. Crown-rump length: 71 mm. Not to scale (Modified from Starck and Kummer 1962)

and this may have hindered a full assessment." He might have overlooked an essential part of Starck and Kummer's (1962, p. 213) paper because "these findings can be characterized as quantitative. . .": (1) different relative sizes of the neurocranium and auditory capsule, (2) tegmen tympani, (3) frontal nasal region, (4) canaliculus chordae tympanic posterior, (5) commissura orbitonasalis, and others. Gould (1977, p. 384), however, did not fall into the Bolkian trap of an all-or-nothing law. Instead, he argued that "most of the classic 'exceptions' to human paedomorphosis are really consequences of retarded development," which Gould described as being the central phenomenon of our heterochronic evolution. Yet his ideas represent an analytic continuation of the Bolkian hypothesis.

Starck and Kummer (1962) did not exclude retardation (as in the commissura orbitonasalis) as an important factor of human development, but they emphasized that accelerations (e.g., the earlier closing of the intermaxillary suture in *Homo*) as well as deviations (e.g., the basicranium) should influence specific developmental processes. Starck's (1962, p. 23) summary revealed that the principles of human evolution cannot be understood through Bolk's hypothesis: important structures of the skull, very often taken as a result of fetalization, are indeed progressive compared with the pongid skull. It is emphasized that the bending of the skull base in man and apes is absolutely different, caused by different morphological structures. Identity of causal factors is not established, if we find external similarities, such as the same size of angles, of relative measurements or indices. This may happen by addition of completely different components.

This statement seems not to be a *furor teutonicus* but rather a well-balanced point of view. Hence, morphometrics might work, but the comparison of morphological details must occur in a correct manner. How do contemporary anthropologists interpret morphological changes of this important cranial region?

Developmental Aspects Concerning the Evolution of the Human Cranial Base

The cranial base represents the oldest component of the vertebrate skull (De Beer 1985). Thus this "conservative" structure is profoundly important in reflecting man's phylogenetic history and comparing primates to reveal essential aspects of human evolution. The keystone of the primate skull is definitely the basicranium. Several regions, such as the upper airway, the brain, and other parts, impinge upon one another here and consequently interact during ontogeny (Moss et al. 1982; Dean and Wood 1984; Lieberman et al. 2000). Biomechanically, the cranial base supplies a platform on which the brain develops and around which the face grows. The cranial base also forms a bridge connecting the cranium with the rest of the corpus: providing conduits for all circulatory and vital neural connections, articulating with the mandible and the vertebral column, forming the roof of the nasopharynx, and connecting the sense organs in the skull. Lieberman et al. (2000, p. 120) stated that "the shape of the cranial base is therefore a multifactorial product of numerous phylogenetic, developmental, and functional interactions."

Scientists are confronted with the problem of complicated circumstances in studying this truly important region. It is not only complexity that matters but also problematic ways of measuring. Furthermore, the fragmentary nature of fossil remains causes major difficulties. Novel analytical techniques, however, have helped to engross our thoughts over the past years. Different hypotheses exist that deal with ontogenetic spatial processes and their phylogenetic implications. I mainly follow Jeffery (2003) in reviewing some of the most popular versions. The *general spatial-packing hypothesis* states that the modern human basicranium is caused by a short cranial base and an enlarged brain. Ross and Ravosa (1993) and Ross and Henneberg (1995) revealed significant positive correlations between increases of relative brain size and cranial base flexion across adult primate taxa: correlation of increasing relative brain size with (1) a coronal reorientation of the petrous bones across extant primates (Spoor 1997), (2) a cranial base flexion using different measurements and landmarks (Spoor 1997; McCarthy 2001), and (3) a cranial base flexion after controlling for the influence of phylogenetic correlations (Lieberman et al. 2000). Enlow and colleagues (Enlow and Hunter 1968; Enlow 1976, 1990) also attempted to demonstrate a determination of cranial base flexion through increases in relative brain size during primate development. Jeffery and Spoor (2002) could not verify these authors' arguments. They analyzed specimens from 10 to 29 weeks of gestation and documented that petrous orientation remains independent of significant increases in relative brain size. Furthermore, a retroflexion of the midline cranial base with relative endocranial size increases has been suggested. This observation contradicts the predicted flexion pattern.

The *infratentorial spatial-packing hypothesis* has been revitalized by Dean (1988), who argued that having coronally oriented petrous bones and a highly flexed basicranium poses the spatial problem of fitting an enlarged cerebellum on a short posterior cranial base. Jeffery and Spoor (2002) showed that ontogenetic data, collected during the second and early third trimesters of human prenatal development, do not support Dean's (1988) claim. They indicate that the petrous orientation and cranial base angulation do not correlate with increases in infratentorial volume relative to posterior cranial base length.

The influence on skull form of patterns of brain growth is addressed by two interesting models. Hofer (1969) and Lieberman et al. (2000) favored the *brain shape hypothesis*, while Ross and Henneberg (1995), Chklovskii et al. (2002), and Sporns et al. (2002) supported a *neural-wiring hypothesis*. These ideas have in common a suggested necessary change in brain topography to maximize cognitive efficiency by reducing neural-wiring lengths. The resulting spatial changes produce a petrous reorientation and cranial base flexion. Distinct volumetric scaling trajectories can be detected across adult extant primates for different regions of the brain (Stephan et al. 1981, 1984; Frahm et al. 1982, 1998; Baron et al. 1987, 1990). Dean and Wood (1984) and Strait (1999) further demonstrated an association of those trends with interspecific variations in basicranial angulation. Lieberman et al. (2000) also confirmed a significant correlation of cranial base flexion with increases of cerebral volume over brainstem volume.

Moss et al. (1956) suggested that brain topography is shaped by differential encephalization patterns which lead to developmental changes in posterior cranial fossa morphology.

A few studies (Guihard-Costa and Larroche 1990, 1992; Jeffery 2002) on the human fetal brain showed greater increases in expansion of the supratentorial portion (containing the cerebrum) compared to the infratentorial portion (consisting of cerebellum and brainstem). However, the independence of human cranial base angulation and petrous orientation of changes from the volumetric proportions of the brain between the ages of 10 and 29 weeks gestation are corroborated by Jeffery and Spoor (2002).

Jeffery (2003) tested the key hypotheses by imaging fetal samples of *Alouatta caraya* and *Macaca nemestrina* using high-resolution MRI. He noted marked increases in brain size, especially "disproportionate increases in the size of the cerebrum" (p. 281), disproportionate growth of the anterior midline basicranium compared with the posterior midline basicranium, coronal reorientation of the petrous bones, and cranial base retroflexion. Contrary to the spatial-packing hypotheses, increase in relative brain size is not accompanied by flexion of the midline basicranium. Retroflexion is documented for the cranial base in both taxa. There is also little evidence supporting the spatial-packing hypothesis for the fetal period of the howler monkey and macaque due to significant and "seemingly" consistent associations with petrous orientation arise based on background covariations with somatic growth. Jeffery (2003) therefore suggested that laryngeal size might be the reason for basicranial retroflexion. He finally compared it to human fetuses and concluded that the establishment of notable interspecific differences in the basicranium occurs much earlier than in the phase he studied.

Craniofacial growth patterns have been studied by several scientists (Giles 1956; Shea 1983, 1985a, b; Jungers and Hartman 1988; Ravosa 1991, 1992; Zumpano and Richtsmeier 2003; Cobb and O'Higgins 2004; Mitteroecker et al. 2004). Lieberman et al. (2000) provided a comprehensive review of primate cranial base studies. As Zumpano and Richtsmeier (2003) pointed out, many previous studies documented postnatal growth processes, usually beginning with growth during the juvenile period. The infant growth period has been incorporated by Ravosa (1992), Richtsmeier et al. (1993), or Shea (1983), while Zumpano and Sirianni (1994) compared fetal to postnatal craniofacial growth patterns. Collections of fetal primates very often do not contain representative specimens (Zumpano and Richtsmeier 2003, p. 340). Yet it is desirable to attempt an integration of these stages since only a completely documented ontogeny delivers deeper insight to reveal whether heterochronic processes are responsible for the modifications that have occurred between human and nonhuman primates.

Zumpano and Richtsmeier (2003) investigated, for the first time, growth-related shape changes in the fetal craniofacial region of humans and pigtailed macaques (*M. nemestrina*), using three-dimensional comparative analysis via cross-sectional samples of CT image data. As they emphasized, a long tradition of studies concentrated on examining the sites of growth of the cranial base, the sites of cranial base flexure, and the determination of the cranial base angle (Bjork 1955; Ford 1956; Dubrul and Laskin 1961; Houpt 1970; Lavelle 1974; Bosma 1976; Lestrel and Moore 1978; Moore 1978; Sirianni and Van Ness 1978; Sirianni and Newell-Morris 1980; Ross and Ravosa 1993; Ross and Henneberg 1995; Zumpano and Richtsmeier 2003). Zumpano and Richtsmeier (2003) showed that decreases in human cranial base length are achieved through the differential growth of posterior and anterior elements. The length of the posterior cranial base decreases, while increases occur in the length of the anterior cranial base. They further argue that a cranial base angle decrease may lead to a total reduction in cranial base length in human fetuses. At a comparable stage, the fetal macaque cranial base does not show a corresponding reduction (increased basicranial flexion). The associated distinctiveness of the differences in midfacial growth and the progression of prenatal cranial base flexion are said to be factors separating these two species. Zumpano and Richtsmeier (2003) also contradicted Bjork (1955) and Ford (1956) in noting a basicranial flexion – not a constant angle – during the fetal period. They further support Lestrel and Moore (1978), and Sirianni and Newell-Morris (1980) are also supported in assuming a constant macaque cranial base angle during fetal growth, although they report a lesser angle (153°). The human anterior cranial base undergoes more relative growth than the macaque anterior cranial base. For the posterior cranial base, no significant growth differences between these two species are observed. Zumpano and Richtsmeier (2003) speculated that the increases in relative length of the anterior cranial base in humans may reflect the faster rate of growth of the frontal lobes of the cerebral cortex in humans relative to macaques (Enlow and Hunter 1968; Moss and Salentijn 1969; Moss 1973; Sirianni and Newell-Morris 1980) and conclude, based on their own observations and the studies of Anemone and Watts (1992) and Swindler (1985), that midface differences between humans and macaques reflect a delayed rate of maturation of the human deciduous dentition *or* an accelerated rate of development. In a tabula rasa manner, Zumpano and Richtsmeier (2003) supported earlier investigations in suggesting the occurrence of shape changes within the fetal craniofacial complex during the last trimester of fetal growth (Grausz 1991; Plavcan and German 1995) rather than assuming an isometric growth process that is, e.g., characterized by size increase without corresponding shape change (Mestre 1959; Houpt 1970; Kvinnsland 1971a, b; Lavelle 1974; Moore and Phillips 1980; Sirianni and Newell-Morris 1980; quoted from Zumpano and Richtsmeier 2003). Zumpano and Richtsmeier (2003, p. 349) finally concluded that "fetal macaques and humans do not share a common pattern of relative growth of the craniofacial complex, both species undergo increases in mediolateral dimensions (widening) of the skull and increases in palatal and anterior cranial base length."

One of the ultimate goals in paleoanthropology is to reveal the precise relationship of humans to the great apes, our closest living relatives. Morphological data favor the monophyly of the African great apes, while molecular biology unites humans and chimpanzees (Mann and Weiss 1996; Ruvolo 1997; Enard et al. 2002; Kaessmann and Pääbo 2002). Wildman et al. (2003) even placed chimpanzees within *Homo* based on molecular data. Pääbo (1999) emphasized the importance of investigating a few genes that are responsible for specific effects during ontogeny (or in adulthood) instead of concentrating on chromosomal rearrangements or the accumulation of point mutations. Hence, Mitteroecker et al. (2004, p. 680) stated that "as it is difficult to study gene expression on a molecular level for the whole organism, we confine ourselves to the study of the morphological effects of gene expression during ontogeny." They therefore created a shape space where each specimen (i.e., its landmark configuration) is represented by a single point. In this context, an ontogenetic trajectory corresponds to the ontogenetic sequence which belongs to one species within this space. As Klingenberg (1998) or O'Higgins (2000a, b) showed, geometric contrasts among ontogenetic shape trajectories distinguish the development of different species. Geometric morphometrics is a promising and complex method of collecting and interpreting data based on morphological patterns (Bookstein 1991; Marcus 1996; Dryden and Mardia 1998; Slice 2005).

Some hominid craniofacial growth studies, applying geometric morphometrics, found more or less parallel trajectories from dental stage I (which corresponds to the first permanent molar) to adulthood (Ponce de León and Zollikofer 2001; Penin et al. 2002). The development of hominid cranial morphology consequently diverges from that of the other apes in an early postnatal or prenatal stage. However, O'Higgins (2000a; O'Higgins et al. 2001) confirmed Richtsmeier et al.'s (1993) assumption of related species subsequently diverging after a similar period of early development. In a comprehensive study, Mitteroecker et al. (2004) measured landmarks and semi-landmarks in relevant specimens following a few days after birth to reveal essential insights into hominid ontogeny. Several principal patterns can be deduced from the set of ontogenetic trajectories. The authors tested three specific hypotheses: (1) “pure heterochrony” of human cranial growth relative to *Pan* is a valid interpretation if the ontogenetic trajectories are identical in shape space, (2) the divergence of human ontogeny corresponds to a similar developmental stage at which the great apes diverge among themselves, and (3) an early divergence of trajectories from common ontogeny could elucidate the considerable morphological differences between humans and great apes because early modifications in development explain drastic transformations of the adult form (Richardson 1999). Studying 206 adult and 62 subadult crania of *Homo sapiens*, *Pan paniscus*, *P. troglodytes*, *Gorilla gorilla*, and *Pongo pygmaeus*, Mitteroecker et al. (2004) collected three-dimensional coordinates of 41 homologous ectocranial anatomical landmarks on the face and cranial base. They demonstrated the expected pattern whereby the youngest specimens are much more similar than the adults (von Baer’s omnipresent discovery). Already at birth, human craniofacial morphology differs markedly from apes (p. 692) “in accord with previous studies based on more traditional methods” (Starck and Kummer 1962; Dean and Wood 1984). The first hypothesis, in contrast, can be rejected because there is no sharing of a common ontogenetic trajectory. Penin et al. (2002) tried to revitalize the “neotenic theory” sensu Gould (1977, p. 365). They do not, however, support a “general, temporal retardation of development” but rather stress that “all the bipedal traits studied, whether in the skull (basicranium) or postcranium (pelvis and femur, see above), do not result from neotenic processes but rather from structural traits” (p. 61).

Additionally, the second hypothesis is falsified, and the third hypothesis is supported, by an earlier divergence of the human growth trajectory from the common hominid allometry (Mitteroecker et al. 2004, p. 692). The African apes also do not seem to be pure allometric variants of one single type. Mitteroecker et al. thus concluded (p. 694) that “pure heterochrony does not sufficiently explain human craniofacial morphology nor the differences among the great apes.” McBratney-Owen and Lieberman (2003) also provide insight into the postnatal ontogeny of facial position in *H. sapiens* and *P. troglodytes* by emphasizing that the ontogenetic integration of complex phenotypes, such as the face, occurs on multiple levels of development, and they further speculate about the effectiveness of ontogenetic analyses for testing hypotheses about natural selection.

Ackermann (2005) investigated similarities in cranial covariation patterns by obtaining measurements from 677 crania of adult and nonadult African apes and sub-Saharan humans to locate underlying developmental and functional causes for the patterning. Defining the points of divergence of the covariation patterns can offer insights into the action of selection on development. Ackermann’s work shows that patterns of integration are similar (not identical) among adult African apes and sub-Saharan humans. Ontogeny documents a sharing of patterns, with each species showing contributions to total integration from the oral region as well as from the zygomatic and to a lesser extent the nasal regions. However, she documented important differences between apes and humans, stating:

"In particular, the lower overall integration within and lack of covariance structure similarity among adjacent ontogenetic stages in early human ontogeny differs from what we see in the other apes. It is not entirely clear why this might be so, although it indicates that selection was working in this lineage – either on humans or the apes – to distinguish them not only in morphology, but in variation patterning" (p. 195).

Quo Vadis? Developmental Aspects Concerning the Evolution of Bipedalism

I have already mentioned Bolk's (1926, p. 6) interesting ideas concerning human bipedalism "… since form became human the posture became upright" (my translation). Summarizing his growth studies on primates, Schultz (1924, p. 163) asserted that "man in some respects is less specialized and has hence remained phylogenetically as well as ontogenetically more original and 'primitive' than various other primates."

Structural and mechanical aspects of the locomotion of primates play a considerable role in many discussions of human evolution (Preuschoft 1971; Schaffler et al. 1985; Demes and Jungers 1993; Connour et al. 2000; Ruff 2002; see also Senut, Volume III). Schultz (1953) analyzed over 350 limb bone circumferences and related the results to locomotion. The evolution of bipedal walking has, naturally enough, inspired scientists to associate locomotor mode with the relative lengths of the forelimb and hindlimb bones (Schultz 1937; Napier and Napier 1967; Jungers 1982). Changes within the hominin lineage in the relative size of the upper and lower limb bones are indications of our transition to bipedality (McHenry 1978; Johanson et al. 1982; Wolpoff 1983; Hartwig-Scherer and Martin 1991; McHenry and Berger 1998; Asfaw et al. 1999; Richmond et al. 2002; Ward 2002).

A few French scientists (Berge 1998) have tried to integrate heterochronic processes into analyses of morphological changes during hominid evolution. These works have concentrated on such classic anthropological topics as the anatomy of the pelvis. Berge (1998, p. 443) emphasized separating the debate on neoteny by negating the idea "that identical heterochronic processes occur in skulls and postcranial skeletons, although we know that the growth of cranial and long bones differs in time, rhythm and velocity." She studied the morphology of two adult pelves and a juvenile hip bone of australopiths, 60 juvenile and adult pelves of modern humans, and 150 juvenile and adult pelves of African apes. The results confirmed a marked difference of the pelvic growth pattern in African apes and humans as reflected in multivariate results, ontogenetic allometries, and growth curves. Two conclusions emerged: (1) a comparison of modern humans to juvenile and adult australopithecines reveals that a unique feature of *Homo* seems to be a prolonged growth in length of hindlimb and pelvis after sexual maturity, while pelvic growth of *Australopithecus* was probably closer to that of apes than to that of humans and that some pelvis traits of adult *Australopithecus* resemble those of neonate *Homo*. Furthermore, (2) at the time of human birth, the appearance of the acetabulo-cristal buttress and the cristal tubercle allows the addition of features, such as the attainment of a proportionally narrower pelvis, with more sagittally positioned iliac blades. In early childhood (as bipedalism is practiced), pelvic orientation and proportions change progressively, while other changes in proportions occur later with the adolescent growth spurt. Neonate *Homo* and adult *Australopithecus* show similar patterns concerning the position of the acetabulo-cristal buttress. This could suggest a later displacement during human evolution. Berge (1998) further documented a progressive displacement of the acetabulo-cristal buttress on the ilium occurring during human growth (from neonate to adult) and hominid evolution (from *Australopithecus* to *H. sapiens*). She finally suggested that the evolution of pelvic morphology in hominids is based on a threefold process – predisplacement, acceleration, and time hypermorphosis – and she rejected pure fetalization (p. 457) by stating that "the present study demonstrates clearly that the concept of neoteny is irrelevant for the pelvis. The study rather implies an accelerated evolutionary process than a retarded one."

Ruff (2003) examined the human development of femoral to humeral proportions using a longitudinal sample of 20 individuals measured radiographically at semiannual or annual intervals from 6 months of age to late adolescence and also included anthropometric data such as body weights or muscle breadths. A series of limb bone length proportion studies included ontogenetic data (Lumer 1939; Schultz 1973; Jungers and Fleagle 1980; Buschang 1982; Shea 1983; Jungers and Susman 1984). Ruff (2003) focused on other limb bone dimensions. He compared his results with a cross-sectional ontogenetic sample of 30 baboons. The results document that femoral/humeral length proportions, which are already close to those of adults, are present in human infants, while characteristically femoral/humeral diaphyseal strength proportions only develop after the adoption of bipedalism (at about 1 year of age). Between the age of one and three, a rapid increase in femoral/humeral strength occurs, and this is followed by a slow increase until mid-late adolescence (when adult proportions are reached). The femoral/humeral length ratio proportions slightly increase throughout growth. There is no apparent growth trajectory change at the initiation of walking and a small decline in late adolescence based on a later humeral growth in length. Also in early childhood, a sex difference in femoral/humeral strength proportions (but not length proportions) develops. Ruff (2003) therefore concluded that they must be largely independent of growth trajectories in strength and length proportions. Baboons (used as a baseline) show contrasting patterns of growth: much smaller age changes in proportions and particularly strength proportions. He therefore stated (p. 342): "Comparisons with an ontogenetic baboon sample highlight the specific nature of the human developmental pattern."

Returning to Adolph H. Schultz, we have an excellent example of a convert. In his youth, Schultz was stimulated by the neoteny hypothesis (see earlier). Following several studies (1953, 1973) although, he rejected Bolk's idea and the theory of man's neoteny.

Heterochrony in Human Evolution: A Compilation

Repetitio est mater studiorum or as Schwartz (1999, p. ix) commented: ". . . it would be foolhardy to cling unreservedly to a particular set of models and hypotheses without at least occasionally questioning their very bases." In *Sudden Origins*, Schwartz reconsidered and discussed inter alia the different interpretation of the Taung child. While Raymond Dart was influenced by ideas of neoteny and concluded that his fossil

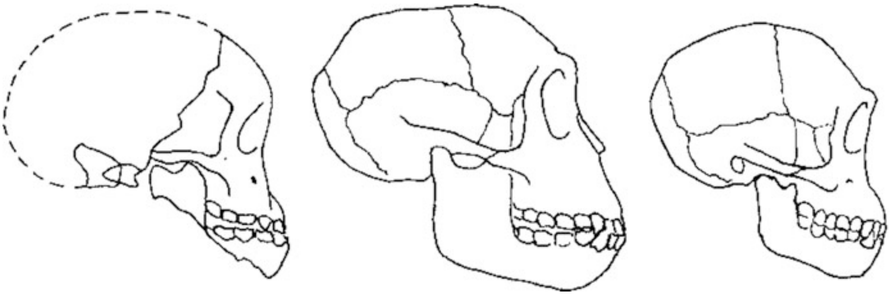

Fig. 3 The Taung child (*left*), compared to the skulls of comparably aged gorilla (*middle*) and chimpanzee (*right*). Dart's desire was to show that the apes had begun to grow away from the juvenile state. The Taung specimen has no brow ridges, small jaws, and a very large brain (Modified from Schwartz 1999, drawing by T. D. Smith, © J. H. Schwartz)

occupied a missing link position, Sir Arthur Keith drew a totally different conclusion and defined the Taung individual as an ape. Ironically, Keith's results were also based on a developmental and even a neotenic chain of ideas (Fig. 3).

Furthermore, Schwartz (1999) critically reviewed the suggestions of the Australian anthropologist Andrew Arthur Abbie, who equated neoteny and paedomorphism, and portrayed *H. sapiens* due to its long legs and a highly arched nose as gerontomorphic (more differentiated from a fetal standard), although he generally described our species as paedomorphic (little differences from a fetal standard). Abbie absorbed the heterochronic perspective but failed to sustain the argument that human morphological variability is not fixed to a limit and that any combination of features can be incorporated in the same individual.

Gould (1977, 1991, p. 2) called attention to the difference between Haeckel's heterochrony, which describes the *pathway of development in an organ relative to the pathways of other organs in the same animal*, and current usage, which defines it as "the course of a trait relative to the ontogeny of the same trait in an ancestor (or related form)." Jena's most famous zoologist was not really interested in elucidating evolutionary mechanisms as a method to explain the patterns of character states. He was rather interested in reconstructing natural history by applying biogenetic laws. Sir Gavin de Beer (1930) opened up new vistas by modifying Haeckel's concept: any change in the timing of a character is compared to the same feature in an ancestor. This established the study of heterochrony within the modern synthesis (Gould 1991).

McNamara (2002, p. 1) defined heterochrony essentially as "change to the timing and rate of development" which produces two major effects: *paedomorphosis* (if there is less growth during ontogeny, the descendant adult will resemble the juvenile condition of the ancestor) and *peramorphosis* (where the descendant undergoes greater development). Three different processes generate paedomorphosis and peramorphosis, respectively: (1) progenesis (prematurely truncated duration of growth in the descendant), neoteny (a lesser growth rate in the descendant than in the ancestor), and postdisplacement (delayed onset of growth) and (2) hypermorphosis (extension of duration of growth in the descendant), acceleration (an increase of growth rate in the descendant), and predisplacement (earlier onset of growth in the descendant). The whole organism can only be affected by progenesis and hypermorphosis, while the remaining aspects affect certain traits of the organism. McNamara (2002) further stated that peramorphosis and paedomorphosis are the products of varied processes rather than being processes in themselves. Hypermorphosis (extensions of the end of growth) and progenesis (contractions of the end of growth) are considered within a global context, “based on changes to the time of onset of sexual maturity and cessation of somatic growth, with the two frequently coinciding” (McNamara 2002, p. 105).

Different views have emerged on how large a role neoteny plays. While Gould (1977), Antón and Leigh (1998), and Montagu (1989) supported true paedomorphosis (neoteny), Shea (1988, 1989, 1992), McKinney and McNamara (1991), and McNamara (1997) favored some kind of hypermorphosis in time. Bogin (1997) suggested a new developmental stage in between (no heterochrony); Alba (2002) on the other hand characterized paedomorphosis and peramorphosis as *interpretative*, not descriptive, terms. He emphasized the importance of modifying conventional clock models based on meaningful variables. Alba (2002) called for a double standardization (initial and final developmental stages) of ontogenetic trajectories and suggests a “complete” model including absolute age (at homologous developmental stages), shape, size, and behavior. As he admitted, this is not an easy undertaking.

McKinney and McNamara (1991) have indicated that, during ontogeny, contractions and extensions can occur at transitions between particular life-history stages and that local growth fields can also be modified. The reality that heterochrony may operate at *any time during ontogeny* (from the point of fertilization until the cessation of growth) has been blurred by the comparison of the cessation of a descendant’s growth with the ancestral condition (McNamara 1983; McKinney and McNamara 1991; Maier 1999). Mammals, for example, are characterized by embryonic and postembryonic (infantile, juvenile, adolescent, and adult) growth phases. In his thought experiments, McNamara (2002) showed how some authors have described paedomorphosis where it was nonexistent. Sequential hypermorphosis (defined by him in 1983 as *terminal hypermorphosis*), for instance, also effects the offset of growth and therefore implicates greater development within each growth stage based on “scaling effects and probable increase in size, either of the part, or of the whole” (2002, p. 108). Hence, the descendant is compared to the ancestor in a relatively more juvenile state. Paedomorphosis, however, should be defined by *adult* characteristics.

What kind of consequences does sequential heterochrony have for our understanding of human evolution? The list of “general neoteny supporters” is long (I have already mentioned Bolk and Gould, but see also Montagu 1989; Wolpert 1991). Montagu’s (1989) favorite ancestor is a form very like the pygmy chimpanzee in order to compensate the incorrect assumption of Bolk that the hominid line has passed through an apelike stage such as the gorilla-orang type. Provided that human is “essentially neotenous,” hominid evolution would have produced an organism characterized by having a smaller body size, brain, and limbs

(Shea 1989; McKinney 1998). McNamara's (2002, p. 115) summary described hominid evolution as involving "a mixture of peramorphic and paedomorphic traits." Forty years back, Starck and Kummer (1962) had come to a similar conclusion via a totally different method.

Shea (2002, p. 95) applied his working hypothesis – size diversification occurs via predominant rate changes (rate hypomorphosis and hypermorphosis) rather than by time changes (time hypomorphosis and hypermorphosis) – to human evolution and concluded that: "Certainly, at present no emergent data support any genetic or developmental basis for a global or generalized neoteny." He accused Godfrey and Sutherland (1996) of revitalizing the idea that hominid evolution has predominantly involved a generalized neotenic transformation. This accusation is problematic in that Godfrey and Sutherland (1996, p. 40) freely admitted that "Gould's neoteny hypothesis for human evolution has been criticized on a number of grounds. The thesis of this paper is that both Gould and his critics overstated their cases: *Nothing that we have said should be construed as a defense of Gould's hypothesis*. Our intention is simply to reopen the dialogue, and to propose a framework for more precise testing of heterochronic hypotheses" (my emphasis).

In contrast, Hall (2002, p. 13) attacked the one-sided concentration on heterochrony as the only way to consider development and evolution by claiming that it "seemed that everyone could find evidence for heterochrony or at least justify use of the term to explain phenotypic changes in their favourite organism. Other mechanisms linking development and evolution were ignored or not sought." He emphasized the importance of heterotopy, the *spatial pendant* of heterochrony.

In summary, I give below some important terms and definitions (see also earlier) based on Minugh-Purvis and McNamaras' (2002) summary, to present a brief synopsis:

Acceleration	A heterochronic process that involves a faster rate of development in the descendant and also produces a peramorphic trait in the descendant
Deceleration	A slower rate of developmental events in the descendant. It produces a paedomorphic trait when expressed in the adult phenotype (syn. neoteny)
Hypermorphosis	Developmental events show a delayed cessation (or offset) in the descendant. Expressed in the adult phenotype, peramorphic traits are produced. Global hypermorphosis can be caused by late sexual maturation (terminal hypermorphosis). But hypermorphosis can also be caused by a delayed cessation in local growth fields
Isomorphosis	Peramorphosis followed by paedomorphosis (or vice versa). The descendant does not show any effective morphological changes. Unusual phenomenon of paedomorphosis
Neoteny	A slower rate of developmental events in the descendant, producing paedomorphic traits when expressed in the adult phenotype (syn. deceleration)
Paedomorphosis	The descendant adult retains subadult ancestral traits
Peramorphosis	The ancestral adult shows development of traits beyond the "usual" ancestral stage

(*continued*)

Progenesis	Developmental events show an early cessation in the descendant. Expressed in the adult phenotype, peramorphosis is produced (syn. time hypomorphosis)
Sequential heterochrony	Contraction or prolongation in the descendant relative to the ancestor of life-history stages or ontogenetic growth
Sequential hypermorphosis	Life-history stages or ontogenetic growth is prolonged in the descendant relative to the ancestor (syn. proportional growth proportion)

Tolkien's Hobbits Came True: *H. floresiensis* and Heterochrony

In his first chapter of his book *The Hobbit*, "An unexpected party," J. R. R. Tolkien described these creatures as wearing ". . . no shoes, because their feet grow natural leathery soles and thick warm brown hair like the stuff on their heads; have long clever brown fingers, good-natured faces,. . ." Furthermore, and more importantly, the author characterized them as "..little people, about half of our height" (Tolkien 2007, p. 4). *Homo floresiensis* was named for Pleistocene hominid remains on the Island of Flores (Indonesia) – these fossils in many ways represent the embodiment of Prof. Tolkien's fantastic creatures. However, for some researchers insular dwarfism by natural selection seems not to be a good explanation (e.g., Jacob et al. 2006). They prefer a pathologic scenario which reminds one of the interpretation of the Neanderthal enigma àla Rudolf Virchow.

The ontogeny-phylogeny nexus might serve as a plausible model for the evolution of *Homo floresiensis*. Kubo et al. (2013) analyzed the endocranial volume of LB1 via high-resolution micro-CT scans. They finally concluded that is mechanistically possible that the dwarfs from Flores evolved from early Indonesian *Homo erectus*. Mammals such as hippos have served as a model for brain size reduction in *Homo floresiensis* (Weston and Lister 2009). However, these studies have not deeply considered the role of ontogenetic processes. Van Heteren (2008) presented an interesting evo-devo approach by adapting the model of heterochrony – that, like the pygmy elephants of Cyprus, *H. floresiensis* might have stopped growth at an earlier age. Additionally, paedomorphic features might have developed "by making the rate of ossification increase" (p. 7).

In support of his hypothesis, Van Heteren (2008) adduced various cranial paedomorphic features such as the orbital index, the mandibular angle, the endocast, and the canine fossa. The dental index also supports his view of *H. floresiensis* as an interesting case of heterochrony. Furthermore, such postcranial adaptations as the humeral and tibial torsion or the brachial index may indicate neoteny. Although the detailed interpretation of these characteristics cannot be considered in this review, the Dutch tradition of considering ontogenetic interpretations when reconstructing phylogeny remains vivid.

As I have shown earlier, the general neoteny theory of human evolution seems not to be the correct general approach to exploring our ancestry. Yet for the interpretation of particular problems of paleoanthropology such as the hobbit phenomenon, ontogenetic studies nonetheless represent powerful tools for phylogenetic research.

Conclusions

Alberch (1982) rightly pointed to the importance of developmental constraints in evolutionary processes. It is nevertheless also important to emphasize the highly informative aspects of development (e.g., Britz and Bartsch 2003; Cracraft 2005; Alemseged et al. 2006; Brakefield 2006) – we should appreciate the synergistic effects. Considering paleoanthropology, Dullemeijer (1975, p. 86) predicted that "the fundamental idea can inspire many in their future research if the foetalization theory is reduced to the right proportions, ... It seems to open great perspectives for anthropology." Two years later, Gould (1977) responded to this challenge and inspired a whole generation of biologists.

Most studies overwhelmingly reject a general neoteny phenomenon in human evolution. The conclusion of man's domination by neoteny represents a pithecocentric perspective: a fruitful but wrong hypothesis. Sophisticated techniques, such as geometric morphometrics, and more embryological data indeed improve the quality of the data sets but on the whole often verify traditional contributions. Gould's (1977) brilliant *forte*, however, was primarily to break down the language barrier and to revitalize the topics of ontogeny *and*Phylogeny. *Summa summarum*, I would like to conclude with Dullemeijer's (1975, p. 84) take-home message – not only in the figurative sense – by stating: "*Homo sapiens* has its own face."

Principles of Taxonomy and Classification: Current Procedures for Naming and Classifying Organisms

Michael Ohl

Contents

Abstract

Taxonomy deals with the naming and classification of organisms and is an integrative part of biological systematics, the science of biodiversity. The information provided by taxonomic research is a fundamental basis for all fields of biology. Current taxonomy focuses on multicharacter integrative approaches, considering all potentially useful sources of information provided by the various fields of biology. The resulting supraspecific classification should be based on the genealogy of organisms, that is, on a phylogenetic analysis, to be objectively testable. However, for pragmatical reasons, a classification based on overall similarity and diagnostically relevant characters might be a heuristically important step in taxonomy and should be perceived as an approximation to a

classification tested by phylogenetic methods. The nested levels in a classification of organisms are usually not only named but also ranked, that is, a set of hierarchical terms, like *genus*, *family*, and *class*, is applied to reflect the hierarchical structure of the classification. Assigning these so-called Linnaean categories to a classification is (1) a voluntary action to make a classification notionally more easy to access and (2) a linguistic activity that is done subsequent to obtaining the scientific results of the systematic analysis.

Introduction

Taxonomy, the science and method of naming organisms, is a fundamental basis for all biological science and its application (Sluys 2013). The primary task of taxonomy is to describe, establish, and give an account of the order that is an inherent property of biological diversity. The order of names provided by taxonomy is arranged as a hierarchical classification, which is considered to portray the hierarchy of species and more inclusive taxa as a result of the continuous chain of species splittings in the evolutionary history of life on earth. Generalizations on organisms as a basic principle in biology are only possible if the infinite number of items in science is classified. Statements about the overwhelming diversity of nature would be impossible without methods for bringing order to this diversity. The world's biota is a vast library of information concerning any aspect of life, and taxonomy is the cataloguing system that everybody must use to access its information. All kinds of biological science and applications link their specific data to species names and use these names for effective communication. As Longino (1993, p. 85) has paraphrased, "… taxonomy is the raw material from which hypotheses of phylogeny are derived." All kinds of comparative biology rely on sound phylogenetic hypotheses, and the reliability of a phylogenetic hypothesis immediately depends on the reliability of the underlying taxonomic data. Moreover, society has an increasing need for reliable taxonomic information in order to allow to manage and understand the world's biodiversity (Wheeler et al. 2004; Costello et al. 2013). Until recently, taxonomy was confronted with what Godfray (2002, p. 17) called a new bioinformatics crisis, evidenced "by a lack of prestige and resources that is crippling the continuing cataloguing of biodiversity." Current biological taxonomy quite successfully adopts methods, data structure, and other demands of techniques and theories invented by new entrants to the biological sciences such as the fields of molecular biology (e.g., DNA barcoding; see De Salle et al. 2005). However, all other useful sources of information are simultaneously gathered in modern taxonomy, and this multicharacter integrative approach has been called *integrative taxonomy* (Dayrat 2005; Wheeler 2005; Padial et al. 2010). It allows taxonomists to create new common visions to meet changing demands of a changing global view on global biodiversity and the threats to it (Wheeler and Valdecasas 2005; Wheeler 2008; Polaszek 2010; Wheeler et al. 2012).

Definitions

Inconsistent terminology is a barrier to communication, results in confusion and misunderstanding, and prevents effective science. The variation in definitions for “taxonomy,” “systematics,” “classification,” and related or derived terms is as complex as it is contradictory. The major problem with these obviously closely allied terms is to differentiate them from each other, and many authors treat them more or less as synonyms, either intentionally or intuitively. In a recent textbook on biological systematics, Schuh (2000) implicitly equated systematics, classification, and taxonomy, when he defined systematics as “the science of biological classification.” The opposite view is held by Hawksworth and Bisby (1988, p. 10), who suggested restricting taxonomy to “taxonomic information systems (classification, nomenclature, descriptions, identification aids)” and defining systematics to include “taxonomy in the above restricted sense together with analyses of variation, of phylogeny, evolutionary processes, etc.”

Probably, most current scientists would agree that the most appropriate name for the scientific area composed of taxonomy, systematics, classification, and all of their respective concepts, theories, and methods is “biological systematics,” or systematics in short.

What are the basic units of systematics? Systematics is not concerned with individual organisms, although these are always studied by systematists as representatives of species or other supraspecific groupings. The simplest and most descriptive statement would be that systematics deals with taxa. What then is a *taxon* (plural, taxa)? Simpson (1961, p. 19) defined it as “a group of real organisms recognized as a formal unit at any level of a hierarchic classification.” This definition recognizes groups of organisms as taxa only if they are already formally classified, which is not always necessary or wanted. Newly discovered groups, hypothetical groups that still await confirmation, putatively artificial groups that are still disputed, and many others do not qualify as taxa under Simpson’s definition. In the field of phylogenetic systematics or cladistics, the taxon definition is often narrowed even further to monophyletic groups of organisms (Sudhaus and Rehfeld 1992; Mayr and Bock 2002). The final objective of systematics is indeed to include monophyletic groups only, but for a wide variety of reasons, this goal can hardly be achieved right away. Hypotheses on monophyly are created and rejected, groups prove to be nonmonophyletic but are still being discussed, and putatively monophyletic groups are still of unknown position within a certain higher lineage. Other problematic cases are fossil stem groups, like Australopithecinae, which are obviously paraphyletic with respect to Hominidae but can be treated as a heuristically important grouping in paleoanthropology. All these groupings are best referred to by a generalized term, and taxon is the most appropriate one. Hence, a definition of the term taxon might be: “A taxon is a group of organisms that can be differentiated from other groups of organisms, and that can be described and named.” Other terms to replace the term taxon have been proposed that are considered to carry specific connotations to reflect a specific framework for which they have been proposed.

Terminal taxon, as used in cladistics, and *operational taxonomic unit* (OTU), proposed by the phenetic school of systematics, are two prominent examples that have been suggested to designate the units of systematics without reference to a particular rank or phylogenetic position. However, the term taxon, as here defined, is sufficient to refer to ranked and unranked groups of organisms.

Biological systematics in fact deals with taxa, that is, biological populations, species, and higher taxa. However, systematics is concerned not only with the taxa themselves and their description and characterization but also with their origin, development, and other kinds of interrelationships. The fundamental and underlying concept of systematics is evolution, and Huxley (1940a, b) regarded systematics as "detecting evolution at work." Simpson's (1961, p. 7) classical definition of biological systematics (or just systematics) is still adequate: "Systematics is the scientific study of kinds and diversity of organisms and of any and all relationships among them." This definition was subsequently simplified to include the modern term "biodiversity," e.g., Mayr and Ashlock (1991) and Sudhaus and Rehfeld (1992, p. 11): "Systematics is the science of the diversity of organisms."

Another term that plays an important role in biodiversity research is taxonomy. Taxonomy is not easy to differentiate from systematics, and it has been frequently intermingled with systematics. If separated, taxonomy usually refers to what Hawksworth and Bisby (1988, p. 10) called "taxonomic information systems," i.e., naming of taxa, nomenclature, descriptions, and identification aids, whereas systematics is widely understood in a general sense of including taxonomy and the analysis of phylogenetic relationships, speciation processes, variation, and others. Since under any definition the terms taxonomy and systematics are closely associated, many authors have simply synonymized them because they consider their separation not to be feasible. The development of a concise methodology and theory of phylogenetic systematics in the last decades has considerably influenced the practice of modern taxonomy. Taxonomy, as understood here, might be treated as a field of systematics, with specific methods, theories, conventions, and terminologies that are different from other systematic fields (Will and Rubinoff 2004). There is, of course, continuous, active transgression of the borders between taxonomy and other branches of systematics, such as phylogeny and biogeography, and the most desired taxonomic revisions are obviously those whose taxonomic decisions are tested by phylogenetic analysis. To summarize, an appropriate definition of taxonomy might be (modified from Winston 1999, p. 9):

> Taxonomy is the branch of biological systematics that is concerned with naming of organisms (according to a set of rules developed for the process), identification (referring specimens to previously named taxa), and classification (ordering taxa into an encaptic hierarchy based on perceived characters).

The set of rules that governs the formation and use of taxon names in zoology is provided by the *International Code of Zoological Nomenclature* (hereafter referred to as the *Code*), published by the *International Commission on Zoological Nomenclature* and currently in its fourth edition. The Code and its bearing on taxonomy will be briefly discussed later. The definition described earlier points out that a classification of organisms is based on perceived characters. Any organism consists of innumerable numbers of characters that can potentially be perceived by a biologist, but not all of them qualify as characters helpful in achieving a meaningful classification. The so-called phylogenetic systematics provides the objective framework for evaluating characters according to their meaning for the evolution of a taxon. The most reliable and testable classification is based on the results of a phylogenetic analysis, which tries to reconstruct the hierarchical structure of organisms as a result of the continuous sequence of speciation events in evolution. This should be the basic goal of all taxonomy. However, for different reasons, phylogenetic relatedness might (still) be unknown, and thus the set of perceived characters for establishing a sound classification might be selected intersubjectively by means of overall similarity and diagnostically relevant characters. A classification based on overall similarity might be a heuristically important step in biological systematics and should be perceived as an approximation to a classification based on phylogenetic hypotheses. In practice, such non- (or pre)phylogenetic classifications might stand for a long time, but they should be regarded as preliminary until tested by phylogenetic methods.

The previously mentioned definition of taxonomy implies that one of its main goals is a classification. As paraphrased by Schuh (2000, p. 15), a “classification represents the codification of the results of [bio]systematic studies.” A general definition of classification might be:

> A classification is a set of names that are ordered hierarchically and more and more inclusive. The hierarchy of names is considered to portray the hierarchy of organisms as the result of the evolutionary process.

Again, the hierarchy of organisms should preferably be recovered by means of phylogenetic methods but might be preliminarily but meaningfully approached by the criterion of overall similarity.

Some authors (Griffiths 1974; Wägele 2005) differentiate classification from *systematization* for fundamental reasons. The term classification originates from the term *class* as in use in the philosophical logic and means a group of objects that have a specific set of properties in common. Which property is selected as class-defining is purely subjective and arbitrary, and a classification based on this property is similarly subjective. Thus, a classification, as defined by Wägele and others, is considered to be a strictly conceptual system and is the product of an arbitrary, linguistic activity. In contrast, organisms are the product of the historical process of evolution, which is expressed as a continuous chain of speciation events during the history of life. The sequence of species splittings over millions of years has resulted in a hierarchical structure of the organisms that systematists achieve to *reconstruct*. Thus, this kind of hierarchy is conceptual as well, but it is considered to represent the hypothetically real sequence of speciation events in evolution. This process is called systematization by Wägele (2005). The conceptual representation of the mental order as achieved by the process of systematization is called a *phylogenetic system*. The difference between a classification and a systematization is of fundamental importance but is usually not considered in practical biological systematics. The term classification is used here for both ordering systems, which is in accord with the widely accepted understanding, but the resulting double meaning of classification and the respective subtle differences to systematization must be kept in mind.

A completed classification is a hierarchy of names that denote hypotheses on taxa. It is organized in a more and more inclusive terminological structure of a theoretically infinite number of levels. These levels may bear names, but many of them, particularly in fully resolved cladograms with vast numbers of levels, remain unnamed for practical reasons. After completing a classification and selecting an appropriate number of higher taxa to be named, the hierarchically organized set of named levels can be given relative ranks as individual designations. Such relative ranks are provided by *categories*, such as classes, families, and genera, and this system of categories is well known as the *Linnaean hierarchy* or the *Linnaean categories*. Although the meaning and the current status of the Linnaean categories will be discussed later in more detail, it should be stressed here that an assignment of Linnaean categories to the level of a classification is (1) a voluntary action in order to make a classification notionally more easy to access and (2) a linguistic activity that is done subsequent to obtaining the scientific results of the systematic analysis.

As has been demonstrated previously, names as linguistic elements are of crucial importance in biological systematics. Names serve as labels to relate to concepts and hypotheses about taxa and their evolution. Names should principally be unequivocal, universal, international, and perpetual. Due to the incommensurably large number of organisms on earth, not to speak of the immense numbers of theoretically possible higher taxa that all could, at least in principle, be named, the need for internationally binding regulations is obvious. The part of taxonomy that is concerned with assigning names to taxa is called *nomenclature*. The sets of regulations that govern the practical application of nomenclature are provided by the International Code of Zoological Nomenclature.

Taxonomy as a System of Ordering Data

Biologists deal with a remarkable diversity of items. For any scientific procedure in biology, it is of critical importance to differentiate and thus to compare these items. It is one of the intrinsic attributes of a comparative process to arrange the to-be-compared items according to specified properties, that is, to *classify* these items. Mayr (1995) differentiated four different kinds of classifications: (1) special purpose classifications (based on particular features of special importance in the context, e.g., ecologists may divide small mammals into soil dwellers and tree dwellers), (2) downward classification by logical division (starting with the entire animal kingdom, groups are defined on the basis of dichotomous splittings in two less inclusive groups, such as the warm-blooded and the cold-blooded animals, until the species level is reached), (3) upward or grouping classification (items are arranged in more and more inclusive groups according to observed characters), and finally, (4) Hennigian phylogenetic or cladistic system (grouping of species and higher taxa on the basis of common descent). With respect to their nature as ordering systems, the upward classification (3) and phylogenetic systematics (4) do not differ, because in both classifications, species are combined into higher taxa (ranked as genera), these higher taxa are combined into even more inclusive taxa, and so forth. However, phylogenetic systematics is a special kind of upward classification in permitting only one criterion as the basis for the classification, that is, common descent.

Five basic objectives of ordering systems can be differentiated in general and apply to biological systematics as well (Vane-Wright 2001; Mayr and Bock 2002): (1) discrimination (delimiting groups against other groups), (2) information storage and retrieval (the structure of classification systems, based on different criteria that are considered to be informative regarding the group, permits storage and retrieval of a large amount of information), (3) recognizing group affiliations (this is called identification and refers to the process of referring an organism to a previously described taxon, e.g., by the use of a dichotomous key), (4) inferences about not yet studied properties (it is a widely held prediction that many of the characters of a taxon studied will be similar or even identical to those of closely or immediately related taxa), and (5) to serve as a baseline in comparative studies (the validity of comparative studies in biology largely depends on the reliability of the preceding research by which the studied items were grouped). These are basic objectives of that part of biological systematics that focuses on the biological items themselves, i.e., organisms, species, and higher taxa. The scientific treatment of these items requires a scientific terminology to communicate, which is provided by biological nomenclature.

Taxonomy and Classification Without Phylogeny: An Outdated Remnant or a Practical Necessity?

There is an increasing shift in taxonomy toward modifying the directives on how to name organisms to reflect genealogical relationships. However, despite the fact that most systematists would agree that the hierarchical system of names in biology should be governed by phylogenetic hypotheses instead of by intuitive similarity, the increasing pressure of phylogenetic demands on the naming processes results in intrinsic conflicts in systematics. Phylogenetic analyses have not been conducted for most groups of organisms yet, and it is highly unlikely that many will be undertaken soon. Additionally, new species are rapidly discovered in large numbers, particularly among invertebrates. Since a taxonomic treatment of such new taxa, that is, formal descriptions in taxonomic revisions or even single taxon descriptions, is a prerequisite to any other scientific exploration, new taxa are more rapidly described and made available than phylogenetic hypotheses are worked out. The taxonomic treatment of certain taxa, such as those that are less known, newly discovered, and/or extraordinarily species-rich, is a fundamental first step that opens up the possibility of continuing with subsequent phylogenetic, genetic, behavioral, and other studies.

In practical taxonomy, it is often necessary or at least recommendable initially to leave a comprehensive revision or a phylogenetic reconstruction aside from research projects and the resulting publications. In principle, Mayr and Ashlock (1991, p. 347) are correct that "the isolated description of ... new species ..., divorced from revisional or monographic work, is the least desirable form of taxonomic publication." But Mayr and Ashlock correctly qualify their assertion themselves in stating that it does not hold "in well-known groups." A well-known group is usually a taxon which is not only well known in terms of scientific research but also which additionally receives extraordinary attention by both the scientific and the general public. It is thus not surprising that isolated descriptions of fossil and recent Primates and large mammals often make their way to the highest-ranked scientific journals (e.g., the description of *Homo floresiensis* by Brown et al. 2004). Obviously, the publicity that results from such publications can be a strong motivation for any scientist to publish a rather isolated description immediately rather than to invest more time to obtain more data for a more comprehensive publication, due to the current system of scientists being under considerable pressure to publish and to compete for limited research money and, finally, jobs.

There are several more potential reasons to conduct *descriptive taxonomy* (Godfray 2002), which may mutually affect each other in most cases. Examples are as follows: (1) it might be desirable to make a new discovery formally available for further studies, which can or should not be conducted at the time of discovery of the new taxon for varying reasons; (2) if a scientist has discovered a new species, and if he intends to describe it formally, this scientist might want to guarantee that the name of this taxon as proposed by him is the first formal description and, thus, has priority over any subsequent name. This might be considered as to imply a connotation of personal rather than true scientific motivation, similar to the argumentation as presented earlier. However, priority is a basic principle of zoological nomenclature, and although it is explicitly thought to be priority of publication without reference to the date of discovery, the publication date here serves as an objectifiable reference point. Hence, priority of publication just replaces the priority of discovery for practical reasons; (3) incomplete knowledge of data might prevent systematists for conducting a comprehensive revision or a cladistic analysis. This might be due to the lack of characters (e.g., in fossils or other incompletely preserved specimens) or material (e.g., modern techniques such as molecular systematics or scanning electron microscopy require fresh or specifically preserved material, but many rare but potentially informative species are known only from dry museum material, which cannot be fully examined).

Another topic concerns the role of biological systematics in the context of a global biodiversity assessment. The development of global species inventories is considered to be an urgent and vitally important task that is a primary step and fundamental activity for any kind of biodiversity research (Stork and Samways 1995; Purvis and Hector 2000; Wilson 2003). Although it seems to be clearly unrealistic to describe every species of organism on earth, not to speak of the monumental uncertainties as to how many species there are (Godfray 2002), any step toward a global inventory of selected “target taxa” should be achieved as soon as possible.

Phylogenies are inherently hypothetical, simply because they portray historical processes, which cannot be inferred directly. Hypotheses, however, can be of different quality. The reliability of a hypothesis largely depends on the quality of the underlying data, which involves numerous theoretical and methodological aspects. Among these aspects, the *completeness* of the data set is of crucial importance. Completeness of characters is an illusion, since each single organism theoretically consists of an infinite number of characters. Completeness of taxa is, at least in principle, possible. With regard to taxon sampling, the perfect systematic study would include all species of a given taxon, perhaps even both still living and extant. Practically, completeness of taxa is unlikely to be achieved in most groups, except perhaps for some exceptionally well-studied taxa such as birds. However, the reliability of a phylogenetic analysis increases with the increasing completeness of the taxon sampling. Conversely, gaps in the taxon coverage result in considerably less reliable phylogenetic hypotheses. In many cases, phylogenetic analysis should better wait for a more complete species inventory, which, particularly in taxa with many species or with a patchy distribution, can hardly be achieved in one step.

In summary, publications concerned with the taxonomy of a given group are most desirable if their classificational results are based on a comprehensive phylogenetic hypothesis. If at all possible, a systematist should try to interpret his taxonomic data with respect to the corresponding phylogeny rather than relying on an intuitive character evaluation as a basis for a classification. Incidentally, since the hierarchical structure of the organisms on earth is the result of a historically real, continuous sequence of species splittings, the hierarchy of organisms as reconstructed by phylogenetic methods is in the end the only objective base for a classification.

Zoological Nomenclature: Governing the Process of Naming

Biologists are considered with myriad items, and these items need to be named to communicate concepts and hypothesis about these items in the biological sciences. It is not only the millions of species that have to be named. The hierarchical structure of the biodiversity of species and the myriad supraspecific taxa result in an almost infinite number of items that in principle can be named. Since names should be unequivocal in an international perspective, the formation and practical handling of names of species and higher taxa obviously need internationally binding regulations. Nomenclature is the part of taxonomy that regulates how names are assigned to taxa, and the underlying set of formal rules of how nomenclature is applied in practical zoology is the International Code of Zoological Nomenclature.

Ranking Hierarchies: Capacity and Limits of Linnaean Categories

The Linnaean categories are terms that identify the hierarchical level in a classification. Examples for categories are *genus*, *family*, and *class*. A limited number of such categories date back to Carolus Linnaeus' publications in the eighteenth century, but the number of categories has increased continuously over time, the better to reflect increasingly complex classifications. The rise of phylogenetic methods in the last few decades has resulted in an increasing number of cladograms that depict complex, not directly linear relationships with a seemingly infinite number of potential levels. It is, thus, not surprising that systematists face a myriad practical problems when assigning Linnaean categories to classifications based on cladograms resulting from phylogenetic analysis (Richter and Sudhaus 2004). Even in earlier phylogenetic publications, such as Hennig (1969), the conflicts between phylogenetic results and categories were well known, and in that publication, Hennig replaced the Linnaean categories by a system of consecutive numbers that directly reflects sister group relationships. However, his system received little attention from the beginning, because in less inclusive taxa, single numbers could be confusingly long (such as 2.2.2.2..4.6..1.1. Trichoptera, the sister group of 2.2.2.2..4.6..1.2. Lepidoptera). Hennig's system seems to have disappeared from consideration.

Since that time, various nomenclatural systems have been proposed to eliminate or replace the Linnaean categories, one of the most recent and popular alternative concepts being the *PhyloCode*. It is beyond the scope of this chapter to present the characteristics, the advantages, and the failures of the PhyloCode, but a critical assessment of the capacity and the limits of Linnaean system will be presented instead. It is still the most popular and widely accepted system of taxonomic ranking, and this is not due to the uncritical persistence of antiquated principles but, conversely, for good reasons. The reader should consult one of the numerous papers on the Linnaean categories and their alternatives for more information, such as Cantino and de Queiroz (2010) in the World Wide Web, Pleijel and Rouse (2003) in favor of the PhyloCode, and the rebuttals of arguments for the PhyloCode and its underlying theories by Nixon and Carpenter (2000, 2003), Carpenter (2003), Schuh (2003), and literature cited therein.

Ranking is an inherent property of any hierarchy in biological systematics, whether it is portrayed in a cladogram or by a formal Linnaean ranking scheme. Since ranking is included in any hierarchy, several unambiguous statements can be made concerning the structure of this hierarchy: for example, if taxon A is more inclusive than taxon B and actually includes B, then B does not contain A. However, the taxon names A and B themselves do not carry any reference per se about their relative position in the hierarchy, that is, whether A includes B, or vice versa, or whether A and B are of equal rank. In complex hierarchies, such as the hierarchy of organisms, the user is concerned with an overwhelming number of taxon names of different relative ranks, and he would be lost if any taxon bore an arbitrary name. Instead, communication is considerably more efficient if the ranking information is stated in addition to the taxon name. The Linnaean categories were invented exactly to convey this information by the use of standardized suffixes (for family group names) and binominal nomenclature for species. As an example, the Cercopithecidae, the Old World monkeys, is usually ranked as a family (indicated by the suffix -idae) and, among others, contains the subfamily Colobinae (with the suffix -inae) (Groves 2001).

The Linnaean ranking system was, and still is, extremely successful, and this is partly because it is easy to understand and to learn. Alternative concepts that have been proposed to replace the Linnaean categories are explicitly rankless. Taxon names still exist, but they do not communicate any information at all about their position in the hierarchy. The user can only understand the hierarchical structure by referring to the underlying cladogram. Hence, discarding Linnaean ranks and the binominal nomenclature results unnecessarily in the complete loss of important information on the taxa. This is not to say that the application of the Linnaean system is always unambiguous. Instead, there are numerous problems involved in taxonomic practice, particularly when portraying complex cladograms in a hierarchical classification. However, it seems unlikely that "[any] single system of nomenclature can ever possess all desirable attributes" (Schuh 2003, p. 60).

Taxa and Categories Are Not the Same

There is a fundamental difference between a taxon and a category. As defined earlier, taxa are groups of real organisms that can be described and named. They can be monophyletic, nonmonophyletic, or phylogenetically untested. In contrast, categories are terms that can be assigned to taxa to connote a certain rank relative to other, more inclusive or less inclusive taxa. Taxa are the objects of biological systematics, whereas categories are a voluntary, notional tool that improves communication among systematists.

Categories and Age

Linnaean categories contain explicit and helpful information about the relative position of a taxon within a certain lineage. The central question in taxonomic practice is, if there is a hierarchy of names that is supposed to reflect a hypothesis of relatedness (or at least overall similarity), how can this hypothesis be aligned with the Linnaean categories in an objective way? To be honest, the "alignment" of the hierarchy of taxa and the hierarchy of categories is determined by practical considerations, which is in the end a matter of subjectivity. However, there is a long-lasting discussion of how to "objectify" the assignment of categories to a specific level in a classification. Actually, all efforts to do this have failed, and future efforts will probably fail. The reasons are easy to understand. Categories, as indicators of relative rank *within* a phylogenetic lineage of organisms, are inherently subjective, at least in a sense. It is a matter of usefulness for verbal communication and of convention and consistency, if, for example, taxon X is ranked as an order or a class. However, neither the hypothetically real hierarchy of organisms nor the categories themselves provide objective criteria on how to applicate them.

However, several approaches to objectify categories have been published. Since phylogenetic reconstruction achieves to reconstruct historical events in the evolution of organisms, it is tempting to try to objectify the assignment of categories to taxa by using age as a criterion. This was already proposed by Hennig (1950, 1966), who discussed the problem of *absolute ranking* of higher taxa in exhaustive details. He suggested that the fossil record allows us to unambiguously define categories by the age of taxa to be classified. His example is the higher-level relationships of insects. Insects are generally considered to be ranked as a class, and since the oldest fossil insects, which belong in the Collembola, have been recorded from the Middle Devonian, the Collembola and their immediate relatives, which must have also been present at that time, would be assigned to what Hennig called a "class stage." This resulted in the following ranking for Collembola: class Insecta, subclass Entognatha, infraclass Ellipura, and microclass Collembola. Hennig, of course, realized that this approach is impracticable and arbitrary. He suggested to "reserve the well-known category designations ("class" and "subclass") for the most important and morphologically isolated groups" (Hennig 1966, p. 185), which can hardly serve an objective criterion. Hennig and subsequent workers were well aware that the age criterion of the categories across organisms or at least animals cannot work, simply because the major evolutionary radiations and subsequent diversifications took place in extremely different periods of time. As an example, the major lineages of the placental mammals that are generally ranked as orders arose in the Cretaceous (Murphy et al. 2001) and thus are comparable in age to the major lineages of Hymenoptera (bees, wasps, and ants), which are considered to be of family rank (Rasnitsyn 2002). If categories could be defined horizontally, the categorical hierarchies of Placentalia and Hymenoptera would have to be adjusted to each other, either by "downgrading" Placentalia to family rank or by upgrading Hymenoptera to class rank. This example clearly shows that a horizontal, *absolute* definition of the Linnaean categories is not only impractical but actually absurd.

However, a *vertical*, relative application of Linnaean categories along a phyletic lineage is a different matter and may be possible as a kind of evidence-based convention. An example is Goodman et al.'s (1998) cladistic analysis of the Primates based on DNA evidence and on extant and fossil morphological characters. Many traditionally recognized taxa appeared to be monophyletic, and their names and ranks as used in current literature were maintained. The ages of these clades were determined using dating evidence as provided by fossils and the model of local molecular clocks. Based on this time scale, clades of roughly equivalent age were assigned the same Linnaean rank. Goodman et al. (1998) analysis resulted in the following dating scheme (category/age [Mio years]/geological period): semiorders/63/early Paleocene, suborders/58–50/late Paleocene to early Eocene, infraorders/45–40/middle Eocene, superfamilies/39–29/middle Eocene to middle Oligocene, families/28–25/middle to late Oligocene, subfamilies/23–22/early Miocene, tribes/20–14/early to middle Eocene, subtribes/14–10/middle to late Miocene, genera/11–7/late Miocene, and subgenera/6–4/late Miocene to early Pliocene.

It needs to be emphasized that an age-related Linnaean ranking might have merits only if applied to clades like the Primates with particular prerequisites. Primates have a widely accepted classificational framework (though the details are still disputed), quite a good fossil record, and cladistic analyses have been published with reliable taxon sampling. If the last common ancestor of the Primates is supposed to be as old as about 63 Mio years, and if the scientific community *agrees* to rank the Primate clade as an order, the highest level of the classification within Primates is defined: clades that arose in the early Paleocene are ranked as orders. Other, younger, fossils can be correlated with a particular rank accordingly. The fossil record, which might include gaps without fossil evidence, is supplemented by the model of the molecular clock, as proposed for Primates. This procedure allows applying the age criterion to any ranking level between the oldest reference point (the putative age of the last common ancestor of the Primates) and the youngest reference points (e.g., the latest splittings to clades generally ranked as subgenera, the youngest fossils).

Approaches like this pretend to be objective in correlating taxa and ranks, at least within the clade they were proposed for. However, it is easy to see that none of the criteria that define the age-rank correlation as proposed by Goodman et al. (1998) leads to an objectively settled ranking. It is a matter of convention if the clade named Primates, which is defined by a set of apomorphies and whose age of origin is defined by a particular fossil, is ranked as an order. Likewise, it is a matter of convention which of the clades within Primates, such as Cercopithecoidea, is assigned superfamily or any other rank. The same arbitrariness applies to the correlation of a clade and an age per se: with respect to the current state of the art in Primate classification, it might be useful to treat the putatively 18-Mio-year-old Cercopithecoidea as a superfamily, but other rank-age combinations might be similarly appropriate if suggested by the total hierarchy within Primates.

Nomenclatural stability is another important issue to be addressed to any classification concept. Stability of nomenclature should minimize changes in the names as they are adopted to changing scientific concepts. Age-defined ranks are, at any hierarchical level, extremely sensitive to the accuracy of the underlying dating of the latest common ancestors. New dating evidence, such as newly discovered fossils or new analytical methods in paleontology or molecular biology, may suggest fundamentally different dates of the origin of particular groups. If, for example, the origin of Primates dates back to 80 Mio years as suggested by Tavaré et al. (2002), the age-related ranking scheme of Goodman et al. (1998) would have to be adopted to the new dating by stretching the ranking range to fit to the longer period of time or by adding more category levels.

The standard approach to calibrating a classification for an age-related application of ranks is to use the earliest known fossils of a particular taxon and to equate their age with the time of origin of this taxon. The resulting age of the taxon under discussion is, obviously, hypothetical and only gives us the so-called *terminus post quem non*, that is, the point of time *after* which the clade cannot have originated. In other words, the fossil record only settles the *minimum* age of the group. This can potentially lead to a serious underestimate of the true time of origin of a clade and, hence, of all other dating results inferred secondarily. As has been pointed out by Martin (2002), this underestimation increases if the fossil record is very patchy. Since this might be the case in many organisms (Tavaré et al. 2002), the oldest fossil of a given clade might be considerably younger than its true stem species. As a result, age-defined ranking schemes are considerably different depending on whether the dating as inferred directly from the fossil evidence, or the dating as indirectly estimated by molecular clock models or estimations of extinction rates and the reliability of the fossil record, is considered.

These applications and problems show that an age-defined, objective correlation of Linnaean categories and clades is as unrealistic, if not impossible, as any other effort toward an absolute definition of ranks. In some cases, such as Primates, age-defined ranks may be useful to some extent, although it must be emphasized that the correlation of ranks and clades even in such cases is at most *intersubjective*, being based on a set of conventions of the respective scientific community. Changing conventions, changing dating evidence, and other factors may considerably alter the putatively objective ranking of Primates. The Linnaean categories are a notional representation of the hierarchical structure of monophyletic taxa representing an inferred, hypothetical sequence of speciation events (or, if a cladistic analysis is still lacking, an a priori assumption of relatedness inferred from overall similarity). As a consequence, the Linnaean system is inherently *relative*, that is, Linnaean ranks denote the hierarchical position of a given taxon relative to other members of the same clade. As has been paraphrased by Schuh (2003, p. 60), "[t]he primary strength of the Linnaean system is its ability to portray hierarchical relationships." It must, however, be emphasized that Linnaean categories are inherently *subjective* in that the exact correlation of a taxon and its rank is not determined by the taxon or the category themselves.

Ranking Fossils

Fossil and recent taxa are basically treated in an identical way in taxonomy. However, if fossils are included in a cladogram, a number of practical terminological problems arise. Fossils are part of the stem lineage of a given taxon, and each single fossil taxon is considered the sister group of the next, less inclusive, taxon. If sister taxa are given the same rank in the hierarchy, each single fossil species that is considered to be the sister species of a taxon that is ranked as an order must be assigned order rank as well. If several fossil species of a given stem lineage in a continuous sequence of sister group relationships with the next less inclusive taxon are known, each of these single species would have to be given a high rank, which would, for example, result in a proliferation of taxa ranked as orders along a single lineage. In principle, each of the pairs comprising a fossil species and its higher sister taxon could also be assigned a new name.

As a consequence, giving a high rank to each of the fossil species would not only appear to be overblown, but this would also ignore the fact that the exact sequence of fossils along a stem lineage cannot be determined accurately in most cases. As an alternative, Patterson and Rosen (1977) have suggested to order fossils according to their hypothetical phylogenetic position but to leave them unranked. Instead, each of these fossils is named *plesion*. The term plesion replaces any rank above the genus level and to tentatively place fossils in cladograms without affecting the hierarchical structure of names and their ranks.

Linnaean Categories as a Communication Tool

Systematists should be aware that the Linnaean categories are a tool for communication. As Griffiths (1976, p. 168) stated, there is no logical reason why taxa *must* be ordered into categories. Linnaean categories do not inherently imply information about the age of a taxon (except if employed within a certain clade by convention, as, e.g., in Primates), the size of a taxon (in terms of species numbers), genetic distinctiveness, or phylogenetic relatedness. The application of a particular rank to a particular taxon is subjective but must fit in the overall hierarchy of the more inclusive taxa.

But Linnaean categories directly mirror the complex, hierarchical relationships in a given clade. Along this lineage, the nestedly ordered categories notionally reflect the nested order of organisms and explicate the relative position of a given taxon to other taxa of the same lineage. The demand for an abolition of the Linnaean categories without substitution involves well-known practical problems and would result in the loss of practical and useful information. There are myriad practical problems involved in the implementation of the Linnaean categories, but this is also the case in any other notional system of ranking. "No single system of nomenclature can ever possess all desirable attributes: i.e., convey information on hierarchical relationships, provide ... stability in the names ..., and provide simplicity and continuity in communicating the identities of the taxa and their relationships" (Schuh 2003, p. 60). Since the discussion about the Linnaean categories reflects the problems how best to express scientific contents linguistically, *applicability* is the central criterion to assess the capability of any ranking concept. The search for the "best" biological nomenclature corresponds to the search for compromise between theoretical demands and practical necessities.

The International Code of Zoological Nomenclature

Systematists and, secondly, subsequent users of the results of biological systematics deal with myriad objects: each taxon, if considered a species or ranked as a genus, family, or order, can be recognized as a biological entity, which, to a varying degree, is distinctly different from other such objects. To enable communication about these objects, in principle, requires the application of unique names, which unequivocally refer to the taxa. Even in pre-Linnaean times, the need to point to groups of organisms by names was obvious. However, before Linnaeus, the names given to taxa were thought to be descriptive or diagnostic terms or phrases rather than proper names, as taxon names are seen today. Although easily recognizable organisms might have been given single names (*uninomina*), or if two closely related forms were known, two-word (*binominal*) names were coined. Increasing knowledge of the diversity of forms made complex, descriptive labels necessary to meet the criterion of uniqueness (e.g., the gentian species that is today known as *Gentiana ciliata* was named *Gentiana angustifolia autumnalis, minor floribus ad latera pilosis* by Bauhin (1623) (Mägdefrau 1992); note that Bauhin and other pre-Linnaean authors already employed unique genus names as more inclusive taxa). Linnaeus, however, introduced a strictly formal nomenclatural system, based on a unique binominal species name. The increasing exploration of remote geographic regions made scientists realize that they are concerned with a seemingly infinite organismic diversity. Due to new discoveries and new techniques, taxon names proliferated. However, it was not only the increase in species descriptions that lead to a rapid increase in the total number of taxon names. Inconsistent or even contradictory terminological systems, development of their own rules by many scientists, replacement of already published names that were considered to be inappropriate or incorrectly formed, and other factors resulted in the strong need for general rules of nomenclature.

Beginning with Linnaeus' works in the eighteenth century, an elaborate body of conventional regulations was developed to provide such general rules. The valid rules of nomenclature in zoology are contained in a judicial text called the International Code of Zoological Nomenclature, here abbreviated as the Code, whose current edition is the fourth. The Code provides a complex set of rules and aims to cover as much of the complexity of the recent and historical naming process as possible. However, cases might show up in which the strict application of the Code might actually threaten nomenclatural stability, and in such cases, every scientist is free to apply to the *International Commission of Zoological Nomenclature* to set aside priority or other provisions of the Code to increase stability. Many provisions of the Code are the result of compromise between conflicting principles, which partly date back to the very beginning of biological nomenclature. Hence, the rules fixed by the Code are far from written in stone but are under constant development. As has been emphatically pinpointed by Mayr and Ashlock (1991, p. 386), "all good law is living law."

An exhaustive description of the Code is far beyond the scope of this chapter, but a few basic principles will be considered here.

Freedom of Taxonomic Thought

The Code does not tell anybody how to classify something or how to recognize species or other taxa. These are scientific decisions that are totally under the responsibility of the systematist. The Code provides rules for a system of communication, a "language," for communicating such taxonomic decisions. This "freedom of scientific thought" is expressly guaranteed in the Preamble of the Code and, indirectly, emphasizes the role of nomenclature in biology as a notional process acting subsequent to the scientific process. As an example, the Code permits a scientist to continue using a name that is considered to be a junior synonym by another author. Conversely, the freedom of taxonomic thought includes also the freedom to make taxonomic mistakes that, as a consequence, do not affect nomenclature. If, for example, a name is erroneously placed in synonymy, its validity is not affected.

New Names and Old Names

The process of naming a newly discovered species properly, that is, in accord with the Code, is surprisingly simple. The Code explicitly provides a set of provisions to be met when describing a species, some of which appear to be commonsense principles. To be usable or, to use the proper term, to be *available*, a name must, first, be *published*. The Codes clearly indicate that distribution "in numerous identical copies ... for permanent record" constitutes a publication. The use of the 26 letters of the *Latin alphabet* for the taxon name is mandatory, although the descriptive text may also be written using a different alphabet. A name must, of course, in principle be *unique* but on different levels: a species name must only be unique in its own genus (there are several animal species with popular species names like *viridis*, meaning green, but no two species (or subspecies) in a genus may bear this name), whereas a genus name must be unique among all animals. However, it is wise to avoid species names that are already in use in closely related genera. In the future, genera might be combined due to changing evidence, which would result in homonymy of such species names. A new species name "must be explicitly indicated as intentionally *new*," that is, by adding a Latin term like "new species" to the newly proposed name or an equivalent phrase or abbreviation. The Code also requires the consistent application of *binominal nomenclature*, which does not apply to names of taxa at ranks above the family group. A new species description must also include an explicit fixation of the name-bearing *type specimen(s)*. A type is an individual specimen to which a given name is attached. In cases in which a taxon previously considered a single species is later split into two species, the species to which the type specimen belongs retains the previously given name. This *type method* is important in taxonomy and will be presented in more detail later. Finally, the Code provides a set of mandatory regulations of more linguistic nature, how new names are to be formed. The most important provision is that names must be either *Latin* or latinized or they must be so constructed that they can be treated as Latin words. Further rules concern practical details such as how names are formed from personal names and other aspects of the correct spelling.

Every scientist who plans to propose a new name for a taxon should consider these simple provisions to be sure that the new name complies with the Code. However, the greater part of the Code is devoted to less simple cases, and most of the problems are caused by names proposed in the past. A smaller part of difficulties systematists face when dealing with previously published names might be caused by the erroneous application of the Code or by erroneous taxonomic decisions. The majority of problems, however, simply portray the continuously changing concepts and applications in the 250-year-old history of biological systematics. Such changes might affect scientific content (e.g., by the invention of alternative species concepts) or might be more formal (e.g., the explicit designation of a name-bearing type was not mandatory at the beginning of biological systematics). As a result, historical names are not only hard to locate in the literature in many cases, they often require time-consuming, elaborate efforts to clarify the correct original spelling, the presence of type material, the identity of the species, the correct date of publication of the original description, and several other potential difficulties. Two of the most common problems that come up when dealing with historical names are *synonymy* and *homonymy*.

The fact that a considerable portion of taxonomic practice is unusually time-consuming when compared to the outcome, i.e., the clarification of a single species name, is part of the legacy of about 250 years of biological systematics. In many groups of organisms, taxonomists are condemned to spend most of their time interpreting the work of pre-twentieth-century systematists. “The past [often] acts as a dead weight on the subject, the complex synonymy and scattered type material deterring anyone from attempting a modern revision” (Godfray 2002, p. 17).

Validity, Synonymy, and Homonymy

As has been explained earlier, a taxon name must fulfill a set of conditions to be available in terms of Code compliance. Among the available names, only the oldest available name is what systematists call *valid* and has *priority* over the younger names. The valid name of a taxon is sometimes referred to as the *correct* name, which means that open nomenclatural problems have been solved and that a single name retained, which under the provisions of the Code is the only approved one. The date of publication of the original description of a name is thus of crucial importance and must be carefully determined. It must be emphasized that the principle of priority applies to the species, genus, and family levels only but not to levels above the family rank.

In by far the most cases, the valid name is the oldest name. Exceptions occur when the oldest name, in case of a species, is already in use in the genus, resulting in homonymy. Then, the younger of the homonymous names would no longer be valid but must be replaced by the next available name of the same species, if any exists. An example is a subspecies of the common chimpanzee, *Pan troglodytes verus* Schwarz, 1934 (originally described as a subspecies of *Pan satyrus* Linnaeus, 1758, the species name of which was suppressed by the International Commission on Zoological Nomenclature in 1999). The oldest available name of this subspecies is *Simia chimpanse* Matschie, 1904, but despite having priority due to the early publication date, Matschie’s name cannot be used because it is a junior homonym of another species, *Satyrus chimpanse* Mayer, 1856. Since *Satyrus chimpanse* Mayer is considered to be identical to, that is, a synonym of, the nominate subspecies, *Pan troglodytes troglodytes*, the species group name *chimpanse* occurs twice within *Pan*, by Matschie, 1904, and by Mayer, 1856, respectively. This is called *secondary homonymy*, since the two names under discussion were first proposed in different genera and got in conflict after being considered to belong in the same genus. *Simia chimpanse* Matschie was published half a century later than *Satyrus chimpanse* Mayer, and thus the younger of the two names must be replaced. The next available name is *Pan satyrus verus* Schwarz, published in 1934, which then becomes valid. In many species, however, no name is available other than the originally proposed name. Then, the revising author has the authority to propose a replacement name, which then becomes available with the reviser as the correct author and the date of his publication.

If a single taxon is given two or more names, each of these names is a *synonym*. The earliest published synonym is referred to as the *senior synonym*, even if it is considered to be the valid name. Any other earlier names of the same taxon are called *junior synonyms*. In most cases in practical taxonomy, systematists are confronted with the question if two independently published species names that were based on different name-bearing types actually represent the same species. This kind of synonymy with different types is called *subjective synonymy* because it expresses the scientific conviction of the revising author that the two names refer to the same thing. Names applied to a species on the basis of the same type specimens are *objective synonyms*.

Typification: Establishing Objective Reference Points

The type method is a guiding principle in biological systematics. In taxonomic practice, the identity of species, particularly when described in the past, is often difficult to establish due to insufficient descriptions or illustrations. As a result, historical species descriptions might apply to more than one currently recognized species. Due to new evidence, taxa might be split up into two or more less inclusive taxa. In all such cases, it might be difficult to establish which of the newly separated taxa has to retain the original name and which should be newly named. This problem is solved by the invention of objective reference points, the types. Types in the broadest sense are zoological objects to which a name is firmly tied. The type of a species is always a single specimen, the type of a taxon at genus rank is a species, and finally, the type of a family-rank taxon is a genus. If a previously described species is considered to be actually composed of more than one species, the type specimen fixes the original name to the species, to which it belongs. The same holds for taxa at the genus and family ranks.

The Code permits the use of a few different kinds of types in taxonomic descriptions. At the genus and the family level, only type species and type genera exist, respectively. A *holotype* is always a single specimen, which is either the only specimen available for the original description or it is explicitly selected out of the original series of more than one specimen to give it precedence over the other specimens, which then are called *paratypes*. In current species descriptions, the explicit designation of a holotype is mandatory. Paratypes do not have special standing under the Code but should be explicitly mentioned as members of the original type series by calling them paratypes. If the original describer in older publications mentions more than one specimen but did not select a holotype, all type specimens are the *syntypes*. A syntype series is of little help in conflicting taxonomic situations because they might actually belong to more than one species. In such cases, a revising author has the authority to subsequently select a single specimen from the original type series, which then would be called a *lectotype*. Accordingly, the remaining syntypes would be the *paralectotypes*, which, again, are only of secondary importance. If the type material of a species is considered to be lost, the revising author may select a specimen that was not part of the original type series, as a *neotype*. In some cases, the lack of type material is of minor importance because the identity of the species is obvious. An example is *Homo sapiens* Linnaeus, 1758, for which no type specimen or specimens have ever been settled (Spamer 1999). A neotype must be designated only if this action facilitates nomenclatural stability so that the name is properly and consistently applied. Since a neotype is required in cases with unsettled and problematic nomenclature, one can almost never be completely sure if the neotype and the original types are really conspecific. Thus, designation of a neotype might be risky and should only be done if absolutely necessary. Numerous other kinds of types have been used in the literature, but only those above are still permitted under the current Code. Examples of types that are not regulated by the Code are allotypes (a specimen of the opposite sex of the holotype, actually simply a paratype) or topotype (a specimen originating from the type locality of the species to which it is thought to belong).

Incidentally, it is a wide held belief that the type specimen or specimens of a newly described species must be dead or should be killed sooner or later to be finally deposited in a museum collection or in another kind of persisting and accessible environment. This means that in most cases, a new species description is based on one or more specimens that are physically available to the scientist during the process of writing the description. The Code requires that the specimen (the holotype) or specimens (syntypes) on which the name is based must be explicitly stated and accompanied by description or diagnosis to differentiate the new taxon. However, this requirement does not include any mandatory provisions about the physical availability, detailed morphological description, or depository of the type specimen (Wakeham-Dawson et al. 2002).

A type specimen need not be especially *typical* for the species to which it belongs. Its function is simply that of a “name bearer” (Simpson 1961). There are several potential criteria for how to select a holotype out of the entire material that is available to a scientist. If the species is differentiated from its congeners by means of complex morphological features of the male genitalia (as is common in invertebrates), it might be appropriate to make a male the holotype. Sometimes, not all type specimens are complete or show the diagnostic characters equally well. It would make sense to choose as the holotype a specimen, which exhibits most or all of the characters that are of diagnostic value at the time of description and with respect to new future discoveries as far as can be predicted.

The description of a new species is always based on all specimens available at the time of description. Since the holotype is just a name bearer, its function is not to serve as the only basis of the original description (except when only a single type specimen is known).

Fossils, Fragments, and Heterogeneous Type Specimens

The Code applies to both living and extinct animals, as is explicitly stated in its Article 1. Thus, the principles of the type method as briefly presented earlier with reference to recent species are equally applicable in paleontology. However, many fossils, particularly complex multistructured organisms, such as vertebrates, inherently lead to practical problems. In most fossil vertebrates, only hard structures are fossilized and thus preserved. In the course of diagenetic processes, soft tissues that connected the hard elements in the living animal are usually decayed so that the resulting skeleton falls apart. In the ideal case, the preserved elements remain in their original position after embedding in a fossilization matrix so that the elements can be easily associated with each other. In many cases, subsequent physical processes might have altered the relative position of the elements or have destroyed parts of the organism.

Fossil hominids are never completely preserved, not even with respect to bones. Sometimes, just a single preserved bone is sufficient to provide evidence for taxonomic identity. If a single bone is the basis of a new taxon, just the bone is referred to as the holotype. An example is the holotype of *Homo heidelbergensis* Schoetensack, 1908, which consists of a complete, adult mandible. There is no ambiguity about the formal basis on which the new species is based. If more than a single element is available, association to individual can be difficult if the elements are not in the original position relative to each other but are more or less dislocated or destroyed. An example is the composition of the types of *Homo habilis* Leakey, Tobias, and Napier, 1964. Several fragments assignable to the new species were available such as mandibles, isolated teeth, parietal and hand bones, and cranial fragments. Due to external evidence, such as the position of the fragments as found during excavation, the fragments could be associated with five individuals. The holotype of *H. habilis* consists of a mandible with dentition and the associated upper molar and parietal and hand bones, originating from a single juvenile individual.

These examples show another principle of the type method. A type is always a zoological object but is not necessarily something that is or is close to a complete organism. A single tooth, an isolated wing, or any other part of an organism is in principle sufficient to serve as the basis for a new species. In a way, incompleteness is an inherent attribute of most preserved specimens because many preservation techniques result in the loss of some characters. Pinned, that is, dried insects and stuffed, mounted vertebrates have usually lost all or most of their soft tissue. Thus, even if a specimen has lost almost the entire physical structure except for a single tooth, this incompleteness of a specimen does not prevent potential type status. It is, however, wise to associate isolated fragments such as a molar and a mandible to a single type specimen only if the evidence is unambiguous. If subsequent evidence is found that the fragments actually belong to different individuals, this might cause a lot of unnecessary nomenclatural confusion.

Conclusion

Names can be seen as the key to biodiversity. Names serve as unique identifiers or tags, which unequivocally refer to biological species and higher taxa. Names form the essential language to communicate about biodiversity. The naming process in biology is an intellectual challenge which happens subsequently to the process of scientific discovery and description. New methods and tools for the discovery of the largely unexplored species diversity on earth have been established in the past decades, which have increased the rate of species description in an unexpected amount. In order to fulfill its function as a tool for an effective organization of biological data, a set of rules needs to be followed to make scientific names unique and unequivocal. Modern taxonomy, the science of naming, identification, and classification of organisms, is an integrative approach, which combines a wide range of methods, tools, and theories for both the recent and past diversity.

Species Concepts and Speciation: Facts and Fantasies

Colin Groves

Contents

Abstract

The identification of the punctuated mode of evolution, an alternative to gradualism, has required renewed focus on the nature of species. A species is an evolutionary lineage and may be recognized by having fixed (absolute) heritable differences from other species. Among the various modes of speciation which have been proposed, allopatric speciation is the best authenticated; it can be

divided into dichopatric and peripatric. Other modes are parapatric, sympatric, stasipatric, and, one which has recently assumed a considerable importance, speciation by hybridization. All these must be considered when thinking about how the various species identified in the hominin fossil record originated.

Introduction

Whereas taxonomy is a product of the human mind, species have a real existence (see, e.g., *Principles of Taxonomy and Classification: Current Procedures for Naming and Classifying Organisms*, in this Handbook): a species is an individuated evolutionary lineage and has been compared to an individual organism. All too many people use the word "species" without really understanding this important distinction, and a consequence of this misunderstanding is the prevalence of catchphrases like "taxonomic inflation" and "how much difference do you need for a species?" Once it has been clearly understood that a species is a lineage, then we can ask meaningful questions of evolutionary theory, such as – How do new species originate? How long does speciation take? Is sympatric speciation possible? How frequent are hybridization and gene flow between species? What is the role of reticulation in the formation of new species? And we can ask informed questions of the fossil record, including – How many hominin species coexisted at any one time? How do we recognize species in the fossil record? And we can inquire about the very origin of hominin species.

The PE Revolution

It is probably true to say that until 1972, most paleontologists had interpreted their fossils as showing gradual change with time, and if they did not show gradual change it could be inferred as failure to demonstrate much, or any change could be put down to the incompleteness of the fossil record. The year 1972 saw the appearance of the paper by Eldredge and Gould introducing the concept of punctuated equilibria (herein after PE), in which they proposed that the major process of evolution is not, after all, one of gradual modification, but a series of stops and starts: there are long periods when nothing happens, succeeded by short bursts of rapid change. The bursts of change, moreover, are not in the central, paleontologically most visible, population of the species, but in small peripheral populations which then have the capacity to invade the center and usurp the parent population.

Long ago, Simpson (1944) had recognized that evolutionary change occurs at different rates; along his rate spectrum he distinguished horotely ("normal" or average rates of evolution), bradytely (unusually slow), and tachytely (unusually fast). Early critics of PE assumed that PE was merely a resurrection of these old Simpsonian categories. But it is not mainly about this: it is about stasis and speciation. Simpson was of course well aware of stasis: he described how in many cases a fossil species did not change at all over a considerable segment of time but remained the same. He, too, was aware of the importance of speciation. From the process of evolution along a single lineage (anagenesis), which he did seem to consider primary, Simpson (1944) carefully distinguished cladogenesis (evolution by splitting of one lineage into two); this typically results in two species resulting where formerly there was one, so cladogenesis can be thought of as, broadly speaking, equivalent to speciation. What Eldredge and Gould had observed was that in many cases long-term stasis is followed by the sudden appearance of a different species which replaced the earlier one. The real innovation of PE was to insist that it is stasis, not anagenesis, that is the usual state of affairs and that speciation, not anagenesis, is the engine of evolution.

Eldridge and Gould were perfectly aware, of course, that they had intellectual precursors. Three of these were especially influential. One of these was Richard Goldschmidt, a geneticist who in 1940 proposed the "hopeful monster" hypothesis, under which major evolutionary changes occurred abruptly. The "hopeful monster" was not part of the original package, but it was espoused in later versions by Gould (1990, 2002). A mechanism for "hopeful monsters" was later proposed by Schwartz (1999).

Another inspiration for PE was Mayr who, in 1963, urged the founder principle as a mechanism of speciation. In founder principle theory, a small segment of a species becomes isolated from the rest (e.g., by geographic or environmental change) and undergoes rapid genetic differentiation. He preferred this mechanism (now often called peripatric) to the generally assumed view that a species, when it becomes divided, splits into two fairly equal halves which then diverge gradually (dichopatric). Schopf (1972), in his editorial introduction to the paper, traced the idea of founder principle back to Haldane in the 1930s and even as far back as Bernard in the 1890s, but there is no doubt that it was Mayr whose careful and detailed formulation of the principle established it as a significant mechanism – or even *the* significant mechanism – of speciation.

The third major influence on the genesis of PE was another geneticist, Sewall Wright, who in a series of papers (see especially Wright 1968) formulated the principles of genetic drift, which is the random change in gene frequencies. As he showed mathematically, later elaborated in detail by Kimura (1983), stochastic processes have a small but finite probability of resulting in the fixation of new genetic variants, even in the face of weak negative selection.

Where does this leave anagenesis? Long-term trends in evolution of course exist. It is how to explain them which has been the problem. Osborn, in 1936, ascribed evolutionary trends to orthogenesis, a sort of (internally controlled) urge to progress onward and upward, always in the same direction. Simpson (1951) effectively demolished orthogenesis and instead proposed what he called orthoselection, in which natural selection forces fairly consistent change in one direction as long as local environments favor it. Eldredge and Gould (1972) suggested how PE might explain evolutionary trends, but the problem was more fully considered by Vrba (1980) whose "effect hypothesis" has become part of the theoretical core of PE. We will return to the matter of long-term trends in a later section.

So we have two apparently opposed models of the evolutionary process. Gradualism allows for anagenesis to be a major evolutionary mode, though it does not mandate it; if, for example, lineage splitting does occur, it is under the gradualistic model followed by the slow mutual divergence of the two daughter lineages. Under PE, it is cladogenesis which is definitely the major evolutionary mode; when lineage splitting occurs, it is asymmetrical, and by the founder effect one daughter lineage diverges but the other generally does not. The major problem that lies at the heart of the difference is the nature of speciation.

The Nature of Species

Species: Theoretical Concepts

Before we can even consider what speciation involves, we must very carefully delineate the nature of species. If we are to contemplate whether species, which are already regarded as the units of ecology, biogeography, and nowadays of conservation strategy, are also the units of evolution itself, then we must be clear exactly what species are. The importance of what we mean by the word "species" goes way beyond systematics, the field of study for which the term was invented.

It is unfortunate in one way, appropriate in another, that there is quite a multitude of different conceptions of what a species actually is. How many "species concepts" one distinguishes is a matter of how finely one is prepared to seek out the fine distinctions between different authors' manner of phrasing. Thus, Harrison (1998) distinguishes only seven and Mayden (1997), and following him Hey (2001), as many as 24. Broadly, we may divide them into those which emphasize the absence of interbreeding and those which do not: "theoretical" and "operational" concepts, in the terminology of Groves (2001). The division also corresponds, in broad terms, to "pattern" versus "process": the pattern that we can observe versus the process which maintains it or brought it about in the first place.

For Dobzhansky (1937) and Mayr (1963), the nature of species lies in its reproductive isolation from other species. This view of reproductive isolation as the defining feature of species is called the biological species concept (BSC). Species were defined by Mayr (1940) as "groups of actually or potentially interbreeding natural populations which are reproductively isolated from other such groups," while Dobzhansky (1950) summarized the situation by saying that the species is "the largest and most inclusive… reproductive community of sexual cross-fertilizing individuals which share in a common gene pool."

Reproductive isolation in turn depends on reproductive isolating mechanisms, which may be either premating or postmating. Premating mechanisms are what prevents potential mates from meeting (seasonal or ecological), or from mating if they do meet (ethological), or from permitting sperm transfer if they actually get as far as mating (mechanical). Postmating mechanisms are what prevents gametes or zygotes from surviving if mating has nonetheless successfully occurred, or hybrids from surviving, or hybrids from breeding if they do survive.

Paterson (1978, 1980, 1982) argued that postmating isolation cannot be more than a symbol of species status: two sexually reproducing genotypes, A and B, do not avoid interbreeding with each other as such, instead A selects other A individuals and B selects other B. They do this by means of specific mate recognition systems (SMRSs): one individual emits a signal to which another responds. A species, for Paterson (1978, 1982), is a population (or group of populations) whose members share a common SMRS: he calls this the recognition species concept. Examples of SMRSs could be vocalizations, such as the distinguished species of bush babies or galagos (Primates: Galagidae), whether sympatric species pairs (Masters 1991; Nash et al. 1989) or allopatric populations within what had previously been deemed unitary species (Bearder et al. 1995); or facial markings, together with the facial expressions, head flagging, and whole-body movements that serve to emphasize these markings, as between species of the genus *Cercopithecus* (Kingdon 1980, 1988). In principle, all one would have to do would be to look at facial patterns in two given populations of animals and, if they are different, separate them as different species. But how much difference is "different"? And what if members of the two populations do, nonetheless, interbreed? The same question could be asked about vocalizations: how "different" do they have to be to qualify?

Templeton's (1989) cohesion species concept is another attempt to modify the BSC. In this concept, a species is defined by the genetic and demographic mechanisms which give it its cohesion: the genetic mechanisms are those which limit its gene flow with other species, and the demographic ones are those which constrain it to its "fundamental niche." This tries to fuse the original BSC with the recognition concept while incorporating a general appreciation that a species must have its own ecological niche; but one would be hard put to use such a concept in practice.

The BSC and the attempts to modify it work very well in cases of sympatry; at least in most cases, although in some populations of a species, the presence of mtDNA characteristic of a different (sympatric) species hints at past gene flow (see below). If two taxa are sympatric, then they are reproductively isolated: they are distinct species, and no further discussion is possible. If they are parapatric, then equally they have the chance to interbreed, and do not. But what if they are allopatric? Several authors have emphasized that the BSC is simply not applicable in cases of allopatry. Berlocher (1998) noted that the first author to point this out was A.R. Wallace himself, in a paper written in 1864.

Mayr et al. (1953; see also Mayr 1969) offered three criteria to decide whether two allopatric taxa are distinct species, or merely subspecies. The amount of difference between allopatric taxa should be compared to that between:

(1) Sympatric taxa in the same group
(2) The most divergent intergrading subspecies
(3) Freely hybridizing populations in the same group

The first criterion founders on such things as the existence of sibling species, i.e., those that are nearly indistinguishable, which nonetheless may vary geographically. Both Dobzhansky and Mayr emphasized the importance of sibling species and described cases in detail, but did not comment on how their very existence renders criterion (1) impossible. As for the second criterion, "degree of difference" is not strongly correlated with the propensity to interbreed: the two most distinctive species of baboons, the hamadryas baboon *Papio hamadryas* and the Olive Baboon *P. anubis*, interbreed along their common geographic border. The third criterion depends on the ability to distinguish between primary and secondary intergradation which, if the hybridization is too “free,” may be a very subjective matter indeed. When all is said and done, “amount of difference” is a very slippery concept, whether we consider morphology, vocalizations, DNA, or any other type of differences.

If we require that a species must be monophyletic (but see below), then we have another problem with the BSC and its modifications. The relationship between common descent and interbreeding has been explored by de Queiroz and Donoghue (1988), who conclude that they may or may not coincide. If they do not, then a species will not be monophyletic.

A different problem is a purely practical one: how do we know, in any given case, whether reproductive isolation really exists or when we are dealing with SMRSs? Detailed field observations may inform us in the end, but these are not available in most cases – whether to test for the reality of SMRSs or for the existence of reproductive isolation.

Yet we have to agree that reproductive isolation, in the cases where it can be demonstrated, is decisive. Many authors, including Groves (1989), have been so impressed by this that they have treated “speciation” as equivalent to “the evolution of reproductive isolation.” And how this occurs is indeed an important question: is reproductive isolation a by-product of divergence, as argued by Harrison (1998), or can it be its cause, as argued, for example, by the advocates of sympatric speciation?

Species: Operational Concepts

If one is working with preserved animals in a museum, or with the fossil record, the species criterion of the BSC – however much one tinkers with it – can be at best an inference, at worst misleading. As Nixon and Wheeler (1990) put it, what can be observed under such conditions can only be patterned, not processed. This was observed more than 30 years ago by Sokal and Crovello (1970) and was the reason why they rejected the BSC, though they did not explicitly propose an alternative; it was left to Cracraft (1983, 1989, 1997; see also Eldredge and Cracraft 1980) to propose the phylogenetic species concept (PSC), under which a species is regarded as the minimal cluster of individuals (i.e., a population or group of populations) that is diagnosably distinct from other such clusters.

The concept was called “phylogenetic” because, under it, species are the terminal points on a cladogram; hence they are the least inclusive phylogenetic units. But it stands to be misunderstood; Avise and Ball (1990), Mallet (1995), and Harrison (1998) all misread it as specifying that a species must be defined by apomorphies. This is not the case: a cladogram depicts sister-group relationships, not ancestors, and a terminal need have no autapomorphic states. It is therefore perfectly possible under the PSC to have a species that is defined only by primitive retentions, a "living fossil" in the broad sense. It follows from this that a species may not be demonstrably monophyletic: indeed, the implication of speciation by founder effect would be that, initially at least, up to half of all species are not. Baum (1992) refers to such nonmonophyletic ancestral forms as metaspecies.

There is also some disagreement over what exactly is distinct under the PSC. "Diagnosably distinct" (Cracraft 1983) may mean one diagnostic character state ("at least one": Baum 1992), or it may require "a unique combination" (Nixon and Wheeler 1990; Christofferson 1995). In the main the case may be academic, but in the extreme case a single fixed heritable difference from its relatives still allows a population to be diagnosable, hence to be a species. But remember that fixed heritable differences may in fact be expressed only in one sex or at one stage in the life cycle. Under the PSC, therefore, species are units of genetic cohesion – not necessarily of reproductive cohesion, contra Kimbel and Martin (1993), because different phylogenetic species may still interbreed.

The PSC is eminently operational. While we can rarely or never be entirely certain that a given character state is fixed (i.e., at 100 %), the PSC relies on the evidence at hand, while the BSC and its modifications demand that we go in for a great deal of inference. Paleontologists have little option but to use the PSC (*contra* Gould 2002:785–789), and in reality neontologists usually have no option either.

What Are the Different Species Concepts Trying to Say?

The Evolutionary Species Concept (ESC) was proposed by Simpson (1961): "A lineage... evolving separately from others and with its own evolutionary role and tendencies." Subsequent authors have modified this, or drawn it out, in different ways; thus, Christofferson (1995) explains that, as far as sexually reproducing organisms are concerned, a species is "a single lineage... genetically integrated by historically contingent events of interbreeding."

The supreme importance of this concept is acknowledged by all commentators; it is the very essence of the species – why the species category is so vital (Mayden 1997) – and is why Ghiselin (1974) reified species as "individuals." It is therefore a different level of concept from either the BSC or the PSC. The fact that Simpson's definition (or Ghiselin's gloss on it, for that matter) cannot be used in decision-making returns us to the PSC as the means whereby we can recognize species.

The evolutionary concept of species was extended by de Queiroz (2007), who argued that this is fundamental: a species is quite simply an evolutionary lineage and that what have in the past been termed "species concepts" are simply different types of evidence for lineage separation; the existence of any one of the properties that have been thought crucial for recognizing species (reproductive isolation, a specific mate recognition system, diagnosability, genetic distance) is evidence for the existence of a species. It follows that, given that the property that delimits species at base is always fixed heritable differences, what we have been calling the PSC, more correctly phylogenetic evidence in de Queiroz' terminology, takes primacy.

When Groves (2001) reclassified the Primates on the basis of the PSC (rather tentatively, probably too tentatively, in some parts), there was little demur: other primate specialists in the main adopted the idea without problem (see, however, Tattersall 2007, and, more recently, Rosenberger 2012). It was when the concept was applied to very large mammals (Groves and Grubb 2011) that strong objections were raised (see especially Zachos et al. 2013), although this reaction, insofar as it was based on reasoning rather than horror at "the shock of the new," was rooted in a series of misunderstandings (Groves 2013; Gippoliti and Groves 2013).

Does Species Status Necessitate a Certain Degree or Quality of Difference?

The literature on species, including in mammals, is full of statements implying that differences between species are of a different order or degree to those between subspecies, populations, or individuals within a species. Often, there are no explicit statements to this effect; rather, it is assumed that this is so, that in some character or other species differ grossly or qualitatively (however that is interpreted), whereas mere subspecies differ quantitatively: thus, between- and within-species differences are not of the same kind.

Bohlken (1958), for example, used an allometric method. He found that on his bivariate plots of skull and horn measurements, different species of Bovini generally have different slopes, and when by contrast he found that two of them (the tamaraw, *Bubalus mindorensis*, and the Indian wild buffalo, *B. arnee*) did not, he used this as a reason for combining them into one species. Imaizumi (1970) also used a variant of this allometric method with respect to Japanese and Chinese deer (*Cervus nippon* group); in this case he plotted skull variables against an index of temperature, on the hypothesis that different species would show different responses to Bergmann's rule whereas different subspecies within a species would respond similarly.

The idea that species ought to be more differentiated genetically than infraspecific groups has a long history. In a classic paper, Ayala (1975) compared values for identity (Nei's I) and distance (Nei's D) at various loci for various animal groups and found that well-differentiated species pairs characteristically have higher values of D than do sibling and sister species which are higher than subspecies which in turn are higher than local populations. Thorpe (1983) collected an even larger amount of data, also using Nei's D, and he too concluded that there is an average difference between species and infraspecific levels. Bradley and Baker (2001) tested genetic distances at different taxonomic levels using cytochrome-b sequence data for a number of bat and rodent genera and once again found that genetic distances do tend to increase in the expected sequence from interpopulational to interspecific; moreover, distances between presumed sister species were less than between congeneric species in general. (The same was found, for a different region of mtDNA, for species of *Macaca* by Hayasaka et al. (1996).)

This of course makes sense under molecular clock assumptions. Avise and Ball (1990) demonstrated by computer simulations that the longer two populations have been separated, the more loci should differentiate them (although smaller effective population sizes will reduce the time it takes for them to become reciprocally monophyletic); if it is true that species have been separated for longer than infraspecific populations, then one should expect that on average there should be higher genetic distances between them.

But scanning Ayala's tabulations, one can observe that the values of D for the four levels overlap widely, at least in his vertebrate examples: well-differentiated species pairs may actually differ *less* than do sibling species, species of any kind frequently differ *less* from each other than do subspecies, and subspecies may differ *less* than do taxonomically undifferentiated local populations. In Thorpe's (1983) dataset, again, the overlap between levels is enormous. One would be foolhardy to insist that above a certain level, two taxa are merely subspecies, while below it they are species.

On average, species of the same species-group differ in their cytochrome-b positions by 9.55 % in rodents but only 6.83 % in bats (Bradley and Baker 2001:963, Table 1) and 7.86 % in macaques (Hayasaka et al. 1996:1048–9, Table 2, and some extra distances calculated from Table 1). But these are average differences; it is possible for different species to differ by much less than this – as little as 2.23 % in the smallest of the rodent comparisons, 2.50 % in bats, and 3.72 % in macaques. The conclusion, and it is a very important one, is that we must simply adjust to the fact that well-differentiated species pairs may show extraordinarily little sequence divergence in a given DNA region. The genetic species concept of Baker and Bradley (2006) is more a recipe for detecting the existence of cryptic species than a species concept itself.

Hybridizing Species

Reproductive isolation may or may not be a result of speciation, and the old controversy over whether such RIMs may exist and precede the evolution of species-specific diagnostic states, or are a by-product of them, is unresolved. But it is evident that species that hybridize are not necessarily each other's closest relatives: cases are known where sister species are intersterile, while less closely related species are not (Baum 1992).

Hybrid zones between distinct species are referred to as tension zones (Key 1968). Their width depends on migration, which acts to widen the zone, and selection, which acts to reduce it (Barton and Hewitt 1985). The most stable hybrid zone is one which follows an ecotone; it widens and narrows in different regions and apparently tracks the ecotone over space and time (Arntzen and Wallis 1991). Whether it persists over long periods of time is arguable; can there be selection against individuals that lack a focused search image, such that they waste their reproductive effort by producing hybrids? Paterson (1978, 1980) argued strongly that such reinforcement is unlikely; Barton and Hewitt (1985), on the contrary, considered that reinforcement may in fact occur, although it is only one in a number of factors which may help to maintain the zone.

There are several well-analyzed cases of hybridization between perfectly distinct species. Two newts, *Triturus cristatus* and *T. marmoratus*, are broadly parapatric in western Europe, where they are characteristic of flat, open country and more hilly, wooded regions, respectively (Arntzen and Wallis 1991). They hybridize in places, and the hybridization appears to be one way, as hybrids all possess *T. cristatus* mtDNA. The authors argued that there was a selection against hybrids because of both theoretical grounds (chromosomal incompatibility) and high frequency of digital anomalies among them; they did find, none the less, evidence that genes had leaked across the hybrid zone into the "pure" species on either side. Whereas for Key (1968) this would have been reason enough to combine the two species into one, Arntzen and Wallis (1991) argued against such an interpretation on the grounds that the two essentially maintain their genetic integrity overall, and even in the hybrid zone itself only 4 % of the population are F1 hybrids.

Among mammals the classic study of a hybrid zone is that by Hunt and Selander (1973) on two commensal mouse species, *Mus musculus* and *Mus domesticus*, across the width of the Jutland peninsula, Denmark. This hybridization process too is asymmetric; mtDNA from one species leaks some distance well beyond the hybrid zone proper into the other species, although interestingly this does not apply along the same species boundary in southern Germany, where the mtDNA and nDNA boundaries are concordant.

Species do not have to form actual hybrid zones: well-differentiated sympatric species may also hybridize. *Cercopithecus ascanius* and *C. mitis* hybridize sporadically in East African forests, and in Gombe Stream National Park, this is so common that the frequency of hybrids is comparable to that of the parent species (Detwiler 2002). But hybridization need not be quite as blatant as this: phenotypes may be for all intents and purposes unaffected, and only the foreign mtDNA remains as a kind of fossil of recent or more remote episodes, as in the case of two species of deer (*Odocoileus*) in Texas which appear quite distinct but may possess the other species' mtDNA (Ballinger et al. 1992).

A phenomenon occurring in many hybrid zones is the high frequency of rare or otherwise unknown alleles, termed hybrizymes (Woodruff 1989). They may result from recombination within loci, increased mutation, or relaxed selection. The very existence of hybrizymes suggests that, for whatever reason, new genetic features may arise in hybrid zones (or perhaps more probably they survive there, where they do not within the pure species) and is clearly part of the general phenomenon of transgressive segregation (Rieseberg et al. 1999), whereby extreme phenotypes are generated by the crossing of poorly compatible genomes.

More recently, it has become clear that there are entire species of hybrid origin in animals, analogous to those which have arisen by polyploidy so frequently among plants. A striking example has been deduced in mammals: the stump-tailed or bear macaque, *Macaca arctoides*, has Y chromosome sequences typical of the *M. sinica* group but mtDNA sequences similar to *M. fascicularis* (Tosi et al. 2000), and most likely the species is derived from an asymmetrical hybridization event. *M. arctoides* is very far from being morphologically intermediate between its presumed parental species and has obviously changed a good deal since it was first generated. Other examples of species that may be of hybrid origin are the wisent or European bison, *Bos bonasus* (Verkaar et al. 2004), and Père David's deer, *Elaphurus davidianus* (Meijaard and Groves 2004).

This phenomenon, known as reticulation (literally the interweaving of different lineages), is an unexpected addition to our understanding of evolution. It in no way challenges the status of the species as an evolutionary lineage: there is no reason at all why genes, including mtDNA (which is of course a single genetic locus), cannot be incorporated from other species as long as a species maintains its own evolutionary identity and remains, in the jargon, "individuated."

Indeed, multiple cases of introgression and evident speciation by hybridization have become known among Primates. They seem to be especially rampant among Colobinae (Wang et al. 2012; Liedigk et al. 2013), but a good case has also been made for introgression into the early hominin gene pool by proto-chimpanzees (Patterson et al. 2006).

Speciation

How Does Speciation Happen?

The literature on speciation is considerable (Barton 2001), but one cannot improve much on the categorization by White (1978) into seven general modes:

(1) Strict allopatry without a population bottleneck. This is dichopatric speciation: ordinary vicariance on either side of a newly arisen barrier, such as a river changing course, when the two daughter populations are both large. If selection is not operating to push the two apart, they still have a low but finite probability of slowly diverging by stochastic processes as modeled by Kimura (1983).

(2) Strict allopatry with a narrow bottleneck of one component. This is of course founder effect; typically, the component that is not bottlenecked remains identical to the parent species, while the bottlenecked component diverges rapidly (peripatric speciation).

(3) Extinction of intermediate populations in a chain of races. There is commonly some clinal variation through the range of a species and, if geographically and morphologically intermediate populations go extinct, the end points will be already somewhat differentiated. It is, consequently, a form of dichopatric speciation. There is some fear that this process may be happening today as populations of widespread species vanish in all but a few isolated reserves, and this pseudo-speciation must be carefully studied to differentiate it from genuine dichopatric speciation (e.g., in the latter case, much deeper divergence can be expected in key DNA sequences).

(4) Clinal speciation. A cline may become stepped over time, resulting in parapatric speciation.

(5) Area-effect speciation. If incompatible alleles or gene complexes arise in different parts of a species' range and spread, there may be selection against hybridization when they meet.

(6) Stasipatric speciation. This was White's own discovery (White 1978, 1979). A chromosomal rearrangement arises and spreads despite low heterozygote fertility and becomes established as soon as its frequency increases to the point where homozygotes begin to be generated. This process, as discussed by Bush et al. (1977) and Meester (1988), creates new linkage groups and breaks up old ones, which might affect gene expression; it may be promoted under some forms of social organization such as clans and harems by limited vagility and dispersal, by distributional patchiness, by individual territoriality, and, generally, by low effective population size.

(7) Sympatric speciation. This is the one guaranteed to start fistfights in bars. Mayr (1963) argued strongly against it, but from time to time it has nonetheless surfaced as a real possibility. Maynard Smith (1966) argued that differential habitat assortment could lead to speciation in the absence of any geographic separation; Bush et al. (1977) urged that it might even be the dominant mode of speciation among parasites and parasitoids. More recent models have tended to invoke sexual selection (Kondrashov and Kondrashov 1999; Higashi et al. 1999). The whole question of sympatric (or quasi-sympatric) speciation has been under study in cichlids for some time by Axel Meyer and his colleagues, whose genomics studies find a variety of mechanisms which differ in different regions: sexual selection and selection in the trophic apparatus are identified in African rift valley lakes and Lake Victoria, while other mechanisms (such as color polymorphisms and breeding systems) are identified in the crater lakes of Nicaragua (see, e.g., Sanetra et al. 2009; Elmer and Meyer 2011; Fan et al. 2013).

Speciation, then, may occur by drift, natural selection, or sexual selection, with or without founder effect; it may involve intrinsic mechanisms such as chromosomal change or be simply a matter of divergence following allelic substitution and it may be allopatric, parapatric, or sympatric. To these mechanisms may be added speciation by hybridization (see below). We may infer the relative importance of these from phylogenetic studies (Barraclough et al. 1998; Groves 1989, 2012), although care must be taken to ensure that only sister groups are compared in such exercises.

How Long Does Speciation Take?

"Species flocks" in cichlid fish are monophyletic clades which are endemic to a single lake, such as Lake Nicaragua and Lake Managua in Central America, Lake Victoria, Lake Tanganyika and Lake Malawi in the Central African rift (see references to Meyer and colleagues, above), and Lake Barombi in Cameroon. In a very innovative study, McClune and Lovejoy (1998) used cytochrome b to compare differentiation, within-species flocks, among sympatric species to that among allopatric sets. The actual sequence divergence between sister species of fish was 2–8 %; this compares to that among geographic populations within given species, which was from 0 % to 5.6 %. The overlap between percent sequence divergence within species and that between species (allowing for the possibility that some species pairs were not sister species) was "time for speciation" (TFS); as the divergence associated with allopatric speciation was 2.0–5.6 % and that associated with sympatric speciation was 0–1.25 %, TFS was calculated to be 1–2.27 myr in allopatry, but anything from "instantaneous" to 0.77 myr in sympatry (using a cytochrome-b divergence rate of 2.5 % per million years). They admitted that these times could well be overestimates because of incomplete lineage sorting (which in some haplochromine cichlids "appears to be epidemic") and possible hybridization. The monophyletic swarm in Lake Victoria consists of 300 species; as the lake is only 12,400 years old, they calculate about 1,500 years per speciation event!

That speciation may take a very short period of time indeed and can be inferred from looking at changes that have occurred in taxa that have been introduced by human agency outside their natural ranges. Three examples have become especially well known:

- Mice (*Mus domesticus*) introduced apparently by the Vikings to the Faroe, Shetland, and Orkney Islands differ noticeably from the ancestral Scandinavian and/or British populations (Davis 1983). The mice of two of the Faroe Islands were described as a new subspecies by Degerbøl (1942), as was the hare whose history is similar.
- Australian wild rabbits differ appreciably from their parent population in the British Isles and are more and more different the further we go from Geelong (Victoria), the place where the small (a dozen or so) founding population was first introduced in 1859 (Taylor et al. 1977).
- In 1916, a pair of rock wallabies (*Petrogale penicillata*) was imported from New South Wales to Hawaii for a private zoo, but they escaped, and over 200 of their descendants now roam wild in the Ko'olau Range of Oahu. They are noticeably different in pelage, size, cranial characters, and body proportions from their ancestral population (Lazell 1980; Lazell et al. 1984).

These three examples are perhaps not actually speciation but certainly serve as examples of very rapid changes following the establishment of small founder populations. The Australian rabbit case also illustrates the principle of isolation-by-distance, meaning that populations that are more distant geographically may also be more distant genetically (the basis for clinal variation); considering the way rabbits disperse, not en masse but by forming small founder colonies, the cause of isolation-by-distance may, at least sometimes, be a progressive series of founder events.

Groves (1989:44–46) pointed out that the amount of heritable change following a founder event will vary in magnitude. Presumably, small gene frequency changes will be most frequent; the greater the degree of change, the less probable – but not vanishingly so. In the “sudden origins” model of Schwartz (1999), mutations of large potential effect, but recessive at first, accumulate in a population until their frequency reaches the point at which all at once they appear abundantly in homozygous state: similar, but not identical, to the way stasipatric speciation was envisaged by White (1978). If this is so, most founder events will not result in speciation, but some certainly will. The trick, of course, is to get these new species to survive when they come into sympatry with their parent species.

Is There Phyletic Speciation?

If founder effect is theoretically the most powerful way of generating new species, would speciation result if an entire population underwent the process (in other words, bottlenecking)? The “founder-flush” model of Carson (1975) relies on the fact that during the re-expansion phase after a population crash, there will be no density-dependent selection until carrying capacity is reached, so all kinds of zany mutants will survive to form new and potentially fit recombinations. Petry (1982) argued that this can apply to entire species. There are in fact real-world examples of this; some were described and discussed by Groves (1989:39–43). Consider: if this happened from time to time in a species with high visibility in the fossil record, it will mimic the appearance of anagenesis. We should be alert to the possibility of examples of punctuated equilibria without cladogenesis; there may be cases where rapid change in a fossil species occurs entirely in situ, rather than in small peripheral isolates. Gould (2002:779–780) was well aware of this; as he noted, cases of phyletic speciation might be distinguished from cases of allopatric speciation because the ancestral species is nowhere to be found.

Can We Detect Speciation Modes in the Fossil Record: Does Anagenesis Really Exist?

Groves (1989) pointed out that, if speciation really does drive evolution, we would expect to find that highly autapomorphic species have fossil records characterized by high rates of speciation, whereas their more plesiomorphic sister species would have had many fewer speciation episodes. The human species is highly autapomorphic, and indeed the fossil record depicts rampant speciation almost throughout; unfortunately, the case lacks a control, as the plesiomorphic sister group, the chimpanzee, has no fossil record whatever prior to the late Middle Pleistocene.

The reality of anagenesis has been vigorously defended by White (1995), and it is true that there are plenty of cases in the Plio-Pleistocene record where a pair of time-successive species (White’s example is in the suid genus *Kolpochoerus*) seem to merge into each other when fossils from intervening time zones become better known. Yet, as White (1995) notes, there are big problems which get in the way of a proper interpretation of the record: gaps are always there, key fossils are frustratingly incomplete, and examples of the same presumed species are not represented by comparable parts. A further problem is that "well-known cases" of anagenesis, which were plausible hypotheses in the state of knowledge of yesteryear, may call for reanalysis when they are looked at anew in the twenty-first century. A classic case of anagenetic gradualism was the inexorable onward-and-upward evolution of the East African Plio-Pleistocene elephant *Elephas recki*. More recently, Todd (2005, 2009) has maintained that all is not well with this icon of anagenesis, and a radical revision of the species (if it is one species) is in order.

How, in any case, would it work? Eldredge and Gould (1972) invited their colleagues to consider the implications of long-term sustained directional change – an environment exerting exactly the same selective pressures over perhaps millions of years. The most plausible scenario would be the Red Queen effect of Van Valen (1973), in which species themselves are constantly changing – usually degrading – their own environment and are forced to evolve continuously in order to track these changes. The Red Queen model incorporates everything from African elephants knocking down trees, and so destroying their own future food supply, to evolutionary arms races between lions and antelopes: everything, in other words, in which no evolutionary stable strategy is resolved. (The African elephant scenario is actually cyclical, although it is likely that natural climatic change does reset the cycles each time; such cases will therefore most likely be episodic, not continuous and sustained – see Cameron and Groves 2004.)

In cases of sustained trends, there is in any case an alternative: the effect hypothesis of Vrba (1980). In this model, new species are continually generated, and these are then subjected to the forces of selection; the ones which survive are those whose innovations happen to make them fitter in their particular habitat. At each round of speciation, this will occur, so that, if the environment has not changed much, an appearance of gradual directional change will result.

If it is difficult to test gradualism in the fossil record, how easy is it to test speciation? The answer is that, unless we catch it in the act, we can only infer it (from a pattern of stasis followed by sudden change); even then, the possibility of phyletic speciation (see above) cannot be ruled out. But there are a few cases where we have caught it in the act. The Morrisville cowpasture site, apparently documenting the evolution of a new species of trilobite, as described by Eldredge (1986, Chap. 3), may be one. Another, which appears to have survived all the criticism that was thrown at it, is the simultaneous eruption of new species in a dozen mollusk lineages in the Lake Turkana deposits (Williamson 1981). This latter case, as argued by Groves (1989), seems to flout the PE model because the new species were generated not by founder events in small isolates, but in huge populations. Yet it might instead shed light on mechanisms, because it occurred not instantaneously, as in cases that we have considered above, but over thousands of years, more as envisaged by Eldredge and Gould (1972) in their original paper; it might thus be explicable by a Kimura-type mechanism rather than by a Schwartz-type one.

Recently Groves (2012) suggested how one might go about deducing possible methods of speciation in the hominin fossil record. A case of simple dichopatric speciation, in which both of two sister species exhibit clear apomorphic states, might explain *Homo walkeri* (erstwhile *Paranthropus aethiopicus*) versus *H. africanus*, whereas the case of *H. africanus* versus *H. garhi* might indicate peripatric speciation in the case of the latter; yet the ubiquity of speciation by hybridization among living Primates warns us to be prepared for reticulation as well as divergence in the hominin record (see, e.g., *Homo ergaster and Its Contemporaries*, *The Species and Diversity of Australopiths* and *Analyzing Hominin Phylogeny* in this handbook).

Conclusion

This chapter has briefly surveyed the arguments over what is a species; the most nearly objective definition, the phylogenetic species concept (or phylogenetic delimitation method, in the model of de Queiroz (2007)), relies on genetic discontinuities and stands at the base of the "evolutionary species," which has a distinct evolutionary history and fate. How do species arise?

Gradualism (anagenetic change) is surprisingly hard to justify theoretically. If it could be demonstrated in the fossil record, this is something we would simply have to live with, but it is doubtful whether it can; at least one case (*Elephas recki*) that has been cited as a classic example of it has been found to need revision, and it is probably time to reexamine other supposed examples in fossil mammals, such as the African pig lineages.

Speciation is, in most cases, most likely a type of rapid cladogenesis; there is evidence to suggest that in some instances it may be very rapid indeed. It may be allopatric (peripatric), by a small population becoming isolated from the main body of the species, but stasipatric and even sympatric models are also plausible. Phyletic speciation, though it does not involve lineage splitting, also falls under the definition of speciation. In the fossil record, speciation would show up as a punctuation.

But, because a punctuation in most of the geological column – prior to the Neogene, anyway – is likely to take no more than "the duration of a bedding plane" (to quote Gould 2002:768), we are unlikely to catch it in the act very often. In most cases we have to fall back on inferring its operation. For example, a period of stasis followed by the sudden appearance of a new species is best explained by PE. And, if indeed speciation is the real focus of evolutionary change, then one expects to find evidence of much lineage splitting in the fossil record of highly autapomorphic species and very little in that of a plesiomorphic species; a proposition which is in need of testing in the future.

Abstract

This chapter reviews Hennigian, maximum likelihood, and Bayesian approaches to quantitative phylogenetic analysis and discusses their strengths and weaknesses and protocols for assessing the relative robustness of one's results. Hennigian approaches are justified by the Darwinian concepts of phylogenetic conservatism and the cohesion of homologies, embodied in Hennig's Auxiliary Principle, and applied using outgroup comparisons. They use parsimony as an epistemological tool. Maximum likelihood and Bayesian likelihood approaches are based on an ontological use of parsimony, choosing the simplest model possible to explain the data. All methods identify the same core of unambiguous data in any given data set, producing highly similar results. Disagreements most often stem from insufficient numbers of unambiguous characters in one or more of the data types. If analyses based on different types of data or using different methods of phylogeny reconstruction, or some combination of both, do not produce the same results, more data are needed. New developments in the application of phylogenetic methods in paleoanthropology have resulted in major advances in the understanding of morphological character development, modes of speciation, and the recent evolutionary history of the human species.

Introduction

Formalized by Willi Hennig in 1950, phylogenetic systematics has emerged as a universal and transparent method for generating and evaluating evolutionary hypotheses. Over the last 50 years, it has developed into a research program ostensibly embraced by a majority of evolutionary biologists who are interested in exploring the patterns and processes of evolution. However, this apparent unity is misleading. As researchers from diverse fields began putting the theory and methods into practice, they approached their studies from different perspectives and used different types of data. This has generated a multitude of quantitative methods and research strategies, the efficiency and validity of which are fiercely debated in the literature.

These debates stem from the nature of phylogeny reconstruction. Unlike much of physics and chemistry (astronomy and astrophysics being notable exceptions), in which experiments in a hypothetico-deductive framework aim to be predictive with respect to spatiotemporally invariant laws, the reconstruction of phylogenies deals with a singular history and thus is descriptive and retrodictive. Attempts to infer causal processes for evolutionary patterns must be based not only on evolutionary patterns of relationships but also on corroboration from independent data (Wiley and Lieberman 2011; Brooks and McLennan 2002). Despite these obstacles, evolutionary biologists strive to provide as accurate an approximation of evolutionary history as possible.

Paleoanthropologists are especially concerned with the accurate reconstruction of primate evolution because fossils provide some of the most powerful evidence supporting evolution, the unifying theory of biology. More particularly, paleoanthropologists are the curators of information about the most fascinating evolutionary story of all, the story of *us*. As a critical part of evolutionary biology, paleoanthropology thus stands to benefit enormously from participation in phylogenetic research programs. Collaborating with researchers in diverse fields and exploring new methods will allow paleoanthropologists to refine their hypotheses and methods while placing them within the larger context of biotic evolution on this planet.

Fount of Stability and Confusion: A Synopsis of Parsimony in Systematics

The principle of parsimony (Latin *parcere*, to spare) is also known as the principle of simplicity. The principle is often connected to the English philosopher and Franciscan monk William of Ockham (ca. 1285–1349), who advocated the use of the principle so forcefully that it is also known as "Ockham's razor": *Pluralitas non est ponenda sine neccesitate* (plurality should not be posited without necessity) and *entia non sunt multiplicanda praeter necessitatem* (entities should not be multiplied unnecessarily). In this sense, the principle represents an epistemological tool or rule of thumb that favors theories or hypotheses that make the fewest unwarranted, or ad hoc, assumptions about the data from which they are derived. This does not necessarily imply that nature itself is parsimonious. Aristotle (350 BCE) articulated an ontological basis for the principle of parsimony, the postulate that "nature operates in the shortest way possible" and "the more limited, if adequate, is always preferable" (Charlesworth 1956). This sense of the principle postulates that nature is itself parsimonious in some manner. Phylogeneticists have used the term "parsimony" in both senses, resulting in much confusion and unnecessary conflict.

The most important concept introduced by Hennig (1950, 1966) was the stipulation that homology should be assumed in the absence of contradictory evidence. Although now known as Hennig's Auxiliary Principle, this concept lies at the foundation of evolutionary theory: "[p]erhaps the correct way of viewing the whole subject, would be, to look at the inheritance of every character whatever as the rule, and noninheritance as the anomaly" (Darwin 1859, p. 13), and "Mr. Waterhouse has remarked that, when a member belonging to one group of animals exhibits an affinity to a quite distinct group, this affinity in most cases is general and not special" (Darwin 1872, p. 409). Hennig's argumentation method is clearly intended to maximize hypotheses of homology and minimize hypothesis of homoplasy, which invokes the principle of parsimony by avoiding the assumption of unnecessary ad hoc hypotheses of parallelism. In the Hennigian system, if evolution were parsimonious, all traits would be logically consistent with the true phylogeny – there would be no conflicting relationships suggested by any set of traits, that is, there would be no homoplasy. The Auxiliary Principle implies that there will be conflicts in the data, which should be resolved in favor of the hypothesis postulating the fewest number of assumptions of multiple origins (homoplasy) over single origins (homology). Contemporary Hennigians assert that both the Auxiliary Principle and the use of parsimony are logical requirements of any attempt to reconstruct phylogeny; if one were to assert that all similarities were due to homoplasy, there would be no evidence of common descent and thus no evidence of evolution. Therefore, if one is going to study evolution, one must use a method that is capable of finding evidence of evolution. Likewise, if one is going to invoke the Auxiliary Principle, one must invoke it for all traits, thereby choosing the phylogenetic hypothesis that minimizes the total number of violations of the Auxiliary Principle for a given set of data. In this manner, the Auxiliary Principle is an epistemological tool practically synonymous with the principle of parsimony (Farris 1983; Wiley et al. 1991). Wiley (1981; Wiley and Lieberman 2011) suggested four main assumptions of phylogenetics: (1) evolution occurs and has occurred, documented by the characters of different species; (2) each species is a historically unique mosaic of plesiomorphic, synapomorphic, and autapomorphic traits; (3) prior to the analysis, it is unknown which characters are homologous and homoplasious; and (4) the phylogenetic relationships and relative or absolute rates of divergence are unknown. The presumption of homology embodied in Hennig's Auxiliary Principle is not an a priori assumption in the sense of a formal model, because the method is designed in part to recognize all mistakenly presumed homologies as homoplasies.

Edwards and Cavalli-Sforza (1963) reconstructed a tree of extant human populations based on frequencies of blood-group alleles, using an approach they developed and called the "Method of Minimum Evolution." Their studies originally aimed to present a maximum likelihood method for phylogeny reconstruction, but their algorithm for a likelihood approach did not work. Edwards (1996, p. 83) later emphasized that "[t]he idea of the method of minimum evolution arose solely from a desire to approximate the maximum likelihood solution," that is, from a maximum likelihood model based on the assumption that evolution has been parsimonious. Felsenstein (2004, p. 127) characterized the method of minimum evolution as a parsimony method while at the same time not seeing a direct connection between Hennig's Auxiliary Principle and the principle of parsimony, e.g., "[i]t is not obvious how to get from this 'auxiliary principle' to the parsimony criterion" (Felsenstein 2004, p. 138). This reveals that for Felsenstein and like-minded phylogeneticists, parsimony is an ontological issue, whereas Hennigians see it as an epistemological issue.

There are two critical distinctions between these positions. The ontological perspective on parsimony requires first that evolution be parsimonious in some manner, usually as defined by certain assumptions and parameters of a model, and second that the resulting phylogenetic hypothesis be accepted as true so long as the model is accepted as true. Practitioners are thus preoccupied with the accuracy of their results and believe it is possible to develop means by which their preferred hypotheses can be verified with respect to the true phylogeny. The Hennigian or epistemological use of parsimony does not imply that the evolutionary process itself is parsimonious. In fact, it suggests that evolution has been so complex that conflicts will always be found in the data, which will require the use of a logical decision-making principle to resolve. An important corollary of this perspective is that there need be no necessary connection between the most parsimonious hypothesis and truth. Practitioners are thus preoccupied with the empirical robustness of their results. The expectation is that if the most parsimonious hypothesis is not true, the accumulation of additional data will force phylogeneticists to abandon it in favor of a new most parsimonious hypothesis; they do not believe that their hypotheses can be verified, but do believe that they can use new data to falsify all or parts of previous hypotheses. Phylogeny reconstruction is thus an open-ended process involving a potentially endless search for information. If, at some point in the future, the accumulation of data has led to a situation in which the phylogenetic hypothesis for a given group is no longer changing with the addition of new data, Hennigians may express the belief that the hypothesis has approached the truth as closely as possible, but in principle it is never appropriate for a Hennigian to claim to have the true phylogeny. Hennigians do feel justified in claiming that they have the most robust hypothesis possible for any set of data.

Today numerous quantitative methods for reconstructing phylogenetic trees are applied to multiple kinds of characters. These methods can be divided into two main types, commonly called parsimony (invoking epistemological parsimony) and likelihood (invoking ontological parsimony) approaches.

Epistemological Parsimony: The Wagner Algorithm

In September 1965, two seminal articles on phylogeny and parsimony appeared. Wilson (1965) introduced a "consistency test for phylogenies based on contemporaneous species." His null hypothesis was that all characters that are used for a phylogenetic analysis are unique and unreversed. In order to pass Wilson's consistency test, the taxa defined by these characters must be nested, and these nested conditions must persist as new species are added to the tree. Colless (1966) was concerned that more than one cladogram might pass the consistency test, that a polyphyletic character state might mistakenly be regarded as unique and unreversed, and that the taxa are in the first place grouped on the basis of similarities. Wilson (1967, p. 104) asserted that his consistency test was internally sound but that he shared one of Colless' main concerns, which "is the lack of efficient methods for selecting the character states."

In the second article, Camin and Sokal (1965) presented the first algorithm for applying the parsimony criterion to phylogenetics and first applied the term "parsimony" to a method of phylogenetic inference. They used a group of imaginary animals (Caminalcules) possessing a number of morphological characters that could change according to particular rules. Thus, the "true phylogenetic tree" was known and could be compared to trees that were achieved by different methodologies. Camin and Sokal (1965) found that the trees that most closely resembled the "true phylogeny" required the least number of changes in the morphological characters, which seems to invoke an epistemological use of parsimony. However, they claimed that their technique examined "the possibility of reconstructing cladistics by the principle of evolutionary parsimony" (p. 312), saying that "the correctness of our approach depends on the assumption that nature is, indeed, parsimonious" (pp. 323–324), an appeal to ontological parsimony. Significantly, Camin and Sokal produced a computer program implementing their method, demonstrating for the first time that quantitative phylogenetic analysis could be performed on as objective a basis as phenetics, thereby undermining one of the strongest arguments in favor of phenetics over evolutionary approaches to systematics (Sokal and Sneath 1963). Their algorithm was, however, unwieldy and inefficient for larger data sets and was never fully adopted nor effectively programmed and made available for widespread use.

Soon afterward, Kluge and Farris (1969; also Farris 1970) presented a new algorithm for reconstructing phylogenetic trees as well as searching among several trees for the most parsimonious tree for a given data set. They named their method "Wagner parsimony" in honor of W. H. Wagner, who formalized an older approach (Mitchell 1901, 1905) called the groundplan-divergence method (Wagner 1952, 1961, 1969, 1980), which formed the basis for Kluge and Farris' algorithm. Kluge and Farris (1969) also discussed explicitly their perspective that the use of the parsimony criterion did not assume that evolution itself is parsimonious, clearly invoking an epistemological use of the principle.

The Wagner Algorithm

The first Wagner algorithm [in later papers termed the "simple Wagner algorithm" of Kluge and Farris (1969)] utilizes a method that minimizes the Manhattan distance between members of a set of taxa via the creation of hypothetical taxonomic units. This initial algorithm required the selection of an ancestral taxon, but in 1970 Farris concluded that it was unnecessary to have an ancestor from which to begin the construction of the tree (Farris 1970). He observed that the choice of ancestor of a given group of taxa changed the topology of the tree. Since the "simple" algorithm did not impose directionality to the evolution of the group, he reasoned that the choice of ancestor is not crucial. Parsimony assumes the least about the way evolution works, so choosing one taxon as an ancestor would be an assumption about the status of that taxon. Farris thus argued that a rootless network would reduce the dependency of the form of the tree on the ancestor. For the creation of networks, he used a method for creating networks that minimized the length of the intervals between taxa (symbolized by nodes), using the shortest network connections method of Prim (1957; Sokal and Sneath 1963). Farris differentiated his use of this method from previous phenetic applications by its use of shared, derived characters and also by the evolutionary implications of the method.

This new Wagner algorithm produces a network, rather than a tree, and does not assume that any of the taxa are ancestral. Farris suggested that the network could be converted into a phylogenetic tree by rooting it at one of the taxa within the tree or an interval within the network. Completing the process of constructing phylogenies using this method requires that the characters be optimized onto the tree.

The earliest programs implementing the Wagner algorithm did not necessarily find the most parsimonious tree for large data sets. The program needed to run multiple times and have a method of comparison in order to determine whether it has indeed found the shortest tree or if there were multiple equally parsimonious trees. In a large matrix, examining every possible tree could require an enormous amount of computer time, and thus it became necessary to develop heuristic methods to try to find the shortest tree. Today's parsimony programs, such as those in PAUP, Hennig86, NONA, and TNT, use a variety of heuristic algorithms to rerun the data to attempt to ensure that the most parsimonious tree or trees are found. For small numbers of taxa and characters, the Branch and Bound algorithm (Hendy and Penny 1982), which guarantees finding the shortest tree, or the Exhaustive Search option, which enumerates all possible trees, can be employed.

As phylogeneticists began to analyze increasingly larger and more complicated data sets, the shortcomings of the original computer programs became evident. In the decade following Farris' (1970) contribution, a number of algorithms were developed and incorporated into the existing programs as alternatives to Wagner parsimony. These differed primarily in their assumptions and restrictions regarding character evolution and are discussed in more detail by Wiley et al. (1991).

The first iteration of the Wagner algorithm did not take into account multistate characters, and therefore technically it was not possible to have unordered states, since polarized binary characters are automatically ordered. Initially, before more variations were developed for the algorithm, it was suggested that all multiple character states be divided into multiple binary characters [e.g., a single multistate transformation series of an imaginary character (absent (0), short (1), long (2)) would be divided into two separate characters (absent (0) and present (1) and short (0) and long (1))]. Current algorithms allow for multistate transformation series and allow characters to be run either polarized or unpolarized, and either ordered or unordered, at the discretion of the user. Again, the advantage of phylogenetic methodology is that these decisions are transparent (if they are reported) and repeatable; with the same data set, anyone can rerun an analysis using the same settings to check the reliability of the analysis or change the settings to see if the results are different.

Whichever algorithm is used to build a tree, in most cases some characters will not be decisive at every node (Farris 1970). It is therefore important for the purpose of studying character evolution to be able to optimize characters on a tree. There are two types of optimization, ACCTRAN (Farris 1970; Wiley et al. 1991) and DELTRAN (Swofford and Maddison 1987; Wiley et al. 1991). The ACCTRAN setting accelerates the transformation of a character on a tree, making the derived state evolve earlier, or toward the root. This is equivalent to preferring parallelisms to reversals as long as the choice does not affect the tree length. DELTRAN delays the transformation of a character on a tree, essentially choosing reversals over parallelisms when they are equally parsimonious (Wiley et al. 1991). When there are no equally parsimonious alternatives, both ACCTRAN and DELTRAN will provide the same result (Figs. 1 and 2).

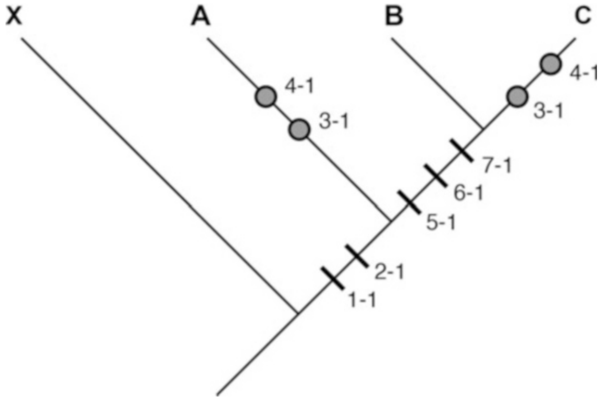

Fig. 1 ACCTRAN tree (length = 9 steps) (Redrawn and modified from Wiley et al. (1991). Characters 3-1 and 4-1 evolve in parallel in taxa A and C)

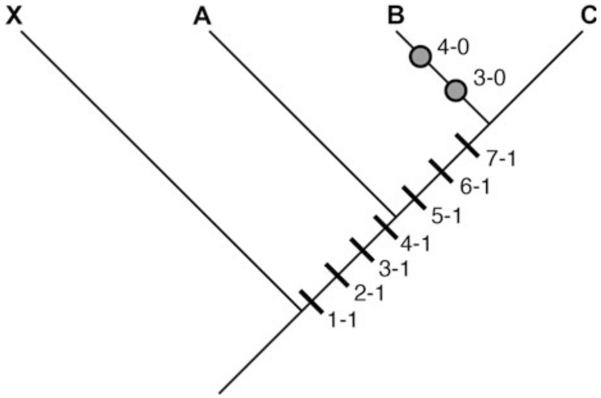

Fig. 2 DELTRAN tree (length = 9 steps) (Redrawn and modified from Wiley et al. (1991). Characters 3-1 and 4-1 are secondarily lost in taxon B)

Development of Outgroup Comparison

As noted above, the Wagner algorithm generates a minimum-length network (sometimes called an "unrooted tree"). In order to convert a Wagner network into a phylogenetic tree, the network must be rooted in some manner. Increasingly, published studies convert the network into a tree by rooting it with an arbitrarily chosen single taxon not included in the group being analyzed (called the ingroup). This protocol should not be mistaken for the method of outgroup comparisons that emerged in phylogenetics during the 1970s. The distinction is slight but significant and must be understood in light of Hennig's perspective on the issue of ancestors.

Hennig objected strongly to the notion that phylogeny reconstruction could be achieved by reconstructing a series of archetypal ancestors from which particular descendant species could be derived. His position was that each species was a unique mosaic of plesiomorphic and apomorphic traits. Archetypes, defined as ancestral species exhibiting only plesiomorphic traits, thus did not exist; therefore, no single taxon could be used to determine the plesiomorphic and apomorphic traits for any analysis. Or, using current jargon, rooting a network with a single outgroup taxon is sufficiently robust in the Hennigian system only if that taxon is the archetype ancestor of the ingroup, something the Hennigian system disavows.

As can be seen from the discussion above, the early development of the Wagner algorithm was not informed directly by Hennigian reasoning. Rather, it relied on the groundplan-divergence method, based on a priori recognition of an archetypal ancestor. When Farris (1970) abandoned the a priori reliance on an ancestor, the Wagner algorithm reverted to a method for producing an unrooted network. Lundberg (1972) made a significant contribution to linking the results of Wagner analyses with Hennigian analyses, by differentiating ancestors from outgroups.

Lundberg developed a method to determine an ancestor from within a network from the data within that same network. He opined that the structure of a network makes certain character states more likely to be ancestral, helping to determine which interval should form the root of the tree of a parsimony-optimized network. The transition of emphasis from searching for ancestors to identifying outgroups was critical in linking Wagner with Hennig. However, the idea that similarity in traits even among distantly related species was due to homology (i.e., plesiomorphy) rather than independent evolution (homoplasy) was established before the development of Hennigian systematics (e.g., Darwin 1872).

Despite the fact that the connection between outgroups and the Auxiliary Principle had been around for a long time, there was no codification until the late 1970s. Engelmann and Wiley (1977) were the first to provide a rationale for outgroup comparisons. They pointed out that the reference to species outside the ingroup permits a researcher to distinguish traits that truly conflict with phylogeny (homoplasies) from those that only appear to conflict (plesiomorphies). This in turn creates the possibility that phylogenetic analysis could become testable, at least with respect to Darwinian concepts. Watrous and Wheeler (1981) expanded on this idea, suggesting a number of rules to determine ancestral states for each independent character on the basis of comparisons with an outgroup taxon. The first algorithm to determine ingroup relationships with reference to multiple outgroups was presented by Maddison et al. (1984), who showed that the most robust outgroup comparisons relied on two or more paraphyletic outgroups. This algorithm is incorporated in the program PAUP to root networks when outgroups are specified.

Linking the Auxiliary Principle to outgroup comparisons thus provides a connection, through the Auxiliary Principle, between outgroup comparisons and parsimony. It is the use of outgroups to root the shortest network that makes the Wagner algorithm Hennigian, accounting for high degrees of consistency between Wagner algorithm, groundplan-divergence method, and Hennig argumentation of the same data.

Evaluating the Robustness of a Parsimony Analysis

Character Evaluation

Hennigian phylogeneticists are preoccupied with assessing the empirical robustness of their results. There are various methods available to accomplish this goal. These “goodness of fit” measures are useful indicators of the degree of internal conflict among the data (characters) used. Measuring the robustness of the characters and knowing how they behave over the tree topology is one useful approach (Wiley and Lieberman 2011).

The simplest summary statistic is the *tree length*; it is merely the number of steps required to produce a particular topology, and it is calculated by adding the number of character changes over the tree (Wiley et al. 1991). Parsimony analysis chooses the tree or trees with the shortest overall length given a set of characters.

Consistency indices (Kluge and Farris 1969) attempt to quantify the amount of homoplasy on a particular tree. The original form of the *consistency index* (CI) is the ratio of the total number of apomorphic states to the tree length. A high CI indicates there is little homoplasy (i.e., the tree length approaches the minimum number of steps required) and a low CI indicates there is a high degree of homoplasy. This measure is independent of a particular data set and thus can be used to compare trees produced by different data. However, the CI can be inflated by autapomorphies, which do not represent tests of relationships and thus are not informative with respect to the robustness of the tree. Farris (1989) therefore proposed the *rescaled consistency index* (RC). The RC is an adjusted version of the CI with the influence of characters that do not change the fit of the tree (e.g., autapomorphies) removed. It still gives a relative measure of the degree of homoplasy on a particular tree topology.

Tree Evaluation

A second type of evaluation assesses the robustness of the tree topology itself. *Decay analysis* (Bremer 1988) determines the number of steps required to collapse nodes. To perform a decay analysis, tree length is increased by successive steps. This shows how many trees exist that are one or more steps longer than the most parsimonious tree (MPT); if there are a few trees of similar length to the MPT, but with different topologies, the MPT is more likely to be accurate. A decay analysis will also reveal how many added steps it takes to collapse individual nodes and which specific characters influence those nodes. This in turn allows a test whether a set of functionally correlated characters influences a particular node.

Hennigian analysis of a data set may produce more than one tree with the same number of fewest possible steps, a phenomenon known as *multiple most parsimonious trees*. With a large number of taxa and characters, especially if they contain large amounts of homoplasy or missing data, parsimony frequently generates multiple MPTs. In these cases, it is not possible to designate a single preferred tree; however, it is possible to generate a variety of *consensus trees* to delineate similarities in topologies of different MPTs (Adams 1972). Consensus techniques are useful as visual summaries of points of agreement or logical consistency between MPTs, but they are not phylogenies, and they are not equivalent to what is produced by phylogenetic analysis of a data matrix.

Bootstrap and *jackknife* analyses attempt to estimate the degree of sampling error in the original data set, by attempting to place confidence intervals on phylogenies by making inferences about the variability in the data set. Bootstrapping (Felsenstein 1985a) samples the data set with replacement; that is, it allows for some characters to be sampled more than once, and for some not to be included at all, and constructs a new data set with the same number of characters. PAUP* (Swofford 1998) and other programs construct a series of these and build a majority-rule consensus tree that summarizes the results of the resampled data. The number of times a particular group is included in the set of trees that form the consensus is an estimate of the reality of that group in that the process has measured the amount of variation between the newly sampled data sets. The bootstrap is, then, a measure of the confidence placed in each node of the tree, like the decay index. Felsenstein (1985a) suggested that a bootstrap value of 95 % or greater offers statistically significant support for a clade.

There are a number of caveats to consider before placing too much faith in the numbers generated by this analysis. Since the bootstrap measures the variation in one set of data, it cannot be used to compare trees built from different data sets. Felsenstein (1985a) stipulated that a bootstrap assumes characters are independent and equally distributed. He was explicit that the bootstrap indicates *repeatability* of an analysis given the data and should not imply the phylogenetic *accuracy* of a tree. It may also be affected by biases such as long-branch attraction (Swofford 1998).

The *jackknife* is another mode of evaluation, similar to the bootstrap in that it estimates variability in the data set. It is a procedure to resample data by deleting a certain number of characters [either half (Felsenstein 1985a) or another fraction (Farris et al. 1996)] and resampling the data without allowing characters to be duplicated. Characters are randomly and independently deleted from the original matrix to create a new “resampled” matrix, and like the bootstrap, many matrices are produced and the results are compiled into a consensus tree.

Ontological Parsimony: Maximum Likelihood and Bayesian Likelihood Approaches

A Precis of Maximum Likelihood in Phylogenetics

Microbiology made significant progress in the late 1950s when the first proteins were sequenced. Molecular data were soon recognized to be an important source of phylogenetic information useful in inferring evolutionary relationships (Sneath and Sokal 1973; Neyman 1974). Edwards and Cavalli-Sforza (1963) first explored the idea that likelihood could be applied to phylogeny reconstruction. Cavalli-Sforza and Edwards (1967) later described a likelihood method for phylogenetic inference using blood-group allele frequency data in human populations. Neyman (1974) was the first to apply likelihood analysis to nucleotide sequences and presciently suggested that this approach might become important in the future. Farris (1973) and Felsenstein (1973) published likelihood algorithms for phylogeny reconstruction; however, computational problems continued to limit a likelihood method for phylogenetic inference to the theoretical rather than practically operational. Felsenstein (1981) introduced the first computationally efficient maximum likelihood algorithm for discrete character nucleotide sequence data. Just as the Wagner algorithm became the algorithm of choice for quantitative Hennigian analyses, nearly all phylogenetic applications of maximum likelihood are adapted from Felsenstein's early work. Since then, maximum likelihood methods have become increasingly popular in phylogenetic studies (Swofford et al. 1996; Huelsenbeck and Crandall 1997; Felsenstein 2004). These approaches are most commonly used in molecular phylogenetics (Swofford et al. 1996; Huelsenbeck and Crandall 1997; Huelsenbeck et al. 2002; Ronquist 2004), but morphology-based and combined likelihood and Bayesian methods are becoming more widely used (Lewis 2001; Ronquist 2004; O'Leary and Gatesy 2008; Wiens 2009; Wiens et al. 2010). Probably due to the relative ease of acquiring molecular sequence data, molecular phylogenies have been published at a far greater rate in recent years than phylogenies based on morphological data. However, morphological characters remain the only source of data for virtually all extinct taxa.

Likelihood Methods

Several methods for inferring phylogenies from nucleotide sequence data are available, resulting in an often-heated debate among evolutionary biologists over the "best" way to approach phylogeny reconstruction (Goldman 1990; Penny et al. 1992; Swofford et al. 1996; Huelsenbeck and Crandall 1997; Steel and Penny 2000). Maximum likelihood methods evaluate a hypothesis of evolutionary relationships using a presumed model of the evolutionary process and evaluate the probability that it would give rise to the observed data, which are typically DNA sequences of the terminal taxa (Felsenstein 1973, 1981, 2004; Swofford et al. 1996; Huelsenbeck and Crandall 1997). Phylogenetic-likelihood approaches use maximum average likelihood, a form of maximum relative likelihood (except Farris 1973, which adopted evolutionary pathway likelihood), and only this form applies to the discussion below (Steel and Penny 2000).

The likelihood of a hypothesis (Fisher 1922) is the probability, P, of the data (D), given the hypothesis (H):

$$L = P(H|D)$$

The likelihood of a parameter is proportional to the probability of the data, and it gives a function that usually, but not always, has a single maximum value, which Fisher called the maximum likelihood. The likelihood equation above the hypothesis, which is assumed to be true in the likelihood formulation above.

Likelihoods are calculated for different possible tree topologies, given the data and assuming a particular model of molecular evolution (Felsenstein 1973, 1981, 2004; Swofford et al. 1996). In the likelihood equation above the hypothesis, H, contains three distinct parts: (1) a mechanism or model of sequence evolution, (2) a tree or a hypothesis of relationships, and (3) branch lengths (Penny et al. 1992). For a given data set, likelihoods are calculated for each of the possible tree topologies or a sample of them, and the tree topology with the highest overall likelihood is the preferred phylogenetic hypothesis. The number of possible tree topologies increases with the number of terminal taxa included in the analysis. This can be computationally laborious if the data set is large and especially if the maximum likelihood model uses rooted trees in its calculus. However, the most general and most commonly used models in molecular analyses are time reversible (Rodriguez et al. 1990; Swofford et al. 1996). With a time-reversible model, the probability of character state change from state *i* to state *j* is the same as the probability of state change from state *j* to state *i* (Felsenstein 1981). Under this condition, the likelihood of the tree does not depend on the position of the root, and the use of unrooted networks greatly reduces the total number of trees to be evaluated and decreases computation time (Rodriguez et al. 1990; Swofford et al. 1996). For a detailed discussion of likelihood methods, see Felsenstein (2004).

Models of Molecular Evolution

Models in likelihood phylogenetics are tools that aid in the estimation of tree topology (Kelchner and Thomas 2007). Likelihood analyses involve similar assumptions about the evolutionary process as other methods, including that evolution occurs in a branching pattern and is independent in different lineages (Swofford et al. 1996). The probability of a particular combination of character states at the internal nodes of the unrooted network is calculated using a specified model of molecular evolution, which requires further assumptions about the nucleotide substitution process, including that sequence evolution can be modeled as a random, or stochastic, process (Rodriguez et al. 1990). Substitution models are typically based on a homogeneous Markov process (Rodriguez et al. 1990;

Swofford et al. 1996) that assumes that the probability of a state change at one site does not depend on the history of that site and that probabilities of substitution do not change significantly in different parts of the tree (Felsenstein 1981, 2004; Swofford et al. 1996).

Models employed in likelihood analyses make explicit assumptions regarding sequence evolution, the number of which depends on the particular model of sequence evolution used in the particular analysis (Swofford et al. 1996). The simplest model, Jukes-Cantor, assumes that all base substitutions are equally likely (i.e., all rate parameters are equal) and that the base frequency parameters are equal. The general time-reversible model (GTR) is the most general stochastic model of nucleotide substitution and is the model most frequently used in the phylogenetic literature (Kelchner and Thomas 2007). It models base substitution as a random Markov process in which substitution rates are independent among sites, constant in time, and equal in two lineages and the ancestral sequence base frequencies represent the equilibrium frequencies (Rodriguez et al. 1990). The GTR model has a maximum of 12 different substitution rates (estimated from the data and using the aforementioned assumptions in their calculus) and at least seven parameters (Rodriguez et al. 1990). Because of its greater complexity, nearly all models can be considered special cases of the GTR model when it is restricted accordingly (Rodriguez et al. 1990).

Characters and their associated probabilities are not independent quantities but are assumed to be in the calculus of the method (Felsenstein 1973, 1981; Rodriguez et al. 1990; Swofford et al. 1996). The non-independence of site change probabilities may be one factor responsible for the fact that the total likelihood of the universe of possible trees does not sum to unity (Felsenstein 1981). The true probabilities for character changes should be calculated on an individual basis, because they are connected with unique and historically contingent events (see below) as pointed out by Farris (1973). But this is clearly impossible, as it not only requires knowledge of the true history before undertaking an analysis, it also requires an objective and consistent way of determining the probability of a novel, context-specific evolutionary event (see below, Farris 1973). It would also be computationally impossible (Felsenstein 1973, 1981; Siddall and Kluge 1997). As currently and commonly employed in phylogenetic maximum likelihood methods, frequency probability theory is technically violated (Yang 1996; Siddall and Kluge 1997).

Choosing a Model: More Ontological Parsimony

The choice of an appropriate model is a critical aspect of a phylogenetic-likelihood analysis. Posada and Crandall (1998) argued that the use of their ModelTest program makes selection of the model objective. There are many models of molecular evolution, and the determination of which to use can significantly influence the results of an analysis. Models range in complexity from the relatively simple Jukes-Cantor model through the most complex GTR model. The overall likelihood score of a tree increases with increasing complexity of the model, but the accuracy of the model decreases due to the increased number of estimated parameters (Huelsenbeck and Rannala 1997a). The program conducts pairwise comparison of the maximum likelihood trees generated under each model using hierarchical-likelihood ratio tests (Huelsenbeck and Crandall 1997; Huelsenbeck and Rannala 1997a; Posada and Crandall 1998). When no statistically significant difference between two trees is found, the simplest model is selected. Model selection based on the *relative* likelihood values is an ontological appeal to the principle of parsimony, because choosing the least complex explanation of the data rules out the possibility that evolution proceeded in a more complex manner (Huelsenbeck and Rannala 1997a).

Criticisms of the Models

Many criticisms of maximum likelihood methods are directed at this a priori dependence on a model. Evolutionary realism of the models employed in likelihood analyses is often compromised by approximations that are designed to improve the computational efficiency of the algorithms. For example, Lockhart et al. (1994) suggested that a modified GTR model, in which time reversibility is relaxed, across site rate variation is considered and the nucleotide compositional frequencies are flexible, allow more evolutionary “freedom” than any other model, and best consider the historical ambiguity and contingency of the evolutionary process. They suggested that this complex, parameter-rich, and computationally intensive model should be logically preferred over all other models, if inferring phylogeny using the most realistic conception of evolution (i.e., evolution is complex) is the goal of the analysis. The problem is that relaxing the time-reversibility assumption introduces the need for rooted trees and is accompanied by additional computational problems (Swofford et al. 1996). Relaxing the assumption that rates are equal across all sites can be accomplished by adding another relative rate parameter to the matrix, which commonly involves modeling rate heterogeneity using the gamma distribution (Swofford et al. 1996). If this distribution is modeled as continuous (as it should be), it again becomes computationally laborious, and a discrete distribution typically serves as a computationally more efficient approximation (Swofford et al. 1996).

The likelihood method also requires that numerous parameters be approximated using the data and relies heavily on the frequency parameters that are taken directly from the observed sequences (Swofford et al. 1996). In this sense, likelihood methods assume that the processes that maintain systems today were persistent throughout the entire evolutionary history of the clade being investigated (Brooks and McLennan 2002). Siddall and Kluge (1997) and Lockhart et al. (1994) provide an empirical example where the nucleotide frequencies are very different across the terminal taxa, proving that the assumption of equilibrium base frequencies is not at all tenable and that the assumption of such can affect likelihood phylogenies. When the model is insufficient or inappropriate, appeals to statistical consistency are rendered moot (Siddall and Kluge 1997).

Criticisms of the Method

Phylogenetic applications of likelihood rely on two fundamental assumptions that evolution is independent in different lineages as well as independent in different sites for a given tree, which are essential for the probability calculations on which the method is based (Felsenstein 1981, 2004; Rodriguez et al. 1990; Swofford et al. 1996). Both assumptions are methodologically problematic because they are unrealistic and/or violated in the calculus (Siddall and Kluge 1997; Huelsenbeck and Nielsen 1999), but likelihoodists appeal to simulations to argue that the method is generally robust to violations of these assumptions (Yang 1994; Swofford et al. 1996). It is also assumed that the same stochastic process of substitution applies in all lineages (Felsenstein 1981).

Many researchers advocate a model-based maximum likelihood approach (Felsenstein 1978, 1981, 2004; Goldman 1990; Penny et al. 1992; Yang 1996; Huelsenbeck and Rannala 1997a; de Queiroz and Poe 2003). Others (Siddall and Kluge 1997; Kluge 2001; Goloboff 2003) cite operational and philosophical problems of likelihood methods and discourage its use in phylogenetic inference.

Likelihood methods rely on a specified model of sequence evolution to infer phylogenetic relationships. This is an inductive approach, as the assumptions of the model are clearly deterministic to the result of the analysis. In phylogenetic-likelihood analyses, like all inductive approaches in science, all interpretations of the results come with the caveat "if the model is true, then. . .." Because likelihood is inductive estimation of phylogeny, particular caution must be taken in interpreting the results and to avoid circularity. ModelTest reveals which of the models best fit the data, but how can the validity of the model itself be independently tested? Testing of the validity of models, although it has been recognized as important (Goldman 1990), is rarely done in practice (Siddall and Kluge 1997). In a hypothetico-deductive framework, the assumptions of the method are background and not deterministic to the result. Only the observable data is considered, maximizing the explanatory power of the hypothesis and minimizing ad hoc hypotheses (i.e., hypotheses that confide in "nonobservables," such as long branches in a likelihood framework). It has been argued that many of the simple assumptions of the evolutionary models (i.e., the frequency of transitions versus transversions) constitute grounded knowledge about the process of molecular evolution and therefore is an acceptable background assumption. However, the maximum likelihood approach suggests that this is and has always been the case throughout the evolutionary history of a group, which is a problematic assertion with respect to the historically contingent nature of the evolutionary process (Siddall and Kluge 1997).

Likelihood methods are based on frequency probability theory. Frequency probability is concerned with prediction of future events (Fisher 1922). The aim of phylogenetic systematics is to discover the unique evolutionary history of a group of organisms or to elucidate its past (Kluge 1997). A species must be considered a historical entity (Kluge 1990), and evolutionary transformations are unique and spatiotemporally restricted historical events (Siddall and Kluge 1997). Frequency-probability-based methods of phylogenetic inference, such as maximum likelihood, apply frequency probability to a *historical singularity*, which is outside of the realm of future-predictive probability theory (Siddall and Kluge 1997). As noted above, likelihood methods assign all trees a nonzero probability, but in reality one tree has a probability of 1.0, and others have a probability of zero. One must be cognizant that maximum likelihood inference of phylogenies is philosophically unsound because it employs frequency probability theory to estimate a nonprobabilistic phenomenon.

Bayesian Likelihood

In spite of these numerous criticisms, most molecular phylogeneticists prefer likelihood approaches because sequence evolution can be explicitly incorporated into the analysis. One of the more popular iterations of likelihood is Bayesian analysis (Huelsenbeck et al. 2002).

Bayesian methods calculate the posterior probabilities of phylogenetic hypotheses (trees) using a version of Bayes' theorem in which the likelihood of the tree and the prior probability of the tree are considered (Huelsenbeck et al. 2002). Huelsenbeck et al. (2001, 2002) provide an excellent review of the history and mechanics of Bayesian inference methods in phylogeny.

Reverend Thomas Bayes, living in the early half of the eighteenth century, was an English mathematician who was interested in the concept of using a priori knowledge to predict future events. His paper, "An Essay Towards Solving a Problem in the Doctrine of Chances," published 2 years after Bayes' death in 1761, introduced what would become known as Bayes' theorem (Barnard and Bayes 1958).

$$P(H|D) = \frac{P(D|H)xP(H)}{P(D)}$$

The posterior probability [P(H|D)] is the probability of the hypothesis given the observations or data (D). Note that this is different from likelihood, which is the probability of the data given the hypothesis. However, the likelihood, P(D|H), is a parameter in the calculation of the posterior probability. P(H) is the *prior* probability of the hypothesis before the observation, data, or analysis and reflects the original beliefs regarding the problem. The probability of the hypothesis is updated to take into account the observations, and Bayes' theorem describes the relationship between the prior and posterior probabilities. It was not until the latter half of the twentieth century that Bayes' ideas would be applied to the inference of phylogenies. Felsenstein (1968) briefly discussed Bayesian ideas as they could apply to phylogeny reconstruction in his Ph.D. thesis, but the statistical and computational framework with which to derive reliable approximations of posterior probabilities was not available at the time (Huelsenbeck et al. 2002). In 1996, three independent groups introduced Bayesian methods similar to those currently in use (Li 1996;

Mau 1996). Bayesian methods to estimate ancestral character states have also been developed (Pagel et al. 2004; Ronquist 2004).

Bayesian phylogenetic inference evaluates phylogenetic hypotheses with the posterior probabilities of trees. The posterior probability of each tree is calculated using the following Bayes-based equation, where the tree topology (including branch lengths) is the hypothesis, and the data are typically molecular sequences of the terminal taxa in the analysis.

$$P(Tree|Data) = \frac{P(Data|Tree)xP(Tree)}{P(Data)}$$

The likelihood parameter, P(Data|Tree), is calculated using the same general methodology and same models of molecular evolution described above for the maximum likelihood approach. However, one major difference between Bayesian and maximum likelihood methods is that Bayesian likelihood calculation not only involves summation over all possible combinations of model parameters and branch lengths but also includes a prior probability density distribution of these latter variables (Huelsenbeck et al. 2002). The prior probability of the tree, P(Tree), is usually considered to be equal for all trees a priori (Huelsenbeck et al. 2001). The use of equal priors implies that no particular topology is preferred over any other a priori and eliminates the sometimes difficult task of calculation of complex priors when hypotheses vary with respect to their preconceived probabilities. However, the prior for any given tree or set of trees can be set to reflect researcher experience, the results of previous analyses, or taxonomy (Huelsenbeck et al. 2002). The denominator, simplified here as P(Data), is a normalizing factor that involves summation over all trees (Huelsenbeck et al. 2002). The posterior probability, P(Tree|Data), can be viewed simply as the probability that the tree is “correct,” *given* the data and the priors, and that the model of character change used in the likelihood calculation is correct (Huelsenbeck et al. 2002). There are several ways to present the results of a Bayesian analysis. The tree with the maximum posterior probability can be selected as the preferred phylogenetic hypothesis; this is also known as the MAP, maximum a posteriori, estimation of phylogeny (Huelsenbeck et al. 2002). Another method is to construct a 95 % credibility consensus tree by starting with the MAP and consecutively adding the next most probable trees until the probabilities total 0.95 (Huelsenbeck et al. 2001, 2002). The method preferred by Huelsenbeck et al. (2002) is to present a summary of the results on the MAP or another consensus tree, as is typically done with bootstrap.

Calculation of the posterior probability of a tree is computationally expensive, because it involves summation over all possible trees, and for each tree requires integration over all possible permutations of branch lengths and substitution-model parameters (Huelsenbeck et al. 2001, 2002). This is not possible in most practical applications due to computational and time constraints and requires that posterior probabilities be approximated (Huelsenbeck et al. 2002). Markov chain Monte Carlo (MCMC) methods are used to approximate the posterior probabilities of trees and allow contemporary Bayesian methods to be computationally feasible

(Huelsenbeck et al. 2001, 2002). The MCMC method is used to sample the posterior probability distribution of trees. The application of the MCMC to phylogeny inference is summarized in Huelsenbeck et al. (2001, 2002) and Pagel et al. (2004). The general process of MCMC, which is used to approximate the posterior probability density, is as follows. First, a random tree is selected. Second, another tree is proposed by changing one variable of the original tree (e.g., topology, branch length, model parameters, etc.), and the two trees are compared using the Metropolis-Hastings algorithm (Metropolis et al. 1953; Hastings 1970; Huelsenbeck et al. 2002). If the tree represents an improvement, it is accepted or sampled. If not, the tree is either accepted or rejected proportional to the likelihood ratio between it and the previous tree (Pagel et al. 2004). The chain stabilizes after a sufficient period of run time (called the "burn-in"). Once stable, the chain randomly walks through the universe of trees, sampling each tree in proportion to its frequency in the actual posterior density (Pagel et al. 2004). The longer the chain is run, the greater precision with which the actual posterior distribution of trees is approximated (Pagel et al. 2004). Metropolis-coupled MCMC uses multiple, simultaneous Markov chains, improves mixing and convergence, and allows exceedingly large data sets that are beyond the scope of conventional single-chain MCMC Bayesian methods to be analyzed (Huelsenbeck et al. 2001, 2002).

Advantages of Bayesian Likelihood

A major advantage of the Bayesian method is the ease with which posterior probabilities can be interpreted (Huelsenbeck et al. 2002). Under the assumption that the evolutionary model is true and that the MCMC has accurately sampled the posterior probability distribution, the posterior probability value represents the probability that the tree is correct given the data and the priors. Similarly, the proportion of trees in the MCMC sample in which a monophyletic group appears represents the probability that the clade is "true," given the caveats of priors, model, and data.

As in maximum likelihood analyses, the result of the Bayesian analysis is dependent on the model of sequence evolution being "correct" (Kelchner and Thomas 2007). Bayesian approaches to phylogeny require a likelihood value of a given tree topology for their calculation of the posterior probability of that evolutionary scenario. The likelihood parameter in the Bayesian method uses the same models and their associated assumptions as the maximum likelihood methods described above, and the caveats inherent in maximum likelihood phylogeny estimation with respect to evolutionary models also apply to Bayesian analysis (see above discussion of likelihood criticisms).

Some view it as an advantage that Bayesian analysis requires the incorporation of previous knowledge or beliefs in terms of prior probabilities. The mechanics of formulating priors can be difficult if one chooses to base these on the results of previous analyses or taxonomy ("complex priors," Huelsenbeck et al. 2002). Making the prior probabilities of each tree equal eliminates the use of complex priors, as well as any a priori assumptions that any hypothesis is more probable than any other in light of prior beliefs; clearly this approach is not in the true Bayesian spirit.

Criticisms of Bayesian Likelihood

Bayesian approaches to phylogeny require a likelihood value of a given tree topology (i.e., phylogenetic hypothesis) for their calculation of the posterior probability of that evolutionary scenario. The likelihood used in the Bayesian method requires the same models and their associated assumptions as the maximum likelihood methods described above, and thus all of the cautions inherent in maximum likelihood phylogeny estimation also apply to Bayesian analysis (see above discussion of likelihood criticisms). Analogous to likelihood, the posterior probability of a tree involves summation over all possible trees, including all their possible permutations in terms of branch lengths and substitution-model parameters (Huelsenbeck et al. 2002). This is impossible to perform in most practical applications due to computational and time constraints and requires that posterior probabilities themselves must by necessity be approximated. Additionally, Bayesian methods require further assumptions about the prior probabilities associated with each tree. Making the prior probabilities of each tree equal minimizes any a priori assumptions that any topology is more probable than any other.

Harper (1979) had considerable foresight in devising a Bayesian framework aimed toward constructing and testing phylogenetic hypotheses, although this method was largely conceptual and significantly differs from the current practice of Bayesian inference in phylogeny. Likewise, Brooks et al. (1986) proposed the D-measure, based on the statistical entropy calculations in information theory. Tribus and McIrvine (1971) suggested that van der Waals proposed the first link of Bayesian reasoning to statistical concepts of entropy in 1911, when he suggested that the highest entropy state for a system was its a priori most probable state. Lewis (1930) subsequently suggested that increases in entropy were associated with losses of information, and Shannon (1948) used the statistical formulation of entropy as a synonym for expected uncertainty as a foundation of information theory. Kullbach (1951) reinforced the link between information theory and Bayesian reasoning by using the term surprisal (first introduced by R. Levine) as an indicator of departure from the most probable/most expected state. Brillouin (1962) showed that there was consistency between Shannon's use of entropy in information theory and the use of entropy in statistical mechanics and probability theory. Jaynes (1957a, b) derived the formal relationship underlying this consistency and proposed the first entropy maximization principle, in which the maximum entropy state of a system could be formally construed as the most probable state.

Gatlin (1975) added to this conceptual framework by discussing two forms of redundancy in the context of biological (specifically DNA sequence) evolution. R-redundancy results from the repeated occurrence of the same symbol in order to get a message across. This is one way to ensure proper communication of a message, but since each symbol must be repeated, R-redundancy is also associated with reduced message variety. D-redundancy, or Shannon redundancy, results when a single symbol appearing once always subsequently stands for the same thing. D-redundancy is associated with increased message variety, since no symbol need be repeated and thus a larger number of possible messages could be transmitted using the same number of symbols than for situations in which some symbols were repeated. This state may also be associated with reduced message fidelity, however, since missing the symbol initially results in a loss of information subsequently, without hope of a recurrence of the symbol. Gatlin associated D-redundancy with optimal coding in communication systems. Finally, R-redundancy is associated with low information density per symbol (each symbol represents only itself) and D-redundancy with high information density per symbol (each symbol represents many observations).

Brooks (1981) first showed that phylogenetic systematics operationally produced the lowest possible informational entropy configuration for a set of observations over a given set of taxa. This corresponds to the state of greatest difference between H_{max} and H_{obs}, or the configuration closest to H_{min} possible given the data. Brooks et al. (1986) later proposed an informal link between this and Gatlin's D-redundancy, proposing the so-called D-measure for choosing optimal phylogenetic trees on the basis of maximum information density.

Neither Brooks (1981) nor Brooks et al. (1986) related these discussions explicitly to Bayesian reasoning, but there is a clear connection. Following Jaynes (1957a, b), Bayesian approaches in information theory are thus those for which the a priori subjective hypothesis is determined by the entropy maximum principle – the a priori most probable result is the H_{max}, in direct analogy is with the maximum entropy state being the most probable for a closed system. This analogy works in a Bayesian framework if the set of observations used in any analysis is a closed subset of all possibilities, i.e., the estimate of H_{max} is based on a subjective subsample of an imperfectly known universe of characters, and no additional observations are introduced during the testing procedure.

The entropy maximum is not only analogous to the a priori expected *most probable* state; it is also the state of lowest *information density* of the observations, hence least informative, hence least surprising (in a Bayesian sense). For any set of observations (subjective in the sense that they are a subjectively selected subset of all observations, drawn from a universe for which the actual size or distribution of variables are unknown – even if the observations are obtained objectively), the most probable state (H_{max}) can be computed. (H_{min}) can be computed to the least probable state, which is the state of greatest information density for the observations and thus the state of greatest surprise.

The most powerful analysis of such data is one that seeks to find the most improbable/highest information density configuration permitted by all the data at hand. For phylogenetic analysis, H_{max} and H_{min} can be calculated from the basic data matrix (hence, H_{max} is a priori), whereas H_{obs} is calculated over a set of trees (hence, it is a posteriori). The preferred result is the one in which H_{obs} approaches H_{min} as closely as possible.

Applying the D-measure leads to a number of conclusions for phylogenetics analysis (Brooks et al. 1986): (1) information density is proportional to evolutionary conservatism; (2) dichotomous solutions are preferred over polytomies, as each instance of conservative evolution increases information density; (3) branching topology is irrelevant, and there is no a priori difference between symmetrical and asymmetrical tree structure in terms of information density, since it is the information that produces the tree, not the reverse; (4) for any data set, the most information-dense set of relationships of all taxa over all characters allowed by the data is the shortest tree; and (5) when there are multiple most parsimonious trees, ACCTRAN provides a more information-dense summary of the data than DELTRAN.

This version of Bayesian thought applied to phylogenetics, therefore, devolves to straightforward support for Hennigian methods. Missing from this formalism are statistical significance tests. There need to be two of them: first, is the result significantly different from the a priori expectation ($H_{\max}$), and second, are less information-dense alternatives (e.g., other equally parsimonious trees or less than most parsimonious trees) for the same set of data significantly different from each other?

How to Decide What Method(s) to Use

There are no objective means by which one can choose among these methods. Consequently, it is no surprise that some of the most contentious interactions among phylogeneticists concern the very subjective issue of which methods are best. It is common for groups of contending scientists, faced with such a situation, to resort to philosophical arguments in an attempt to claim priority for one viewpoint over another on the basis of some set of first principles. This has certainly been the case with phylogenetics.

Popper

The first salvo fired in this conflict was by Wiley (1975), who, in defending phylogenetic systematics against claims that it was not falsifiable, proposed that phylogenetic hypotheses of homology could be seen as an exercise in hypothetico-deductive reasoning.

> Once a hypothesis of homology is formulated from the world of experience, it is tested in two phases: by its own set of potential falsifiers and by a set of potential falsifiers of the phylogenetic hypothesis to which it belongs as a proper subset (i.e., it is tested by other hypotheses of synapomorphy through the testing of the phylogenetic hypotheses which they corroborate). Both phases of testing must be done under the rules of parsimony, not because nature is parsimonious, but because only parsimonious hypotheses can be defended by the investigator without resorting to authoritarianism or apriorism. (Wiley 1975, p. 236)

Hypotheses of homology, together with their connected hypothesis of phylogenetic relationships, can be tested by other independently proposed homologies, which then represent the so-called potential falsifying hypotheses (Popper 1968, p. 87). Wiley emphasized that such a process is not circular, but represents a case of "reciprocal illumination," something Hennig (1966) also claimed. Wiley noted that the preferred phylogenetic hypothesis is the one that has been refuted the least number of times. That Hennigian phylogenetics was justified by the hypothetico-deductive approach of Popper quickly gained support and still has strong adherents (Kluge 2003) who consider Hennigian phylogenetics to be strongly deductive in nature.

De Queiroz and Poe (2001) attempted to link Popperian thought with likelihood approaches, suggesting that likelihood is the basis for Popper's degree of corroboration. However, for Popper, corroboration was embedded in a falsificationist context, whereas these authors sought to decouple Popper's ideas about corroboration from those about falsificationism. In this context their degree of corroboration is identical with Popper's formalization of degree of confirmation (Popper 1997, p. 222). This merely leads back to the position that if a model is accepted as true or highly typical, its use is justified. But no objective means is provided for verifying or falsifying the validity of the model beyond the arguments about statistical consistency, which has shortcomings discussed below. Regardless of semantic arguments about corroboration and confirmation and possibly a high degree of revisionist interpretation of Popper's views on the relationship between corroboration and falsification, these arguments do not counter the basic observation that maximum likelihood methods are more inductive than deductive in nature. And, if the difference between the epistemological and the ontological parsimony approaches is the difference between a preference for deduction and a preference for induction, the history of science shows that there is no objective means for choosing between them.

However popular it has been among some systematists, this battle of philosophical perspectives has been subject to extensive criticism by philosophers, best summed up by Sober (1988), who identified phylogenetic analysis as abductive, that is, neither exactly deductive nor exactly inductive. This is explained by the fact that the phylogenetic inference is a retrodictive analysis of historically unique events. Among other things, this means that inference from effects to cause(s) is ampliative. Systematists only observe the effects under the causal theory of descent with modification (i.e., observable synapomorphies), but possible causes for conflicting data are also reversals and parallelisms. Thus, multiple conclusions about the cause(s) are possible in phylogenetic inference. By contrast, true deduction is nonampliative, enabling inferences from cause to effect(s), with singular conclusions for any given analysis.

Statistical Consistency

A method is said to be statistically consistent if it converges on the true tree as progressively more data are added to the analysis. One reason likelihood has gained popularity in the last two decades is that it has been suggested that other methods of phylogenetic inference, namely, Hennigian parsimony, are statistically inconsistent under certain, largely hypothetical models of evolution (Felsenstein 1978; Penny et al. 1992). The region of statistical inconsistency has been referred to as the "Felsenstein Zone," and it is the result of a process termed "long-branch attraction." The long-branch attraction problem occurs when convergent homoplastic changes are more frequent than nonreversed changes in an informative part of the tree (Felsenstein 1978). This confounds Hennigian phylogenetic systematics because, under the Auxiliary Principle, the convergent homoplasies will tend to be considered as homologies and thus the taxa with their convergent "long branches" will be grouped together (Hennig 1966; Felsenstein 1978). In simplest terms, when the *data are lying* about the relationships of the taxa, phylogenetic systematics (i.e., Hennig 1966) may fail to discover the true relationships. How often this occurs in nature is unknown, but Huelsenbeck (1997) has cited one case involving insects as exemplifying the long-branch attraction problem in a real data set (but see Siddall and Kluge 1997, pp. 319–320). The concern that "noise" or random data misdirects phylogenetic systematics is also overblown (Wenzel and Siddall 1999).

Maximum likelihood has been reported to exhibit the favorable property of statistical consistency in these situations (Felsenstein 1978; Penny et al. 1992; Yang 1994). It is true that in statistics the maximum likelihood estimate of a parameter is consistent (Fisher 1922; Edwards 1972). Simulation experiments have shown this to be true in phylogenetic context (Yang 1996), but *only* when the same random model used to generate the data is used and/or only when a certain correction factor is implemented (Steel et al. 1993; Siddall and Kluge 1997; Steel and Penny 2000; Goloboff 2003). It is an important caveat that maximum likelihood methods are only consistent (i.e., converge on the "true tree") under a certain set of circumstances which typically requires that the "correct" model is used but that the correct model and the true tree are both unknowable for real systems.

Farris (1973) suggested a protocol by which parsimony methods could be interpreted as derivatives of statistical estimation methods. This probabilistic view of parsimony was critiqued by Felsenstein (1973, 1978, 1981, 1983), who focused on the statistical deficits of parsimony when viewed as a likelihood method. In general, parsimony and likelihood approaches produce the same results under the assumption of particular parameters for parsimony, i.e., low rates of evolutionary changes or equal rates of evolution among the observed lineages or low rates of homoplasy (Felsenstein 1983). It has also been demonstrated that parsimony-based methods can be consistent (Steel et al. 1993; Siddall and Kluge 1997; Steel and Penny 2000, with a correction factor). Siddall and Kluge (1997) and Steel and Penny (2000) correctly point out that all methods are potentially consistent or inconsistent (Steel et al. 1993). Statistical consistency is not a property of a method, but the property of a specific data set, the model, and specific situations.

Likelihood methods generally require that the processes maintaining current systems were always present and consistent in the past, and this is likely not the case. Models range from relatively simple to complex, but all make approximations for computational efficiency that impair evolutionary realism. When the model is insufficient or inappropriate, as is common, arguments of statistical consistency are rendered moot. As noted earlier, frequency probability theory is violated in the calculus of current maximum likelihood methods (due to violation of independence requirements). Maximum likelihood uses a method intended to predict the future out of a range of simultaneously possible outcomes to infer a nonprobabilistic historical singularity, the evolutionary relationship of organisms.

It appears that neither epistemological nor ontological parsimony methods for inferring phylogenies can be justified, or given precedence over the other, by any part of Popper's philosophy. Nor can either approach be given priority by appeals to statistical consistency. And, finally, each approach can be given a Bayesian interpretation. Is there an objective way to choose between or to reconcile these subjectively divergent approaches?

An appeal to collegial pluralism seems like a good idea at first glance. It is becoming a common practice for an author to present maximum parsimony, maximum likelihood, and Bayesian analyses of the same data set. There is increasing evidence that in many cases both parsimony- and likelihood-based approaches reach the same topology (Rindal and Brower 2011). In a study of 1,000 papers published between 2007 and 2009 in the journal *Molecular Phylogenetics and Evolution*, Rindal and Brower (2011) found that there was strong incongruence between the results of parsimony and likelihood analyses in only 2 out of 504 studies that used multiple methods; in 502 of 504 studies, maximum parsimony and likelihood approaches yielded the same results. Similarly, Wiley and Lieberman (2011) showed that Bayesian and parsimony analysis of the same data produced the same results. Although the "true" evolutionary history of a clade is unknowable, these results suggest that with the inclusion of sufficient data (morphological characters or genetic sequences), different phylogenetic methods converge on the same results. Rindal and Brower (2011) "encourage the use of analytical approaches unencumbered by ad hoc assumptions that sap the explanatory power of the evidence."

Individual data analyses without reference to an explicit evolutionary model or hypothesis (i.e., epistemological parsimony) are not explanations. They are descriptions, admittedly highly sophisticated descriptions, but just that. Fitting data to a model provides explanations, but does not give any means of testing the veracity of the model or its assumptions. Independent description and assessment relative to explanatory models both appear to be necessary but not sufficient for robust explanations. Or, if models do not agree with the empirical data, chances are the models, not the data, should be reevaluated. This is not an antimodel stance. A mutually reinforcing and mutually modifying dialogue between models and empirical discovery enhances progress.

Kluge (1991, 1997, 1999) has argued persuasively that historical sciences progress through cycles of discovery and evaluation, both of which are necessary but neither of which is sufficient for complete understanding and both of which require objective methods of study. Hennigian (epistemological parsimony) analysis is the best discovery method in phylogenetics. This is because its results are dependent on a minimum of a priori assumptions, and thus the range of potential discoveries indicated by the data is greater than for any ontological parsimony approach. At the same time, this feature of Hennigian phylogenetics renders it relatively weak as an instrument of evaluation.

It appears that the various maximum likelihood and Bayesian likelihood approaches are admirably suited as evaluation methods. Epistemological and ontological parsimony methods can be used together in a form of reciprocal illumination, not in the narrow sense of deriving a tree from multiple characters, but in a broader sense of cycles of discovery and evaluation. How would this work?

To begin with, suppose a Hennigian analysis, a maximum likelihood analysis, and a Bayesian analysis produce the same result. This suggests that a relatively independent discovery (the Hennigian tree) supports an evolutionary model (the likelihood tree). In this case, no one should have any concerns using the likelihood model to infer divergence rates on the Hennigian tree. Now, what does it mean if these different analyses do not produce the same result? The findings by Rokas et al. (2003) suggest that all such situations are an indication that not enough data have been used. Their total-genome (107 gene sequences) analysis of a clade of 7 yeast species showed that a minimum of 20 genes (i.e., roughly 20 % of the genic characters possible) was required to ensure that all methods produced the same phylogenetic tree. Different methods gave different results when not enough characters were used to compensate for ambiguities of various kinds in the data, which are handled in different ways by the different methods discussed in this chapter. These results were anticipated experimentally by Hillis et al. (1992, 1993; Huelsenbeck and Hillis 1993), who produced a phylogeny for bacteriophages maintained in the laboratory. They discovered that most model-based approaches and Hennigian phylogenetics converged on the same and true (since it was known) phylogeny as more and more traits were sampled. These results would seem to suggest that the primary response to any situation in which the different approaches to phylogenetics produce different answers should be

> . . . When in doubt, get more data. (Brooks and McLennan (2002, p. 148))

What should systematists do while waiting for enough data to give the same answer with all methods? Hillis et al. (1992, 1993; Huelsenbeck and Hillis 1993) showed that when a limited quantity of data is available, some models generate the correct phylogeny better than Hennigian approaches. Although this finding has been interpreted by some as an indication that model-based methods are inherently superior to Hennigian methods, Hillis et al. (1994) pointed out a significant tradeoff. Model-based approaches provide a distinct answer based on little data, but the confidence in that answer is proportional to the modeler's belief that the model used accurately reflects the evolutionary process over extended periods of time for the clade analyzed.

The issue becomes: Which model typically gives the truth? Hillis et al. (1992) took a critical first step by generating an experimental phylogeny. The next step is to ask, how typical of evolution is that phylogeny? Remember that the phylogeny (1) involved bacteriophages and (2) was generated in the laboratory according to rules invoked by the researchers. Some have suggested that prokaryote evolution has produced not a phylogenetic tree but a highly reticulated network, in which case the experimental phylogeny produced by Hillis et al. (1992) is not typical of evolutionary history for their model organisms. Nonetheless, their results may still be typical of phylogenesis for eukaryotes.

More important is the question, how large a role has the historical contingency that is such a critical part of Darwinian mechanisms played in phylogenesis? Some have asserted that such contingencies do not affect phylogenetic reconstruction, while others have asserted the opposite (see Yang and Bielawski 2000 for a review). Seen in this light, it is possible that the reason Hennigian and model-based approaches converge with increasing data is that the more data considered, the more historical contingencies will play a role, in which case model-based approaches will progressively choose models whose set of "allowed possibilities" most closely approximates the minimal "a priori restrictions" of Hennigian phylogenetics. For example, Gissi et al. (2000) reported lineage-specific evolutionary rates for different mammalian mtDNA genes, suggesting that recovering the correct phylogeny might require a different mode for each gene, and used their findings to support contentions by other molecular systematists that, given uncertainty about the true phylogeny, the model that will give the correct phylogeny is not known and thus as many genes as possible is analyzed to help determine the appropriate model (Mitchell et al. 2000). For those researchers, the appropriate response to the assertion that "Nature is not as simple as our models . . .. But this should not be taken as a criticism of the use of a model" (Pagel 1992) is "Yes, it should" (Wenzel and Carpenter 1994).

This is the conundrum facing systematists. The next step involves a form of reciprocal illumination. That is, use the Hennigian result, rather than ModelTest, to determine the best likelihood model (i.e., what likelihood model gives the Hennigian tree). Then use the implied divergence rates from that model to add an explanatory context to the phylogenetic description without fear of introducing an element of circularity (by using the same model to build the tree and to test using the tree). When repeated across a variety of clades, this approach might suggest that some models fit the data more often than others, thus shedding light on the *general* process of evolutionary divergence patterns and rates. Perhaps some models would be suitable so rarely that they could be excluded from consideration of such general processes.

Similarly, one could use the maximum likelihood model "chosen" by the Hennigian analysis to assess the accuracy of the phylogenetic reconstruction, e.g., by linking the inferred divergence times with biogeographic or stratigraphic data. A likelihood framework has been used to incorporate or evaluate the probability of the phylogenetic hypothesis given the stratigraphic (i.e., temporal) distribution of taxa in the fossil record (Huelsenbeck and Rannala 1997b; Wagner 1998). These analyses require additional assumptions about the completeness of the fossil record and the reliability of the stratigraphic correlations. Wagner (1998) presented an analysis of hyaenids in which the strato-likelihood tree was ten steps longer than the most parsimonious tree, but it was putatively more consistent with the fossil record of the taxa. If the phylogenetic tree corresponds to a model that is in stark contrast with fossil evidence, it is time to get more data and reassess your tree and also time to dig for more fossils.

Phylogenetics in Paleoanthropology

This is an exciting time for paleoanthropologists to be involved in evolutionary biology. New discoveries of previously unknown primates and new fossil material of poorly known taxa are constantly changing perspectives on how close human relatives evolved and behaved. Phylogenetic systematics is a powerful investigative tool for generating and evaluating new evolutionary hypotheses. Its power lies in its transparency and paucity of assumptions; rather than appealing to the authority of what is "already known," phylogenetic analysis generates hypotheses that allow the raw data to speak for themselves. Phylogenetic systematics has been extensively employed in many branches of evolutionary biology and has stimulated new research directions and breakthroughs in the understanding of evolutionary patterns; however, it has yet to gain widespread use in paleoanthropology (Nunn 2011). Many workers use an intuitive approach to generate hypotheses of evolutionary relationships, combining chronological, geographical, and selected morphological data to produce their preferred pattern of relationships (Strait 2013). However, phylogeny-based methods allow the generation and testing of novel evolutionary hypotheses in ways that would not be possible without objective phylogenetic data. Although not as widespread in paleoanthropology as in other disciplines, a large and growing number of paleoanthropologists use phylogenetic systematic methods in evolutionary studies of the primates (e.g., Groves 1978; Strasser and Delson 1987; Begun et al. 1997; Nunn 2011; Strait 2013; Strait et al., chapter "▶ Analyzing Hominin Phylogeny: Cladistic Approach," Vol. 3").

Currently, the areas of most vigorous debate and prolific research in the application of phylogenetic techniques to the primate fossil record concern the following: (1) issues of morphological character choice, (2) whether human evolution is best interpreted as an evolving lineage of many grades (primarily through anagenesis) or as a series of speciation events with many extinct branches (primarily through cladogenesis), (3) the incorporation of landmark-based geometric morphometric characters in phylogenetic analysis, and (4) the use of ancient DNA in phylogenetic analyses of recent human lineages.

How to Choose Morphological Characters

The choice of which characters to include is one of the first steps in a phylogenetic analysis and also one of the most critical. The features chosen, how they are coded, and their polarity (whether they are determined to be primitive or derived) are what determines the final tree topology. As such, the procedure for choosing and describing characters is the subject of vigorous and necessary debate in all primate systematics, but perhaps most passionately by those in the field of human phylogenetics.

Some paleoanthropologists are skeptical about the utility of morphological characters for understanding evolutionary relationships; they suggest that many characters are the result of convergent evolution and thus not informative about evolutionary relationships. Some have suggested that complicating factors *specific* to hominins may result in incorrect results using phylogenetic systematics (e.g., Lieberman 1999; Collard and Wood 2000, 2001, 2007; Hawks 2004). Hawks (2004) explored the degree to which cladistic methodology is able to clarify relationships within hominins. He cited problems with character choice, character independence, atomizing continuous traits, and coding polymorphic characters as key causes undermining the reliability of phylogenetic methodology. Collard and Wood (2007) suggest that in hominins the ratio of homoplasies to homologies is about 1:2, which results in multiple most parsimonious trees. Homoplasies may be the result of convergent evolution, including tightly connected morphological constraints termed "integrated cranial modules" (Goswami 2006; Cardini and Elton 2008; Goswami and Polly 2010; Gómez Robles and Polly 2012); or they may be phylogenetically misleading morphological similarities due to nongenetic factors related to mechanical loading (termed "homoiologies") (Collard and Wood 2000, 2001, 2007). Homoiologies have been suggested to be especially prevalent in primates compared to other groups (Collard and Wood 2000, 2001, 2007; Grehan and Schwartz 2009). These concerns about character choice are based on the idea that a set of characters have all evolved in concert, as a result of convergent selection vectors, yet could produce a robust Hennigian result that was nevertheless an incorrect depiction of phylogeny.

Strait and Grine (2004) found that when they included extinct taxa, craniodental characters produced a result that is consistent with the hominoid phylogeny based on molecular data. Based on quantitative characters (cranial and dental measurements) in extant hominoids and papionins, Collard and Wood (2000, 2001) found that correlated functional convergences in the catarrhine face and jaws made phylogenetic analyses using only those characters unreliable. However, in 2007, Collard and Wood reported that phenotypically plastic features of the hominoid face were actually congruent with the molecular phylogeny. Similarly, von Cramon-Taubadel (2009) and von Cramon-Taubadel and Smith (2012) found that measurements of the cranium and mandible reflected genetic relationships in hominoids, particularly when humans were removed. In a total evidence analysis (including both morphological and molecular data), Lehtonen et al. (2010, 2012) used a total evidence approach to refute the hypothesis that humans and orangutans are sister taxa (Grehan and Schwartz 2009). The total evidence approach is becoming more common; most systematists are realizing that incorporating as much data as possible often results in a more robust hypothesis consistent with multiple lines of evidence (e.g., O'Leary and Gatesy 2008; Wiens 2009; Wiens et al. 2010).

Integrated functional complexes potentially exist in many other taxa; for example, Goswami (2006) found that diet was correlated to morphological similarity in some carnivorans. However, Goswami and Polly (2010) found that in primates, trait correlation did not have a strong influence on morphological evolution over long time periods. It is true that for any data set in which correlated homoplasies outnumber homologies, Hennigian methods will produce an incorrect result. Which characters are homoplasious is not known a priori, so correlated homoplasies cannot be known a priori. However, if there are empirical data showing that characters are non-independent, the solution is to change the way in which characters are coded.

Coding integrated cranial features as separate discrete characters would violate Kluge's Auxiliary Principle (Brooks and McLennan 2002), which assumes characters are independent. In this way, the accumulation of developmental and functional data informs character choice based on empirical evidence rather than subjective supposition. Overall, if characters are known to be correlated, they should not be treated as independent in a phylogenetic analysis. However, in the absence of evidence of non-independence, the default treatment of all characters is to initially score them as independent and critically assess the results.

These examples illustrate how methodological choices, like which taxa and characters to include in an analysis and the level at which an analysis is conducted (intergeneric, interspecific, or intraspecific), can have dramatic effects on the results. However, because these choices are explicit, the results are open to reanalysis and interpretation by other researchers, which enables the procedure to be refined and permits a continuous expansion of data sets. Through incorporation of testable phylogenetic techniques and in reference to specific, falsifiable phylogenetic hypotheses of relationships, researchers are able to converge on a consensus.

Speciation Mode: Anagenesis Versus Cladogenesis in Hominins

One of the critiques of applying phylogenetic methods to the hominin record has been that the method forces each taxon onto a terminal branch; the default mode of speciation in the end result of a phylogenetic analysis is cladogenesis. However, phylogenetic systematics does not negate the possibility of anagenesis; in fact, it allows an explicit test of that hypothesis. A species can only be ancestral to another if it is reconstructed as the sister species and lacks autapomorphies. Although the final tree may place a possible ancestor on a neighboring branch, through critical evaluation of the results, the hypothesis can be assessed that an extinct species is a candidate for a direct ancestor. Therefore, phylogenetic systematics does not ignore the possibility of anagenesis; it simply requires post hoc evaluation. For hominin systematics, when there is a real possibility of ancestor–descendant relationships among the taxa of interest, this hypothesis can be tested by using both the pattern of relationships and reconstructions of character evolution. For example, Kimbel et al. (2006) performed a phylogenetic analysis using operational taxonomic units (OTUs) based on geographical location to test the hypothesis that *Australopithecus anamensis* was the direct ancestor of *A. afarensis*. Their results supported this hypothesis, because the two species are chronologically separated and *A. anamensis* has no apomorphies that are not also present in *A. afarensis*. Likewise, Antón (2003) proposed that *Homo erectus* was a widespread, variable, long-lived species composed of "geographically replacing allotaxa." These fascinating hypotheses can be tested using a comprehensive phylogenetic framework, which would also allow ancestral character states to be reconstructed and morphological evolution assessed within the clade.

Interestingly, there is much less debate about non-hominin primate phylogeny reconstruction, for example, in early primates (Rose et al. 2011) and papionins (Gilbert 2011). This may be due to the taxonomic level of the analysis; it may be easier to reconstruct relationships among species that are more distantly related to each other. It also likely reflects the extreme interest in hominin taxa as opposed to other groups of organisms.

Geometric Morphometric Methods in Phylogenetics

The popularity of geometric morphometrics (GM) has exploded in paleoanthropology in recent years (Slice 2005, 2007); geometric morphometrics is a collection of methods that analyze biological shape using landmark coordinates, allowing the user to conduct powerful multivariate statistical analyses (Slice 2007). These techniques can be applied to a number of research areas including functional morphology, allometry, development, inter- and intraspecific variation, as well as phylogenetics. In some studies, GM data are directly incorporated into a phylogenetic analysis during the character coding phase. For example, Cardini and Elton (2008) applied 3D morphometrics to assess how concordant the phylogenetic signal from different cranial regions was with a molecular estimate of phylogeny in guenons. They found that only the shape of the chondrocranium had a phylogenetic strong signal. Gilbert (2011) used 3D morphometrics to extract phylogenetically informative characters from the papionin basicranium. He was able to eliminate the effects of allometry on cranial shape and generate cranial characters to incorporate into a phylogenetic analysis. Von Cramon-Taubadel and Smith (2012) used GM to test whether different regions of the hominoid cranium were reliable indicators of phylogenetic relationships. They found that all regions of the hominoid cranium were strongly congruent with molecular estimates of phylogeny.

In other studies, the shape of a morphological feature is mapped onto a previously constructed phylogeny – one that was constructed excluding those shape characters (e.g., Wiley et al. 2005; Fleagle et al. 2010). The results of shape change over time are then interpreted based on the evolutionary pattern suggested by the tree topology. This allows researchers to address many different questions and estimate the predicted ancestral morphology at a node (Wiley et al. 2005; Nunn 2011). For example, Wiley et al. (2005) were able to estimate the skull shape of the hypothetical ancestors of old-world monkeys by combining information from molecular phylogenetic trees with three-dimensional surface scans of crania from extant species.

Increases in computational power and memory capacity, as well as innovations in statistical programs, have contributed to the advancements in the field, with many more likely to come. Paleoanthropology has been at the forefront of these developments, and there is likely to be an increase in the incorporation of GM data in phylogenetic analysis.

DNA Analysis of Recent Human Lineages

Paleoanthropology has also been on the cutting edge of sequencing ancient DNA, and many methodological improvements and startling discoveries have come from the extraction and amplification of badly degraded and extremely old DNA (e.g., Green et al. 2006, 2010; Krause et al. 2010; Reich et al. 2010, 2011; Meyer et al. 2012). These sequence data can be characters in phylogenetic analyses, and they also reveal evidence of interbreeding and the presence of unknown ancient lineages. See Hummel (chapter "▶ Ancient DNA," Vol. 1) for a detailed discussion. These new discoveries have the potential to generate further novel data, for example, integrating morphological characters with molecular characters in a "total evidence analysis" of hominins, including Denisovans and Neanderthals.

Conclusion

Phylogenetic analysis of any kind is merely an analytical tool. If the results of a Hennigian analysis are unexpected, there is nothing in the methodology that requires belief that the results of any given analysis are true. Rather, there are several possibilities: (1) the data are lying and no amount of additional data will rectify the problem, (2) the method is flawed, or (3) there are not enough data. If the first two possibilities are accepted, the systematist must choose a model that better fits his or her beliefs, experience, or understanding of the evolutionary process than do the data, then reconcile the data to the model.

If it seems likely that there are insufficient data, character choice needs to be exhaustive and explicit, new data should be included, hypotheses should be frequently reevaluated, and independent data should be used to corroborate or refute those hypotheses. Phylogeneticists must be explicit about the methods they use to generate and evaluate trees, and those evaluating their publications need to be aware and informed of the methods used. A list of character descriptions as well as the data matrix used to generate the tree should be available so that other researchers can evaluate the authors' character codes. Consistency indices, decay analyses, bootstrap values, branch lengths, and consensus trees are important procedures for assessing the robustness of results and should be published. As well, the techniques employed to generate these results should be clear. Other elements to consider when generating or evaluating phylogenetic hypotheses include: Do independent data (e.g., fossil dates, biogeography, behavior) corroborate or refute the hypothesis? Were all known taxa included? If not, is it because of poor preservation or lack of adequate sample size?

This transparency will facilitate discussion and evaluation of morphological characters and allow the generation and testing of novel evolutionary hypotheses. It will enable assessment of whether characters are functionally correlated, and result in the reevaluation of character choice and coding, strengthening the phylogenetic hypotheses generated. While the goal of a phylogenetic analysis is to reconstruct relationships based on shared, derived characters, the really interesting evolutionary enigmas in any clade are the homoplasies. These convergences and parallelisms direct attention to possible functional or environmental selection responsible for the visible pattern of evolutionary change:

> "Or, [there are] . . . four guiding principles: (1) phylogenetic trees are necessary but rarely sufficient for explaining evolutionary origins and diversification; (2) the systematist must always be responsible for well-formulated questions; (3) the systematist must always be responsible for the quality of the data used in any level of analyses, from generating phylogenetic hypotheses to testing general theories; and (4) everything learned implies yet more cycles of discovery and evaluation . . .". (Brooks and McLennan (2002: 22))

Homology: A Philosophical and Biological Perspective

Olivier Rieppel

Contents

Abstract

Current discussions of the concept of homology center on metaphysical and epistemological issues: what are homologs, and how can they be discovered? Homology is the relation of common ancestry shared by homologs. Homologs are the "same" parts of two or more organisms under every variation of form or function that are shared due to inheritance from a common ancestor. Homology is the key to phylogeny reconstruction, because the hierarchy of homologs/homologies is isomorphic with the phylogenetic hierarchy of taxa. Consequently, the discussion of homologs as evolving entities shares many parallels with the discussion of species evolution. Homologs are conceptualized as tokens of natural kinds that engage in causal processes of ontogeny, phylogeny, and physiology. Operational criteria for the discovery of homology are the topological relations (connectivity) shared by homologs. These operational criteria are (at least to some degree) grounded in ontogeny, where developmental modules may share the relation of homology. In that sense, the operational criteria for the

discovery of homology are aligned with the structure of the causal processes in which the homologs qua tokens of natural kinds engage. The discussion of concepts of partial homology and the complementarity of static (taxic, hierarchical) versus dynamic (developmental, transformational) approaches to homology reveals empirical as well as a semantic components.

Introduction

The pretheoretical use of the concept of homology reaches far back into the preevolutionary history of comparative biology (Panchen 1994). Belon (1555) is usually taken as *locus classicus* for the earliest illustration of the relation of homology (Fig. 1), although the concept must have been implicit in Aristotle's recognition of dolphins as mammals (Russell 1982, p. 6).

For Etienne Geoffroy St. Hilaire, the unity of type was based on the relation of "analogie," a concept that captured the correspondence of relative topological relations (*connectivité*) of constituent elements of the organism tied together

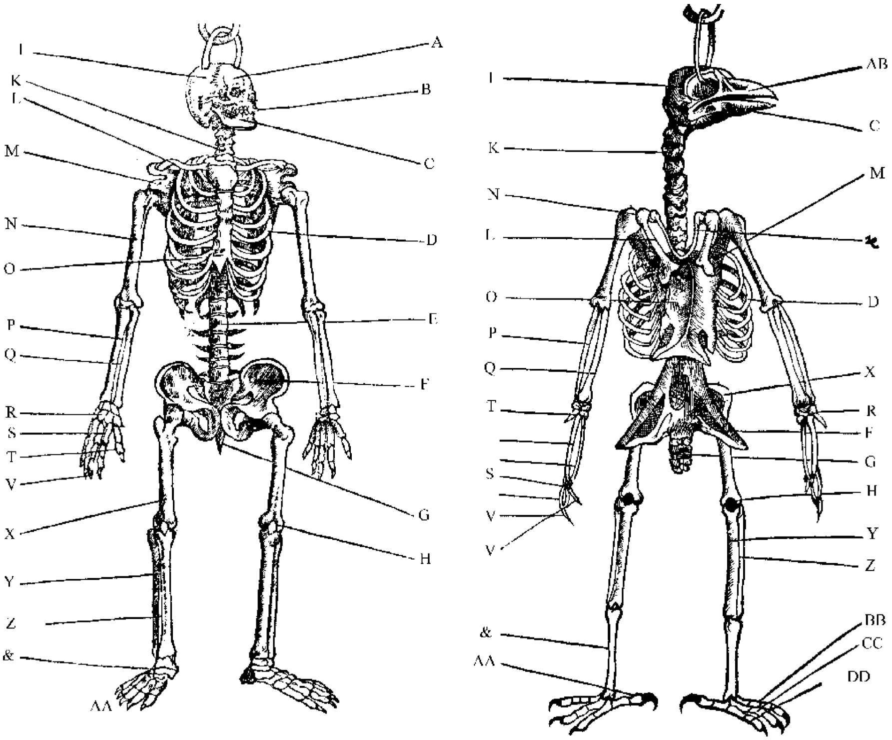

Fig. 1 In a comparison of the skeleton of man and a bird, Belon (1555) recognized the topological equivalence of constitutive elements (Courtesy of the Field Museum Library, Mary W. Runnells Rare Book Room)

throughout ontogeny by the blood-vascular system (Rieppel 1988, 2001). Geoffroy's "analogie" became Richard Owen's "homology," meaning "the same organ in different animals under every variety of form and function" (Panchen 1994, p. 40; Williams 2004, p. 192). Owen contrasted this concept with "analogy," meaning "a part or organ in one animal which has the same function as another part or organ in a different animal" (Panchen 1994, p. 40; Williams 2004, p. 192). Panchen (1994, p. 44) drew attention to the fact that, as used by Owen, homology and analogy were not necessarily mutually exclusive concepts, so a third term was required to characterize structures analogous between two or more organisms but not homologous. This was Lankester's (1870) "homoplasy." In fact, Lankester (1870) restricted the use of the term homology to its preevolutionary connotations; he called the evolutionary use of the concept that implies common ancestry "homogeny."

At the hands of Geoffroy St. Hilaire or Owen, homology was meant to capture structural correspondence, rooted in "laws of structure" as expressed during ontogeny. The relation of homology (and analogy) was reconceptualized (Kitcher 1993, p. 32) by Darwin (1859), who found that, on his theory, "unity of type is explained by unity of descent" (Darwin 1859, p. 206). The term homology continued to apply to the same constituent parts of organisms that were recognized as homologs by Owen, but the meaning of the term changed to something roughly like "shared similarity due to common ancestry." The history of the concept of homology has been variously sketched, sometimes in great detail (Panchen 1994; Williams 2004), and needs not to be retraced here. Instead, the focus of this chapter will be on issues that are central to the contemporary discussion of the concept of homology in systematics and developmental biology. How does "similarity" relate to the concept of homology, or, in other words, how can the relation of homology be rendered empirically accessible? Is there such a thing as "partial homology"? What does it mean to say, in Owen's words, that homologs are "namesakes," i.e., parts that "merit the same name" (Patterson 1988, p. 605), or that "the same names can be given to the homologous bones in widely different animals" (Darwin 1859, p. 434)? What does "sameness," "structural identity" (Wagner 1994), or "historical identity" (Grant and Kluge 2004) mean in reference to homologs, or, in other words, what kind of names refer to homologs? Are homologs particulars (individuals), denoted by proper names, or tokens of natural kinds, denoted by general names?

Semantics of Homology Statements

To better understand the semantics of homology statements, it is worthwhile to first introduce some distinctions, derived from Lankester's (1870) terminology (Table 1).

Homology assessment has been recognized to be, minimally, a two-step procedure (Jardine 1969; Rieppel 1988, 2004a; dePinna 1991; see Brower and Schawaroch 1996 for a more elaborate account). An initial conjecture of homology, based on some similarity relations that obtain between the organisms under

Table 1 A comparison of Lankester's (1870) and contemporary use of the terms homology and homoplasy (for further discussion, see text)

	Topology/connectivity	Congruence	Incongruence
Lankester 1870	Homology	Homogeny	Homoplasy
Contemporary systematics	Primary homology	Secondary homology	Homoplasy

analysis, represents an observational statement. The relation expressed by that statement was called homology by Lankester (1870), which corresponds to the "topographic homology" of Jardine (1969, p. 357) or the "primary homology" of dePinna (1991). Statements of primary homology are observational statements that relate to the organisms under analysis (Rieppel 2004a). The putative phylogenetic information content of those observation statements is subsequently tested on the basis of congruence (see further discussion later). If the statements pass the test (if they turn out coherent/congruent), they are called homology statements that correspond to dePinna's (1991) "secondary homology" (phylogenetic homology sensu Jardine 1969). These statements of (secondary) homology imply "similarity due to common ancestry" and therefore are theoretical statements, i.e., theoretical (meta) statements *about* the observational (object) statements (Rieppel 2004a). If coherence/congruence fails to obtain, the observation statements are said to be statements of homoplasy, which imply convergent similarity relations or chance similarity. Parallel evolution is said to result in a similarity relation between related lineages that is not inherited from their common ancestor. Consequently, congruence of observation statements (of primary homology) may theoretically be due to parallel evolution, but given the tools of phylogenetic systematics, there is no way to empirically distinguish (secondary) homology from parallelisms. From these considerations, Farris (1983) drew the agnostic (Sober 1985) conclusion that whereas incongruence undermines, congruence does not necessarily confirm phylogenetic hypotheses.

Observation statements deploy predicates that are meant to apply to the objects observed. For example, a chordate is an animal with a notochord; a "renate" is an animal with kidneys. The sentence "a chordate is an animal with a notochord" is of a subject-predicate structure, symbolized as Fx, where F is the predicate "… is an animal with a notochord" and x is the subject that is an animal with a notochord. More generally, "chordates" is the set of all animals that have a notochord, and renates is the set of all animals that have kidneys. The fact that homology statements deploy predicates (Mahner and Bunge 1997; Wiesemüller et al. 2003) threatens to create an ontological inconsistency in an evolutionary context that is rooted in what philosophers call the "one-over-many" problem: "the selfsame property [e.g., to have a notochord] can be instantiated by numerically different things [e.g., rabbits and tigers]" (Swoyer 2000, p. 2). The extension of a predicate is typically taken to be the set of all things to which the predicate truthfully applies: the extension of the predicate "… with kidneys" is the set of all animals with kidneys. But sets are abstract entities, not historical entities, and the semantic value of a predicate is usually taken to be a universal, not a particular (but see Swoyer 2000 for further discussion). Homology statements predicate properties of organisms, and properties, in contrast to particulars (individuals such as objects or bodies), are universals (properties include the attributes or qualities or features or characteristics of things) (Swoyer 2000, p. 2). Under the paradigm of nominalism, only particulars can claim existence (i.e., the occupancy of a particular space-time region), universals such as properties cannot. If we think of each term as referring to (denoting, designating) a thing (object, body), then predicates would have to refer to entities, with the consequence that universals, such as "redness" (*x* is red) or "rabbit-hood" (*x* is a rabbit), acquire some sort of Platonic existence as abstract entities. To avoid this conclusion, Devitt and Sterelny (1999) proposed to conceptualize predicates not as referring expressions but instead as expressions that apply to particulars (which in turn occupy a particular space-time region). For what would be particulars "when stripped of their clothing of universals" (Devitt and Sterelny 1999, p. 278)? The predicate ". . . is red" can thus apply to this or that or yet another apple, and the predicate ". . . is a tiger" can apply to this or that or yet another individual organism.

If the predicate ". . . is red" is applied to "this apple" (to which I point), then this apple is said to instantiate the property redness, but redness does not exist as a spatiotemporally restricted entity. In contrast, kidneys exist as spatiotemporally restricted entities: they can be removed or replaced by surgery. So what is the difference between "this apple is red" and "this creature is an animal with kidneys"? One way to look at the issue (Haack 1998, p. 133) is to claim that the predicate ". . . is red" marks out the set of all red things and apples are (or can be) members of that set. Similarly, the predicate ". . . is an animal with kidneys" marks out the kind of all animals with kidneys, i.e., the renates. The set of red things that includes apples, cars, and billiard balls is unlikely to be tied together by a unifying causal process, but the renates, which (for the sake of the argument) are here equated with vertebrates, are tied together by unifying causal processes, namely, those of ontogeny and phylogeny. In other words, redness is not a property that is causally efficacious; the set of red things therefore is not a natural kind. In contrast, to have kidneys is a causally relevant property that is shared by all renates, and it is in virtue of engaging in these causal processes that renates form a natural kind, as do vertebrates and also apples – red, green, or yellow – but not red things.

Under such analysis, individual tigers become tokens of a natural kind, namely, parts of the sum of all tigers. "Tiger" thus becomes a name associated with a natural kind term, and the extension of that natural kind term (of the predicate ". . . is a tiger") is the sum of all tigers, i.e., the natural kind tiger that is marked out by a common evolutionary origin. In other words, the common evolutionary origin is the relevant property that marks out the natural kind tiger. Each individual tiger that shares the same evolutionary origin is therefore a token of its kind. Each individual vertebrate is a token of the natural kind "renate" or "chordate," if the relevant property that marks out the natural kind "renate" or "chordate" is commonality of evolutionary origin.

Natural kinds come in hierarchies (Platts 1997): the individual lemon is not only a token of its proper kind but also a token of the natural kind "citrus fruit," as well as a token of the natural kind “fruit.” The same is true for animals: the individual tiger is a token of tigers, of “mammals,” and of “vertebrates.” A lemon can be squeezed, a tiger captured, and a kidney removed or replaced. The sum of all kidneys constitutes a natural kind; its tokens are instantiated by all renates. “Notochord” is a natural kind term; the tokens of its kind are instantiated by all chordates. Renates and chordates constitute a natural kind, if they share a common evolutionary origin; particular kidneys and notochords (taken from rabbits or tigers) are tokens of natural kinds that share a common evolutionary origin if kidneys and notochords are homologs of vertebrates. If kidneys and notochords were homoplasies (e.g., homoplastic in rabbits and tigers), they would be tokens of nominal kinds (the corresponding terms nominal kind terms). The key to “natural kindness” is the fact that the tokens of the kind take part in causal processes and that their properties are causally efficacious (Sober 1981; Quine 1994; Shoemaker 2003).

Conceptualization of homology in terms of natural kind term semantics offers a key to why homology statements have to be tied to a conditional phrase (Bock 1974), given the fact that natural kinds, as well as homologies, come in hierarchies. Let us follow Quine (1964) into a foreign country where people speak a language that I do not understand. In that situation, a native points at a passing rabbit and utters “gavagai.” Seeing what the native points at and hearing her utterance does not tell me whether the native means “rabbit,” “rodent,” “mammal,” or “vertebrate”. In a similar sense, the statement that “bird wings and bat wings are homologous” remains underdetermined. Given that statement only, I cannot decide whether it is right or wrong relative to the background knowledge of the currently accepted theory of vertebrate phylogeny. But if the statement is “bird wings and bat wings are homologous as (*qua*) tetrapod limbs,” I know that the statement is right; if it is “bird wings and bat wings are homologous as (*qua*) wings,” I know it is false, given the background knowledge (see the discussion of the “*qua* problem” in Devitt and Sterelny 1999).

Homologs have been claimed to be individuals, or historical individuals, on ontological grounds (Grant and Kluge 2004). The reason is that only particulars, or individuals, can take part in causal processes such as descent with modification. Sets, or classes, cannot. If homology is a property, and properties are universals that mark out sets, or classes, then homologs cannot evolve. On the analysis described previously, causally efficacious properties mark out natural kinds. The common evolutionary origin marks out the natural kind tiger, but it is individual tigers, i.e., the particular tokens of the natural kind, that engage in causal processes such as descent with modification. If homologous, the sum of kidneys constitutes a natural kind, but again it is individual kidneys, i.e., the particular tokens of the natural kind, that engage in causal processes such as ontogeny. However, ontogeny, or descent with modification, requires plasticity if evolution is to occur. In order for this to be possible, an adequately weak notion of a natural kind must therefore be invoked such as the “homeostatic property cluster natural kind” proposed by Boyd (1991, 1999).

Common evolutionary origin can be the (essential: La Porte 2004) property that marks out biological natural kinds, like taxa or homologs, but tigers and their parts, such as their kidneys and their parts, such as kidney tubules, share other properties as well. For example, tigers share a genetic constitution, which they transmit – more or less reliably – to offspring as they engage in the causal process of reproduction. Kidneys engage in the causal process of excretion, a function that changed in some regards as renates evolved from water to land. Tokens of natural kinds which in virtue of their properties engage in developmental and physiological processes must be capable of plasticity if evolution is to occur. On the other hand, variation must not be so rampant as to disrupt ontogeny or physiological function. The clustering of properties in a variable and partially overlapping pattern that characterizes homeostatic property cluster natural kinds is believed to be affected by homeostatic mechanisms, which are themselves plastic and capable of variation and change (West-Eberhard 2003). "Because the clustering in the world that defines such a kind can be an ongoing process, the properties in the cluster can sometimes vary over time, and the kind's boundaries can be historically delimited if the clustering is historically delimited" (Keller et al. 2003, p. 105). With genealogy itself being a homeostatic mechanism of property cluster natural kinds (Boyd 1999), the latter can also be conceived of as historical kinds (Sterelny 1994, p. 11), a perspective that accommodates species as well as homologs.

Similarity, Homology, and Congruence

The relation of homology is a theoretical concept because it is based on common evolutionary descent. Since common evolutionary descent cannot be observed, it must be inferred from observation. Traditionally, biologists will take some sort of similarity relation to be indicative of common ancestry (Rieppel and Kearney 2002). Indeed, under the paradigm of evolution, homology is frequently defined as "similarity due to common descent" (West-Eberhard 2003, p. 485).

However, similarity is a highly loaded concept. Goodman (1972, p. 437) called similarity "a pretender, an imposter, a quack," whereas Hull (1999, p. 35) found it "unanalyzed, perhaps unanalyzable." "As philosophers have long recognized, similarity without theory is empty" (Sober 1984, p. 336; see also Ruse 1988, p. 60; Dupré 1993, p. 45). So "similarity" is taken to be a primitive concept that cannot be further defined, and yet it is hardly possible to "imagine a more familiar or fundamental notion than this, or a notion more ubiquitous in its application" (Quine 1994, p. 42).

In the face of these problems, contemporary systematics has experienced the revival of an outdated empiricism (Sneath and Sokal 1973) that was thought to have been put to rest long ago. It consists in a purely instrumental-algorithmic approach to homology in which the array of all phylogenetic hypotheses possible for *N* number of terminal taxa is used as an instrument to generate statements of putative homology. As argued by Härlin (1999, p. 497), "too much emphasis is put on particular characters" given the "logical priority of the tree over the characters." Similarity as a tool of systematics is declared bankrupt, and theory is eschewed on grounds of lack of positive knowledge. Critical character analysis is rejected as a "disturbing trend toward data selectivity" (O'Leary et al. 2003, p. 861) by proponents of the "total evidence approach," who cite Kluge (1997) in support of the notion that inclusion of all data, including all "published data," results in a stronger test of homology and phylogenetic relationships (O'Leary et al. 2003, p. 862). But to eschew theory in favor of an instrumentalist-algorithmic approach to character analysis does not mean to take an atheoretical stance, and as pointed out by Ruse (1988, p. 60):

> As soon as one starts breaking organisms into parts, one must bring in theory . . . Take two bears, one white and one brown. Do they differ in one feature, or does one take each hair separately . . . The point is whether someone who explicitly eschews . . . theory has the right to combine all the hairs into one feature.

Proponents of the "total evidence" approach (Kluge 1989) argue, "there is no one operation for determining character states in this system-it can be anything that leads to the testable hypothesis of synapomorphy" (Kluge 2003a, p. 356; emphasis added). Even more drastic yet more sophisticated is Griffith's (Griffiths 1999, p. 225; emphasis added) assertion that

> cladistic analysis can proceed from a list of arbitrary measurements by looking for congruence among the evolutionary trees produced by different measurements . . . thus 'bootstrapping' itself into a reliable character set.

Such a data set, "holding itself up by its bootstraps" Audi (2003, p. 187), has been called the result of "phenetic cladistics: elegant analyses with many sources of error" (Wägele 2004, p. 109). "We might just [as well] stop tugging at our bootstraps altogether" (Quine 2001, p. 457).

Contemporary systematists see homology assessment as a two-step procedure: the conjecture of homology (primary homology statements sensu dePinna 1991) and the test of those on the basis of congruence (yielding secondary homology statements sensu dePinna 1991). With a misguided appeal to Popper's philosophy of science (Kluge 2003b, 2004), the proponents of the phenetic approach to cladistics consider the contextual origin of primary homology statements (conjectures of synapomorphies in Kluge 2003a) irrelevant, *as long as* there is a method to test those statements. The test of choice is not Popperian, however, but built on congruence. The issue is not whether an observation statement is accepted as falsifying the theory from which its negation was deduced, as is the case in Popper's hypothetico-deductivism (Rieppel 2003a, 2004b). Instead, the issue is whether character statements cohere to a degree that seems sufficient for the (provisional) acceptance of a phylogenetic hypothesis.

Patterson (1982, p. 74) considered Wilson's (1965) consistency test for phylogenies "a more rigorous formulation of my congruence testing." The work done by the test of congruence is to maximize the consistency of all available data in marking out an encaptic (inclusive) hierarchy. In a "pattern cladist" approach, Patterson (1982) took characters to mark out sets and analyzed the consistency of their distribution in terms of mutual inclusion, mutual exclusion, or overlap of the sets the character statements define. The same logic underlies "Hennig argumentation" (Hennig 1966), ultimately based on the "inclusion/exclusion principle"

(Wiley et al. 1991, p. 45). Accordingly, the test of congruence is based on logic as it tests for coherence versus contradiction of character statements, but logic has a linguistic foundation (Soames 2003, p. 136). Coherence and contradiction are logical relations that obtain between sentences only and the propositions they express, not between organisms and their parts. Kidneys and notochords cannot cohere or contradict each other, only statements about kidneys or notochords can. The test of congruence therefore does not test for descriptive accuracy, causal relevance of character statements, or the like. It only tests for coherence (consistency relative to a hierarchy of sets within sets or, in the present analysis, kinds within kinds) of character statements. That is why phenetic cladistics is prone to many sources of error. If the contextual origin of conjectures of homology (primary statements of homology) were indeed irrelevant, and if the test of congruence were indeed sufficient for phylogeny reconstruction, there would be no theoretical basis on which to reject the purely operational "punch-card approach" (Sneath and Sokal 1973, Fig. 3.1) to the automatic scanning of characters. If congruence and nothing else is used in a test of character statements, then the support for a phylogenetic hypothesis derives exclusively from the mutual support of the coherent character statements, without consideration of how those character statements do or do not refer (apply) to the organisms under analysis. The individual character statements, and with them the phylogenetic hypothesis they putatively support, potentially remain hanging in the air. Haack (1998, p. 27) found such inference to fall victim to the "drunken sailor argument" that invokes the picture of two drunken sailors who believe they can mutually support each other by standing back to back when both stand on nothing.

Of course there can be no doubt that character congruence, i.e., the coherence of character statements relative to a hierarchy, is a necessary condition for phylogeny reconstruction. Incoherent talk about the world makes no sense, not in phylogenetics nor in any other domain of discourse. But the mere coherence of character statements is not also a sufficient condition for phylogeny reconstruction. If they are not to be left hanging in the air, character statements must somehow be grounded in the organisms under analysis, i.e., rooted in causal theories of inheritance, development, and/or function. Homologies are natural kinds only if their tokens (at least potentially) take part in causal processes. To thoroughly investigate the genetic, developmental, even functional background of each character used in phylogeny reconstruction is beyond practical reach, however. Homology is a theoretical relation that has to be inferred from observation, but observation cannot proceed meaningfully without theory and outside the context of background knowledge (Hanson 1961; Haack 1998). Quite simply put: to be relevant to a theory, the predicate deployed by an observation statement must have a theoretical counterpart in the theory (a set of theoretical sentences) to which the observation statement is meant to relate to (Körner 1970; Mahner and Bunge 1997). Theory and background knowledge will therefore have to be brought to bear on observations that result in the formulation of primary homology statements. Even if the distinction is unsharp and sometimes difficult to draw, this is how relevant evidence is generally distinguished from total evidence (Haack 1998). More specifically, a method is required that will allow to ground primary homology statements at least approximately and certainly defeasibly (the hypothesis of primary homology may be wrong) in causal theories of inheritance and development. This method consists in the application of the "operational criteria of homology," such as topology and connectivity (Remane 1952; Riedl 1977 showed that the additional operational criteria of homology formulated by Remane 1952 ultimately all reduce to topology and connectivity).

Quine (1994, p. 43; emphasis added) found that "there is something *logically* repugnant about" similarity in its primitive, innate, unanalyzed, and unanalyzable sense (Goodman 1972; Hull 1999). But science sheds this kind of similarity as it matures. Quine (1994, p. 53) used chemistry as an example of a maturing branch of science, in which "comparative similarity of the sort that matters for chemistry can be stated . . . in terms of chemical composition. Molecules will be said to *match* if they contain atoms of the same elements in the same topological combinations." The causal efficacy of chemical kinds is thus explained as a consequence of the topological relationships of their constituent elements. This is exactly the kind of similarity that also matters for the relation of homology. Systematists do not look for any kind of similarity, but for a special kind that is established on the basis of operational criteria of homology, i.e., the relative topological position and connectivity of constituent parts of an organism (both morphological and molecular) in their temporal (ontogenetic) and spatial (ontogenetic, molecular) manifestations. Topology and connectivity yield the special kind of similarity that delivers promissory notes for potential homology. Sameness or (historical) "identity" has been invoked for homologs that carry the same name, but there is no "perceptual sameness" (Kluge 2003b, p. 236, and n. 12) in a comparison of the lower jaw of a shark and the outermost ear ossicle of a mammal. However, there is perceptional topological correspondence (during early ontogenetic stages) that justifies the conjecture of homology (Reichert 1837).

The operational criteria of homology can be compared to "correspondence rules" (Rieppel 2003b) which, stripped of their positivist background, mean nothing more than either an experimental setup or an observational procedure (Nagel 1961). Mahner and Bunge (1997) use the broadly equivalent term "indicator hypothesis" which, in the present context, would be hypotheses that do not tell us what homology is, but instead guide us how to "look for" potential homology. The operational criteria of homology have empirically been found to be eminently successful in the reconstruction of the tree of life (Remane 1952; Riedl 1977), which is why it may be assumed that they provide a (defeasible, i.e., potentially mistaken) proxy for the causal grounding of hypotheses of homology in theories of inheritance, development, and evolution. In Boyd's (1991, 1999) terms, the use of the operational criteria of homology seems to be well aligned with the causal structure of the world, at least to some degree, and defeasibly so (Rieppel and Kearney 2002). The use of operational criteria of homology cannot, therefore, be theory free. They do not establish a purely "operational" link that maps a theoretical statement of homology onto an observational statement of topological correspondence of parts. The theoretical background that justifies the use of operational criteria of homology is the recognition that topology and connectivity are expressed in development and that evolutionary transformation of morphology occurs through the transformation of development (see further discussion later). A similar adherence to correspondence rules is known in molecular systematics: "Alignment of sequences requires explicit and objective rules if inferences of positional homology are to be robust" (Hillis 1994, p. 349; but see Wheeler 1998).

Development and Homology

Homologs share a common evolutionary origin, but "neither traits nor representations of traits are transmitted to offspring. Instead, they are made-reconstructed-in development" (Oyama et al. 2001, p. 2). Both development and evolution can be conceived of as a "process of *construction* and *reconstruction* in which heterogeneous resources are contingently but more or less reliably reassembled for each life cycle" (Oyama et al. 2001, p. 1). Development results in pattern formation, an "activity by which embryonic cells form [spatially] ordered arrangements of differentiated tissues" (Gilbert 1988, p. 589), and comparative morphology analyzes these patterns in terms of topology and connectivity. Raff and Sly (2000, p. 102) noted that developmental modules "occupy specific physical sites within the embryo" and "exhibit varying degrees of connectivity to other modules within the embryo." This is the juncture at which the operational criteria of homology find their partial, and defeasible, causal grounding in the process of development. It is for these reasons that developmental modules, themselves natural kinds (Wagner 1996, 2001; Brandon 1999; Rieppel 2004c), have been identified as the "traditional units for claims about homology" (Winther 2001, p. 117). However, the use of ontogeny to causally ground homology statements is riddled with difficulties.

For Darwin (1859, p. 449), "... community in embryonic structure reveals community of descent. It will reveal this community of descent, however much the structure of the adult may have been modified and obscured." However, in the fourth edition of the *Origin* (1866 p. 312; see Peckham 1959), Darwin added: "... community in embryonic structure reveals community of descent; but dissimilarity in embryonic development does not prove discontinuity of descent." The reason is that structures considered homologs may share strikingly different developmental trajectories. A simple and classic example is the generally accepted homology of the vertebrate brain in spite of the fact that the neural plate delaminates, rather than invaginates, in teleosts. Hall (1995) presented a review of the role of ontogeny as a criterion of homology, concluding that "homology can no longer retain its historical links to shared embryonic development," for "there are so many examples of homologous structures arising from nonhomologous developmental processes" (Hall 1995, p. 8; see also Rieppel 1993; Hall 1994; Rieppel and Kearney 2002). But just as potential homologs can develop along different ontogenetic trajectories, so can a similar developmental background generate very distinct morphologies: "The transcription factors 'distal-less,' 'engrailed,' and 'orthodenticle' each have orthologs involved in patterning very different structural features in different metazoan taxa" (Mindell and Meyer 2001, p. 435).

Similarly, Raff (1996, p. 352) found it surprising "that both genes and principles of appendage development are shared between two phyla," i.e., arthropods (*Drosophila*) and vertebrates (tetrapods). As summarized by Wagner (1994, p. 275), organs with the same structural organization (structurally identical body parts) may have different developmental pathways, may use different genetic information for their development, and may not share a common phylogenetic origin.

Developmental biologists therefore recognize different concepts of homology, of which the one discussed in the preceding section – the phylogenetic or "taxic" concept of homology – is only one. In addition, there is the "morphological homology concept" that uses "structural identity for its definition," and the "biological homology concept," which is based on "shared developmental constraints" (Wagner 1994, p. 174; Roth 1984 emphasized shared developmental pathways instead). According to the latter concept, "structures from two individuals or from the same individual are homologous if they share a set of developmental constraints, caused by locally acting self-regulatory mechanisms of organ differentiation. These structures are thus developmentally individualized parts of the phenotype" (Wagner 1994, p. 275; see also Wagner 1989).

In contrast, West-Eberhard (2003, p. 486) distinguished what she called "broad-sense homology" (corresponding to "biological homology") from "cladistic homology." In contrast to cladistic homology, broad-sense homology allows for parallelisms (see the discussion above on the problem of an empirical distinction of parallelisms from taxic homology) and the recurrence of features previously lost in phylogeny. As such, broad-sense homology includes cladistic homology as a subset, the two concepts in fact representing "complementary approaches to understanding the evolution and stability of structure" (West-Eberhard 2003, p. 488; on the issue of complementarity, see the discussion later). Indeed, statements of biological homology and statements of phylogenetic (taxic, cladistic) homology may be expected to be congruent if the developmental mechanisms underlying the corresponding structures are so complex that their repeated evolution would seem very unlikely (Shubin 1994, p. 206). However, because of the problems outlined previously, "there is no rigorous way in which biological homology concepts can be used to distinguish between phylogenetic homology and homoplasy" (Shubin 1994, p. 206). It is for these reasons that comparative studies of development "can be used to trace homology, but developmental differences do not negate it" (West-Eberhard 2003, p. 496). Similarity of gene expression patterns and developmental pathways as captured by biological homology may support hypotheses of taxic homology but not the other way around (Rieppel 2004c).

Partial Homology or Partial Reference?

If true that development is a "process of *construction* and *reconstruction* in which heterogeneous resources are contingently but more or less reliably reassembled for each life cycle" (Oyama et al. 2001, p. 1), a situation might arise in which a developmental biologist would want to invoke a concept of partial homology.

The concept of modular development (Raff 1996; West-Eberhard 2003; for a review and references, see Rieppel 2004c) builds on connectivity yet dissociability of developmental modules. If developmental modules are dissociable, they can potentially "be reorganized somewhat independently of each other" (West-Eberhard 2003, p. 60), thus providing the resources for reassembly of traits derived from heterogeneous resources in descendant life cycles. Such "mosaic development" results in heterochrony, heterotopy, and other effects (Raff 1996) that led West-Eberhard (2003, p. 60) to speak of homology as "not an all-or-nothing phenomenon but rather a continuum of more or less similarity due to common ancestry." This conclusion, startling from a systematist's point of view, would seem to be supported by Raff's (1996) review of appendage development in *Drosophila* and tetrapods. Why not speak of partial homology of appendages in those widely separated lineages in which "appendages have a deep underlying and (prior to the findings of developmental genetics) completely unexpected homology" (Raff 1996, p. 353; see also Shubin et al. 1997; Gilbert and Bolker 2001)? Very basal building blocks are used to develop vastly different structures. But is it true that through such mosaic development, "evolution makes a mess of homology" (West-Eberhard 2003, p. 497)? Such a conclusion seems subject to a naturalistic fallacy. Homology is a theoretical concept. It may, indeed, be the case that our theoretical concepts are somewhat messy, but this is not because of evolution. The evolutionary process just unfolds the way it does, and this may be a way that is difficult to capture conceptually.

The call for partial homology can have two sources: the heterogeneous combination of ancestral resources in descendant life cycles as outlined previously or gradual and continuous morphological change as in Sattler's (1990, 1996, and references therein) "continuum morphology," which essentially reduces structure (s) to process(es). Although at odds with cladistics, Weston (2000, p. 141) considered it an avenue toward holism if partial homology was fitted as a distance measure on a tree. Why this appeal to holism?

The corollary of "continuum morphology" is that it "acknowledges gradations between typical structures . . .. From this point of view, homology is a matter of degree" (Sattler 1996, p. 577). The tension identified by Sattler (1990, 1996) between "typical structures" and the "continuity of developmental processes" broadly corresponds to the tension between "evolution and stability of structure" that was used by West-Eberhard (2003, p. 488) in support of her claim for complementarity. Indeed, the contrast between pattern and process can quite generally be conceptualized in terms of complementarity (Rieppel 1988), although this may in turn result in some tension with scientific realism that adheres to ontological monism. Ontological monism holds that there is one, and only one, way to carve nature at its joints, i.e., that particles and waves are not two different kinds of light but rather a reflection of our imperfect understanding of light. Accordingly, McMullin (2002, p. 252) argued that complementarity invoked in physics does not also invoke an ontological dualism, but rather points to the issue of partial reference of the terms deployed in complementary theories. The same seems true for biology.

The discussion of partial homology in terms of morphological stasis versus continuity of developmental change mirrors the paradoxical discussion of "species" as spatiotemporally delimited chunks of a genealogical continuum. With respect to species, Hey (2001, p. 168) found that “systematists and evolutionary biologists have both placed incommensurable demands on a word,” in which the word “species” is supposed to function in the context of pattern as well as process analysis (Hull 1997), and the same is true of homology. But again “a tendency for different perspectives by different biologists [must not] be confused with different kinds of reality” (Hey 2001, p. 150). Indeed, if species transformation is a gradual process, any species concept will be subject to the “sorites paradox” (Rieppel 2003b): take a heap of sand and remove grains one by one – when would one stop calling it a “heap”? Under the paradigm of gradualism, species boundaries will be unsharp, fuzzy, no matter which concept is deployed in their delineation (Hey 2001). The same is true of homology in cases in which morphological transformation (developmental and phylogenetic) is a gradual process. There is, however, a conceptualization of species that specifically allows for such fuzziness, which is that of homeostatic property cluster natural kinds (Boyd 1999; see also Griffiths 1999; Wilson 1999; Keller et al. 2003). The same concept can be applied to homologs, as was discussed previously (Rieppel 2004c). The conclusion is not that evolution makes a mess of homology but that it is the names associated with the natural kind terms (predicates) we deploy in statements of homology that may have imprecise, or even only partial, reference (the terms apply only imprecisely, or partially, to the organisms under analysis).

A second issue to consider in relation to the concept of partial homology is the fact that natural kinds, such as taxa or homologs, come in hierarchies and thus raise the *qua* problem for natural kind terms as discussed previously (Devitt and Sterelny 1999). The statement “bird wings and bat wings are homologous” makes little sense unless it is tied to a conditional phrase. The same is true of the statement “arthropod and tetrapod appendages are partially homologous,” unless the question is raised in which sense they are homologous, partially or not. The concept of partial homology may reflect a tendency of developmental biologists to use broad-sense homology independent of a hierarchical conception of development. If the sense of partial homology in this example relates to certain gene expression patterns (a “similar genetic cascade”) (Shubin et al. 1997, p. 646), then the homology relation exists not at the level of appendages, but at the level of genes, which ties the homology relation to its proper hierarchical level. Gilbert and Bolker (2001, p. 447) speak of such gene-level homology as “deep homology,” for insect “legs” and vertebrate “legs” obviously cannot be homologous as appendages, because “phylogenetically intermediate taxa (particularly basal chordates) do not possess comparable structures” (Shubin et al. 1997, p. 645). However, Gilbert and Bolker (2001, p. 449) added a note of caution to this tale of wings and legs. Applying the “small toolbox argument” to developmental processes in the name of parsimony, they draw attention to the fact that genetic resources that regulate basal (early) patterning processes in development are limited, for which reason convergent gene expression patterns are difficult to rule out. For example, much of the “toolbox” that is involved in early limb development is also involved in the early development of vertebrate teeth.

Taxic Versus the Transformational Approach to Homology

The phylogenetic literature that deals with species, taxa, as well as with homologs, is replete with dismissals of taxa, or homologs, as natural kinds, for these are considered abstract entities, like sets, or classes (Hull 1999). The same is true of properties (attributes), which are dismissed as universals that cannot be instantiated by evolutionary entities (Grant and Kluge 2004). Hey (2001, p. 153), for example, dismisses property cluster kinds as polythetic classes, where "a polythetic class is just a category in which the members need only meet some, not all, of the membership criteria." But as emphasized previously, for property cluster kinds (as well as for other kinds) to be natural requires that their properties are relevant to causal processes, i.e., that tokens of kinds take part in causal processes by virtue of their properties (Sober 1981; Boyd 1999; Shoemaker 2003; La Porte 2004; Lipton 2004).

Homologs (Grant and Kluge 2004), as well as species (Hull 1999), have been considered to be particulars (individuals). This move was motivated by a certain reading of Hennig (1950, 1966), which found him to have replaced "intensional" with "extensional" thinking in systematics (Dupuis 1984). Such reading of Hennig has led to the assertion that systematics must rely on "ostension" and "extensionality" (Kluge 2003a). The meaning of extensionality as used in this context remains obscure (Dupuis 1984, p. 13: "Hennigian taxonomy is extensional since, for appraisal of each attribute, it requires an extensive consideration of various objects"), whereas the relation of ostension is more easily understandable. In the simplest case, ostension is the relation of "pointing at" an object in order to establish that object as the referent of a proper name or of a sentence of the subject-predicate structure (Fx). But for Grant and Kluge (2004), it is not objects and their properties that serve as homologs. Instead, "only the transformation from one character state to another, $a \rightarrow a'$, constitutes evidence in phylogenetic inference" (Grant and Kluge 2004, p. 25). If only transformation events constitute evidence, and if systematics is to be ostensional, then systematists would have to be able to "point at" such transformation events. The collapse of a bridge or the burning of a house are events that witnesses can point at, but the transformation events that are of interest to systematists are events of the past. What is required, therefore, is identification of character states and inference of their transformation. "However, character state transformation has always been treated primarily as a metaphor .... Furthermore, character states themselves can be seen as manifestations of the transformational metaphor" (Weston 2000, p. 135). In this quote, I would replace the term "metaphor" with that of "concept," for as convincingly argued by Hanson (1961), perception itself entails a conceptual component (Rieppel 2004a). As noted earlier, the mere pointing at a rabbit and the utterance of "gavagai" by a native speaker does not tell the English-speaking audience what the native speaker means by gavagai: a rabbit, an undetached rabbit part, or a rodent (Quine 1964)? It seems impossible to meaningfully talk about the world without concepts (Luntley 1999).

A transformation series of character states purported to be homologous does not result from mere ostension but from character conceptualization ("transformation series analysis . . . begins with the *construction* of an initial transformation series": Kitching et al. 1998, p. 218; my emphasis). Hennig (1966, p. 94) was very clear on this issue: "the belonging of characters to a phylogenetic transformation series . . . cannot be directly determined." To solve the problem, Hennig (1966, p. 94) turned to an account (in Cain and Harrison 1958, pp. 86–88) of J.H. Woodger's analysis of morphological comparison in the language of logical positivism (Rieppel 2003b), which "to that extent is exact" (Hennig 1966, p. 94). According to Woodger (Cain and Harrison 1958), morphological comparison individuates parts of organisms in terms of their relation and compares them in terms of their properties. The description of properties of, and relations between, objects is the cornerstone of the positivist philosopher Rudolf Carnap's "construction theory," i.e., the theory of how science reconstructs the logical structure of the world (Mayhall 2002). As argued earlier, the same theoretical background underlies Hennig's (1957, 1966) conceptualization of the cladogram (Rieppel 2003b). There is no need to look back on Carnap, Woodger, or even Hennig, however, to understand that the identification of characters, character states, and transformation series entails a conceptual component (Hanson's (1961) work was, after all, a stab at the positivists' adherence to something akin to "simple" observation). In his talk announcing his own transformation, Farris (Mitter 1980, p. 188; see also Dupuis 1984, p. 16) asserted that "morphologists do not sample characters, they synthesize them." If "extensional" systematics must be based on ostension, but if it admits only character transformation as evidence, then the argument boils down to the claim that systematists must be able to "point at" concepts. This conclusion merely shows that such arguments confound concepts with objects (Mahner and Bunge 1997).

The discussion of transformation series reflects back on the "transformational" versus "taxic" approach to homology that was hinted at by West-Eberhard (2003) in her distinction of broad-sense versus cladistic homology. The essence of this debate (that started with Patterson 1982) is that the transformational approach allows homology to encompass both symplesiomorphy and synapomorphy, whereas the taxic approach requires homology to be synonymous with synapomorphy (it requires a statement of homology to be coextensive with a statement of synapomorphy). Wiesemüller et al. (2003, p. 89) consider the taxic approach as too coarse-grained because it blurs the distinction of plesiomorphy and apomorphy, in addition to the fact that the concept of homology cannot easily be applied to "absence" – characters. The latter problem was (arguably) "solved" semantically: snakes do not have "no legs," but instead they have "modified legs," i.e., "lost legs" (Platnick 1978; see the discussion of the deduction of different meanings from different premises in Rieppel 2004b, p. 79). The distinction of homology from symplesiomorphy and synapomorphy on the other hand is related to the *qua* problem. "Bird wings and bat wings are homologous" violates the requirement for coextensionality of statements of homology and of synapomorphy because it implies a symplesiomorphy: birds and bats share tetrapod (fore)limbs, not wings.

Patterson's (1982) goal simply was to remove ambiguity and render statements of homology testable by congruence, in claiming that homology statements should always be assessed as (*qua*) statements of synapomorphy – since what is a symplesiomorphy at one level (jaws of amniotes) becomes a synapomorphy at a more inclusive level (jaws of gnathostomes). An interesting evolutionary talk about a comparison of bird wings with bat wings would be a talk about convergence, but then bird wings and bat wings could not be homologous.

Conclusion

Homology is one of two perennially discussed topics in comparative biology – the other is species. The two discussions show many parallels, as indicated previously: proper names versus general names, individuals versus classes, sets, or kinds. To turn homologs into individuals and anatomical (or molecular) terms into proper names (Grant and Kluge 2004) is patterned on the argument that species are individuals (e.g., Hull 1999). This latter argument has received a lot of attention from evolutionary biologists, who largely missed an important part of its theoretical foundation. In his defense of the argument from a philosophical point of view, Hull (1976, p. 179, n. 4) drew attention to the semantic behavior of species names in evolutionary theory, which in his analysis corresponds to the semantic behavior of proper names as "rigid designators" (Kripke 2002). Such behavior of proper names is tied to a specific theory of reference for proper names, i.e., the "historical," "causal," or "direct" theory of reference (Hull 1976, p. 179, n. 4; see also Hull 1988). These are all rather technical issues that need not be reviewed here; there is also no need to deliver a verdict on the ontological status of species here. The important point is that authors who want to use – in an evolutionary context – the "names" that refer to "the same organ in different animals under every variety of form and function" as proper names will need to worry about those technicalities but have not done so far.

In the present context, homology is conceptualized in terms of natural kind term semantics, and the names associated with natural kinds can be general names or singular terms (Soames 2002). Kripke (2002) himself already expanded his theories to also apply to natural kind terms, such as "tiger," "water," or "gold," but as noted by Devitt and Sterelny (1999), the use of such terms – at least in the case of biological natural kinds – at some level involves some descriptive account (for Kripke 2002, a descriptive account may help to fix reference, but does not determine reference, of proper names or natural kind terms). This means that the use of names (associated with natural kind terms) to refer to "the same organ in different animals under every variety of form and function" must be tied to a conditional phrase that specifies the hierarchical level at which the use of that name gains some cash value in terms of marking out monophyletic groups. This in turn means that phylogeny reconstruction cannot be a matter of mere extensionality and ostension (Kluge 2003a, b; Grant and Kluge 2004), but requires a conceptual, i.e., a theoretical framework. There is no immediate access to objective reality, but this only means that careful phylogenetic analysis will require at least an attempt to causally ground hypotheses of homology, proximally in criteria of topology and connectivity, ultimately in the theories of inheritance, development, and evolution.

Chronometric Methods in Paleoanthropology

Daniel Richter and Guenther A. Wagner

Contents

Abstract

Chronometry or numerical dating aims to provide age estimates in terms of years for archaeological and paleoanthropological events or processes. Most of the methods currently applied with success are based on the physical phenomenon of radioactivity, which provides the clock. Ongoing developments in the last few decades provide rapid progress in the growing field of chronometric dating. In particular, improvements in time resolution and application to novel sample materials as well as the extension of the age ranges have left a strong impact on

current paleoanthropology. This contribution introduces the reader to the principles of radiometric dating. The most frequently applied dating methods, such as potassium–argon, uranium-series, luminescence, electron spin resonance, cosmogenic ^{26}Al/^{10}Be, and radiocarbon techniques, are described. Their potential for paleoanthropology is illustrated using various examples covering the entire period since hominini entered the scene a few million years ago.

Introduction

In paleoanthropology – as in any historically oriented discipline – the *time* when something happened is fundamental. The recorded events are by themselves poorly informative until they are arranged in their correct chronological order. Once such an order is established, a mutual causal relation between the events may be confirmed or rejected. For instance, the coexistence of Neanderthals with modern humans excludes any hypothesis of simple evolution of the former into the latter within the given geographical area. Furthermore, a firm chronological database enables assessing the duration and the rate of processes, as in the case of the remarkably fast spread of *Homo erectus* out of Africa. It is for these reasons that the rapid progress that chronometric dating has experienced during the past few decades has substantially fostered the development of modern paleoanthropology.

Chronometry refers to the measurement of past time in terms of years and provides numerical age results. Before the introduction of chronometric dating to the field of prehistory, age determination relied essentially on the principles of stratigraphy, which reveals merely relative datings. A turning point came with the development of radiocarbon dating around 1950, soon followed by potassium–argon and other dating techniques. Nowadays, several chronometric dating methods are available, based on physical phenomena. Since the result of a physical measurement represents only a more or less accurate approximation of the sought-after true value – which is and which remains unknown – the often used term "absolute" dating seems inappropriate and should be avoided. Instead, the terms "chronometric" and "numeric" dating are recommended. The estimated deviation of the measured age value from the true one is given by the uncertainty. The uncertainty $\pm \sigma$ describes an interval from $(t-\sigma)$ to $(t + \sigma)$ surrounding the calculated age t, which is usually the mean of multiple measurement results. Within this confidence interval, the true value is expected at a certain probability. Consequently, the uncertainty is an integral part of the age result and must not be omitted in interpretation and discussion. In interpretation it is essential to use a high probability (95.45 %, i.e., $\pm 2\sigma$) to bolster confidence that the "true" age lies within the age range given, by subtracting and adding 2σ from the mean age provided. Here it is essential to note that the "true" age can lie anywhere within this range; and when comparisons are made, age results with overlapping ranges have in general to be considered as statistically being of the same age.

While understanding that chronometric dating results provide a probability range, and not a single "true" value, it is also important to consider the relationship between the event dated and the event being addressed (Dean 1978). Dating an associated bone determines the time of decease of the organism; and only by inference can it be concluded that, say, the deposition of an artifact is contemporaneous with the death of the animal dated. It is very rare to date an event that is directly related to remains of hominine or human manipulation of objects. In many cases, ages have to be established by correlations, sometimes based on series of logical arguments, which are obviously less strong than direct dating.

In numerical dating a "clock" is required, i.e., natural time-dependent processes that lead to quantifiable changes within prehistorical time scales, whereby the rate of the process needs to be known. Furthermore, the process must be either started or reset – like a stopwatch – at the moment of interest to the paleoanthropologist. For example, in case of stone artifacts, it is not the age of the rock itself but that of manufacture or use which is of interest. Processes fulfilling these requirements are rare, but the discovery of radioactivity by Henri Becquerel in 1896 provided an avenue to knowledge of such processes. Because radioactive decay is a property of the atomic nucleus, its decay rate is insensitive to ambient parameters such as temperature, pressure, and chemical bonding. The radioactive clock thus runs steadily, regardless of environmental influences. Because of this unique property, radioactivity may aptly be called the "mother of chronometry."

A *nuclide* is an atomic species characterized by its numbers of nuclear protons and neutrons. Their sum is the mass number, which is indicated as superscript to the upper left of the element symbol. For example, the nuclide ^{14}C consists of six protons, which define the element carbon, and eight neutrons. Nuclides belonging to the same element are called *isotopes*, which means that they have the same number of protons but different mass numbers, such as the three carbon isotopes ^{12}C, ^{13}C, and ^{14}C. Most natural nuclides are stable, but others disintegrate spontaneously – a phenomenon called *radioactivity*. The rate of this disintegration is nuclide characteristic. The radioactivity dN/dt (in the unit of *Becquerel Bq* [s^{-1}]) is defined as the fraction dN of the radioactive parent nuclide N (with initial amount N_0) that disintegrates within the time interval dt into the radiogenic stable daughter nuclide D ($= N_0 - N$)

$$\frac{dN}{dT} = -\lambda \cdot N = -\frac{\ln 2}{t_{1/2}} \cdot N \tag{1}$$

where by λ [a^{-1}] is the decay constant and $t_{1/2}$ [a] the half-life ($= 0.693/\lambda$).

By integration one obtains the equation

$$\frac{N}{N_0} = e^{-\lambda \cdot t} \tag{2}$$

and substituting (D + N) for N_0

$$\frac{D}{N} = e^{\lambda \cdot t} - 1 \tag{3}$$

The age t [a] can be derived, depending whether N_0, N, or D is known, according to one of the following equations:

$$t = \frac{1}{\lambda} \cdot \ln\left(\frac{D}{N} + 1\right) \tag{4}$$

$$t = \frac{1}{\lambda} \cdot \ln\left(\frac{N_0}{N}\right) \tag{5}$$

The use of a radioactive system for age determination presupposes that neither the parent nor the daughter nuclides are lost or gained except through the decay process itself – a condition that is known as *closed system.*

There are several types of radioactive decay: α-decay takes place under emission of an α-particle, which is a ^{4}He nucleus. During β-decay the nucleus emits a β-particle, which is an electron, whereby a neutron is converted into a proton. Electron capture occurs when the nucleus captures an extra-nuclear, orbiting electron from the innermost atomic shell (K-shell) whereby a nuclear proton is converted into a neutron. During spontaneous fission, the atomic nucleus splits into two heavy fragments and 2 or 3 neutrons. Some nuclides exhibit a dual decay mechanism, as α-decay and spontaneous fission for ^{238}U. Radioactive decay is generally accompanied by the emission of energy-discrete γ-rays, which are a type of electromagnetic radiation from the exited nucleus.

Instead of being stable, the daughter nuclide may be radioactive and disintegrate itself. Several such radioactive daughter nuclides may be following each other to form a decay chain until finally a stable end product is reached. Most prominent for chronometric dating is the decay chain starting from ^{238}U and ending at ^{206}Pb involving several steps of α- or β-disintegration. If the decay chain stays undisturbed, i.e., under closed-system conditions, a balance between production and decay of the interim members is gradually established. At this stage, which is called radioactive or secular equilibrium, all radioactive members N_1, N_2, N_3, etc., assume equal radioactivity dN/dt.

$$\lambda_1 \cdot N_1 = \lambda_2 \cdot N_2 = \lambda_3 \cdot N_3 \ldots \text{etc.} \tag{6}$$

In nature various kinds of radioactive nuclides occur, and many of them can be used for chronometry. Due to their origin, these nuclides can be divided into various groups: *Primordial nuclides* are left over from the time of nucleosynthesis and, thus, are older than the formation of the Earth (e.g., ^{238}U). *Radiogenic nuclides* are produced by radioactive decay (e.g., ^{230}Th). *Cosmogenic nuclides* are formed by the interaction of cosmic rays with the atmosphere and the Earth's surface (e.g., ^{14}C). *Anthropogenic nuclides* are produced in nuclear plants and explosions (e.g., ^{3}H). For the Quaternary period, there is a wide spectrum of dating methods available (Wagner 1998; Walker 2005; Taylor and Aitken 1997; Noller et al. 2000), and the following presents an outline of the radiometric dating methods (Fig. 1) with sound paleoanthropological potential.

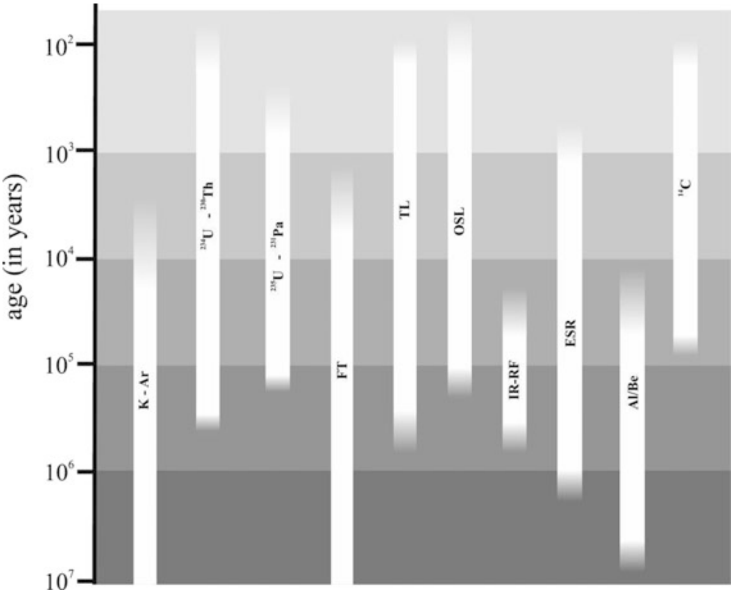

Fig. 1 Important radiometric dating methods for the Pliocene/Pleistocene period with their application ranges

In addition to chronometric application at sites, such methods are also used for relative dating by providing numerical ages for calibration or as anchor points. The relative dating method of paleomagnetism (e.g., Gubbins and Herrero-Bervera 2007) is important in paleoanthropology. It employs the directional changes of the Earth's magnetic field (reversal of polarity), which is synchronously recorded in rocks or deposits during their sequential formation. Such worldwide events can be numerically dated at one location, and an age is therefore provided for all other sites where this event is detected. This is especially useful for sites which cannot be dated by chronometric methods, but it also provides further evidence of the age of sites or sequences and is also employed as a verification/falsification tool.

Potassium–Argon

The K–Ar method covers the whole age range from the beginning of the solar system to the Holocene and has become undoubtedly one of the most important chronometric dating tools since the first attempts by Smits and Gentner (1950). The term "potassium–argon" stands for several dating techniques. Apart from the conventional K–Ar technique ($^{40}Ar/^{40}K$), these are the argon–argon ($^{40}Ar/^{39}Ar$) and the argon–argon laser techniques. In particular the latter ones play a crucial role in Pliocene/Pleistocene geochronology whenever volcanic materials are involved.

All techniques are based on the same phenomenon: the radioactive decay of the potassium isotope ^{40}K into the argon isotope ^{40}Ar. In its relation to the potassium content, the amount of accumulated radiogenic argon becomes a measure for the age. The various techniques essentially differ in their analytical and gas extraction procedures.

Potassium is the eighth most common element in the Earth's crust and occurs widely in rock-forming minerals such as feldspar and hornblende. One of its three natural isotopes, ^{40}K, with an isotopic abundance of 0.01167 %, is radioactive. It disintegrates under electron capture, with a decay constant λ_e of 0.58110^{-10} a^{-1}, to the stable argon isotope ^{40}Ar. The long half-life of 11930 Ma implies that in the time span of a few Ka, only very low amounts of radiogenic $^{40}\mathrm{Ar}_{\mathrm{rad}}$ are produced. Thus, potassium-rich minerals, such as sanidine, are preferred in Quaternary applications. Recent developments in ultrasensitive analytical technology, however, allow the determination of ages as low as few thousand years. The clock provided by K–Ar is used to date events correlated with the last complete degassing. In Pliocene/Pleistocene contexts such events are essentially the solidification of minerals in relation to volcanic eruptions. Important materials are widespread tephra layers, for which K–Ar dating yields excellent tephrochronologic time markers, for example, tephras intercalated with early-hominid-bearing sediment layers.

The K–Ar-age t [a] is assessed under the assumptions that no $^{40}\mathrm{Ar}_{\mathrm{rad}}$ was present in the sample at the moment of the last degassing, which had to be complete, and that the subsequently produced $^{40}\mathrm{Ar}_{\mathrm{rad}}$ remained quantitatively in the sample. Argon is analyzed by mass spectrometry and potassium by atomic absorption. This technique is called *conventional K–Ar dating*.

Apart from radiogenic ^{40}Ar, there are contaminant sources of this isotope. Samples always contain more or less *atmospheric derived argon* $^{40}\mathrm{Ar}_{\mathrm{atm}}$, which must be subtracted from the total ^{40}Ar in order to obtain the radiogenic fraction $^{40}\mathrm{Ar}_{\mathrm{rad}}$. This correction is possible because of the known isotopic abundance of atmospheric argon $(^{40}\mathrm{Ar}/^{36}\mathrm{Ar})_{\mathrm{atm}} = 295.5$ and requires the measurement of the isotope ^{36}Ar in addition to ^{40}Ar. As a noble gas, argon is chemically inert and thus should be driven out of the crystal lattice during heating so that the K–Ar clock is reset. If the degassing is incomplete, an *extraneous ^{40}Ar* component is left in the mineral, resulting in an overestimation of the K–Ar age. Such non-atmospheric argon contamination needs to be identified and is accounted for in single-grain or isochron-dating techniques. The younger the rock, the less abundant is the radiogenic ^{40}Ar and the larger is the fraction from contaminant argon sources. Therefore, special K–Ar techniques which allow analyzing minute proportions of radiogenic argon have been developed for age determination of Quaternary samples.

After the resetting event, the K–Ar system must stay closed. Partial loss of argon results in an underestimate of the K–Ar-age value. The leaking of argon from minerals may happen continuously during weathering or episodically during thermal overprint. For unweathered Quaternary volcanites that cooled quickly after eruption to surface temperature, and stayed cool afterwards, argon loss is rare. If present, argon loss can be recognized and corrected by the step-heating *$^{39}Ar/^{40}Ar$ plateau technique*.

In the *^{39}Ar/^{40}Ar* technique, potassium is determined through a nuclear reaction instead of chemical analysis. The sample is irradiated with fast neutrons, whereby the argon isotope ^{39}Ar is produced from the main potassium isotope ^{39}K. The abundance of the artificial isotope ^{39}Ar is measured together with ^{40}Ar and ^{36}Ar by mass spectrometry. The age is determined against a standard of known age, which is irradiated jointly with the sample to be dated. This requires the measurements only of isotope ratios, and not explicit quantities, which improves accuracy. A further advantage of this technique over conventional K–Ar dating is the ability to recognize argon loss or extraneous argon. This is achieved by stepwise heating and differential degassing of the sample, whereby for each step, the ^{40}Ar/^{39}Ar ratio of the released argon is measured. In the absence of argon loss and of excess argon, the corresponding ages display the same age for the heating steps, which is called the plateau.

The *laser technique* is a variant of the ^{39}Ar/^{40}Ar technique in which the heating is achieved under a laser beam. The sample is either incrementally heated and finally fused – analogous to the plateau technique – or, without gradual degassing, directly fused and analyzed. The main advantage of this technique is its ability to analyze single grains in the sub-milligram range. The grain-discrete probing enables identifying contaminating detrital grain populations by their greater age.

To test whether the K–Ar system is disturbed by excess argon, the *isochron technique* is also used. It relies on cogenetic fractions from the same rock sample having different potassium contents. In the isochron diagram, ^{40}Ar/^{36}Ar is plotted against ^{39}Ar/^{36}Ar. All data points of the subsamples lie on a straight line (isochron) where the slope defines the age, and the intercept with the y-axis reveals the initial ^{40}Ar/^{36}Ar ratio, which exceeds the present atmospheric ratio of 295.5 in case of excess argon. ^{36}Ar/^{40}Ar versus ^{39}Ar/^{40}Ar diagrams are also employed, in which straight lines of negative slope define undisturbed systems. Usually isochron plots are applied in connection with laser single-grain analysis. In such cases it is important to probe a sufficiently large number of crystals in order to discriminate between xenocrysts (older crystals incorporated into the volcanic rock), phenocrysts (crystals that solidified from the volcanic melt before eruption), and the crystals formed during the volcanic eruption (Chen et al. 1996).

Of particular significance in paleoanthropology are widespread tephra horizons intercalated in sedimentary sequences. The eruption ages yield invaluable tephrochronologic and stratigraphic time markers. Current knowledge about the timing of hominid evolution rests essentially on K–Ar data from such tephra (Brown and McDougall 2011). However, tephra layers in sediments may be reworked and thus contaminated with mineral detritus of various provenances. In such cases, bulk K–Ar or Ar/Ar dating of mineral concentrates yields an integrated age which is not related to a specific volcanic eruption. For this reason, but also for the recognition as correction of excess argon, single crystal probing is required in order to identify the various components of different age. This is optimally achieved with the grain-discrete Ar/Ar laser technique. Suitable mineral phases are potassium-bearing feldspars, such as sanidine and plagioclase, but also biotite, hornblende, and acidic glass shards.

One of the most renowned sites with early hominin fossils is Olduvai Gorge, Tanzania. The ca. 100 m thick Pliocene/Pleistocene sediments contain numerous tephra horizons and lava flows. Remains of *Australopithecus boisei* were uncovered as well as stone tools in Bed I. Continuous efforts to date this bed had aroused controversial views on *Homo habilis* and its age. Finally, single-grain ^{40}Ar/^{39}Ar laser-fusion dating succeeded in establishing a detailed and reliable chronology (Walter et al. 1991). Feldspar-grain populations of different ages were observed, allowing the decisive tuff component to be distinguished from older, reworked contamination. The weighted means of single grains from this juvenile component are 1.798 ± 0.004 Ma for Tuff IB and 1.779 ± 0.007 Ma for Tuff IF, located within sedimentary layers that include the fossil hominids. The oldest Oldowan-type stone tools, discovered at Gona, Ethiopia, have an age of 2.6–2.5 Ma. They are associated with cut-marked bones. The dating of the artifact-bearing layer is based on an overlying tuff, which yielded 2.53 ± 0.15 Ma as weighted mean of single-plagioclase ^{40}Ar/^{39}Ar ages, and the underlying Gauss–Matuyama paleomagnetic boundary, which is placed at 2.58 Ma (Semaw et al. 2003). Even older use of stone artifacts is postulated by the presence of cut marks on bones from sedimentary deposits dated by ^{40}Ar/^{39}Ar on intercalated tephra to 3.39 Ma at Dikika in Ethiopia (McPherron et al. 2010). The interpretation as well as the association, however, was challenged (Domínguez-Rodrigo et al. 2012). While the consumption of animal tissue certainly predates the use of stone tools, it has to be acknowledged that marked bones might be more informative on early stone use than the stones themselves, the anthropogenic origin of which might be much more difficult to identify.

At the Pliocene site of Fejej, Ethiopia, with dental remains attributed to *Australopithecus afarensis*, the fossil-bearing sandstone is capped by fine-grained basalt flows. Whole rock samples from the two lowest basalt outcrops were analyzed with the laser ^{40}Ar/^{39}Ar incremental-heating technique. Both samples provided long age plateaus from which mean ages of 3.94 ± 0.05 Ma and 4.06 ± 0.07 Ma, respectively, were calculated. When combined with paleomagnetical data from the site, a minimum age of 4.00–4.18 Ma was assigned to the fossil teeth, making them some of the oldest remains of *Australopithecus afarensis* (Kappelman et al. 1996).

As to the question of the origin of *Homo erectus* (sensu lato), K–Ar data are of special interest. The earliest fossil trace of this species in Africa occurs in the Koobi Fora region, Kenya. Based on K–Ar dating (McDougall 1985), an age of 1.8–1.9 Ma is assigned by interpolation (Feibel et al. 1989). According to K–Ar evidence, *Homo erectus* seems to have appeared at almost the same time in Western Asia. At Dmanisi, Georgia, fluvio-lacustrine sands with several hominid remains assigned to this archaic species are directly under- as well as overlain by volcanic flows and ashes. This stratigraphic situation allows the application of ^{40}Ar/^{39}Ar age bracketing, resulting in 1.85 ± 0.1 Ma and 1.81 ± 0.05 Ma for the lower and upper volcanic events, respectively (de Lumley et al. 2002). The morphology of these early Dmanisi *Homo erectus* appears primitive. Based on ^{40}Ar/^{39}Ar laser-incremental ages (1.81 ± 0.04 Ma and 1.66 ± 0.04 Ma) on hornblende, separated from pumice of two *Homo erectus* (*Pithecanthropus*) sites in Java, Swisher et al. (1994) claimed that *Homo erectus* appeared concurrently in Southeast Asia. However, the stratigraphical position of the former hominid finds seems to be above the dated pumice, so that these ^{40}Ar/^{39}Ar ages can be considered merely as a *terminus post quem* for these hominids in Java (Semah et al. 2000). Still, *Homo erectus* appears not much later on Java, because a recent find can be dated with an ^{40}Ar/^{39}Ar plateau age of 1.51 ± 0.08 Ma on epiclastic pumice, located stratigraphically slightly above and in close proximity to the in situ find spot of a maxilla (Zaim et al. 2011). The current sparse evidence of morphology and numeric dating actually allows currently opposing interpretations of *Homo erectus* moving from Asia to Africa, as well as from Africa to Asia (Wood 2011). Nevertheless, several *Homo* species roamed Africa after 1.95 Ma, with most of the dating evidence provided by Ar/Ar (Leakey et al. 2012).

For the emergence of anatomically modern humans, the discovery of fossil *Homo sapiens* at Herto, Ethiopia, in fluvial and lacustrine sandstone with Lower and Middle Stone Age technocomplexes is of prime importance (Clark et al. 2003). The upper age limit for this sandstone unit was determined by ^{40}Ar/^{39}Ar incrementally heated multigrain analysis of anorthoclase from embedded pumice, yielding 163 ± 3 Ka and 162 ± 3 Ka, respectively, and of embedded obsidian clasts, yielding 160 ± 2 Ka. The lower age is constrained by the ^{40}Ar/^{39}Ar laser-fusion mean age of 154 ± 7 Ka of single grains from the juvenile sanidine component separated from a tuff which caps the fossiliferous unit elsewhere, but is correlated by a series of stratigraphical and isotopic arguments. While these data provide evidence for the out-of-Africa model of *Homo sapiens* origin, the lack of chronometric evidence for the fossil-bearing layer has led to questioning the proposed minimum age (Faupl et al. 2003 vs. Hart et al. 2003). Similarly, the other unequivocally anatomically modern human from Omo Kibish (Ethiopia) is dated by correlation of various tephra deposits and stratigraphical lines of arguments. Again, ^{40}Ar/^{39}Ar dating of these correlated pumices provides numerical age estimates, which all together place the age of these human remains at ca. 196 Ka (Brown et al. 2012). But they do not give direct age estimates for the human fossil nor for the fossil-bearing deposit.

Uranium Series

This general term comprises several closely related dating methods based on the radiometric disequilibrium within the radioactive decay series arising from the two uranium isotopes ^{238}U and ^{235}U (Ivanovich and Harmon 1992). The terms decay series, disequilibrium, or uranium–thorium methods of dating are also occasionally used. In paleoanthropology the ^{230}Th/^{234}U method is mostly applied, with a dating range to about 400 Ka in age, but U/Pb dating has been used as well (e.g., de Ruiter et al. 2009; Balter et al. 2008). Of particular interest for ^{230}Th/^{234}U dating are secondary carbonates of caves and springs and to a lesser degree also fossil teeth and bones. Occasionally the ^{231} Pa/^{235}U method is applied, up to 150 Ka.

The uranium-isotope ^{238}U, which constitutes 99.3 % of natural uranium, is radioactive and decays over a chain of intermediate radioactive daughter nuclides to the stable lead-isotope ^{206}Pb. In closed systems, equilibrium develops with time among all radioactive nuclides within the decay chain. In the state of radioactive equilibrium, all radioactive nuclides possess equal activity (Eq. 6). In nature, most minerals and unweathered rocks represent closed systems, in which radioactive equilibrium persists simply as a result of their geologically large ages. If such a system is disturbed, it will take some time, practically five half-lifes, until the daughter nearly returns to equilibrium with its parent nuclide. For the system ^{230}Th/^{234}U, in which ^{234}U decays by α-emission to ^{230}Th, disequilibrium arises through geochemical fractionation. Uranium is readily dissolved in groundwater and available for uptake by secondary carbonates as well as by dental/bone tissue. Thorium, on the other hand, preferentially stays adsorbed to mineral particles and thus is not easily dissolved in groundwater. Consequently, fresh calcareous deposits incorporate uranium but not thorium, that is, $(^{230}\mathrm{Th}/^{234}\mathrm{U})_{t=0} = 0$. During the following 400 Ka, corresponding roughly to five times the ^{230}Th half-life of 75.6 Ka, the ^{230}Th/^{234}U system gradually builds up to equilibrium. The time-dependent increase of ^{230}Th/^{234}U enables the determination of the time t elapsed since the event of disturbance, which equals here the precipitation of the mineral.

The essential requirements for dating are the negligibly small (or known) initial abundance of the daughter product (^{230}Th), and that after the disturbance, the radioactive system is/remains closed. Complications in ^{230}Th/^{234}U dating have various sources: (1) During incorporation ^{234}U is not necessarily in equilibrium with its radioactive predecessor ^{238}U, since in groundwater the activity ratio is $^{234}\mathrm{U}/^{238}\mathrm{U} > 1$, so that the ^{234}U/^{238}U ratio must be determined and taken into consideration for age calculation. (2) The requirement that the investigated material is free of ^{230}Th is frequently not fulfilled since thorium, and consequently also ^{230}Th, may be present. Negligible ^{230}Th contamination is indicated by $^{230}\mathrm{Th}/^{232}\mathrm{Th} > 20$. (3) The system may experience a secondary opening as a result of the geochemical mobility of the uranium.

Originally the activity of the Th and U isotopes was analyzed by α-spectrometry. The introduction of thermo-ionization mass spectrometry (TIMS) by Edwards et al. (1986/87), which requires less than 1 g of sample material and provides high age precision, brought a great impetus for ^{230}Th/^{234}U dating. More recently multicollector inductively coupled plasma mass spectrometry (MC-ICPMS) has been used. This can additionally provide spatial information when coupled with laser ablation (LA-MC-ICPMS), but at the cost of precision compared to solution MC-ICPMS or TIMS. Under favorable circumstances, age precisions better than 1 % can be obtained. The uranium content should be more than 0.1 μg g^{-1}. When sampling, e.g., *speleothems* (calcareous flowstones formed on the cave floor), dense and pure carbonates should be collected in order to minimize potential problems, i.e., open-system behavior and ^{230}Th contamination by detrital components.

This was carefully investigated in the dating of very thin secondary carbonate crusts, which had developed on top of Upper Paleolithic rock art or was already present at the time of the creation of the art. The resulting U-series ages obviously can provide only *ante quem* and *post quem* dates for the rock art, with uncertainties below 2 % at the 95 % confidence limit. It was shown that European rock art dates back to the Early Aurignacian period, with a minimum age of 40.8 Ka (Pike et al. 2012). Artwork therefore appears to have already been part of the repertoire of *Homo sapiens* when colonizing Europe at this time, or shortly beforehand, as also evidenced by painted stones and elaborate figurative art in southern German caves (cf. TL and radiocarbon dating).

In the Tongtianyan Cave, Guangxi, China, one of the few Pleistocene fossils of *Homo sapiens* in Asia was discovered. Several speleothem layers, intercalated in the cave sediments, were dated by ^{230}Th/^{234}U. The age results of 13.5 ± 2.3 Ka, 63.1 ± 2 Ka, and 148 ± 4 Ka, for three layers from top to bottom, follow the stratigraphical order (Shen et al. 2002). Although the stratigraphic position of the hominid find is to some extent uncertain, it was certainly located below the second layer. This renders this find as one of the earliest in East Asia, indicating that modern humans arrived there before ca. 60 Ka ago.

Depending on the measurement precision, the ^{230}Th/^{234}U system in speleothems older than 350 Ka often shows equilibrium, so that only a *terminus ante quem* can be given for the age. This situation was met in the fossil hominid sites known as the Sima de los Huesos, Spain, and the Caune de l'Arago, France. At Sima de los Huesos, the numerous human individuals, which are considered as evolutionary ancestors of the Neanderthals, are overlain by a speleothem in equilibrium and thus older than 350 Ka (Bischoff et al. 2003). Analogously, the pre-Neanderthals found in the Middle Pleistocene unit III at Caune de l'Arago have to be older than 350 Ka (Falguères et al. 2004). At the famous Zhoukoudian site near Peking, yielding the *Homo erectus* commonly known as Peking Man, speleothems which were intercalated in the fossiliferous sediments were ^{230}Th/^{234}U dated. In most samples the ^{230}Th/^{234}U system was close to equilibrium. However, high-precision analysis of these nuclides enabled to push the dating method to its upper limits, which is in the 500–600 Ka age range with the present instrumentation (Shen et al. 2001). The results indicate that the youngest member of *Homo erectus* at this site is >400 Ka and the oldest members from the lower layers are significantly older than 500 Ka.

The ^{230}Th/^{232}Th–^{234}U/^{232}Th-isochron technique permits determining the initial ^{230}Th/^{232}Th ratio. Schwarcz (1989) used this technique for dating the sinter crust on the cranium of the classic Neanderthal at Monte Circeo, central Italy. The encrustation on the cranium consisted of a brighter inner and a dark-brown outer layer. The outer layer provided an age of 16 Ka. From the inner layer, which contained detrital contamination, several subsamples of different U/Th ratios were obtained through fractionated leaching. The slope of the straight line (isochron) through the data points in the ^{230}Th/^{232}Th–^{234}U/^{232}Th diagram provided a more reasonable age of 51 ± 3 Ka.

Precise ^{230}Th/^{234}U dating of *travertine*, a spring sinter built from secondary carbonates, is hampered by the common detrital ^{230}Th-contamination and by open-system behavior. Applying a micro-sampling technique, in which 100 mg of sample material was selectively drilled from the micrite/sparite phases, Mallick and Frank (2002) dated successfully travertines from various Thuringian (Germany) sites, among them Weimar-Ehringsdorf with pre-Neanderthal remains. The results assign these finds firmly to oxygen-isotope stage 9.

Buried *teeth* absorb uranium from the groundwater. The knowledge of the time function of the uranium uptake is crucial for the ^{230}Th/^{234}U-age evaluation. Since the exact temporal development of uptake is unknown, one has to rely on models, such as early (EU) or linear (LU) uptake (cf. ESR), and must also consider leaching. For instance, the age of Neanderthal remains from Payré (France) was constrained by direct LA-MC-ICPMS U-series analysis of a Neanderthal tooth yielding an apparent minimum age of 200 Ka, which is in good agreement with TIMS U-series ages for an underlying flowstone between 200 and 230 Ka (Grün et al. 2008).

The mode of uranium uptake can be constrained when ^{230}Th/^{234}U is combined with ESR dating (Grün et al. 1988; Shao et al. 2012) which now is more common practice than stand-alone U series of organic tissue. With a combination of Th/U and Pa/U dating, it is theoretically possible to obtain ages back to 1 Ma, but analytical constraints limit the potential range to 600–700 Ka, and application is hampered by the required large sample size (Grün et al. 2010). Falguères et al. (1997) reported coupled ^{230}Th/^{234}U and ESR dating on horse teeth from Acheulian and Mousterian levels at la Micoque, France. The ^{230}Th/^{234}U ages of enamel and dentine ranged widely from 150 to $>$350 Ka. However, when combined with ESR dating, consistent ages between 300 and 350 were obtained. Open-system behavior is even more crucial for U-series dating of bones, and the development of new models is essential (Sambridge et al. 2012). Sophisticated techniques and multiple approaches are required to provide ages for bones by U series and preferentially should be supported by independent age evidence. However, this approach can serve as a tool for the verification of the antiquity of bones or determining if bones are intrusive and not of the same age as associated material. This was how the antiquity of one of the earliest modern humans (Omo Kibish 1) was confirmed. Agreement with Ar/Ar dating of 195 Ka for correlated material was obtained by a minimum age of 155–187 Ka with LA-MC-ICPMS U series, on bone fragments believed to belong to the calvaria (Aubert et al. 2012).

In principle, nondestructive U-series dating techniques based on γ-spectrometry can be used on valuable specimens. However, the complex detection geometries of human remains and the low resolution of the method prevent standard application, and uncertainties of results are large, usually preventing the determination of appropriate U-uptake models (e.g., Schwarcz et al. 1998 vs. Millard and Pike 1999).

Fission Track

Although fission tracks (FT) are not applied as commonly as the other radiometric dating methods in paleoanthropology, they have made significant contributions at some important sites in volcanic regions. Fission tracks are formed by the spontaneous nuclear fission of uranium. Natural uranium consists of the isotopes ^{238}U (99.3 %) and ^{235}U (0.7 %), whereby ^{238}U decays by spontaneous fission. The fission decay rate is 10^6 times less than that of the α-decay of the same isotope. During fission the uranium nucleus splits up into two fragments. Due to their kinetic energy, both fission fragments are expelled in opposite directions and leave along their path a zone of damage in the crystal lattice of a mineral. Both branches together form a straight fission track of 10–20 μm in length and several 10^{-3} μm in diameter. By chemical etching, the fission tracks can be made visible for optical microscopy. In the course of time, the tracks accumulate in the mineral, and if they are all preserved, their number is a function of the age of the event dated. Obviously, the track number depends also on the uranium content which is determined by exploiting the thermal-neutron-induced fission of ^{235}U, where the number of the induced ^{235}U fission tracks is proportional to the U content. Thus, the procedure of fission-track dating essentially involves the counting of spontaneous ^{238}U fission tracks before and induced ^{235}U fission tracks after a neutron irradiation.

The principles and application of fission-track dating were described in detail by Wagner and Van den haute (1992). With fission tracks, either the age of mineral formation or its last heating when all previous tracks were erased, i.e., the clock was reset, is dated. The fission-track method is applicable for a time span of >10 Ka. This requires, however, sufficiently high uranium contents above 100 μg g^{-1}. Zircon, due to its high uranium content, is most frequently used in paleoanthropological applications. Of particular interest are volcanic ashes that are intercalated in sedimentary sequences containing hominid remains and Paleolithic sites. Also volcanic glass, such as obsidian and pumice, is frequently used for fission-track dating.

A common problem in fission-track dating is the annealing of tracks. Latent fission tracks gradually fade over time. The fading is accelerated at elevated temperatures, in a process known as annealing. Since annealing reduces the apparent fission-track age, it is of fundamental importance to quantify this effect by track-length measurement, since annealing shortens the tracks. Fortunately, tracks in zircon are rather stable and do not show any signs of fading over several million years at ambient temperatures, although tracks in natural glasses certainly may fade under such conditions.

For fission-track dating of tephra, mainly zircon grains and, to a lesser degree, also glass shards and apatite as well as titanite grains are used. When relying on heavy minerals, the possible different provenance of the various grains needs to be taken into consideration, a difficulty already discussed (cf. K–Ar dating). Primary volcanic grains in the presence of detrital ones can be identified – apart from mineralogical criteria – by single-grain fission-track data. A good case study was conducted for the Pliocene/Pleistocene sedimentary sequence of the Koobi Fora formation, Kenya. It contains several tuff horizons, which primarily consist of glass fragments and pumice cobbles, but shows signs of redeposition. Of particular interest is the KBS Tuff, which is intercalated in hominid-bearing layers. In the 1970s, K–Ar data on the KBS Tuff raised a controversy between supporters of a long chronology (2.61 ± 0.26 Ma: Fitch and Miller 1970) and those of a short chronology (1.82 ± 0.04 Ma; Curtis et al. 1975). FT dating on zircon (2.44 ± 0.08 Ma; Hurford et al. 1976) at first seemed to support the high K–Ar age. A later FT study of zircon from the pumice yielded 1.87 ± 0.04 Ma (Gleadow 1980) in accordance with the short chronology. Besides methodological aspects, the main reasons for the previous fission-track overestimate of the KBS Tuff are detrital, old zircon grains. A far-reaching study on tuffaceous zircon was reported by Morwood et al. (1998). At the site of Mata Menge, Flores (Indonesia), a layer with stone tools is intercalated in tuffaceous deposits. FT dating on zircon from the lower and the upper tuffaceous layer yielded 880 ± 70 Ka and 800 ± 70 Ka, respectively. Provided that these grains are primary and not reworked, these findings imply that at that time *Homo erectus* had already reached the island of Flores from Southeast Asia – a journey that requires an amazing sea-crossing capability, even at periods of lowest sea level.

Ashes in prehistoric fireplaces may contain sufficiently heated grains of apatite, zircon, and titanite. At Zhoukoudian near Peking, with its numerous remains of *Homo erectus* (Peking man), several hundred grains of titanite in the size range of 50–300 μm were separated from ashes sampled from layers 10 and 4. The length of the fission tracks was utilized as criterion for discriminating completely from partially annealed titanite grains. Altogether, 100 grains showed complete resetting and gave mean ages of 462 ± 45 Ka for layer 10 and 306 ± 56 Ka for layer 4 (Guo et al. 1991), which are younger than the abovementioned uranium-series ages for this site (Shen et al. 2001).

Luminescence

Since its introduction by Daniels et al. (1953), luminescence dating has gradually developed into a powerful chronometric technique, particularly for quartz- and feldspar-bearing materials (Aitken 1985, 1998; Bøtter-Jensen et al. 2003; Yukihara and McKeever 2011). In the meantime, luminescence dating has significantly contributed to paleoanthropology. As to the techniques of luminescence dating, one distinguishes between thermoluminescence (TL) and optically stimulated luminescence (OSL). For the latter the term “optical dating” is also used. Luminescence dating covers a wide age range between 10 and 10^5 years and thus is able to reach well beyond the limits of radiocarbon dating. Datable materials comprise various inorganic sediments, such as sand and loess, heated stones, and bleached stone surfaces.

Luminescence dating is based on the time-dependent deposition of energy in the crystal lattice of minerals. This energy stems from ionizing radiation, which originates from natural radioactivity, as well as cosmic radiation and is omnipresent in nature. The radiation, consisting of energetic α- and β-particles as well as photons (γ-rays), interacts with the atoms of a mineral and removes some electrons from their original valence-band position in the atom shell. Freed electrons diffuse for a short distance through the crystal lattice, and some of them become trapped in lattice imperfections. Such electrons are trapped at higher energetic levels than those in the valence band. With time t the electron traps are increasingly filled – the process that forms the basis of the luminescence clock. When the crystal is stimulated by heat or light, the electrons are released from their traps, enabling them to recombine with opposite charge carriers whereby the formerly trapped energy is set free. Some of this energy appears as emission of visible light, the luminescence. Depending on the kind of stimulation, one differentiates thermally (TL) from optically stimulated luminescence (OSL) from radiofluorescence (RF), the latter of which is stimulated by ionizing radiation. OSL is further differentiated according to the type of stimulating light, such as OSL by green/blue or IR-OSL (IRSL) by infrared stimulation. Recent approaches consist of various steps of heating and illuminating the samples (e.g., post-IR IRSL) or employ the isothermal decay of the luminescence signal (IT-TL) for dating.

The intensity of the luminescence signal is related to the accumulated energy dose *AD* (in unit of Gray, *Gy*) and, thus, to the time interval *t* (age) during which the mineral has been exposed to the ambient ionizing radiation. The luminescence age is calculated from the accumulated *AD* and the rate of ionizing radiation *DR* (dose per time, in unit of $Gy\ a^{-1}$).

$$t = AD/DR \tag{7}$$

From this equation, it becomes clear that the dating procedure consists of two steps: the determination of *AD* and *DR*.

With increasing radiation dose, the number of empty traps still available becomes fewer, so that the growth curve of the luminescence signal assumes the shape of exponential *saturation*. In most cases saturation is reached after doses of few 10^2 Gy. This behavior restricts luminescence dating to the last few 10^5 years. In order to convert the luminescence signal into a dose value (*AD*), the *sensitivity S* to ionizing radiation (luminescence signal per dose, i.e., the slope of the growth curve) has to be determined, varying from sample to sample. For a given sample, it is the same for β- and γ-radiation but different for α-radiation. The sensitivity ratio S_α/S_β, the so-called a-value, needs to be determined, but is mostly around 0.1.

Another behavior limiting the age range is *fading* of the latent luminescence signal in the course of time, violating the prerequisite that all centers involved in the signal generation are stable over the complete age range in question. Like any other type of radiation damage, latent luminescence signals are subjected to fading whose kinetics is essentially thermally controlled. As far as near-surface materials at normal ambient temperatures are concerned, natural fading limits the datable age range up to a few 10^5 years.

An important concept in dating is the *resetting* of the system: The luminescence systems need to have been reset at the event of interest. Complete or at least partial resetting of the latent luminescence signals is caused by exposure to heat or light. Consequently, the last occurrence of such an event can be dated, for example, the deposition of sediments or the heating of flint artifacts.

The past few years have seen a lot of progress in laboratory protocols. Previously, it was common practice in *AD* evaluation to prepare multiple subsamples (aliquots) and apply various doses in addition to the natural one. Lately, the so-called SAR protocol (Single Aliquot Regeneration) is increasingly preferred, which regenerates the luminescence signal after artificial resetting (Murray and Wintle 2000).

When using regenerated growth curves, *AD* is evaluated through the value of the artificial dose required to produce exactly the same luminescence intensity as the natural one. In order to normalize for sensitivity changes due to the laboratory procedure, a constant test dose is applied and measured for each aliquot at every step in the procedure. However, it is debated if the initial sensitivity changes can be accounted for (e.g., Singhvi et al. 2011). The advantages of the SAR protocol over the conventional multiple-aliquot (MA) technique are smaller sample size, less time for sample preparation, and improved analytical precision due to replicate *AD* determination. The present technology is directed towards single-grain protocols that allow the differentiation of *AD* populations in order to select the results from grains showing the same apparent luminescence age on statistical grounds, which bears a great potential for novel applications (Roberts et al. 1997; Greilich et al. 2002; Greilich and Wagner 2006; Jacobs et al. 2003, 2013).

Apart from the accumulated dose *AD*, the natural dose rate *DR* needs to be determined for the age calculation. The ionizing radiation at the Earth's surface originates predominantly from the radionuclides ^{232}Th, ^{235}U,^{238}U, and their daughter products, as well as ^{40}K and ^{87}Rb and, to a minor extent, from cosmic rays. These nuclides emit α-, β-, and γ-radiation, each of which has a different penetration depth, amounting in rocks to ca. 20 μm, 2 mm, and 30 cm, respectively. The internal component originating within the luminescence sample as well as the external radiation from the immediate surroundings, i.e., sediment, has to be taken into account. The age determination requires materials of a uniform and defined dose rate. For this reason one separates the sample into certain sizes, usually the fine-grain (4–10 μm) or coarse-grain (100–200 μm) fractions. Since any water residing in pore volumes attenuates the dose rate, the moisture content and its possible temporal variation in the sample as well as its environment need to be estimated. Also the on-site intensity of the cosmic rays has to be assessed. It mainly increases with topographic altitude and decreases with depth below the surface. Temporal variation of the dose rate might be caused by changing contents of radionuclides in sediment due to disequilibrium within the decay chains. All these factors have to be considered carefully, since they may cause major uncertainties in luminescence dating. For dose-rate evaluation, several techniques are available, among them α- and β-counting, γ-spectrometry, atomic absorption, ICP-MS, and neutron activation analysis.

Luminescence dating of *clastic sediment* enables to determine when it was deposited, provided all of the sedimentary grains were sufficiently exposed to daylight before and during deposition. In this way paleoanthropological remains which are embedded in such sediment series can be dated. In Central Europe – as well as in other periglacial areas – numerous loess profiles with Paleolithic finds have been TL dated (e.g., Zöller et al. 1991). Also many sands have been dated by OSL. An example is the dune sands of the Acheulian open-air site of Holon/Israel where alkali feldspar and quartz fractions were dated by OSL as well as TL (Porat et al. 1999). The presence of sediment remnants in the endocranial cavity of a modern human from Hofmeyer (South Africa) allowed the OSL dating of the deposition of the skull, despite the impossibility of locating the original position of the specimen in its sedimentological context. Quartz grains were extracted and yielded OSL ages of 40.9 ± 4.2 Ka, 33.0 ± 2.5 Ka, and 34.7 ± 3.4 Ka, which were combined to a depositional age of the endocranial sediment of 36.2 ± 3.3 Ka (Grine et al. 2007).

However, the presumption that all grains had been completely bleached at deposition is not necessarily fulfilled. In particular, fluvial sands, where grains were transported under water cover, may contain partially bleached or even unbleached grains. In this case the apparent luminescence age would be an overestimate. Also, post-depositional vertical mixing between sedimentary layers, such as bioturbation, leads to erroneous ages. In addition to such phenomena, trampling and human modifications might lead to sediment particles being displaced in archaeological sites.

Luminescence measurements of individual grains enable the identification of such disturbances. Because of microdosimetric concerns, this might not always be straightforward because a priori it cannot be differentiated whether the determined *AD*s are influenced by bleaching or the heterogeneity of the radiation field (microdosimetry). Single-grain OSL dating is always based on the interpretation of statistical analysis of *AD* results. Strictly, the models applied are those for dose, and not “age” models, which are always analyzed under the assumption of the validity of the statistical parameters and models employed. The potential of single-grain OSL dating was convincingly demonstrated in the case of the Jinmium rock shelter in northern Australia. Fullagar et al. (1996) reported TL ages of 176 ± 16 Ka and 116 ± 12 Ka for the artifact-bearing deposit, which would predate other results for the first arrival of humans in Australia by more than 100 Ka. The data were determined on multiple-grain aliquots of quartz, despite the known presence of erosional fragments from the mother rock in this sandstone abri. An intensive OSL-dating program on the same deposits by Roberts et al. (1999), using the single-grain approach, yielded ages of less than 10 Ka when considering only those grains which had been fully bleached before burial. Furthermore, in Australia single-grain OSL ages of quartz from Malakunanja II now date the early human occupation to 55.5 ± 8.2 Ka (Roberts et al. 1998) and the human burials of Lake Mungo to 40 ± 2 Ka (Olley et al. 2006).

Burned flint is well suited for TL dating. Due to a relatively low internal dose rate and good TL-stability behavior, its datable age range reaches back to at least 500 Ka and thus covers a large part of the Paleolithic period. TL dating of flint requires prehistorical annealing (>400 °C) of the TL signal, which, fortunately, has been the case for a considerable number of flint artifacts. Because of the dosimetric heterogeneity of most archaeological sites, it is advisable to collect several flint samples from each layer to be dated. Heterogeneity of the internal dose rate can be suspected for flint or similar materials. Such heterogeneities were shown by autoradiography for some samples (Schmidt et al. 2013), but were significant for dose evaluation only in macroscopically well-visible inclusions or veins. Such samples are usually rejected from analysis in any case, because of suspicions of differences in mineralogy and thus luminescence properties, unless mineral phases can be separated. Most TL-dating applications of burnt flint follow MA protocols, which require individual sample sizes larger than can be provided from many sites where burnt material is scarce and small. Detecting the luminescence in a different wavelength, however, allows the successful application of the SAR protocol and thus on small sample sizes (Richter and Krbetschek 2006). Perfect agreement with independent other dating evidence is obtained for an Eemian age site, allowing the direct dating of a prehistoric human activity (Richter and Krbetschek 2014; Sier et al. 2011).

Intensive TL-dating studies were carried out at several Levantine sites with rich Lower to Middle Paleolithic lithic industries and human remains of Neanderthals as well as early Moderns. From the site of Tabūn/Israel, Mercier and Valladas (2003) report stratigraphically consistent TL ages between 302 ± 27 Ka and 165 ± 16 Ka, indicating that the technological transition from the Acheulian to the Mousterian occurred some 250 Ka ago. Thermoluminescence dating of heated flint revealed the antiquity of the North African technocomplex of the Aterian and its problematic use as a chronostratigraphical meaningful unit. The TL dating of a stratigraphical succession of alternating Aterian (AT) and Mousterian (MOU) industries at Ifri n'Ammar (Morocco) resulted in 83.3 ± 5.6 Ka (AT), 130.0 ± 7.8 Ka (MOU), 145 ± 9 Ka (AT), and 171 ± 12 Ka (MOU) in correct stratigraphic order (Richter et al. 2010).

At the site of Kebara (Israel), a skeleton of a Neanderthal and, at the sites of Qafzeh and Skhūl, remains of archaic early modern humans were recovered. TL dating on 20 flint fragments from the hominid-containing layer in Qafzeh yielded 92 ± 5 Ka. At Kebara, 30 flint artifacts from several layers provided TL ages from 50 to 70 Ka, and the layer with the skeleton of the Neanderthal provided 60 Ka. At Skhūl six burnt flints from the level with the remains of archaic early modern humans yielded a TL age of 119 ± 18 Ka (Mercier et al. 1993). These data reveal that early forms of anatomically modern humans were present in the same geographical area as Neanderthals long before modern humans spread into Europe. However, these findings do not reveal if both species were occupying this area at the same time and an alternating scenario related to climate changes is favored.

At the early Upper Paleolithic site of Geißenklösterle/Germany, seven flint artifacts from the Early Aurignacian, and two from the Aurignacian levels, ultimately satisfied the criteria of being sufficiently heated (Richter et al. 2000), providing weighted mean ages of 40.2 ± 1.5 Ka and 37.0 ± 1.4 Ka, respectively. The disagreement with radiocarbon ages on bones from the same levels was later determined to have been caused by insufficient removal of contaminants in radiocarbon dating (Higham et al. 2012). The radiocarbon ages confirm the TL data and show their accuracy, while altogether these data imply a much earlier beginning of the Upper Paleolithic figurative art in Central Europe than anywhere in Western and Southwestern Europe.

A novel development is the OSL dating of stone surfaces, when daylight exposure in the past reset the OSL signal. Provided the surface was shielded from light since then, the moment of the last exposure to daylight can be determined. This approach opens – at least in principle – a large potential for archaeological, paleoanthropological, and geomorphological applications such as the dating of the construction and destruction of stone structures and buried lithic implements as well as deposited boulders. Hitherto, the new method has been corroborated for

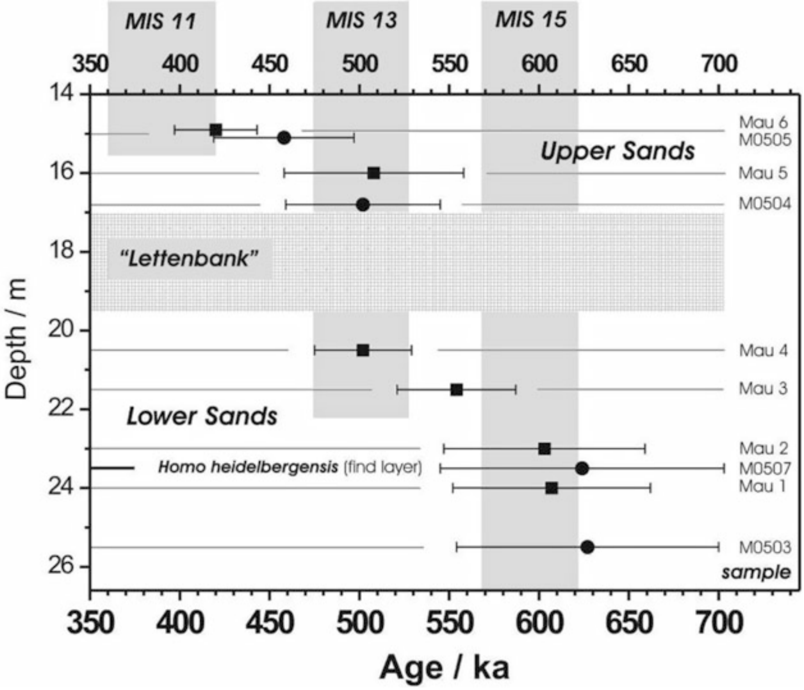

Fig. 2 IR-RF (*squares*) and ESR/U-series (*circles*) ages with 1-σ uncertainties of samples from the sand pit Grafenrain at Mauer (From Wagner et al. 2010)

granitoid rocks and successfully applied in particular to the famous Nazca geoglyphs in southern Peru (Greilich et al. 2005; Greilich and Wagner 2006).

Infrared radiofluorescence (IR-RF) is a new method developed by Trautmann et al. (1998) for potassium feldspar and is of particular interest for age ranges beyond 10^5 years because of its long-term signal stability (Erfurt and Krbetschek 2003). This new method has been shown to provide excellent agreement with a large number of independent age estimates (Degering and Krbetschek 2007). For example, IR-RF dating of the "Mauer sands" at the holotype site of *Homo heidelbergensis* is in excellent agreement with electron spin resonance dating of animal teeth from the sequence (Fig. 2). However, concerns have been raised on the general applicability (Buylaert et al. 2012), and more data from more than the currently only two laboratories is needed.

Various other new luminescence techniques are applied to establish the time of bleaching of sedimentary deposits. Namely, thermally transferred optical stimulation (TT-OSL) and post-infrared infrared stimulated luminescence (post IR-IRSL or pIRIR) are more frequently applied, including sites of paleoanthropological interest (e.g., Sun et al. 2013; Schmidt et al. 2011, respectively). The accuracy of such recent developments, however, has not been shown by fully independent methods so far.

Electron Spin Resonance

Electron spin resonance (ESR) dating is also based on the accumulation of radiation-induced energy in minerals and thus has close links to luminescence dating. Although first attempts to exploit the ESR phenomenon for dating go back to the 1960s (Zeller et al. 1967), it did not flourish as a dating method before the 1980s and is still being developed. The ESR method permits age determination up to a few million years, far beyond the range of the luminescence methods, and covers the whole Quaternary period. The most important material for paleoanthropological application is tooth enamel, but quartz separates from sediments at prehistoric sites also have a certain potential (Rink 1997), as well as fluvial sediments. With ESR dating, either the event of the death of a mammal (set equal to sediment deposition and/or, e.g., human occupation), the resetting of a previous system as a result of bleaching of sedimentary quartz grains, or the event of heating of stones is dated.

The ESR phenomenon is caused by paramagnetic centers in the crystal lattice. Radiation-induced trapped electrons (see "Luminescence") form such centers and give rise to characteristic ESR signals. The intensity of the ESR signal is a function of the number of trapped electrons and therefore of the accumulated energy dose *AD* that has been absorbed from the ionizing radiation in the course of time. In order to calculate the ESR age, the value of *AD*, obtained from the ESR measurement, is divided by the dose rate *DR*, in the same manner as already discussed for luminescence (Eq. 7).

The quantity of *AD* is determined by ESR spectrometry, which exploits the fact that trapped electrons are unpaired. Brought into a variable magnetic field and exposed to a given microwave, unpaired electrons show spin resonance at a specific strength of the magnetic field. The condition at which resonance happens is described by the g-value, which is characteristic for the type of the paramagnetic center. The energy necessary for the resonance is absorbed from the microwave so that its intensity reduction is a measure for the concentration of the center. The resulting ESR spectrum shows the specific microwave absorption for various centers with different g-values. Owing to measurement-technical reasons, the ESR spectra of the microwave absorption are not directly recorded; instead their first derivation as a function of the field strength is plotted. For the evaluation of *AD*, known artificial doses are applied in addition to the natural one and a signal growth curve is established. ESR has the advantage over luminescence that the concentration of the probed centers is not disturbed by the measurement procedure, thus permitting one to establish an additive growth curve with accumulating doses on the same aliquot. Most samples show exponential saturation functions. At normal ambient temperature of sediment, most ESR centers are sufficiently stable for applying ESR dating up to a few million years. The dose-rate determination follows the same principles as already mentioned for luminescence. For ESR-dating samples of a few grams are sufficient, provided the material is homogenous, but usually larger sample sizes are preferred as they allow the separation of suitable materials in the laboratory to conduct microdosimetric measurements.

ESR dating of fossil *tooth enamel* plays an important role for Paleolithic sites, mainly because teeth are commonly preserved. Mammalian dental issue consists essentially of enamel, dentine, and cementum layers. ESR dating is based on the mineral hydroxyapatite, in particular on its carbonate-containing subspecies dahllite, within the enamel. Dentin and cementum are less dense, contain more organic tissue, and take up uranium more easily than enamel. For these reasons, they are not used for ESR analysis, but must be taken into account for microdosimetric reasons. The ESR spectrum of tooth enamel has, at $g = 2.0018$, a suitable signal of good sensitivity and high thermal stability.

The quantity of the dose rate introduces considerable problems into ESR-age evaluation. Strongly varying uranium contents on the microscopic scale often cause steep dose-rate gradients in teeth, which is in particular the case for the β-component since the β-radiation range (ca. 2 mm) is similar to the thickness of the enamel layers. Teeth gradually take up uranium from the groundwater after burial. In vivo they contain less than 1 $\mu g\ g^{-1}$ of U, but fossil ones have up to 1,500 $\mu g\ g^{-1}$. This means that the dose rate increases with time and that the closed-system condition is not fulfilled. To allow for the time dependence of the dose rate, distinct models of uranium uptake are assumed, such as the early uptake (EU), the linear uptake (LU), and recent uptake (RU) models. The EU model results in a lower ESR age compared to the LU model due to a higher dose rate on the average. Both model ages may considerably differ from each other, especially for sample with high uranium contents so that samples low in uranium are preferable. Most published ESR-age data are based on assumed U-uptake models. In order to set constraints to the validity of the model, ESR dating is coupled with uranium-series dating (Grün et al. 1988), with new uptake models developed by Shao et al. (2012). The comparison of theoretical closed-system ages of $^{234}U/^{238}U$ and $^{230Th}/^{234}U$ with that of ESR enables to discriminate among the hypothetical models. Combined ESR/uranium-series dating has become more and more the routine for tooth enamel dating.

The Early and Middle Paleolithic sites of Tabūn, Kebara, Skhūl, Qafzeh, and Hayonim (Israel), with rich lithic and human bone inventories, play a fundamental role with respect to the early human out-of-Africa dispersion through the Levantine corridor. In order to establish a firm chronology of this process, ESR dating has been repeatedly applied to mammalian tooth enamel from these sites, in addition to uranium series and luminescence. Worth mentioning in this context are two results in particular. First, the combined ESR/uranium-series tooth age of 387 ± 50 Ka confirms a 340 ± 33 Ka TL age on burnt flint for the Lower Paleolithic Yabrudian lithic industry at Tabun, whereby the U uptake appears to be more recent than linear (Rink et al. 2004). Second, the ESR ages on teeth from Middle Paleolithic contexts support the early dating of anatomical Moderns to 80–120 Ka, with the amazing consequence that the Levant was alternating, inhabited by Moderns and Neanderthals for about 60 Ka.

At the well-known South-African site of Swartkrans, with its wealth of remains of *Australopithecus robustus*, Curnoe et al. (2001) determined one of the oldest ESR ages so far reported. Coupled ESR/uranium-series dating on two human and two bovid teeth yielded 1630 ± 160 Ka, with a possible maximum of 2110 ± 210 Ka, indicating that ESR dating can provide reasonable results for samples of Late Pleistocene/Early Pleistocene age. Also the Atapuerca Gran Dolina site, northern Spain, with the earliest human remains in Europe of *Homo antecessor*, was investigated by combined ESR/uranium-series dating. From the bottom of the Aurora stratum, where the very early human remains were recovered, three ungulate teeth gave a mean age of 731 ± 63 Ka, which is in agreement with the paleomagnetic age estimate of >780 Ka (Falguères et al. 1999).

ESR also permits the dating of calcareous sinter deposits that show complex ESR spectra partially as a result of organic radicals. Important Paleolithic cave sites have been dated, among them Caune de l'Arago at Tautavel, southern France. ESR dating of calcareous deposits under- and overlying the hominid-bearing layer allowed its bracketing between 242 and 313 Ka as upper and 147 Ka as lower age limits, respectively. This result is in good agreement with uranium-series data of 315–220 Ka (Hennig and Grün 1983).

The holotype of *Homo heidelbergensis* was found in 1907 in fluvial sands at Mauer near Heidelberg. The associated mammalian fauna and the geological context place the find layer in the early Middle Pleistocene, but confirmatory chronometric evidence has only been recently achieved by the coupled ESR/U-series dating of mammal teeth and infrared-radiofluorescence dating (IR-RF) of feldspar grains from the sands (Wagner et al. 2010). These "Mauer sands" are subdivided into two distinct units, the "lower sands" and the "upper sands," separated by a clay/silt layer (Fig. 2). The mandible of *Homo heidelbergensis* was recovered from a 0.1 m thick gravel layer within the "lower sands." Both sand units are renowned for their rich early Middle Pleistocene mammal faunas, which clearly indicate warm climate conditions. The good preservation of the mammal bones – and in particular of the human mandible – indicates that they were transported from a nearby fluvial floodplain before becoming embedded in the river deposits, i.e., they have the same geological age as their surrounding sediment layers. Eight herbivore teeth (five from the "lower sands" and three from the "upper sands") were analyzed with the ESR/U-series technique. Most of the Mauer dental-tissue samples show evidence of postmortem uranium uptake, allowing the calculation of reliable ages (Fig. 2). The IR-RF ages determine the last light exposure of sand grains, i.e., their depositional age. Ten samples from six sediment layers of both sand units were dated using small subsamples of K-feldspar grains (Fig. 2). The weighted mean of the two sand samples Mau 1 and Mau 2, and the dentine sample M0507, yields 609 ± 40 Ka for the find layer of *Homo heidelbergensis*. This result demonstrates that the mandible is the oldest hominin fossil reported so far from Central and Northern Europe.

ESR may also be applied to quartz grains from *clastic sediments*, provided the grains were exposed to light for about 6 months during sedimentary transportation so that the minimum signal level in Al centers is reached. However, there are so far only a few examples of successful application in paleoanthropology, one being the early Pleistocene Monte Pogglio site, Italy, where more than 4,000 Paleolithic flint artifacts were found in sandy beach deposits. Detrital quartz extracted from different archaeological levels provided a mean age of 1065 ± 165 Ka, which is in agreement with paleomagnetical data (Falguères 2003).

Radiocarbon (^{14}C)

Among the physical dating methods, radiocarbon is the most widely known and most commonly applied in archaeology. Essentially, it utilizes organic remains from the last 50 Ka. In the context of paleoanthropology, this covers only the periods from the Late Middle Paleolithic onwards, which comprise a relatively short section of human presence on Earth. Furthermore, its application in the pre-Holocene time range (>12 Ka) is complicated by the fact that calibration procedures for ^{14}C dates cannot be based on high-precision tree-ring data, resulting in low accuracy of the true age. Towards the upper age limit, contamination by modern carbon becomes a dominating problem.

Recent natural carbon consists of the two stable isotopes ^{12}C (98.89 %) and ^{13}C (1.11 %), and in very minor traces the radioactive ^{14}C ($^{14}C/^{12}C \times 10^{-12}$) that decays ($t_{1/2} = 5730$ a) under β-emission. ^{14}C is naturally produced in the stratosphere by interaction of neutrons from cosmic rays with atmospheric nitrogen atoms according to the reaction ^{14} N(n,p)^{14}C. The average global ^{14}C production rate is 7.5 kg a^{-1}, but is subject to considerable temporal variation. Depending on this rate, an equilibrium value between production and radioactive decay is established. Bound in CO_2, ^{14}C becomes quickly distributed throughout the atmosphere. By photosynthesis CO_2 enters the plants and via the food chain the biosphere. Through dissolution and gas exchange, it is introduced into the hydrosphere, from where it is incorporated as $CaCO_3$ into marine or limnic sediments and organisms. As long as these reservoirs participate in the carbon cycle, their ^{14}C concentration maintains the atmospheric equilibrium value.

The carbon becomes separated from the cycle with the death of the organism or with carbonate precipitation, so that the ^{14}C input is interrupted. Thereupon, the $^{14}C/^{12}C$ ratio declines due to the radioactive decay of ^{14}C. Initially it was assumed by Libby (1952) that the atmospheric $^{14}C/^{12}C$ was constant. According to this model, the *conventional* ^{14}C age is calculated (cf. Eq. 5) from the present $^{14}C/^{12}C$ and an assumed fixed value for $(^{14}C/^{12}C)_0$. The conventional ^{14}C age is linked to the reference year 1950 AD, with the notation "BP" (before present).

Conventional ^{14}C ages do not directly provide the right age information, since the simple model condition of a constant initial $^{14}C/^{12}C$ is invalid. Tree-ring data, for instance, show that within the past 11 Ka, the initial $^{14}C/^{12}C$ decreased by ca. 10 %, so that a 10 Ka old sample results in a ^{14}C age being ca. 1 Ka too young. In order to obtain accurate ages, the temporal fluctuation of ^{14}C must be corrected for. This is achieved by ^{14}C dating of samples of independently known age (e.g., tree rings). Apart from possible oscillations of the primary cosmic ray flux, the fluctuations in the atmospheric $^{14}C/^{12}C$ level are attributed to changes in the ^{14}C-production rate, caused by the varying magnetic shielding of the primary cosmic rays; in particular the geomagnetic minimum ca. 40 Ka ago doubled the production rate (Beck et al. 2001). Also, magnetic disturbance originating from solar activity modifies the production rate, although to a lesser degree and on shorter time scales. In this way, high magnetic intensities imply low ^{14}C-production rates and, thus, high apparent ^{14}C ages. On the other hand, the carbon exchange between different reservoirs, mainly the ocean and the atmosphere, affects the atmospheric $^{14}C/^{12}C$ level. In periods, when the oceanic circulation slows down, less of the "aged" oceanic CO_2 is released into the atmosphere, so that atmospheric $^{14}C/^{12}C$ level increases, leading to apparently younger ^{14}C ages.

Regardless of their origin, these fluctuations necessitate calibration of the ^{14}C results. By calibration the chronologically irrelevant *conventional* radiocarbon age is converted to a calendar time scale. This is achieved via calibration curves, in which conventional ^{14}C ages are plotted versus the true known calendar ages of the same samples determined by other means. For the Holocene this is achieved with high accuracy by dendro-calibration. For the late Pleistocene, other archives than tree rings are needed due to the scarcity of trees during glacial climate. Annually varved sediments, shallow-water corals, and planktonic foraminifera, which can be independently dated with uranium-series techniques, have been used for this purpose, with the latest efforts presented as the INTCAL09 curve (Reimer et al. 2009). While this calibration curve covers the entire radiocarbon age range of ca. 50 Ka, its reliance on marine material for the correction of terrestrial material is not favorable because of the required marine reservoir correction. However, the IntCal13 radiocarbon calibration curve under construction will be much more based on terrestrial high-precision records of the varved sediments from Lake Suigetsu (Bronk Ramsey et al. 2012) in its lower age range, together with speleothems from the Bahamas and Hulu Cave, and support from marine data for its entire time range (Reimer et al. 2013).

Nevertheless, a particular complication resulting in lower precision is posed by the strong ^{14}C fluctuations that are associated with the magnetic minima during the Laschamp and Mono Lake geomagnetic excursions around 40 and 33 Ka ago, respectively, which are crucial periods in the peopling of Europe.

In order to distinguish calibrated ^{14}C ages from conventional ones, they are characterized by the notations "cal BC" (calendar years BC), "cal AD" (calendar years AD), or "cal BP" (calendar years before 1950 AD). In publications it always has to be stated which calibration curve and which software were used. Furthermore, the original radiocarbon date should always be provided together with the lab code. This will allow future calibration with improved calibration curves that are expected to provide increased precision and accuracy, as has already been the case for the dendro-calibrated age range.

Apart from the temporal fluctuations, problems arise from spatial ^{14}C inhomogeneities in the materials and reservoirs participating in the carbon cycle. One distinguishes *isotope fractionation* and *reservoir effects*. Photosynthesis, for instance, enriches the light ^{12}C over the heavy ^{13}C, and in turn the latter over the even heavier ^{14}C, so that the carbon in plants is isotopically lighter than in the atmosphere. For most materials, the age corrections caused by isotope fractionation are less than 80 Ka, but may amount up to several hundred years, as in the case of marine limestones and organisms. The *reservoir effect* deals with the isotopic variation of carbon within the reservoir, from which the organisms extract their carbon. Such spatial changes may have various causes. If the carbon stays long – with respect to the ^{14}C half-life – within the same reservoir, the ^{14}C concentration declines ("aging" of carbon). A prominent example is the "marine reservoir effect" in the oceans where upwelling regions have present-day apparent ^{14}C ages of around 400 Ka. Also the admixture of "aged" carbon lowers the ^{14}C concentration, such as in the "hard-water effect" in carbonaceous groundwater and surface water. Reservoir effects result in an apparent increase of the ^{14}C age and are difficult to assess.

As in other radiometric dating methods, the ^{14}C system has to remain closed, i.e., carbon must neither enter nor leave the sample. The ^{14}C age is lowered by uptake of recent carbon. Common sources of contamination with recent carbon are the presence of rootlets, humic acid infiltration, and bioturbation. The smaller the authigenic ^{14}C amount and the older the sample is, the more the danger of contamination by modern carbon increases. For this reason the applicability of ^{14}C dating at old ages is limited by unavoidable contamination rather than by the instrumental capabilities of ^{14}C detection. The upper dating limit (*maximum age*) is reached when the ^{14}C of an old sample cannot be discriminated with sufficient statistical confidence from the background. The AMS technique has the great potential to lower the instrumental background and thus to extend the maximum age, but the latter is effectively limited by the ^{14}C background due to contamination of samples themselves and by sample preparation, as well as by techniques employed for sample purification. As a rule of thumb, the oldest radiocarbon age from a given context with unequivocal association with the sample and that satisfies all quality criteria would provide the closest radiocarbon age estimate of the true age where contamination of samples is believed to be a problem. Recent developments in pretreatment chemistry to remove contamination have yielded older radiocarbon age estimates for the majority of samples, but not all.

The amount of sample required for ^{14}C dating depends on the carbon content, the conditions of preservation, the degree of contamination, and the technique of ^{14}C detection. For β-counting, either in gas or liquid scintillation counters, 5–10 g of extracted carbon usually is needed. The AMS technique requires carbon in the mg range. Note that the quoted amounts refer to carbon, and not to sample. The required amount of the latter one might be larger by a factor of 10 or so, depending on the carbon content.

Bones and *antler* are among the most frequently used paleoanthropological sample materials for ^{14}C dating. As long as their inorganic fraction was used, bones were considered as a problematic material for ^{14}C dating due to open-system behavior. However, their organic substance consisting predominantly of various proteins, generally classed as collagen, is more resistant to exchange. The collagen is chemically extracted as acid-insoluble residue, sometimes physically separated (e.g., ultrafiltration), and then usually subjected to AMS analysis. Contamination issues appear to be drastically reduced with procedures like ultrafiltration, but cannot be entirely ruled out a priori, especially for old bones with little collagen preservation or which had been subjected to preservation, e.g., with glue. This is particularly problematic with human bones, which are more frequently treated, and establishing the time of Neanderthal replacement by modern humans has been especially hampered by significantly varying radiocarbon dating results for the same human bones both between and within laboratories. However, by extraction, identification, and subsequent single amino acid radiocarbon dating of the collagen specific compound of hydroxyproline, it can be assured that only carbon from collagen of a particular bone is dated (Marom et al. 2012) and contamination is thus reduced to the maximum extent possible. This specific technique was applied to the early modern human skeleton from Kostenki 14 (Markina Gora), which has been attributed to the Upper Paleolithic but yielded direct radiocarbon ages between 4 and 14 Ka ^{14}C. By single amino acid radiocarbon dating, an age of 33 Ka ^{14}C was established and the Upper Paleolithic age confirmed (Marom et al. 2012).

Such diversities in radiocarbon dating results have fed extended debates particularly on the Neanderthal replacement, which corresponds to the Middle to Upper Paleolithic "transition" of European lithic industries. Human remains are exceptional, and radiocarbon dating of archaeological layers is therefore usually based on associated animal bones, which provided AMS radiocarbon results, e.g., between 28 and 40 Ka ^{14}C for the Aurignacian levels of the Geißenklösterle Cave (Germany). This long time span, which is inconceivable with other evidence, was attributed to unusually strong variations in the production of atmospheric radiocarbon and/or taphonomic processes resulting in the mixing of the bones of various ages within the site. Only a systematic study with thorough decontamination (ultrafiltration) techniques eventually yielded consistent radiocarbon dating results for the site (Higham et al. 2012). The preexisting chronostratigraphy already established by thermoluminescence (TL) dating results on burnt flint (Richter et al. 2000) was confirmed by good agreement. These data show the presence of the Aurignacian and elaborate figurative art earlier than anywhere else in Europe.

Within the same framework, radiocarbon dating of bone has shown the human burial at the Vogelherd Cave (Germany), believed to be associated with similar artwork, to be a Holocene intrusion (Conard et al. 2004). Similarly, a number of other supposedly Upper Paleolithic human remains from Europe were dated by radiocarbon to be of much younger age, emphasizing the crucial requirement of establishing an unequivocal association of dated sample and archaeological context. In light of the recent possibility of single amino acid radiocarbon dating, however, reinvestigations might need to be considered. On the other hand, the oldest directly dated anatomically modern human remains from Peştera Cu Oase (Romania) are not associated with any archaeological remains and are dated by radiocarbon to 34,000–36,000 ^{14}C years BP (Trinkaus et al. 2003), which translates to ca. 42–37.8 Ka cal BP.

Another important dating material is *charcoal*, which is often viewed as much more reliable than bone radiocarbon dating because of more efficient methods for decontamination. In the age range of interest in paleoanthropology, which is close to the limits of the method, however, the application of pretreatment methods indicates underestimation of many radiocarbon dates on charcoal in the 40 Ka range. Comparison of radiocarbon dating of charcoal associated with the independently well-dated Campanian Ignimbrite (CI) tephra showed consistent older and more accurate ages with ABOx-SC pretreatments, compared to the simpler chemical sample preparation of ABA (Wood et al. 2012). Charcoal radiocarbon dating shows the contemporaneity of the lithic technocomplexes of the Proto-Aurignacian and the Uluzzian, the latter of which is considered as a "transitional" industry. While the former is believed to be associated with modern humans, the latter is traditionally assigned to Neanderthals, and these species appear to have occupied different parts of Italy at the same time before the Campanian Eruption 39 Ka ago. Likewise bone radiocarbon dating, the association of charcoal samples should be shown first, e.g., by verification, if the plant species is in accordance with the paleoenvironmental setting.

Limnic sediments form an important archive for the climatic fluctuations of the past, and if they contain organic matter, ^{14}C dating can be directly applied, in particular to peat and sapropel. An excellent material for AMS ^{14}C dating is macrofossils, such as nutshells, fruit kernels, and leaves, recovered from sediments. Such fossils are short-lived and free of the hard-water effect. When dating secondary *calcareous sinter*, the uptake of a certain fraction of "dead" carbon from geologically old limestone must be taken into account, which lowers the reliability of such dates. When using mollusk shells, the marine or hard-water reservoir effect, depending on the habitat of the mollusks, needs to be considered. Paleolithic *rock paintings* commonly contain organic material, such as charcoal, carbonized plant matter, pigments, plant fibers, blood, fatty acids, and beeswax, which enables ^{14}C dating. Radiocarbon dating of micro-samples of charcoal from elaborate rock paintings at the cave of Chauvet-Pont-d'Arc (France), which was sealed by 21 Ka ago, provides further evidence on the early "artistic" expressions of modern humans, with radiocarbon ages around 30 Ka ^{14}C (Valladas et al. 2005). These thus belong among the earliest examples of prehistoric rock art so far discovered.

Cosmogenic ^{26}Al/^{10}Be

The Earth is exposed to a steady flux of cosmic rays – mainly hydrogen and helium nuclei – which interact with the atoms of the atmosphere and reach the Earth's surface strongly attenuated and modified. There they are shortly stopped by nuclear reactions producing in situ radioactive as well as stable cosmogenic nuclei. For dating applications, the radioactive cosmogenic nuclides ^{10}Be, ^{26}Al, ^{32}Si, ^{36}Cl, and ^{41}Ca are used. Due to nuclear reactions, the cosmic rays become absorbed essentially within the upper few meters of the rock surface. Most cosmogenic nuclides occur in extremely low concentrations, requiring very sensitive detection techniques such as accelerator mass spectrometry.

For radioactive cosmogenic nuclides, concentration N [atoms g^{-1}] grows gradually with the duration of exposure, until after about five half-lifes ($t_{1/2}$) it reaches an equilibrium level Ng between production and decay. The "exposure age" of a sample, at first completely shielded from and later suddenly exposed to cosmic radiation, derives from the amount of the radioactive nuclides N according to

$$t = -\ln\left(1 - \ln 2/t_{1/2} * N/P\right) * t_{1/2}/\ln 2 \tag{8}$$

where P is the cosmogenic production rate of N. If a sample already at its level Ng is suddenly shielded from cosmic radiation, so that production is suspended, the nuclide content N declines by radioactive decay and the beginning of shielding, i.e., the "burial age," can be dated according to

$$t = \ln\left(N_g/N\right) * t_{1/2}/\ln 2 \tag{9}$$

The exact knowledge of the production rates of the various cosmogenic nuclides is a prerequisite for their dating application. These rates are derived by experimental measurements as well as theoretical calculations. The decrease from the poles to the equator is known as *latitude effect*. Also an *altitude effect* needs to be taken into account, since P increases strongly with altitude.

The analysis of ^{26}Al should always be combined with that of ^{10}Be (^{26}Al/^{10}Be method), in order to eliminate uncertainties about production rates. For the production rate ratio ^{26}Al/^{10}Be in quartz, a value of 6.1 was reported (Nishiizumi et al. 1989). Once the rock is shielded from further cosmogenic production, this ratio decays with an effective half-life of 1.36 ± 0.07 Ma, which enables its application in the 10 Ka to 10 Ma age range.

Burial dating with cosmogenic ^{26}Al and ^{10}Be was first applied to quartz gravels in caves for deriving river incision rates (Granger and Muzikar 2001). Later the hominin sites at Sterkfontein (Partridge et al. 2003) and Sima del Elefante at Atapuerca (Carbonell et al. 2008) were dated with this technique. ^{26}Al/^{10}Be burial dating of quartz-bearing sediments and artifacts from the lower strata of the Zhoukoudian karstic cave, where early representatives of *Homo erectus* were discovered, has been carried out by Shen et al. (2009). There, the sediment was transported by fluvial processes from the source into the cultural layers, ca. 20–25 m below the current surface at the time of occupation. The weighted mean age of three sediment samples and three quartzite artifacts gave 770 ± 80 Ka for the lower layers 7–10. However, these ages are substantially older than previous dating attempts (cf. uranium series and fission track).

Conclusion

Dating methods based on radioactive decay are in principle independent clocks, that is, they rely solely on the measurement of radiometric quantities, on known physical constants, and on natural isotopic abundances. The potassium–argon, fission-track, luminescence, electron spin resonance, uranium-series, and ^{26}Al/^{10}Be methods exploit such independent clocks. Radiocarbon, on the other hand, is a dependent clock, since it requires calibration by independently derived ages, for instance, by dendrochronology, varve chronology, and/or uranium-series dating.

Radiometric dating provides the baseline for calibration of other dating approaches, such as isotope stratigraphy, climate stratigraphy, bio-stratigraphy, and magneto-stratigraphy, as well as by astronomical and chemical means. All these latter techniques rely on natural changes with varying rates that are more or less predictable. Only through calibration do these techniques become chronometric tools.

During the last few decades, a solid chronology for the time since hominids entered the scene some five million years ago has been established through radiometric dating. Present methodological developments focus primarily on improving the time resolution of these methods, a prerequisite of deciphering natural and cultural processes. Paleoanthropological knowledge and concepts have greatly benefited from these advances.

Abstract

The history of life on Earth, from the earliest microscopic cells to the modern world populated by the rich variety of animals, plants, fungi, and microbes, is more than 3,500 Myr long. Documenting the diversity patterns through the Proterozoic and Phanerozoic has been a major task in the past decades and is fraught with many methodological problems. The emerging picture is one of a very irregular increase in diversity. The most significant episodes of diversification occurred during the Cambrian–Ordovician and throughout the Mesozoic–Cenozoic. In the Phanerozoic alone, 5 major and more than 15 smaller mass extinctions disrupted the diversification of life and sometimes drastically altered the way of evolution. There was no common cause for these events, but all were the consequence of large-scale environmental perturbations. There is growing concern that we are currently entering a "Sixth" major extinction, caused by human impact on nature.

Introduction

This chapter reviews the history of diversity, the "ups and downs" of life, during the past 3,500 Myr. There are many reasons why the history of life's diversity on Earth is an important avenue of paleontological research. (1) Such studies can give us insight into the relative importance of various mechanisms of evolution. (2) The analysis of diversification and extinction can help to clarify the respective roles of biotic (intrinsic) versus abiotic (extrinsic) factors. (3) The importance of regional versus global patterns/mechanisms can be investigated. (4) The analysis of extinctions might enable us to see if there are common patterns. (5) The possibility that *Homo sapiens* is causing yet another mass extinction fosters interest in other such events in the geological past.

One emergent theme when documenting patterns of diversification and extinction is that the major disruptions/discontinuities were not the consequence of some lineages' "racial senility" or "genetic exhaustion" but rather caused by large-scale environmental perturbations. The world as we know it today, with its current climatic and atmospheric conditions and present-day biosphere, is not a good actualistic example for the remote past, where sea levels and mean annual temperatures were vastly fluctuating, continental plates had entirely different positions, and CO_2 and O_2 levels in the atmosphere showed secular changes.

This chapter is organized as follows:

- First, an overview of major events in the history of life is given, together with an overview of changes in abiotic conditions. Here some emphasis is placed on the Precambrian.
- The patterns of diversification of Phanerozoic life are reviewed, most extensively for marine animals with preservable hard parts.

- Methodological problems in documenting diversity (as a measure of taxonomic richness) through time are discussed.
- In a special subchapter, some of the most important radiations and extinctions are treated in stratigraphic order.

A Short History of Life on Earth

According to the newest dating, the Earth is 4,567 Myr old (Fig. 1; Van Kranendonk 2012). Already ~4,500 Myr ago, the planet experienced probably its most dramatic event: the impact of the mars-sized protoplanet "Theia" led to the formation of the moon (Taylor 2007). Between 4,500 and 4,400 Myr ago, the Earth changed from a planet with a liquid magmatic surface to one with a solid surface. Some detrital zircon grains from the Jack Hills in Australia are up to 4,400 Myr old, and their composition might indicate that liquid water and a thin crust were already present at that early date (Wilde et al. 2001; Van Kranendonk 2012). The oldest rocks currently recognized (Acasta gneiss from the Northwest Territories, Canada) are dated as 4,030 Myr (Nelson 2004). The earliest Eon of Earth history, the Hadean, thus left no directly observable documents. It is nowadays assumed that the initially high temperatures following the accretion of the Earth had dropped by around 4,400–4,000 Myr ago to below 100 °C. During the earliest Archean, the surface temperature was probably quite low (faint early sun). By that time, liquid water was present on the Earth's surface, brought to the planet by icy asteroids (Kramers 2007). Yet, the "heavy bombardment" with bodies exceeding 250 km in diameter lasted until 3,800 Myr ago (Late Heavy Bombardment (LHB) between 3,900 and 3,800 Myr ago; Van Kranendonk 2012). This must have led to repeated boiling of the oceans and the vaporization of their water (Nisbet and Sleep 2001, 2003).

Contrary to earlier beliefs (e.g., those assumed in the famous Miller experiment), most researchers today think that the Hadean and Early Archean atmosphere was only mildly reducing, with mainly CO_2 and N_2 present but also smaller amounts of CH_4, NH_3, and H_2 (McClendon 1999; Raven and Skene 2003; McCollom 2013). Free oxygen perhaps built through photodissociation of water vapor in the upper atmosphere, but quickly reacted with Fe^{2+} and other unoxidized compounds. The early atmosphere was therefore devoid of free oxygen (McClendon 1999; Miller and Lazcano 2002; Westall 2012).

Under these conditions life originated (for reviews, see Oró et al. 1990; Brack 1998; McClendon 1999; Fenchel 2002; Taylor 2005; Deamer 2011; Westall 2012). Organic compounds could form in the atmosphere through UV-photolysis, electrical discharges, and major impact shocks (McClendon 1999; Lazcano 2001; McCollom 2013), and a major source of organic molecules was probably also comets and interplanetary dust (Lazcano 2001; Miller and Lazcano 2002). But early life certainly evolved in the sea (Raven and Skene 2003; Westall 2012). It is now widely assumed that an RNA world preceded life based on proteins and DNA (Lilley and Sutherland 2011; Gargaud et al. 2012). The first cells were probably

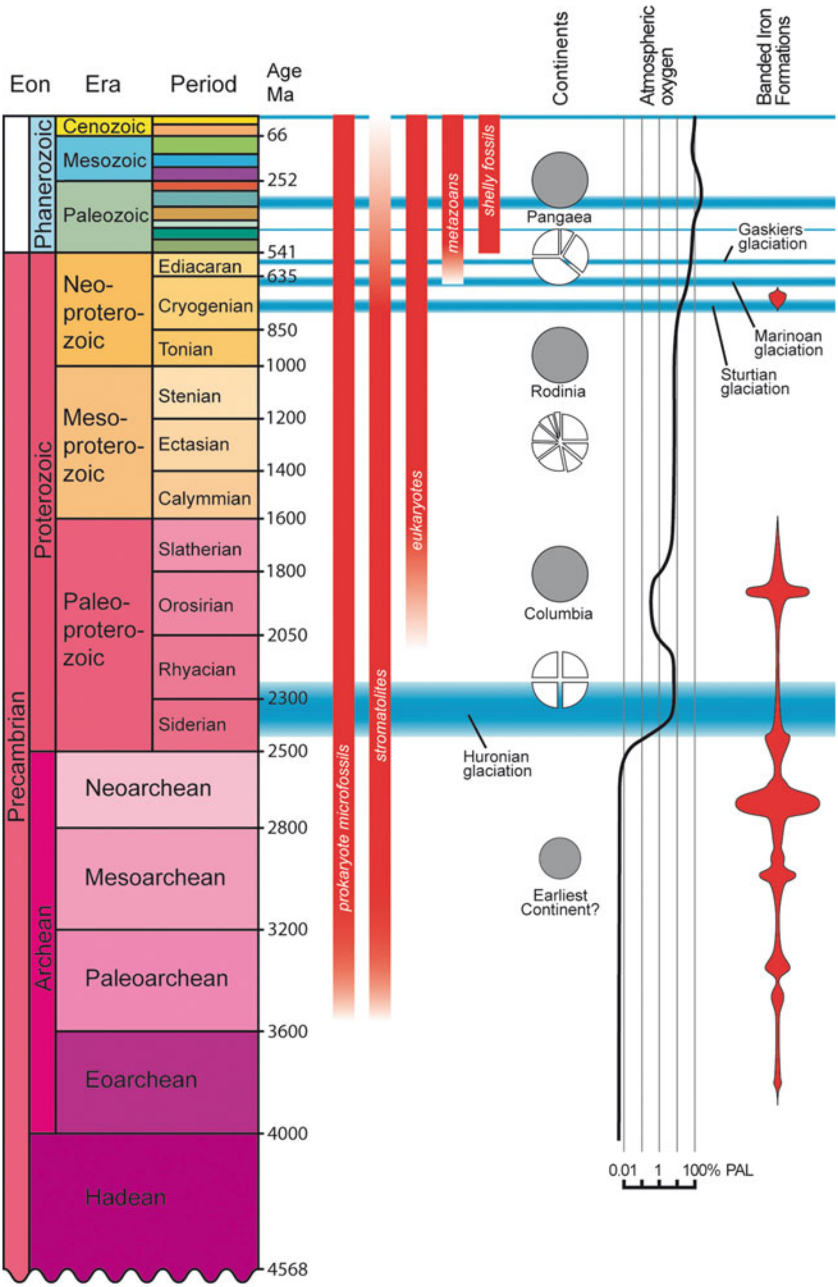

Fig. 1 Major events in earth history in the Precambrian (Modified after various sources)

heterotrophs (Lazcano and Miller 1996; Peretó 2011; but see Huber and Wächtershäuser 1997; Wächtershäuser 2000, 2006). As possible sites where cellular life evolved from prebiotic precursors, continental thermal springs, volcanic vents, warm hypersaline lagoons (Darwin's "warm little pond"), and deep submarine vents are the most likely candidates (Schopf 1999; Westall 2012). In this respect it is noteworthy that the earliest branches of both the Archaea and Bacteria are thermophilic (Pace 1997). Yet, an extraterrestrial origin of cellular life cannot totally be excluded ("Panspermia"; Horneck 2003).

Perhaps life originated sequentially several times, but was always exterminated by the heavy meteorite bombardment ("impact frustration"; Schopf 2002). Yet, all life on Earth shares a common origin (Theobald 2010). The "Last Universal Common Ancestor" (LUCA) might have been a diverse community of cells that experienced extensive horizontal gene transfer (Woese 1998, 2002; Glansdorff et al. 2008). Organismal lineages established themselves with the subsequent splitting into the three domains "Bacteria", "Archaea," and "Eukarya" (Woese 1998). The tree of life is thus at its base a web (Doolittle 1999) or even a ring (Rivera and Lake 2004).

The fossil record of the Archean is notoriously sparse. The presumed oldest cellular microfossils come from 3,500- to 3,450-Myr-old sediments in Western Australia (Schopf 1992a, 1993, 2004, 2006; Van Kranendonk et al. 2008; De Gregorio et al. 2009; Schopf and Kudryavtsev 2012; but see Brasier et al. 2004; Wacey 2009; Wacey et al. 2009). Almost as old (3,400–3,200 Myr) are microfossils in the metasediments of the Onverwacht and Fig tree groups (South Africa). Putative microfossils (*Isuasphaera*) were described (Pflug 1978) from even older (3,800 Myr) metamorphosed sedimentary rocks from Greenland (Isua Greenstone Belt) but are probably of inorganic origin (Bridgwater et al. 1981; Appel et al. 2003).

According to most authors (Mooers and Redfield 1996; Sheridan et al. 2003; Hedges 2009), the split between bacteria and archaea–eukaryota must have occurred more than 3,500 Myr ago. The Proterozoic fossil record (Hofmann and Schopf 1983; Mendelson and Schopf 1992; Schopf 1992a, b) documents an increasing diversification and complexity of cells, but the evolution of metabolic pathways cannot be deduced from the morphology of the microfossils. Yet, by 2,700 Myr ago, oxygenic photosynthesis, methanogenesis, and methylotrophy had probably developed, perhaps also sulfate reduction and nitrogen fixation (Buick 2001; Sleep and Bird 2007; Copley and Summons 2012).

In contrast to cellular fossils, the record of stromatolites is quite good. These are biosedimentary structures built by microbial mats which trap sediment particles (Riding 1991, 2000; Walter 2001; Bosak et al. 2013). The oldest stromatolites date from 3,500- to 3,200-Myr-old sediments in Australia and South Africa (Wacey 2009; Van Kranendonk 2012), but their fossil record remains spotty until the Neoarchean (Walter 1983, 2001; Grotzinger and Knoll 1999). They diversified considerably in the Proterozoic, and in the Mesoproterozoic a large number of different types had developed, growing sometimes to impressive sizes

(Awramik and Sprinkle 1999; Walter 2001; Riding 2006a). Stromatolites declined both in diversity and abundance in the terminal Proterozoic, and in the Phanerozoic they remained largely restricted to marginal marine environments (Riding 2006a, b). This decline was traditionally seen as a consequence of the rise of the metazoans, which consumed the microbial mats (Mata and Bottjer 2012), but it might also have abiotic reasons (Awramik and Sprinkle 1999; Riding 2006a, b).

Significant changes in the carbon and sulfur isotope signatures of rock and kerogen samples in the latest Archean between 2,750 and 2,500 Myr ago point to increased microbial productivity and rapid crust formation. For some time, biological and geological processes were out of equilibrium (Van Kranendonk 2012). Between 2,400 and 2,200 Myr ago, the atmosphere changed rather abruptly from reducing ($pO_2 < 0.01$ % present atmospheric level PAL) to oxidizing ($pO_2 > 1$ % PAL; Fig. 1), largely as a result of the activities of oxygenic photoautotrophs (Schopf 1992a; Holland 1994; Canfield 2005; Van Kranendonk 2012; for alternative scenarios of atmosphere evolution, see Ohmoto et al. 2004). This is known as the "Great Oxidation" in the Early Proterozoic (Goldblatt et al. 2006). Until about 2,400 Myr ago, free oxygen was constantly removed by oxidation of weathered reduced minerals (Nisbet and Sleep 2001; Lenton 2003; Goldblatt et al. 2006). Detrital pyrite and uraninite are common until 2,200 Myr ago and indicate still very low levels of free oxygen; otherwise these minerals would have been oxidized (Schopf 1992a; Holland 1994). Likewise, the genesis of banded iron formations (BIFs), which are absent in rocks younger than 1,700 Myr, requires reducing conditions in the deeper parts of the seas (Simonson 2003; Van Kranendonk 2012).

From 2,450 to 2,200 Myr ago, the Earth witnessed the first well-documented ice age, the "Huronian" or Makganyene glaciation (Pierrehumbert et al. 2011). As a consequence of insufficient time resolution, the exact duration of glacial intervals during this Paleoproterozoic time period is unknown (Young 2004; Van Kranendonk 2012). The onset and the termination seem to have been gradual (Young 2004). Perhaps the increase in atmospheric oxygen was the cause of the Huronian glaciation (Kopp et al. 2005). If methane was a major contributor to a greenhouse effect prior to that time, it would have been oxidized in a more oxygen-rich atmosphere, and the removal of this greenhouse gas could well have led to global cooling and the onset of an ice age. However, the causes of the Early Proterozoic glaciation are still debated (Van Kranendonk 2012).

The origin of the eukaryotes can be placed at some time before 2,100 Myr ago. Large and unquestionably eukaryotic acritarchs are known from 1,800-Myr-old rocks (Lamb et al. 2009), and the macroscopic "algae" *Grypania* is most likely also a eukaryote, putting the oldest eukaryotic record to 2,100 Myr (Han and Runnegar 1992). Eukaryote-specific biomarkers were even reported from 2,700-Myr-old metasediments of Western Australia (Brocks et al. 1999) but proved to be contaminants (Fischer 2008). Perhaps the origin of eukaryotes was linked to the increased oxygen content of the atmosphere and shallow waters where a nucleus and its protective membrane would be advantageous (Dyer and Obar 1994). Subsequent evolution of the eukaryotes took place by serial endosymbiosis (Margulis 1981) in which engulfed α-purple bacteria became mitochondria and cyanobacteria became plastids (Dyer and Obar 1994; Pace 1997). In part, even secondary and tertiary endosymbiosis must have occurred in which photosynthetic eukaryotes were engulfed by nonphotosynthetic eukaryotes (Woese et al. 1990; Chan and Bhattacharya 2010).

Little is known about the early evolution of the eukaryotes (Knoll et al. 2006). Apart from the acritarchs that are a heterogeneous assemblage of planktonic, unicellular eukaryotes known from the Late Paleoproterozoic and extending into the Phanerozoic (Martin 1993; Knoll 1994), other fossils of the eukaryotic clade include various carbonaceous films that are not easy to interpret (Hofmann 1994; Knoll et al. 2006). Judged from isotopic signatures and sedimentologic features, between 1,800 and 800 Myr ago was a time of environmental stability that has been dubbed "the boring billion" or "Earth's dullest period of time" (Buick et al. 1995). Yet, this was also the time of formation of the supercontinent Rodinia and of major diversification of eukaryotes (Van Kranendonk 2012). New molecular dates, which are in reasonable agreement with paleontological findings, give some clues as to when new groups originated. The divergence between protists and crown-group plants may be as young as 1,300–1,100 Myr, the origin of the fungi is placed at 1,200–1,000 Myr ago, the split between choanoflagellates and eumetazoans occurred 1,000–900 Myr ago, and the first bilaterians made their appearance 900–700 Myr ago (Douzery et al. 2004; see also Peterson et al. 2004, 2008; Peterson and Butterfield 2005; Bhattacharya et al. 2009; Blair 2009; Erwin et al. 2011).

Between 800 and 600 Myr ago in the Cryogenian period, the Earth witnessed several large glaciations. The last two episodes are well dated. The Sturtian glaciation occurred around 715 Myr ago and the Marinoan ("Varanger") glaciation around 635 Myr ago (Allen and Hoffman 2005; Pierrehumbert et al. 2011; Shields-Zhou and Och 2011). Some, perhaps most, continental land masses had near-equatorial positions at that time. Glaciers might have reached equatorial regions and perhaps extended down to the sea level. According to the most dramatic scenario (Hoffman et al. 1998; Hoffman and Schrag 2002; Hoffman 2009; but see Chandler and Sohl 2000; Poulsen 2003), temperatures initially dropped due to some unknown mechanism, but as soon as glaciers reached a critical extension in low latitudes, enough solar energy was reflected back into space that ice sheets could grow at an ever-increasing rate. In this "runaway albedo" model, not only all the land masses became ice covered, but the surface of the oceans were also globally frozen ("snowball earth"; Kirschvink 1992; Hoffman et al. 1998; Hoffman and Schrag 2002). The seas became anoxic and BIFs could accumulate again (Hoffman et al. 1998). Eventually, enough volcanic CO_2 accumulated, and the glaciations ended abruptly. Later Neoproterozoic glaciations are documented, but these did not reach equatorial regions (Pierrehumbert et al. 2011; Shields-Zhou and Och 2011).

Shortly after the last of these major Neoproterozoic glaciations, the first metazoans enter the fossil record. Enigmatic soft-bodied fossils 580–541 Myr old are known from localities around the world and named Ediacara assemblages (after the Ediacara Hills in South Australia). Although the nature of the flattened, segmented, or quilted Ediacara organisms is still disputed (mainly cnidarians and annelids

(Glaessner 1983, 1984; Jenkins 1992) or organisms not related to any of the extant animal phyla (Seilacher 1989, 1992; Buss and Seilacher 1994)), they are accompanied by traces produced by bilaterian metazoans (Knoll and Carroll 1999; Valentine et al. 1999; Martin et al. 2000; Erwin and Valentine 2013). Yet, tracemakers were small and rare and did not disrupt the sediment. This only changed near the Precambrian–Cambrian boundary when bioturbation markedly increased, and the sediment became unstable (Erwin and Valentine 2013). This probably led to the extinction of the immobile Ediacara organisms (Seilacher 1999).

Within a short time after the beginning of the Cambrian at 541 Myr, the most remarkable episode in the history of life started, the so-called Cambrian explosion. Within only 20 Myr, all animal phyla with preservable hard parts (with the exception of the bryozoans) appeared (Knoll and Carroll 1999; Erwin 2001a; Valentine 2002, 2004; Erwin and Valentine 2013). With the beginning of the Cambrian, and continuing throughout the Phanerozoic (Fig. 2), we have a very reliable fossil record especially for the marine invertebrates with easily preservable hard parts. Fossiliferous localities that show exceptional preservation are interspersed in the stratigraphic record and provide us with information on the soft-bodied fauna (Bottjer et al. 2002; Seldon and Nudds 2012). Information on the Phanerozoic history of life can be found in many textbooks on paleontology, evolution, and historical geology (Stanley 2009; Cowen 2013; Monroe and Wicander 2011; Storch et al. 2013), and extensive treatment is beyond the scope of that chapter. Details on selected episodes of radiation and extinction are given in the last part of this chapter.

During the Cambrian, life was exclusively marine and dominated by trilobites and a variety of other arthropods. Because the trilobites were highly diverse, are easily determined, and show a high species turnover, trilobites are the most important index fossils for this period. Brachiopods were small and belonged mostly to the inarticulate groups. Among the mollusks, hyoliths and monoplacophorans were the most conspicuous, but in the Late Cambrian, the first small nautiloids appeared, marking the beginning of a highly successful group of marine predators. Cambrian echinoderms belonged mostly to groups that were immobile and became extinct during the Early Paleozoic. Already during the Early Cambrian, the first true reefs built by the spongelike archaeocyathans developed, but archaeocyathans became extinct at the end of the Early Cambrian, leaving a reef gap until the Middle Ordovician. The first chordates and agnathan fishes appear to have been rare, with the exception of the conodonts.

The extinction events in the Late Cambrian affected most severely the trilobites and several echinoderm groups. Ordovician and Silurian seas became dominated by articulated brachiopods and stalked echinoderms (crinoids and blastoids). Although the first deep burrows appeared at that time, life was still mainly epibenthic. Large reefs dominated by tabulate and rugose corals and stromatoporoids developed, and bryozoans became an important component of marine hard bottoms. Among the planktonic organisms, the graptolites diversified considerably and have proven to be the most valuable index fossils for the Ordovician and Silurian. Large predators developed among the nektonic nautiloids and among the eurypterids.

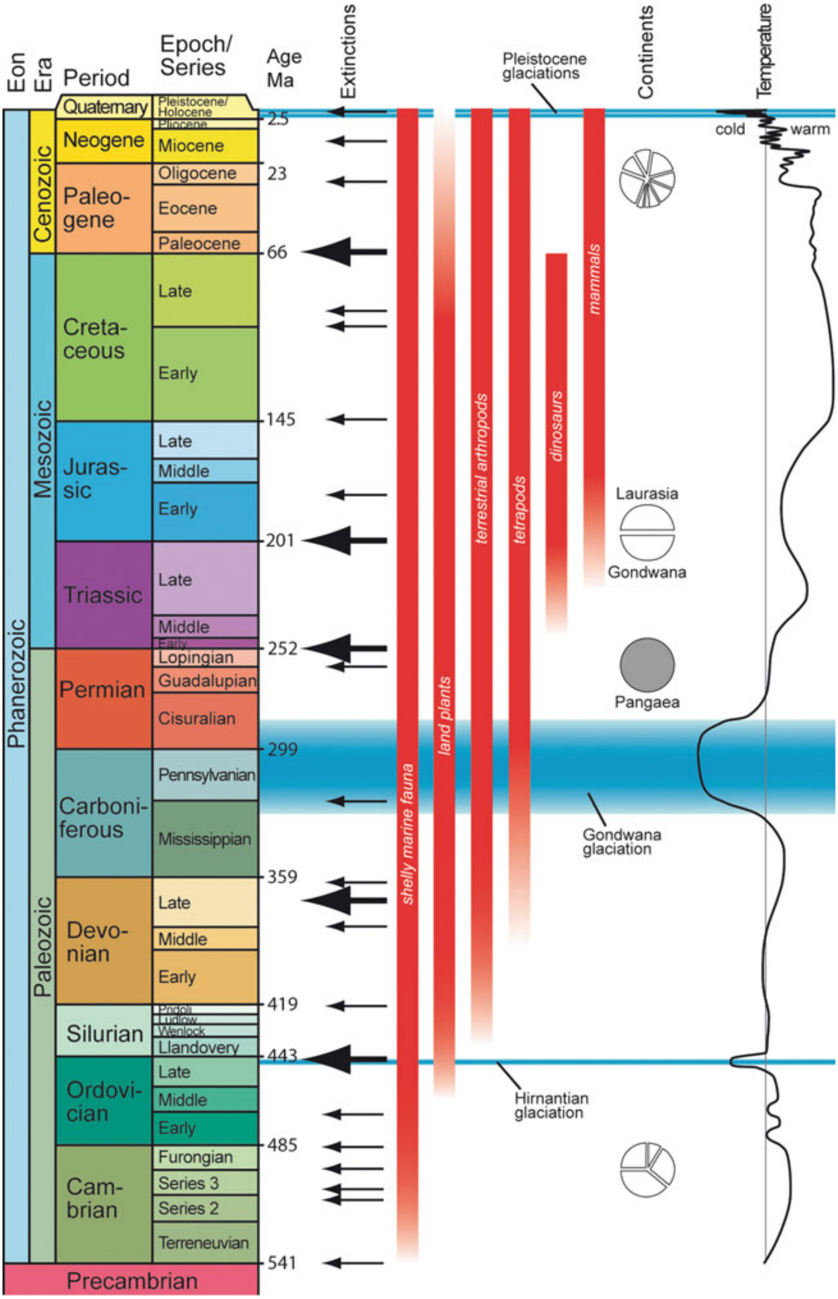

Fig. 2 Major events in earth history in the Phanerozoic (Modified after various sources)

Several groups invaded freshwater environments, among them the arthropods and various fish groups. Colonialization of the land started in the Ordovician–Silurian, first by plants (although algal crusts and fungi may have been present earlier), then by mites, arachnids, millipedes, and scorpions. Among the vertebrates, the appearance of the first jawed fishes in the Late Silurian was a major innovation.

During the Devonian and Carboniferous, land plants diversified in an explosive manner leading to the first true forests, and the first seed plants had developed by the Carboniferous. The first wingless insects appeared in the Early Devonian, but it was not until the Carboniferous that the first winged insects conquered the air. In the vertebrates, huge marine predators developed among the placoderms. The Devonian, also called the "age of fishes," saw the first appearance of the chondrichthyans and actinopterygians, while the agnathans considerably diversified. The first tetrapods appeared during the Middle–Late Devonian, and the amniote egg evolved in the Late Carboniferous. Among the marine benthic organisms, tabulate–rugose–stromatoporoid reefs attained a new climax. Articulate brachiopods and stalked crinoids still dominated most seafloors. Among the nektonic organisms, the evolution of the ammonoids was a major innovation during the Early Devonian. This group provided the most important index fossils for the Devonian to Cretaceous periods. In the latest Paleozoic, life in the seas did not radically change, but the absence of the heavily armored fishes is notable, and among the cephalopods the stoutly shelled nautiloids also declined, while the ammonoids flourished. Reef building was confined to smaller constructs after the Late Devonian mass extinction. On land, the mammal-like reptiles were the dominant herbivores and carnivores.

After the end-Permian mass extinction, life in the seas and on land dramatically changed. Seafloors were no longer dominated by epifaunal brachiopods and crinoids but by gastropods and burrowing bivalves. Reef production came to a halt during the Early Triassic, and it was not until the Middle Triassic that scleractinian coral reefs became established. This type of reef building would dominate throughout the rest of the Mesozoic and Cenozoic. Only during part of the Cretaceous were the corals replaced as principal reef builders by a group of aberrant bivalves, the rudists. The open waters were dominated by ammonoids and actinopterygian fishes, and during the Mesozoic three groups of planktonic organisms which play an eminent role in biogeochemical cycles made their appearance: the planktonic foraminifers, the coccoliths, and the diatoms. The largest creatures of the seas, and the top predators, were the marine reptiles: nothosaurs, plesiosaurs, ichthyosaurs, marine crocodiles, turtles, and mosasaurs.

On land, the conifers, cycads, and ginkgos flourished and dominated the forests until the late Early Cretaceous when they became increasingly replaced by the flowering plants (angiosperms). Among the amphibians, the last stegocephalians died out, while the first frogs and salamanders appeared. After the end-Permian mass extinction, the mammal-like reptiles had become marginal players, and the archosaurs, most notably the dinosaurs, became the rulers of the Earth. The pterosaurs were the first vertebrates to conquer the air, by the Late Triassic; and in the Late Jurassic, the first birds evolved. Mammals arose already during the Late Triassic, but remained mostly small and peripheral throughout the Mesozoic.

The mass extinction at the Cretaceous–Tertiary boundary, although much less severe than the extinction at the end of the Permian, nevertheless severely altered the structure of both marine and terrestrial ecosystems. In the seas, the shelled cephalopods became entirely extinct with the exception of a small group of nautilids, and among the marine reptiles, only the turtles survived. The vacant ecospaces were filled up by actinopterygian fishes and mammals. The mammals also played a central role in the restructuring of the terrestrial communities. During the remarkable radiation in the Paleogene, mammals occupied almost all available niches on land, invaded the seas (whales, pinnipeds, sea cows), and conquered the air (bats). Birds equally radiated considerably, and in some regions, large, flightless birds even became the top predators. After the Eocene–Oligocene climatic revolution, the flora and fauna had an essentially modern organization, and grasses as the most important terrestrial producers became widespread during the Miocene. The Miocene radiation of the apes ultimately led to the development of our species, *Homo sapiens*.

Directionality Versus Contingency

During the Precambrian, eukaryotes evolved from prokaryotes, and in the Cambrian, most animal phyla evolved. Ever more environments were colonialized during the Phanerozoic, including the land and the air. For the evolution of the vertebrates, the long-portrayed succession of the "age of fishes," "age of reptiles," and "age of mammals" is of course a gross oversimplification. Osteichthyans and chondrichthyans were never as diverse as today! Yet, although measuring morphological complexity is not straightforward, there was clearly a trend toward increasing complexity in the evolution of life from bacteria to today's biota (Carroll 2001; Rosslenbroich 2006; McShea and Brandon 2010; Korb and Dorin 2011).

There are two fundamentally different views on this complexity increase. According to one view, the rise and ultimately dominance of complex life forms were an inevitable outcome of natural selection, whereby more complex organisms outcompete the more primitive ones. It also inevitably culminates with the development of intelligent animals. Such a view is championed, e.g., by Conway-Morris (1998, 2003) and is reminiscent of an Aristotelian "chain of being."

A radically different view of the evolution of life does not see complex mammals as superior to bacteria. The increase in diversity is not neglected, but is explained in a different way. Bacterial cells cannot evolve toward ever-smaller sizes, unicellular eukaryotes cannot evolve toward zero cells but only toward multicellularity, and marine organisms cannot evolve to colonialize a nonexisting environment, although they can evolve land-dwelling species and among animals also flying taxa. The evolution toward greater complexity is thus simply a move away from an "impermeable left wall" and an increase in variance; but in a sense we still live in a bacteria-dominated world (Gould 1996).

Perhaps the truth lies somewhere in between. There is no necessity to evolve toward intelligence, but ultimately this was made possible through successive evolutionary steps after the increasing variance crossed several thresholds.

In such a view, life on Earth followed a megatrajectory along the following sequence (Knoll and Bambach 2000): prokaryote diversification (including metabolic pathways, but inability for sexual reproduction), early eukaryote diversification (first consumers, multicellularity, increased size, sex), aquatic multicellularity (large size, packaging of biomass, fast movement, complex food chains), invasion of the land (huge biomass of producers, adaptation to widely fluctuating environments), and ultimately intelligence (which perhaps could also have evolved in the water). Nevertheless, if “life’s tape were replayed,” the outcome would certainly be totally different (Gould 2001).

Diversity Patterns: The Broad Picture

The Textbook Version

The last decades have witnessed a veritable boom of publications documenting the diversity patterns of life during Earth history and the pace of large-scale evolution. Outstanding contributions came especially from the late “Jack” Sepkoski. His 1981 curve of Phanerozoic diversity patterns of marine families (and subsequent refinements down to the genus level; Fig. 3; Sepkoski 1996, 1997, 2002) is one of the most often reproduced figures in the paleontological literature (equaling perhaps the Berlin *Archaeopteryx* specimen; Benton 2001), and this benchmark is an ideal starting point for the discussion of life’s ups and downs during the last 541 Myr.

Assembling literature-based compilations of the worldwide temporal distribution of marine families (Sepkoski 1982, 1992) and genera (Sepkoski 2002), the number of described taxa and hence diversity for every successive stratigraphic interval (usually stages) could be determined. In addition, the times of origination (first occurrence) and extinction (last occurrence) of these taxa could be deduced.

By means of a factorial analysis, Sepkoski (1981) could show that the marine families grouped into three rather well-delineated entities each showing a common pattern of origination, diversification, and decline. These three “evolutionary faunas” were called “Cambrian fauna,” “Paleozoic fauna,” and “Modern fauna” (Sepkoski 1981). A division into finer intervals (nine “Ecological Evolutionary Units”) was suggested by Boucot (1983) and further refined by Sheehan (1996, 2001a); yet, these intervals mainly portray ecological communities and not evolutionary units.

According to Sepkoski’s figures, diversity at the family level shows a sharp rise at the beginning of the Cambrian, continuing well into the Middle Cambrian. In the Middle Cambrian, a plateau was reached, and several drops in diversity occurred. The main representatives of this Cambrian fauna were trilobites, inarticulate brachiopods, hyolithids, monoplacophorans, archaeocyathids, and eocrinoids (Sepkoski 1981, 1984). During the Early Ordovician, diversity increased again to reach a level about three times that of the Cambrian. Responsible for that fast and unprecedented increase in diversity were members of the Paleozoic fauna, mainly

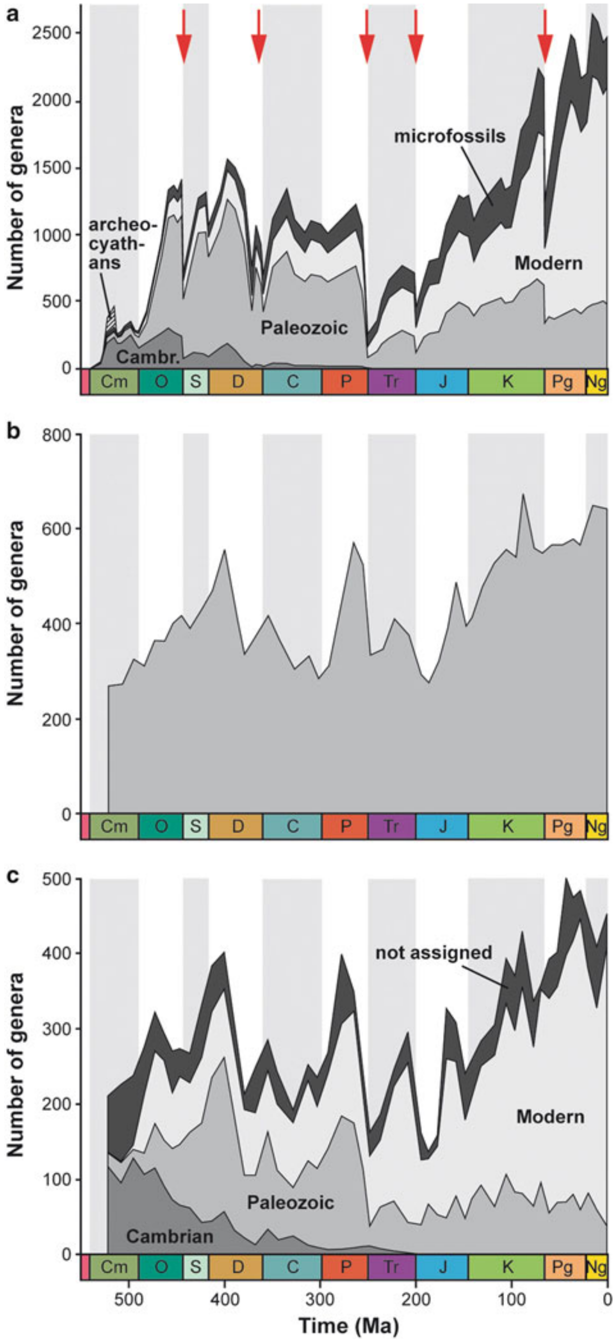

Fig. 3 Genus diversity over the Phanerozoic ((**a**) After Sepkoski 1997; (**b**) After Alroy et al. 2008; (**c**) After Alroy 2010)

articulate brachiopods, crinoids, rugose and tabulate corals, ostracods, cephalopods, bryozoans, asteroids, ophiuroids, and graptolites. The diversity reached by the Ordovician radiation remained almost constant through the rest of the Paleozoic, interrupted only by punctuations of extinctions and subsequent recoveries.

The Late Permian witnessed a dramatic extinction pulse, and the members of the Paleozoic fauna lost their dominance. The Modern fauna (demosponges, bivalves, gastropods, gymnolaemate bryozoans, and malacostracan crustaceans) had its origins in the Paleozoic, but its members remained a minor component up to the Permian. During the Triassic, Jurassic, and Cretaceous, members of the Modern fauna originated at a considerably faster rate than members of the Paleozoic fauna, and overall diversity increased steadily throughout the Mesozoic. The end-Cretaceous extinction appears at the family level only as a minor perturbation, and the diversity increase continues throughout the Cenozoic. By the end of the Neogene, family diversity had reached a level almost twice that of the Paleozoic.

The taxic diversity trends observed by Sepkoski were accompanied by several other notable trends which relate to the structuring of marine communities. During the Phanerozoic, the species numbers within open marine assemblages increased through time (denser “species packing”; Bambach 1977), and between the three evolutionary faunas, a significant increase in the number of feeding types and occupied substrate niches (“guilds”) is documented (Bambach 1983). In addition, the proportion of mobile taxa and of predators increased (Bambach et al. 2002; Bush and Bambach 2011). This is paralleled by changes in the spatial structure of marine benthic communities. Animals of Cambrian communities neither extended high above nor burrowed deep into the substrate, but during the mid-Paleozoic to mid-Mesozoic, many suspension feeders evolved that stood highly erect above the substrate, and several tiers of epifaunal benthos developed (Ausich and Bottjer 1982; Bottjer and Ausich 1986; Signor 1990; Bush and Bambach 2011). A complex tiering, as documented by trace fossils, also developed among the burrowing endobenthos, although very deep burrows only became common in the latest Paleozoic.

Following the broad interest in the Phanerozoic diversity trajectories documented for marine animals, various researchers also published figures for other groups of organisms (for earlier work, see Valentine 1985). For insects, a synoptic curve for the number of families was published that shows an increase in diversity from the Devonian to the recent. The only notable event that led to a significant decrease in the number of families seems to be the end-Permian mass extinction (Labandeira and Sepkoski 1993; Labandeira 1999). Extensive data have also been assembled for fishes (Lloyd and Friedman 2013) and tetrapods (Benton 1993; Benton et al. 2013). Here, the most significant outcomes are an only slight overall diversity increase from the Devonian to the Late Cretaceous and a huge increase in the number of families after the end-Cretaceous extinction (Benton 1999; Fig. 4). Plants differ from the various animal groups in that the family richness over the Phanerozoic follows a much smoother path, and extinctions had little effect on family diversity (Niklas 1997). At lower taxonomic levels, however, plants also suffered heavily from mass extinctions (McElwain and Punyasena 2007).

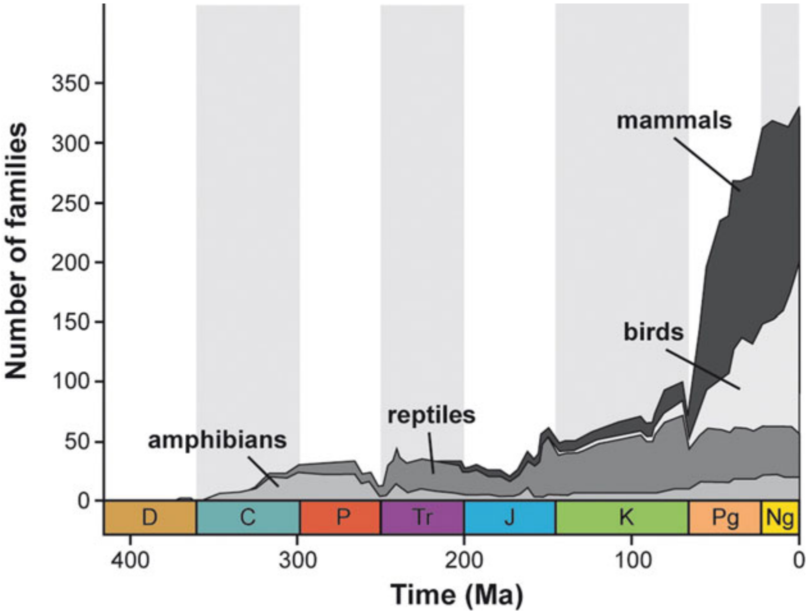

Fig. 4 Phanerozoic family diversity in tetrapods (After Benton 1999)

Methodological Problems and Newer Developments

The documentation of Phanerozoic diversity patterns goes back to Phillips (1860), who used data from marine rocks in Great Britain to distinguish between Paleozoic, Mesozoic, and Cenozoic life, and showed that diversity increased throughout the Phanerozoic (see Miller 2000). Renewed interest in these large-scale patterns arose in the 1960s and 1970s, stimulated especially by the pioneering publications of Gregory (1955), Simpson (1960), and Newell (1967). The first diversity patterns published thereafter (Valentine 1969; Raup 1972, 1976a, b; Bambach 1977) showed mainly that this was a very difficult task. The results were, in part, grossly dissimilar, especially with respect to the diversity increase in the Cenozoic. Although a "consensus paper" was published shortly thereafter (Sepkoski et al. 1981), discussions of methodological problems continue. The interpretations of Phanerozoic diversity patterns have thus fluctuated between two extremes: it might be the real picture or an artifact of databases affected by different and heavy biases.

A first problem is how to count. Should we omit taxa that occur in only one time bin? This would prevent taxa known only from Fossil-Lagerstaetten or a single monograph from summing up to exceptional high diversity in that time bin (Foote 2000). On the other hand, omission of single occurrences can exclude whole groups of short-lived taxa. There may be problems with the taxonomic databases used, which can add noise and possibly induce false signals (Signor 1985). Yet, two databases at the family level compiled by Sepkoski (1982, 1992) and a team of specialists (Benton 1993) produced very similar results. A further problem is unsampled ranges. A taxon can extend further back in time ("ghost range") and also reach further upward ("zombie lineages") than recorded in the database (Lane et al. 2005). Ghost ranges can potentially be elucidated with a phylogenetic approach, whereas zombie lineages cannot. Correcting for these errors has hitherto met with limited success (Lane et al. 2005). The "pull of the recent" is another potential source of error and refers to the fact that the modern biota is much more completely sampled than fossil strata. Therefore, it tends to extend the stratigraphic ranges of extant families, or species that are known from some time in the Cenozoic, through intervals where fossils of those taxa are missing. This bias was either seen to be a negligible quantity (Jablonski et al. 2003) or a major source of bias (Alroy et al. 2008; Aberhan and Kiessling 2012).

Uneven sampling in different regions and in different periods is a fact that cannot easily be corrected for (Smith 2003). All the compendia are heavily biased toward occurrences in Europe and North America, with the important side effect that from the Jurassic onward tropical environments are underrepresented (Aberhan and Kiessling 2012). Uneven time spans of the sampled intervals (usually stages) are a further problem. To correct for this, longer stages are subdivided, and very short ones are amalgamated (Sepkoski 1996). Taphonomic biases (differential preservation) are usually thought of as occurring randomly through the Phanerozoic (Kidwell 2005; Cooper et al. 2006) although this is contentious (Alroy et al. 2008). But potential biases can occur, e.g., through taxa that are only rarely preserved (in extraordinary deposits, see above), producing a local peak in diversity for that stratigraphic interval (Sepkoski 1996). Culling of the data by removal of single occurrences (taxa that are confined to a single time bin) is the common procedure to remove this bias (Sepkoski 1996). Cenozoic samples are, on average, less often lithified than Paleozoic or Mesozoic ones (Hendy 2009) and therefore yield more fossils than their lithified counterparts. This again, like the "pull of the recent," will lead to an overestimation of the Cenozoic diversity increase (Alroy et al. 2008).

Perhaps the most distracting factor when analyzing diversity patterns is that the sedimentary rocks available for study are not evenly dispersed through the Phanerozoic (Raup 1972, 1976b; Ronov 1983; Peters and Foote 2001; Smith 2001; Smith and McGowan 2011). There is a correlation between sedimentary rock volume and apparent diversity, although its extent is still debated. Are the diversity trajectories real and independent of the outcrop area/sediment volume (Miller 2000), or does the close match even suggest a common cause for diversity increase and patterns of sedimentation (Hannisdal and Peters 2011)? Or does the correlation point to an important bias (Smith 2007) that needs to be corrected for?

There are many more problems surrounding the analysis of Phanerozoic diversity trajectories (Sepkoski 1996; Smith 2007; Alroy et al. 2008; Aberhan and Kiessling 2012). Several of these cannot be addressed using the existing compendia, and it was felt necessary to develop a new database. The Paleobiology Database (PBDB) is a huge collection of locality-specific inventories in the Phanerozoic record (Alroy et al. 2001, 2008; Adrain and Westrop 2003; Miller 2003; Aberhan and Kiessling 2012). Hopefully, the PBDB will allow for a much better correction of taphonomic and sampling bias (Alroy et al. 2001; Bush et al. 2004); will yield new insights into the respective contributions of alpha, beta, and gamma diversity to the Phanerozoic taxonomic richness (Bush and Bambach 2004); and will enable us to dissect geographical components of diversity changes.

Two global diversity curves for the Phanerozoic using subsampling methods of the PBDB have been published (Alroy et al. 2008; Alroy 2010). These show important differences from the Sepkoski curve (Fig. 3): Paleozoic diversity was probably underestimated in earlier curves, and the diversity increase during the Cenozoic was much less pronounced. However, the PBDB suffers also from inherent limitations, and some maintain that currently it is not a good reflection of the fossil record (Krug et al. 2009; Erwin 2009; Marshall 2010). The differences between the 2008 and 2010 curves also show that there is still some way to go until a new consensus is reached (Marshall 2010).

Expansion and Equilibrium Models

The interpretations of Phanerozoic diversity trajectories have remained problematic. For the increase in familial and generic diversity, three basic models derived from population ecology can be invoked to explain the pattern (Miller 1998; Benton 2001). First, if rates of species origination and extinction are unconstrained by existing diversity, and origination exceeds extinction rates, an exponential increase in taxic diversity will result, only interrupted by major extinction intervals. The second, linear model of diversity increase requires the addition of a fixed number of taxa in each unit time. This would require a constant decrease in the rate of evolution (speciation) or a regularly increasing rate of extinction, and this model is generally rejected as improbable (Benton 2001). The third, density-dependent, model assumes that after an initial slow diversity increase, a rapid rise occurs, followed by a slowing rate of increase and finally a plateau (logistic growth).

In a “decoupled logistic” simulation of the three Phanerozoic evolutionary faunas at the family level, allowing for major mass extinctions, Sepkoski (1981, 1984) achieved a rather good fit to the observed picture. In a variation of the theme, it was proposed that the diversifications from Ordovician to recent were best matched by a series of four simple logistic curves without interaction between evolutionary faunas and only reset by mass extinctions (Courtillot and Gaudemer 1996). Exponential growth (Benton 1995) is currently no more supported for marine animals (Alroy 2010), but the nearly exponential increase in several terrestrial groups indicates that these taxa are still far from reaching saturation (Benton 2001).

Extinctions and Biotic Recovery: Generalities

From the conservation biologist’s point of view, the extinction of even a single species is a catastrophe. From a paleontologist’s viewpoint, species extinction is normal, and more than 99 % of all the species that ever inhabited Earth are now extinct (Raup 1991b). Yet, there is a further, more important dimension to this: during the history of life, mass extinctions also provided huge opportunities for taxa that hitherto had played only minor roles, by removing or marginalizing incumbents (Jablonski 2001).

The same databases used in diversity studies can be used to construct plots of extinction (and also origination) intensities over time. Two major points emerge from such an analysis: peaks of high extinction intensities are separated from each other by times of lesser extinction, and overall extinction intensities decline over the Phanerozoic (Sepkoski 1996; MacLeod 2003, 2013; Fig. 5). According to Raup and Sepkoski (1982), there were 5 major and at least 18 lesser mass extinctions in the Phanerozoic, and the "big five" major extinctions (Table 1) are also recognized in newer studies (Hallam and Wignall 1997; MacLeod 2003, 2013; Bambach et al. 2004; Taylor 2004). A "mass extinction" is an event that (1) was nearly global, (2) removed a significant proportion of the existing species (perhaps more than 30 %), (3) affected species from a broad range of ecologies, and (4) happened within a (geologically speaking) short time.

For the decline in background extinction intensity, widely disparate explanations have been proposed. The change might reflect the general decrease in "volatility" between the three evolutionary faunas (Sepkoski 1981) or secular changes in the geochemistry and nutrition levels in the seas (Martin 1996). Yet, it might also just be a taxonomic artifact: through the Phanerozoic, there is a trend toward more species per family/genus. More species therefore need to become extinct for the entire family/genus to become extinct (Taylor 2004).

An extinction event can be abrupt, or stepped, or gradual. An abrupt or "pulse" extinction evidently leaves a species no time to adapt or migrate, whereas this would be possible during a gradual or "press" extinction (Erwin 1996b, 2001b). Yet, it has proven difficult to establish the exact times of disappearance of taxa, especially the rare ones. As a consequence of the imperfect fossil record, the observed last appearance of fossil taxa is always "smeared back" in time through a time interval before their actual extinction (Hallam and Wignall 1997; Taylor 2004). This "Signor–Lipps effect" (Signor and Lipps 1982) will lead to the perception of a gradual extinction pattern even if it was abrupt. The "zombie" lineage, that is, the unsampled portion of a taxon's range occurring after the final appearance of the taxon in the fossil record prior to its actual extinction (Lane et al. 2005), can be inferred at some level of probability using statistical methods (Marshall 1990).

Not even the largest mass extinctions acted in a completely random manner. Extinction selectivity can be geographical (e.g., tropical versus nontropical, terrestrial versus marine), taxonomic (different extinction rates among higher taxa, e.g., dinosaurs versus mammals, plants versus animals), or linked to trait (e.g., body size, trophic level; McKinney 1997, 2001; Twitchett 2006). The selectivity patterns seen during a major extinction interval can be the same as those acting during pre- and postextinction times ("fair game" selectivity) or they can differ ("wanton" selectivity; Raup 1991b). Random survival with respect to trait and taxonomy was termed "field of bullet" selectivity (Raup 1991b).

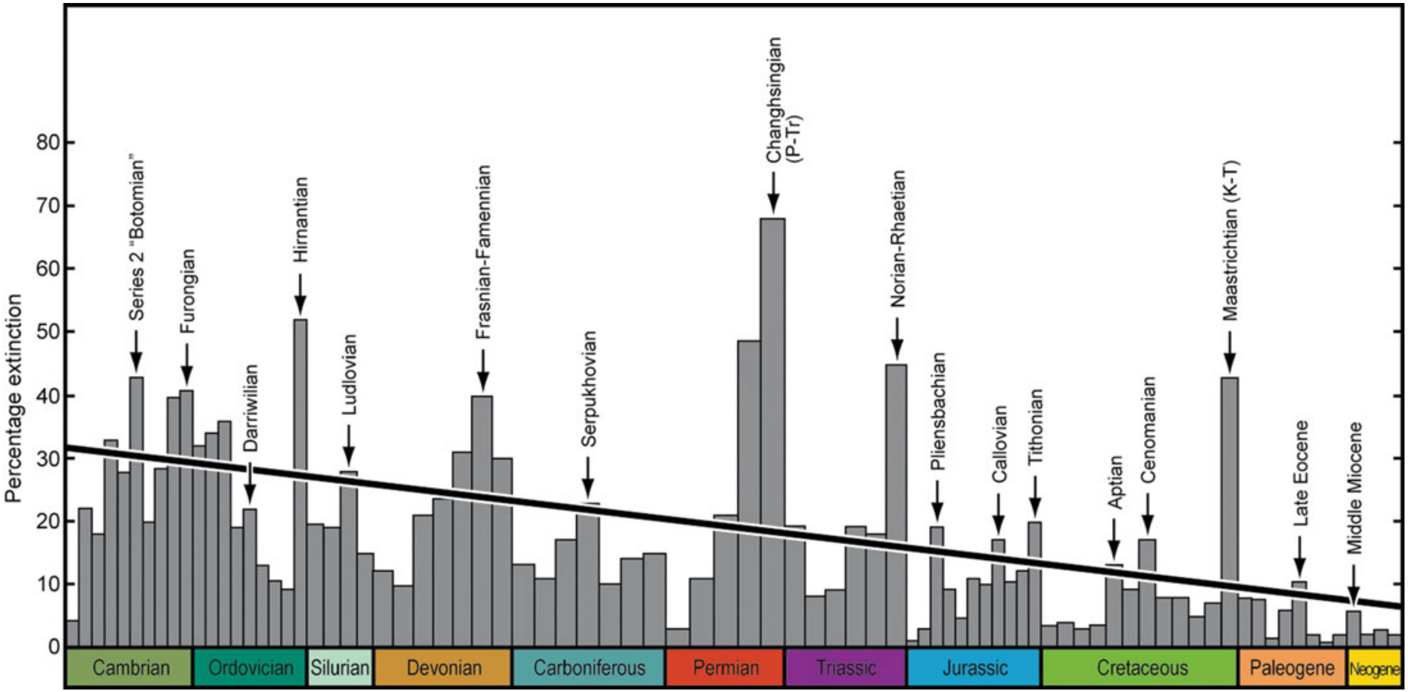

Fig. 5 Extinction intensities in the Phanerozoic. Mass extinctions clearly stand out against background intensities, which decreased during the Phanerozoic (After MacLeod 2003)

Table 1 Observed (families, genera) and calculated (species) extinction intensities at the five major Phanerozoic mass extinctions

Mass extinction	Families extinct (%)	Genera extinct (%)	Species extinct (%)
End Ordovician	26	60	85
Late Devonian	22	57	81
End Permian	51	82	95
End Triassic	22	53	80
End Cretaceous	16	47	73

Simplified after Hallam and Wignall 1997

Major discussion has centered on the question of whether mass extinctions qualify as a separate class of evolutionary mechanism and are, therefore, different from background extinctions (Jablonski 2001; Bambach et al. 2004). There is certainly a continuity of magnitude, with the "big five" and some Early Paleozoic events occupying the ranks of the highest intensities (MacLeod 2003; Wang 2003), although the simple relationship between extinction intensity and mean waiting time (kill curve; Raup 1991a) is no longer accepted because continuity of cause is lacking (Wang 2003; Prothero 2006). The processes operating during mass extinctions are not the same as those acting during background extinctions (Wignall 2004). Continuity of effects is also no longer tenable; for example, the end-Ordovician and end-Devonian mass extinctions both had about the same intensities, but the former had only minor consequences for the structuring of marine communities, while the latter had a profound impact on ecosystems (Droser et al. 2000). Mass extinctions therefore did have a major impact on the evolution of life even though most species have gone extinct during times of background extinction intensities (Taylor 2004).

Did the major mass extinctions during the Phanerozoic have a common cause? This subject was treated by several authors, and the mechanisms include impacts (as assumed, e.g., by Raup and Sepkoski (1984); see review by Racki (2012)), sea-level changes, and the spread of anoxia (Hallam and Wignall 1997; Peters 2008), large-scale volcanisms (Courtillot 1999; Prokoph et al. 2013), and perhaps global cooling (Stanley 1988). It is not always easy to distinguish between the different mechanisms (MacLeod 2003, 2013; Table 2). Yet, there is now overwhelming evidence that the major mass extinctions had their individual signature, and at the present state of knowledge, the search for a common cause no longer makes sense (Prothero 2006; MacLeod 2013).

It has been suggested several times that the history of life follows some large-scale cyclic pattern (Fischer and Arthur 1977; Fischer 1984). Yet, the notion that Phanerozoic extinction patterns show a periodicity with an interval length of 26 Myr (Raup and Sepkoski 1984) has spurred intensive debates about extinction mechanisms. But with increasing accuracy of the geological time scale, it has received little support from other researchers. Currently, few paleontologists would subscribe to the idea that the mass extinctions show any periodicity, despite continued search for possible (mainly extraterrestrial) mechanisms

Table 2 Environmental effects of the most commonly cited mass extinction mechanisms

	Extinction mechanism		
Environmental effect	Comet/asteroid impact	Flood-basalt volcanism	Sea-level change
Increased atmospheric particulates	x	x	x
Increased cloud cover	x	x	
Increased greenhouse gases	x	x	
Reduced greenhouse gases			x
Acid rain	x		
Global wildfires	x		
Shock heating	x		
Habitat fragmentation	x	x	x
Intensification of climate gradients	x	x	x
Enrichment of trace elements		x	

After MacLeod 1998

(e.g., invisible companion of the sun, "nemesis," inducing a comet shower when passing through Oort Cloud; an eccentrical "planet X" doing the same job; the passing of our solar system through the spiral arms of our galaxy, again perturbing bolides in the Oort cloud; movement of the solar system through the galactic plane; Sepkoski 1990). It comes as a major surprise that a new study indicates again that the diversity of life on Earth followed some cyclic pattern, this time with a 62-Myr periodicity (Rohde and Muller 2005). This pattern was recently corroborated (Melott and Bambach 2011a, b); yet statistical support is weak (Melott et al. 2012) and it might just be the inevitable outcome of the applied methods (Smith 2007).

The phase after a mass extinction usually shows a peculiar fauna and flora that change gradually during the time following the extinction. Some terms have proven to be helpful for the characterization of these intervals (Kauffman and Erwin 1995; Fig. 6). The extinction phase is the time where most of the affected taxa had their last appearance. This is followed by the survival phase, where some groups not severely affected by the extinction (holdover taxa) have already began to diversify. During the survival phase, there are usually a small number of opportunistic taxa that could temporarily spread at the expense of the other fauna. "Lazarus taxa" (Jablonski 1986) are those that disappear, probably by becoming very rare (and not retreating to refugia; Wignall and Hallam 1999) during the survival phase, only to later reappear during the recovery phase when new ecosystems are being established, while "Elvis taxa" (Erwin and Droser 1993) are those that have newly entered the fossil record but mimic the shape of extinct taxa. The new communities are largely shaped by progenitor taxa, the most prolific during the recovery phase (Kauffman and Erwin 1995; Hallam and Wignall 1997).

It has long been recognized that after mass extinctions reefs show a prolonged recovery interval. This "reef gap" (Hallam and Wignall 1997; Stanley 2001;

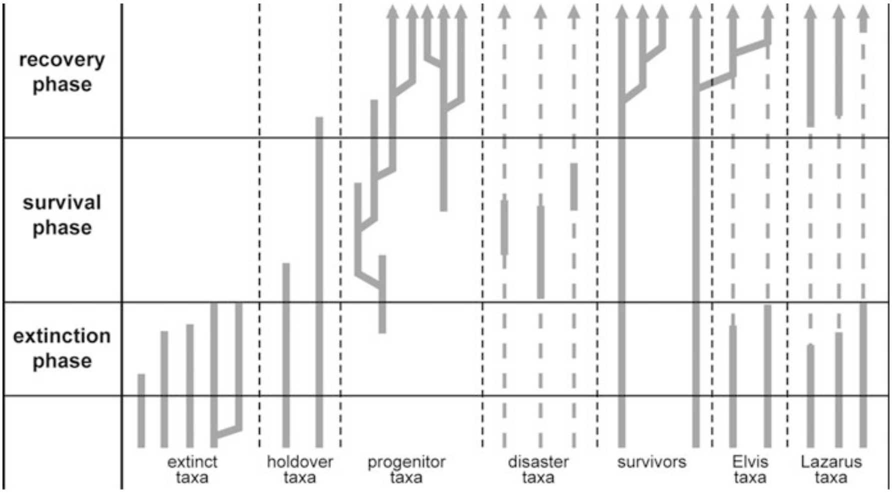

Fig. 6 Faunal patterns during extinctions and subsequent recovery (After Hallam and Wignall 1997)

Flügel and Kiessling 2002; Jablonski 2003), which is evident after all of the "big five" and also after the extinction event after the end of the Lower Cambrian (extinction of the Archaeocyatha; Copper 1988), probably reflects the longer time required to reassemble complex ecosystems (Jablonski 2003).

Selected Case Studies

The Cambrian Explosion and Its Prelude

The tracking of the appearance and early diversification of the animals in the fossil record (Fig. 7) is a rapidly progressing field of paleontology (Fedonkin et al. 2007; Erwin and Valentine 2013). New input has come especially from molecular systematics (Adoutte et al. 2000; Giribet 2002; Pennisi 2003; Halanych 2004; Peterson et al. 2004; Hedges 2009; Edgecombe et al. 2011) and through precise absolute dating of fossiliferous Late Neoproterozoic and Early Cambrian sections, allowing the establishment of a reliable chronostratigraphic framework (Martin et al. 2000; Knoll et al. 2004; Peng et al. 2012).

Possibly the oldest metazoans are ring- and disk-shaped impressions from the Mackenzie Mountains in Northwestern Canada, from the Late Cryogenian Period. This soft-bodied fauna represents perhaps cnidarian grade animals (Erwin 2001a). Considerably more diverse but younger so-called Ediacaran (= Vendian) assemblages are known from a number of localities around the world (Bottjer 2002; Brasier and Antcliffe 2004; Narbonne 2005; McCall 2006). The fauna of these assemblages consists exclusively of soft-bodied forms. The body wall of these organisms must have been quite rigid as is evident from the taphonomic behavior

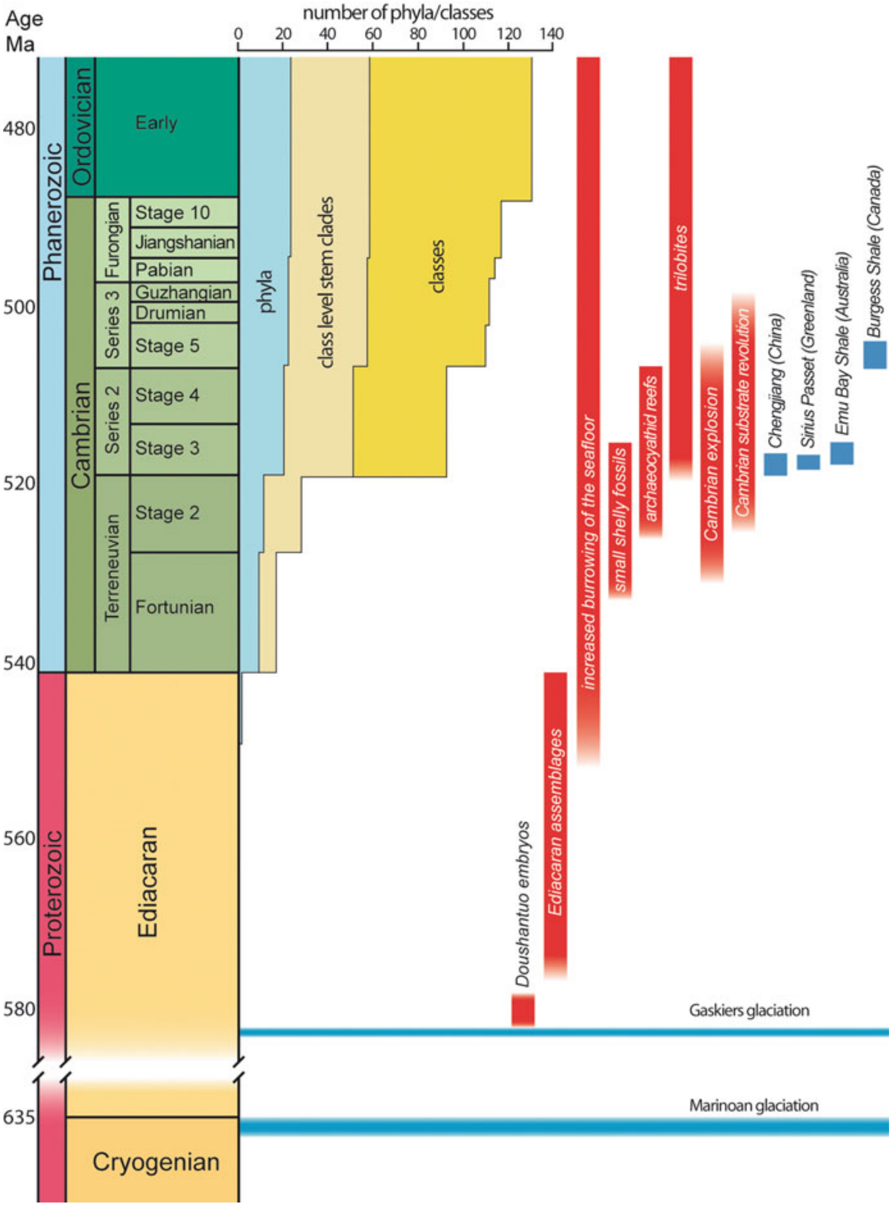

Fig. 7 Major events during the latest Neoproterozoic and the Cambrian (After Erwin and Valentine 2013)

of the Ediacaran biota. They are preserved, mostly intact, as impressions at the base of event beds (storm layers, turbidites) that quickly buried them (Erwin 2001a; Bottjer 2002).

Most of the forms are flattened, segmented, or quilted, and some of them attain considerable sizes (Narbonne and Gehling 2003; Xiao and Laflamme 2009). Classification of these organisms has been highly controversial. Traditionally, the various species were assigned to extant groups like medusae, sea pens, polychaete worms, and stem group echinoderms (Wade 1972a, b; Glaessner 1983, 1984; Jenkins 1992), with most of them belonging to cnidarians. Today most researchers believe that the majority of the enigmatic Ediacaran organisms represent "lost constructions" (Seilacher 1989, 1992; Buss and Seilacher 1994; Narbonne 2004, 2005). With the exception of the 555-Myr-old *Kimberella*, which is now considered to be an ancestral mollusk (Fedonkin and Waggoner 1997; Fedonkin et al. 2007; but see Dzik 2003; Budd and Jensen 2004) and therefore the oldest body fossil of a bilaterian, Ediacaran organisms seem to lack a mouth and a digestive tract. Most were immobile, many of them recliners, but some also mud-stickers (Seilacher 1999). Nutrient uptake was either through the body surface, or these organisms lived in symbiosis with photosynthetic/chemosynthetic protists or bacteria (McMenamin and McMenamin 1990; Narbonne 2005). Still another interpretation of these creatures as lichens (Retallack 2013) is rejected by most paleontologists (e.g., Xiao 2013).

Although sponges and cnidarians were most probably also present, predators were notably absent. The immobile organisms thus lived in a "Garden of Ediacara" (McMenamin and McMenamin 1990). The sediment surface was frequently sealed by microbial mats that were not disrupted by larger burrowing animals. Traces including some radular scratch marks are small and rare and are proof of the presence of bilaterians. Claims for evidence of bilaterians earlier than the Ediacaran assemblages (e.g., traces from 1,200-Myr-old rocks in India; Seilacher et al. 1998) are published with some frequency but are not accepted (Erwin and Davidson 2002; Jensen et al. 2006).

A new window into Late Proterozoic life recently opened with the discovery of 580–560-Myr-old fossiliferous phosphorites at Doushantuo, Southern China (Xiao et al. 1998). In addition to various algae, microscopic multicellular aggregates with preserved nuclei were found. These aggregates were initially described as metazoan embryos (Knoll and Carroll 1999; Valentine et al. 1999; Chen et al. 2000; Hagadorn et al. 2006) but rather seem to be cleavage stages of some unknown "holozoans" or germination stages of protists (Butterfield 2011; Huldtgren et al. 2011). Newer claims for small bilaterian animals (*Vernanimalcula*) with preserved coelom and digestive tract from the same locality (Chen et al. 2004) have been rejected (Stokstad 2004; Bengtson et al. 2012). The Ediacaran biota largely went extinct at the Precambrian–Cambrian boundary (Brasier and Antcliffe 2004; Xiao and Laflamme 2009), with perhaps a few survivors into the Middle Cambrian (Conway Morris 1993; Shu et al. 2006).

The base of the Cambrian, defined by the first occurrence of the trace fossil *Treptichnus pedum* (Buatois and Mangano 2011) and now dated at 541 Myr (Peng et al. 2012), marks the beginning of an interval which is the most remarkable in the history of life. During the Early Cambrian, a wide range of skeleton-bearing animals made their debut, and within only 20 Myr, almost all phyla with preservable hard parts entered the fossil record (sponges already earlier, bryozoans in the Late Cambrian; Valentine 2002, 2004; Marshall 2006; Erwin and Valentine 2013). This apparent explosion of animal bauplans, which had already puzzled Darwin, is still one of the greatest enigmas, although it has become clear in the last few years that there was a prelude of perhaps tens of million years (Lieberman 2003), seen both among traces and in the shelly fossils, but no lengthy time gap between the Ediacaran assemblages and the lowermost Cambrian (Knoll and Carroll 1999; Erwin 2001a; Valentine 2002; Erwin and Valentine 2013).

At first we see an increasing size and complexity of burrows/traces across the Precambrian–Cambrian boundary and then an ever-increasing diversity during the Early Cambrian (Crimes 1992, 2001; Droser and Li 2001; Buatois and Mangano 2011). In parallel, there was a huge diversification in the so-called small shelly fossils (Rozanov and Zhuravlev 1992; Conway-Morris 1998, 2001; Grotzinger et al. 2000). The appearance of new animal phyla and other higher taxa was concentrated in an interval between the Late Terreneuvian and the early Series 2 spanning perhaps 10–20 Myr, and this interval is called the "Cambrian explosion" (Dzik 1993; Valentine et al. 1999; Conway Morris 2000). During this interval, biomineralization was acquired by a multitude of organisms, including mollusks, brachiopods, echinoderms, and chordates (see Lowenstam and Weiner 1989; Bengtson 1994; Zhuravlev and Riding 2001; Wood and Zhuravlev 2012 for an overview). Complex arthropods like trilobite enter the fossil record early in Series 2, and later in Series 2 a plateau in diversity was reached (Marshall 2006; Erwin and Valentine 2013).

Our picture of the Cambrian explosion is facilitated by several wonderful, exceptional fossiliferous settings (Fossil-Lagerstaetten), including the Early Cambrian localities of Chengjiang (China; Xian-guang et al. 2004), Sirius Passet (Greenland; Conway Morris 1998), Emu Bay Shale (Australia; Nedin 1995), and the most famous Middle Cambrian Burgess Shale (Canada; Briggs et al. 1994). Several very important questions surround debates about the Cambrian explosion. (1) Is it real or just an artifact of the imperfect fossil record? (2) Does the origin of metazoan phyla substantially predate their appearance in the fossil record? (3) If the event was real, what was the triggering mechanism?

The current consensus is that the Cambrian explosion was indeed real and happened in just a 10–20-Myr interval in the Late Terreneuvian and early Series 2 (Valentine et al. 1999; Chen et al. 2000; Conway Morris 2000; Marshall 2006; Erwin and Valentine 2013). Yet, the Cambrian explosion does not record the initial split of the metazoans, but rather the diversification at a high taxonomic level (so is therefore, strictly speaking, not a radiation; Erwin and Valentine 2013) of the three fundamental metazoan groups into the crown groups and the modern phyla (Douzery et al. 2004; Peterson et al. 2004; Valentine 2004; Erwin and Valentine 2013). Ecologically, the Cambrian revolution led to a massive restructuring of the marine benthos (Bush and Bambach 2011). An increasing percentage of animals were burrowers that fed on nutrients within the sediment or that constructed tubes. As a consequence of the increasing bioturbation (Droser and Li 2001), the sediment became destabilized, and the superficial microbial mats were lost. This "agronomic revolution" (Seilacher 1999) or "Cambrian substrate revolution"

(Bottjer et al. 2000) led to an uppermost mixed layer, and besides the Ediacara organisms, many immobile recliners and mud-stickers like the helicoplacoid echinoderms went extinct early in the Cambrian (Bottjer et al. 2000; Dornbos and Bottjer 2000; Dornbos et al. 2005).

With respect to the triggering mechanism(s) of the Cambrian explosion, our explanations are still very speculative. The synchronous radiation of many disparate phyla has led strong support to the idea that there must have been an environmental trigger (physical or biological; Valentine 2002, 2004; Marshall 2006; Budd 2008). Among the hypotheses advanced is a significant increase in oxygen in the oceans, but this hypothesis is at odds with observations that oxygen reached sufficient levels to sustain metazoan life long before the Early Cambrian (Knoll 1996; Love et al. 2009; but see Hedges 2004). The amalgamation of continental plates, followed by a transgression, was also cited as a possible trigger (Brasier and Lindsay 2001). There were certainly dramatic changes in the chemistry of the oceans during the latest Precambrian as is evident from isotope studies. Increased nutrient levels in the oceans might have facilitated the radiation (Brasier 1992). Furthermore, a major increase in Ca^{2+} levels is documented during the earliest Cambrian, which certainly facilitated biomineralization (Brennan et al. 2004; Wood and Zhuravlev 2012; Kouchinsky et al. 2012). One of the most commonly involved biological explanations of the radiation is that skeletons developed in a number of groups as an answer to increasing predator pressure (Conway Morris 2001; Porter 2011; see also Stanley 1973) and perhaps also the evolution of animal vision (Parker 2003), thereby allowing new adaptational opportunities. The Cambrian saw the appearance of many carnivores and scavengers, and this trophic group accounted for up to 25 % of the species in the Middle Cambrian (Burzin et al. 2001). Furthermore, the development of planktonic habits in a range of groups greatly increased the complexity of food webs and was also responsible for animal diversification (Butterfield 2001, 2009). In more recent years, the evolution of developmental mechanisms has received much attention. It might well be that key innovations in gene regulation and recombination in early metazoans facilitated the Cambrian explosion (Valentine 2002; Erwin and Valentine 2013).

Many paleontologists were deeply impressed by the wide variety of different body plans, especially among arthropods, that appeared during the Cambrian explosion. The number of taxa known from the famous Cambrian Lagerstaetten that do not fit easily into any classification scheme based on living animals is extraordinary. It was claimed that morphological disparity among Cambrian animals was even higher than that seen today (Gould 1989, 1991) and that some extraordinary evolutionary mechanisms acted during the Cambrian explosion. Measuring morphological disparity is a relatively new field and seems to be a promising avenue to complement measures of taxonomic diversity (Foote 1997; Wills 2001; Erwin 2007). Detailed analyses of arthropods showed that disparity among the Cambrian forms was not higher than among modern species, and the level of appendage specialization is much higher today than in the Cambrian (Briggs et al. 1992; Wills et al. 1994). Special evolutionary processes do not, therefore, seem to have operated during the Cambrian explosion. Yet, it remains nevertheless remarkable how early and synchronous the multitude of higher animal taxa appeared in the fossil record.

The Ordovician Radiation

During the Ordovician, taxic diversity at the family and generic level reached a new maximum which was three to four times that of the Late Cambrian (Miller 1997, 2001). While during the Cambrian explosion numerous phyla and classes representing basic body plans originated, the Ordovician radiation was manifested by an unprecedented burst of diversification at lower taxonomic levels. According to the global picture of Sepkoski (1979, 1997), the Cambrian fauna (e.g., the trilobites) declined, while the articulated brachiopods, the crinoids, stenolemate bryozoans, and other members of the Paleozoic fauna showed a sharp increase. To a lesser degree, members of the Modern fauna like gastropods and bivalves also diversified (Miller 2001, 2012; Servais et al. 2009, 2010).

The almost exponential increase in diversity was much more rapid during this Great Ordovician Biodiversification Event (GOBE) than at any other time of the Phanerozoic (Sepkoski 1997; Webby 2004; Servais et al. 2009). This global diversity increase seems to have been the combined result of an increase in α- (within community), β- (between communities), and γ-diversity (biogeographical differentiation between faunal provinces; Webby 2004). New ecological guilds appeared, and the spatial organization of the benthic communities became considerably more complex (Bottjer and Ausich 1986; Droser and Bottjer 1989, 1993; Servais et al. 2009, 2010). The Ordovician was also a time of marked shift in the reef biota. Whereas Early Ordovician reefs were mainly built of microbial mats and stromatolites, large metazoan-dominated framework reefs had developed and spread on all continents by the end of the Ordovician (Webby 2004; Adachi et al. 2011). The diversification and spread of metazoan reefs was accompanied by an increase in bioeroding organisms colonizing reefs and hardgrounds (“bioerosion revolution”; Wilson and Palmer 2001).

Yet, when the global picture is dissected at finer taxonomic, geographical, and environmental levels, some surprising results emerge (Miller 1997). The diversification seems not to follow a global trajectory but to respond much more to local conditions in paleogeography, sedimentary environment, and orogenic activity. The general decline of Sepkoski’s Cambrian fauna is an oversimplification. The “smooth” global diversity increase during the Ordovician is thus the aggregate record of many regional patterns which were for the most part abrupt (Miller 1997, 2001, 2004, 2012; Westrop and Adrain 1998).

Not a single reason, but rather a combination of paleogeographic, sedimentologic, geochemical, and perhaps intrinsic factors, seems to have been responsible for diversity increase during the Ordovician (Harper 2006a; Miller 2012). The paleogeographic situation was one of a highly fractured continental crust with many small continents. Together with a very high sea-level stand and

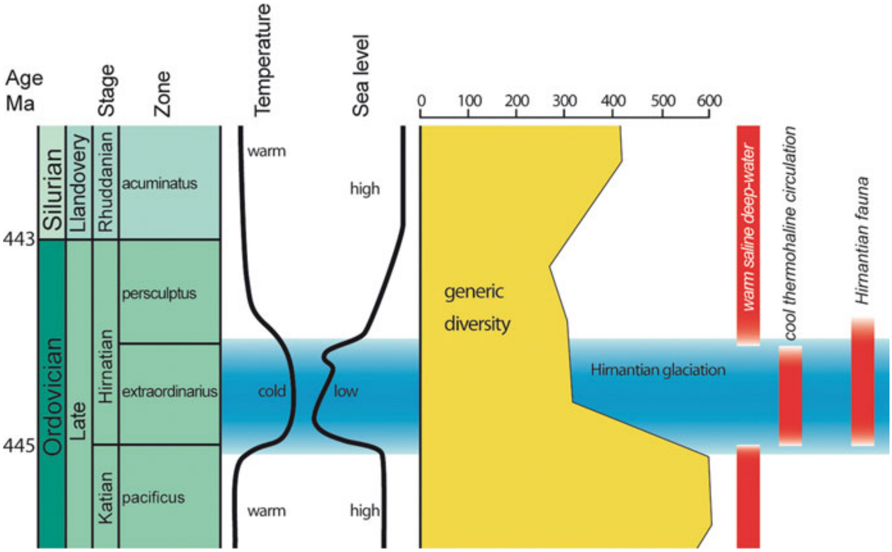

Fig. 8 Major events during the Late Ordovician mass extinction (Modified after Brenchley 2001)

increasing nutrient inputs, this provided extensive shelf areas in many different parts of the world and, therefore, a multitude of colonizable areas (Miller 1997). There is also a good correlation between diversity increase and orogenic activity. Throughout the Ordovician and the remainder of the Paleozoic, there was clearly a trend toward increased primary productivity and away from oligotrophic conditions (Martin 1996). Whether climate change (Trotter et al. 2008) and a series of impacts (Schmitz et al. 2008) also promoted the diversity increase remains to be scrutinized.

The Late Ordovician Mass Extinction

With 26 % of the marine families, up to 60 % of the genera and an estimated 85 % of all the species becoming extinct, the Late Ordovician mass extinction was one of the most severe extinction episodes in the Phanerozoic, surpassed in its magnitude only by the end-Permian mass extinction. Its extent was global, and it affected nearly all benthic and pelagic groups (Hallam and Wignall 1997; Brenchley 2001; Sheehan 2001b; Rasmussen and Harper 2011; Fig. 8).

During the Late Ordovician greenhouse conditions prevailed. But during the latest stage (Hirnantian), a short glaciation of approximately 0.5-Myr duration occurred (Brenchley 2001; Sheehan and Harris 2004; Delabroye and Vecoli 2010). The glaciation probably started when Late Ordovician orogenic activities led to extensive exposure and weathering of silicate terrains and, therefore, CO_2 consumption. Under falling CO_2 levels, ice sheets started to grow and albedo feedback led to an extensive Gondwana glaciation. The ice cover in turn inhibited silicate weathering, and CO_2 levels rose again. After a threshold was reached, greenhouse conditions returned and the ice caps melted quickly (Kump et al. 1999). It is now well documented that the mass extinction during the Late Ordovician was a two-phase event, and the first extinction pulse at the base of the Hirnantian *extraordinarius* zone corresponded to the initiation of the Gondwana glaciation and the second pulse in the first third of the *persculptus* zone to the rapid decay of the polar ice cap.

During the first extinction event, various groups suffered heavy losses, and the graptolites nearly died out. Thereafter, an impoverished and remarkably cosmopolitan benthic fauna was present on most shelves from high latitudes to the tropics. This so-called Hirnantia fauna can be regarded as a cool-adapted, opportunistic community that spread after the extinction removed the hitherto dominant species (Brenchley 2001; Sheehan 2001b; Jia-Yu et al. 2002). Primary productivity was obviously much reduced during the Hirnantian.

The second extinction phase was again sharp and hit most of the groups that had already suffered during the first extinction pulse. It eliminated much of the benthic Hirnantia fauna, but the recovery interval did not last very long. It is most surprising that the faunal turnover during the Late Ordovician mass extinction was accompanied by very little ecological change and the structure of Silurian communities is remarkably similar to those of the Late Ordovician (Droser et al. 2000; Bottjer et al. 2001; Sheehan 2001b; McGhee et al. 2004).

The causes of the two extinction pulses were certainly linked to the rapid onset and the later abrupt termination of the Gondwana glaciation during an otherwise warm climatic mode (Fortey and Cocks 2005; Delabroye and Vecoli 2010). Responsible for the necessary lowering of the atmospheric CO_2 was perhaps the expansion of the first land plants (Lenton et al. 2012). Global cooling of the oceans of perhaps as much as 8 °C together with a loss of benthic habitat due to regression might have, in part, been responsible for the first extinction (Berry and Boucot 1973; Brenchley et al. 1994; Armstrong 1996). Yet, pelagic forms also suffered heavy losses, and changing circulation patterns in the oceans were probably crucial (Hallam and Wignall 1997). The widespread deep anoxic waters, the extensive dysoxic zone, and the nutrient-rich surface waters vanished during the onset of the glaciation when cold, deep water led to intensified ocean circulation. During the second pulse, the termination of cold, deep water production led again to widespread stratified oceans with anoxic deep and intermediate dysoxic waters. Black shales accumulated again, and the transgressing dysoxic waters eliminated most of the benthic Hirnantia fauna and other benthic organisms not resistant to oxygen-poor conditions (Hallam and Wignall 1997; Rasmussen and Harper 2011).

The Late Devonian Biodiversity Crisis

Between 11 and 16 global events have been identified in the Givetian through Famennian stages (Walliser 1996; Becker et al. 2012), but only the lower and upper

Kellwasser events (Frasnian–Famennian boundary) and the Hangenberg event (uppermost Famennian) are of a magnitude that would deserve the name mass extinction (Hallam and Wignall 1997). Yet, the stress imposed by the many smaller events, especially the earlier Taghanic event in the Late Givetian (Aboussalam and Becker 2011; Zambito et al. 2012), was probably crucial for the overall extinction patterns in maintaining a high level of environmental stress throughout the Late Devonian. The label "mass extinction" is somewhat misleading as it was rather an anomalously low speciation rate that was responsible for the drop in biodiversity (Bambach et al. 2004; Stigall 2012).

At least 70 % and perhaps as many as 82 % of the marine species vanished during this time period (McGhee 1996, 2001; Fig. 9). Among the groups that were most severely hit were the reef builders (Fagerstrom 1994; Hallam and Wignall 1997; Copper and Scotese 2003), but other benthic organisms, especially tropical families, also suffered heavy losses during both major crises. The toll was no less severe in planktonic and nektonic groups (Racki 2005), and the armored agnathans and the placoderms went completely extinct (Hallam and Wignall 1997).

Quite important for the elucidation of the possible causes of the Late Devonian mass extinctions is that their selectivity differed between the different events. The Taghanic event affected mainly benthic taxa from low-latitude, shallow-water environments (Hallam and Wignall 1997). The Kellwasser events also affected mainly warm-water species as well as planktonic and pelagic groups. During the Hangenberg crisis, it was the planktonic and nektonic groups that were most severely hit, while the benthic groups showed a better survival than at the Frasnian–Famennian boundary.

The extinction patterns in the Late Devonian were highly complex and a result of several mechanisms spread over a time period of more than 10 Myr, with the most severe perturbations concentrated at the Frasnian–Famennian boundary and in the latest Famennian (Sandberg et al. 2002; Stigall 2012). Global cooling of the oceans (Copper 1986) was certainly one of the main causes of the extinctions (McGhee 1996, 2001; Brezinski et al. 2009), although the Gondwana glaciation only started in the Late Famennian (Caputo 1985; Algeo and Scheckler 1998). Yet, besides the cooling, frequent sea-level changes including both eustatic rises associated with spreading anoxic waters and regressions responsible for habitat loss are also well documented (Sandberg et al. 2002; Ver Straeten et al. 2011). The Late Devonian was also a time of increased impact frequency. Well-dated craters, shocked minerals, and microtektites as well as iridium anomalies are known from different continents (McGhee 1996, 2001; Sandberg et al. 2002), and these impacts probably increased the environmental stress.

Devonian to Carboniferous Expansion of Land Flora

Undisputed vascular land plants are known from Late Silurian strata, but spores occur already in the Middle Ordovician (Taylor et al. 2009; Kenrick et al. 2012).

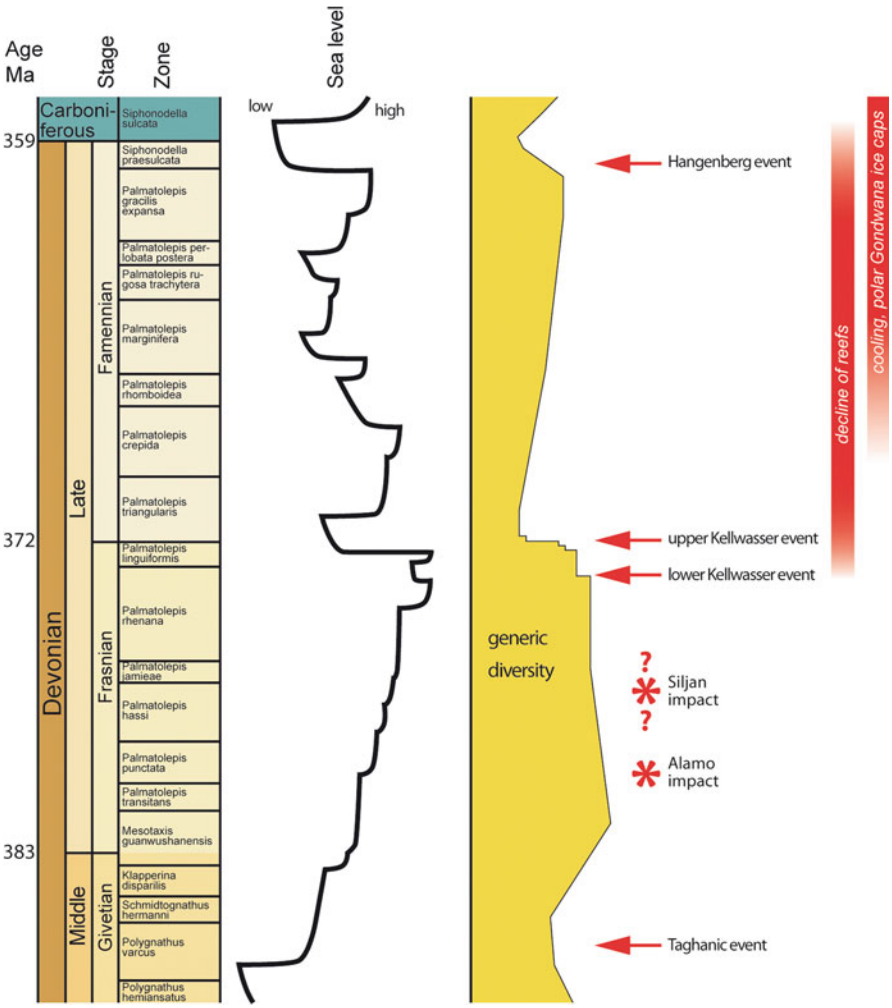

Fig. 9 Major events during the Late Devonian mass extinction (Modified after various sources)

Colonization of the terrestrial environment, at least in moist lowlands, obviously happened rather quickly, and within only 45 Myr, all major land-plant lineages and organizational grades (except for flowering plants) developed (Niklas 1997, 2004; Willis and McElwain 2002; Taylor et al. 2009). All the morphological adaptations including a protective outer covering (waxy cuticula) against desiccation, stomata to allow gas diffusion, specialized tissues for the transport of liquids, and rigid cell walls (Chaloner 2003) developed in the Devonian, although accompanied only by a modest diversification at the species level (Niklas 1997; Willis and McElwain 2002). By the end of the Devonian, the terrestrial environment saw the first globally distributed forests with large trees (Chaloner 2003; Taylor et al. 2009).

This resulted in a huge increase in biomass that culminated in the Late Carboniferous. Much of this organic material was not decomposed and recycled, but instead buried in moist anoxic soils (acidic swamps; Chaloner 2003).

This expansion of the land flora had a profound impact on Earth's environmental conditions. Most important was the removal of large quantities of CO_2 from the atmosphere through photosynthetic carbon fixation. The most widely accepted models for Phanerozoic CO_2 show a sharp decrease from about 15 times the present level (15 PAL) at the beginning of the Devonian to 10 PAL at the Devonian–Carboniferous boundary and a further decrease to less than 2 PAL in the Late Carboniferous (Berner 1998; Royer et al. 2000). With the massive drop in available CO_2, a high stomatal density became crucial, and the laminate leaf rapidly became widespread (Beerling et al. 2001) although at the cost of higher water loss through transpiration (Chaloner 2003; Taylor et al. 2009).

During the Devonian, an increase in the sizes of the trees was accompanied by increasing depth and complexity of the roots (Algeo and Scheckler 1998). This in turn accelerated silicate weathering and led to a further drawdown of carbon as bicarbonate into rivers and ultimately into the seas (Kump et al. 2004). The most obvious consequence of this huge decrease in atmospheric CO_2 was the onset of the Gondwana glaciation. In the Late Devonian, the southern continents were assembled near the South Pole, and the first polar ice caps developed in the latest Devonian. However, the main phase of the Late Paleozoic glaciation started in the Early Carboniferous. With its duration of more than 80 Myr (Crowley and North 1991; Frakes et al. 1992; Vaughan 2007), well into the Permian, this glaciation was by far the longest and also the latitudinally most extensive of the Phanerozoic ice ages. Yet, it was not associated with any major mass extinction pulse.

The very high productivity of the plants during the Devonian and Carboniferous also led to a significant increase in atmospheric oxygen, with 30–38 % O_2 in the Late Carboniferous (Berner 1999; Berner et al. 2003; Bergman et al. 2004). This seems to have had yet another impact on life. With increasing oxygen partial pressure, the diffusive flux is increased considerably, allowing the evolution of gigantic sizes (Graham et al. 1995; Dudley 1998), most notably among fish, terrestrial arthropods, and amphibians (Briggs 1985; Graham et al. 1995; Dahl et al. 2010; Harrison et al. 2010). For the giant flying insects, the higher density of the atmosphere might also have played a role (Dudley 1998, 2000).

The End-Permian Mass Extinction and Subsequent Recovery

The mass extinction at the end of the Permian has long been recognized as the most severe of all the Phanerozoic perturbations (Phillips 1860). The radical faunal change associated with this biotic crisis was the reason for distinguishing between the Paleozoic below and the Mesozoic above. More than 50 % of marine and terrestrial families went extinct and an estimated 80–96 % of all the species. Until recently (Erwin 1990, 1993), the end-Permian mass extinction was seen as a protracted crisis, which lasted for approximately 10 Myr. Newer research has

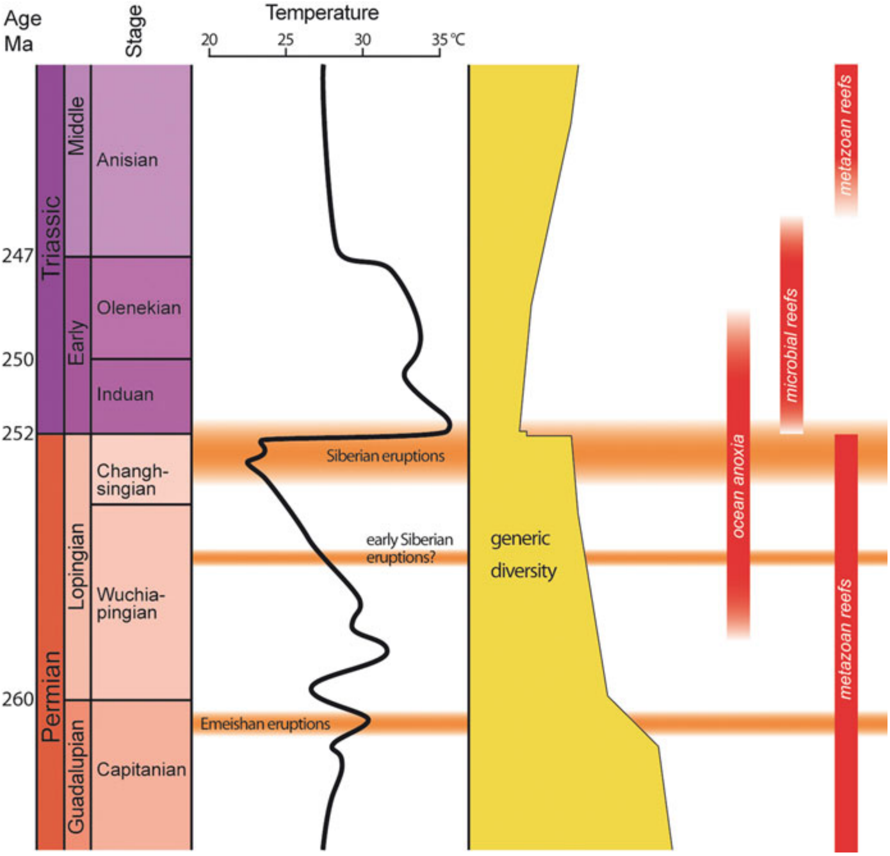

Fig. 10 Major events during the end-Permian mass extinction (Modified mainly after Chen and Benton 2012; Sun et al. 2012)

shown that there were actually two discrete events (Fig. 10). The first occurred in the latest Guadalupian (terminal Middle Permian) and affected only some groups in a more gradual way (Hallam and Wignall 1997; Clapham et al. 2009). The event at the very end of the Permian, and reaching slightly into the lowermost Triassic, was apparently of quite short duration (probably less than 0.2 Myr; Erwin et al. 2002; Shen et al. 2011). It is this interval that has been called "the mother of all extinctions," "the great dying," or the "Paleozoic nemesis" (Erwin 1996a, 2006; Benton 2003). This massive crisis affected all groups of organisms, both in the seas and on land (Benton and Twitchett 2003; Algeo et al. 2011).

In the Middle Permian, the seas were teeming with life, and many different faunal provinces can be distinguished. Highly diverse stromatoporoid–coral reefs were widely distributed. On soft and hard bottoms, rich communities dominated by brachiopods and echinoderms flourished, and in the water column, numerous ammonoids and various fish groups had attained a high diversity. On land, insects had reached their highest diversity in the Paleozoic, and tetrapod communities were probably as complex as modern mammal communities (Benton 2003; Sahney and Benton 2008). Plants were also highly diverse and distributed in different biogeographical provinces.

During the first extinction event, which occurred at the end of the Middle Permian (Guadalupian), some groups were affected both on land and in the seas, but none became entirely extinct (Hallam and Wignall 1997; Algeo et al. 2011). The reasons for this first extinction pulse are not well understood, but global cooling, loss of habitat area, and spread of anoxic waters have been cited as underlying causes (Stanley 1988; Hallam and Wignall 1997; Clapham et al. 2009).

The second, and by far the more severe, extinction pulse near the Permian–Triassic (P–Tr) boundary affected all the taxonomic and ecological groups, both in the seas and in the terrestrial environment. Among the larger groups that went completely extinct in the seas were the rugose and tabulate corals, fenestrate bryozoans, and orthid brachiopods. On land, glossopterids and cordaitales were suddenly replaced by a low-diversity conifer–lycopod–fern assemblage with little provinciality. Palynological samples from immediately above the P–Tr boundary are dominated by fungal spores which normally account for only a small proportion of the pollen and spores. This “fungal spike” (Eshet et al. 1995; Visscher et al. 1996; some fungal spores might rather be freshwater algae; see Wignall 2008) was similar in its magnitude to the “fern spike” at the Cretaceous–Tertiary boundary and might indicate vast areas of rotting plants which were decomposed by fungi (Hallam and Wignall 1997; Benton and Twitchett 2003). A wide range of tetrapods, among them the hitherto dominant pareiasaurs, went abruptly extinct, and the Early Triassic vertebrate faunas were completely dominated by the single genus *Lystrosaurus* (Hallam and Wignall 1997; Benton and Twitchett 2003; Ward et al. 2005; Sahney and Benton 2008). Both the magnitude (up to an estimated 96 % of the marine species) and the extraordinary long recovery interval were remarkable. It took almost 100 Myr for family diversity to reach preextinction levels and almost 10 Myr for complex ecosystems like reefs to become established again (Benton and Twitchett 2003; Erwin 2006). The first communities that appeared during the recovery interval are composed of a remarkably cosmopolitan, opportunistic fauna of thin-shelled bivalves (e.g., *Claraia*) and lingulid brachiopods (Hallam and Wignall 1997). Burrowing organisms were almost completely absent, and disaster taxa like stromatolites became locally abundant (Schubert and Bottjer 1992). Lazarus taxa were especially common among the gastropods, and most of them were small (“Lilliput” effect; Twitchett 2006). The long-term consequences for seafloor communities were the replacement of the hitherto dominant epibenthic sessile suspension feeders by a vagile, epi- and endobenthic, mollusk-dominated fauna (Hallam and Wignall 1997; Algeo et al. 2011; Campi 2012). The recovery interval after the end-Permian mass extinction was longer than for any other extinction event (although not for all groups, e.g., ammonites; Brayard et al. 2009), indicating that the ecosystems were almost completely devastated and severe environmental perturbations continued through the Lower Triassic (Twitchett 1999; Payne et al. 2004; Chen and Benton 2012).

The scenario for this mass extinction and its likely causes has received much attention in the last decade. All the evidence indicates that the mass extinction event lasted less than 200 kyr and occurred during a phase of marine transgression and severe global warming (Shen et al. 2011). The catastrophe probably started with the release of huge amounts of CO_2 into the atmosphere, first through volcanic eruptions in South China (Emeishan flood-basalt province; Lo et al. 2002) and perhaps also through coal oxidation (Hallam and Wignall 1997), later through vast eruptions in Siberia (Siberian traps; Courtillot 1999; Wignall 2001a; Benton and Twitchett 2003; Heydari et al. 2008). This led to global warming and in the seas to decreased ocean circulation and oxygen depletion (Wignall and Twitchett 1996), perhaps concentrated in the later part of the extinction event (Song et al. 2013). With further increasing CO_2 levels, methane hydrates began to melt and released large quantities of methane, which first acted as greenhouse gas and later was oxidized to CO_2. Through this positive feedback, a "runaway greenhouse" developed, which went out of control after some threshold was reached (Benton and Twitchett 2003). The seas flooding the shelves became hot, anoxic, and perhaps even sulfidic (Kump et al. 2005; Sun et al. 2012) and killed most of the benthic and pelagic organisms (Clapham and Payne 2011; Payne and Clapham 2012). Ocean acidification was especially deleterious for heavily calcified taxa (Knoll 2013). On land, the vegetation suffered a severe deterioration with equally devastating consequences for the animals, which perhaps also experienced hypoxic stress (Huey and Ward 2005).

Inevitably, many additional or alternative explanations have been presented. A major global regression during the terminal Permian was long a popular explanation for the extinction, but this is no longer tenable. There was clearly a transgression during the P–Tr boundary interval (Hallam and Wignall 1997). Darkening and global cooling with a collapse in photosynthesis was also proposed as extinction cause (Campbell et al. 1992), but all the evidence points to global warming at the end of the Permian. Older suggestions include brackish oceans and an increase in cosmic radiation. The claim for evidence of an impact is relatively recent (Becker et al. 2001, 2004; Frese et al. 2009). However, the impact hypothesis has not received much support (Erwin 2003, 2006). The end-Permian mass extinction thus seems truly "homemade" (White 2002; Benton and Twitchett 2003; Erwin 2006; Payne and Clapham 2012).

End-Triassic Extinction

The extinction at the end of the Triassic (Fig. 11) is recognized as one of the "big five" Phanerozoic mass extinctions, but documenting the exact timing and the causes of biotic overturn has proven difficult. There was a widespread regression at the end of the Triassic, and marine sections which span the Triassic–Jurassic (Tr–J) boundary are known from only a few localities (Hallam and Wignall 1999; Ogg and Hinov 2012a).

Many marine groups suffered a dramatic and sudden decrease in diversity at the end of the Rhaetian, but others witnessed a major reduction in diversity already at

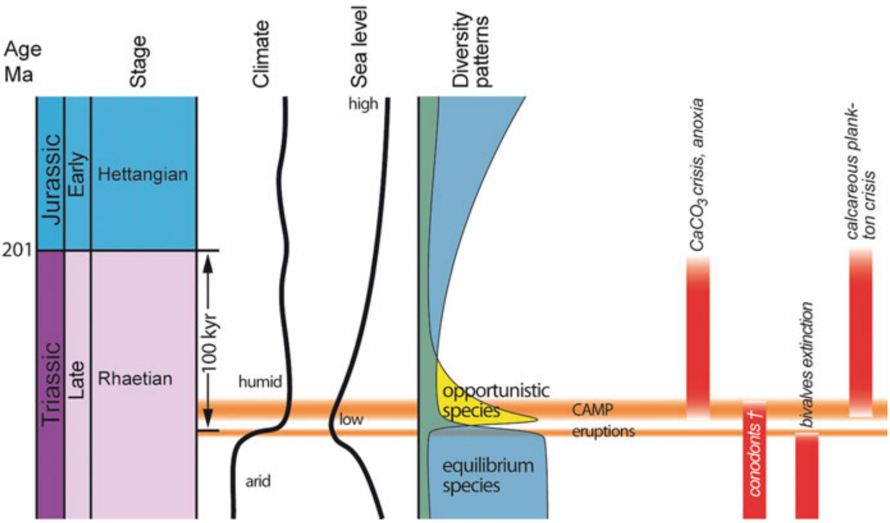

Fig. 11 Major events during the Late Triassic mass extinction (Modified after McRoberts et al. 2012)

the Carnian–Norian boundary and during the Early Rhaetian (Teichert 1990; Hallam 2002; Tanner et al. 2004; Wignall and Bond 2008). Terrestrial plant extinctions are concentrated around the Carnian–Norian boundary and at the Tr–J boundary (Deenen et al. 2010), and the latter boundary layer contains an unusually high fern spores/pollen ratio (Olsen et al. 1990, 2002). Among terrestrial vertebrates, a major extinction is undisputed, but the main turnover occurred near the Carnian–Norian boundary (Benton 1994; Lucas 1994).

Habitat loss and changing substrates associated with the regression in the Late Rhaetian, followed shortly thereafter by a transgression at the Rhaetian–Hettangian boundary, together with shallow water anoxia and perhaps ocean acidification (Greene et al. 2012; McRoberts et al. 2012), were responsible for the observed pattern in the marine realm.

The two extinction phases correspond to two pulses of flood-basalt volcanism (Deenen et al. 2010). This extensive and widespread volcanism related to the rifting of Pangaea around the North Atlantic at the Tr–J boundary was only recently recognized. The outgassing of CO_2 from this Central Atlantic Magmatic Province (CAMP; Marzoli et al. 1999; Wignall 2001a) might have had truly deleterious effects like enhanced seasonal fluctuations and an increase in the number and severity of hot days as well as a decrease in ocean water oxygenation (Huynh and Poulsen 2004). Extreme greenhouse warming, perhaps combined with the release of toxic gases, also explains the extinction patterns on land (Deenen et al. 2010).

An impact scenario (Olsen et al. 2002) is largely dismissed today because the extinction pattern is not a sudden, catastrophic one, various impact craters have been dated as Carnian–Norian, and claims for significant iridium anomalies and shocked quartz could not be verified (Hallam 2002; Tanner et al. 2004).

Mesozoic Marine Revolution

The term "Mesozoic marine revolution" (MMR) (Vermeij 1977) refers to the idea that during the Mesozoic, a profound reorganization in the marine communities led to a significant increase in predation pressure and prey species developed various adaptations (thicker shells, spines, behavioral responses) to cope with this increasing pressure ("arms race" or "escalation"; Vermeij 1987; Harper 2003, 2006b). It is undisputed that during the Mesozoic, especially during the Jurassic and Cretaceous, the number of marine grazers as well as durophagous and drilling predators increased considerably (Vermeij 1977, 1987, 2004; Bambach et al. 2007; Finnegan et al. 2011).

This rise in predatory groups was accompanied by profound changes in marine benthic communities. The epifaunal guilds, like stalked crinoids and brachiopods, that were so characteristic of Paleozoic communities vanished from shallow-shelf environments, and those epifaunal species that did persist in shallow water show a high frequency of regeneration and, therefore, of predator attacks (Vermeij 1987). A marked shift toward infaunal life modes is documented in post-Paleozoic echinoids, gastropods, and especially bivalves (Stanley 1977; Thayer 1983; Vermeij 1987), although this shift predates the appearance of most shell crushers (Harper 2003, 2006). The most conspicuous changes during the MMR occurred in shell architecture. Overall, the shells became sturdier, more highly armored, and developed spines, ribs, and thickened and narrowed apertures (Vermeij 1977, 1987, 2004; Ward 1981, 1983). At least among gastropods, shell-repair scars became much more frequent, pointing again to increasing predation pressure.

According to Vermeij (1987), it was the biological interactions (competition, predator–prey relations) that led to the evolution of these long-term trends. Yet, the biological evolution toward increasing predator-resistant shells might also have been facilitated by changes in the abiotic conditions. Extensive volcanism, which in turn augmented water temperature, high nutrient levels, and a high sea-level stand, facilitated the production of energetically expensive massive shells (Vermeij 1995) and perhaps as well the general increase in diversity and increasing "fleshiness" of the fauna throughout the Mesozoic and Cenozoic (Bambach 1993; Bambach et al. 2007; Bush et al. 2007). For several groups, the timing of changes does not support biological interactions as driving forces (Harper 2003, 2006; Madin et al. 2006; Baumiller et al. 2010; Kosnik et al. 2011).

Secular changes in oceanographic and geochemical conditions most certainly spurred other important changes in the marine biota during Middle and Late Mesozoic times. Planktonic foraminifers appeared in the Middle Jurassic and became numerically important during the Cretaceous. Coccoliths are known since the Triassic, but they became widespread and abundant during the Late Jurassic and the Cretaceous (Ogg and Hinov 2012a, b). This rise in planktonic calcifiers was perhaps facilitated by the intensified bioturbation of the seafloor which effectively recycled nutrients (Kelley and Hansen 2001), but had in turn tremendous effects on the carbon cycle and the $CaCO_3$ saturation of the oceans (Ridgwell 2005).

End-Cretaceous Mass Extinction

This is certainly the most widely known and probably also the best investigated of the major mass extinctions, simply because the popular (nonavian) dinosaurs disappeared at the Cretaceous–Paleogene (K–Pg) boundary (formerly known as the K–T boundary, but the Tertiary is no longer a formal unit of the revised time scale). Yet, it is, with a 16 % loss of the families, a 47 % loss of the genera, and an estimated loss of at least 70 % of the species in the marine realm, the least severe among the five major mass extinctions in Earth history (Jablonski 1994; Hallam and Wignall 1997; Fig. 12). Some marine groups disappeared completely at the end of the Cretaceous (e.g., ammonites, large marine reptiles), others suffered heavy losses (especially planktonic groups), but there were also groups that exhibited little or no reduction over the last Cretaceous to the lowermost Paleogene (MacLeod et al. 1997; Norris 2001; MacLeod 2013).

On land, plants suffered a sharp decrease in diversity that was previously underestimated (Nichols and Johnson 2008), and in many sections a short proliferation of ferns at the expense of angiosperms ("fern spike") is documented. Among the tetrapods, amphibians, turtles, crocodilians, and eutherian mammals were only mildly affected by the K–Pg boundary event, whereas lizards and marsupials suffered heavy losses (Archibald and Fastovsky 2004; Longrich et al. 2012). Primates had their origin in the Late Cretaceous (Chatterjee et al. 2009; Steiper and Young 2009). Yet, because the oldest primate fossils date from the Paleocene (Williams et al. 2010), it is unknown whether this group experienced losses during the K–Pg extinction. For the ornithischians and the (nonavian) saurischians, this

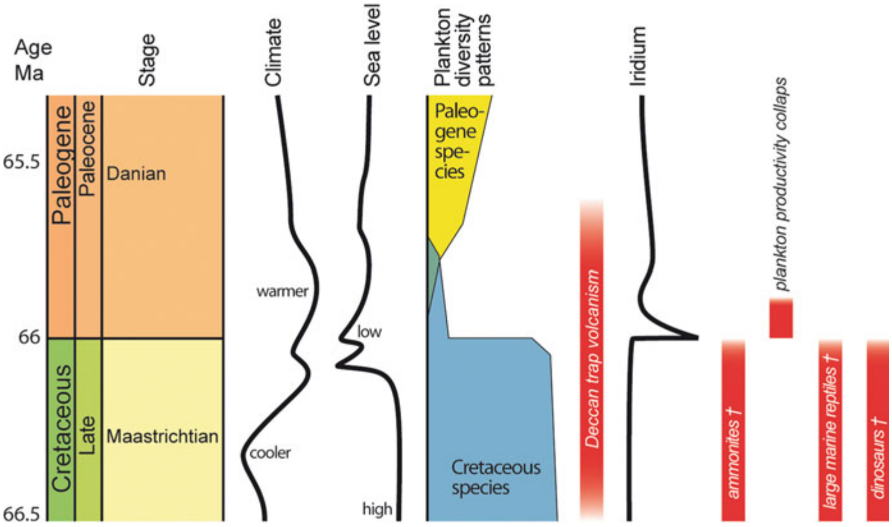

Fig. 12 Extinction patterns during the K–T mass extinction (Modified mainly after Schulte et al. 2010)

event was of course the end of a long era. Land-dwelling species were more severely hit than freshwater inhabitants, endothermic tetrapods (including ornithischians and saurischians) more than ectothermic, and larger more than smaller species (Archibald 1996, 2011; Archibald and Fastovsky 2004).

Evidence for both a gradual decline in dinosaur species richness as well as for a catastrophic and (geologically spoken) instantaneous extinction of the dinosaurs has been presented (Hurlbert and Archibald 1995; Archibald and Fastovsky 2004; see review in Brusatte 2012), but recent data indicate that there was no gradual decline in dinosaur diversity in the latest Cretaceous (Upchurch et al. 2011). The picture is equally complicated in marine exposures in which again evidence for both a gradual as well as a sudden extinction was presented (see MacLeod et al. 1997; D'Hondt 2005). Yet, resampling of formerly investigated sections extended taxonomic ranges upward, and the reported gradual decline of many groups might well be a consequence of the Signor–Lipps effect (Ward 1990).

Among the possible causes for the K–Pg mass extinction that are still considered today are volcanism, climatic fluctuations, and marine regression and an asteroid impact (Benton 1990; Archibald 2011; MacLeod 2013). There is indeed overwhelming evidence that the Earth was hit by a major asteroid perhaps 10 km in diameter that had a devastating impact on Earth's life. This evidence includes molten sediment particles (glass spherules), shocked quartz grains, and a worldwide recognized enrichment in iridium in K–Pg boundary layers (Alvarez et al. 1980, 1995). The impact hypothesis received further support with the discovery of a 66-Myr-old impact crater (Chicxulub) on the Yucatan peninsula, Mexico (Hildebrand et al. 1991). Yet, it has also been demonstrated that the latest Cretaceous was a time of major climatic fluctuations (Skelton 2003) and the pronounced marine regression at the end of the Maastrichtian has been recognized for a long time. In addition, intensive volcanism, which spanned less than 2 Myr over the K–Pg boundary, is documented from the so-called Deccan Traps (Courtillot 1990, 1999). These represent immense outpourings of lava in what is today India and must have had a profound impact on the biosphere (Kelley 2003).

Currently, there are two schools of thought to explain the K–Pg mass extinction. According to the gradualistic, multiple-causes scenario (Archibald 1996, 2011; Archibald and Fastovsky 2004; MacLeod 2013), the climatic fluctuations and the marine regression near the end of the Cretaceous profoundly changed the available habitats in both the terrestrial and marine environments. This biotic stress led to a gradual decline in the dinosaurs and other terrestrial vertebrates. Likewise, the regression also imposed a major stress on the marine animals by reducing the available shelf environments. Further stress was imposed by the Deccan Trap volcanism that erupted large amounts of dust into the atmosphere, with general cooling of the globe, drying of many terrestrial ecosystems, and slowing of the photosynthetic activity as the most likely consequences.

The asteroid impact at the K–Pg boundary is not disputed by most in the gradualist camp, but is seen merely as a moderate "last strike" that led to the collapse of already weakened ecosystems and extinguished animal groups that were already in decline (MacLeod 2013). Only a few researchers deny that the

Chicxulub impact played a crucial role in the K–Pg extinction. These maintain that the impact either postdated (Hildebrand et al. 1991) or predated (Keller et al. 2003; Keller and Adatte 2011; Keller 2012) the K–Pg boundary by several hundred thousand years and that there were perhaps several impacts, all unrelated to the extinction. Yet, it has been shown repeatedly that the impact and the extinction were synchronous (Schulte et al. 2010; Renne et al. 2013).

Those researchers who favor a single cause for the mass extinction at the K–Pg boundary emphasize the almost apocalyptic effects a bolide impact would have (Alvarez et al. 1995). This impact ejected considerable volumes of molten rock particles and dust into the atmosphere. Furthermore, it produced huge tsunami-type waves that devastated the coastal plains, and an immense fireball ignited vast wildfires. The dust particles would remain in the atmosphere for months, perhaps even years, leading to global cooling and darkening. Photosynthesis came almost to a halt, at least in plants adapted to higher light intensities. The fern spike recorded from many terrestrial boundary sections testifies to this sudden decline in higher plants and the spread of the ferns which could cope with darker conditions. As a consequence of the collapse of the ecosystems, first the consumers and then the carnivores died out within years. Those animals that did survive were preferentially small, unspecialized, opportunistic species that could feed on a variety of diets. That ecosystems were also severely and almost instantaneously hit in the marine realm is indicated by the patterns of the stable carbon isotopes across the boundary. These were previously interpreted as indicating an almost lifeless ocean after the K–Pg boundary ("Strangelove Ocean"; Hsu and McKenzie 1985; Zachos et al. 1989). Yet, marine productivity probably collapsed for only a few years (Alegret et al. 2012).

The normal succession in Caribbean coastal sections agrees well with the impact scenario (after Alvarez et al. 1995): above the Maastrichtian limestone, larger airborne particles (microtektites, glass spherules) were deposited first, then come tsunami deposits containing reworked Maastrichtian limestone and charcoal (from wildfires), and then dust-borne iridium and shocked quartz, and finally we see a return to normal sedimentation. Yet, a modified multiple-causes scenario seems at present to explain best the observed patterns (Archibald 2011; MacLeod 2013). Such a scenario emphasizes sea-level fluctuations, climate change, and continental flood-basalt volcanism, but accepts the Chicxulub as a devastating event that played a crucial role in the mass extinction.

Eocene–Oligocene Transition

In a diagram of Phanerozoic extinction intensities, the Eocene–Oligocene transition period barely stands out as an important event, and yet this time marked the most significant episode since the extinction of the dinosaurs (Prothero 1994). The Eocene was a time of warm temperatures, with widespread tropical forests, archaic mammals, and reptiles occurring above the Arctic Circle (Prothero 1994, 2006; Ivany et al. 2003). Within a time period of 10 Myr, this "greenhouse" world shifted to "icehouse," with decreased global average temperatures and markedly increasing seasonality, accompanied by major shifts in the biota of terrestrial environments and the seas (Berggren and Prothero 1992; Pälike et al. 2006; Zachos et al. 2008; Vandenberghe et al. 2012).

The record in the marine environment is one of a rather gradual turnover. A displacement of warm-adapted taxa by invading high-latitude forms is observable in both planktonic and benthic taxa and was obviously accelerated around the Middle–Late Eocene (Bartonian–Priabonian) boundary and within the Early Oligocene (Rupelian) (Berggren and Prothero 1992; Prothero 2006). As much as 90 % of the genera disappeared in some groups (Hallam and Wignall 1997). Fishes survived this period almost unaffected, while among the whales the more basal archaeocete whales were replaced by the first modern toothed and baleen whales (Prothero 1994).

On land, the flora changed between the Middle Eocene and Early Oligocene from widespread forests to open shrublands (perhaps with early grasses), and the leaf record as well as the amphibian and reptile fauna show a marked cooling and drying trend (Prothero 1994, 2006). Among the mammals, a fundamental difference between the Eocene and Oligocene faunas, the "Grande Coupure," has long been recognized (Stehlin 1909; Legendre and Hartenberger 1992). In Europe, there is a gradual replacement of archaic by modern mammals throughout the Late Eocene and Early Oligocene, with a pronounced peak of extinctions at the Grande Coupure (Hooker et al. 2004). This latter event is now dated to the Early (but not earliest) Oligocene (Prothero 2006). Almost all new taxa are immigrants from Asia, which could reach Europe after the closure of the Turgai strait in the Ural region. Similar trends are observable on the other continents (Prothero 1994, 2006).

High-resolution oxygen isotope studies over the past decades have considerably helped to clarify the climatic evolution from the Early Eocene to the Early Oligocene. Global temperatures reached a peak between 52 and 50 Myr ago, during the so-called Early Eocene Climatic Optimum (EECO). This was followed by a 17-Myr-long trend toward cooler conditions, with a dramatic increase in $\delta^{18}O$ at the Eocene–Oligocene boundary (Zachos et al. 2001; Vandenberghe et al. 2012). This latter shift in the oxygen isotope values reflects not only cooling but also a significant increase of the Antarctic ice cap. The first ephemeral ice sheets appeared already during the Late Eocene and were probably the result of both declining atmospheric CO_2 levels (DeConto and Pollard 2003) and an increasing thermal insulation of Antarctica. Plate tectonic movements had led to the separation of Australia and Antarctica and to the opening of the Drake Passage between Patagonia and Antarctica. By the end of the Eocene, the passage south of Tasmania was deep enough that the circum-Antarctic cold deep current could become established and the Antarctic ice cap rapidly grew (Prothero 1994, 2006; Ivany et al. 2003; Kennett and Exon 2004). Yet, on land, the extinctions associated with the Eocene–Oligocene transition were not simply the result of global cooling, increased seasonality, and increasing aridity but also a consequence of large-scale migrations. As an alternative or perhaps additional cause of the terminal Eocene turnover, impacts by comet showers have been proposed (Poag et al. 2003). Yet, the biotic turnover patterns do not correspond to an impact scenario (Ivany et al. 2003), and the Siberian Popigai (100 km) and the Chesapeake Bay crater (85 km) have now been dated as Late Eocene, when no extinctions occurred (Prothero 2006).

Pleistocene and Modern Extinctions

During the Pleistocene, between 2.6 and 0.01 Myr ago, the Earth witnessed large climatic fluctuations. Both plants and animals on all continents showed large shifts in their geographical distribution during this period, but the extinction levels were not above background values (Alroy 1999). This is true for such disparate taxonomic groups as insects, amphibians, reptiles, birds, and mammals. Yet, there is one major exception to this rule: the so-called mammalian megafauna (animals $>$ 44 kg).

Fifty thousand years ago, more than 150 genera of this megafauna populated the continents, but by 10,000 years ago, at least 97 of these genera were extinct (Barnosky et al. 2004; Koch and Barnosky 2006). There have been continued debates over whether these extinctions were caused mainly by environmental changes associated with climatic fluctuations or were the consequences of human impacts. It is undisputed that humans were responsible for the extinction of large mammals and large birds on islands such as Madagascar, Antillean, Mediterranean, East Asian Islands, and New Zealand (Barnosky et al. 2004; Burney and Flannery 2005). Here hunting and habitat fragmentation led to extinctions, even in the absence of climatic change.

An important aspect is that mammalian megafaunal species on all continents became extinct, but both magnitude and timing of the extinctions differed between continents (Roy 2001; Barnosky et al. 2004; Koch and Barnosky 2006). The extinctions were most severe in Australia where 14 out of 16 (88 %) giant marsupials succumbed. In addition, all seven genera of megafaunal reptiles and birds went completely extinct (Barnosky et al. 2004). Humans arrived on that continent somewhere between 71,500 and 44,200 years ago, and most megafaunal species became extinct before 40,000 years ago (Koch and Barnosky 2006; McGlone 2012). In North America, 33 genera (72 %) went extinct (Roy 2001) within a short time interval between 11,500 and 10,500 years ago, closely correlating with the arrival of Clovis-style hunters (Alroy 1999; Roy 2001; Koch and Barnosky 2006). In South America, 50 genera (83 %) vanished during the arrival and spread of humans about 12,900–10,000 years ago. In Eurasia (excluding Southern Asia), 9 genera out of 25 (36 %) became extinct during two pulses (45,000–20,000 years ago, 12,000–9,000 years ago). These extinction pulses correlate also with the spread and then the population increase of modern humans (Barnosky et al. 2004; Koch and Barnosky 2006). In Africa, the losses were relatively mild at only 8 genera (18 %). When considering only mammals $>$1,000 kg, the differences between continents are even more marked. In North America all four genera were lost, Eurasia saw the demise of four out of five, but in Africa, no such genus went extinct (Roy 2001; Koch and Barnosky 2006).

Many phases of human colonization were coeval with marked climate changes. Because earlier, similar climate changes were not accompanied by marked extinctions, hunting by humans (overkill) was proposed as the main mechanism responsible for the extinctions (Martin 1984), either by heavy and selective hunting ("Blitzkrieg") or through habitat fragmentation, nonselective hunting, and the introduction of exotic species ("Sitzkrieg"). The current consensus picture for megafaunal extinctions on the continents is that extinctions were most pronounced where a rapid spread and increase in *H. sapiens* populations coincided with marked climatic shifts (Burney and Flannery 2005). But it was not primarily large-sized but rather slow-breeding species (this is, in part, correlated with large body size), which were at the highest risk of extinction (Johnson 2002). Even if the proportion of deaths caused by humans was low at any one time, slow-breeding megafaunal mammals were driven to extinction.

Yet, the story is not over. Since the age of colonialization, the exploitation of nature has reached a new level, and the fate of the dodo (*Raphus cucullatus*) is just one very sad and telling example of human impact. This flightless bird was discovered in 1598 on Mauritius after Portuguese sailors first reached this island in 1507 and became extinct by 1690, not only by hunting but also by the introduction of domestic species, such as goats, pigs, and rats, which devoured the eggs and the young. The list goes on, and even extremely common species like the passenger pigeon in North America (*Ectopistes migratorius*) have proven to be no match for intensive hunting humans.

Starting during the epoch of industrialization, exploiting nature and destroying natural habitats have proceeded at an ever-increasing rate (Wilson 1994). The human impact on nature has become so profound and is already so visible in the stratigraphic record (Wolfe et al. 2013) that for the time since the beginning of the industrialization the new term "Anthropocene" was proposed (Crutzen and Stoermer 2000; Crutzen 2002). It became accepted rather quickly in the scientific literature (Steffen et al. 2011; Zalasiewicz et al. 2012; Ruddiman 2013). There is no question that current extinction rates for plants and animals have reached in the Late Anthropocene a level perhaps 2–3 magnitudes above background rates (Nott et al. 1995; Pimm et al. 1995; Ricketts et al. 2005; Barnosky et al. 2011). Scaling the available estimates of current extinctions up to a magnitude where we can compare them to past Phanerozoic mass extinctions reveals that if species losses continue at the present rate, 96 % of species will be extinct within just a few hundred or thousand years (May et al. 1995; Sepkoski 1997; "Sixth" extinction). This is the maximum estimate for species losses during the most severe of all the Phanerozoic mass extinctions, the one that occurred at the Permian–Triassic boundary! Yet, although the end-Permian mass extinction is no longer seen as a crisis spanning millions of years, current estimates are still on the order of a hundred thousand years. There is even further concern. As several episodes of mass extinctions have shown, even a moderate increase in global temperatures of a few degrees, if it happened fast enough, has proven fatal for life on the entire planet.

Conclusions

After more than 30 years of intensive research, the picture of life's diversification on Earth has attained an unprecedented level of accuracy. Much progress has been made in Precambrian research, notably in the study of the oldest fossils and their environment. Major input into studies of radiations and extinctions has come from geochronology, which has provided a new, accurate time scale. Other important developments have been the establishment of a new animal systematics and the considerable advances made in the dating of lineage splits.

The quintessence of diversity studies, the global diversity trajectories for the Phanerozoic, has been refined in many ways, and Sepkoski's classical, iconographic figure of the marine animals has recently come under scrutiny. Many of the dogmas are being reevaluated, a new database is being developed, and methodological problems are receiving considerable attention. What is needed for further refinement will especially be studies at the local level that take into account ecological data and ultimately can be assembled into a new global picture.

Mass extinctions have received a tremendous amount of attention since 1980, and for most of them, a consensus interpretation exists today. Emerging is that each extinction event had its own signature, and no common cause has been found. Hot topics at the moment are the diversification of the metazoans and the Cambrian and Ordovician radiations, and here we will most likely see much progress in the next few years.

Taphonomic and Diagenetic Processes

Gisela Grupe and Michaela Harbeck

Contents

Abstract

The recycling of matter within an ecosystem is a fundamental process and, therefore, fossilization of a body or its parts is always the exception to the rule.

The transition of organic remains from the biosphere to the lithosphere (=taphonomy) comprises the successive steps of necrology, biostratinomy, burial, and diagenesis. Focusing on the taphonomy of vertebrate skeletons, fossil types, and the main processes leading to preservation and/or destruction of a dead body and how these are intertwined are introduced. All in all, fossilization is not a random process. Almost all the first-order changes a dead body is subject to prior to fossilization may lead to alterations in size and shape of a skeletal part, which might be mistaken for artificial manipulations (pseudoartifacts). Taphonomic processes without doubt lead to a stepwise loss of information about the formerly living being. Today, methodological progress especially in the field of archaeometry permits the evaluation of a variety of lifetime parameters. However, deep insights into taphonomic, especially diagenetic, processes are the indispensable prerequisites.

Introduction

The recycling of matter is one of the fundamental processes of life. Fossils, on the other hand, are evidence for the possibility that either complete organisms or their parts may be transferred from the biosphere to the lithosphere with preservation of morphological and even biochemical features. With regard to the various biogeochemical cycles which are characteristic for ecosystems, fossilization is necessarily the exception to the rule.

Taphonomy

Taphonomy is the paleontological subdiscipline that unravels the processes an organism is subject to from its death until its recovery (Fig. 1). The term "taphonomy" was introduced by the Russian paleontologist Efremov (1940) as the study of the transition of organic remains from the biosphere to the lithosphere, whereby the etymological origin of the term from the Greek taphos = tomb implies the necessity that the dead body or its parts become buried sooner or later after death (note the origin of the term "fossil" from the Latin word fossilis = excavated, related to fadere = to dig, or effodere = to excavate). Carcasses that remain on the surface usually do not have a chance to turn into a fossil and will instead undergo complete decomposition. The preserved fossil record is greatly biased toward organisms which have durable, hard parts like mineralized tissues and to those organisms which occur in large numbers, hence with high population density. Fossilization is therefore not a random process. Taphonomy is a field of scientific research which is primarily dedicated to fossils, but today also relates to bioarchaeological remains. This is expressed by the flexible definition by Behrensmeyer et al. (2000), according to which a fossil is a "nonliving, biologically generated trace or material" that is studied "as part of the record of past life."

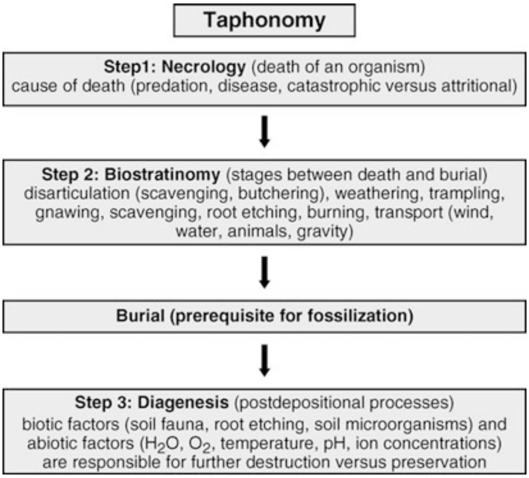

Fig. 1 The consecutive steps of taphonomy (cf. text)

Taphonomic Analysis

The first step of taphonomic analysis comprises *necrology*, the actual death of an organism. While most animals die *in toto*, entire plants frequently do not but rather shed parts like leaves or pollen, which may fossilize. After death, *biostratinomy* is responsible for the further condition of a carcass prior to its burial and includes processes like disarticulation (by scavengers or intended dismemberment by butchering), weathering and trampling, gnawing and scavenging, root etching, and even heat exposure (accidental or intended). Moreover, the body or its parts can be subject to transport by wind, water, animals, or simply to gravity, when it is exposed somewhere uphill. As a consequence, most fossils will be removed from their original context and the place of recovery will differ from the place of individual death. In the case of hominins, this situation changed not before humans started to intentionally bury the dead. Finally, the bodily remains become buried, and *diagenesis* sets in. Diagenetic processes involve all interactions of the dead body or its parts with the surrounding sediment, which either end up in the complete disintegration and dissolution of the body or in its lithification. “Diagenesis” is a term derived from the earth sciences and refers to the biological, chemical, and physical changes that take place in sediments after the deposition of the body and which may end up in lithification.

In this narrow sense, diagenesis also applies to fossils. Today, this term is frequently used in its broader sense, is synonymous with “decomposition,” and refers also to subfossil and prehistoric bones and to finds of forensic relevance. The state of preservation of a dead tissue will give clues to burial conditions, to burial practices, and sometimes even to *ante mortem* conditions such as cause of death or existing diseases. *Ante mortem* injury or infection or any pathology which causes tissue breakdown during life is likely to accelerate decomposition. Even after lithification, fossils may show up on the surface due to erosion, where they are again subject to weathering and trampling. Taken together, the taphonomic processes lead to a stepwise loss of information about the formerly living being or at least to a decline of the integrity of the information through the many ways that the evidence can be altered (Reitz and Wing 1999). However, the statement by Shipman (1981a, p 3) “in short, through death most evidence of the interesting information about animals what they look like, what they eat, how they move, where they live, and so on – is lost” now requires, more than 30 years later, some revision: Methodological progress, particularly in terms of archaeometry, permits the evaluation of several of the abovementioned parameters, including genetic relationships in cases of preserved DNA. But it becomes also clear that any research on the molecular or crystal level necessitates deeper insights into taphonomic, especially diagenetic, processes. Thus, the early statement by Weigelt (1927) that taphonomy and disintegration will give clues to the paleoenvironment in which the fossils were buried still holds today, and taphonomy has now become an integral area of paleoenvironmental research.

Nonetheless, taphonomy has largely changed from a paleontological subdiscipline into a scientific field of its own, where research mostly focuses on either biostratinomy or diagenesis. Since the 1980s several books covering this topic provide proof of the development of this field of research (Behrensmeyer and Hill 1980; Binford 1981; Brain 1981; Shipman 1981a; Allison and Briggs 1991; Donovan 1991; Lyman 1994; Martin 1999). Taphonomic analyses are also of great importance for archaeozoology, since animal bone deposits are usually the remainders of killing or butchering sites or village or home-based refuse. The animal bones are characterized by several kinds of manipulation before being deposited, and the individual animals have been transferred from the living community into the archaeological deposit (Reitz and Wing 1999). With regard to the aims and scopes of this handbook, this chapter concentrates on the taphonomic and diagenetic processes acting on the vertebrate skeleton, since the mineralized parts of a body have a higher probability of turning into a fossil than soft tissues. However, depending on the mode of preservation, the latter may also leave their traces.

Modes of Preservation

Several modes of preservation exist, which are briefly explained in the following sections.

Mineralization

This involves organic matter and necessitates exposure to water. Organic matter is gradually infiltrated and replaced by minerals derived from the watery environment, and mineralization results in the preservation of the shape of the organic component, sometimes down to individual cells (Nicholson 2001).

Carbonization

This results from heat and/or pressure, which removes all volatile organic components and leaves nothing but a carbon layer. This way, coal is generated from dead plant tissue.

Permineralization or Petrification

This is the result of the infiltration of natural hollow spaces of plant tissue, such as the xylem of woods, by infiltration and precipitation of exogenous minerals. If this exogenous material is made out of silica, wood will petrify.

Recrystallization

In its narrow sense, this is a process during which original mineral crystals change in size and shape, mediated by temperature and pressure. The chemical composition, however, is not changed, as in the case of the change of aragonite ($CaCO_3$, rhombic crystals) into its more stable form, calcite ($CaCO_3$, trigonal crystals). After death, mineralized tissues may be subjects of a spontaneous rearrangement of the crystalline matrix. Since the crystals change in both size and shape, morphological details will not be preserved, and even destruction may occur. Frequently, the term “recrystallization” is used in a quite broad sense and refers to almost all changes of the mineral portion of a skeleton, including heteroionic substitution (see below).

Heteroionic Substitution or Replacement

This is a mode of preservation in the course of which the mineralized components of a body are substituted molecule by molecule, or ion by ion, with exogenous material. This process takes a long time because the original mineral has to first dissolve before it can be replaced by exogenous precipitates, like silica, which are less soluble. Morphological details will be preserved, contrary to recrystallization; hence, substitution may lead to a “perfect” fossilized skeletal part.

Molds and Casts (Authigenic Preservation)

These are special fossil types wherein a body part gets trapped into sediments which harden, while the original bodily tissue (mostly bone or shell) dissolves. Thus, a void is produced within the sediment, and its negative relief can preserve the impression of the former body part left on the still soft sediment. Hardening sediment, producing a cast (with a positive relief), may again infiltrate this void.

It is also possible that sediment infiltrates a shell or a hollow space of a skeleton, e.g., the brain case, and hardens while the shell or bone dissolves. The resulting mold will also have a positive relief as in the case of the brain cast of the Taung child. Under special circumstances, bodies may be preserved unaltered, like insects trapped into amber.

Trace Fossils

This special category can be defined as modifications brought about by activities of living organisms on substrates and therein. Trace fossils include gnawing and butchering marks on bones (feeding traces, see later) but mainly concern visible tracks of a no longer visible body (or its parts), like fossil rodent burrows, sleeping pits of hibernating cave bears, or the so-called bear polish, a gloss on stones resulting from the polishing action of bears' fur in narrow cave passages (for review, see Gautier 1993). The most famous such fossil in the paleoanthropological record is the preservation of the australopithecine footprints from Laetoli. Such impressions will be preserved when they are buried quickly. Rapid burial is less uncommon than sometimes assumed, since not only volcanic ash eruptions but also storms, floods, or landslides may cause sedimentation within hours.

In this sense, fossilized feces called *coprolites* (from the Greek copros = dung and lithos = stone) can also be included into this highly variable group of trace fossils because coprolites are the result of the metabolic transformation of living organisms (edible plants and animals) into feces that later fossilized. Coprolites from many animal species including dinosaurs have been recovered, and they are mostly preserved by mineralization after rapid burial. However, very old coprolites are not easily identified in terms of their origin, and this holds especially for the fossilized feces of omnivores. Coprolites suggested to be of hominin origin were, e.g., removed from the *Australopithecus africanus* site at the Olduvai Gorge, from the *Homo erectus* site at Terra Amata, and from a *Homo neanderthalensis* site at Lazaret. In none of these cases could their hominid origin be confirmed by conventional coprolite identification methods (cf. Trevor-Deutsch and Bryant 1978).

Bog Bodies and Mummies

These are not fossils in the narrow sense since they are not lithified. The development of bogs set in after the last glaciation and was driven by substantial precipitation and water masses set free from the melting glaciers. In such regions where precipitation exceeds evaporation, peat bogs are generated which are characterized by an acidic pH between 3 and 5. When precipitation accumulates in natural depressions close to the groundwater, fens develop the pH of which can reach alkaline values. As a consequence, bodies buried in fens exhibit well-preserved mineralized and keratinized tissues, whereby bodies from peat bogs suffer from an advanced demineralization of the skeleton but have well-preserved soft tissues due to tanning. The spectacular bog bodies are therefore recovered from peat bogs, where the polysaccharide sphagnan of the *sphagnum* mosses not only inhibits microbial growth but also plays a key role in the tanning process through interactions with amino acids. Since peat bogs are free of molecular oxygen with the exception of the most superficial layers, activity of oxygen-dependent enzymes is reduced or even completely inhibited (Freeman et al. 2004).

Natural mummification is bound to burial conditions which either rehydrate a dead body rapidly or which inhibit microbial growth and action (such as lack of oxygen, cold, dry heat, high concentration of heavy metals or toxic elements). This way, initial putrefaction will be stopped, and soft tissues will be preserved. Such natural mummification leads to dry mummies (desert dry soils, soils with high nitrate concentrations), crypt mummies (at constant ventilation and air flow), ice mummies (cold at high latitudes or altitudes, preferably in combination with low humidity), or salt mummies (in salt deposits). Moist conditions accompanied by a relative lack in oxygen may lead to moist preservation with soft tissues preserved in a collapsed and advanced state of degradation. Even in archaeological skeletons, brain tissue may be recovered from an otherwise completely skeletonized body. Obviously, the inner brain case, protected by the skull bones, constitutes a favorable microenvironment. In addition, the myelin layer of the nerve cells may play a role. Such preserved brains, however, are mainly preserved in a state of advanced adipocere generation (Papageorgopoulou et al. 2010).

Preservation by lithification is thus not a common fate of a dead body and will occur only under special circumstances. As a result, not all places in the world have the same likelihood of bearing fossils somewhere under the surface. For instance, the acidic soil conditions of densely forested areas do not permit fossilization at all. Karstic caves, on the other hand, are characterized by low-temperature fluctuations and slightly alkaline conditions, which constitute a nearly ideal environment for fossilization. Normally, however, complete decomposition is the fate of a dead body, and the speed of the processes involved depends on the local burial environment. The tissues will suffer from stepwise destruction, and some destruction usually precedes preservation.

Alterations of Dead Bodies

Abiotic and biotic factors may both be responsible for the alterations of dead bodies in the course of necrology, biostratinomy, and diagenesis. These processes are also referred to as "first-order changes" because they are independent from archaeological activities and are opposed to "second-order changes" which are under control of the archaeologist, such as choice of site (where to excavate), excavation technique, etc. (Reitz and Wing 1999).

Preburial modification of body parts is brought about by scavenging, gnawing, digestion, butchering, weathering, trampling, transportation, and heat exposure.

Postburial modifications are the result of the burial environment, which is characterized by the availability of water and oxygen, temperature, pH, abundance of microorganisms, faunal and floral elements, and ion concentrations. Many taphonomic changes may resemble pathologies or even intended manipulations and give rise to killing or cannibalistic scenarios – another facet of taphonomic research which is responsible for distinguishing a biological signal from a taphonomic alteration.

The amount of paleobiological information that can be deciphered from a fossil is a function of all three steps of its taphonomic history. For instance, the body of individuals that died of predation have a smaller chance of preservation because the mineralized body parts will undergo at least same partial destruction by chewing and stomach acid etching. In ideal, rare cases, individuals are caught in natural traps like the famous La Brea tar pits in California. Such sites can contain fairly large amounts of accumulated fossil bones (Shipman 1981a).

Catastrophic death due to flash floods, volcanic eruption, etc. has to be distinguished from attritional death by natural causes, since the age structure of the resulting bone assemblage will differ drastically. While catastrophic death leaves a sort of snapshot of a formerly existing animal community, attritional death will lead to an overrepresentation of the more vulnerable very old, very young, and diseased individuals (see chapter "▶ The Paleodemography of Extinct Hominin Populations," Vol. 1).

The majority of alterations to vertebrate skeletons later recovered in fossilized form are due to biostratinomical processes. The recovery of a nearly complete fossilized skeleton or even of several parts of the same skeleton (e.g., the case of *Australopithecus afarensis* AL 288-1 "Lucy," the "Nariokotome Boy," *Homo erectus* KNM-WT 15000, or *Ardipithecus ramidus* ARA-VP-6/500, "Ardi") is exceptional. Usually, single skeletal elements or their parts are recovered out of their former anatomical context, with the teeth constituting the majority of fossil finds. This is the result of the natural disarticulation sequence of a vertebrate body, which is altered and enhanced by predators or scavengers and which depends on the structure and composition of an individual bone. The teeth are more frequently found in fossil assemblages because they are small and buried rapidly, and the enamel is densely mineralized and therefore not prone to microbiological decomposition. The over- or underrepresentation of specific skeletal elements at the australopithecine site of the Makapansgat limeworks has already been stated by Dart (1957) and was confirmed at the Sterkfontein, Swartkrans, and Kromdraai sites, giving early rise to both experimental and fieldwork (Brain 1967). Still, a major concern of taphonomic studies is the differentiation between natural and cultural origins of bone accumulations. Experimentation, the results of which are necessarily interpreted by uniformitarian assumptions, is usually straightforward despite its inherent limitations (for review, cf. Nicholson 2001; Denys 2002).

The mobility of joints and the presence of more resistant tissues like tendons control the natural disarticulation sequence. First, the skull and limb bones are disconnected, followed by the ribs. Next, the limb bones and the lower jaw become disarticulated, and only when the final stage is reached, when weathering will mostly have already set in, does the vertebral column become scattered (Toots 1965).

Once skeletonized and disconnected, the resistance of individual bones toward further destruction is a function of bone density (Lyman 1984). At this stage, the process of destruction appears to be rather constant and less a function of the exact taphonomic context. Best preserved are skulls, followed by the shafts of limb bones and their denser epiphyseal parts, while the sternum, clavicle, and scapula are usually the least well preserved.

Preburial Modification Processes of Body Parts

Weathering and Trampling

When talking about weathering, most people intuitively think of bone exposed to climatic conditions while it is still on the surface and not yet buried. Sufficient evidence exists that disarticulation and fragmentation of skeletons are mainly of biogenic origin (Behrensmeyer et al. 2000).

In her pioneering fieldwork, Behrensmeyer (1978) defined six stages of bone weathering, from stage 0 (no cracking or flaking) to 6 (bones mechanically fall apart into pieces), but made it clear that weathering may destroy a bone *in situ* “either on surface or within the soil.” While it is a common occurrence that bones buried within the soil may still “weather,” although at a much slower rate, the main interest of paleontologists, anthropologists, and forensic scientists is to define the time a skeletal element has spent on the surface or how much time has elapsed until a bone assemblage was formed.

In their critical evaluation of Behrensmeyer’s weathering stages and the conclusions drawn from them, Lyman and Fox (1997) confirm the main factors governing bone weathering (size and density, species-specific texture, stability of the environment – three factors only, but enough to render the process quite complex) but clearly point out that one is still “a long way from safely inferring time of bone assemblage formation, let alone hominid behavior, on the basis of bone weathering data.”

In the course of the weathering sequence a bone undergoes while still on the surface, longitudinal fractures appear first, followed by fractures running transversely to the shaft of a long bone. Fragments which become abraded may resemble bone artifacts like needles and awls. Needlelike bone splinters even with holes, strongly resembling needles at first glance, may be the product of stomach acid etching after bone ingestion by scavengers (Sutcliffe 1970).

Experimental work revealed that trampling of a bone can produce scratches by sediment grains that strongly resemble cut marks. Real cut marks, in contrast, may be completely erased by trampling. This is another example of pseudoartifacts which have been mimicked by natural phenomena and which can lead to serious misinterpretations of a fossil. It has therefore been emphasized that a correct identification of cut marks is greatly supported by their location on a bone (site of ligament or muscle attachments) and by their microscopic features (Behrensmeyer et al. 1986).

Transportation

Although whole bodies can be transported away from the original place of death by such agents as floods, the likelihood of transport is much higher for disarticulated body parts. These are taken away by predators and scavengers or are relocated by wind currents or gravity. However, "water is perhaps the most ubiquitous taphonomic agent transporting, modifying, and accumulating remains" (Haglund and Sorg 2002). The authors emphasize that many fossil hominin finds, such as the Nariokotome Boy or the australopithecine "First Family," have been recovered from sand or gravel sediments deposited by moving water, which are highly suitable for rapid embedding and burial. Since water environments differ in current, temperature, depth, salinity, and other features, disarticulation sequences and decomposition processes of a dead body are difficult to predict. Experimental taphonomic work with human bones in an artificial flume, which constitutes an ideal and not a natural water transportation simulation, has revealed different transport groups of bones according to their size and shape (Boaz and Behrensmeyer 1976). This does not only lead to a removal of skeletal parts from their original place but also to a sorting of the bones in terms of their morphological properties. Certainly, water transport causes additional damage to bones, especially by abrasion in sediment-rich water.

Scavenging and Gnawing

It is the scavenger's business to clear dead bodies from a site. Spontaneously, one would think of middle-sized mammals, like hyenas, but also small rodents, toads, and some land snails are efficient scavengers. Many more species gnaw bones, mostly to meet their calcium and phosphorus demands. These include nonhuman primates, canines, weasels, raccoons, hyenas, cats, artiodactyls, squirrels, beavers, mice, rats, porcupines, rabbits, hares, varanids, and same desert tortoises (cf. Reitz and Wing 1999). Osteophagia is especially common in artiodactyls (cattle, red deer, reindeer, muntjac, camels, and giraffes) as a symptom of phosphorus deficiency in regions with low phosphorus content of parent rocks. Since the bones are chewed with the molars, such gnawed bones reveal a pattern resembling forks and prongs, which may again be mistaken for human artifacts (Sutcliffe 1973). Rodents, which have to wear their ever-growing incisors, leave very characteristic gnaw marks, preferably on the edges of the bone, in the form of parallel grooves. Bite marks left by carnivores do not occur as parallel grooves but as irregular grooves and pits (Fig. 2). Four types of tooth marks, namely, punctures, pits, scoring, and furrows, have been identified by Binford (1981). The trabecular parts of the bones may be completely consumed, and the thicker compact shaft will exhibit splinters and sharp, pointed ends. According to Shipman (1981a), carnivore tooth marks have a V- to U-shaped cross section. Bones that have been digested are eroded and pitted by stomach acids. They are usually of very small size and will mostly be recovered only by sieving feces or regurgitants.

Fossil bone assemblages raise the question whether the bones have been accumulated by scavengers or by hunters (natural vs. cultural accumulations), especially

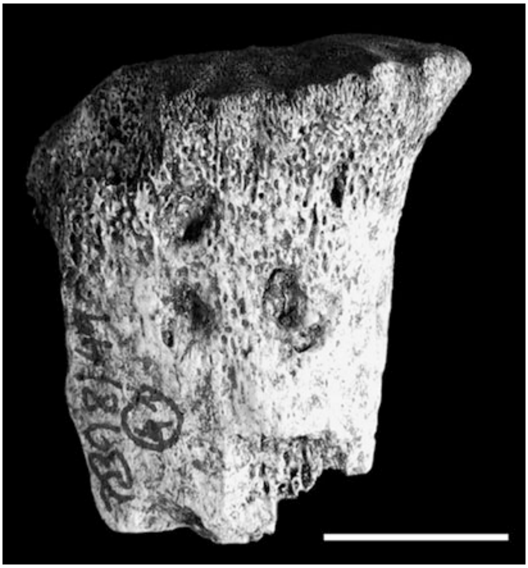

Fig. 2 Bite marks on the epiphyseal end of a tibia from a sheep/goat. Punctures are produced by canine teeth. Bones from juvenile animals like this one are rather soft and easy to chew. Note the additional cut mark at the *right lower end* of this fragment. The bone thus shows features of both butchering and gnawing (Photo: S. Bischler)

in the case of early hominins which are assumed to have practiced a mixed hunting-scavenging subsistence strategy (Shipman 1986). Extensive fieldwork revealed a fairly general consumption sequence of medium- to large-sized carcasses (Blumenschine 1986): Consumers proceed in two cycles from the back to the front of the carcass, consuming first the easily accessible, high-yield nutrients of the flesh and viscera and second the more difficult-to-access bone marrow and brain (Fig. 3). Blumenschine (1986), therefore, postulated a relationship between body part representation and an inverse consumption sequence. Bone assemblages due to hunting consist of more or less complete sets of body parts including those with large, easily accessible, meaty portions, whereas bone accumulations as a result of scavenging should consist of the less valuable parts of a carcass. A reevaluation of the hominin fossils recovered from Sterkfontein Member 4 (Pickering et al. 2004) in fact revealed that the paucity of postcranial remains, and the carnivore tooth marks on the fossils, strongly supports the “carnivore-collecting hypothesis” as the underlying mechanism for the accumulation of fossils at this site (cf. Brain 1981). Forensic studies also confirmed that canid disarticulation of human bodies follows this rather consistent sequence but may cover highly variable time spans. Total disarticulation was achieved between 5 and 52 months, and characteristically, the cranium could always be recovered in contrast to other skeletal elements (Haglund 1997).

Butchering

Butchering marks are cut marks produced by the tools utilized in the process of dismembering or skinning a carcass (Figs. 4a, b). While their cross section may be very similar to carnivore bite marks, they frequently exhibit fine, parallel striations

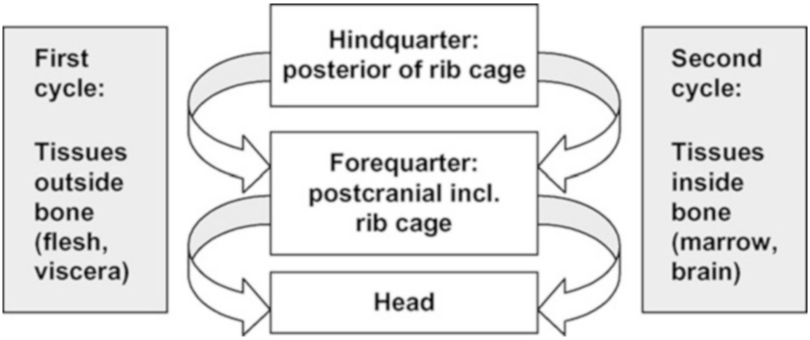

Fig. 3 General consumption sequence of carcasses according to Blumenschine (1986). Deviations from this general pattern are due to carcass size, age of the dead individual, and consumer type

Fig. 4 (**a**) Cut mark on a pig calcaneus (Photo: S. Bischler). (**b**) Damage to a pig tibia due to butchering that permitted access to the bone marrow (Photo: S. Bischler)

(Shipman 1981a, b) and have specific locations on the skeleton. According to Noe-Nygaard (1989), butchering marks reflect the tool type; hence, cut marks can be distinguished from scrape marks, hack marks, saw marks, and blows. Blows, especially, will fracture the bone and serve getting access to the bone marrow.

According to experiments carried out by Walker and Long (1977), cross sections through a cut mark permit the identification of the tool, and the shape and depth of cut marks vary with the applied force.

Other experiments by Bromage and Boyde (1984) open up the possibility of telling the directionality of cut marks on the bone, which would give clues to the handedness of their producers. However, the microstructural properties of the marks are highly dependent on the bone properties (type of bone, bone density, etc.).

Heat Exposure

Excluding natural fires, cremation as a special burial custom, and all cannibalistic scenarios, food processing is the most probable event when a bone is exposed to elevated temperatures for a prolonged time, and this will hold for animal bones in the majority of cases after hominins became capable of controlling fire. As long as a bone has been in direct contact with the heat source, burning and incineration will leave characteristic traces. Even after very short exposure, when charring is still absent, the denatured collagen will produce both longitudinal cracks (similar to those produced by weathering) and also transverse cracks in the bone, which are the result of recoiling of broken collagen fibers that had been previously under tension (Shipman 1981b).

Cremation has been practiced for millennia as a means of disposal of dead bodies (e.g., Bowler et al. 2003; Potter et al. 2011), and fire-exposed bone can also constitute a significant component of zooarchaeological assemblages. Thermally induced bone changes can be used to identify the circumstances and the temperature at which a bone was burned (Lyman 1994). The underlying temperature-induced changes in bone exposed to fire have been extensively studied and reviewed in numerous publications (e.g., Schmidt and Symes 2008; Ubelaker 2009); therefore, only the main changes induced by heat exposure of intact bone will be summarized here (as observed by Harbeck et al. 2011).

Between 100 °C and 300 °C, the bone dehydrates and an initial degradation of the organic matrix is observable. From 300 °C to 600 °C, the combustion of organic material and the loss of carbon in the form of CO_2 take place. As soon as the major proportion of organic material is gone (normally between 500 °C and 600 °C), structural rearrangements of the remaining chemical constituents in the hydroxyapatite structure of the cremated bone set in, and an increase in crystallite size can be observed. Between 600 °C and 800 °C, a sintering process takes place, which is sometimes accompanied by transformation of bone mineral to tricalcium phosphate.

These processes lead to the following macroscopic and histological changes, which permit the identification of a direct contact with a heat source for a particular bone: Bone changes its original color at temperatures ranging between 300 °C and 600 °C in the order of brown to black to gray, resulting from the oxidation of organic carbon. Above 800 °C, the bone shrinks, becomes "calcined," and develops a chalky constituency and white color (more detailed in Walker et al. 2008). Initial alteration of bone microstructure first becomes visible at 200 °C, manifesting itself in the form of small fissures. Above 300 °C, the lamellar structure is accentuated with a brown-black coloration, which vanishes around 500 °C. Microfissures are increasing in number, and at 800 °C and beyond, the original histological appearance entirely disappears (e.g., Hanson and Cain 2007). It should be noted that the quoted temperatures may vary according to the conditions and duration of the heat exposure (e.g., Walker et al. 2008).

The most probable event during which a bone is exposed to elevated temperatures for a prolonged time is food processing. During baking, roasting, or boiling, a bone is normally protected by surrounding flesh and not directly exposed to the fire. Hence, it will not even reach the initial stage of the thermal alteration outlined above. Boiled bones show no observable macro- or micromorphological changes (Munro et al. 2007; Roberts et al. 2002). Heating experiments in which bones were boiled for several hours revealed that protein loss is accompanied by increased crystallinity (Munro et al. 2007, 2008) and porosity (Roberts et al. 2002) – effects that are also caused by diagenetic deterioration.

However, even these changes require boiling times for extensive periods. Conventional boiling times have little or no physicochemical effects (Roberts et al. 2002). Therefore, unlike burnt bone, boiling, roasting, or baking leaves no *obvious* traces. Koon et al. (2010) suggest an inspection by transmission electron microscopy to detect collagen fibril changes caused by low temperatures to distinguish cooked and uncooked bones. Heating experiments with subsequent study of the changes induced by temperatures typical for food processing to date led to opposing results. Boiling whole bovine for several hours revealed that protein loss was accompanied by increased crystallinity and porosity, effects that might cause accelerated diagenetic deterioration (Roberts et al. 2002). Boiling fresh bones by Bosch et al. (2011) in contrast showed that structural changes of collagen should be responsible for the macroscopically evident smoothed surface of boiled bones and that porosities are rather closed, rendering the bone inaccessible to other decomposition factors, thereby reducing diagenesis. Whether the one or the other hypothesis holds true, another bias in terms of the composition of bone assemblages will have to be expected. However, diagenetic processes (see in the following section) may have precisely the same effects.

Postburial Modification Processes of Body Parts

Diagenesis

Diagenetic processes are controlled by the various features of the burial environment, that is, the availability of oxygen and water; temperature and its fluctuations; soil pH; the presence of soil flora, soil fauna, and especially soil microorganisms; and the availability of free ions (Fig. 5). Biodegradation can usually be differentiated from chemical degradation, but both pathways may be intertwined.

Biodegradation

Even after rapid burial, the general decomposition sequence of a dead body is maintained. Microorganisms present in the intestines, and bodily enzymes that

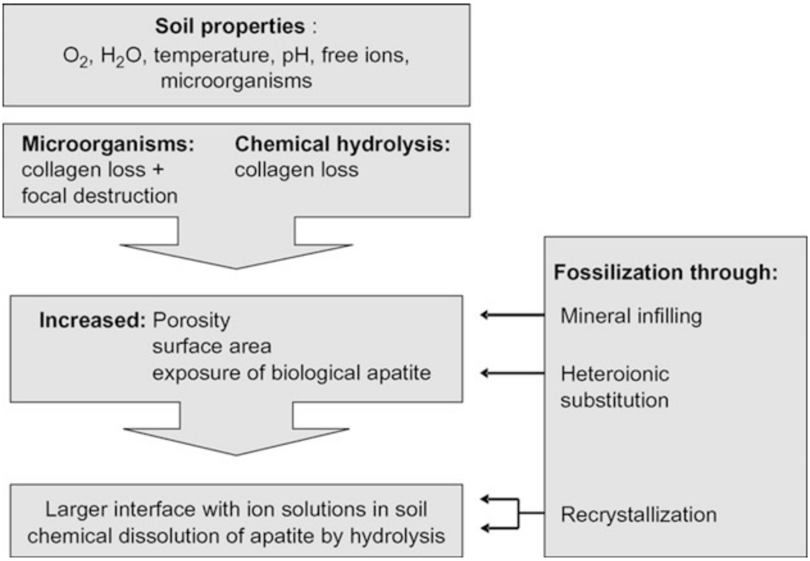

Fig. 5 Main parameters of diagenetic processes and possibilities for fossilization

continue working until the energy storage is exhausted, cause autolysis of the body's soft tissues. Autolysis also initiates putrefaction, a process mainly driven by bacteria. The next steps are liquefaction, disintegration, and finally skeletonization of the body (Dent et al. 2004). Moisture, temperature, and pH are responsible for the abundance of soil microorganisms, which get easy access to a bone by invasion through the natural hollow spaces. Microorganisms consume organic matter to meet their energy demands; therefore, the biological breakdown of a bone's organic constituents is also far from random (Balzer et al. 1997). Primary metabolic products of this organic matter metabolism are CO_2 and H_2O. In addition, many microorganisms are capable of secreting acid metabolites, which will subsequently dissolve the biological apatite, leaving characteristic destructive foci (Fig. 6), which were classified by Hackett (1981) into four different types. The majority of observed destructive foci are so-called linear-longitudinal tunneling and budded tunneling, followed by lamellate tunneling, which seems to be associated with budded tunneling, and fungi-associated Wedl tunneling (Jans et al. 2004). However, the higher resolution of electron microscopy techniques shows that most of these tunnels appearing in light microscopy are actually comprised of numerous smaller pores, often surrounded by a hypermineralized border (e.g., Turner-Walker 2012).

Many bacteria, like those of the genus *Streptomyces*, are capable of selectively cleaving collagen by their collagenases. Consequently, collagen is lost from the bone, leaving a higher porosity of the specimen. Together with the focal destruction, the surface area of the specimen is enlarged (Grupe 2001). Even in the absence of microorganisms, soil pH may lead to a slow loss of collagen from a bone by

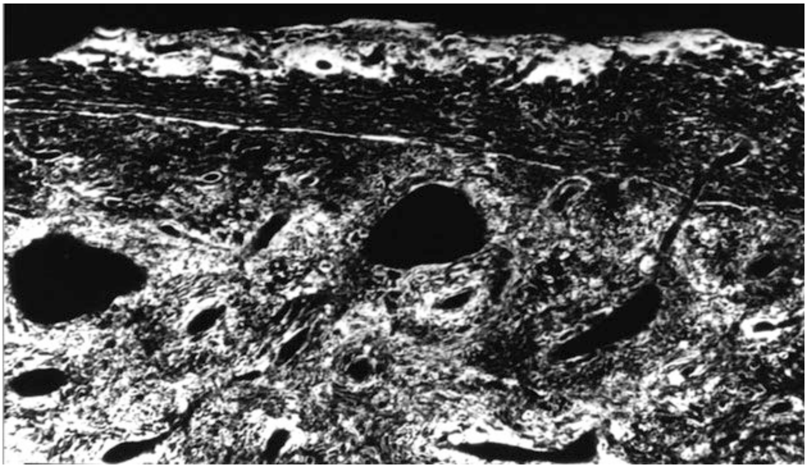

Fig. 6 Microradiograph of medieval human compact bone (Espenfeld, Thuringia), showing intensive focal destruction after microbial invasion

chemical hydrolysis (Fig. 7). Mineral infilling of the diagenetic porosities is considered a key mechanism leading to bone fossilization (Collins et al. 2002).

In general, it is plausible that microbial invasion of a buried bone plays a key role in bone decomposition, since prolonged microbial attack will prevent fossilization and accelerate breakdown. Since microbial activity is temperature and moisture dependent, warm and wet climates are less suitable for bone preservation. Exposure to excess humidity on the other hand will reduce the necessary oxygen supply, and microbial activity is suppressed. Microbiological diagenesis is also reduced in cold climates (Grupe 2001).

Mineral Changes

Normally, bone mineral is protected by its intimate association with collagen. Losing this association, it is vulnerable to dissolution and loss.

The enlarged surface area is an important factor in decomposition rates, since the exchange of matter (minerals and ions) between bone and the surrounding soil is facilitated. Exposed bone mineral may be subject to heteroionic substitution, supporting fossilization. Several elements are prone to be taken up by the bone, especially F, U, and rare earth elements (REE), whereby the latter serve as indicators for considerable diagenesis (Metzger et al. 2004) (see chapter "▶ Paleosols," Vol. 1). More frequent, however, is the chemical dissolution of the apatite by hydrolysis, depending on the soil pH. This will result in free ions, mainly calcium and phosphate ions, which will either be leached from the bone by soil moisture and precipitation or be recrystallized as soon as a critical ion density is reached. This recrystallization and/or the preferential loss of smaller crystallites in the course of mineral dissolution leads to an increase of the bone's crystallinity, a most fundamental aspect of bone diagenesis. Newly formed crystals are generally more soluble

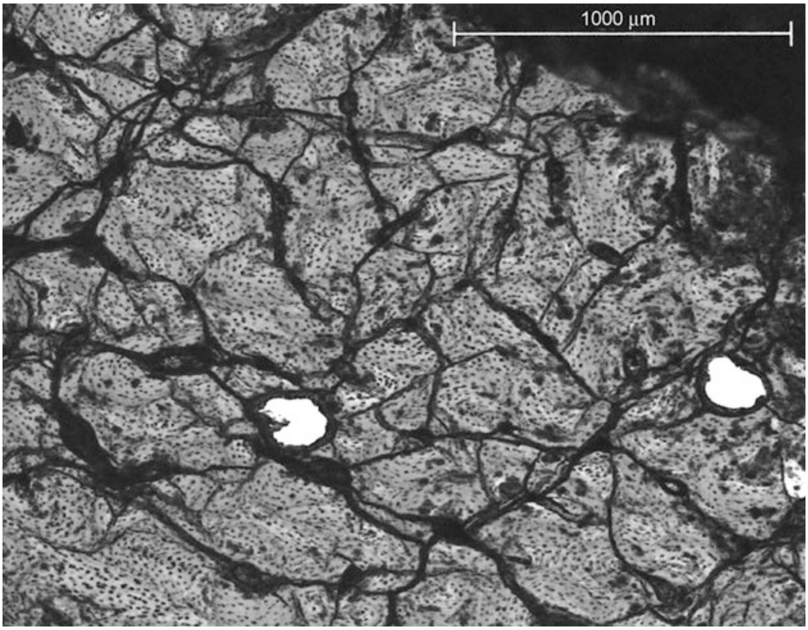

Fig. 7 Subfossil human bone (Göbekli Tepe, Anatolia, 9,500–8,500 cal BC). While the microstructure is well preserved with the exception of several microfissures, this specimen did not show any birefringence under polarized light. No collagen was retrievable from this specimen (Photo: S. Dummler)

than the original bone mineral, and disintegration proceeds. This holds, for instance, for the transformation of the original bone mineral, a calcium-deficient hydroxyapatite [$Ca_5(PO_4)_3(OH)$] into brushite [$CaHPO_4 \cdot 2H_2O$] as described by Herrmann and Newesely (1982). However, recrystallization may also lead to more stable mineral configurations and is therefore a means of fossilization: As soon as bone mineral is no longer subject of *in vivo* conditions, its crystallites recrystallize spontaneously into larger crystals (Berna et al. 2004), thereby decreasing its solubility. They nevertheless maintain a rather large surface which exhibits a considerable cation exchange capacity once exposed. As the organic components of bone (mainly collagen) are subsequently lost in the course of diagenesis, the thus generated intracrystalline porosity may be closed by the growing apatite crystals, which reduces the surface area available for ionic exchange. In a fully recrystallized bone, a minimum of 25 % of its volume must have been filled with exogenous, secondary minerals (Trueman et al. 2008). Together with other substitutions, such as F^- ions substituting type A carbonates at the OH^- position, such recrystallization may reduce the mineral solubility and enhance the chances for fossilization. According to Trueman et al. (2008), organic loss is the rate-limiting step, since the related exposure of crystals permits for the adsorption of exogenous ions with subsequent recrystallization. By an experimental study, Berna et al. (2004)

determined a quite narrow, alkaline pH range between 7.6 and 8.1 (the so-called recrystallization window), where the original bone crystals dissolve and recrystallize into another form of carbonated hydroxyapatite. As a consequence, and as a rule of the thumb, a bone will remain well preserved in sediments with a higher pH than 8.1, well preserved but with recrystallization in alkaline to neutral conditions, and will be totally replaced by authigenic apatite at pH values below 7.5. This, however, does no longer hold when recrystallization happens under inclusion of exogenous ions and formation of more stable phases (Berna et al. 2004). Diagenetic changes of the bone mineral phase are usually assessed by X-ray diffraction (measurement of the crystallinity index) or Fourier transform infrared spectrometry (measurement of the splitting factor).

In sum, the many parameters which characterize the burial conditions of vertebrate hard tissues and their change over time are responsible for the state of preservation at the time of excavation. In general, time elapsed after burial is a less crucial factor than the sediment conditions, whereby even small changes of some parameters such as pH may have considerable impacts.

Preservation of Biomolecules

In the course of the past few years, technological improvements led to a massive increase of ancient biomolecule research, especially in the field of DNA (e.g., Hofreiter et al. 2012).

It is, for instance, now possible to retrieve nearly complete genomes from more than 30,000-year-old Neanderthal bones (Green et al. 2010). This ancient DNA is highly diagenetically altered and persists only in low quantity in the form of highly fragmented molecules with chemically modified bases that may change the original sequence (see chapter "▶ Ancient DNA," Vol. 1).

For this reason and due to the high risk of contamination with modern DNA, the field of ancient DNA research has seen a lot of controversy as to which data sets can be considered as authentic and which not (e.g., review in Gilbert et al. 2005). Especially reports of DNA preservation in million-year-old fossils were mostly not confirmed (review in Willerslev and Cooper 2005).

There are several factors that influence DNA long-term survival. Besides the early postmortem enzymatic breakdown of DNA, the most common causes of damage are hydrolysis and oxidation. These processes depend on the presence of free water and oxygen, and their rate is increasing with increasing environmental temperature. Therefore, the best preserved DNA is usually found in cold environments. The oldest ancient DNA fragments recovered so far originate from 450,000- to 800,000-year-old Greenlandic ice cores (Willerslev et al. 2007). Because the burial conditions of these samples should have been close to being optimal, they represent the currently accepted limit of DNA survival. Allentoft et al. (2012) calculated a DNA decay rate using radiocarbon ages and measures of DNA integrity of moa bones. For room temperature, they estimated the half-life of DNA to be 521 years, while a short fragment of DNA (30 base pairs in the bone) will have a half-life of 158,000 years at −5 °C. This implies that DNA fragments in the bone may still be preserved in samples deposited in deeply frozen environments more than one million years ago. However, the study also shows that it is extremely unlikely to successfully sequence DNA fragments from millions of years old fossils, like dinosaur bones. Currently the oldest mammalian DNA sequenced so far comes from a jawbone of a polar bear buried in permafrost soil and dated around 120,000 years (Lindqvist et al. 2010).

There is also an ongoing discussion regarding the possibility of long-term survival of proteins in fossils, which reminds on the early days of ancient DNA research. In 2007, Asara et al. (2007) reported the detection of collagen peptides in a 68-million-year-old *Tyrannosaurus rex* bone by shotgun proteomics, and Schweitzer et al. (2009) have recovered protein sequences in an 80-million-year-old hadrosaur fossil. However, the discovery of intact protein in such an ancient sample has been called into question (e.g., Buckley et al. 2008; Pevzner et al. 2008).

In environments protected from microbial attack, chemical degradation plays the major role in collagen deterioration. Here, the primary process is the hydrolysis of peptide bonds which leads to the formation of protein fragments. But the rate of collagen degradation in the bone is slow because of its intimate association with the bone apatite. This association stabilizes the collagen fibrils, which is also evidenced when heated: Unmineralized collagen will melt at a temperature of about 68 °C, while mineralized collagen will not change until 150 °C is reached (Nielsen-Marsh and Hedges 2000). Therefore, in the absence of enzymatic degradation, collagen may persist in bones for many thousands of years particularly in cold environments. However, by all means collagen will undergo slow chemical hydrolysis which can be accelerated by increasing temperatures. Experimental diagenesis suggests a maximal collagen survival at 10 °C between two and seven million years (Buckley and Collins 2011). Long-term survival for longer time periods would require an as yet unknown alternate mechanism of preservation (Hofreiter et al. 2012).

When microbial activity and mineral dissolution are involved, the collagen molecule will degrade much faster. In this case the amino acid profile of collagen can be considerably altered, since microorganisms preferably tend to metabolize amino acids with a higher number of carbon atoms as a source of energy (Grupe 2001). This may also lead to shifts of carbon and nitrogen stable isotope values, which are commonly used for the reconstruction of dietary patterns of ancient populations (for a recent review see, e.g., Schwarcz and Schoeninger 2011). In order to assess potential diagenetic alterations or collagen contaminations, several criteria such as the molar C/N ratio are usually applied.

As the study of ancient biomolecules is both time-consuming and cost intensive, an expedient preselection of samples containing well-preserved target biomolecules would be useful as a screening tool in the situation when a large number of specimens are available and need to be assessed. Many studies, therefore, attempt to define easily obtainable predicators for molecular preservation like microstructural preservation or UV autofluorescence of the bone (e.g., Hoke et al. 2011). Numerous methods, such as collagen content measurement, crystallinity index analyses, and thermal age calculation (e.g., Götherström et al. 2002), have been suggested as marker for DNA survival. Particularly the extent of racemization of aspartic acid has widely been used for an assessment of DNA degradation (based on Poinar et al. 1996). Recently, the correlation between this measure and DNA preservation has been reassessed in some studies (Collins et al. 2009; Fernández et al. 2009), all concluding that the racemization of aspartic acid cannot be seen as an efficient marker for DNA preservation. Such disagreements are evident for nearly all proposed diagenesis marker showing that the underlying mechanism of degradation and the relationship between DNA, collagen, and hydroxyapatite are complex and need further clarification (see also Campos et al. 2012).

Conclusion

As time progresses, the conditions of a burial environment may change considerably. Therefore, any excavated bone specimen exhibits a certain status quo of its diagenetic history, which is hard to unravel in detail. Considering the gross diagenetic processes, it is obvious that certain environments are more suitable for preservation (anoxia, dryness, cold temperatures), while others enhance decomposition. It is a common experience that rather young archaeological bones may be much less well preserved than older ones. First, the simple explanation holds that a well-preserved or even fossil specimen must have been buried in a preserving environment. Second, diagenesis should also be considered a self-limiting process in many cases, especially when the burial environments are favorable for mineral infillings, recrystallization, and ionic replacement. The majority of recovered specimens will have undergone diagenesis to a certain degree.

Contribution of Stable Light Isotopes to Paleoenvironmental Reconstruction

Julia Lee-Thorp and Matt Sponheimer

Contents

Abstract

In this chapter, we focus our attention on the potential links between hominin evolution and environmental change in Africa as revealed by stable light isotope evidence. We begin with an exploration of some of the gaps to which isotope approaches may be applied to good effect and follow with an overview of the principles and the materials typically available for analysis. The results for carbon isotope ratios of pedogenic carbonates and faunal enamel have now pushed back the emergence of C_4 grasses, and thus more open environments, to ca. 9 Ma. These data also show that in spite of a trend toward more open

grassy environments observed from the Pleistocene and Pliocene records, consideration of the Late Miocene and Early Pliocene sequences as well suggests that proportions of grassy and forest habitats fluctuated on very broad timescales. New high-resolution biomarker records from Olduvai, and a single speleothem record from South Africa, show that, within the broader framework, shifts also occurred on shorter, orbitally controlled timescales. Faunal data indicate that herbivore families adapted to emerging C_4 resources at very different rates, with hominins showing signs of engaging with C_4 biomass only after 4 Ma. Aridity indicators reflect generally dry and warm conditions in East Africa, but the relationship between humidity and aridity on the one hand, and forest or open grassy cover on the other, varies for different environments. All lines of isotopic evidence from East and South Africa suggest a significant change to more open, grassy ecosystems ca. 1.8 Ma, broadly concordant with the emergence of *Homo ergaster*.

Introduction

It is widely accepted that understanding the environments that hominins inhabited provides essential contextual information to help us comprehend evolutionary trends. Most obviously, we need the environmental context to tell us about the kinds of opportunities available for the basics of life – food, water, and shelter – and the biological and the technological means to obtain these things. Next, we should consider how environmental and climate shifts have influenced the course of hominin evolution and that of other coeval fauna. Here, paleoenvironmental studies must take a broader, more long-term view. Large-scale, global climate shifts are often invoked as major influences acting on evolutionary pathways (e.g., deMenocal 2004, 2011), but in practice demonstrating the linkages is not straightforward (Feibel 1997). Firstly, climate is one of a number of forces acting on topographically complex landscapes and their floral and faunal communities. Further, climate and environmental evidence on land is patchy in time and space, so that what we observe are but short glimpses. This problem is exacerbated by the difficulties of establishing chronology with confidence.

One of the ways to address this problem is to take a much broader perspective that can discern patterns and hopefully process, from local noise. At the same time it's worth bearing in mind that behavioral (and biological) responses of hominins occur at the local level, which is the most important for understanding the lives of individuals. In other words, scale is important, both geographically and temporally. In this chapter we focus our attention on paleoenvironments of Africa, for the obvious reason that much of early hominin evolution occurred in this vast continent.

Standard investigative tools for reconstructing paleoenvironments at the site level rely strongly on geological context, faunal abundances, and, where possible, floral indicators such as fossil wood or pollen, as indicated elsewhere in this volume. All of these approaches naturally have their own advantages and constraints. For instance, although vertebrate faunal abundances provide essential indications about local faunal composition, the material is strongly filtered by the accumulating agents and by preservation. Additionally, interpretation of habitat preferences is hindered by poor knowledge of the ecology of extinct animals, for which there are often no modern analogues. In fact, we very often do not understand enough about the habitat requirements of modern congeners where they exist (see Cerling et al. 2003; Sponheimer et al. 2003). Here, stable isotope approaches can contribute complementary evidence that allows more precise identification of faunal dietary and hence habitat preferences.

There are greater challenges in placing these site- or regional-based occurrences into the context of climate and environmental evolution over the period of interest to students of human evolution, from the Upper Miocene onward. The evolution of global climate over this period and its pace and rhythms are largely understood from marine sediment cores. Ice-core records have revolutionized our understanding of the scale and rapidity of atmospheric and temperature shifts, but most reflect high-latitude conditions in the Late Pleistocene, with the exception of the 750 Ka EPICA core. How do spatially heterogeneous African environments reflect these global shifts reflected in marine sediments and ice cores, and how do we connect them?

Some marine sediment records near continental margins, fortunately, contain material derived from the adjacent continent, which provide direct, sequential information about continental conditions. The highly variable quantities of windblown Saharan dust in cores off Northwest Africa reflect a multiple alternating sequences of hyper-arid and humid conditions in the Sahara from the Miocene onward (deMenocal 2004, 2011). The most recent moist episode, the “African Humid Period” (AHP), is now constrained to between 11.8 and 4.9 Ka right across the Sahara and eastern Africa (McGee et al. 2013). The pace and intensity of shifts has been established from a series of well-dated, continuous marine records; the results point to strong orbital, particularly precessional, control over the intensification of monsoons that bring moisture to West, Central, and East Africa. Similarly, windblown pollen in marine cores off tropical West Africa provide the clearest view of the pattern of contraction and expansion of West African equatorial forests in the Pleistocene (e.g., DuPont 1999).

According to known site distributions, there are fewer well-dated continuous continental records in areas where hominins lived. Here the East African lake systems are exceptional, with sedimentary records for lake levels and lake conditions. The presence or absence of East African lakes is, however, influenced by tectonic activity in addition to rainfall shifts (e.g., Bergner et al. 2009; Trauth et al. 2009), leaving frequent long absences of any information. In spite of the discontinuities, opportunities exist. For instance, precise Ar/Ar dating of exposed diatomite beds has pointed to precessional control of extinct lakes in the Late Pliocene in Kenya (Kingston et al. 2007). The extensively studied sedimentary and lake system sequences associated with Olduvai Gorge ca. 1.8 Ma show strong environmental shifts on millennial scales (e.g., Ashley 2007). More universal information about the evolution of the terrestrial environments closely tied to hominin sites emerges from faunal abundance data (e.g., Vrba 1985, 1988; Behrensmeyer et al. 1997; Reed 1997; Bobe and Eck 2001). Vrba's "turnover-pulse" hypothesis postulating a direct link between evolutionary trends in bovids and climate shifts ca. 2.4–2.6 Ma (Vrba 1985) was based on bovid abundances, as were studies that challenged it (Behrensmeyer et al. 1997; Bobe and Eck 2001). In special circumstances pollen profiles are well preserved enough to provide detailed floral sequences (e.g., Bonnefille et al. 2004).

Stable light isotope-based methods can help to address some of the gaps. Biogeochemical tools have several advantages: they are versatile and can be used to study many different archives, and they produce qualitative and quantitative data. Stable light isotope applications to paleoenvironments in general have been extensively reviewed in the literature, and the field is broad (for a global review see Koch 1998). Our intention here is to restrict discussion to some key examples that we believe have made, or look set to make, substantive contributions to understanding the environmental context of hominin evolution. They reside principally in the area of shifts in floral composition, particularly in the relative abundance of C_4 grasses in the flora and implications for open or closed habitats and the important climate features of humidity or aridity. Since the last edition of this handbook series, significant advances have been made in documenting these features at different scales. We concentrate on examples reliant on materials from hominin or paleontological sites or from sequences that are closely associated in space and time.

Isotopic Environmental Indicators

This section provides a brief overview of the main isotopic environmental indicators and the sample materials that are used to provide indications of prevailing conditions. We limit discussion to the principles as they apply to each potential archive.

Basis of Stable Isotope Tools

The stable light isotopes of principle interest as environmental proxies are the isotopes of hydrogen, carbon, nitrogen, and oxygen. In all cases, the chemistry of the different isotopes of an element remains the same as chemical properties are controlled by electron configuration. But among the light isotopes, the mass difference owing to one or two extra neutrons is sufficient to cause small but predictable differences in the rates of physicochemical reactions, resulting in partitioning of isotopes. If the starting materials and the products of a reaction are partitioned, or facilitating enzymes are sensitive to mass, isotopic fractionation occurs.

Hydrogen **(D/H) and** ***Oxygen*** **($^{18}O/^{16}O$) Isotope Effects**

Fractionation of *hydrogen* (D/H) and *oxygen* ($^{18}O/^{16}O$) isotopes[1] in nature follows similar patterns because the isotope effects are dominated by the processes undergone by water – evaporation, condensation, and freezing. The magnitude of fractionation in precipitation is controlled largely by temperature for both isotopes, but isotope effects are greater for hydrogen because of the larger mass difference between deuterium (D or ^{2}H) and hydrogen (^{1}H), compared to oxygen (^{18}O and ^{16}O). Water vapor evaporates mostly from low to midlatitude ocean surfaces, and sea surface temperature of the oceanic source influences isotopic ratios of moisture-laden weather systems (Dansgaard 1964). The subsequent transport of the weather systems across the continent induces further (negative) fractionation related to the distance traveled, mountains crossed, and height and temperature of rain clouds (Dansgaard 1964; Rozanski et al. 1993). Evaporation has the opposite effect, leading to enrichment in the heavier isotopes. It is an important process in arid environments where water deficits are high. Soil- and groundwater isotope values reflect this history, as do those of carbonates precipitated from these waters, with the additional influence of temperature, since fractionation during carbonate precipitation is temperature dependent (Craig 1953). In plants, evapotranspiration leads to isotopic enrichment, which is enhanced under hot, dry, low relative humidity conditions, and is passed on to oxygen and hydrogen bound in plant sugars (Yakir 1992).

Carbon **($^{13}C/^{12}C$) Isotope Effects**

Carbon ($^{13}C/^{12}C$) isotope fractionation provides fundamental information about pathways in the terrestrial carbon cycle. Of most interest to African ecosystems is the isotopic distinction between plants following the C_3 and C_4 photosynthesis pathways. The RuBisCO (ribulose bisphosphate carboxylase oxygenase) enzyme involved in catalyzing the conversion of CO_2 to plant sugars discriminates strongly against $^{13}CO_2$. This results in low $\delta^{13}C$ values in plants using the ancient C_3 (or Calvin-Benson) pathway alone (Farquhar et al. 1989). Some families and genera have evolved a mechanism to first concentrate and fix CO_2 by means of another enzyme, PEPCase (phosphoenolpyruvate carboxylase), before it enters the RuBisCO cycle, so the isotope effect of this enzyme is weakly expressed (Sage 2004). As a result the $\delta^{13}C$ values of C_3 and C_4 plants are distinct (Smith and Epstein 1971). Almost all trees, shrubs and herbs, and temperate or shade-adapted grasses follow the C_3 pathway, while C_4 photosynthesis is common among grasses and sedge families in warm, often dry, environments with strong solar radiation in the growing season. C_4 plants exhibit a relatively narrow $\delta^{13}C$ range (from about -9 ‰ to -14 ‰, global mean of ca. -12 ‰), whereas C_3 plants are sensitive

---

[1] Isotope ratios are by convention expressed in the δ notation, in parts per thousand (‰) relative to a standard: δX (‰) $= (R_{sample}\text{-}R_{ref})/R_{ref} \times 1000$, where $R =$ isotopic ratio. V-SMOW (Standard Mean Ocean Water) is used as the reference for D/H and $^{18}O/^{16}O$ in water, V-PDB (Peedee Belemnite) for $^{18}O/^{16}O$ and $^{13}C/^{12}C$ in carbonates and organic materials, and atmospheric N_2 (AIR) for $^{15}N/^{14}N$.

to environmental influences and show broader ranges (from about −22 ‰ to −38 ‰ at the extremes, with a global mean ca. −26 ‰) (Smith and Epstein 1971). A third photosynthetic pathway, crassulacean acid metabolism (CAM), fixes CO_2 by night and utilizes RuBisCO by day, so that $\delta^{13}C$ values can vary considerably. However, these plants are primarily succulents that are sparsely used by most mammals and are not considered important components of environments inhabited by hominins (Peters and Vogel 2005).

The carbon isotopes in plants are ultimately incorporated into the tissues of animals that consume them so that, for instance, grazers are isotopically enriched in ^{13}C compared to browsers, or frugivores. These distinctions are passed in turn to higher trophic level consumers. All tissues reflect the source of carbon but the diet to tissue offset (expressed as $\varepsilon_{d\text{-}t}$) differs among them (e.g., hair, liver, bone collagen, muscle).

Nitrogen ($^{15}N/^{14}N$) Isotope Effects

Nitrogen ($^{15}N/^{14}N$) isotope ratios reflect the pathways of the nitrogen cycle in soils, plants, and animals. Nitrogen enters the terrestrial food web via N_2-fixing bacteria in soils or plants, to form nitrates or ammonium ions that are utilized by plants. The net effect of the biological fixing of nitrogen into nitrates or ammonium ions utilized by plants, and subsequent loss from soils, is a slight enrichment in ^{15}N. The balance is strongly influenced and affected by local environmental conditions (Heaton 1987). A negative correlation between moisture availability and both leaf and soil $\delta^{15}N$ has been observed (Handley et al. 1999), but subsequent studies suggested instead that other factors such as plant taxonomy are more influential (Craine et al. 2009; Codron et al. 2013). Stepwise trophic enrichment about 2–6 ‰ occurs in animals.

Sample Materials

The sample materials most often analyzed for isotopes to infer environmental conditions consist largely of sediments or carbonates in close chronostratigraphic association with sites, and fossil bones and teeth within them.

Sediments

A history of overlying vegetation may be preserved for long periods in remnant organic compounds and pedogenic carbonates in paleosols (see Quade and Levin 2013 for a review). Carbon isotopes in the organic and inorganic components of soils systematically reflect differences between overlying vegetation following the C_3 and C_4 pathways, allowing calculation of the relative mix of woody and grassy plants on the landscape. $\delta^{13}C$ of paleosol organic matter, where preserved, is a reasonably direct reflection of the mean isotopic composition of the vegetation, with a slight enrichment in ^{13}C due to decomposition. Pedogenic carbonates form about 0.5–1 m below the active soil horizon from soil-respired CO_2 (Cerling and Quade 1993). The net enrichment (ε) in ^{13}C of 14–17 ‰ is made up of the combined effects of diffusion of plant-respired soil CO_2 (4.4–5 ‰) and equilibrium isotope effects associated with carbonate precipitation (9.5–12.5 ‰) (Cerling and Quade 1993). Pedogenic carbonate nodules are not formed in all soils; formation occurs in semiarid to arid conditions where mean annual rainfall is less than ~1,000 mm/a. Applying the diffusion model requires identification of "true" pedogenic nodules formed where diffusion enrichment is complete, that isotopic equilibrium can be confidently assumed, and that plant-derived CO_2 dominates rather than atmospheric CO_2 (Quade and Levin 2013).

While pedogenic carbonate isotope analyses have long dominated the sediment literature, leaf and algal wax biomarkers preserved in ancient marine and lacustrine sediments have emerged as an important new source for establishing plant composition and moisture regimes, based on carbon and hydrogen isotopes (Diefendorf et al. 2010; Feakins and Sessions 2010; Magill et al. 2013a, b). They have decided advantages – preservation in incremental sediments so that the sequence of shifts is preserved in situ – and fewer diagenetic effects than most other sources (Diefendorf et al. 2010). $\delta^{13}C$ values of the nC_{31} leaf-derived wax biomarker reflect dominant photosynthetic pathway of terrestrial plants, while heptacosane (nC_{17}) is derived from lake algae (Diefendorf et al. 2010; Magill et al. 2013a). Their hydrogen isotope ratios (δD) likewise express water sources and effects in soils, while algal values reflect more directly water balances within the lake system.

Cave Speleothems

Cave flowstones and stalagmites are composed of calcium carbonate formed from CO_2-rich seepage water degassing and precipitating in cave systems. Precipitation of carbonates is governed by temperature-sensitive equilibrium reactions, so speleothem $\delta^{13}C$ and $\delta^{18}O$ values reflect the proportions of C_3 and C_4 plants in overlying vegetation, isotopic composition of the water, and the temperature of cave carbonate formation, in a manner similar to pedogenic carbonates (Fairchild et al. 2006). Speleothems have advantages as they form in a protected environment, and they can be precisely dated using thorium-uranium or, more relevant for Pliocene and Pleistocene material, uranium-lead disequilibrium methods (Woodhead and Pickering 2012). Speleothems can yield near-continuous, high-resolution records of a quality unlike any of the other proxies discussed here, but their distribution is restricted to karstic landscapes and older records are unfortunately very rare.

Biominerals

Biominerals (bones, tooth enamel, and ostrich eggshell) preserve isotopic information about many of the processes and conditions to which an animal was subjected when it was alive, and they are abundant in most paleontological and archaeological sites.

Bones consist of an organic component made up mostly of a fibrous polypeptide, collagen (ca. 25 % by weight), while the embedded mineral makes up ca. 70 %. Collagen can be readily purified and analyzed for $\delta^{13}C$ and $\delta^{15}N$, but it decomposes rapidly (within millennia) in warm African environments. Bioapatites, the mineral phase, are weakly crystalline calcium phosphates with multiple substitutions that increase reactivity and solubility. The exception is fluoride, which has the opposite effect (LeGeros 1991). In vivo and *postmortem* substitutions affect the preservation of original isotopic composition in fossils. Enamel is far more stable than bone (Lee-Thorp and van der Merwe 1987), and consequently most isotope studies of fossils have relied on enamel as sample material. The component ions of interest are phosphate (PO_4^{3-}) and carbonate (CO_3^{2-}), with the latter occurring as a substitution in small amounts (3–6 %). Therefore, the isotopes available for study in this system are carbon and oxygen isotopes, the latter extracted from either PO_4^{3-} or CO_3^{2-}.

Biophosphate $\delta^{18}O$ was developed first as a paleotemperature tool, based on the rationale that body water $\delta^{18}O$ ($\delta^{18}O_{bw}$) reflects environmental or drinking water ($\delta^{18}O_w$), which can in turn be correlated with latitude and/or temperature effects on rainfall (Longinelli 1984; Luz and Kolodny 1985). In low- to midlatitudes, the effects of source, storm tracks, amount, and evaporation dominate as influences on precipitation and environmental water $\delta^{18}O$. Animals, however, also derive significant amounts of water and oxygen from their food (Kohn et al. 1996; Bocherens et al. 1996; Sponheimer and Lee-Thorp 2001), and we now know that thermophysiology, and drinking and feeding behavior, modulate the manner in which these environmental signals are reflected in bioapatites. For instance, obligate drinkers such as equids better reflect freshwater $\delta^{18}O_w$ values than do non-obligate drinkers such as giraffids that use a good deal of leafwater. The $\delta^{18}O_{phosphate}$ or $\delta^{18}O_{carb}$ of non-obligate drinkers is useful for exploring behavior in extinct forms. Additionally the isotopic difference between non-obligate and obligate drinkers, expressed as ES (evaporation sensitive) and EI (evaporation insensitive) versus local water deficit values, is exploited to develop an isotopic aridity (Levin et al. 2006).

Stable carbon isotope ($\delta^{13}C$) analysis of herbivore tooth enamel indicates the relative amounts of C_3 plants and C_4 grasses consumed. The framework for calculations of the proportions is based on our understanding of typical plant values today, the manner in which these are affected by climate variables, and the difference between diet and enamel values ($\varepsilon_{diet\text{-}en}$). There is some blurring here. Fractionation in C_3 (but not in C_4) plants is sensitive to climate conditions. C_3 plants are enriched in ^{13}C under hot, dry conditions and markedly depleted in ^{13}C in closed-canopy forests with low light intensity (Farquhar et al. 1989). Furthermore, $\varepsilon_{diet\text{-}en}$ is not *precisely* established and likely differs slightly for families; some observe +12 ‰ across many wild species (Lee-Thorp and van der Merwe 1987), while others have observed up to +14 ‰ in equids (Cerling and Harris 1999).

Still, this does not obscure the large $\delta^{13}C$ distinction between browsing and grazing forms and between occupation of open and forest-canopy habitats. Unlike pedogenic or cave carbonates, $\delta^{13}C$ values for fauna on their own do not represent the mix of plant types in a landscape, but rather what those particular taxa preferred. This is useful, for instance, in comparing the evolution of grazing across families, but in order to determine the proportions of plant functional groups in the environment (i.e., deduce the closed or open nature of prevailing vegetation), the data must be further reduced.

Ratite eggshell is a tough, mostly calcium carbonate structure which survives well for long periods (Ségalen et al. 2006). The carbon and oxygen isotopic composition follows similar "rules" to enamel, as it reflects carbon dietary sources in $\delta^{13}C$ and body water isotope composition in $\delta^{18}O$. Ostriches have an extremely low requirement for freshwater, while their eggshell reflects a narrow window of time reflected in the breeding season. Thus, ostrich/ratite eggshell $\delta^{18}O$ is a good aridity indicator, but the windows are narrow.

The following sections describe applications of isotopic approaches to paleoenvironmental issues of relevance in hominin evolution.

Emergence of C_4 Grasses

One important application of carbon isotopes has been to document the global expansion of C_4 grass systems from ca. 8 to 6 million years ago (Cerling et al. 1997). This ultimately revolutionized floral communities in tropical and subtropical regions across the globe, resulting in more open environments in many regions. The drivers of the shift are still unclear but global climate shifts must be implicated (Jacobs et al. 1999; Sage 2004). Given the profound nature of changes to African environments, and the timing of C_4 emergence and establishment prior to the probable age of the Last Common Ancestor (LCA), the importance of this floral shift to the hominin lineage has long been debated. The shift was first detected in pedogenic carbonate nodule isotope ratios from East Africa and Pakistan (Cerling et al. 1988; Cerling 1992; Quade et al. 1989), which showed a large-scale shift from C_3- to C_4-dominated systems around 7–8 Ma. Data from the Turkana Basin suggested the appearance of C_4 grasses about 7–8 Ma (Cerling et al. 1988), a pattern of first appearance apparently mirrored in $\delta^{13}C$ of fossil fauna in Africa, North and South America, and Pakistan (Cerling et al. 1997). Some authors have suggested an earlier first appearance prior to 12 Ma, based on carbonate nodules and fossil isotope values from the Tugen Hills (Kingston et al. 1994; Morgan et al. 1994), but these data are few and have not been replicated.

No older pedogenic carbonates have been found in the well-dated formations in the Samburu Hills and Lothagam in Kenya, but new enamel $\delta^{13}C$ data demonstrates that C_4 grasses emerged in this region at 9 Ma (Uno et al. 2011). The data prior to 9 Ma reflect only C_3 diets for all families, an observation consistent with $\delta^{13}C$ data for windblown terrestrial plant biomarkers in marine cores off NE Africa (Feakins et al. 2005). These data indicate only C_3 terrestrial plant waxes until 9.2 Ma, but a discontinuity immediately afterward prevents observation of a subsequent shift (Feakins et al. 2005).

One further notable observation from the Turkana fossil faunal data is that families clearly responded to the new resource at different rates (Fig. 1). While almost all families suggest responses at ca. 9 Ma, most are muted and variable, Equidae show a clear and immediate response, with $\delta^{13}C$ values rapidly reaching 0 ‰ by ca. 9 Ma (Uno et al. 2011). Gomphotheriidae, Rhinocerotidae, Hippopotamidae, and Bovidae show highly variable and less marked shifts, while

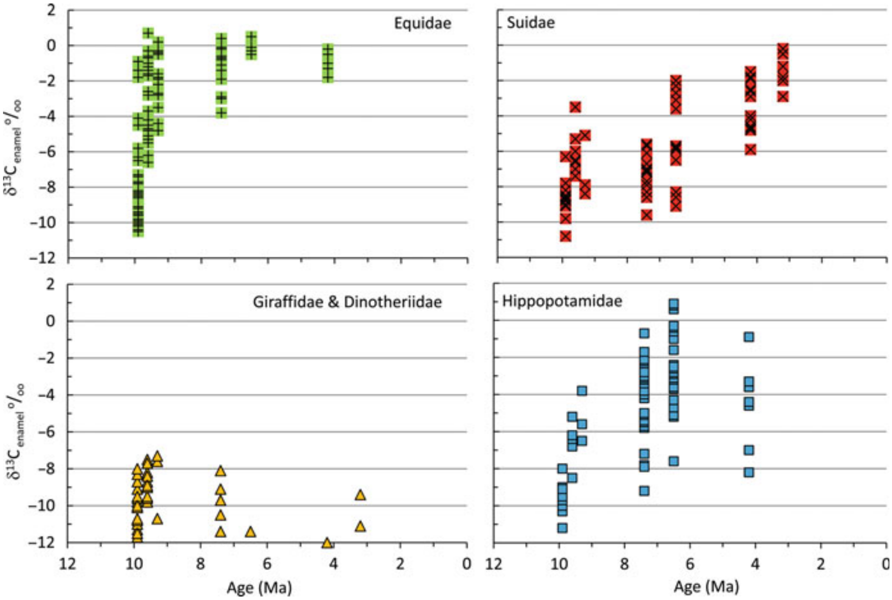

Fig. 1 The carbon isotope data for four families in the Lothagam/Samuru Hills/Nakali sequence, Kenya, are plotted against age in millions of years (Ma). The Equidae clearly show an immediate and rapid response to the new grass just prior to 9 Ma. Giraffidae and Deinotheriidae are plotted to show their relative invariance. Suidae and Hippopotamidae seemed to have responded slightly differently; in both cases earlier data are highly variable, but by 4 Ma and certainly before 3 Ma, the Suidae had adapted completely, while Hippopotamidae remain generalists. The data are from Uno et al. (2011). No attempt has been made to correct the $\delta^{13}C$ data according to palaeo-CO_2 values, as they did

Suidae show less enthusiasm for C_4 plants until much later – values shift modestly in the 6.5 Ma Upper Nawata Beds, and high $\delta^{13}C$ values emerge only in the Apak Beds (ca. 4.2 Ma). Deinotheriidae and Giraffidae remain dedicated C_3 feeders as also noted elsewhere (e.g., Cerling et al. 1997; Roche et al. 2013).

The age at which C_4 vegetation first appeared in southern Africa is unclear, as there are few Upper Miocene sites. Cerling et al. (1997) suggested an extension model in which first appearance of C_4 photosynthesis in low-latitude equatorial regions spreads subsequently to the midlatitudes. The present modest evidence seems consistent with this hypothesis. Ratite eggshell data document the emergence of C_4 and differentiation of the $\delta^{13}C$ records between the southern and northern Namib about 5–6 Ma, based on biostratigraphy (Ségalen et al. 2006). A large undated, collapsed cone speleothem in the Makapansgat Limeworks in South Africa indicates relatively invariant C_3 vegetation from the $\delta^{13}C$ record, suggesting that it was formed prior to C_4 grasses reaching this region at ~27°S (Hopley 2004). C_4 plants do not seem to have penetrated into the southwestern Cape of South Africa to any significant extent based on faunal $\delta^{13}C$ data from Langebaanweg at ca. 5 Ma (Franz-Odendaal et al. 2002). The much later hominin sites in the Makapansgat and Sterkfontein Valleys from ca. 2.8 to 1.2 Ma all show consistent but variable presence of C_4 grass from faunal $\delta^{13}C$ data (Lee-Thorp et al. 2007).

Overall, the main body of evidence is consistent with first expansion of C_4 grasses in lower latitudes at 9 Ma, expanding over the next few million years to midlatitudes (Cerling et al. 1997). The expansion of C_4 grasslands across large parts of the world demands a global explanation, but the nature of the drivers has remained curiously elusive. Cerling et al. (1997) and Ehleringer et al. (1997) proposed that plummeting CO_2 levels in the Late Miocene to levels below 500 ppm favored C_4 photosynthesis, based on the known tolerances of C_4 plants for lower levels of pCO_2. But evidence from marine cores suggests that pCO_2 levels were already lower (Pagani et al. 1999). It may be the case that reduction of pCO_2 in the late Middle Miocene/early Upper Miocene drove an earlier evolution of C_4 photosynthesis, but their later success may have been also assisted by climate factors such as solar insolation and enhanced rainfall seasonality.

Evolution of Open African Environments

A great deal of interest and controversy has surrounded the question of how forested versus open were the environments inhabited by early hominins, and the possible links to bipedalism and diet. The decline of large-scale dense forests and opening up of the African landscape is of course intertwined with the spread of C_4 grassy vegetation. Tree cover density has been shown to be strongly, linearly correlated with mean annual rainfall (MAP) in African savannas with a critical transition at 650 mm/a; below this, woody cover coexists with grasses and is sensitive to disturbance, while above it, savannas become "unstable" systems; MAP is sufficient for canopy closure and disturbance such as fire is required for coexistence with grassy vegetation (Sankaran et al. 2005).

Some years ago the "savanna hypothesis" held that forest shrinkage/savanna expansion in Africa was a primary driver of hominin bipedalism, because it was thought that these two trends occurred at about the same time. This hypothesis fell from favor once it became apparent that bipedalism emerged before 4 or 5 Ma, within, as it appeared, relatively wooded habitats (e.g., WoldeGabriel et al. 2001). Nevertheless there have undoubtedly been important and influential changes in the vegetation structures across Africa. The "turnover-pulse" hypothesis relied on the observed radiation of open-country, grazing bovids to draw inferences about shifts to more open landscapes in the Pliocene and Pleistocene (Vrba 1985, 1988). Vrba proposed that a shift to bovid lineages with open-country preferences between about 2.4 and 2.6 Ma coincided with the onset of Northern Hemisphere glaciation observed from marine oxygen isotopes in marine sediment core records (Shackleton et al. 1984). The idea of a turnover pulse has been challenged, however, although it is acknowledged that faunal changes occurred between 2 and 3 Ma (Behrensmeyer et al. 1997; Bobe et al. 2002). Moreover, we now know that the Bovidae radiation is one of several that occurred in response to the emergence of new C_4 grass resources and that these radiations occurred at different times.

A large body of work on pedogenic carbonates has shown that, after emergence in the Late Miocene, C_4 grasses persisted with high variability through the Pliocene (Cerling et al. 1988; Cerling 1992; Kingston et al. 1994; WoldeGabriel et al. 2000; Wynn 2000, 2004). They clearly became a more consistent component of the floral biomass at all sites after 2 Ma (Fig. 2a). A shift in $\delta^{18}O$ also occurs at about this time, suggesting that the source area and vapor transport pathway changed

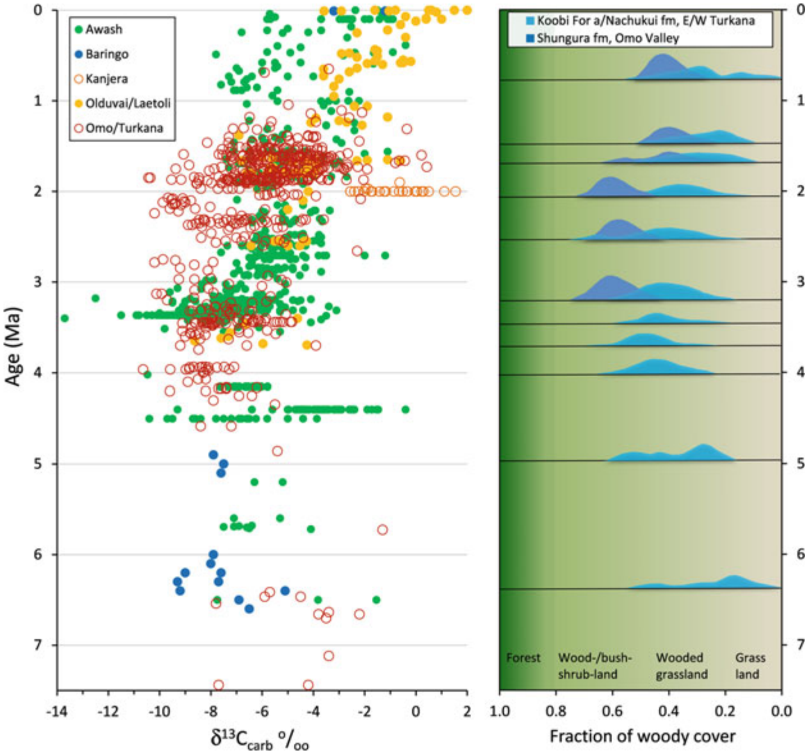

Fig. 2 Pedogenic carbonate nodule $\delta^{13}C$ data for locations in eastern Africa, where sufficiently large datasets exist, are shown plotted against chronology in the left panel. What is immediately apparent is the extreme variability, even at one time and place. Even so some regions were clearly more enriched in ^{13}C, suggesting unambiguously open landscapes (e.g., Kanjera), while others also fluctuate in time. For instance, the Awash data contains a positive excursion at about 4.2 Ma that cannot be due to internal variability. The panel on the right shows $\delta^{13}C$ data for Omo/Turkana region transformed to a normalized probability density function (PDF) in a series of time bins. The PDFs are plotted against "fraction of woody cover" on the horizontal and time (in Ma) on the vertical axis, based on a framework established from multiple modern locations as described in the text (Cerling et al. 2011). The Koobi Fora/Nachakui (*light blue*) and Shungura (*dark blue*) PDFs are shown separately as the latter preserves different environments compared to the rest of the Basin. This is apparent in the figure as Shungura Formation carbonates are consistently more depleted in ^{13}C, indicating higher fraction of woody cover, with the exception of the period ca. 1.7–1.5 Ma. The PDFs indicate a very broad overall trend from more open environments ca. 6 Ma to more wooded ca. 3–4 Ma and back to more open after 2 Ma (The PDF figure is adapted from Cerling et al. (2011), and all data were obtained from the compilation by Levin (2013))

(Cerling et al. 1988). The $\delta^{13}C$ sequences for the Turkana basin shown in Fig. 2a illustrate the highly variable nature of the data, even for each place and period. As the Turkana Basin/Omo sequence is well dated and rich in pedogenic carbonate $\delta^{13}C$ data, Cerling et al. (2011) were able to invert the interpretation to produce, instead of an index of C_4 biomass, rather an index for woody cover, or a "paleoshade" proxy. This was achieved by quantifying the fraction of woody cover from a suite of modern tropical ecosystems from $\delta^{13}C$ of soil organic matter. In this system, "forest" is defined as having continuous tree canopy cover (≥ 80 % cover), "woodland/bushland/thicket/shrubland" contains 40 % of tall woody or bushy cover, "wooded grassland" comprises 10–40 % woody cover, while "grassland" represents grass/herblands with ≤ 10 % woody cover. After transformation for application to carbonates, the fossil pedogenic isotope data are represented as probability density functions (PDF) for each temporal bin in the Awash Valley and Omo-Turkana Basin sequences (shown in Fig. 2b). The results show that woody cover at these sites was for the most part lower than 40 % throughout the 6 Ma timespan, pointing to frequency of open environments at most of the associated hominin fossil sites (Fig. 2b). They also suggest that there is little evidence for a long-term trend toward progressively more open environments, as the data for 6.4 Ma shows less woody cover and more open environments than occurs even after 2 Ma.

A number of isotopic datasets now available for Miocene, Pliocene, and Pleistocene faunas from eastern Africa, Central Africa, and southern Africa also suggest that even after C_4 grasses had become well established, the proportions of C_4 (grass) over C_3 (browse, fruits, herbs, some underground storage organs) resources for fauna did not necessarily increase steadily, but fluctuated. However, because families adopted C_4 resources at different times, it is more difficult to discern proportional plant functional group patterns unless the data are reduced. In order to produce a taxon-free "C_3/C_4" index (following Sponheimer and Lee-Thorp 2003; Lee-Thorp et al. 2007), the frequencies of C_3, C_4, and mixed feeders were calculated for selected sites where several time periods are represented by faunal $\delta^{13}C$ data. The underlying idea is that browsers/frugivores will be favored in a closed habitat with significant tree cover, while grazers will be favored in open, grassy landscapes (Sponheimer and Lee-Thorp 2003). The results (Fig. 3) show considerable variability, at least partly due to the nature of the faunal assemblages. The Central African Chad data stand out with high proportions of C_4 feeders in all sites (Zazzo et al. 2000), suggesting significant open grassy vegetation from the Late Miocene through the Pliocene. This is hardly surprising given the setting alongside a fluctuating Paleolake Chad. Where sufficient $\delta^{13}C$ data is available for the Upper Miocene, as for the Turkana region (Uno et al. 2011) and to a lesser extent in the Tugen Hills (Roche et al. 2013) example shown (where several formations are "lumped"), it is apparent that even at that early stage, shifts occur from earlier open/grassy to more closed environments (Fig. 3). Among the South African hominin sites, the results suggest that the most significant shift toward more open, grassier landscapes occurred ca. 1.7 Ma (Fig. 3 lower panel), consistent with the eastern African Pleistocene data.

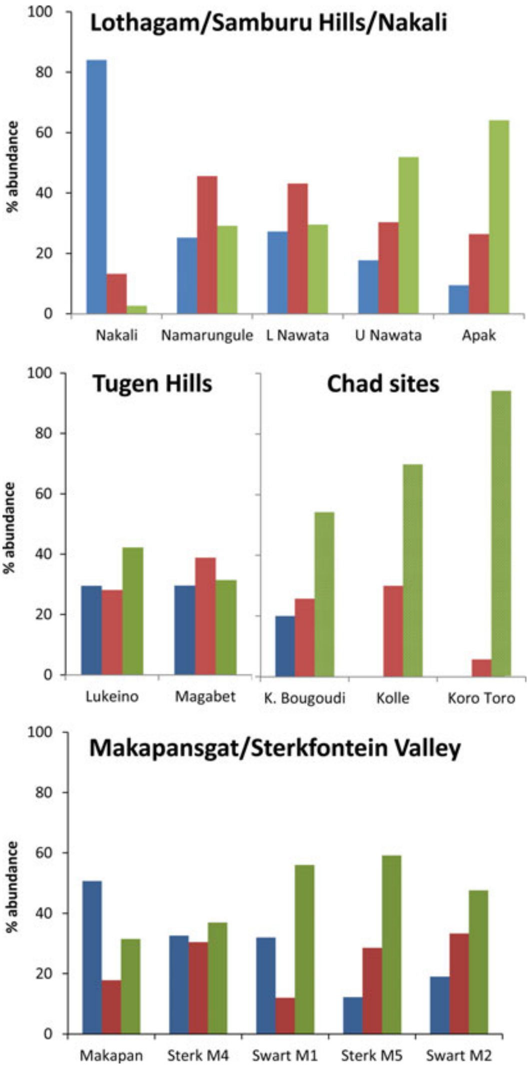

Fig. 3 The taxon-free C_3/C_4 index shown for a variety of sites in eastern and southern Africa for which sufficient data were available. Tooth enamel $\delta^{13}C$ data are reduced according to bins and shown as frequency diagrams, without regard to family, genus, or species, in contrast to the original version (Sponheimer and Lee-Thorp 2003) that used only Bovidae. The bins represent habitual C_3 feeders ($\delta^{13}C$ below −8 ‰), mixed feeders ($\delta^{13}C$ −7.9 to −3 ‰), and habitual C_4 feeders ($\delta^{13}C$ above/more positive than −2.9 ‰). The sites are, from *top*, the Lothagam Samburu Hills/Nawata sequence (Data from supplementary information in Uno et al. 2011), *middle*, the Tugen Hills sequence (Data from Roche et al. 2013) and the Chad sequence (Zazzo et al. 2000), and *below* a composite from the South African hominin sites of Makapansgat, Sterkfontein, and Swartkrans (From Lee-Thorp et al. 2007)

In some cases, faunal isotope $\delta^{13}C$ data apparently run counter to the perspective afforded by pedogenic carbonates, or to faunal abundances. For instance, de Heinzelin et al. (1999) suggest a wooded environment at ~2.5 Ma in the Awash, Ethiopia, based on soil isotope values, but faunal $\delta^{13}C$ data suggest a significant proportion of C_4 grazers (Levin et al. 2004). Pickford and Senut (2001) reconstructed the Tugen Hills environment in the Late Miocene and Early Pliocene to have been mostly forest, based on the presence of the closed habitat preferences of some of the fauna, but Roche et al. (2013) showed that at least for the Lukeino Formation C_4 feeders are more common in the faunal assemblage. A similar situation occurs in relation to environments associated with *Ardipithecus* sites in

Ethiopia, where arboreal or forest loving faunal elements indicated closed-canopy forest or woodland at Aramis (White et al. 2009), while $\delta^{13}C$ analyses at Gona also associated with *Ardipithecus* suggested high proportions of animals reliant on C_4 vegetation (Levin et al. 2008), but these apparent discordances may relate simply to scale and suggest that different parts of the ecosystem are being sampled.

The pedogenic carbonate and faunal $\delta^{13}C$ data, although informative about vegetation trends, are nevertheless constrained by relatively crude chronologies using large time bins. Two isotope proxies offer a means to discern shifts at much higher resolution – speleothems and plant wax biomarkers from lake sediments.

A large flowstone in Buffalo Cave, in the Makapans Valley, South Africa, provides highly resolved $\delta^{13}C$ and $\delta^{18}O$ data, yielding information about vegetation change and hydrology in the period between 1.95 and 1.5 Ma (Hopley et al. 2007). Variation in the $\delta^{13}C$ vegetation sequence is dominated by the obliquity cycle and in the $\delta^{18}O$ hydrology sequence by the precessional cycle. The sequence captures the shift to higher proportions of C_4 plants at 1.7 Ma, but, importantly, it shows that this change forms part of a series of orbitally controlled cycles. The differences in dominant orbital forcing modes for the two proxies emphasize the complexities of climate and environment and the need for multiple sources of evidence.

A different approach to obtaining high-resolution proxy information has been obtained from Olduvai paleolake sediments between 1.8 and 2.0 Ma, using $\delta^{13}C$ and δH signatures for lipid biomarkers extracted from lake sediment organic matter (Magill et al. 2013a, b). Isotope values for the leaf-derived wax biomarker (nC_{31}) are used to deduce the nature of terrestrial plant functional groups (forest to open vegetation) and the climate influences (rainfall amount, relative humidity) acting on them, while the algal biomarker (nC_{17}) reflects rather conditions related to hydrological conditions in the lake. Using published data for modern plants and soils in East Africa, the authors first constructed a framework for interpretation of ancient biomarker $\delta^{13}C$ and δD signatures. The ancient biomarker results show, firstly, that the proportions of closed versus open vegetation, and precipitation, are correlated. This observation is consistent with the Sankaran et al. (2005) modern survey. Secondly, leaf wax $\delta^{13}C$ indicates multiple recurring ecosystem shifts, from open C_4-dominated grasslands to more closed tree-dominated systems. Thirdly, these changes occurred on rapid timescales, within centennial or millennial scales. Unlike the Buffalo Cave record, the $\delta^{13}C$ (vegetation) shifts are correlated with the precessional cycle. These data provide a far more nuanced, detailed view of environmental and climate evolution, compared to the grosser scales provided by, for instance, pedogenic carbonates. They suggest, again, that the long-held inferences about stepwise aridification and opening of East African landscapes are incorrect. In some degree this may be a question of scale, but additionally the nature of links between savannas and precipitation has been poorly understood.

What does the floral information tell us of relevance to hominin evolution? For one, disputes remain about whether locally environments remained relatively closed versus open, as deduced from, say, faunal abundances. In combination these results suggest that in order to make these inferences, we need to base them on multiple sources of information, and certainly including isotopic data.

Despite the orbitally controlled variability shown in the more detailed sequences from Olduvai Paleolake and Buffalo Cave, the appearance of more open, grassy habitats around 1.7–1.8 Ma seems to have been pervasive in both eastern and southern Africa. Given the increasing evidence for presence of a fully bipedal, larger-brained, better technologically equipped hominin at this time, one is tempted to draw links between these two occurrences – habitual use, perhaps, of more open, more strongly seasonal, and exposed open environments with their own set of resource opportunities. Finally, the evidence for cyclical woody/open shifts requires reappraisal of previous interpretations of long-term trends. These new sequential data suggest that our view has been colored by the nature of the proxies available. Most of the existing data relies on material which may, in principle, reflect small time windows, but the time bins are quite gross. As a result, only large-scale environmental trends emerged. Yet the more rapid shifts visible in the biomarker and speleothem data are on a scale that must have impacted on resource and foraging opportunities of early hominins.

Aridity Indices From Oxygen Isotopes

Africa did not experience glaciation and large temperature swings associated with the glacial to interglacial shifts at higher latitudes. The climate variable of most importance and influence is undoubtedly rainfall, and thus there have been many attempts to capture this relatively elusive property. For many years, the perception has existed of an overall aridification trend based on observed trends toward more open, grassier African landscapes over the last ca. 5 Ma. As discussed above, however, grassy presence or dominance does not show such a trend when the entire sequence from the Upper Miocene is considered. Additionally C_4 presence is not an indication of aridity per se, although these grasses are successful in environments with relatively low rainfall. Canopy cover has been shown to be directly and more tightly correlated with mean annual precipitation (Sankaran et al. 2005), so it is likely a better indication of humidity. Given the difficulties of directly linking precipitation or aridity and vegetation cover (with some notable exceptions), it is important to explore multiple indicators to achieve this goal.

Wynn (2004) developed a new application of the pedogenic carbonate record, applying an empirical relationship of the "calcic depth" at which paleosol carbonates form and mean annual precipitation (MAP) derived from modern observations. In this relationship increasingly shallow calcic depth is associated with lower rainfall. Application to those sections of the existing Turkana Basin record (Wynn 2000) where calcic depth can be determined, at various noncontinuous intervals from 4.3 Ma, shows that prior to 2.5 Ma, calcic depth is greater, giving MAP estimates of about 600 mm/a. There follows an estimated decrease in MAP, interrupted by more humid conditions near 1.8 Ma. Interestingly, higher C_4 composition is not necessarily correlated with indications for higher aridity. Wynn (2004) points out that several extended intervals, dating to 4–3.6, 3.4–2.5, and 2.2–1.9 Ma, respectively, lack sufficiently developed carbonates to determine depth in spite of indications of sufficient humidity for soil development. Thus, it seems that the calcic horizon/MAP index is capturing only part of rainfall history.

Two recently proposed aridity indexes exploit the effects of relative humidity on evapotranspiration in plants and hence on the animals that rely on them to a greater or lesser extent. The first exploits the effects of relative humidity on plants and then fauna, using $\delta^{18}O$ differences between animals that use environmental water more directly (termed evaporation sensitive or ES) and those that rely mostly on plant water (termed evaporation insensitive or EI) (Levin et al. 2006). The isotopic difference between a suite of modern ES and EI taxa was found to correlate with a water deficit function for the site. Although the isotopic difference ($\varepsilon_{ES\text{-}EI}$) differs in absolute value for different pairs of ES and EI taxa, the slope of the relationship to water deficit remains relatively consistent. So far the relationship has been sparsely applied. Results for the Middle Pleistocene Asbole fauna, in the lower Awash Valley, Ethiopia, show that the ^{18}O enrichment between ES and EI taxa provides an estimate of a mean annual water deficit of 1,470 mm for the period ca. 0.8 Ma (Bedaso et al. 2010). This value is similar to that found in the area today. The advantage of this approach is that it is independent of $\delta^{18}O_{mw}$ values, but to obtain some meaningful idea of shifts in aridity over time requires extensive application to fossil faunas. This has not yet occurred.

An ostrich or ratite eggshell $\delta^{18}O$ aridity index is also ultimately reliant on relative humidity effects on plants. Ratite eggshell is ubiquitous in many arid archaeological and paleontological sites, and ostriches are known as arid-adapted birds that inhabit dry areas. Thus, the $\delta^{18}O$ composition of their eggshells provides a relatively direct indication of aridity. Data from modern and Late Pleistocene-Holocene archaeological sites show that eggshell $\delta^{18}O$ is correlated with mean annual rainfall and strongly with relative humidity (Lee-Thorp and Talma 2000; Lee-Thorp and Ségalen Unpublished Data). Ostriches rely primarily on plant and recycled metabolic water (Williams et al. 1993), so body water and eggshell $\delta^{18}O$ is strongly influenced by the effects of decreasing relative humidity on plant evapotranspiration. Eggshell $\delta^{18}O$ has been used to show high but fluctuating aridity levels in the Namib, from the Miocene through to the present (Ségalen et al. 2006). In this sequence the main constraint is chronology, as it is based on biostratigraphy and thus provides only crude time intervals.

Warm temperatures contribute to aridity because it promotes evaporation and reduces relative humidity levels. It has been suggested that conditions in East Africa were cooler in the Pliocene, along with being more densely wooded. Temperature has been difficult to assess independently but a new application of “clumped isotopes” that utilizes the distribution of ^{13}C–^{18}O bonds in pedogenic carbonates provides a means for estimating soil temperatures (Passey et al. 2010). The results for carbonates in the Turkana Basin, Kenya, show that the region has been not just warm, but hot, for the past 4 Ma (Passey et al. 2010). Estimated daytime soil temperatures regularly reached well above 30 °C, similar to temperatures in the region today.

Other than estimation of moisture or relative humidity, it is also useful to understand possible shifts in atmospheric circulation in the evolution of climate.

One variable is the dominant moisture source, since it has broader implications for atmospheric circulation. The Turkana Basin pedogenic carbonate $\delta^{18}O$ sequence strongly suggests that a significant change in vapor source or transport occurred in East Africa around 1.8 Ma. $\delta^{18}O$ values prior to this time were more negative, and thereafter significantly more positive. The most likely explanation is a shift in dominant vapor source from a distant one, likely the Atlantic Ocean, to a closer source, likely the Indian Ocean. $\delta^{18}O$ values for the latter period are sufficiently high to suggest that evaporation also exerted an influence on $\delta^{18}O$ as they do today. This data thus provides hints about atmospheric circulation, but little direct information about humidity or aridity.

Conclusions

In this chapter we have attempted to place some of the long-standing questions about the possible linkages between hominin evolution and environmental changes in an isotopic context, and on a sound footing. A number of principles and constraints must be considered for application of isotopic methods to paleoenvironmental questions, or the results are of limited value. In doing so we may have overemphasized the problems and constraints. So, in our concluding remarks we would like to emphasize some of the solid advances that have been made over the last couple of decades.

A great strength of isotopic approaches to paleoenvironments clearly lies in the area of delineating and quantifying vegetation changes, most particularly the presence and proportions of C_4 grasses in the plant biomass or, conversely, woody canopy. There are a couple of relatively minor discordances evident from some of the pedogenic carbonate compared to faunal enamel approaches, but in general the sequence of events is reasonably clear. The emergence of C_4 grasses as a significant part of the vegetation has been pushed back to 9 Ma ago in the low latitudes of Africa. According to the well-dated Samburu Hills/Turkana Basin sequences, this occurred quite rapidly, judging by the rapidity with which equids switched to C_4 plants. Although the data from southern Africa are far more fragmentary, they suggest that this floral shift took place rather later. After the initial major shift to C_4 grasses and sedges (as the evolution of C_4 photosynthesis also occurred in sedges at around the same time or perhaps earlier), these plant groups remained a significant component of the vegetation for millions of years. Taking the full faunal and soil carbonate isotope sequence into account shows that there was no progression toward more and more open environments. Rather there were continual shifts in the proportions of woody and grassy vegetation, varying spatially and on different timescales.

Among the larger-scale vegetation fluctuations, the shift around 1.8 Ma to more extensive grasslands stands out, since it occurred concurrently in both eastern and southern Africa. It may coincide with the emergence of the modern Walker Cell atmospheric circulation, so some of the circulation effects may have included more marked rainy and dry seasons. It is at this point that we see the birth of a "modern world," complete with vegetation and faunal distributions, and variable wet and dry seasons that we associate with "typical" African savanna environments.

At the same time, new high-resolution biomarker and speleothem isotope data point to the inherently cyclical nature of environmental change, at various scales, for both vegetation composition and rainfall. These data demonstrate that orbital forcing of African rainfall, with its strong implications for tree canopy cover, has considerable time depth. This is consistent with interpretations of the Saharan dust cycles (deMenocal 2004, 2011), which effectively indicate the converse, arid components of the system. Other than the still-rare lake biomarker and speleothem sequences discussed above, isotopic evidence for aridity or humidity and any trends in these features is still thin. However, significant advances have been made in developing new methods to address them.

We can use the isotopic data to evaluate the idea of a large climate-driven radiation about 2.4–2.8 Ma ago, as suggested in the "turnover-pulse" hypothesis (Vrba 1985). The evidence from $\delta^{13}C$ in fauna and pedogenic carbonates from East and South Africa suggests that, after the first explosion of C_4 vegetation about 7–9 Ma ago, the most significant biomass change to open, grassy ecosystems occurred near 1.8 Ma. It is tempting, but nevertheless speculative, to suggest that the emergence and success of a habitual, fully bipedal, well-equipped hominin, viz. *Homo ergaster*, is in some way connected with this significant environmental change. The nature of much of the isotopic evidence produced so far does not permit a detailed test of the "climate variability" hypothesis (Potts 1996), but high-resolution sequence data such as developed for the Olduvai paleolake may at last provide an appropriate means to do just that. This is because most data represents large chunks of time, and shorter periodicity is hidden. The new highly resolved lake sediment biomarker approach promises to break this impasse for the first time, although the possible locations for such studies are more limited than the coarser paleosol and faunal approaches. High-resolution speleothem isotope data are an equally promising archive, but are even more restricted in time and space, limiting their application and impact.

What can these shifts and large- and small-scale cycles tell us about hominin adaptations and evolutionary pathways? Are these issues linked, and if so, how? As noted above the "savanna hypothesis" ceased to be popular some time ago because the emergence of older dates for evolution of bipedalism was pushed back in time to periods in which canopied forests dominated the landscapes occupied by early hominins. Or so it appeared. Greater attention to the timing and interpretation of the paleosol carbonate and faunal isotope data suggest rather that open landscapes dominated for millions of years. It is also apparent that vegetation cover and humidity varied on relatively shorter timescales as well. These are scales that perhaps carried greater significance for hominin adaptation. Additionally we now know that hominins began to exploit C_4 resources from a relatively early stage (at least after 4 Ma) (Sponheimer et al. 2013). The implication is that when C_4 food resources became available, hominins often chose to make use of them, while our closest living relatives did not. Thus, it might be time to rethink the relationship between hominin evolutionary trends and the emergence of "savanna" landscapes yet again.

The Paleoclimatic Record and Plio-Pleistocene Paleoenvironments

John Rowan and Kaye E. Reed

Contents

Abstract

New evidence from relatively recent methodological advances into hominin autecology presents interesting and often contradictory data. This article presents a broad overview of various paleoecological methods and summarizes what is known about the paleoecology of late Miocene hominins, through the hominin genera that begin to appear in the early Pleistocene, ~2.0 Ma. The use of taxon-free methods is emphasized in elucidating hominin habitats, and a more careful consideration of taphonomic and depositional biases that often result in "mosaic" reconstructions is advocated. Methods that focus on understanding the behavioral ecology of early hominin and other mammalian taxa are reviewed.

Introduction

Paleoecology is concerned with understanding the ecology of organisms from the past, inasmuch as ecology can be reconstructed using the available evidence. The paleoecological evidence, whether biotic or abiotic, is then often compared with modern ecological patterns and processes to arrive at an understanding of the fossil taxon, taxa, or habitats of interest. Ecological patterns can be discerned in the past, but the processes that caused those patterns must be inferred. These can then be compared with modern ecological studies, wherein hypotheses about the processes are developed from observed patterns and subsequently linked to processes. For example, there are several hypotheses of community assembly processes, i.e., understanding why particular taxa co-occur in a circumscribed area, and these continue to be tested today (e.g., Hubbell 2001; Chase et al. 2005; Salisbury et al. 2012). There are many areas of inquiry that fall under the paleoecology rubric, including, but not limited to, geological depositional environments and paleosol analysis, habitat reconstruction, climate modeling, taphonomy, community ecology, biogeography, and autecology.

This chapter briefly outlines a variety of paleoecological methods that are used currently to develop reconstructions of the past habitat, climate, and behaviors of early hominins. What is currently known about early hominin ecology is synthesized, and those taxa recovered from the late Miocene, beginning at ~7 million years ago (Ma) to the end of the Pliocene, ~2.5 Ma, are included (Table 1).

Table 1 Habitat and dietary data for early hominin taxa

Taxon	Habitat	Isotopes	Microwear	References
Sahelanthropus tchadensis	savanna with some woody cover; semi-desert?	_	_	(Vignaud et al. 2002; Le Fur et al. 2009; Blondel et al. 2010)
Orrorin tugenensis	Forest-woodland mosaic	_	_	(Pickford and Senut 2001)
Ardipithecus kadabba	Riparian woodland	_	_	(Su et al. 2009)
Ardipithecus ramidus	Predominantly woodland; possibly bushland-grassland	C_3 dominated	_	(White et al. 2009; Louchart et al. 2009; Cerling et al. 2011a)
Australopithecus anamensis	Woodland; Woodland with gallery forests	C_3 dominated	Low complexity and anisotropy values; soft foods	(Leakey et al. 1995; White et al. 2006)

(*continued*)

Table 1 (continued)

Taxon	Habitat	Isotopes	Microwear	References
Australopithecus afarensis	Habitat generalist: riparian forest through bushland	Eurytopic; Individuals range from predominantly C_3 to predominantly C_4	Low complexity and anisotropy values; soft foods	(Reed 2008; Ungar and Sponheimer 2011; Wynn et al. 2013; Behrensmeyer and Reed 2013)
Australopithecus bahrelghazali	Grassland around lake margins	Predominantly C_4	–	(Brunet et al. 1996; Lee-Thorp et al. 2012)
Australopithecus africanus	Riparian woodlands, edaphic grasslands, dense to open woodland, and bushland	C_3/C_4 mixed feeder	Low complexity and anisotropy values; soft foods	(Reed 1997; Sponheimer and Lee-Thorp 1999; Sponheimer et al. 2005)
Australopithecus garhi	Grassland around lake margins	–	–	(Asfaw et al. 1999; de Heinzelin et al. 1999)
Australopithecus sediba	Grassland to woodland	Predominantly C_3	Moderate anisotropy, high complexity; some hard-object feeding	(Dirks et al. 2010; Henry et al. 2012)
Paranthropus aethiopicus	Wooded and wet in the Omo; dry and arid in the Ndolanya Beds, Laetoli	Predominantly C_4	–	(Bobe and Eck 2001; Harrison 2011; Cerling et al. 2013)
Paranthropus robustus	Woodland and grassland near water sources	C_3/C_4 mixed feeder	Hard-object feeding as evinced by pitting?	(Reed 1997; Ungar and Sponheimer 2011)
Paranthropus boisei	Mesic woodlands near lakes; grasslands at Konso, Ethiopia	Predominantly C_4	Low complexity and anisotropy values; soft foods	(Cerling et al. 2011b, 2013; Ungar and Sponheimer 2011)

(*continued*)

Table 1 (continued)

Taxon	Habitat	Isotopes	Microwear	References
Kenyanthropus platyops	Woody, well-vegetated (although the Nachukui Formation is generally the most arid in Turkana Basin)	Eurytopic; Individuals range from predominantly C_3 to predominantly C_4	_	(Leakey et al. 2001; Cerling et al. 2013)
Homo habilis	Generally open and arid grasslands; possibly wooded environments	C_3/C_4 mixed feeder	Low complexity and anisotropy values; soft foods	(Bobe and Behrensmeyer 2004; Ungar et al. 2006; Cerling et al. 2013; Kovarovic et al. 2013)

The Paleoclimatic Record

Research interest in the links between climate, ecology, and macroevolution has led to the advent of various proxies for paleoclimate during the African Plio-Pleistocene. While fauna has been historically used (e.g., Vrba 1985), new methods have come to the forefront of paleoclimatic studies, including records of terrigenous dust in marine drilling cores (e.g., deMenocal 1995), stable isotope analysis of paleosols (e.g., Cerling et al. 2011a), and stable isotope analysis of plant leaf wax (Feakins et al. 2013).

Vrba (1985, 1995) explored the interplay between paleoclimate and macroevolution using the fossil record of African mammals, primarily bovids, and such studies led to the formulation of the turnover pulse hypothesis (i.e., faunas “turnover” in synchronous-like fashion as a response to perturbations of climate). She suggests that the radiation of cool and arid-adapted mammals over warm and moist-adapted mammals is evidence that Africa became increasingly cooler and more arid over the past 5 million years. Indeed, the origins of *Paranthropus* and *Homo* have been linked with the cooling event shortly after 2.8 Ma. Marine isotopic evidence (e.g., Zachos et al. 2001) also supports cooling in Africa during this time, along with intensification of glaciation at Northern Hemispheres.

Using records of continental dust derived from marine drilling projects in the Arabian Sea and Gulf of Aden, deMenocal (1995, 2004) has suggested three steplike increases in aridity, as evinced by an increase in dust, in East Africa over the last few million years. Dust production increased between 3.0–2.6 Ma, 1.8–1.6 Ma, and 1.2–0.8 Ma, all three of which are broadly consistent with periods of turnover in African faunas previously proposed by Vrba (1995).

Overall, it is clear that over the past 7 Ma in Africa, climate was becoming increasingly cooler, terrestrial ecosystems were becoming more arid, and the variability of climatic changes was becoming more dramatic. While various hypotheses have been proposed to explain key events in the human lineage (e.g., bipedalism and material technology), none is universally accepted although none are mutually exclusive. The remainder of this chapter will provide habitat descriptions for hominin species, but will refrain from speculating on the impetus for innovations in human evolution. For further reading, an in-depth review of paleoclimate and hypotheses regarding hominin evolution was recently provided by Potts (2013).

Paleoecological Methods

Faunas as Paleoenvironmental and Paleoecological Indicators

The remains of other fossil vertebrates, primarily mammals, have historically played a large role in the reconstruction of hominin habitats, and this method is still used today. The last few decades have witnessed a paradigm shift in paleoecology from taxon-based to taxon-free methods (i.e., analyses that do not rely on taxonomic or phylogenetic information). Traditional taxon-based methods, such as the relative abundance of grazing taxon x vs. browsing taxon y, rely on the assumption of taxonomic uniformitarianism. Under such an assumption it is supposed that fossil taxa share dietary and habitat preferences with their extant congeners and that these ecological traits can be used in paleoenvironmental reconstructions. This is problematic. For example, some lineages were diverse in the past and have only a single or few living representatives (e.g., *Theropithecus*), while others exhibit changes in their dietary ecology through time that would have been completely unforeseen under expectations of ecological continuity between fossil and extant taxa. For example, Bibi et al. (2012) recently showed that the suid *Kolpochoerus limnetes* and the tragelaphin bovid *Tragelaphus nakuae* from the Shungura Formation of southern Ethiopia increasingly consumed C_4-based resources after 2.8 Ma, despite showing little craniodental change through time. The result was unexpected for both species, as modern analogs (*Potamochoerus* spp. and *Tragelaphus* spp.) are typically found in closed habitats, and C_3 plant sources make up the majority of their diet (Harris and Cerling 2002; Kingdon and Hoffmann 2013). This variation through time in lineages should caution future researchers wishing to reconstruct habitats based solely on taxonomic grounds. Unfortunately, taxonomically based methods remain pervasive in the hominin literature (e.g., Reynolds and Kibii 2011).

Bovids (antelope and their kin) are the most common mammalian family used in habitat reconstructions of the East and South African Plio-Pleistocene and provide a good model to explore the assumption of taxonomic uniformitarianism. Persistently, the relative distribution of bovid tribes in fossil deposits has been used as a proxy in habitat reconstructions and paleoenvironmental studies for sites of the

African Plio-Pleistocene (e.g., Vrba 1980; Shipman and Harris 1988; Harris and Leakey 1993). This methodology is based on the principle of taxonomic uniformitarianism, an idea itself based on the two postulates that (1) living representatives of bovid tribes collectively exhibit generalizable ecological preferences and that (2) these tribal preferences can be extended to their fossil representatives. However, there are notable difficulties with both of these assumptions.

With regard to living species, although members of a tribe may seem to collectively exhibit preferences for a certain habitat, the generalization is usually imprecise and there are always exceptions. For example, the sable antelope *Hippotragus niger* deviates from Hippotragini's generalized preference for open and arid grassland to semidesert habitats by instead preferring woodland and ecotones in the miombo (miombo is the Swahili word for the genus *Brachystegia*) woodland zone of southeastern Africa (Estes 2013). In Botswana, the southern limit of the sable's range happens to be limited by an annual rainfall isohyet of 500 mm, while fellow hippotragins *Oryx* and *Addax* persist, respectively, in habitats that receive much less than 500 and 100 mm of annual rainfall (Estes 2013; Knight 2013; Newby 2013). Similarly, the eland *Tragelaphus oryx* abandons its tragelaphin "tribal preference" for habitats with substantial woody cover and is found in habitats ranging from Kalahari semidesert scrub through Serengeti grassland to high-altitude alpine moorland on Mt Kilimanjaro (Thouless 2013). Through these examples, and there are many more, it is evident that homogenizing various habitat preferences of particular species into oversimplified habitat preferences for extant tribes, and then extrapolating this single homogenized tribal preference to fossil species living millions of years ago, is problematic without further explanation.

While the presence or absence of particular tribes might be of some paleoenvironmental significance, for example, the absence of reduncins at Laetoli (which indicates the lack of wetlands, lakes, or rivers (Gentry 2011)), paleoenvironmental and habitat inferences based on tribal relative abundance are subject to distortion by preservational, taphonomic, collection, and identification biases. For example, assemblages accumulated in fluvial systems may contain animals from multiple habitat types that often result in a "mosaic" reconstruction of early hominin habitats. Similar weaknesses characterize assemblages accumulated by carnivore activity, such as the size of prey that is accumulated and the resulting bias eliminating various size classes of animals that would be used in a paleoecological analysis.

In light of these issues, there has been a recent movement in paleoecology towards taxon-free methods of ecological and environmental reconstruction, based on fossil mammal specimens that do not rely on taxonomic or phylogenetic information. Such methods include isotopic analysis of herbivore enamel (Sponheimer et al. 2003; Cerling et al. 2011), mesowear of molar teeth (Fortelius and Solounias 2000; Kaiser 2011), craniodental ecomorphology (Spencer 1997), and postcranial ecomorphology (DeGusta and Vrba 2003, 2005a, b; Plummer and Bishop 1994). These taxon-free methods are used to re-create patterns of habitat use in mammals that existed with the early hominin taxa. Thus, the isotopic analysis of ungulate teeth from a particular site should provide an indication of the overall habitat from which the animals derived. Mesowear, craniodental, and postcranial ecomorphology provide the same types of patterns, although an improved pattern is developed if all of the methods are used and compared at one locality as this may identify taphonomic biases in the information. Since many hominin habitats have been reconstructed on taxonomic grounds, the evidence is included here, but strong conclusions based on these data are not possible.

Dental Microwear

Microscopic examination of the enamel surfaces of molars and incisors provides data in the form of scratches and pits on the teeth that can be used to infer what members of a fossil taxon were actually eating. Microwear has been utilized to understand the diet of hyraxes, bovids, monkeys, carnivores, and hominins (e.g., Walker et al. 1978; Grine and Kay 1988; Merceron et al. 2004; Scott et al. 2005; Ungar et al. 2008, 2010b). Traditionally, microwear has been assumed to exhibit scratches on the teeth caused by ingestion of food in the last weeks of the animal's life (Teaford 1988). Recently, however, Lucas et al. (2013) have called this into question. They suggest that what the microwear is measuring is grit, since other foodstuffs do not, in an experimental setting, mar teeth to the extent that dirt does. This obviously needs further investigation, but considering these claims it is remarkable that browsing bovid teeth and grazing bovid teeth, as evinced by extant samples, show consistent differences between these groups (e.g., Schubert et al. 2006). This analysis of diagnostic wear patterns can be extended to primates, as monkeys that eat hard seeds and nuts show pitting on their teeth, while those that eat soft and abrasive foods do not. The results of microwear analyses of hominin taxa are included as paleobiological data in the section on hominin taxa, as are some interesting problems that arise when comparing these analyses with other methods of reconstructing hominin diets, such as stable isotope analysis.

Isotopes in Paleoecology

Of all skeletal tissues, dental enamel is ideal for isotopic studies because it is more highly mineralized than bone, and is thus unlikely to undergo postdepositional chemical alterations (i.e., diagenetic changes), and because changes in diet throughout ontogeny can be investigated since enamel is an incremental tissue (Ungar and Sponheimer 2011). For dietary information ^{13}C is the most suitable isotope for inferring the feeding ecology of extinct taxa, as its composition is directly related to the physiology and isotopic composition of the plants from which it was derived. Different terrestrial plants use different photosynthetic pathways, and this is reflected in their ^{12}C and ^{13}C ratios; these ratios are of interest to paleoecologists because, depending on which species of plant are consumed, a diagnostic ratio becomes incorporated into the enamel of herbivorous mammalian taxa. In tropical environments like Africa, browse vegetation such as woody trees, forbs, and shrubs exhibit the signature of a C_3 photosynthetic pathway. Conversely, savanna and tropical grasslands are associated with a C_4 photosynthetic pathway. As previously stated, enamel has very low rates of diagenetic alteration and has proven to be a useful indicator for distinguishing between modern and fossil browsing (e.g., *Giraffa* spp.) and grazing species (e.g., *Equus* spp.). Quantitatively, browsers show ^{13}C values of $-8^0/_{00}$ to $-10^0/_{00}$, while grazers exhibit values greater than $-2^0/_{00}$ to $1^0/_{00}$. As would be expected, mixed feeders are characterized by intermediate values.

Stable isotopes of oxygen are useful for interpreting climatic conditions, as ^{18}O composition in organisms is largely determined by the ^{18}O composition of local drinking water (thus presenting a snapshot of altitude, aridity, precipitation, etc.). However, interpreting the results of stable isotope analyses of oxygen is confounded by the fact that organismal physiology and diet also influence oxygen ratios in mammals and must be taken into account when drawing conclusions from data. With mammals in particular, ^{18}O is strongly influenced by drinking behavior. Depleted levels of ^{18}O are observed in aquatic taxa and higher levels of ^{18}O are common in C_4-adapted and arid taxa.

Carbon isotopes can also be used in chemical analyses of paleosols, if there are carbonate nodules (Cerling and Hay 1986; Sikes 1994; Wynn 2000). These nodules usually form under drying conditions and can give representation of the percentages of grasses and dicots (bushes and shrubs) that were present when the soil was formed. In addition, the soil carbon and carbonates can be used to estimate carbon dioxide in the atmosphere, which enables a better understanding of the paleoclimate (Cerling 1992).

Recently, Cerling and colleagues (2011a) have developed a method using soil carbon isotopes to evaluate the percentage of woody cover that was present on the landscape when the paleosols were formed. The percentage of woody cover is based on the amount of shrubs, bushes, and trees that had the C_3 pathway in the paleosol. The woody cover method is especially important in reconstructing environments for ancient African landscapes, as most hominin fossil localities in eastern and southern Africa are believed to have been deposited under "savanna environments." A savanna is defined as having various amounts of woody cover (C_3) from 80 % to 20 % (Pratt and Gwynne 1977), with grasses (C_4) as ground cover. Reconstructions of past habitats and, in particular, hominin sites have suffered from the inaccuracy of the term "savanna" to describe what the habitat looked like, and indeed many people think of open grassland when they hear the term savanna, although 20 % woody cover is required. Cerling et al. (2011a) designed a formula to interpret exactly how much woody cover was present, although this method cannot differentiate between the types of woody cover. However, if methods are used in tandem a better depiction of the landscape is possible. For example, Cerling et al. (2011a) reconstruct the Dikika locality, where "Selam" was recovered, as a woodland, bushland, or shrubland, based on the fraction of woody cover. If one uses the fauna recovered from the Basal Member of the Hadar Formation to add to this interpretation, one would see many browsers and mixed feeders that independently indicate a bushland or medium density woodland. Using multiproxies to examine hominin ecology allows better understanding of the taxa and their relationship with their environments.

Finally, strontium isotopes have also been in play recently and have been used to investigate movement of hominin species on the landscape. Strontium isotopes are dependent upon the underlying composition of rocks and soil in any given area; for example, they have been used extensively in France to show that a particular wine grape was in fact grown in the area that is noted on a bottle of wine (Hodgkins 2012). In South Africa, Copeland et al. (2011) used these data to examine ranging patterns in early hominins and showed that the smaller hominins recovered in the Malmani dolomite region of South Africa had evidence of ingesting strontium outside of the range seen in that area. The authors suggested that this might reveal that male australopiths had relatively small home ranges and that females ranged widely. Thus, isotopic analyses permit inferences of social and reproductive behavior in the hominin fossil record.

Botanical Remains as Paleoenvironmental Indicators

Pollen, phytoliths, and wood have all been used to reconstruct the plant species that were present in ancient environments (Bonnefille and Riollet 1980; Bonnefille et al. 2004; Henry et al. 2011, 2012; Bamford 2005; Bamford et al. 2006). Fossilized plant material is subject to the same vagaries as fossilized animals, in that it is only preserved under certain conditions. Despite this, pollen has been recovered from many fossil localities, e.g., Hadar, Ethiopia, but only from particular strata, such as the Sidi Hakoma Tuff and in the base of the Denen Dora Member, and it has been noted that no pollen was preserved from the upper Kada Hadar Member. The conclusion is that reeds and grasses from the paleolake dominated Hadar, and through the section there were both increasing and decreasing proportions of tree and shrub species. Again, these data can be compared with the faunal data and isotope data, where available, to arrive at a better understanding of the habitat of *Australopithecus afarensis*. For example, there is a spike in the abundance of reduncin bovids at the beginning of the Denen Dora Member, indicative of lacustrine and wetland deposits that are consistent with the pollen data.

The analysis of fossil woods allows identification of the actual tree species that existed in the region, and this often helps in determining the types of woody cover and the habitat. Bamford et al. (2006) used both macro-plant fossils and phytoliths to refine the habitats from the broad vegetation reconstruction previously done. At the HWKEE (Henrietta Wilfrida Korongo East East) site, they determined that the region was first dominated by palm trees and then a mixture of palms, grasses, and other dicot plants.

Phytoliths have come into the forefront in analyzing hominin diets. Henry et al. (2012) noted phytoliths of various plant materials in the calculus of *Au. sediba*. These included a fruit phytolith and a bark phytolith, consistent with the C_3 diet reconstructed using isotopic data. Phytolith analyses like that of Henry et al. (2012) offer a promising avenue of research for reconstructing hominin autecology.

The Ecology of Hominin Taxa

Sahelanthropus tchadensis

The earliest potential hominin comes from ~6 to 7 Ma perilacustrine sediments in Toros-Menalla, northern Chad. TM 266-01-060-1, “Toumai,” is the holotype of *Sahelanthropus tchadensis*, a distorted cranium possessing a thick supraorbital torus, small canines, and a cranial capacity of about 360 cc. The site was biochronologically dated as apparently older than the Lukeino Formation fauna (ca. 6 Ma), and the Toros-Menalla assemblage appears most similar to the Lower Nawata fauna of Lothagam (ca. 5.2-7 Ma) (Brunet et al. 2002).

Over ten species of fish, and abundant hippopotamid and crocodile remains, suggest a large and permanent lake, in concordance with the depositional evidence. The terrestrial habitat was reconstructed as a mosaic ranging from savanna to gallery forests at the edge of the watercourses, along with floodplain environments. Evidence for desert or semidesert conditions within the mosaic comes from fossil sand dunes, proposed by the authors as the earliest evidence for desert conditions in the southern Sahara (Vignaud et al. 2002).

Savanna conditions at Toros-Menalla seem to have been more prevalent than previously proposed, since a recent analysis of bovid mesowear implies the presence of extensive grasslands and open environments (Blondel et al. 2010). The dominance of Hippotragini and Reduncini at Toros-Menalla is also suggestive of open expanses of herbaceous vegetation, as extant representatives of both tribes are typically grazers (Kingdon and Hoffmann 2013). Gerbils and ground squirrels, along with fossorial genera like *Orycteropus* and *Serengetilagus*, also indicate dry savanna environments (Le Fur et al. 2009).

No isotopes or microwear studies have been published on *Sahelanthropus*.

Orrorin tugenensis

Senut et al. (2001) erected the genus *Orrorin* for late Miocene hominoid remains from the Lukeino Formation in the Tugen Hills of Kenya dated 6–5.7 Ma (Pickford and Senut 2001; Sawada et al. 2002). The hominin status of *Orrorin* is mainly supported by the morphology of the proximal femur in BAR 1002’00 which suggests that it may have been a biped (e.g., Richmond and Jungers 2008); but this view is not unanimous (e.g., Wood and Harrison 2011). Pickford and Senut (2001) described the associated fauna, but no isotope or microwear analyses have been performed. The late Miocene habitat of *Orrorin tugenensis* was reconstructed as a woodland mosaic based on the predominance of *Aepyceros*, a genus whose extant representative prefers ecotones between light woodland and savanna (Fritz and Bourgarel 2013). Colobine monkeys were interpreted as evidence for the presence of forests in close proximity to the depositional center, which alternates between fluvial and lacustrine throughout the Lukeino sequence. Crocodiles, hippos, fish, and freshwater snails suggest large, permanent bodies of water.

Ardipithecus kadabba

Ardipithecus kadabba is a late Miocene species of hominin recovered from sediments along the western margin of the Middle Awash, Ethiopia (Haile-Selassie and WoldeGabriel 2009). The hominin-bearing Asa Koma and Kuseralee Members of the Adu-Asa Formation have been dated to 5.54–5.77 Ma and ca. 5.2 Ma, respectively (WoldeGabriel et al. 2009). Su and colleagues (2009) associated *Ar. kadabba* with a densely wooded and well-watered landscape characterized by riparian woodland. The Asa Koma and Kuseralee Members are particularly rich in reduncin bovids, and this was taken as evidence for edaphic grasslands or swampy areas on the landscape. In contrast, Levin et al. (2008) interpret the habitat of *Ar. kadabba* at Gona as being predominantly bushland-grassland, based on carbon isotopes from herbivore tooth enamel suggesting diets dominated by C_4 grasses. This implies some habitat flexibility for early *Ardipithecus*.

Ardipithecus ramidus

The early Pliocene hominin *Ardipithecus ramidus* is best known from Aramis, a locality in the Middle Awash region of Ethiopia. The Lower Aramis Member of the Sagantole Formation is bracketed by two marker tuffs that constrain the age of Aramis to 4.4 Ma. The depositional environment has been characterized as a low-relief aggrading floodplain. White and colleagues (2009) recently published a comprehensive synthesis of the Aramis paleoenvironment using various lines of evidence (e.g., taxonomic abundance, mesowear, isotopes), and it is thus no surprise that the paleoenvironment of *Ar. ramidus* is the most completely known for all of the late Miocene-early Pliocene hominin taxa. The habitat evidence from Aramis is consistent with woodland exhibiting grassy and closed patches (although see Cerling et al. 2011a).

Carbon isotopes for *Ardipithecus ramidus* reveal a diet primarily comprised of C_3 plant products. The oxygen isotope data for *Ardipithecus* are slightly lower than the Aramis monkeys, suggesting that *Ar. ramidus* "obtained more water from fruits, bulbs, tubers, animals, and/or surface sources" (White et al. 2009). Dental morphology is broadly consistent with the isotopic data and indicates that the diet of *Ardipithecus* was generally derived from forest and woodland components. Suwa et al. (2009) showed that the enamel thickness of *Ar. ramidus* is intermediate between *Pan* and *Australopithecus* and suggested that the combined evidence indicates generalized omnivory and frugivory.

The community composition at Aramis is particularly interesting, being dominated by tragelaphin bovids and colobine monkeys. Cercopithecids in general are strikingly common at Aramis, as specimens attributable to *Pliopapio alemui* and *Kuseracolobus aramisi* comprise 30 % of the large mammal fauna, with the latter being the most common monkey in the assemblage. Conversely, equids are rare although the *Eurygnathohippus* species present at Aramis appears to be postcranially adapted to open-county running. *Tragelaphus* is the most common bovid, comprising 85 % of all antelope specimens collected. *Aepyceros* is also relatively common at Aramis, while Alcelaphini and Hippotragini are uncommon. Parrots and the peafowl *Pavo* dominate the avifauna, and it was suggested by Louchart et al. (2009) that the relatively rare arid-adapted rodents of Aramis were transported by raptors, since woodland micromammals comprise most of the assemblage.

Ecomorphological analyses of postcrania investigated habitat-linked traits in cercopithecid and bovid specimens, almost all of which were classified as "forest." Mesowear analyses revealed browsing preferences for the Aramis giraffids, tragelaphins, and "neotragins," while *Aepyceros* fell closer to the grazing end of the spectrum. Enamel isotopes reveal that grazing taxa were relatively uncommon and that browsing taxa dominated the assemblage. Notably, most fossil mammals at Aramis conformed to dietary expectations based on their extant congeners, which, in this case, supports the validity of taxon-based methods (e.g., relative taxonomic abundance) used to reconstruct the paleoenvironment of *Ardipithecus* at Aramis. The analysis of White and colleagues (2009) is a model example of the use of taxon-based methods, once independent lines of evidence have confirmed the supposed ecologies of indicator taxa.

Australopithecus anamensis

Australopithecus anamensis is the first species in the genus *Australopithecus* and has been found in sites in both Ethiopia and Kenya, appearing at Kanapoi, Allia Bay, Fejej, Aramis, Asa Issie, and Galili in roughly contemporaneous sediments indicating an origin of *Australopithecus* about 4.2 Ma. At Asa Issie, *Au. anamensis* is found in a woodland environment (White et al. 2006), while Kanapoi and Allia Bay were reconstructed as woodland mosaics with extensive gallery forests (Leakey et al. 1995).

Like *Ardipithecus*, the carbon isotopes of *Au. anamensis* reveal a narrow and C_3-based diet (Cerling et al. 2013). White et al. (2006) hypothesized niche expansion in early *Australopithecus* as the dentognathic morphology of *Au. anamensis* is indicative of consumption of tough, abrasive food resources relative to earlier hominins like *Ardipithecus*. Microwear analyses of *Au. anamensis* are notably similar to its descendant *Au. afarensis*, suggesting some dietary continuity between the lineages, although the evidence from isotope data contradicts this (Ungar and Sponheimer 2011; Wynn et al. 2013).

Australopithecus afarensis

Australopithecus afarensis is the most completely known species of Pliocene hominin (Kimbel and Delezene 2009), likely due to its extensive geographic and temporal distribution. This species persists from roughly 3.8 to 2.95 Ma and is best documented by the well-constrained sediments in the Afar of Ethiopia and, to a lesser extent, the Upper Laetolil Beds of Laetoli, Tanzania (Harrison 2011). *Au. afarensis* is likely present 2,500 km west of the Rift Valley at Koro Toro, Chad (as *Au. bahrelghazali* sensu Brunet et al. 1996), but it is relatively rare in the Omo-Turkana Basin, represented by poorly preserved craniodental remains, despite the Basin's close proximity to other East African sites (e.g., Suwa et al. 1996; Kimbel 1988).

The earliest well-documented specimens of *Au. afarensis* come from the Upper Laetolil Beds of Laetoli, Tanzania. The paleoenvironment of Laetoli has been subject to debate. In the seminal 1987 volume on Laetoli edited by Mary Leakey and John Harris, most contributing authors concluded that past and present environments at Laetoli were effectively equal. This implied that the region must have been continuously characterized by savanna habitats, with some mixture of open woodland, since the mid-Pliocene when the Lower Laetolil Beds were deposited on bedrock. However, this view of habitat uniformity through time no longer appears to be true for Laetoli based on various lines of evidence including bovid ecomorphology (e.g., Kovarovic and Andrews 2007), vegetation structure (e.g., Andrews and Bamford 2008), and stable isotope analysis of herbivorous mammals (e.g., Kingston and Harrison 2007). These studies converge on the conclusion that Laetoli was wetter and more wooded during the deposition of the Laetolil Beds (3.8–3.5 Ma) than originally reconstructed. Ephemeral streams and ponds were likely present; however, the lack of aquatic taxa suggests permanent bodies of water were never present at Laetoli during this time. Hippopotamuses, crocodiles, and reduncin bovids are all absent from Laetoli, while they are common elsewhere in the East African Plio-Pleistocene. Despite this significant habitat difference, hominins are present at Laetoli and were probably more common than their relative abundance alone would suggest due to taphonomic biases related to body size (Su and Harrison 2008). Overall, the most recent data are in disagreement with original reconstructions of Laetoli, and the habitat of *Australopithecus afarensis* at Laetoli does not seem overtly anomalous with respect to other sites where the taxon is found, such as Hadar, which is discussed below.

The Hadar Formation of Hadar, Ethiopia, ca. 3.45–2.9 Ma, has produced the bulk of *Au. afarensis* specimens and permits longitudinal studies of this hominin's ecology since *Au. afarensis* is found throughout the entirety of the Hadar sequence (Campisano 2007). The paleoecology of the well-constrained Pliocene sediments at Hadar was recently reconstructed by Reed (2008). She provided habitat reconstructions for all members of the Hadar Formation by synthesizing faunal evidence with pollen and depositional data. In general, going up in the sequence, environments are wooded and closed during Sidi Hakoma times, transitioning to a wetter period in the Denen Dora when edaphic grasslands spread during the DD-2 submember and finally to more open and arid grasslands in the Kada Hadar Member (Reed 2008). *Au. afarensis* is most common in the Sidi Hakoma Member and, after declining in abundance, bounces back during the DD-2 submember when waterlogged grasslands dominate the landscape as evidenced by a substantial peak in reduncin bovids (Reed 2008). From the DD-2 submember on, the abundance of hominins stays relatively constant until they decline slightly in the KH-2 submember and then disappear from the Hadar fossil record roughly 2.95 Ma (Reed 2008; Kimbel and Delezene 2009). The evidence from Hadar supports the notion that *Australopithecus afarensis* was a habitat generalist as previously hypothesized (e.g., White et al. 1993).

Other habitat reconstructions are available for *Au. afarensis*. Woodland habitats dominate at Woranso-Mille, as the fauna is rich in Tragelaphini, *Aepyceros*, and *Theropithecus oswaldi* aff. *darti* (Geraads et al. 2009; Haile-Selassie et al. 2010). At Dikika, *Au. afarensis* is associated with woodlands around a delta, but grasslands may have also been present (Wynn et al. 2006). Two molars of *Au. afarensis* have been recovered from a Ledi-Geraru site sampling the Denen Dora Member of the Hadar Formation that contains numerous reduncins, alcelaphins, and antilopins suggestive of areas containing wet and dry grasslands. White et al. (1993) reconstructed the environment at Maka in the Middle Awash as woodland-bushland using faunal evidence.

Microwear studies of *Au. afarensis* have revealed a lack of pitting and low complexity values, i.e., no evidence for hard-object feeding (Grine et al. 2006), despite the general robusticity of *Au. afarensis* craniodental architecture (e.g., Rak et al. 2007). Carbon isotopes imply that *Au. afarensis* was a dietary eurytope, as individuals throughout the Hadar Formation were consuming both C_3 and C_4 resources, with the latter being more common (Wynn et al. 2013). The isotopic evidence for *Au. afarensis* has broader implications for hominin evolution, as the time period ~3.5 Ma seems to represent a dietary shift among hominins to C_4-based resources, at least partially, as this trend is also seen in contemporaneous Chadian *Australopithecus* and *Kenyanthropus* (Lee-Thorp et al. 2012; Cerling et al. 2013; Wynn et al. 2013). The proposition that *Au. afarensis* was using stone tools and consuming meat by 3.4 Ma at Dikika, as evinced by purported cutmarked bones (McPherron et al. 2010), requires further evidence.

Australopithecus bahrelghazali

Brunet and colleagues (1996) erected a new species of *Australopithecus*, *Au. bahrelghazali*, for a fragmentary hominin mandible recovered in ca. 3.5 Ma sediments at Koro Toro, Chad. The validity of *Au. bahrelghazali* has been called into question since the mandible shares strong similarity with *Au. afarensis*, known from contemporary sediments at Hadar, Ethiopia (White et al. 2000). The fauna at Koro Toro is similar to that of Hadar, sharing some common elements (e.g., *Kolpochoerus afarensis* and *Parmularius pachyceras*) and hinting at potential faunal exchange across north-central Africa during or before this time (Brunet et al. 1996; Geraads et al. 2001, 2012). Evidence from the Koro Toro bovids suggests open environments as Reduncini and Alcelaphini dominate, while Tragelaphini and *Aepyceros* are notably absent. The absence of other primate taxa at Koro Toro may also point to a lack of canopy cover on the landscape.

Isotopic evidence reveals *Au. bahrelghazali* was incorporating large amounts of C_4 foodstuffs in its diet ca. 3.5 Ma, as evinced by its significantly high ^{13}C values (Lee-Thorp et al. 2012). C_4 sedges with associated tubers and corms provide a potential explanation. The sedge genus *Cyperus* is widely distributed in tropical environments today and is often found around the margins of watercourses in Africa, including modern Lake Chad (White 1983; Lee-Thorp et al. 2012). It is possible that *Au. bahrelghazali* was exploiting sedges or similar plants around waterways, in a predominantly savanna environment. Thus, the dietary evidence would be in concordance with the faunally based habitat reconstruction and shows that Chadian *Australopithecus* lived and died in grasslands, suggestive of some degree of dietary and habitat flexibility in mid-Pliocene hominins considering that contemporaneous sites are typically wooded and well watered (e.g., Hadar).

Australopithecus africanus

Dart (1925) identified this taxon from the Taung mining dumps, and in the next several decades more individuals were discovered at the former cave sites of Sterkfontein and Makapansgat, although at first these hominins were referred to different species (Broom 1938; Dart 1958). Teeth were also recovered from the Gladysvale site in the 1990s (Berger and Tobias 1994). New paleomagnetic and uranium-lead dating of these cave sites suggests an age range of 3.0–2.0 Ma (Herries et al. 2013).

Habitat reconstructions differ for each of these sites. Makapansgat, considered the oldest of the localities, has been reconstructed as a mosaic of riparian woodlands, edaphic grasslands, and bushlands, with possible riverine forests (Dart 1925; Reed 1997). A study of bovid taxa, using both isotope values and ecomorphology of the masticatory apparatus, indicated that there were more browsing taxa than expected, and thus when the fauna was deposited, there may have been more closed woodland bushland than previously thought (Sponheimer et al. 1999). Taung has been reconstructed as dense woodland (Dart 1925; Berger and Clarke 1995); Sterkfontein has been reconstructed as open woodland, riparian forest, and bushland (Reed 1997; Clarke 2013). Finally, Gladysvale is considered to have ranged from closed to open vegetation (Berger and Tobias 1994).

Early works on both dental microwear and carbon isotopes were accomplished on this taxon. Grine (1986) and Grine and Kay (1988) suggested that the diet of *Au. africanus* was likely soft fruit and leaves, based on comparisons with chimpanzee microwear. However, later work on isotopes showed that this taxon had a very large range of carbon isotope values that included both C_3 and C_4 plants (Sponheimer and Lee-Thorp 1999; Sponheimer et al. 2005). Sponheimer et al. (2013) suggests that *Au. africanus* may have had greater population densities than forest-dwelling great apes due to their broad dietary patterns. Finally, Copeland et al. (2011) suggest that in *Au. africanus* females dispersed from their natal group, as evinced by strontium isotope analysis of the hominin teeth from Sterkfontein.

Australopithecus garhi

Australopithecus garhi is an enigmatic species of hominin known from a maxilla with complete dentition and postcranial remains from the Hata Member of Bouri, Ethiopia, ca. 2.5 Ma (Asfaw et al. 1999). The habitat of *Au. garhi* was reconstructed as grassy margins around a large freshwater lake, as evinced by high proportions of alcelaphin bovids and water-dependent taxa including hippos and crocodiles. If some Omo specimens are attributable to *Au. garhi*, as suggested by White (2002), this would place *Au. garhi* in a wetter and more heavily wooded environment than it is found in at Bouri (Bobe and Eck 2001; Bobe et al. 2007).

The remains of *Au. garhi* at Bouri are associated with zooarchaeological evidence for butchery and meat consumption. Cutmarks and percussion marks from stone tools were found on bovid and equid bones during the excavation of the BOU-VP-12/1 locality (de Heinzelin et al. 1999). The oldest stone tools occur at Gona about 2.6 Ma and are therefore roughly contemporaneous with the occurrence of cutmarked bones in the Hata Member (Semaw et al. 1997).

Australopithecus sediba

Discovered in August 2008 (Berger et al. 2010), this species appears to combine a more derived dentition with a primitive australopith body plan. Indeed, its generic attribution to *Australopithecus* was questioned during initial publication. Carbon isotopes indicate *Au. sediba* was feeding primarily on C_3 plant resources, and wood or bark has been suggested as a potential component of the diet, based on phytoliths recovered from dental calculus (Henry et al. 2013). It is interesting that *Au. sediba* incorporated no or very few C_4 food in its diet, as this is generally opposite the pattern observed in East Africa *Australopithecus*, with the exception of *Au. anamensis* (Sponheimer et al. 2013), although this may be an artifact of the small sample size of *Au. sediba*, as the Hadar hominins vary greatly in their isotopic signatures and thus the Malapa hominins could be sampling only the C_3-end of the spectrum.

Paranthropus aethiopicus

Arambourg and Coppens (1968) named a new species of hominin, *Paraustralopithecus aethiopicus*, and designated an edentulous mandible from Member C of the Shungura Formation as the holotype. The species was later realized to be the oldest member of the genus *Paranthropus* once the "Black Skull" KNM-WT 17000 was discovered (Walker et al. 1986).

The Omo habitat of *Paranthropus aethiopicus* was likely dry, closed, and wooded, since the lower part of the Shungura Formation shows a shift from wet woodlands in Member B to drier woodlands in Member C (Bobe and Eck 2001). *Paranthropus aethiopicus* has recently been reported from the Ndolanya Beds of Laetoli and is placed into the context of a savanna habitat with nearby woodland (Harrison 2011).

Cerling et al. (2013) found that Turkana Basin specimens of *P. aethiopicus* were characterized by diets high in C_4 content, as C_3 plant material comprised 50 % of the diet or less. Notably, 85 % of the diet of KNM-WT 17000 was found to derive from C_4 resources. This trend apparently continued in the eastern African *Paranthropus* lineage, as *P. boisei* typically exhibits the highest C_4 values of any hominin species for which we have isotopic data.

Paranthropus robustus

This taxon was discovered and named by Robert Broom (1938) at the Kromdraai mining site. Individuals have been recovered since that time at other cave locations in South Africa: Swartkrans, Drimolen, Gondolin, and Coopers D. Habitat reconstructions for these sites (except Drimolen) show them to be open woodland and grassland, although there always appears to be water in the form of rivers or wetlands in the vicinity as represented by the fauna (Brain 1993; Reed 1997; de Ruiter et al. 2009).

Robinson (1954) first suggested that *P. robustus* ate harder and different foodstuffs than *Au. africanus* because of the differences in the morphology of the masticatory apparatus in the two taxa. Grine (1986) tested this hypothesis by examining the microwear of both taxa, concluding that *P. robustus* had heavier pitting on its molars, and therefore a harder diet. Isotopic data suggest that this species ate a broad range of plant material ranging from trees and shrubs to grasses, i.e., C_3 and C_4. Strontium isotopes also suggest that the female of this species was the sex to leave the natal group, if the smaller teeth represent female individuals (Copeland et al. 2011). Finally, a study by Grine et al. (2012a) suggests that extremely large males of this species may be missing from the fossil record, as a large molar from Gondolin exceeds the size specifications of most other males. These researchers propose that taphonomic biases against these larger individuals have underestimated sexual dimorphism in this species.

Paranthropus boisei

The paleobiology of *Paranthropus boisei* has been the subject of debate since its initial description as *Zinjanthropus boisei* by Louis Leakey (1959). Consequently, more research has been devoted to the dietary and habitat preferences of *P. boisei* than to virtually any other hominin. Leakey dubbed OH 5 "nutcracker man" because of its dished and buttressed face, prominent sagittal crest, huge postcanine dentition, and nubby anterior teeth. Everything about the craniodental morphology of OH 5 seemed adapted for crushing hard, brittle food items with powerful jaw muscles, and this view persisted until relatively recently (e.g., Wood and Strait 2004).

P. boisei has been often linked with a closed and mesic habitat preference (Shipman and Harris 1988) although specimens of *P. boisei* from Konso in southern Ethiopia are associated with an arid grassland fauna (Suwa et al. 2003), similar to the habitat of *P. boisei*'s presumed ancestor *P. aethiopicus* in the Upper Ndolanya Beds of Laetoli (Harrison 2011). Reed (1997) found that *P. boisei* was found in more open environments and that *P. aethiopicus* was associated with closed habitats. At Olduvai, *P. boisei* specimens from Bed I and lower Bed II are associated with woodland environments, although habitats tend to appear wetter in the latter due to the presence of the Olduvai paleolake (Sikes 1994; Kovarovic et al. 2013).

The occlusal microwear of *Paranthropus boisei* is low in complexity and anisotropy values, similar to *Au. anamensis* and *Au. afarensis* (Ungar et al. 2008; Ungar and Sponheimer 2011). The evidence from microwear throws doubt on the title of *P. boisei* as "nutcracker man" and is instead suggestive of a frugivorous diet. Fallback hypotheses have been put forth to explain the discrepancy between the hyper-robust craniodental morphology of *P. boisei* and the evidence from microwear studies. Was *P. boisei* preferentially eating soft and fleshy food resources (i.e., fruits), only consuming harder and more brittle foods during times of resource stress? More evidence is needed, and the carbon isotope data make the story even more puzzling.

Cerling et al. (2011b) revealed that the vast majority of *P. boisei*'s diet was derived from C_4 plant sources, using carbon isotope analysis. *P. boisei* was also a highly water-dependent taxon as evinced by low $\delta^{18}O$ values, second only to *Hippopotamus* (Cerling et al. 2011b), throwing support behind mesic habitat reconstructions for the species. C_4 sedges are a potential food source based on the carbon and oxygen evidence, as sedges are often found around the perimeter of East African wetlands today and might also be characterized by relatively low $\delta^{18}O$ values as they are not subject to evapotranspiration pressures facing other terrestrial plant species (Lee-Thorp, 2011). Similarly, van der Merwe et al. (2008) hypothesized that *P. boisei* at Olduvai Gorge was consuming swampy C_4 vegetation, possibly papyrus.

Kenyanthropus platyops

Kenyanthropus platyops is a curious hominin of uncertain phylogenetic placement from mid-Pliocene sediments in West Turkana, Kenya (Leakey et al. 2001). High proportions of Alcelaphini and Antilopini in members of the Nachukui Formation in West Turkana suggest open and arid habitats throughout most of the sequence (Bobe et al. 2007). However, Leakey and colleagues (2001) reconstructed environments in localities LO4, LO5, LO6, and LO9 of the Lomekwi member as well vegetated and relatively wet in their initial publication of *Kenyanthropus platyops*. They report a high proportion of ecotonal (e.g., *Aepyceros*) and forest-dwelling (e.g., *Tragelaphus*) species relative to taxa of other bovid tribes. The synthetic picture of West Turkana during the mid-Pliocene emerges as relatively arid, with patches of woodland, while development of riverine forests was supported by small fluvial systems draining along the western margin of the basin (Leakey et al. 2001).

Carbon isotopes of *Kenyanthropus* dental specimens reveal a flexible diet similar to contemporaneous *Au. afarensis*, with diets spanning the C_3 to C_4 spectrum (Cerling et al. 2013).

Homo habilis

The Maka'amitalu Basin of Hadar is most notable for producing what is generally accepted as the earliest specimen of the genus *Homo*, a maxilla designated AL 666-1, with in situ Oldowan tools dated to 2.3 Ma (Kimbel et al. 1996). Earlier occurrences from Lake Baringo (ca. 2.3 Ma) and West Turkana (ca. 2.34 Ma) in Kenya have been proposed, but the evidence is fragmentary, consisting of a temporal bone and juvenile lower molar, respectively (Hill et al. 1992; Prat et al. 2005). The origin of the genus *Homo* has often been linked with environmental change, primarily in the form of increasing seasonality and aridification during the late Pliocene. It is thought that increasingly arid terrestrial environments and greater oscillations of climate imposed novel selective pressures on the human lineage during this time. For example, Bobe and Behrensmeyer (2004) note, "The fundamental importance of grasslands may lie in the complexity and heterogeneity they added to the range of habitats available to the early species of the genus *Homo*." Furthermore, Vrba (1985) proposed that an environmentally driven turnover in bovids between 2.7 and 2.5 Ma corresponded to the extinction of *Australopithecus* and the origin of *Homo* and *Paranthropus* in South Africa. Although savannas have been implicated as drivers for various events in human evolution (e.g., encephalization, toolmaking, and bipedalism), the expansion of grassland ecosystems in Africa has most often been implicated in the origin of *Homo*.

The paleoenvironment of AL 666-1 is under current study, but preliminary results suggest relatively open and arid conditions with the presence of nearby thickets or woodland. Conversely, Reed and Geraads (2012) reconstructed the Busidima Formation locality AL 894 as a woodland-to-forest habitat that was well watered based on a rodent assemblage dated to ca. 2.4 Ma. Given that these two sites are separated by nearly 100,000 years of time, the results are not mutually exclusive. Throughout East Africa, Reed (1997) showed that *Homo* is often associated taxa indicative of open and arid environments. The Olduvai record of *H. habilis* occurs in more heavily wooded environments and the presence of the Olduvai paleolake in lower Bed II provided a permanent water source (Kovarovic et al. 2013).

Specimens of early *Homo* from the Turkana Basin exhibit dietary breadth and were apparently consuming both C_3 and C_4 resources (Cerling et al. 2013).

Conclusions

In his description of the Taung Child, Raymond Dart proposed savannas were a driving force in human evolution, stating that "… a vast open country with occasional wooded belts and a relative scarcity of water, together with a fierce and bitter mammalian competition, furnished a laboratory such as was essential to this penultimate phase of human evolution" (Dart 1925). Indeed, researchers have recognized the importance of environments in early human evolution ever since Darwin, traditionally focusing on the faunal context of hominin sites. Taxon-free methods like ecomorphology and isotopes have superseded such approaches and new methods are continually being developed, such as woody cover reconstructions based on carbon fractionation from paleosols (Cerling et al. 2011a).

The habitats of the earliest hominins are somewhat perplexing. Faunal evidence implies *Orrorin* existed in a forested habitat and both species of *Ardipithecus* are associated with fairly closed woodland habitats, while *Sahelanthropus* is purportedly associated with savanna and semidesert conditions along a lakeshore. The accumulating evidence for wooded habitat preferences during the early stages of human evolution is in stark contrast to decades of associating the origin of Hominini (and bipedalism) with the expansion of grasslands during the late Miocene. In contrast, Cerling et al. (2011a) recently resurrected the idea that savanna habitats played a large role throughout the course of human evolution and, in conjunction with growing dietary evidence, that some hominins shifted to C_4-dominated diets by 3.5 Ma.

Sites containing *Australopithecus* are often reconstructed as "mosaics," but this could be due to time averaging and depositional processes or actually represent various habitats across the landscape. *Au. afarensis* persists at Hadar despite various environmental changes throughout the Hadar Formation (Reed 2008). *Au. afarensis*, and possibly all of *Australopithecus* species, were habitat generalists. The isotopic evidence supports a broad diet for four of these taxa, if one considers that eating both C_3 and C_4 plants indicates something bordering on a generalist diet. While both *Au. anamensis* and *Au. sediba* appear to have consumed only C_3 plant material, the specifics of those C_3 foods are not known, and indeed an impressive range of plants and plant parts could have made them dietary generalists as well. The microwear evidence presents somewhat of a conundrum when these results are compared with the isotopic data in some species (Grine et al. 2012b; Ungar et al. 2010a). The South African taxa *Au. africanus* and *P. robustus* both exhibit variability in their dental microwear (Grine 1986) that matches the variation in C_3 and C_4 plant foods that they consumed, whereas the East African *Au. afarensis* exhibits extreme uniformity in the microwear scratches on teeth but included both plant types in its diet. It is possible that *Au. afarensis* ate the same types of foods, e.g., roots and tubers, from both C_3 and C_4 plants. In the future, if extraction of phytoliths from dental calculus in these species is possible, a better idea of the actual diet consumed may be available.

The impressive craniodental complex of *Paranthropus* is likely derived from an australopith ancestor ~2.6 Ma that began focusing on some different form of food. This is complicated further by the isotopic differences in the East and South African species. Repetitive loading, i.e., intensive chewing, could provide the adaptive explanation for such headgear. Conversely, various "fallback" explanations have been proposed to explain the discrepancy between microwear, isotopes, and the highly derived craniodental morphology of *Paranthropus* spp., but none is a particularly satisfying explanation. If the massive jaws of *Paranthropus* are in fact adaptations to fallback foods, then it seems likely that *P. robustus* engaged in this behavior more often than *P. boisei*, as the former exhibits pitting and high complexity values indicative of hard-object feeding (Ungar and Sponheimer 2011). As the jaws and teeth of *P. boisei* are even more robust, this is an obvious area for further study.

The role of environments in human evolution is as important as ever, and improving the accuracy of habitat reconstructions is critical as we delve deeper into the autecology of the earliest hominins with the refinement of microwear, isotopes, biomechanics, and other analyses. While it is true that most African habitats are somewhat mosaic in that they contain a diverse vegetation physiognomy, a more careful consideration of taphonomic and depositional biases, especially time averaging, is warranted. For faunal habitat reconstructions, the use of taxon-free methods (e.g., enamel isotopes) over taxon-based methods (e.g., tribal relative abundance) is encouraged because the latter involves considerable assumptions. In closing, while this chapter provided only a brief summary of methods and reconstructions of hominin habitats, the subject is worthy of a lengthier review. New methods are continually being developed and often contradict what we thought we knew about human evolution, and an in-depth synthesis of current lines of evidence would benefit all researchers in paleoanthropology.

Geological Background of Early Hominid Sites in Africa

Ottmar Kullmer

Contents

Abstract

Hominid remains are rare elements in the fossil record. Probably, the small population sizes of early hominids, in combination with preservation constraints, limit any probability of a higher frequency of fossil discoveries. The early evolution of mankind appears to be a Pan-African story, even though the distribution pattern of remains concentrates on eastern and southern Africa. More recent findings from the Chad Basin in central Africa demonstrate that fossil hominid remains are not restricted to the eastern part of Africa. The success of exploration in paleoanthropology depends on the discovery of appropriate sediment layers, mainly lake and river deposits with an upper Miocene through Pleistocene age. Knowledge of the geological framework is of great importance in evaluating the potential for fossil preservation in a certain area. To date, three major types of geological megastructures have yielded almost

all fossil remains of early hominids: the East African Rift Valley (EARV), the intracratonic basin of Lake Chad, and the fossil-rich cave deposits in South Africa. Each of these regions provides a unique sedimentary setting bearing fossil-rich layers comprising a specific time-span within the last few million years.

Introduction

The fossil record of humans is scanty, and discoveries are rare. It seems that the farther back in time we go, the fewer the fossil remains we can expect (Cooke 1983). There are probably several factors involved in diminishing the hard evidence of our own evolution. When a mammal dies in the open, scavengers will immediately work on the carcass, scatter its pieces, and probably destroy the bones (Shipman 1981). The surviving parts may be exposed to the hot sun during the daytime, and cooled down at night. Extreme temperature differences between day and night lead to cracking due to loss of water and reduction of organic material in the bone fibers. Usually, this process is accompanied by the activity of microorganisms, and may be also by physical transport in riverbeds or on floodplains during torrential rain falls. All of this modifies the original surface of bone, or even breaks elements apart. Most of the time, the history of an animal body ends in its complete destruction, unless the bones are covered and protected, e.g., by rapid burial with sediments (Cooke 1983). Sometimes animals are trapped in cavities, like fissures or pits, and their bones are preserved articulated. But even if we have a favorable environment for rapid covering, most of the time, postburial chemical and physical processes are destructive, with some rare exceptions favored by special geological environments.

For this reason, the search for hominid fossils depends at a larger scale on the geological setting, because the sedimentary environment is a limiting factor upon chances of finding early hominids. Due to the multifarious influences for destruction, each fossil we collect seems to be a stroke of luck. In Africa, the hunt for the discovery of the origin of mankind concentrates on three major types of geological settings with a great potential for new discoveries. These are graben structures (e.g., Chorowicz 2005), cave deposits (e.g., Brain 1981), and intracratonic basins (e.g., Vignaud et al. 2002) that developed during the last 8 million years (Ma), after the hominids diverged from their last common ancestor with the African great apes. Consequently, the East African Great Rift Valley (EARV), with its widespread outcrops of fossil-rich Miocene to Pleistocene deposits, presents a unique situation for paleoanthropological field research. The Rift provided permanent water sources for our oldest ancestors and a rich fauna (WoldeGabriel et al. 2001; Pickford and Senut 2001). A very similar situation is found in intracratonic basins like the Chad depression, occurring as relatively static systems with large lake transgression and regression cycles, varying in time, and sometimes producing fossiliferous deposits of enormous lateral extension (Vignaud et al. 2002). In contrast, the famous South African cave sites, Makapansgat, Sterkfontein, Swartkrans, and Kromdraai, were formed by extensive freshwater karstification and sedimentation processes, and their complex cavities were used as shelters for hominids and probably functioned also as traps and scavenger caves (Brain 1981).

Geological and paleoanthropological research at African hominid sites has produced a rich database during the last century (Bromage and Schrenk 1999). Today the geological background information influences the search for the origin of humankind, and the growing knowledge about geology helps us to understand the processes of fossilization and supports the interpretation of individual situations at fossil localities. And the application of digital geographical information systems (GIS), in combination with high-resolution satellite images, has provided a huge additional database for field investigations (e.g., Anemone et al. 2011). Potential fossil localities, in Rift valleys, intracratonic basins, and karstified limestone, can be localized by satellite image analysis. Nevertheless, extensive surveys by experienced field teams will continue to be the fundamental basis for the discovery of new fossil hominid remains (Fleagle and Gilbert 2008).

Geological Setting

The geological setting at hominid localities is not only an important source of information about environmental settings and changes through time in specific localities or areas, but also an indicator of the probability of finding fossilized bones; and it is therefore an essential aspect influencing survey strategies. Moreover, it is an important aspect of the transfer of knowledge relevant to a broad understanding of human evolution as a Pan-African story (Schrenk et al. 2004).

Sedimentary formations with a high potential for fossilization are the required geological setting. These consist of deposits that are products of weathering and transport, erosion, and deposition. Sediments are a mixture of different minerals and organic materials deposited on the earth’s surface, or in caves, in interaction with the atmosphere, hydrosphere, and biosphere. Common examples are clays, silts, sands, gravels, and breccias. Due to subsidence of some hundred meters, up to a few kilometers, deposits are typically transformed into sedimentary rock, like sandstone, claystone, or limestone.

Accumulation areas of sediments are divided into marine and continental depositional space.

Even if some of the fossil sites, like Saldanha or Klasies River Mouth in South Africa, are located closely to the ocean shoreline, the most important hominid fossil sites are located in continental deposits. Potential continental bone accumulation localities are fissures, caves, swamps, tar pits, river channels, flood plains, lagoons, and lakes. Such depositional areas can be described as geomorphological units characterized by climate, size, and shape of a sedimentary basin. Geometry and composition of sediments, and the relationship between units, provides information about the milieu of deposition (Reineck and Singh 1980). Physical, chemical, and biological parameters (Table 1) inform us about the depositional environment and climatic conditions. These parameters have to be recorded during fieldwork. The sum of all primary characteristics of a sedimentary unit defines the sedimentary

Table 1 Sedimentary parameters of depositional environments

facies (Reineck and Singh 1980). The analysis of the facies permits us to understand the sedimentary factors responsible for the appearance of the deposit and the fossils.

Medium, current, wave intensity and velocity, as well as water depth, are relevant physical factors (Table 2); these are the important hydrodynamic conditions for the transport of animal remains. Mineral and groundwater composition, including climate, are understood to be the chemical factors of sedimentation and fossilization. Fortunately, sediments sometimes contain biological factors, faunal and floral remains, in different stages of preservation. The appearance of animal remains in a sedimentary matrix depends on its so-called taphonomic history (Shipman 1981). The taphonomy (Efremov 1940) includes two processes, biostratinomy and diagenesis, that describe the pathway from a carcass to a fossil. Biostratinomy (Weigelt 1927) deals with everything that happens to a carcass after an animal's death, before the remains are buried. Afterward, the fossilization process, including mineral exchange and compaction, is called diagenesis. The fossilization process reduces information about an animal, but it also tells us a story that contains information about the paleoenvironment. The possibility that parts of a given animal will survive for some million years is relatively low due to taphonomic factors. Fossils are not randomly distributed. There are only a few spots on earth where we can find mammal remains, and there are even fewer places where we can discover hominid fossils. In most assemblages of large mammals from a single locality, the abundance of hominid specimens is less than 0.5 %.

Nevertheless, the number of collected fossils has increased rapidly during the last decades. More and more research teams, with sophisticated survey strategies, explore for and investigate new fossil sites (Urbanek et al. 2005; Kullmer et al. 2008). Extensive sedimentologic and taphonomic analyses at known localities lead to a broad understanding of fossil site creation (Bobé et al. 2007).

Commonly, the geographical distribution of hominid localities is used to interpret the origin of mankind and the migration patterns of early hominids (Coppens 1994). One has to consider, though, that the interpretation of the biogeography of a species, or even of an evolutionary lineage, can be heavily biased by the factors mentioned earlier, as well as by others such as burrowing and the preservation of animal remains (chapter "▶ Taphonomic and Diagenetic Processes," Vol. 1).

White (1988) pointed out that the fossil record in eastern Africa is biased toward a representation of the watered axial basins. Classic hinterland sites lacking permanent water sources, e.g., Laetoli, are rare indeed. But this does not imply that these were minor constituents; they may just have not been discovered yet. The preservation of fossils is heavily dependent on the sedimentological environment (e.g., WoldeGabriel et al. 2009). Fluviatile milieus do not necessarily grant permanent burial; many of the fossil localities in eastern Africa are associated with rivers, and a migrating channel bed can alter even a lake margin or a floodplain within a short time period.

Chances of finding an original bone association decrease with the transport distance from the point of origin. When discovered, the bone assemblage is likely to represent different individuals from different localities and different time periods (Hanson 1980). Time averaging, the mixing of noncontemporaneous populations, has also to be considered when interpreting the history of bone assemblages. Nevertheless, beside sedimentological factors, the effects of time averaging are also dependent on stable or highly fluctuating populations (Behrensmeyer and Chapman 1993).

East African Rift Valley

If we look at the geographical distribution of early hominid findings in Africa, we recognize that many of the famous sites are aligned in a chain along eastern Africa from Ethiopia via Kenya and Tanzania, to Malawi in the southeast. Localities like Hadar, Middle Awash, Omo, Lake Turkana, Olduvai, Laetoli, and others have yielded a great number of hominid specimens during the last 50 years (chapters "▶ The Species and Diversity of Australopiths," "▶ The Earliest Putative *Homo* Fossils," and "▶ The Miocene Hominoids and the Earliest Putative Hominids," Vol. 3). These sites are positioned in a geological megastructure, the EARV (Fig. 1). The EARV extends about 6,400 km from northeast to southeast.

The suture of the EARV follows a fault zone in the Continental crust. Plate tectonics explains the process of break-apart and rifting (Chorowicz 2005).

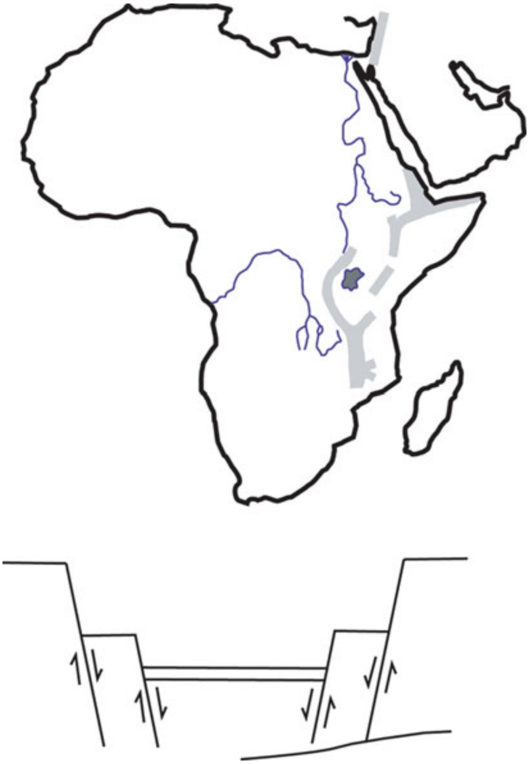

Fig. 1 The geological megagraben of the EARV (*gray area*) with its famous hominid sites extends over more than 6,400 km from the Gulf of Aden and the Red Sea in the north into the Indian Ocean in the southeast, at the level of Madagascar. The main rift splits into eastern and western branches just north of Lake Victoria. A schematic transverse section (*below*) through the Rift Valley shows that the graben shoulders are composed of a stepped block-system separated by normal faults. The center is lowered due to crustal extension and divergence and uplift of the shoulders

The Nubian and Somalian plates diverge along the main rift axes and result in a great graben with an average width of 30–40 km. The flanks are uplifted, while subsidence forms the graben floor. Active east–west extension leads to an enlargement of the accumulation space. A sedimentary fault basin develops as soon as the subsidence is great enough that an initial drainage system grows along the main faults. Minor rivers and alluvial fans transport material into the basin from the rift shoulders. A complex erosion-sedimentation interaction system starts in the active rift zone.

The expression "rift," or "rift valley," can be traced back to the definition of Gregory (Gregory 1896). Accordingly, a rift valley, like the Malawi Rift, is a parallel-sided down-faulted valley some tens of kilometers in width and at least a few hundred kilometers in length (Ring and Betzler 1995). Several smaller-scaled tectonic structures, like halfgrabens, horsts, warped blocks, major faults, transform faults, and pull-apart basins can occur within a rift system. All these geological structures provide space for accumulation, and for erosional processes to bury and unearth skeletal remains.

In the history of a mature rift system, diverse environmental settings may be recorded, representing a wide range of habitats (chapter "▶ The Paleoclimatic Record and Plio-Pleistocene Paleoenvironments," Vol. 1). Rifting may end in a marine transgression phase and the birth of an ocean, when the continental breakup continues and rift floor subsidence extends toward the coast, as we can observe happening in the Red Sea and the Gulf of Aden. In other cases, the rifting dynamics may stop after some active phases.

The EARV is probably one of the most attractive and interesting rift systems, reflecting several stages of rift development in its longitudinal extension. It therefore provides an important field of research for understanding crust breakup in a continental setting. Over the last 110 years, extensive research has been focused on the EARV (Gregory 1896; Wegener 1912; Krenkel 1922), making the East African rift system one of the best documented continental rift systems on Earth (Ring and Betzler 1995). Two areas have been of major interest: the Ethiopian Afar Triangle (Baker et al. 1972; Mohr 1987) in the Northeast at the horn of Africa, because of its special rifting situation as a triple junction of three crustal plates (Beyene and Abdelsalam 2005); and the Kenyan or Gregory Rift (Baker et al. 1972, 1988; King 1978; Crossley 1979; Strecker et al. 1990), as the eastern branch of the graben system.

Extensive magmatism and volcanism has accompanied sedimentation in the graben. The oldest rifting phases are recognized in the northeastern part, at the western boundary of the Sinai Peninsula marking the boundary of the Arabian plate. The Red Sea and the Gulf of Aden are probably the oldest segments of the rift system, starting with its initial uplifts and doming of the crust, probably in the Oligocene. Initial volcanism is evident as early as the Eocene (e.g., Trap series), producing widespread lava (Beyene and Abdelsalam 2005). In the Miocene, thick flood basalts produced by large shield volcanoes filled the proto-rift in the Afar region. A highly active rifting phase followed in the Miocene, and produced accumulation space for extensive sedimentation of the erosional material from the rift shoulders and the rift volcanism. Sedimentation was always interrupted or accompanied by flood basalts and other volcanic eruptions, changing the landscape and sedimentation environments within the basins.

There is no doubt that due to the spreading process, the EARV witnessed some habitat changes in eastern Africa. Faulting, uplifts, and subsidence support the development of all common fluvial processes, with meandering and braided rivers, flood plains, alluvial fans, oxbow lakes, and natural levees. Major rift lakes, like Lake Turkana, developed permanent water sources during long-term transgression phases. Regression/transgression cycles are evident through changes in sedimentary formations (Frostick et al. 1986).

Afar Depression

The Afar Depression in Ethiopia (Fig. 2) is one of the world's hotspots in two ways. The temperature can climb up to more than 45 °C during daytime in the endless plains of the Afar, and fieldwork is a great challenge in the extreme African sun. Still, for paleoanthropologists and paleontologists who deal with the evolution of early humans, this investigation can be of the greatest interest since the area of

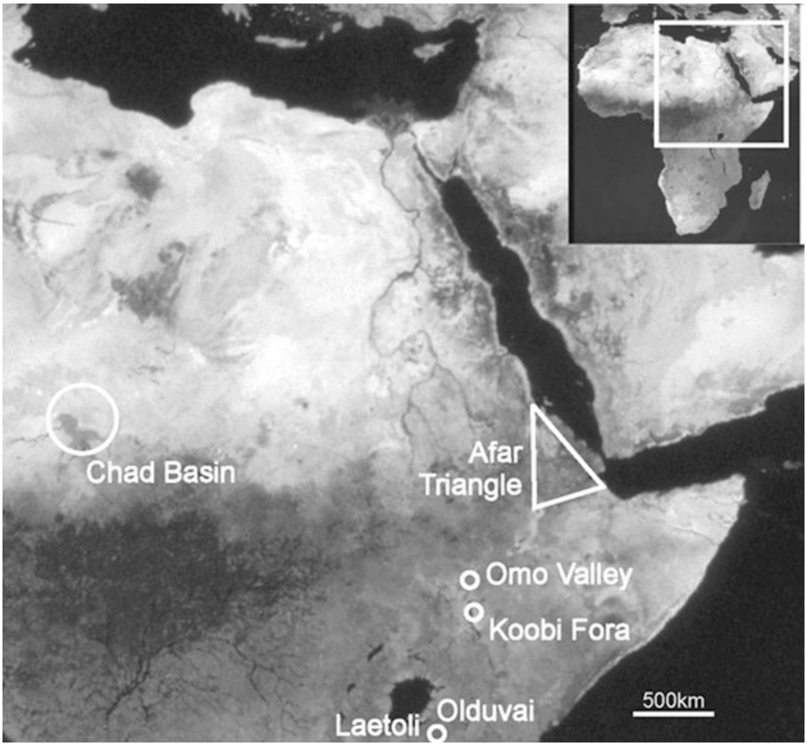

Fig. 2 The outlines of the Afar depression in the northeast of Ethiopia draw a triangle of about 150,000 km^2. This huge basin contains fossiliferous sediments ranging in age from the Upper Miocene to recent times. The most famous hominid localities in the Afar triangle are at Hadar and in the Middle Awash. The Omo Valley is located far south in the main rift, where the Omo river crosses the border into Kenya. The fossil-rich area of Koobi Fora belongs to the Lake Turkana localities in Kenya, where thick sediment deposits surround the recent Lake. Olduvai and Laetoli are positioned within the eastern branch of the EARV, while the Chad Basin reflects an intracratonic depression about 2,500 km west of the Great Rift Valley with widespread deposits of the ancestral Lake Chad

about 150,000 km^2 bears some of the richest hominid sites in the world. In that context, the Afar Depression contains fossils from the earliest time interval of humankind, 5–6 Ma, right up to the youngest (WoldeGabriel et al. 2001, 2009).

Since the beginning of the 1970s, the Afar Triangle has been in the spotlight of international paleoanthropological field research. Numerous hominid findings, like the skeleton of the famous “Lucy,” come from here (Taieb et al. 1974,) (chapter “▶ The Species and Diversity of Australopiths,” Vol. 3). Paleontological work in Ethiopia started in 1902, when the Frenchman Robert de Bourg de Bozas discovered fossil-rich deposits in the lower Omo Valley north of the Kenyan boundary (Fig. 2).

Nevertheless, the first fossil hominid from Ethiopia, a lower jaw, was discovered only in 1933, in a cave close to Dire Dawa in the east. Likewise in 1933, the French paleontologist Camille Arambourg led an expedition to the fossiliferous sediments of the Omo River (Arambourg 1933). Although no hominid remains were discovered during the field trip, the team collected numerous animal fossils (Arambourg 1947). In 1967, an Ethiopian-American-French-Kenyan team under the direction of Clark Howell and Yves Coppens, and with the collaboration of Camille Arambourg, started the intensive search for hominid fossils in the Omo region (Arambourg et al. 1967; Arambourg and Coppens 1968a, b; Coppens et al. 1976). By 1973 they had recovered several hominid remains in the Usno, Mursi, and Shungura formations in the Omo River Basin. This initiated a "hominid-rush" in Ethiopia, which continues today.

When the French geologist Maurice Taieb in 1970 announced the discovery of fossil-rich deposits at Hadar, further north in the Afar depression, the search for hominid remains shifted into the Afar region (Taieb et al. 1972, 1974). It was at Hadar that Donald Johanson and his team found the most complete *A. afarensis* skeleton in 1973 (Johanson et al. 1978). Inspired by a Beatles song, they named it "Lucy" (Johanson and Edey 1981). From 1975 to 1978, the American geologist Jon Kalb explored, with his colleagues of the "Addis Abeba Rift Valley Research Mission in Ethiopia" (RVRME), the sediments in the "Middle Awash" region (Kalb et al. 1982a, b), where they documented one of the best known lithological sequences in the Afar Triangle containing fossil evidence of human evolution. The sediments cover a time-span of more than 6 Myr. Intercalated volcanic ash and lava horizons permit the absolute dating of sandwiched river and lake deposits, and thereby provide a unique insight into the evolutionary history of humankind. Since the early 1990s, Tim White and his "Middle Awash Research Project" have investigated these deposits successfully, collecting a large mammal assemblage including numerous hominid fossils such as the first remains of *Ardipithecus ramidus* (chapter "▶ The Miocene Hominoids and the Earliest Putative Hominids," Vol. 3) (White et al. 1994). Since the of 2000, the international PAR-Team (Paleoanthropological Research Team), under the direction of Horst Seidler, has investigated deposits further south of the "Middle Awash" in a fossil-rich area in the Somali region called Galili (Weber et al. 2001), about 100 km north of the Awash railway station and town, in the vicinity of the rift shoulder (Macchiarelli et al. 2004; Urbanek et al. 2005; Kullmer et al. 2008).

Central Rift

Further South in the EARV, in the Turkana Basin of northern Kenya, Richard Leakey and his team started to explore the eastern shore of Lake Turkana from 1968 through the early 1970s (Leakey and Leakey 1978), while investigations in the Omo River Valley were continuing. They surveyed the areas in the vicinity of Koobi Fora (Fig. 2), a place where fossil bones were reported as early as 1940, and mentioned by the District Commissioner of Marsabit to Dr. L.S.B. Leakey, Richard Leakey's father (Leakey 1978). The Koobi Fora Research Project collected fossils including many hominid remains from Plio-Pleistocene lake, river and flood plain silt, and sand deposits that are bordered by Miocene volcanic lava in the east and south, and by the recent Lake Turkana in the west.

Extensive volcanic activity accompanied the rifting process along the major axis of the rift valley, forming depositional bodies with material from ash rains and lava flows. Those tuffs, basalts, and ignimbrites are important marker horizons, intercalated in the sediment successions. Radiometric dating allows the determination of their absolute age, and therefore also of the sandwiched fossil-bearing sediments at many hominid sites, in a region running from north of Lake Turkana in the Omo Valley, along the eastern and western shoreline, and into the southwest at Kanapoi and Lothagam. The sediment succession tells a story of transgression and regression phases during the development of the great graben (Trauth et al. 2005). Today, sediments of different age outcrop at the same level alongside them, due to small-scale tectonics producing uplift and subsidence of single blocks and leading to a patchwork of sedimentary deposits. To sort the sediments into a logical lithostratigraphic column at a particular fossil locality is one of the many challenges for sedimentologists reconstructing the sedimentary settings. It took many years to reconstruct the development of the sedimentary bodies deposited during the last 6 Myr at Lake Turkana.

Further south in the EARV, the axis of the major graben seems to be nebulous. On a larger scale, the continental fracture in the earth's crust splits in northern Tanzania into western and eastern branches, forming a large island structure between them that holds an intracratonic basin, a large depression with Lake Victoria at its center. The western branch of the EARV, with its northern deposits at Lake Albert in Uganda, has also produced a rich fauna, eroding from lake beds and river deposits from the Upper Miocene onward (Pickford et al. 1993).

So far no hominid fossils have been discovered in these sediments, whereas in the southern part of the eastern branch, the fossil localities of the famous Olduvai Gorge in northern Tanzania have produced many hominid remains. In the vicinity of Olduvai, a remarkable magmatic province, with the Ngorongoro caldera, Lemagrut, Sadiman, and Oldeani volcanoes, produced immense amounts of ash during Plio-Pleistocene times, including the thick volcanics that mark the base of the Olduvai succession. The volcanic eruptions supported the creation of a fossil site that seems to be unique in the EARV. Most likely the oldest volcano, Sadiman (K-Ar age of 3.7 Ma), was the source of the volcanic sediments of the Laetoli region (Hay 1987). The distinctive geochemical composition is compatible with the Laetolil Beds, while Lemagrut and Ngorongoro produced lavas of a different petrology. The fossiliferous Laetolil Beds, close to the village Endulen, were discovered by some local Masai. Erosional processes unearthed several hominid remains, and in addition, a rich fauna was discovered. The first hominid remains at Laetoli were collected by a German explorer, Kohl-Larsen in 1939, 4 years after the first visit to Laetoli of Mary Leakey. She traveled again to Laetoli in 1959 (Leakey 1987), while she and her husband Louis were excavating in the sediments of the famous Olduvai Gorge in the North. Later in the 1970s, Mary Leakey discovered one of the most remarkable pieces of evidence for the upright gait of early hominids: a footprint trail in a volcanic ash deposit. The lowermost sediments, the Laetolil Beds, were deposited on an uplifted peneplain prior to movement along the Eyasi Fault (Hay 1987), a large fault creating the steep Lake Eyasi cliff. Some modern inselbergs give evidence of the uneven surface of the peneplain, where the sedimentary deposits in the valleys mark the paleodrainage and point to east–west as the major flowing direction. Obviously, the steep Eyasi fault did not exist when the water-laid deposits developed (Hay 1981), because today the river systems in the south flow more or less perpendicular to the Eyasi fault. The Laetolil Beds deposits are divided into dominantly water-laid tuffs in the south, with the addition of extensive aeolian tuffs in the north. In the upper sequence, some lava flows and clay deposits occur. In recent times, doming and resulting uplift led to erosion in the Laetoli region and to the exposure of the stratigraphic sequence of fossil-rich sediments (Ditchfield and Harrison 2011).

Chad Basin

While today water erosion and fluviatile deposition during short and heavy rainy seasons is the most active land-forming process in the eastern African savanna, the Sahara desert is dominated by wind erosion and dune deposition. Brunet et al. (1995) reported the first *Australopithecus* remains far west of the EARV from the desert of central Africa, more than 30 years after Coppens (1961) announced the first hominid discovery in Chad. Since 1994, the Mission Paléoanthropologique Franco-Tchadienne, led by Michel Brunet, has explored Miocene and Pliocene deposits in the Djurab Desert of northern Chad. The deposits are located in a large intracratonic basin, which includes modern Lake Chad in the southern sub-basin, and the Chad lowlands in the northern sub-basin (Vignaud et al. 2002). Fossiliferous sediments in the basin have been known since 1960, when Coppens reported Quaternary fossils from Koro Toro (Coppens 1960).

Recent aeolian deflation in the northern sub-basin formed the Djurab Desert, with arid conditions, while the southern depression, under semiarid to wet conditions, reflects the latest lacustrine episode in the region. A "Mega Lake Chad" existed in Holocene times, but progressive desert extension of the Sahara toward the south reduced the water column of Lake Chad to its present shallow-water situation. An average water depth of 2–4 m can be measured today, and compares with a maximum depth of 180 m during ancient times. The basement of the Chad Basin is built of Precambrian rock, and forms a large depression which is filled with lacustrine, fluviatile, and lake sediments. The fluviatile facies is described by flooding channels, probably deposited during torrential rainfalls, because no mature river system, like meandering or braided channels, is reported (Vignaud et al. 2002).

In the northern sub-basin, extensive aeolian sands contain well-sorted quartz grains, frequently formed since Upper Miocene times as dunes and shifting sands. The fossil content, including rich fish remains, crocodiles, and semiaquatic mammals like hippos, gives evidence of a permanent water source during the time when *Sahelanthropus tchadensis* (chapter "▶ The Miocene Hominoids and the Earliest Putative Hominids," Vol. 3), the oldest known hominid, lived probably in a gallery forest along the shoreline of Proto-Lake Chad. The so-called anthracotheriid unit of the *Sahelanthropus* site is interpreted to be a shallow perilacustrine environment, and consists of a well-sorted and well-cemented sandstone. It yielded all the terrestrial vertebrate remains (Vignaud et al. 2002).

However, the desert already existed in the vicinity, and produced sedimentary material through aeolian deflation that gradually covered the lake floor and also animal carcasses. Along the flat margin of the ancient lakes, drainage systems developed during rainy seasons. Floods reworked the aeolian deposits surrounding the lake. Temporarily thin soil layers developed on floodplains, as confirmed by root casts developed in the major fossil layer at the *Sahelanthropus* locality Toros Menalla (Vignaud et al. 2002). The sedimentary situation in the Lake Chad Basin is controlled by transgression and regression phases of the lake and the Sahara desert (Schuster et al. 2006).

South African Caves

In South Africa, the famous hominid sites of Sterkfontein, Swartkrans, Kromdraai, and Makapansgat (Fig. 3) are formed in a very specific geological setting that contrasts with the eastern African hominid localities. The fossil hominid-containing sediments accumulated in caves developed in Precambrian dolomite limestones, in Plio-Pleistocene times, through extensive karstification. The cave limestones belong to the Malmani Dolomite, which is part of the Transvaal Supergroup (Eriksson et al. 1976). The age of the Malmani dolostones, deposited in the intracratonic Transvaal Basin, is considered to be between 2.5 and 2.6 billion years (Button 1973). The thickness of the deposits reaches 1,450 m in the Sterkfontein area (Eriksson and Truswell 1974), and there is a large sedimentary hiatus from the Precambrian to the Late Tertiary. Abundant faulting and folding of the dolomite limestone makes determining the exact stratigraphic position of the basic cave material difficult. The occurrence of stromatoliths in the Makapan Valley led to the idea that at least some of the limestone sediments had been formed in the intertidal zone (Eriksson et al. 1976) near the shore line of the ancient sea.

The initial cave development probably followed the fracture pattern in the dolomite rock, and extensive and deep karstification took place due to groundwater level changes. A typical feature of the Transvaal karst is the occurrence of a three-dimensional hyperphreatic maze of fissure passages (Martini et al. 2003), although large caverns did develop. As a result of erosion, cave ceilings collapsed and opened larger chambers. Carbonate solutions and mineralization built up thick travertine layers on the floors. The rich travertine deposits attracted miners at the end of the nineteenth century because of their pure calcium carbonate content. On the other hand, the carbonate is responsible for the consolidation of clastic sediments that filled up caverns through openings from the land surface. Sand, chert, dolomite, quartzite materials, and also bones were washed down into the caves. Winds probably brought fine grains, following the law of gravity. Possibly several

Fig. 3 The caves at Makapansgat belong to a large Precambrian dolomite formation (*above*), showing profound karstification and sedimentation during Plio-Pleistocene times. Limestone cavities (*below*) are filled with travertine and characteristic carbonatic bone breccias. Mining for carbonates hollowed the filled cavities and brought thousands of fossils to light. The preservation of the fossils differs from sites in the EARV due to very different processes of site formation

transporting agents led to the high bone accumulation at some localities in the cave systems. Some of the caverns were completely filled up with exogenous material, and their sediments concreted to cave breccias with a fine-grained matrix and carbonate cement. Differences in color and grain size may indicate different modes and phases of sedimentation. Accessing the bones, which are enclosed in the breccias, demands sophisticated physical and chemical preparation techniques.

Gravity and water transport, together with typical processes like collapses, solution, and remineralization, are responsible for the complex geological setting of many of the caves. The extensive lime works in the South African caves brought thousands of bone fragments to light, although blasting operations destroyed many natural features of the caves. Consequently, reconstruction of the diagenesis of the South African cave sites has been a real challenge, and many aspects still need further investigation. The analysis of the taphonomic history of bone accumulations at the South African cave sites needs detailed on-site observations, and also further lab work. Bob Brain and his team investigated many years at Swartkrans before he came up with his last model of cave development, in which he proposed nine diagenetic steps (Brain 1993). The formation started with a probably Miocene cavern below the level of standing water. After the opening of the cave, surface sediment began to accumulate inside the cave. The interpretation of the fossiliferous “pink breccia” of the Outer Cave, which was shown to be an infilled remnant, the Hanging Remnant Unit of Member 1, proved to be especially time-consuming.

Swartkrans Members 1–3 yielded *inter alia* the remains of *Australopithecus robustus*, which is likely to have an age of 1.8–1 Ma. Members 4–5 are Middle Stone Age and ca. 11,000-year-old, respectively.

Extensive investigations at Swartkrans and other South African cave sites have led to definitive models of the development of the deposits, and their fossil content in time and space. The experience and strategies used in the past provide the knowledge, which together with modern dating methods (Pickering et al. 2007) allow further exploration of development of fossil sites in the karstified limestones in South Africa.

Conclusions

Although it seems to be clear that the chance of finding hominid fossils is limited by the factors mentioned earlier, there is no doubt that many fossils still await unearthing, either by erosion or by humans. The types of sediments and the geological contexts likely to yield hominid fossils are known. We just have to look for the right deposits. So far, early hominids have only been discovered in eastern and southern Africa, with the exception of the Chad Basin in central Africa. This is probably due to the auspicious geological setting and time represented in the EARV, rather than reflecting the paleobiogeographic distribution pattern of early hominids, although the occurrence of permanent freshwater sources, represented, e.g., by large rift lakes, probably attracted early hominids, because they were not capable of carrying a larger amount of water from one location to another.

No doubt the hominid richness of the Rift sediments is unique altogether. There is still a high potential to recover more remains at long-known places, because erosion is always at work, and the immense deposits in the EARV are far from fully explored. Huge areas, for instance, in the Afar Triangle and in other places, have never been surveyed for fossils. New techniques, like satellite imagery with a resolution of a few meters on the ground, are of potential help for exploration work. Additionally, airborne survey can provide access to remote places such as the Danakil depression in the northern Afar. Nevertheless, extensive studies of satellite images will almost certainly discover new fossiliferous localities in smaller-scaled graben and basin structures at places in central, western, or southwestern Africa. It seems just a matter of time until the first early hominid is reported from the other side of the African continent.

Paleosols

Gregory Retallack

Contents

Abstract

Soils are known to be products of environmental factors such as climate, vegetation, topographic setting, parent material, and time for formation, so that paleosols, or fossil soils, can potentially reveal changing environments of the past. Evidence from paleosols for past climate and vegetation in East Africa does not support traditional narratives of human evolution during a single transition from primeval forest to dry climate and open grassland. Instead, paleosols indicate climatic oscillations between wet and dry, and alternating expansion of woodland and grassland, since at least 18 Ma (million years ago). Acquisition of dry grassland adaptations such as thick enamel by 18 Ma, adducted hallux by 14 Ma, and cursorial legs by 1.8 Ma, alternated with woodland adaptations such as short stiff back by 16 Ma, erect stance by 6 Ma, and flat face by 3.5 Ma. Our ancestors survived profoundly changing climate and vegetation, with some adaptations lasting only to the next environmental shift, but others proving to be of lasting value.

Introduction

Our species, and its ancestors of millions of years ago, evolved on the soils of Africa (Darwin 1872; Fleagle 1998). Many of those soils have been eroded or altered beyond recognition by deep burial, but many paleosols are buried within floodplain, volcanic, lacustrine, alluvial plain, and cave deposits of Africa (Retallack 2001a). These paleosols provide much of the colorful banding and mottling seen in East African badlands and dongas, including many fossil hominoid localities (Fig. 1). Many fossils of human ancestors come from paleosols (Retallack et al. 1995, 2002; Radosevich et al. 1992; Wynn 2004a, b), which are also records of past environments of our evolutionary antecedents (Fig. 1). Modern soils are known to be products of environmental factors such as climate, vegetation, parent materials, topographic setting, and time for formation (Jenny 1941). These formative factors can be interpreted from fossiliferous paleosols to provide hitherto unavailable details of the habitats of fossil apes and humans.

The vegetation of fossil ape and human sites is central to long-standing theories of the evolution of upright stance. “The hands and arms could hardly have become perfect enough to have manufactured weapons, or to have hurled stones and spears with a true aim, ‘. . . so long as they were especially fitted to climbing trees’” (Darwin 1872). Other ideas are that grasslands selected for upright stance because of the need to be vigilant against predators (Dart 1926), to manipulate small seeds (Jolly 1970), to minimize exposure to the sun (Wheeler 1984), or to cover long distances with less energy by walking (Rodman and McHenry 1980) or running (Bramble and Lieberman 2004). Wooded grasslands and open woodlands are also plausible sites for evolution of upright stance from squat feeding on the ground (Kingdon 2003) or moving between scattered fruiting bushes (Sanford 2003). Alternatively, upright stance may have evolved in forests because it allowed erect-back climbing (Tuttle 1981), hands free to care for premature infants (Lovejoy 1981), phallic display to females (Tanner 1981), or intimidation displays to rivals (Jablonski and Chaplin 1993).

Paleosols are relevant to these questions, because the fine root traces and crumb structure of grassland soils are distinct from the thick clayey subsurface horizons of both woodland and forest soils (Jenny 1941). Woodland and forest soils differ markedly in their clay minerals and chemical composition (Retallack 1997). Even the aquatic theory of human origins (Morgan 1982) can be evaluated from paleosols because mangal, littoral, lake margin, and streamside paleosols are distinguished by virtue of relict bedding and common burrows of crabs and clams (Retallack 2001a).

Paleoclimate also is of interest as a selective pressure on hominoid evolution through drought and other hardships. Paleoclimate was also a primary control of past vegetation in which hominoids found food and shelter. Paleoclimatic shifts to drier climate and more open grassy vegetation have been held responsible for major evolutionary innovations in hominoids and bovids (Vrba 1999), as have changes in degree of climatic variability (Potts 1996). Soils of dry climate have calcareous nodules at a shallower depth than soils of humid climate (Retallack 2005) and also

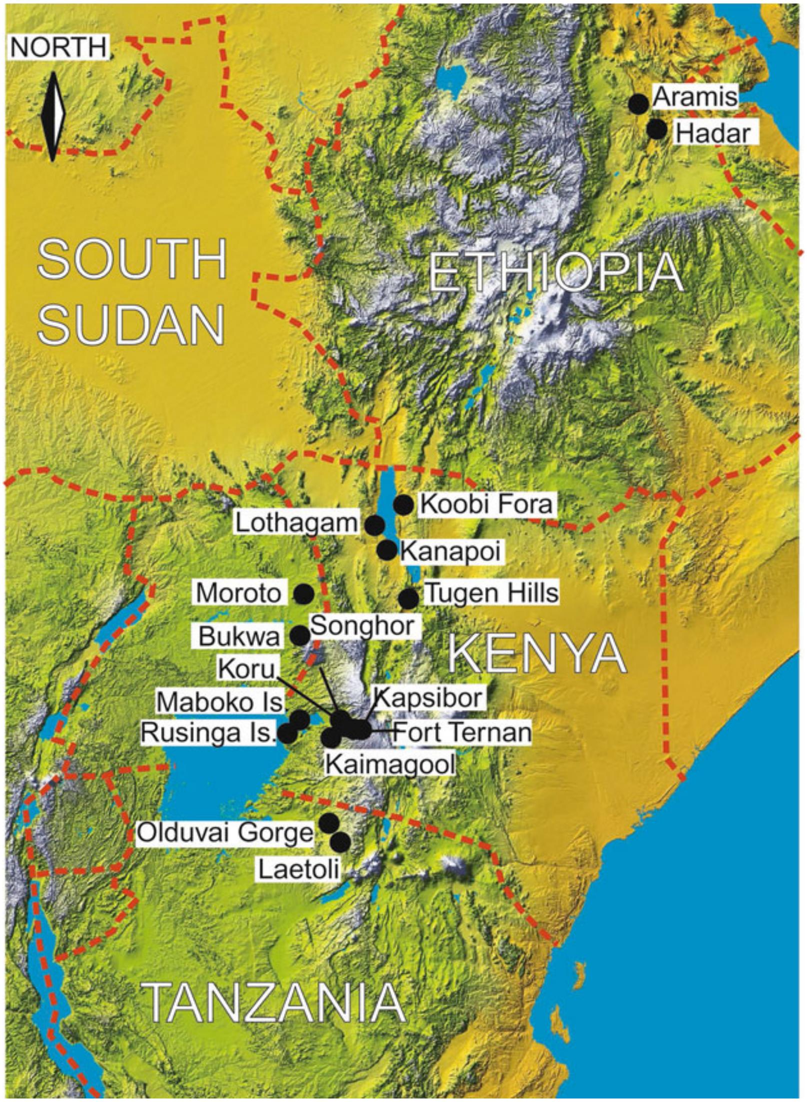

Fig. 1 Localities for paleosol studies in East Africa

are less leached of cationic nutrients (Ca^{2+}, Mg^{2+}, K^{+}, Na^{+}) than humid-climate soils (Sheldon et al. 2002). Paleosols can thus provide paleoclimatic records at the very sites of early human ancestors, rather than inferred from remote records of deep-sea cores (de Menocal 2004).

This review emphasizes climate and vegetation, but other soil-forming factors of parent material, topographic position, and duration of soil formation can also be inferred from paleosols. Highly calcareous and saline carbonatite volcanics are an unusual parent material of many African hominid sites (Retallack 1991a), fortunate because of their remarkable preservative effects for fossil bones, seeds, and insects (Retallack et al. 1995). Many East African paleosols preserve a record of well-drained fluvial terraces, infrequently flooded, and some volcanic apron paleosols represent foothills environments (Retallack 1991a), thus revealing environments beyond the usual lowland constraints of sedimentary environments. Degree of soil development can also be used to infer duration of paleosol formation and rates of sediment accumulation, with implications for the geochronology of ape and human ancestor sites (Retallack et al. 1995, 2002).

Recognition of Paleosols

Paleosols are often distinctive and striking bands of red clay (Bt horizon), calcareous nodules (Bk horizon), or coal (O horizon) in sedimentary and volcanic sequences (Fig. 2). Three general classes of observations are especially helpful in paleosol recognition: root traces, soil horizons, and soil texture (Retallack 1997).

Root traces are the most diagnostic evidence of paleosols, and fossil roots may be made more obvious by erosion-resistant cementation (Kabisa pedotype of Fig. 2). Difficulties arise in recognition of root traces, because they are often replaced by other minerals and ramify in three dimensions in such a way that one rock face reveals little of the overall pattern. Few fossil roots are carbonaceous or reveal histological structures like permineralized fossil wood (Retallack 1997). The original root has commonly rotted out, and the hole it occupied is filled with claystone or siltstone, or encrusted with iron oxide or calcium carbonate. Drab haloed root traces are very distinct, green gray mottles, in reddish paleosol matrix, formed during early burial chemical reduction by microbes fueled by consumption of root organic matter (Retallack 1991b). In all these cases, root traces are truncated at the surface of the paleosol, and branch and taper downward. These features distinguish root traces from most kinds of burrows in soils, although the relationship between burrows and roots can be complex. Roots may preferentially follow soft fill of burrows rather than hard soil matrix, and burrows may congregate around roots on which the burrowing animals fed (Retallack 1991a).

Soil horizons develop through thousands of years, whereas sedimentary beds are deposited in days. Unlike sedimentary beds, which have sharp bottoms and usually sharp tops as well, paleosols have a sharp top, representing the ancient land surface, but gradational lower contacts (Retallack 2001a). Sedimentary beds also include a variety of sedimentary structures, such as lamination, cross bedding, and ripple marks (as in Tek pedotype of Fig. 2), whereas soil horizons develop with obliteration of these original features (Tut pedotype of Fig. 2). Similarly, soil formation progressively destroys the original crystalline structure of volcanic or granitic parent materials (Retallack 1991a). In dry climate soils (Aridisols), primary sedimentary or volcanic structures are obscured at first by filaments and soft, small

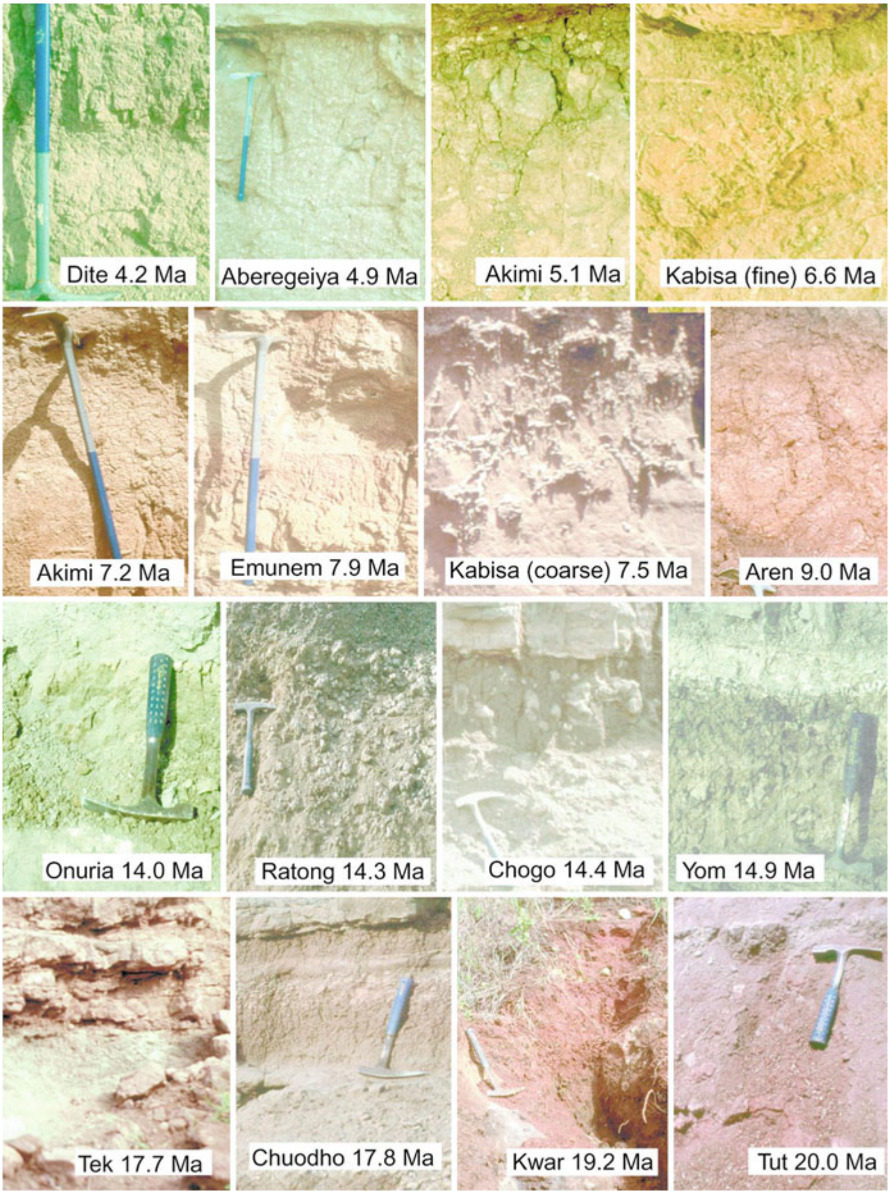

Fig. 2 Kenyan Miocene paleosols have been given field names using local Luo and Turkana languages. These pedotypes are objective field mapping units for paleosols: their interpretation and classification requires laboratory study

carbonate masses, then large, hard, carbonate nodules (calcic or Bk horizon of Chogo pedotype in Fig. 2), and finally thick carbonate layers (petrocalcic or K horizon of Soil Survey Staff 2000). In sod-grassland soils (Mollisols), primary lamination and crystalline structure is broken up by fine roots and replaced by dark, fecal pellets of earthworms to create a crumb-textured, organic surface horizon (mollic epipedon of Dite, Chogo, Yom, and Onuria pedotypes of Fig. 2). A variety of other kinds of soil horizons are recognized and important to soil classification (Retallack 1997, 2001a; Soil Survey Staff 2000).

Soil structure also develops within soil horizons, and is very distinct from sedimentary bedding and igneous crystalline texture. The fundamental elements of soil structure are modified cracks and other surfaces (cutans), and the clods they define (peds). Cutans include clay skins (argillans) lining cracks in the soil and rusty weathering rinds (sesquans) around clods and pebbles in soil (Retallack 2001a). Peds have a variety of shapes: lenticular in swelling-clay soils (Vertisols: Aberegaiya pedotype of Fig. 2), blocky subangular in fertile forest soils (Alfisols: Tut pedotype of Fig. 2), and crumb shaped (small and ellipsoidal) in grassland soils (Mollisols: Dite, Chogo, Yom, and Onuria pedotypes of Fig. 2). Although cracks and other voids are not preserved in paleosols due to compaction by overburden, peds and cutans are common and conspicuous (Retallack 1991a). Other soil structures less diagnostic of soils include concretions, nodules, and crystals (Retallack 2001a).

Methods for the Study of Paleosols

Just as soil individuals (pedons) are studied as soil columns in soil pits, paleosols are studied in columnar stratigraphic sections of the sort also used in sedimentology and stratigraphy (Fig. 3). Grain size is emphasized, because it is important to soil formation, as weathering transforms sand and silt grains to clay. A graphical representation of grain size profiles conveys important information on the abruptness of horizon transitions. Color from a Munsell chart should also be represented, as redness denotes the degree of chemical oxidation and drainage of soils and paleosols. Calcareousness determined by relative effervescence with dilute hydrochloric acid also is important as a guide to chemical leaching and soil nutrient status (Retallack 1997).

Laboratory studies of paleosols do not employ techniques identical to those used in soil science because some important soil measures, such as base saturation, are altered upon burial of soils (Retallack 1991b). Petrographic thin sections are especially useful for revealing soil microfabrics, and the point counting of thin sections furnishes estimates of changes in grain size and mineral composition of paleosols. For example, increased subsurface clayeyness can be used to recognize diagnostic horizons (argillic horizon) for forest soils (Alfisols and Ultisols), whereas traces of nutrient-rich minerals, such as calcite and feldspar, distinguish fertile forest soils (Alfisols) from infertile forest soils (Ultisols: Retallack 1997).

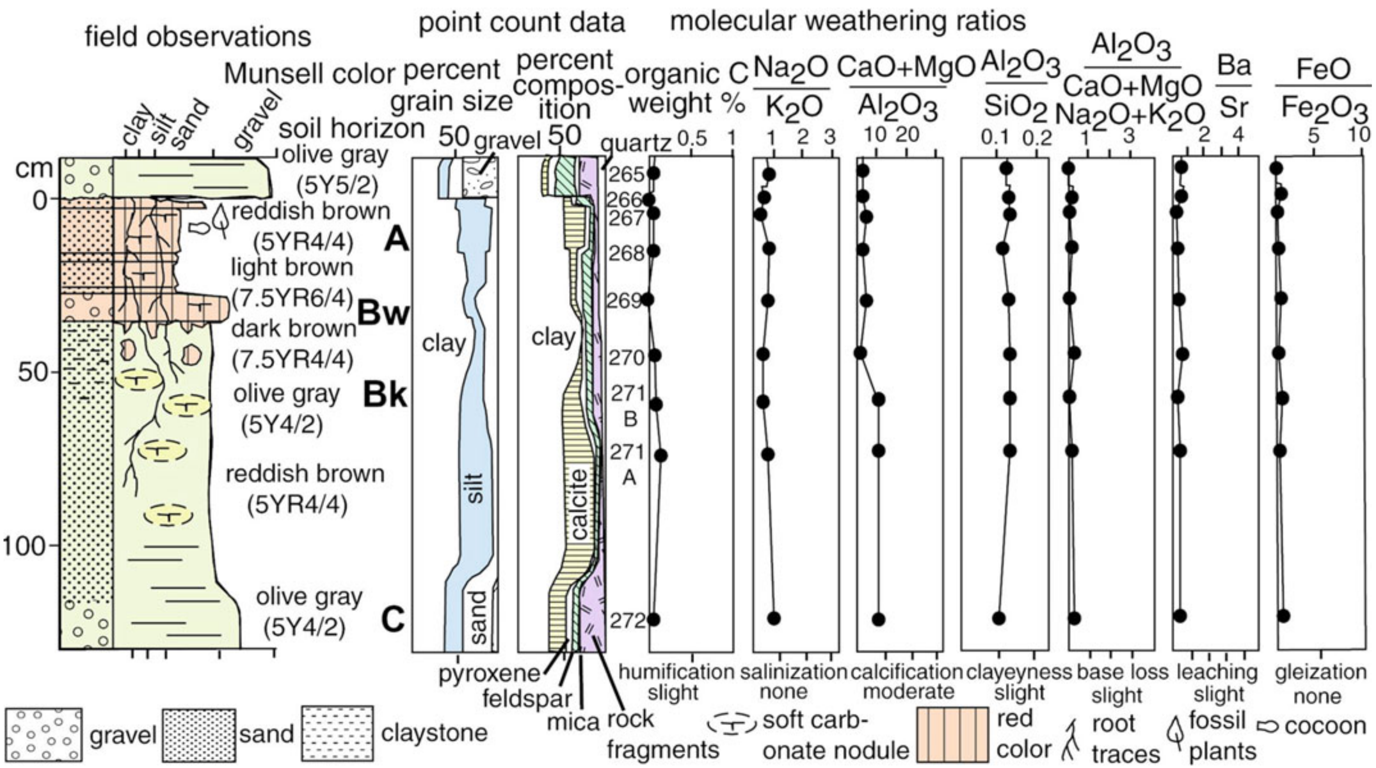

Fig. 3 Petrographic and chemical data for the Tek paleosol from the 18 Ma Hiwegi Formation of Rusinga Island, Kenya [Data from Retallack et al. (1995)]

Chemical analyses also are useful in characterizing and classifying paleosols, especially molar ratios designed to gage the progress of common soil-forming chemical reactions. The hydrolysis reaction common in silicate weathering leaches cationic bases (Ca^{2+}, Mg^{2+}, K^+, Na^+) from host minerals, such as feldspar, to create clay (Al rich) and is thus indicated by high ratios of alumina/bases. An alumina/ base ratio higher than 2 is a good proxy for the transition from fertile forest soils (Alfisols) to infertile forest soils (Ultisols). Soda/potash molar ratios in excess of 1 indicate unusually salty soils. Ferrous/ferric molar ratios in excess of 1 indicate well-drained soils (Retallack 1997). By these criteria, the petrographic and chemical data on the 18 Ma Tek paleosol from Rusinga Island Kenya (Fig. 3) indicate a fertile Inceptisol that was nonsaline and well-drained. These data allow identification of analogous modern soils (Retallack et al. 1995) and refine understanding of the ancient landscape and its ecosystem (Fig. 4).

Carbon isotopic compositions of paleosol carbonate were at first thought to be useful indicators of grasslands, because most tropical grasses have a C_4 photosynthetic pathway which creates isotopically heavy carbon (Cerling 1992). The most prominent failure of this technique was in its application to the Middle Miocene (13.7 Ma) locality of Fort Ternan (Pickford et al. 2006), with paleosol carbonate isotopically like rain forest (Cerling et al. 1997a), but fossil soils, grasses, trees, and antelope like those of a mosaic of wooded grassland and grassy woodland (Retallack 1991a, 1992; Koch 1998; Turner and Antón 2004). Subsequently, it was found that even tropical grasses used the C_3 photosynthetic pathway until about 7 Ma or younger (Cerling et al. 1997b; Fox and Koch 2003). The quality of graze (C_3 more nutritious than C_4) can be assessed by isotopic studies of teeth and paleosols, but the question of grass or shrub diet is better assessed from mammalian tooth microwear, hypsodonty, and cursoriality (MacFadden 2000). The advent of C_4 grasses within tropical grasslands is most likely related to declining Late Miocene atmospheric CO_2 content (Cerling et al. 1997a). Another failure of carbon isotopes to indicate past vegetation is Sike's (1994) forest interpretation of the paleosol at Olduvai fossil locality FLK yielding *Australopithecus boisei*. This paleosol, with relict bedding, zeolites, little clay, and shallow carbonate, is unlike forest soils, and probably supported salt-tolerant, lake-margin shrubs (Retallack 2001a), which have a similar C_3 isotopic value to forest (Sikes 1994). Isotopic values of carbon and oxygen in paleosols and animals are controlled by so many factors that biotic and pedogenic constraints are needed (Koch 1998). Carbon isotopic studies of paleosols are now more useful for assessing atmospheric CO_2 from carbonate and organic isotopic offsets (Ekart et al. 1999) and soil productivity from isotopic depth functions (Yapp and Poths 1994). Carbon isotopic depth profiles of paleosols also provide new insights into carbon cycling within different kinds of ancient ecosystems. Grassland paleosols (Chogo and Onuria pedotype of Fig. 5) show more effective humification at the surface (higher $\delta^{13}C$ values) than woodland soils (Tut of Fig .5), and swelling-clay paleosols have flat carbon isotopic profiles due to soil mixing (Chido of Fig .5). Preservation of such carbon-cycling signatures known from modern soils within different pedotypes gives additional evidence for paleosol classification and interpretation (Bestland and Krull 1999).

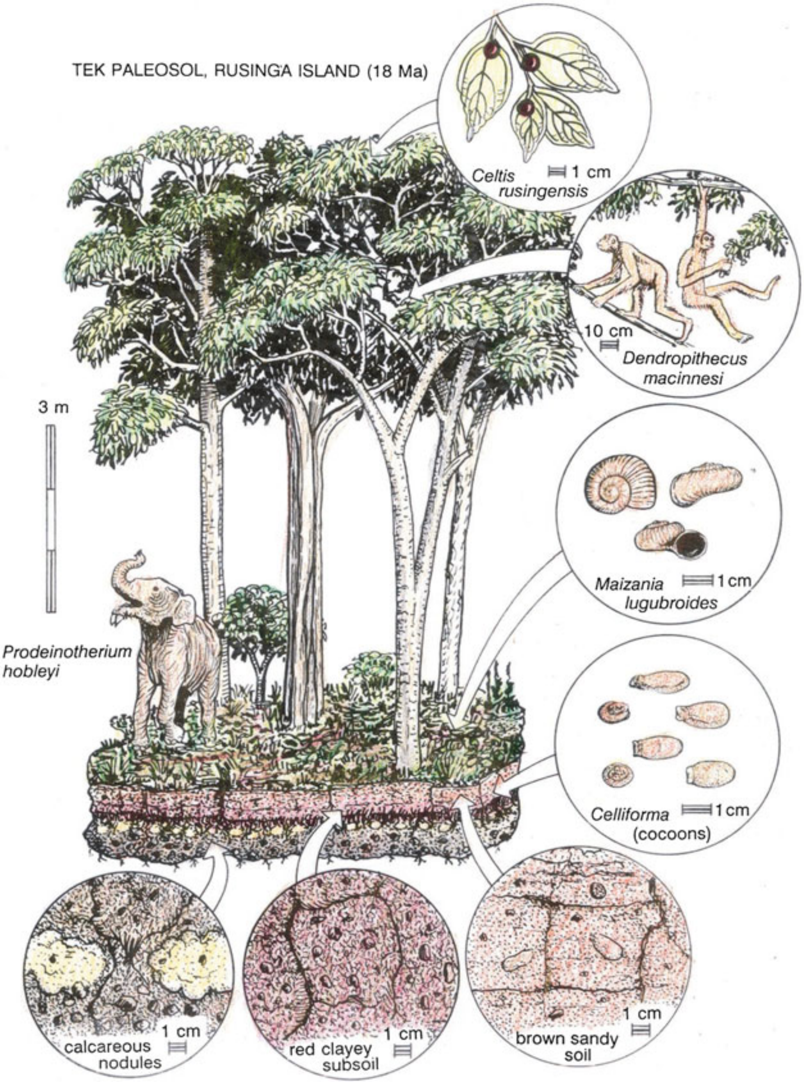

Fig. 4 Reconstruction of the Tek paleosol from the 18 Ma Hiwegi Formation of Rusinga Island, Kenya [Data from Retallack et al. (1995)]

Paleosols as Proxies of Paleoprecipitation

Climatic zonation of soils was a key element in the Russian origins of soil science (Jenny 1941), and a variety of relationships between particular soil features and climatic variables can be applied to East African paleosols in order to reconstruct paleoclimate. For example, depth to carbonate horizon (*D* in cm) is related to mean

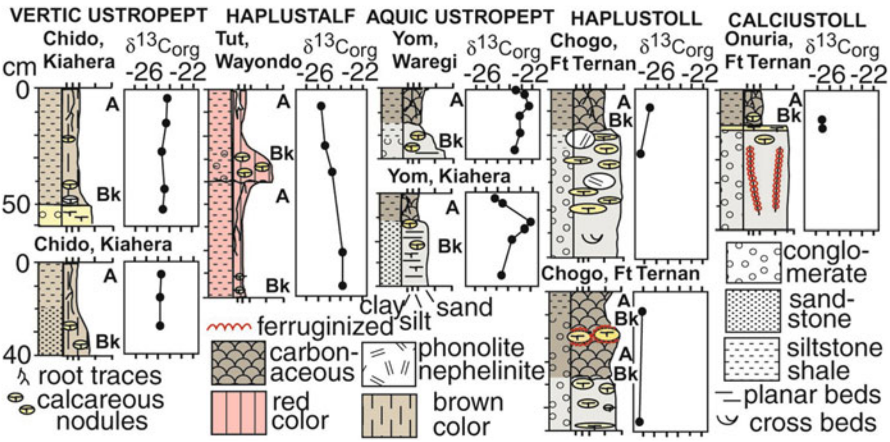

Fig. 5 Carbon isotopic ($\delta^{13}C_{org}$) depth profiles of Kenyan Miocene pedotypes, showing strong surface humification in grassland paleosols (Chogo and Onuria pedotypes), subsurface humification in Alfisols (Tut), and mixing in vertic Inceptisols (Chido). Carbon isotopic data is from Bestland and Krull (1999) and Cerling et al. (1997a), and paleosols are described by Retallack (1991a), Retallack et al. (1995), and Bestland and Krull (1999)

annual precipitation (*P* in mm) by a formula from Retallack (2005). This depth can be corrected for compaction due to overlying sediment using geological estimates of overburden and standard formulae (Sheldon and Retallack 2001). Also related to mean annual precipitation (*P*) is nutrient base content ($C = Al_2O_3/(Al_2O_3 + CaO + MgO + Na_2O)$ in mol) of soil Bt horizons by a formula from Sheldon et al. (2002).

Chemical weathering also alters the mineral content of soils, especially their clay minerals, which begin as smectites and then lose cationic bases with further chemical weathering to become kaolinite (Retallack 2001). This indication of paleoprecipitation works best with noncalcareous soils, which are found in climates receiving more than 1,000-mm mean annual precipitation (Retallack 2005). In East Africa today, smectite is dominant in soils receiving less than 1,200-mm mean annual precipitation, and kaolinite dominant in wetter climates (Mizota et al. 1988). Thus, noncalcareous, smectitic soils define a limited paleoclimatic window of 1,000–1,200-mm mean annual precipitation.

A new compilation of Kenyan paleoprecipitation over the past 20 million years (Fig. 6b) includes previously published data on African depth to Bk (Wynn 2001, 2004a,b; Wynn and Retallack 2002; Retallack 2001b; Retallack et al. 2002), and paleosol chemical (Retallack et al. 1995, 2002; Bestland 1990; Retallack 1991a; Wynn and Retallack 2002) and clay mineral composition (Retallack 1991a; Behrensmeyer et al. 2002), as well as published inferences from size and shape of fossil leaves (Jacobs 2002). This compilation is limited to data from around Lake Victoria for the early-middle Miocene, the Tugen Hills for the mid-late Miocene, and the Turkana Basin for the Miocene to Quaternary. The geological time scale is from radiometric dating of these various fossil primate sites (Deino et al. 1990;

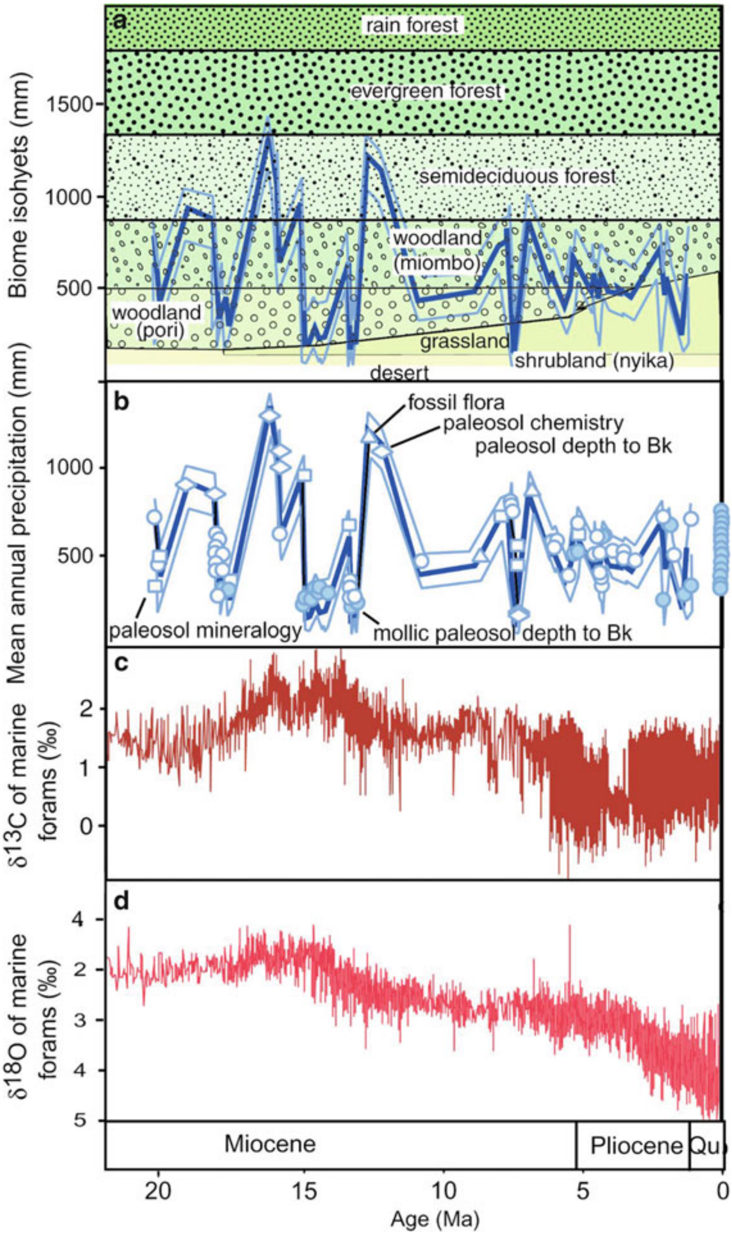

Fig. 6 A 20 million year record of vegetation (**a**) and paleoprecipitation (**b**) from Kenya, compared with carbon (**c**) and oxygen (**d**) isotopic composition of marine foraminifera. Paleoprecipitation data from paleosols (**b**) is from depth to carbonate (*open circles*), clay minerals (*diamonds*), and chemical composition (*squares*) after Retallack (1991a), Retallack et al. (1995, 2002), Wynn (2001, 2004a, b), and Wynn and Retallack (2002). Paleobotanical estimates from Jacobs (2002) and Jacobs and Deino (1996). Modern vegetation precipitation limits are from Anhuf et al. (1999)

Retallack 1991a; Jacobs and Deino 1996; Behrensmeyer et al. 2002; Hill et al. 2002; Pickford et al. 2006).

These new data reveal not just one Neogene aridification event at about 7 Ma, as has long been implied by the "Tertiary pluvial hypothesis" (Leakey 1952), the "Miocene lake hypothesis" (Kent 1944), the "Miocene rain forest hypothesis" (Andrews and Van Couvering 1975; Andrews 1996), and the "Late Miocene grassland hypothesis" (Cerling 1992; Cerling et al. 1997a,b). These theories had already been discredited by discovery of earlier Miocene desert dunes, shrubland snails, alkaline lakes, open-country grasses, grazing mammals, and grassland paleosols in East Africa (Pickford 1986a, 2002a; Retallack et al. 1990, 2002).

Instead the data (Fig. 6) reveal a Neogene paleoclimatic roller coaster of at least nine dry spells with intervening wet periods, of which humidity spikes at 16 and 13 Ma were the wettest of the last 20 million years. This new paleoprecipitation curve is similar to paleotemperature variations for Africa inferred from north-south oscillation through time of Ethiopian and Palearctic biogeographic realms (Pickford 2002a) and from paleoclimatic transfer functions from East African mammal assemblages (Retallack 2012). These new data are also similar to foraminiferal oxygen isotope curves from the deep sea (Zachos et al. 2001), commonly used as a basis for evaluating human evolution in Africa (de Menocal 2004), but the match is not precise (Fig. 6b,c). A general trend of extreme and volatile middle Miocene values, but subdued late Miocene to Quaternary values, is evident from both isotopic and paleosol data. The paleosol record reveals much greater variation in rainfall than would be inferred from carbon isotopic values of marine foraminifera, which are damped by global oceanic mixing with time lags of several thousand years. More profound damping is seen in oxygen isotopic values of marine foraminifera, which show a long-term increase unlike local rainfall and foraminiferal carbon records. This increase is plotted on reversed axes in Fig. 6d, because it has been interpreted as a long-term temperature decline (Zachos et al. 2001), but part of this long-term trend is due not just to temperature but to water recycling with plate tectonics (Veizer et al. 2001). The global oxygen isotope record also shows an increase after 3 Ma due to continental icecap sequestration of isotopically light oxygen, in addition to temperature effects (Zachos et al. 2001). Despite these problems, the East African paleosol record and global isotopic records present a very different concept of climatic variation experienced by our distant ancestors than the past idea of a seminal Late Miocene climatic event. Instead of a single origin of humanity at a turning point of environmental change, the new record implies rather that our lineage responded to a gauntlet of changing conditions with a variety of adaptations (Table 1), as discussed later.

Paleosols as Trace Fossils of Ecosystems

Australopithecus afarensis is known from body fossils, such as the partial skeleton "Lucy" (Johanson et al. 1982), as well as from trace fossils, such as the footprints of Laetoli (Leakey and Harris 1987). The soils of *A. afarensis* also are known,

Table 1 Geological age of African climatic events, selected adaptations, and hominoid diversity (*D*), origination (*O*), and extinction (*E*)

Age (Ma)	Hominoid adaptations and extinctions	*D*	O	E
20.2 dry	Robust mandible for hard food (*Rangwapithecus*)	10	9	0

1.7 wet	Occipital bun for competition (*Homo erectus*)	4	0	3
1.0 dry	Globular brain for generalist roles (*Homo antecessor*)	4	2	1
0.1 wet	Magdalenian tools and culture (*Homo sapiens*)	1	1	4

especially at the “first family” site near Hadar, Ethiopia (Radosevich et al. 1992; Behrensmeyer 2008). Here a troop of at least 13 individuals, young and old, died, rotted, and were partially disarticulated, before being interred in flood deposits on a crumb-structured soil of grassy streamside woodland (Fig. 7). The paleosol is not only a matrix to the bones but a trace fossil of their ecosystem. Furthermore, paleosols by definition are in the very place they formed, not redeposited. Unlike the skeleton of “Lucy,” found in the sandstone of a former river channel (Johanson et al. 1982), and thus transported some distance from its natural habitat, the first family was found where it died and had lived (Radosevich et al. 1992; Behrensmeyer 2008). Thus, paleosols give a finer resolution of primate paleoenvironments in time (Fig. 6) as well as space (Fig. 7).

The various paleosols containing Miocene ape fossils in southwest Kenya can also be used to constrain their habitats (Fig. 8). The fragmentary and weathered nature of most of these fossils is evidence that they accumulated through natural processes of death and decay on the paleosols in which they are found (Pickford 1986a). The great diversity of fossil apes in this region (Gommery et al. 2002; Harrison 2010; Ward and Duren 2002) is in contrast to the low diversity of great apes today (Fleagle 1998), leading to the idea that Miocene apes, defined from apelike dentition, were ecologically more like monkeys today (Andrews 1996). Analysis of their occurrence in paleosols shows that there was some ecological separation of different species to different soil types, but still high diversity within a soil type (Fig .8). In the 20 Ma sites of Koru and Songhor, for example, one very

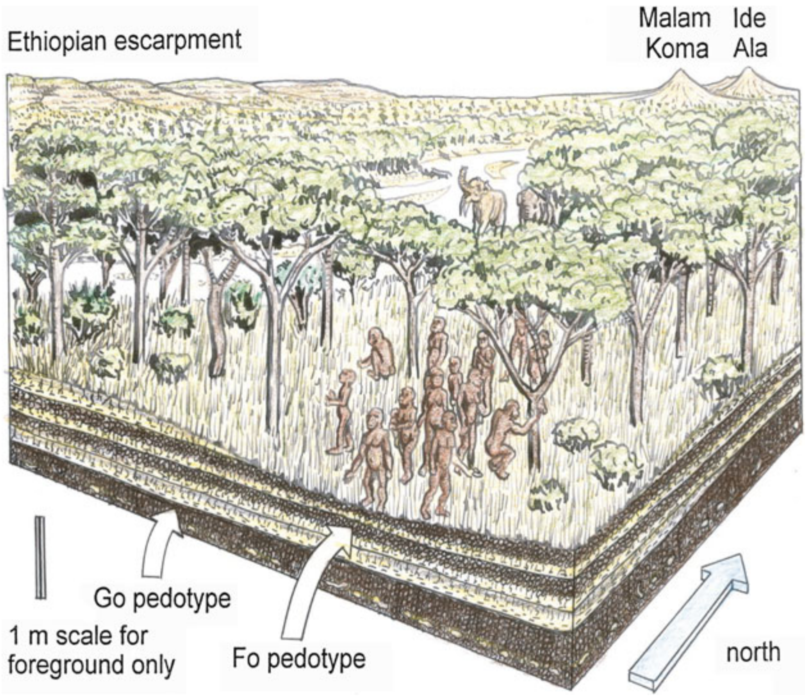

Fig. 7 Reconstruction of paleosols at the "First Family site" for *Australopithecus afarensis* at Hadar [Data from Radosevich et al. (1992)]

large taxon (*Proconsul major*) shows little habitat specificity through a variety of tropical dry forest habitats, but small taxa (*Kalepithecus*, *Micropithecus*) are found in upland soils and larger taxa (*Proconsul*, *Rangwapithecus*, *Dendropithecus*, *Limnopithecus*) remained in lowland forests closer to water. One paleosol type (Kiewo pedotype) has as many as six taxa including a large ground species (*Proconsul major*), three likely suspensory feeders (*Limnopithecus evansi, L. legetet, Dendropithecus* from small to large) and two likely overbranch feeders (*Proconsul africanus*, *Rangwapithecus*, from small to large). The contrasting sizes and other differences between these taxa suggest niche partitioning of forest canopy tiers.

Diverse catarrhine communities persisted into the dry woodland landscapes of Rusinga Island at 17.8 Ma, when paleosols with the crumb peds and iron-manganese nodules of dambo grasslands (Yom pedotype) appear, but are rare and barren of primate fossils (Retallack et al. 1995). Other evidence for grasslands of about the same age is abundant bunch grasses at the Ugandan fossil site of Bukwa (Pickford 2002b). Yom paleosols of dambo grassland are much more common by 14.7 Ma on Maboko Island (Retallack et al. 2002), where they contain abundant vervet-like monkeys (*Victoriapithecus*: note change of scale for this exceptional collection in Fig .8). These seasonally inundated grasslands of dry climates were

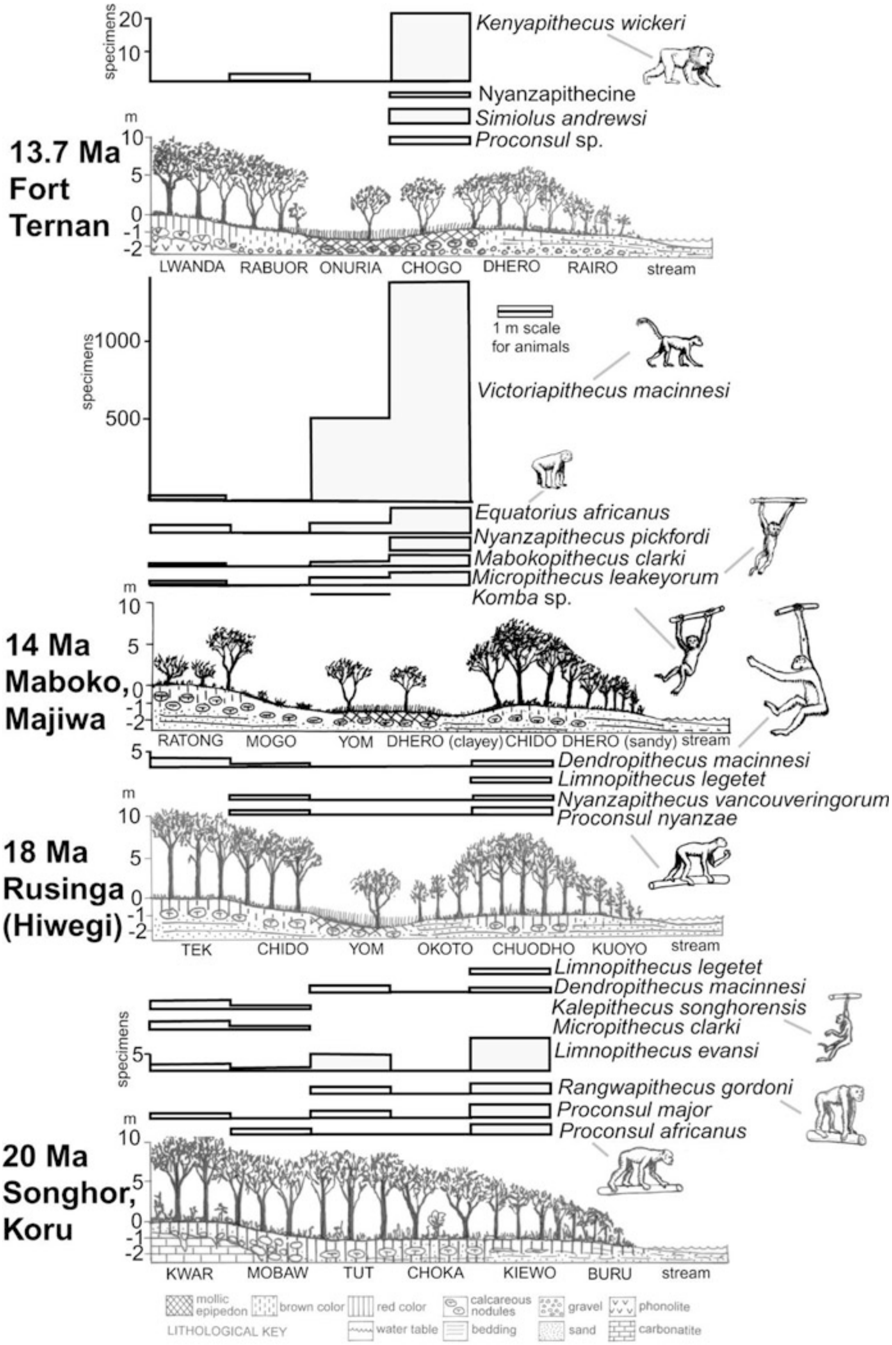

Fig. 8 Paleosols of Miocene apes from southwestern Kenya [Data from Retallack (1991a) with taxonomy after Retallack et al. (2002), Ward and Duren (2002), Harrison (2010)]

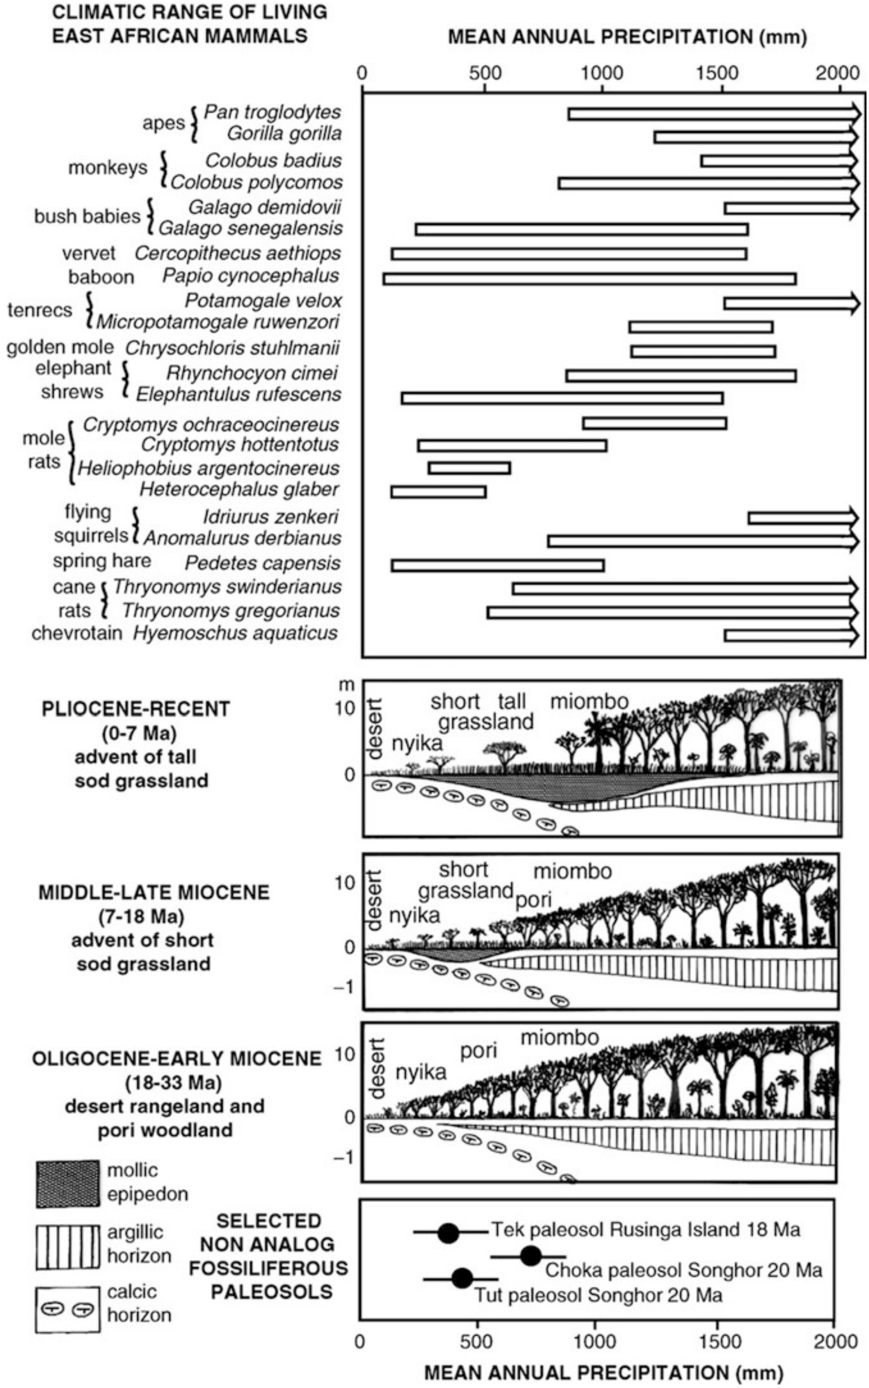

Fig. 9 (continued)

not encouraging to fossil apes, which were more common in riparian woodlands (*Nyanzapithecus*, *Mabokopithecus*, and *Micropithecus* of Dhero paleosols). More wide ranging was *Equatorius*, found in both riparian woodland (Dhero) and nyika shrubland (Ratong), which it exploited more effectively than other apes because of its thick enameled, large molars useful for tough foods (Martin 1985) and its macaque-like limbs and feet (McCrossin et al. 1998). A similar pattern of wide ranging *Kenyapithecus* and forest-dependent other apes (*Simiolus*, *Proconsul*, Nyanzapithecine) persisted in grassland mosaics of Fort Ternan and Kapsibor at 13.7 Ma (Pickford et al. 2006), when well-drained short-grass, wooded grassland was widespread. The appearance of grasslands that was encouraging for victoria-pithecine ancestors of vervets and colobines was not so hospitable to apes, which remained rare components of the fossil fauna.

Reconstruction of rainfall from paleosols implies also vegetation belts (Fig .6a), by comparison with Holocene climatic ranges of plant formations (Anhuf et al. 1999). There was rainforest in central Africa during the past 20 million years as indicated by rare finds of fossil plants (Bancroft 1932, 1933), but evidence of rain forest has not yet been found in the East African areas yielding hominoid fossils (Retallack 1991a; Jacobs 2002). Paleobotanical interpretations (Fig .6a) are well in accord with indications of vegetation from paleosol classification, profile form and root traces (Retallack 1991a), as evidence that the climatic range of most vegetation types did not change over the past 20 million years.

An exception is the evolution of grasslands, which expanded their climatic range to displace extinct kinds of woodlands (Figs. 6 and 9). There is not yet any East African evidence of grasslands before 17.8 Ma, when crumb-textured, brown, simple (A-Bk) profiles of dambo were rare at Rusinga Island (Retallack et al. 1995) and bunchgrasses grew luxuriantly at Bukwa (Pickford 2002b). Well-drained, short-grass, sod-grasslands were widespread by 14.4 Ma (Retallack 1991a; Retallack et al. 2002) and well-drained, tall-grass, sod-grasslands expanded their climatic range considerably by 7 Ma (Wynn 2004a, b). Grasslands were a newly coevolved ecosystem of the Cenozoic, with grasses uniquely suited to grazing by virtue of their intercalary meristems, modular growth, basal tillering, and sod formation, and grazers uniquely suited to coarse grassy fodder by virtue of their wide muzzles, hypsodont teeth, and hard hooves (Retallack 2001a). A world without grasslands was transformed over some 20 million years to a Plio-Pleistocene world with grassland covering at least a quarter of the land surface. Holocene humans spread grassy agroecosystems to almost all parts of the world (Retallack 2001a). Neogene expansion of grasslands within the paleoclimatic belt

Fig. 9 A scenario for stepwise evolution of East African grasslands with modern precipitation tolerances of African mammals related to those found fossilized in paleosols (Tut, Choka, Kwar) of pori woodlands that preceded the expansion of grasslands. The advent of grasslands disrupted formerly overlapping ranges of apes, bush babies, flying squirrels, mole rats, and spring hares. Climatic ranges of modern mammals are from Kingdon (1971, 1974a, b, 1979) and of paleosols from Retallack (1991a), Retallack et al. (1995)

Table 2 Comparison of extinct pori woodland with extant East African vegetation

Local name	Pori	Miombo	Nyika	Savanna
Vegetation	Dry woodland	Dry woodland	Dry bushland	Wooded grassland
Key genera	*Celtis*	*Brachystegia*	*Acacia*	*Combretum*
Floral origins	Zambezian	Zambezian	Zambezian	Eurasian
Spinosity	Unarmed	Unarmed	Spinose	Spinose
Leaf set	Semideciduous	Deciduous	Deciduous	Deciduous
Fruit size	Large	Large	Small	Small
Snails	*Cerastua*	*Limicolaria*	*Achatina*	*Pupoides*
Snail origins	Somalian	Somalian	Somalian	Somalian
Mammals	Apes, rodents	Antelope	Antelope	Antelope
Ungulates	*Walangania*	*Aepyceros*	*Tragelaphus*	*Connochaetes*
Primates	*Proconsul*	*Cercopithecus*	*Papio*	*Papio*
Mammal origin	Zambezian	Zambezian	Zambezian	Eurasian
Fire frequency	Low	High	High	High
Soil organics	Low	Low	Low	High
Soil fertility	High	Low	Low	High
Soil type	Alfisol	Oxisol, Vertisol	Aridisol	Mollisol, Vertisol
Parent material	Volcanic	Granitic	Granitic	Volcanic

roughly defined by the 300–750 mm per annum isohyet enabled grasslands to capture the planetary modal rainfall belt and most fertile soils, with consequences for global change including a significant contribution to global cooling (Retallack 2001b).

Before the expansion of the grasslands, an extinct woody vegetation occupied their climatic range (Fig. 6). These extinct dry woodlands can be called pori (Table 2), from a Hadza word for bush (Woodburn 1968). A good example of a pori ecosystem is the Tek paleosol of Rusinga Island (Figs. 3 and 4), which has yielded fossil primates and other mammals, snails, and plants (Pickford 1995; Retallack et al. 1995). Other examples of pori ecosystems include Tut, Choka, and Kwar pedotypes of Songhor and Koru dated at 20 Ma (Retallack 1991a). From the soil perspective, these paleosols have no clear modern analog, because they are red and clayey, with large root traces and blocky structure like woodland soils, yet have shallow calcareous horizons like those found in modern African semiarid to subhumid grassland soils. Modern African soils with such shallow carbonate have very different crumb structure, fine root traces, and dark brown organic-rich surface horizons from abundant grasses.

From the paleoanthropological perspective, these ancient communities have no modern analogs, because they have so many fossil hominoids, as many as six species in the Kiewo pedotype (Fig. 8). No community has so many species of hominoids today. Nor do modern hominoids live in such dry climates. Mt. Assirik in Senegal with 956 (854–1224) mm mean annual precipitation is the driest climate with chimpanzees (Kappelman 1993), although Kingdon (2003) gives anecdotes of chimpanzees in wooded grassland. It is now clear that Miocene apes filled a variety of niches like those today filled by vervets, baboons, and colobines as well as apes (Retallack et al. 2002). Pori ecosystems such as the Kwar paleosol at Koru (20 Ma) also show peculiar associations of other mammals, including a mix of dry climate taxa, such as mole rats (*Bathyergoides*), with wet climate taxa such as flying squirrels (*Paranomalurus*), giant elephant shrews (*Miorynchocyon clarki*), tenrecs (*Protenrec tricuspis*), golden moles (*Prochrysochloris miocaenicus*), and chevrotains (*Dorcatherium songhorense*: Retallack 1991a). Similarly, the Tut and Choka paleosols at Songhor (20 Ma) and Tek paleosols on Rusinga Island (17.8 Ma) have wet climate flying squirrels and tenrecs as well as dry climate mole rats and spring hares (Retallack 1991a; Retallack et al. 1995). These nonanalog combinations of fossil mammals can be explained by a theory of evolutionary replacement of pori with grassland within semiarid to subhumid regions. Before the advent of grasslands, woody vegetation became smaller in stature and biomass from wet to dry regions (Retallack 2012). This continuum was disrupted as grasslands evolved to usurp the climatic range of pori woodland. Grasslands expanded their range to create a biogeographic divide between nyika shrubland and miombo woodland (Fig. 9).

Fossil primates of East Africa not only coped with changing mixes of animals, but with changing climate and vegetation (Fig. 6). Wynn (2004b) has introduced the concept of evolutionary entropy to explain effects of climate and vegetation change on hominoid diversity. Climatically dry episodes encouraged grassland mosaic environments with a more varied landscape of open grassland and local woodland, and thus greater landscape disorder or negentropy. Wet episodes of forest vegetation presented more uniform landscapes of higher entropy. Compilation of

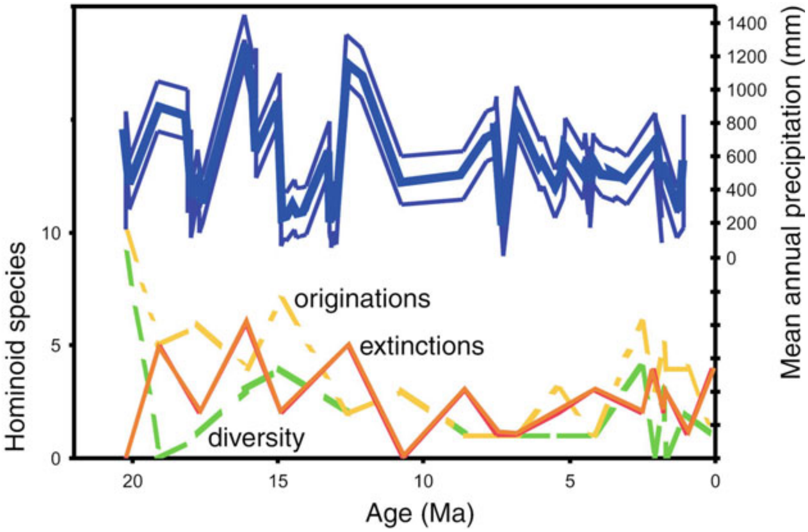

Fig. 10 Mean annual precipitation and hominoid diversity, extinctions, and originations in East Africa over the past 20 million years. The paleoprecipitation curve is from Fig. 6. Hominoid data is from Pickford (1986b, 1987), Ward and Duren (2002), and Carroll (2003)

hominoid diversity, originations, and extinctions (Table 1, Fig. 10) supports the view that dry episodes correspond with diverse primates, whereas wet episodes lead to extinctions, particularly of specialized arid-adapted taxa. The concept of ecosystem entropy in hominoid evolution is similar in some respects to Vrba's (1999) "turnover pulse hypothesis," but ecosystem entropy presents diffuse and long-term selection pressures, rather than episodic crises or "turnover pulses." Recent compilations of mammalian data from the Turkana region do not show such crises (Bobe et al. 2002), revealing instead an oscillating diversity compatible with less synchronized selection by ecosystem entropy.

A major caveat for such theories is the generally inferior fossil record of climatic wet phases, because their soils and sediments are noncalcareous and so not favorable to the preservation of bone (Retallack 1998). There is still no primate fossil record from paleoclimatic wet phases of the early Miocene, but there are discoveries of wet climate human ancestors from 13 Ma (Hill et al. 2002), 6 Ma (Brunet et al. 2002; Galik et al. 2004), and 4–3 Ma (Carroll 2003). The soil-taphonomic bias against wet climate fossils makes the search difficult, not impossible (Peterhans 1993).

Each fluctuation in climate and vegetation presented new crises and opportunities to primates. The correlation of climatic events with critical adaptations presented here (Table 1) is only an outline of a new research agenda, to be fleshed out with further studies of the critical intervals. The late Miocene paleosols and primate fossils of the Tugen Hills, for example, remain very poorly known compared with those of the Lake Victoria and Turkana basins. Nevertheless, there are general themes apparent from this compilation. We did not evolve from apes in one seminal event, but by a protracted process of growth and pruning of our evolutionary tree. Some specialized features such as procumbent incisors at 18 Ma evolved in dry grassy woodlands, but did not survive succeeding forest expansions (McCrossin and Benefit 1997). Some specialized features such as long arms by 20 Ma for suspensory locomotion in forests did not persist through succeeding grassland expansions (Harrison 2010). Other forest adaptations such as a short stiff back by 16 Ma (Pickford et al. 1999), erect stance by 6 Ma (Senut et al. 2001; Galik et al 2004), and flat face by 3.5 Ma (Leakey et al. 2001) proved advantageous in the long term, just as did grassland adaptations, such as thick enamel by 18 Ma (Martin 1985; McCrossin and Benefit 1997), adducted hallux by 14.7 Ma (McCrossin et al. 1998), and long legs for endurance running by 1.8 Ma (Bramble and Lieberman 2004). Although each of these ideas could be debated individually, the general concept of human evolution as a generalist path through a gauntlet of environmental challenges (Potts 1996) is increasingly supported by a burgeoning fossil record (Carroll 2003). There will always be a need for dating and finding more human ancestor fossils, but paleosols now provide new evidence of evolutionary selection pressures with high temporal and spatial resolution.

Past hypotheses of a Miocene pluvial, lake and rain forest (Kent 1944; Leakey 1952; Andrews and Van Couvering 1976; Andrews 1996) and late Miocene grassland (Cerling 1992; Cerling et al. 1997a, b) find a counterpart in long-standing theories linking late Miocene evolution of human upright stance or large brains with hunting prowess (Darwin 1872), vigilance against predators (Dart 1926), manipulation of small seeds (Jolly 1970), minimization of sun exposure (Wheeler 1984), long-distance walking (Rodman and McHenry 1980) or running (Bramble and Lieberman 2004), squat feeding on the ground (Kingdon 2003), or moving between scattered fruiting bushes (Sanford 2003). Forest explanations of upright stance allowing erect-back climbing (Tuttle 1981), hands free to care for premature infants (Lovejoy 1981), phallic display to females (Tanner 1981), or intimidation displays to rivals (Jablonski and Chaplin 1993) move the event back into the "Miocene rain forest" (of Andrews and Van Couvering 1975; Andrews 1996), for which there is little evidence at hominoid sites in East Africa (Fig. 6a). All these views can be reassessed in light of the improved record of East African paleosols, which suggests that there were many alternating habitats in East Africa, not just one seminal environmental shift. Darwin's (1872) idea that erect stance was linked to tool use and brain expansion has been out of favor since the discovery of "Lucy," when it became clear that erect stance preceded tool use and brain expansion by millions of years (Johanson et al. 1982). Erect stance now appears to have occurred in wooded habitats by 6 Ma (Pickford and Senut 2001; Vignaud et al. 2002; White et al. 2009), perhaps selected by the use of hands in nest provisioning (Lovejoy 1981). We are a mosaic of a complex evolutionary history and no longer need to settle for simple or single allegories of human evolution.

Conclusion

There is a copious and informative fossil record of soils at most of the fossil ape and human ancestor sites in Africa, and study of these paleosols is now giving important insights into the long evolutionary career of our ancestors. The primate evolutionary radiation of the Neogene has been a long saga of changing habitats and adaptations. The fossil record of soils now allows us to address its complexity on a scale appropriate to primate home ranges and to recognize nonanalog habitats of the past. Our distant ancestors have run an evolutionary gauntlet of changing vegetation and climate that has spawned many evolutionary innovations, some of them lasting only to the next shift in climate and vegetation, but others of them proven to be of lasting value.

Quaternary Geology and Paleoenvironments

John A. Van Couvering

Contents

Abstract

The Quaternary is defined by its unusual climate, which was originally characterized as advances and retreats of continental ice sheets in the Northern Hemisphere. The earliest such glaciation, at about 2.6 Ma, is now recognized as one step in a worldwide cooling trend that began some 38 million years ago when the world ocean first felt the effect of the great Antarctic ice sheet. With the loss of ocean warmth, the cycles in the Earth's orbit that affect the solar radiation reaching the surface have had a steadily increasing influence on world climate, and glacial-interglacial swings have grown progressively stronger. The earliest *Homo* appears in the fossil record at the same time that the more extreme Quaternary climate changes began to increase grasslands in Equatorial Africa, giving wider opportunity for bipedal, stone-wielding scavengers.

Introduction

The Quaternary – the final hour of geological time – is a highly distinctive interval with unique attributes, even if we refrain from giving undue significance to the evolution of genus *Homo* within its limits and even if we treat the consequences as being outside the range of a geological review.

The individuality of this time period was first recognized by Giovanni Arduino, who in 1759 had proposed a Primary (igneous-metamorphic) and Secondary (lithified and folded) organization of formations as seen in the geology of the Apennines (Arduino 1759). As a side note, he recognized an informal third subdivision of "low mountains and hills of sand and gravel" and a fourth and final subdivision – that of "earth and rocky materials and alluvial debris." In 1810, the third subdivision gained the title of Tertiary (actually, *tertiaire*) in Alexandre Brongniart's description of strata younger than the massive Late Cretaceous chalks of the Paris basin. Marcel de Serres, after initially recognizing the fourth of Arduino's subdivisions merely as *quatrième formation d'eau douce* (in Creuze de Lesser 1824, p. 174), in 1830 used the term *quaternaire* for such superficial deposits. He subsequently (de Serres 1855) claimed to have thereby invented Quaternary as a lithostratigraphic term, but the honor goes, somewhat unjustly, to Desnoyers (1829), who proposed to call all the nearly horizontal, relatively unconsolidated younger strata of the Loire and Rhône basins *Quaternaire ou Tertiaire récent*, as follows:

(3) *Récent*
(2) *Diluvium*
(1) *Faluns de Touraine, la molasse suisse*, *et le Pliocène marin de Languedoc*

In this way, the first use of the term Quaternary referred to strata as old as the Lower Miocene! This was partly because *tertiaire* in France was initially applied only to the Lower Cenozoic strata of the Paris basin and perhaps also because the southern French Miocene, to which Desnoyers referred, was much less indurated or deformed than the coeval Italian Miocene which Arduino placed in his third subdivision. However, the earlier usage of de Serres, which he restated in 1830 in confining Desnoyers' *quaternaire* to "diluvium" only (de Serres 1830), was more in line with that of Arduino, and it established the modern meaning of the term. The purely lithological concept of Quaternary is still a strong tradition in geology, and many relatively unconsolidated, unfossiliferous formations are mapped as "Quaternary terrace" or "Older Quaternary alluvium" with no further attempt at formally dating them.

A second defining concept for Quaternary, that of a period equivalent to the span of human existence, was also suggested by de Serres (1830), who asserted that early man had lived during the deposition of the Quaternary "diluvium." The first major treatise on the *Terrain quaternaire ou diluvien* (Reboul 1833) thus proposed that this time interval be considered as the "Période anthropiénne." Other writers called it the "Periode homozoique" (Vezian 1865) and "Terrain humaine" (Mercey 1874). At the International Geological Congress of 1888 in Great Britain, Jean Gaudry, with the approval of Joseph Prestwich and Albert De Lapparent, made the proposal that mankind – represented in particular by artifacts – was the characteristic element of the Quaternary and that this justified its separation from the Tertiary.

A different logic for defining the final part of the geological record was outlined by Charles Lyell, who never referred to "Quaternary." Instead, he began with formally defining the term Pliocene, already in use as a general descriptive word for fossils of relatively young age (e.g., Desnoyers 1829), with reference to certain marine formations in Great Britain, the Lowlands, and Italy in which 50 % or more of the molluscan species they contained as fossils survived to the present day (Lyell 1833, p. 61). Within this interval, he recognized "Newer Pliocene" formations with at least 90 % of the surviving species.

In 1839, Lyell replaced "Newer Pliocene" with "Pleistocene," again without any reference to Quaternary (Lyell 1839). At almost the same moment, Agassiz (1838) made the bold suggestion that the European continent had been invaded by great lowland glaciers during the Quaternary. By this time, it was already widely understood that the continental Quaternary deposits and "younger Pliocene" marine deposits were roughly coeval. It took very little time for Forbes (1846), after noting that the molluscan faunas to which Lyell had referred in setting up the Pleistocene were adapted to a colder climate than those of the Pliocene, to conclude that the marine Pleistocene, like the continental Quaternary, should be recognized as ". . . the time distinguished by severe climatal conditions throughout the great part of the northern hemisphere" (Forbes 1846, p. 402).

"The first glaciation," however, was still only one of a variety of criteria that were cited as definitions for the base of the Quaternary (and/or Pleistocene) at the middle of the twentieth century, as follows:

Paleoanthropologists: first evidence of man or tools
Paleoclimatologists: first (major) global cooling or glacial advance
Vertebrate paleontologists: first joint occurrence of *Equus*, *Leptobos*, and *Elephas* in Eurasia
Marine invertebrate paleontologists: first occurrence of cold-water species in late Neogene sediments of Mediterranean basin
Paleobotanists: first "glacial" floral association or exclusion of certain southern elements from European floras

To further complicate matters, each of these conceptual criteria could be and usually was interpreted locally, with often highly inconsistent results. In one very notable example (cf. Van Couvering 1997), the Quaternary community in North America, Western Europe, and China consistently placed the beginning of the Quaternary at the first appearance of glacially derived tillites or loess in temperate high plains sequences. On the other hand, Russian and East European workers held that Forbes' definition of "fully glacial" conditions meant that the Pleistocene – and thus the Quaternary – began when the first continental ice sheet completely covered Northern Europe during the Menapian glacial maximum, at the same time as the first appearance of modern cold-climate biota (Nikiforova 1997). It was well recognized that these concepts differed markedly in age, even before modern dating confirmed that the first was related to a cold period close to the Gauss/Matuyama boundary, at ca. 2.5 Ma, while the second was applied to the beginning of the modern glacial-interglacial climate at 0.9 Ma, just subsequent to the Jaramillo subchron (cf. Lourens and Hilgen 1997). Such special pleading, however, was countered, if not silenced, at the 18th (London) International Geological Congress in 1948. At this Congress, the Temporary Committee for the Study of the Pliocene/Pleistocene Boundary recommended that the boundary "... should be based upon changes in marine fauna, since this is the classical method of grouping fossiliferous strata" (King and Oakley 1950). In other words, the paleoclimatic and other special attributes of the Quaternary, which various groups had cited in their conceptual definitions, were irrelevant to its meaning as the youngest Period, and uppermost System, in the geological time scale.

If the Committee had done no more than this, it would have earned its laurels. Under the influence, however, of the new "Cambridge school" of analytical stratigraphers, led by W. Brian. Harland, the Committee made a bold step onto new ground that has since revolutionized chronostratigraphy and made its boundaries accessible to modern techniques used in biostratigraphy, magnetostratigraphy, and geochronology. This was the first enunciation of the principle informally called the "golden spike" (cf. Ager 1973), which we now identify as the GSSP or Global Boundary Stratotype Section and Point – i.e., not only that a chronostratigraphic boundary be typified in an appropriate marine section but also that it be anchored to a specific physical stratum. This was inherent, if not clearly stipulated in the Committee's recommendation that ". . . the Lower Pleistocene should include as its basal member in the type-area the Calabrian Formation (marine) together with its terrestrial (continental) equivalent the Villafranchian." Aside from the egregious and, as it turned out, mistaken inclusion of the significantly older Villafranchian, which seems to have been a sop to the nonmarine specialists on the Committee, this was the key element to pinning down this hitherto elusive boundary.

The new principle of a physical definition superseded the various "model" or conceptual criteria of the past, including climate-induced changes in the marine invertebrate fauna, although this fact was not clear to everyone at the time. In fact, the Committee itself justified its proposal by pointing to changes in the marine and continental faunas that were understood to coincide with the Calabrian in southern Italy. Nevertheless, such changes were merely supportive of the decision where to locate a physical pointraphic criterion that, once put in place, would stand apart from any theoretical model of past events. In so doing, they made the record of climate, fauna, or flora, irrelevant to the actual definition of the boundary, although such evidence was more significant than ever because of the greater precision demanded by reference to a single physical point in its correlation.

Modern Definition of the Quaternary: A Continuing Controversy

With attention thus focused on the Calabrian Stage, the question became one of its appropriate stratotypes for location of a fixed physical reference point, or "golden spike." In the original type section, as described by Gignoux (1913) at Santa Maria di Catanzaro, Calabria, the lower part of the section is not well exposed. In 1965 at the 7th (Denver) Congress of the International Union for Quaternary Research, better known as INQUA, it was proposed to fix the base of the Pleistocene at a better exposure about 40 km distant at Le Castella. To follow up on this question, in 1974 the International Geological Correlation Program launched IGCP Project 41, "Neogene-Quaternary Boundary," which was charged with comparing the suitability not only that of the sections at Santa Maria di Catanzaro and Le Castella but also that of a third seacliff exposure of Calabrian strata at Vrica, further to the east near Crotone. After it turned out that glacially lowered sea level during the early Calabrian had in fact created a hiatus at the base of the two shallow-marine sections at Santa Maria di Catanzaro and Le Castella (Colalongo et al. 1981), attention turned to the deeper-water section at Vrica, where a boundary point was chosen in a layer, now dated 1.81 Ma in the uppermost part of the Olduvai Event (Hilgen 1994; Gradstein et al. 2004), that makes the transition to typical Calabrian lithology and molluscan fauna in the Italian sequences. The Vrica boundary was approved in a joint meeting of IGCP Project 41 and INQUA in Moscow in 1985, and the formal proposal for this new identity of the Pleistocene was adopted by the IUGS (International Union of Geological Sciences) in 1986 (Cowie et al. 1986). The final report of IGCP Project 41 (Van Couvering 1997) reviewed the flood of studies on the Vrica boundary and its worldwide correlation.

The main problem with the Vrica-defined Pleistocene was that the cold-water episode that introduced "boreal visitors" such as the clam *Arctica islandica* into Calabrian faunas, as noted in the 1948 Commission's decision, was not the first glacial-climate cycle at the end of the Cenozoic. The marine community readily accepted the Vrica definition, because it could be precisely correlated in deep-sea cores on the basis of paleomagnetism, micropaleontology, oxygen isotopes, and (in later years) cyclostratigraphy (cf. Gradstein et al. 2004), and most continental paleontologists and paleoanthropologists were comfortable with the date as well. It was unacceptable, however, to the continental stratigraphers who dominated INQUA and who continued to use a paleoclimatic definition of Quaternary that was based on the earliest glacially derived lowland deposits in north temperate sequences. This was a criterion that the Vrica boundary, linked to Lyell's marine biostratigraphic definition, did not satisfy.

In May 2009, the IUGS ratified a proposal made by INQUA to the Quaternary subcommission of the International Commission on Stratigraphy, which was approved by the full ICS against the opposition of its Neogene subcommission (cf. Van Couvering et al. 2009). This proposal gave the Quaternary formal status as a System/Period in the standard geological time scale (Finney 2010), placing the lower (and only) boundary of the new unit at the base of the Gelasian Stage at San Nicolá, Sicily. This boundary, dated at 2.59 Ma, was selected because of its

Table 1 Quaternary terminology. Classic "ice age" names (*interglacials in italics*) in continental ice sheets of the Northern Hemisphere, coordinated with dated peaks in the oxygen isotope curve from deep-sea cores. Some names in the early Quaternary refer to generalized intervals in which individual advances and retreats were not easily distinguished in the field

North America	North Sea	Alpine	Peak AGE, Ma	Marine isotope stage (MIS)

proximity to the isotopically recorded cold peak at ca. 2.6 Ma (Table 1), which was responsible for the earliest known glacially derived sediments in Northern Europe (Head et al. 2008). But in addition, the IUGS also agreed to redefine the Lyellian Pleistocene by moving its GGSP from the base of the Calabrian Stage, where it had been located since 1948, to that of the Gelasian Stage, increasing its duration by some 44 %.

The action of IUGS was heavily criticized (i.e., Aubry et al. 2009), because the establishment of the new period flouted all basic guidelines of geochronology (Hedberg 1976; Salvador 1994). To begin with, it was framed in paleoclimatic terms and not in the context of marine paleontology, as for all other units in the time scale. In addition, it imposed a gross and undefended revision of the Lyellian Pleistocene in violation of the hierarchical logic of the GTS. Critics further pointed out that this ad hoc agreement to the preferences of the INQUA group disrupted half a century of literature in many other important areas of research, from marine paleontology to paleoanthropology, vertebrate paleontology, cyclostratigraphy, and paleoceanography, for whom the long-established and clearly dated Pliocene-Pleistocene boundary at Vrica, and not the concept of Quaternary climate, was a fundamental metric. Again, by imposing a new Period/System to replace the later Neogene without any justifying paleontological argument, the IUGS was seen to arbitrarily invalidate the Neogene (Hilgen et al. 2008). And finally, by casting aside Lyell's (1833) original biostratigraphic characterization of the Pleistocene that was embodied in the 1948 London recommendation, the IUGS casually destroyed the first and most historic GSSPs in the time scale.

In its consideration of the INQUA proposal, the ICS rejected counterproposals to make the Quaternary a Neogene subunit and did not consider other alternatives such as making it a separately defined "paleoenvironmental" sub-era of the Cenozoic on a par with Tertiary rather than Neogene or to restore the Pleistocene by inserting a new basal epoch (Hilgen et al. 2008; Aubry et al. 2009). The IUGS decision cannot be reopened for further discussion until 2019, at which time this long-enduring controversy may well be finally resolved (Table 1).

Quaternary Time Frame

The Milankovitch Cycles The unusual climatic conditions that distinguish the Quaternary were last seen over 300 million years ago, in the cyclothems of the Carboniferous. The advances and retreats of huge continental ice sheets in temperate latitudes are a response to cyclic variations in the Earth's orbit, which change the amount and location of solar radiation reaching the Earth's surface. Known as Milankovitch cycles after the Serbian geographer and mathematician Milutin Milankovitch, who first calculated them (see Imbrie and Imbrie 1979), these are caused by oscillations in the Earth's angle and in the shape of its orbit around the sun (Hays et al. 1976; Einsele et al. 1991).

Briefly, *precession* refers to the slow swing in the orientation of the axis every 22 kyr. Because the Earth's annual orbit is not precisely circular, at present, the winter solstice (i.e., when the North Pole points directly away from the Sun at midday) occurs when the Earth is closest to the Sun. This gives rise to warmer winters and cooler summers in the northern hemisphere and the opposite in the southern hemisphere. 11 kyr ago, it was the opposite, such that winters in the northern hemisphere were very cold, but summers were very warm.

The *obliquity* cycle refers to the rocking of the Earth's axis between 22° and 24.5° every 41 kyr, with minor frequencies of 29 and 54 kyr. This cycle has the greatest effect in high latitudes, because low obliquity means that there is less difference between summer and winter, and thus lowers melting rates of accumulated snow and ice.

Regular variations in the *ellipticity* of the Earth's oval orbit, under the influence of other planets, result in changes from nearly circular to more elliptical in cycles that repeat at irregular intervals concentrated around a 100-kyr frequency, as well as changes in the amplitude of the variation on a roughly 400-kyr period. Unlike the other two major cycles, ellipticity controls the total amount of solar radiation reaching the Earth's surface.

The overlapping cycles, each with their own frequency, reinforce or suppress each other's effects in evenly spaced harmonic "beats," recorded in a variety of proxies in the geological record (Berger et al. 1984; Burroughs 1992). Normally, the orbital cycles have relatively minor influence on world climate and are seen mainly in pulses of ocean productivity recorded as rhythmic bands of organic-rich layers, or *sapropels*, in deep-sea cores. The Cenozoic, however, is not a normal time, but one characterized by the rare condition of a major continent isolated under one of the poles (as with Gondwanaland in the Carboniferous, the last time the world experienced major glacial cycles). In these special circumstances, a great cap of ice will form that refrigerates the enclosing waters, which then sink into the depths and gradually fill the ocean basins from below. The effect of the Antarctic ice, which expanded to reach sea level some 38 million years ago, has changed the average temperature of the world's ocean (save for the thin sun-warmed film above the thermocline) from ca. 20 °C in the Eocene to ca. 4 °C today. Without the moderating influence of a warm ocean, continental climates in the higher latitudes have grown steadily more seasonal, and the Milankovitch cycles have had a steadily increasing influence.

In recent years, Milankovitch's calculations have been significantly extended and refined in computerized treatments that bring out the internal complexity of the orbital oscillations. Precisely because of this complex reality, the numerical values used in general discussions such as these are only convenient approximations. Furthermore, we need to keep in mind that each of the orbital variations differs from the others in its quality as well as its timing. The impact of astronomical forcing on Quaternary environments, as interpreted from the geological record, is reviewed in the following sections.

The "*Ice Ages*" Initially, with geological research confined to surface exposures on the land, only the broad effects of orbitally forced climatic cycles could be seen in the stratigraphy of continental and estuarine deposits adjacent to the continental ice sheets, where successions of tillite and loess, interspersed with region-wide erosional unconformities, were seen as evidence of the advances and retreats of continent-spanning ice, and Milankovitch's calculations remained largely speculative. The glacial histories were somewhat uncertainly correlated because the fossil record was not entirely adequate to distinguish one climax from the next and because the stratigraphy lacked consistent interregional detail. The more recent glacials could be more confidently identified around the world because the climatic swings had shifted to a new, more widely spaced and more pronounced rhythm (see below). These major peaks, as well as a few of the more notable pulses in the lower Quaternary, were the basis for the "glacial-interglacial" terminology of Quaternary paleoclimatists. More precise measurements have thoroughly exposed the inability of such conventional formulation to describe the climatically dominated history of the Quaternary, and the older "ice age" nomenclature is now seldom used. Even so, these terms, which identify the main features of the record, are still relevant to a complete picture of this time.

The difficulty of making out the precise details of Quaternary climate history in the prewar years was largely due to the nature of the data. The record on land, even taking into account the relative completeness of the record in North Sea estuaries (Zagwijn 1985), is still essentially discontinuous because of the episodic impact of thousands of cubic miles of ice moving on and off the continents, with major shifts in base level as world sea level rose and fell by hundreds of feet, together with the physical disruption of older sequences being plowed up by later ice sheets. For this reason the remains of a given "glacial stage" in most places on land represent but a small fraction of a glacial cycle, and much of the history of events during that time is not preserved. On the other hand, in the relatively undisturbed and uninterrupted deposition of fine annual layers in the deep ocean basins, the variations in environmentally controlled features can provide a virtually continuous record of long-term climatic change on a fine scale, and that can be compared on a worldwide basis.

Marine Isotopic Stages Soon after World War II, with new techniques in isotopic chemistry available as a side effect of the development of nuclear weapons, research began on whether long-term climate variations could be traced by changes in climate-dependant isotope ratios in seawater, as preserved in the calcium carbonate ($CaCO_3$) of marine shells. The research initially focused on the two stable isotopes of carbon, ^{12}C and ^{13}C, from piston cores in the Caribbean. The relative proportions of these isotopes vary directly with local water temperature, which required that sampling be limited to planktonic foraminifera from the upper few meters of the ocean, in order to maintain a constant environmental context. The results, however, were highly encouraging, showing a distinct periodicity at about 100,000 years (assuming a constant sedimentation rate), in clear synchrony with the Milankovitch calculations. These results justified the proposal, which was swiftly adopted by the profession, that marine isotopic stages, or MIS as they became known, could provide an improved calibration for the alternating glacial and interglacial cycles of the Quaternary (Emiliani 1955, 1966). From the beginning, the MIS were numbered so that the warm maxima – with the present interglacial as number 1– are odd and the cold peaks are even.

It was soon found that the ratio of the two most common isotopes of oxygen, ^{16}O and ^{18}O, exhibited a similar if not precisely coincident variation, also in the carbonates from deep-sea cores, but that the ratio was independent of local temperature and was instead constant in fossils from all paleodepths, indicating that the same oxygen isotope ratio characterized all ocean waters of a given time. On the other hand, the ratio of ^{18}O in freshwater is significantly lower than in seawater. Because the two isotopes differ strongly in mass, with ^{18}O some 13 % heavier than ^{16}O, water molecules with the lighter isotope evaporate at a distinctly higher rate than water with the heavier molecule and thus go preferentially into atmospheric water vapor, rain, and snow. Although ^{18}O is only 0.2 % of surface oxygen, the huge amounts of isotopically fractionated freshwater moving into ice sheets and back into the oceans during continental glacial cycles would result in measurable changes to the ratios in seawater. The oxygen isotope curve is then properly recognized as an ice-volume (i.e., sea level) curve rather than a paleotemperature curve (Shackleton 1967). Because the carbon isotope ratios are subject to uncontrolled sampling uncertainty, including unknown effects of postdepositional diagenesis and interaction with colder water at the seafloor, the oxygen isotope curve became the standard by which the effects of Milankovitch astronomical cycles were tracked in the Earth's climate history.

Using lengthy cores from DSDP (Deep Sea Drilling Project) sites in the Pacific, the oxygen isotope curve was subsequently extended into older levels (Shackleton and Opdyke 1976). Since the cycles in the deep-sea layers could not be directly dated, in the absence of unaltered volcanic debris, and because sedimentation rates are inherently irregular even in the least disturbed settings, the isotopic peaks were initially calibrated against the radiometrically dated boundaries of the paleomagnetic time scale. In a striking turnabout, however, the paleomagnetic boundaries themselves were subsequently redated in a new astronomical polarity time scale, or APTS, based on an improved version of Milankovitch's calculations, in which the mathematically determined age of orbital cycles was used to date the oxygen isotope peaks and thereby the associated paleomagnetic boundaries (Hilgen 1994). In the new calibration, the age of paleomagnetic reversals was slightly older, so that, for example, the Brunhes/Matuyama boundary went from 0.73 to 0.78 Ma, the top of the Olduvai went from 1.66 to 1.77 Ma, and the Gauss/Matuyama boundary went from 2.47 to 2.60 Ma (Berger and Loutre 1991; Hilgen 1994).

Whether the isotopic curve reflects global temperature indirectly or continental ice volume directly, it provides a clear story of changing and intensifying climatic swings over the span of the upper Pliocene and Quaternary. Aside from the stepwise increase in ^{18}O of seawater, which reflects the increase of permanent ice in the Antarctic ice cap, the most notable feature of the curve is the shift at MIS 22 from an obliquity-controlled frequency of ca. 41 kyr to an ellipticity-controlled frequency of approx. 100 kyr, with increased amplitude – i.e., greater volume of ice during more widely spaced glacial maxima. The first of these super maxima corresponds to the Menapian or Nebraskan at ca. 0.88 Ma and the beginning of the classic "ice ages" in the sense of Agassiz. The glacial-interglacial swings from this time to the present were still confusingly frequent to early stratigraphers, who often combined them, but their relation to orbital eccentricity signifies that the total amount of solar radiation reaching the Earth had become the controlling factor, rather than the variations of seasonality at high latitudes controlled by obliquity. In other words, that global cooling had reached a new low.

In pre-Menapian climatostratigraphy, two other distinct "ice age" glaciations were commonly identified, in maximum cold events that we now link to the roughly 410-kyr ellipticity amplitude beat. In the most thoroughly studied and most complete section exposed on land, in the Rhine delta of Belgium and the Netherlands, the glacial advance that corresponds to what is seen in the isotopic curve as the bifurcate maximum at MIS 60–62 (approx. 1.8 Ma) was termed the Eburonian. This event, which coincides with the cold-water deposits of the Calabrian Stage, was considered to be the opening episode of the Pleistocene until the IUGS moved the boundary. The other composite maximum of MIS 98–100 at approx. 2.5 Ma was identified as the Pretiglian glacial, a conspicuous event that climaxed the end of a significant downward step in climate, as the cyclicity shifted from precession-controlled, with a dominant frequency of 22 kyr, to the obliquity-controlled 41-kyr pattern of the next 1.6 million years (Lourens and Hilgen 1997). This was when the first continental ice sheet formed in Northern Europe and the first loess was deposited in northern China (Ding et al. 1997; Ehlers et al. 2011), justifying the current definition of the Quaternary and the relocation of the Pleistocene boundary to the base of the Gelasian Stage at 2.59 Ma. Shackleton et al. (1984) noted the presence of ice-rafted debris in North Sea cores slightly earlier in MIS 102, but this could have been due to mountain glaciers breaking off into the ancestral Rhine during this glacial maximum. The notable isotopic peaks at MIS 78 and 82, the strongest of pre-Menapian time, were in fact largely unrecognized in continental sequences aside from the North Sea, where this episode was seen as a glacial interlude in the extended Tiglian interglacial (Kuhlmann et al. 2006). The prolonged Waalian interval (MIS 25–55) was also generally considered to be an interglacial by the continental geologists, apparently because it was warmer overall than the Menapian and because its glacial maxima were relatively feeble in comparison with those of more recent times.

At the other end of the Quaternary time scale, the detailed history of the most recent glacial episodes, in which the history of *Homo sapiens* itself is involved, has been reconstructed back through four major glacial-interglacial cycles to about 420 kyr, according to variation in carbon dioxide and methane, and thus temperature, in lengthy cores taken from the stable ice caps of Greenland and Antarctica (e.g., Petit et al. 1999). Of particular interest is the termination of the final episode, the Weichsel or Wisconsin, whose great ice sheets in Eurasia and North America reduced sea level and exposed Beringia for the passage of humans into the New World, together with other still-enduring imprints on the fauna, flora, and topography of the higher latitudes.

At the present time, we live in one of the rare warm spells known as “true interglacials,” when the northern hemisphere ice sheets melt completely away from the lowlands surrounding the Arctic Ocean, leaving only the Greenland ice cap. The history of the next previous interglacial is instructive. This interglacial, identified as MIS 5e at 127 Ka, is the earliest of three subcycles in the brief warm interval prior to the Weichselian or Wisconsinan advance (Shackleton et al. 2003). During this maximum, identified as the Eemian or Sangamonian in continental stratigraphy, global sea level was several meters higher than at present – or, in other words, global warming, without any human intervention, was significantly greater than today. This would clearly suggest that our own interglacial is measurably colder than the previous one and that we are only at the beginning of the Ice Ages.

The record of the last glacial maximum – and, presumably, of the previous ones in the ellipticity-dominated later Quaternary – was punctuated by sudden melting episodes, known as Heinrich events after their discoverer (Heinrich 1988). These take the form of enormous catastrophic ice slides, equivalent to the sudden collapse of valley glaciers, or *jökellaups*, but of far greater scope, that covered the Atlantic in jostling armadas of gigantic icebergs and whose melting leaves distinctive layers of bouldery glacial debris across the ocean floor. The absence of normal planktonic microfauna in these deposits documents the presence of a relatively deep and long-lasting layer of freshwater that built up across the ocean as these masses of ice melted away over perhaps hundreds of years. This would have interrupted, or severely limited, the normal “conveyor belt” circulation that brings Gulf Stream warmth to the North Atlantic, suggesting that the Heinrich events created, rather than were created by, changes in ocean circulation (Broecker 1994; Sowers and Bender 1995). The relationship of Heinrich events to orbital forcing is not at all clear, given that the intervals between the last four events decreased from 13,000 to 7,000 years.

The ice core data have been interpreted (Sowers and Bender 1995) as evidence that concentrations of CO_2 and CH_3 began to rise, indicative of warming oceans, between 2,000 and 3,000 years before the final retreat of the ice caps.

Quaternary Climate and Environments

As noted above, the cooling of the world ocean, augmented by mid- to late Cenozoic breakdown of equatorial circulation due to the northward movement of Africa, Australia, and South America across the formerly open midlatitude seaways, led to progressive steps of Quaternary climate deterioration at 2.5, 1.8, 0.9, and 0.4 Ma – i.e., Pretiglian, Eburonian, Menapian, and Elsterian glacial stages (Table 2). Each of these steps was more severe than the previous one, and each left an imprint on flora and fauna that was not erased in the subsequent warmer period. As a result, the world's biota became steadily more fragmented and impoverished, and weather patterns changed irrevocably into new patterns that had not been seen before.

Under natural conditions, just as with man-made pollution, the carbon dioxide content of the atmosphere plays a major, perhaps critical, role in controlling air temperatures and is the principal means by which orbitally driven insolation cycles influence climate. Solar radiation, in itself, does not heat the atmosphere. Instead, the energy in the visible and ultraviolet spectrum passes through, to be absorbed and reradiated from the Earth's surface in the infrared as heat energy. This recycled energy is emitted mainly from rocks and water and somewhat less from clouds and vegetation, which tend to reflect solar radiation back into space. Most of the reradiated heat is trapped in atmospheric water vapor, but carbon dioxide absorbs a great deal more per molecule. In this way, small changes in CO_2 can cause significant changes in the temperature of the atmosphere, with a strong secondary transfer of atmospheric heat back to the ocean surface.

The influence of CO_2 on temperature is itself dependent on temperature, in a crucial feedback loop only exhibited by this particular greenhouse gas. This comes from the fact that the amount of CO_2 in the atmosphere, setting aside the transient effects of vulcanism or drought, is fundamentally regulated by the process known as the "solubility pump," based on the changing solubility of CO_2 in ocean surface waters in opposition to changes in water temperature. As surface water warms, its ability to hold CO_2 decreases, leading to more CO_2 in the atmosphere and thereby even higher water temperatures and even more atmospheric CO_2, in a runaway escalation. On the other hand, the reflective properties of the Earth's surface, or albedo, affect the amount of radiant energy that is absorbed and reradiated as heat, so that a slight increase in reflective clouds and ice will decrease the heat energy available for CO_2. The declining atmospheric temperatures allow the oceans to

Table 2 Quaternary time scale. The ages of major Quaternary climate cycles in the North Sea record, as well as consensus land mammal terms, are given in the A(P)TS or astronomical (*polarity*) time scale and compared with climate cycles documented by oxygen isotope variations in deep-sea cores. Some significant localities and events applying to paleoanthropology are shown on the right

absorb more CO_2, lowering air temperatures even further and removing more CO_2, in a reversal of the self-reinforcing warming process. In this way, carbon dioxide acts to very significantly amplify the climatic effect of orbitally triggered variations in solar radiation.

Quaternary glacial episodes follow a very fixed pattern, beginning when orbitally forced lower winter temperatures result in increased winter precipitation (*pluvials* in the tropics) with deeper snow packs. With varying rates depending on reciprocal summer conditions, permanent ice cover will expand to cover ever wider areas, in a trend greatly augmented by reduction in atmospheric CO_2 and the growing size and persistence of polar air masses. At some point, however, the ice-covered area reflects so much solar radiation that global average temperatures reach a point where evaporation and thus precipitation is greatly reduced. The decline in cloud cover allows even more radiation to be reflected back into space, in yet another self-reinforcing feedback. This trend is augmented by the decline in rainfall outside of the glaciated area, which reduces vegetative cover and further increases reflectivity. Thus, all glacial-climate episodes of the later Cenozoic, whether mild or intense, normally begin with cool and wet conditions and climax with cold and dry; in higher latitudes, the climax is known as the *polar desert* phase. Because they "make their own climate," the cold, highly reflective continental ice sheets of the Northern Hemisphere tend to persist well past the climax phase and then catastrophically collapse during the early part of the interglacial interval. In much the same way, the climate and temperature trend leading to glacial maxima are relatively gradual compared to the sharp transition to interglacial conditions once the peak is reached. This asymmetry, as well as intensity, in Quaternary climate cycles is entirely due to the way the enhancing processes affect climate, in the absence of the smoothing influence of a warm ocean.

Adaptations of Quaternary Flora and Fauna The Quaternary glacial cycles had an enormous impact on the terrestrial biosphere, during the "full glacial" interval that began with the MIS 22 Menapian at 0.9 Ma, and not only in the higher latitudes. To choose a widely applicable and highly appropriate example, Grichuk (1997) itemized the sharp decline in diversity and range of the mid-Pliocene woody plant flora that was found across Eurasia, ranging from Italy and the Netherlands to central Russia and Siberia to southern China, over the course of the Quaternary. Of more than 70 genera that were present across the continent during the Pliocene warm climates prior to MIS G20, 60–75 % disappeared from their former regions in a progressive displacement or depauperizing that appears to have begun, in a mild way, in the latest pre-Quaternary, and which was essentially complete by the Menapian (MIS 22, 0.9 Ma). This displacement affected the less cold-tolerant majority of the paleoflora such as the contemporary species of walnut, cedar, hemlock, laurel, pomegranate, grape, and fig, among many others, leaving behind the modern forest assemblages that consist mainly or wholly of genera classed as panholarctic (pine, fir, willow, poplar, birch, etc.) and north temperate (oak, elm, beech, maple, linden, etc.), that persisted virtually unchanged through the remainder of the Quaternary.

A similar pattern of rapid pre-Menapian development of the "typical" Quaternary fauna of Eurasia was noted by Aguirre et al. (1997). To begin with, just as the Quaternary began, *Equus* and arvicolid rodents arrived from North America and *Mammuthus* from Africa – perhaps not unconnected to the Pretiglian sea level lowering – simultaneously with an overturn in the ruminant fauna. From this level up to the Menapian, the authors noted rapid evolution in small mammals and the last occurrence (extinction and/or emigration) of a number of Pliocene large mammal lineages including *Mastodon*, *Hipparion*, *Nyctereutes*, *Chasmaporthetes*, *Leptobos*, *Megalovis*, *Gazella*, and *Gazellospira*, coupled with the first appearance (evolution and/or immigration) of the modern genera *Canis*, *Panthera*, *Pachycrocuta*, *Hippopotamus*, *Bos*, *Bison*, *Dama*, *Capra*, *Ovis*, and *Cervus*, among others – not to mention *Homo*. As with the temperate forests, it seems clear that the Eurasian mammalian assemblages that developed in the early Quaternary were sufficiently well adapted to intensifying climate change that they could continue, with little further modification, after the beginning of the "full glacial" conditions at 0.9 Ma to the present day despite the greater stress imposed by these more extreme conditions.

Quaternary in Africa The relatively highly developed state of geochronometry and paleontology in Africa allows a detailed analysis of the effect of Quaternary climate cycles in the tropics, with direct application to human evolution. According to Trauth et al. (2007), the late Cenozoic climate of East Africa prior is characterized by brief, widely spaced intervals, during which the climate varies rapidly with short precession-driven cycles of extreme wetness and extreme aridity, which marked by expansion of Rift Valley lakes. Prior to 2.7 Ma, these unstable intervals occurred every 400 kyr in synchrony with the fundamental cycles of ellipticity amplitude, whereas during the Quaternary they occurred only three times on an 800-kyr frequency at 2.7–2.5 Ma, 1.9–1.7 Ma, and 1.1–0.9 Ma (perhaps a one–two beat in the amplitude variation?). These three major lake phases in the equatorial region are coincident with the three most significant transitions in the downward trend of global climates during the Quaternary: the onset of Northern Hemisphere glaciations during the Pretiglian stage, the intensification of the Walker Circulation in the Eburonian stage, and the mid-Pleistocene Revolution or "full glacial climates" in the Menapian stage, respectively. A fourth major event at ca. 0.2 Ma is not apparent, and it would seem that post-Menapian conditions may have moved to a new level in which phenomena typical of the early Quaternary are no longer expressed. The coincidence of rapid climate swings in the tropics with these major glacial advances is due to the stepwise compression of the Intertropical Convergence Zone, which made East Africa locally sensitive to precessional influence.

The influence of precession in the tropics is seen in the variation of precipitation during the summer monsoon in East Africa (Kingston et al. 2007). The monsoon, which was initiated by the onset of Walker Circulation in the Indian Ocean in early Quaternary time, has steadily intensified with continued cooling of the upwelling water, whose temperature contrast with warm surface water is essential to this wind pattern (Tuenter et al. 1993). The precipitation maxima during monsoons are more intensified and extend further northward during minimum precession and maximum obliquity. Precession also influences the seasonal timing of the occurrence of the maximum precipitation.

The cool climate peaks in the Quaternary appear to coincide with, and thus arguably to influence, both major events and also the adaptive directions in the cladogenesis of the Hominidae. In the *habitat theory* of Vrba et al. (1996), it is argued that paleoclimatic oscillations, with corresponding changes in vegetation, are correlated to pulses of faunal extinction and speciation. A basic assumption in this theory is that the fundamental adaptations of a taxon to specific vegetational habitats, which can become acquired and enhanced during the 100-kyr span of a single eccentricity-driven climate cycle, become more pronounced through natural selection and will thus be recognizable characteristics in the clades that emerge in this habitat. In this way, terrestrial mammal biomes may be characterized by a "vegetational physiognomy" that reflects the habitat of the ancestral population.

The most compelling, though still controversial, evidence for the relationship of climate change to human evolution is based on studies of the fossil evidence dated to or slightly before the crucial 2.5 Ma step in global cooling that marks the beginning of the Quaternary (Behrensmeyer et al. 1997). At approximately this time, biome boundaries, grading from dry grasslands through open woodlands to tropical forests, shifted markedly toward the Congo Basin, with the result that the grassland vegetation expanded at all latitudes, together with grassland-adapted mammals, including steppe inhabitants from the north such as *Equus* and *Oryx*. Supporting evidence for this shift comes from an increase of open-grassland pollen in both marine and terrestrial (particularly low-altitude basin) samples, although overall the regional environmental settings remained a mosaic of habitats.

The floral changes suggest a period of relatively xeric conditions and appear to correspond to a pulse of faunal extinctions and speciations in response to the relatively extensive and rapid environmental shifts. The selective pressures of this habitat change appear to have favored megadont adaptations for feeding on tougher, more fibrous fruit, leaves, and grass in the dry, open woodland-savanna environment. Among the megafauna, the bovids, suids, and elephantids with larger teeth and more robust jaws became more diverse and more abundant at this time, and this was also true for early hominines as well. In *Paranthropus robustus*, *Paranthropus boisei*, and *Homo rudolfensis*, all of which appear to have evolved ca. 2.5 Ma or soon after, the same tendency is seen to postcanine megadontia, heavily reinforced and massive facial skeletons supporting relatively large masticatory musculature and relatively thick enamel. In the retention of thick enamel, at least, modern humans exemplify Vrba's habitat theory and carry the signature of the grasslands where *Homo* first appeared, as the Quaternary opened the door for new specializations and opportunities.

Conclusions

The appearance of *Homo* just as climate changes became significantly more extreme with the beginning of the Quaternary cannot be a meaningless coincidence; the link would seem to be that both events are synchronous with the expansion of the grassland habitat of Africa, to which hominins were already adaptively committed. As the world continues to cool with no end in sight, the increasingly stressful impact of orbital cycles on the planetary environment may also be linked to the increasingly resourceful adaptations of the hominin lineage. In fact, if we accept that natural selection is driven primarily by environmental change, we cannot avoid a very strange and simple conclusion: that the breakthrough into sentience that makes us able to read and write these words about the Quaternary would not exist, but for the existence of the Quaternary itself.

Quaternary Deposits and Paleosites

Klaus-Dieter Jäger

Contents

Abstract

Due to the mineral content of bones and teeth, the majority of fossil hominid remains are represented by these tissues; soft parts of the human body are preserved only very rarely. Whether or not fossils are well preserved depends not only on their own composition but also on the nature of the deposits that enclose them, which as a rule are sediments of the Pliocene, Pleistocene, or Holocene age. Numerous methods are now available for chronometric dating of hominid fossils, though none of them is applicable in all situations. However, it is still necessary to situate each hominid fossil within the larger stratigraphic framework. Hominid evolution began well over 4 million years ago and continued through the final part of the Neogene (Upper Tertiary). As a result, ongoing international discussions of stratigraphic boundaries over this time span are significant for the assessment of hominid evolution. In addition to providing

stratigraphic information, paleoanthropological sites offer insights not only into the environmental background of the fossils they yield, but in later periods commonly also into the cultural evolution of mankind and its relatives.

Introduction

The Tertiary-Quaternary boundary lies between the Pliocene and Pleistocene epochs. Due to the fact that the terms Tertiary (resp. "*tertiaire*") and Quaternary (resp. "*quaternaire*") were proposed in the early nineteenth century (for the scientific history of this question see Van Couvering, this volume) there is ongoing debate on the proper definition and even the usefulness of both terms (Cepek and Jäger 1988; Gradstein et al. 2004; Jäger and Ložek 2003, 2005; Pillans 2004). While in the past the most frequently accepted timing of the T-Q-boundary was around 1.8 Myr ago, with the beginning of the Calabrian Stage, in 2009 the International Union of Geological Sciences (IUGS) redefined it at the base of the Gelasian Stage, approximately coincident with the isotopic cold peak that occurred at about 2.6 Myr.

The Quaternary, consisting of the Pleistocene and Holocene epochs, is a comparatively short geological period, characterized by a series of significant long- and short-term climatic fluctuations, by the origin and expansion of the genus *Homo*, and finally by the rise of anatomically-modern *Homo sapiens*. Since the Quaternary paleoenvironmental background is essential for fleshing out the evolution of our genus, this contribution focuses on the following seven aspects, in turn: (1) the characteristics of fossil remains; (2) the characteristics of fossiliferous deposits; (3) possible methods for dating; (4) geochronometric perspectives; (5) global stratigraphic contexts; (6) environmental dependencies of paleosites; and (7) archaeological context.

Characteristics of Fossil Remains

Among preserved human remains, hard components from the skeleton, i.e., bones and teeth, are more commonly found, whereas soft parts are rare. The preservation of bones and teeth is determined by the content of calcium carbonate in the fossiliferous deposits. In the case of soft parts, their accessibility to decomposition is determined by the contemporaneous availability of water and atmospheric oxygen. If one of these two factors is kept to a minimum, the decomposition processes slow down or cease.

The availability of atmospheric oxygen is reduced in the case of subaquatic sedimentation or sediment conservation (e.g., in inland waters) or in the case of deposits lying below the groundwater table (e.g., peat in boggy terrain). Such conditions characterize the sites of bog bodies. On the other hand, desert areas with minimal water supply provide plenty of access to atmospheric oxygen, but the decomposition of organic matter is impeded by the lack of water. In these areas, an essential precondition for a lot of chemical processes is missing. Consequently, under such conditions the decomposition of organic matter is reduced. Instead, deserts frequently offer the prerequisites for mummification.

More often the preservation of fossil remains is restricted to hard components only. Independent of the local presence of water and atmospheric oxygen, the preservability of bones and teeth is a function of their apatite content, characterized by the formula $3Ca_3(PO_4)_2 \times CaF_2$.

Fossils in limeless deposits are protected from progressive corrosion and destruction since the superficial precipitation is not pure water.

As rainwater passes through the atmosphere prior to precipitation, it is contaminated by carbon dioxide (CO_2). Consequently, a weak carbonic acid (H_2CO_3) touches every surface, and the lime content in the soil comes in contact with the acid according to the following formula:

$$CaCO_3 + H_2O + CO_2 \rightarrow Ca(HCO_3)_2$$

If the subsoil contains a lot of calcium carbonate or a diffuse lime distribution, the first stages of decalcification are concentrated on the lime content of fossiliferous deposits and buried soils, and for a while bones and teeth remain protected against corrosion and dissolution. In limeless deposits, by contrast, such fossils are the only objects vulnerable to corrosive processes.

Characteristics of Fossiliferous Deposits

At more advanced stages of decalcification, even bones and teeth in limy deposits are exposed to corrosive destruction, but to a lesser degree. It is more or less insignificant whether the fossiliferous sediments in such limy deposits are loose ones with high porosity (such as sands or loess) or solid rocks (like travertine). Both provide sufficient and favorable conditions for the preservation of human skeletal remains, and this is why finds and sites of paleoanthropological significance are mainly connected with such deposits. Specifically, favorable conditions are shared mainly by the following sediment types:

1. Fresh-water lime deposits (calcareous deposits from inland waters, as a rule consisting of >90 % $CaCO_3$, frequently modified by diagenesis and found especially in travertines)
2. Loess (dust deposits of eolian origin, characterized by lime content usually ranging between 15 % and 30 % $CaCO_3$) with dust layers, intercalated by buried soils, frequently with calcareous (and also with decalcified) humus horizons
3. Cave deposits, especially in karstified calcareous mountainous regions, where caves originated from subterranean drainage ways and were subject to human entry and settlement after drying (which often happened after rerouting of the original waterway)

4. Calcareous debris, especially in mountainous regions, in open-air sites (with the lime content of the rock detritus being identical to that of the solid rock, perhaps less in the intermediate matter)
5. Calcareous fluvial and deltaic gravels and sands (although these more commonly contain displaced objects)
6. Calcareous lacustrine and beach deposits, as a rule silty and clayey, sometimes laminated

In addition to these site types, those favoring the preservation of soft parts (as in the case of bog bodies) have to be considered; these typically consist of peat and limnic mud layers.

Finally, tephras, i.e., pyroclastic deposits traced back to nearby volcanic eruptions—as in the case of Vesuvius during August of AD 79—enable the origination and preservation of human body imprints, which can be replenished by means of gypsum after detection. The method for such a procedure has been applied since the 1860s (since the year 1863, to be precise), first of all by the Italian archaeologist Giuseppe Fiorelli. Fiorelli was the long-standing leader of the excavations at the ancient town Pompeii, which was covered by tephra and pumice on the occasion of the AD 79 Vesuvian eruption (Mau 1899). Exceptional finds of this type are, e.g., the brain endocasts from the Eemian travertine at Gánovce in Slovakia (Vlček 1955, 1958).

Possible Methods for Dating

In many places, the geological preconditions for fossilized human remains coincide with sites of archaeological discoveries proving previous human presence or even settlement. That is why it is frequently the case that sites of significant paleoanthropological finds are also highly important in terms of archaeology. Not least, such in-site combinations facilitate the dating and the cultural-historical assignation of the respective paleoanthropological observations.

Moreover, the calcareous deposits mentioned above enable not only the preservation of human skeletal remains but also of comparable animal records. Both the paleozoological investigation of skeletal parts, yielding evidence for the early presence of micro- and macromammals, and the determination and examination of fossil shells, providing evidence of former molluscs or ostracods, contribute to biostratigraphic datings and paleoecological assessments. The investigation of mollusc remains is of special validity in central and western Europe, since precise species determinations have been achieved in these regions based merely on conchylia or even just their fragments (Ložek 1955, 1964). Comparable methods of dating are also in preparation in other parts of Eurasia (Meng 2003). However, investigations of micromammals as well as of molluscs are not restricted to qualitative records. On the contrary, both categories of fossils provide opportunities for quantitative analysis and statistical consolidation of results. Moreover, their examination permits the reconstruction of faunal assemblages as a basis for paleoecological interpretation (Rousseau 1990). They thus contribute to the characterization of the natural environment surrounding previous human populations.

In travertines, the paleozoological record is often complemented by leaf imprints and incrustations of various plant structures, contributing both to the dating of sites and to their paleoecological characterization. In sequences of peat and limnic layers of mud or marl, pollen analysis frequently offers an adequate method for dating. Thus, paleobotany as well supports the dating of fossil human remains as well as the reconstruction of the paleoenvironment, especially in the case of travertine and bog sites.

However, all of these paleontological and archaeological procedures and observations contribute only to the *relative chronology* of sites (see chapter "▶ Chronometric Methods in Paleoanthropology," Vol. 1), whereas the establishment of an absolute chronology—or "*calendar chronology*"—covering the whole time span of fossil hominids requires another methodology.[1] The calendar chronology of fossil hominids is based mainly on physical procedures, as summarized by Geyh (1980, 1983) and Wagner (1995, 1998), among others (see chapter "▶ Chronometric Methods in Paleoanthropology," Vol. 1). The preferred methods are radiometry (based on ^{14}C, uranium series, $^{40}K/^{40}Ar$, and others) and luminescence procedures (TL, OSL, IR-RF). The last 10–12 Ka is also within the reach of the botanical method of dendrochronology, but in practical terms this method is restricted to wooden objects. Consequently, paleoanthropological finds can only be dated by means of dendrochronology when they are associated with preserved wood. In central Europe, the range of oak chronology provides "a high-resolution time scale for nearly the last 12,000 years" (Spurk et al. 1998, p. 1114). However, the preservation of wood is, as a rule, subject to the same prerequisites as mentioned above with regard to soft parts of human bodies.

Geochronometric Perspective

The choice among procedures that are suitable for the numerical dating and calendar chronology of finds proving the presence of fossil men or early hominids is influenced to a high degree by the characteristics of the surrounding fossiliferous deposits. Different compositions of preserved material require the application of different methods. It follows that there will be differences in precision and range of dating. As a general rule, a short range is the inevitable consequence of precise temporal resolution and vice versa. Consequently, and independent of the datable material, the older the finds are, the more imprecise the numerical dating will be.

---

[1] A note on terminology: As a rule, the search for more or less precise dates, both in the geosciences and in archaeological disciplines, is focused on so-called "absolute" chronology. However, already during the early 1980s, the paleontologist Jaeger (1981) claimed that this term is erroneous and – strictly speaking – inadmissible, since it assumes the existence of absolute time, which is physically and philosophically impossible.

The trade-off is comparable to the situation in optics, where the perceptibility of objects decreases with increasing distance. But this is only one aspect of geochronometry.

Another aspect relates to the dated material. Fossil remains of men from historical times and, going back further, from the last millennia can frequently be dated directly, e.g., by using the radiocarbon method. In contrast, fossil remains from the Middle Pleistocene – that is, finds that are several hundreds of thousands of years old – are not datable directly; however, as a rule the enclosing fossiliferous deposits may be subjected to numerical dating, e.g., by means of uranium series in the case of travertine deposits or by application of luminescence procedures in the case of loessic deposits. A larger age characterizes the early stages of hominid evolution, as evidenced by the occurrence of australopithecines. Such discoveries can be dated with only a few methods, e.g., the potassium-argon method (^{40}K/^{40}Ar); as a result, only rocks and loose deposits of volcanic origin can be analyzed. This has the useful application, however, that layers of lava rocks and tephras can be dated at sites of fossil hominid remains, if such layers are included in the stratigraphic sequence. In these cases, then, the materials subjected to dating are not the fossiliferous deposits themselves, but distinct layers in the sequence that includes the fossiliferous deposits. Consequently, the chronological investigation is restricted to time-marks in the local stratigraphy of the research site (cp., e.g., Fitch and Miller 1976; Ullrich 1983, Fig. 3).

Global Stratigraphic Context

Hominid evolution started more than 4 Myr ago (cp Johanson and Blake 1996, p. 23). As mentioned in the Introduction, according to resolutions of the IUGS on the occasion of international congress meetings (London 1948, Moscow 1984), this time span was subdivided by the boundary between two different geological systems, i.e., the Tertiary and the Quaternary (see chapter "▶ Quaternary Geology and Paleoenvironments," Vol. 1) (Aguirre and Pasini 1985; Partridge 1997; for background on the history of this decision, see Cepek and Jäger 1988). The chronological position of the boundary was set down at 1.64 or 1.8 Ma. The Tertiary and Quaternary systems share the common feature of significant long-term climate fluctuations, but are nevertheless noticeably distinguished by the average magnitude of the temperature oscillations around their mean values, especially in middle and higher latitudes of the globe.

Recently, the International Commission on Stratigraphy (ICS), a body of the IUGS with the authority to make recommendations related to a worldwide geological timescale, has presented a proposal aimed at the removal of this stratigraphic boundary by extending the preceding system of the Neogene, i.e., the Upper Tertiary, to the present (Gradstein et al. 2004). However, there are serious objections to this proposal (Claque et al. 2004), in light of the fundamental environmental changes during the relevant period (Gibbard 2004; Pillans 2004; Van Couvering 1997).

Independent of these ongoing discussions, the actual fixation of the debated global stratigraphic boundary at 1.64 or 1.8 Ma seems an unfortunate decision (Cepek and Jäger 1988). The chronological base of the younger system or period might be defined more properly at 2.6 Ma (Gelasian stage of the Pliocene series of the Neogene to date; Pillans 2004).

Environmental Dependencies of Paleosites

Climatic fluctuations over several hundreds of thousands of years, as mentioned above, not only determined the environmental conditions for previous hominids both in the temperate zones and in polar and subpolar regions, but also influenced human site selection and the chances of fossil preservation. Varying climate conditions favored different processes of sedimentation and, consequently, different types of deposits.

Thus, during prolonged cold periods, i.e., the glacials, the advance of glaciers in subpolar and mountainous regions was accompanied by periglacial and climatically continental circumstances in lowlands and hilly uplands of midlatitudes, which favored eolian deposition, mainly of dust. Consequently, hominid finds from glacial periods have frequently been made in loess sequences, as for instance at Dolní Věstonice in the Czech Republic and at Austrian sites.

On the other hand, many sedimentation processes can take place under warm—frequently under warm and wet—environmental conditions only. The respective deposits could originate either under a constant warm climate, as in the tropics, in lower latitudes, or in the warm phases of glacial cycles, the so-called interglacials, in the midlatitudes. This is why the interglacials favored such deposits as travertine and peat. Travertines may be defined as consolidated freshwater lime deposits, especially calcareous tufas.

As mentioned above, especially the travertines have provided excellent conditions for the preservation of finds, as well as for environment reconstruction. Moreover, the origination of these deposits required the proximity of springs and water, due to the dependence of all freshwater lime deposits on hard water. Owing to the significance of water for human life, sites of travertine formation were also frequently preferred locations of human presence and settlement. Consequently, man has often visited such sites and his remains can be discovered there frequently. Examples in central Europe are the well-known interglacial sites at Gánovce, Tata, Taubach, Stuttgart-Bad Cannstatt, Weimar-Ehringsdorf, Bilzingsleben, and Vértesszölös. Due to human presence and activities at such sites, they are significant not only when seen from a paleoanthropological angle but also as a result of archaeological discoveries.

As a rule, interglacial deposits, such as peat, mud, or travertine, contain assemblages of floral and faunal fossils and thus provide opportunities for quantitative paleontological analyses. Differences in age are reflected in differences in assemblage composition recorded by pollen, conchylia, or micromammal bones and teeth. Consequently, suitable methods of quantitative paleontological analysis aimed at biostratigraphic indications and correlations are pollen analysis (peat, mud), paleomalacology, and the investigation of micromammal remains (especially in travertines).

When differences related to the composition of the flora and fauna which accompany fossil hominid remains are taken into account, a relative chronology of sites can be developed based on biostratigraphy.

This approach is exemplified by the application of paleomalacology to famous interglacial travertine sites in central Europe (Jäger and Ložek 2003), including significant places of paleoanthropological discoveries (Jäger and Ložek 2005). Sometimes biostratigraphic indications lead to revision of previous chronological assignations of particular sites. This was the case, e.g., at Weimar-Ehringsdorf in Thuringia, Germany (Jäger 2001; cp also Mania 1993; Steiner 1993). Such corrections may help clear up seeming discrepancies in the paleoanthropological record. At Weimar-Ehringsdorf the original stratigraphic assignation to the Eemian (last interglacial of the Pleistocene) seemed to recommend a classification of the finds within the realm of the Neanderthals, whereas their later examination by Emanuel Vlček (Prague) emphasized similarities of the cranium (e.g., the occiput) to stratigraphically earlier crania at Steinheim (Baden-Wurttemberg, Germany) and Swanscombe (UK) (see chapter "▶ Neanderthals and Their Contemporaries," Vol. 3). As chronometric datings of the accompanying fauna and flora by Mallik et al. (2000) have confirmed, the stratigraphically determined age and the osteological record of the human remains are now in line.

Archaeological Context

The majority of the sites providing fossil human remains, both from early hominids and from modern humans, have enabled archaeological observations. To be precise, at many sites bones and teeth prove the previous presence of human beings, while at the same time accompanying archaeological finds or man-made modifications of the site tell us about human activities, behavior, and lifestyle. This is why frequently at sites of paleoanthropological significance, archaeological discoveries are made as well. This is true both with respect to early hominids like Koobi Fora (in the Turkana Basin, Kenya: Coppens et al. 1976) or Hadas (Awash region, Ethiopia: Kimbel et al. 1982) and with respect to later humans (see chapters "▶ The Species and Diversity of Australopiths," and "▶ Role of Environmental Stimuli in Hominid Origins," Vol. 3).

Since the Middle Paleolithic, a considerable share of the available evidence has come from burials. This dating means that even Neanderthals are among the number of specimens recorded in this way (cp. the summarizing survey by Bosinski 1985, pp. 44–52). In this context one might mention, for example, the famous specimens at Le Moustier and La Chapelle aux Saints in France, or the "Old Man" from the Shanidar cave in Iraq (see chapters "▶ Neanderthals and Their Contemporaries," and "▶ Dispersals of Early Humans: Adaptations, Frontiers, and New Territories," Vol. 3).

During the Upper Paleolithic, the number of burials increased (see chapters "▶ Cultural Evolution During the Middle and Late Pleistocene in Africa and Eurasia," "▶ Dispersals of Early Humans: Adaptations, Frontiers, and New Territories," and "▶ Neanderthals and Their Contemporaries," Vol. 3). Among the finds from this era is a female individual from the Pavlovian site at Dolní Věstonice (Moravia, Czech Republic) who was portrayed in a contemporaneous ivory carving from the same site (Klima 1983, pp. 83–89). During the Holocene, comprising the last 11,600 years (Litt et al. 2001), *Homo sapiens* is represented not only by single burials but rather by multi-individual cemeteries of different age, occasionally comprising hundreds of burials or more (e.g., Hallstatt in Austria, Early Iron Age, mainly eighth to sixth century BC, where ca. 1,300 burials going forward all the way to the twentieth century AD have been discovered: Kromer 1959; Sacken 1868; later Pauli 1975).

Burials favor the preservation of bones and teeth jointly, frequently even in the original articulation (see chapter "▶ Taphonomic and Diagenetic Processes," Vol. 1). Burials aside, the previous presence of humans at a site of discovery can often be proved for other reasons. Thus the preselection of sites of later—or current—evidence of habitation for paleontological investigations could involve a sleeping site in the case of early hominids (see chapter "▶ The Paleoclimatic Record and Plio-Pleistocene Paleoenvironments," Vol. 3), as exemplified by the cave system of Swartkrans in Southern Africa (with finds of *Paranthropus*, according to Brain 1983). In later periods, humans frequently used the sites of record for settlement as well as for activities of everyday life, art, and other cultural purposes. Well-known examples have been recovered in caves as well on open ground.

An outstanding example of cave occupation by previous residents is given by site 1 at Chou Kou Tien (Zhoukoudian) near the Chinese capital Beijing (Peking), well known as the eponymous site of the so-called Peking Man (*Sinanthropus* respectively *Homo erectus pekinensis*; chapters "▶ Later Middle Pleistocene *Homo*," and "▶ Defining *Homo erectus*," Vol. 3; Wei 1988; Huang 1998; Brühl and Laurat 2000, pp. 9–10 and pp. 94–100). Evidence of Neanderthal men found in these caves has proved that these locations were both residential and burial sites. The former are usually distinguished from the latter by the irregular scattering of more or less isolated bones and teeth.

The same feature of co-occurrence of paleontological and archaeological finds characterizes residential sites on open ground. However, if calcareous deposits are present in the subsoil to some extent, then such archaeological sites also favor the preservation of bones and teeth and, more frequently, of isolated and often fragmentary objects.

In situ preservation of the original depositional conditions is provided especially at travertine sites (e.g., Vértesszölös in Hungary: Kretzoi and Dobosi 1990; Bilzingsleben in Germany: recently Mania 1999; Weimar-Ehringsdorf, likewise in Germany: comprising Steiner 1981; Vlček 1993) and at loess sections (e.g., Dolní Věstonice in Moravia, Czech Republic: Klima 1983; Vlček 1991; chapters "▶ Dispersals of Early Humans: Adaptations, Frontiers, and New Territories," and

"▶ Cultural Evolution During the Middle and Late Pleistocene in Africa and Eurasia," Vol. 3).

Fluvial and deltaic as well as—rarely—marine deposits as a rule contain not only isolated and more or less fragmentary parts of the human skeleton, but also dislocated parts. Well-known examples are the famous early mandibles from Dmanisi in Georgia (Bosinski 1995; chapters "▶ *Homo ergaster* and Its Contemporaries," and "▶ Defining *Homo erectus*," Vol. 3; Dzaparidze et al. 1992; summary by Justus et al. 2000; Lordkipanidze et al. 2013; Sander 2013) and from Mauer near Heidelberg in Germany (recent discussion of the local situation: Fezer 1992; Zöller and Stremme 1992; Löscher 1996; von Koenigswald 1996; Wagner et al. 2007), as well as the cranium found at Steinheim/Murr in southwestern Germany (Adam 1988).

By contrast, in the case of bog bodies preservation has frequently taken place not only of the original articulation of bones and teeth but also of soft parts of the human body (see a.o. Hahne 1918; Dieck 1965; Glob 1969; Brothwell 1986; Turner and Scaife 1995; Gebühr 2002).

Conclusion

Depending on the composition of fossil human remains (mainly bones and teeth), their preservation as a rule is associated with certain sediments— mainly calcareous ones—from either the late Neogene (Pliocene) or, quite often, the Quaternary (Pleistocene and Holocene). The stratigraphic position of these fossils within the realm of the Quaternary or Neogene enables chronological arrangement of the finds, with increasing precision towards the present. Remains of fossil flora and fauna provide additional insights into the environment and circumstances of life of past human beings. Frequently, the detection and discovery of fossil remains has been favored by archaeological excavations and investigations of former settlement and burial sites.

Abstract

Starting from Ernst Haeckel's famous definition of ecology, our review considers the premises and the meaning of paleoecological research. Unlike current ecology, paleoecology has to pay more attention when dealing with "real" reconstructions. The concept of uniformitarianism is presented and demonstrates the importance of philosophical constructs in scientific work. Middle-range theory attempts to filter out false conclusions. Abiotic factors have had a strong influence on adaptive evolution; volcanism, tectonics, and climate exemplify this. Subsequently, we address biotic aspects of fossil findings, and in this context we discuss taphonomy, stratigraphic research, and interactions between floral and faunal environment. In a synthesis, we present three cross sections of human evolution at different time horizons (early-middle-late) to exemplify the inevitable multidisciplinarity of paleoecology, and we present some key events that probably altered the direction of radiations among hominids. Obviously, human evolution is not a special kind of evolution; it follows the rules of evolutionary biology, and hence depends undoubtedly on environmental influences.

Introducing (Paleo)ecology

In a strict sense, paleoecologists try to detect all processes which have affected a fossil organism *antemortem* (Behrensmeyer 1992). *Postmortem* events are analyzed by the methods of taphonomy and by studying diagenesis (Andrews 1992; Lyman 1996). One has to realize that these two fields are inseparably linked when dealing with fossils and the reconstruction of their environments. Here is illustrated briefly what (paleo) ecology is, followed by a discussion of actualism (or uniformitarianism) as an essential aspect of paleoecology.

Neoecology Versus Paleoecology?

Haeckel (1866, p. 286), who introduced the term "ecology" (German, Oecologie; nowadays, Ökologie) stated:

"Ecology is a part of science that deals with the relationships between organisms and their surrounding environment, wherein we can place all conditions of being in the broadest sense. These are of partly organic, partly inorganic nature; and both are of utmost importance for the form of organisms, because they force it to adapt to them" (translated and shortened by the authors).

Haeckel included the following aspects in his "conditions of being":

1. Abiotic factors (physical, chemical, climatic, electricity conditions; inorganic food; composition of water and soil)
2. Biotic factors (all relationships between organisms)

More recently, modern ecology has been defined as "the study of the relations between organisms and the totality of the physical and biological factors affecting them or influenced by them" (Pianka 1983, p. 3). Among its most interesting branches are the distribution and frequency of organisms/populations/communities, hence natality, mortality, and migration (Begon et al. 1998). It makes sense to divide ecological research into three subsections (Table 1).

All of these definitions are crucial when talking about ecology; however, for several reasons, it is not that easy to simply insert the prefix "paleo" for the study of ancient ecologies (Andrews 1992; Rull 2010).

There are not only strong connections between paleoecology and recent (neo, contemporary) ecology (sensu Rull 2010) but also some basic differences (Table 2). In spite of these differences, Rull (2010, p. 1) claims that "...ecology and paleoecology are only different approaches with a common objective, which is the ecological understanding of the biosphere. [...] It is recommended that ecologists and palaeoecologists develop joint projects," and further on "... a palaeoecologist is not simply a palaeoscientist whose data may be of interest for ecology but is primarily an ecologist working on another time scale, with different methods."

Table 1 Subsections of ecological research: (1) autecology that aims at all aspects of an individual as representative of its species and intraspecific questions, respectively; (2) demecology that deals with the interactions of a certain population with its environment; and (3) synecology that refers to all questions of interspecific relationships within an ecosystem

	Reference object	Reference parameter
Autecology	Single organism	Environment
Demecology	Homotypical community of organisms (population)	Contemporaries and environment
Synecology	Heterotypical community of organisms	Contemporaries and environment

Translated according to Schwerdtfeger (1968) and Tischler (1993)

Table 2 The differences between contemporary ecology or neoecology and paleoecology

Contemporary ecology or neoecology	Paleoecology
Source: currently living organisms in an intact ecosystem	*Source*: fossil assemblages and age estimation data
Precise and comprehensive description of environments and organisms in an ecosystem, parameters can actually be measured	Mostly characterization of a former milieu in order to subsequently state inferences on environmental and organismic factors
Potentially all faunal and floral components are available in the observed biocenosis	Fossils are the only documents available; hardly ever is the fossil record complete and many questions remain unanswered
Data acquisition is limited to a few years or even months/days	Excavated facies span a time of thousands and even millions of years

Compiled and extended from Etter (1994)

Paleoecological research is aimed mainly at analyzing long-term trends because when dealing with fossils, short-term processes (e.g., successions, microevolution) are not recognizable, or recognizable only with difficulty. Frequently, paleoecological analyses focus on the development of communities, in particular paleoenvironments, over time spans of millions of years (Stanley 1994; de Menocal and Bloemendal 1995). Or they combine the fossil record with molecular phylogenetics focusing on diversification patterns and speciation requirements (Benton and Emerson 2007). Despite the fact that there is a conspicuous nexus between organismic paleoecology and geologically orientated facies observations, it is preferable in practice to separate the two, since both disciplines are in themselves multilayered and sophisticated networks (Etter 1994; Seppä 2009; Sahney et al. 2010). Contemporary paleoecological questions include:

- Are similar as well as different morphological characters linked to adaptations in the same kind of habitat?
- Are there interdependencies between paleomilieu and life cycles/life-history parameters/population densities?
- How is distribution and diversity of life on Earth dependent on ecological requirements – especially biome shifts and ecosystem development (Sahney et al. 2010)?
- How do these transformations interact to species adaptation/migration and population changes?
- Can extinction and even speciation events be traced back to major changes in the environmental conditions, and if so, to which?
- What are the rates of speciation and extinction?

All of these questions require a high degree of multidisciplinarity and cannot be solved only in terms of single-factor analyses (Seppä 2009). They also have to encompass multiple factors that build ecosystems like the one covering our planet.

After a short look at the approach of actualism/uniformitarianism, we will take the previous quotation by Haeckel as a guidepost for the following sections. After touching on abiotic factors, we proceed to the biotic ones and finally merge them in a third step that we designate as synthesis. In the latter we try to focus on hominid or near-hominid evolutionary perspectives and ignore, because of solely talking about terrestrial systems, important paleoecological aspects that refer to marine ecosystems.

"The Present Is a Key to the Past": A Valid Premise?

One of the most important concepts in the geosciences is *uniformitarianism*, a principle introduced by the Scottish physician and geologist James Hutton (1726–1797). Originally, this was framed as an antithesis to the idea that catastrophic phenomena might have formed the Earth's surface. It was the establishment of the idea that the laws of nature stay constant that made geology a mature part of the scientific endeavor. This philosophical approach is axiomatic in physics, but it was Sir Charles Lyell, "Darwin's guru and intellectual father figure"

(Gould 1994, p. 6764), who placed this idea before a broader scientific community. The application of this principle inspired Darwin, although Gould (1994) warned against the pure extrapolationism of Darwin's uniformitarian perspective. Gould's (1994, p. 6768) attractive musings on paleontology's meaning are more important than ever. The simplemindedness of universal reduction to lower levels must be abandoned: "Our evolutionary world is a hierarchy of levels, each of legitimacy and irreducible worth." Riedl (1981) also emphasized the limitations of each methodological level.

Based on Gould (1984); Etter (1994) reduced the philosophy of actualism to four principles:

1. Laws of nature do not change on Earth in time and space.
2. Processes that influenced geological phenomena in the past occur in the same manner now.
3. The speed of geological and biological processes does not change.
4. In the past the same materials and the same conditions existed.

The first two of these are methodological assumptions that are necessary to conduct inductivist research. Points three and four are less definite. As Etter (1994) points out, the adoption of all four premises may be limited due to (1) constraints of observing the past and (2) the strong fluctuations of geological phenomena which occurred long ago (e.g., the circumstances of the dinosaurs' extinction). Even if the core of uniformitarianism is still valid, today's researchers expand their view, monitoring large-scale systemic processes or patterns that may explain what we are really able to learn about the guidelines in the continuum past-present and how we are able to adopt the results for future predictions (Dearing et al. 2006; Rull 2010). Although the mass of available data increases drastically, we should not forget to use the fossil record as a "litmus paper" to adequately evaluate the results (Jackson and Erwin 2006).

Dodd and Stanton's (1990) taxonomic uniformitarianism is a derivative of substantive uniformitarianism and an attempt to reconstruct ecological niches by assuming that the environment of a fossil will have been identical with that of the nearest extant relative. But it is obvious that reliable conclusions can only be made in this way if a fossil is a member of an extant species. This can virtually never be the case except for Pleistocene and Holocene deposits (Etter 1994), and even then there are also theoretical problems, one of which is the fragmentary knowledge researchers have of former ecological niches. An absence of enemies could, for example, have caused an expansion of the niche. Thus Etter (1994) admits that taxonomic uniformitarianism should be limited to fossils with extant representatives or relatives. Yet the method can be improved by investigating groups of species within a taxonomic group rather than just one.

Tattersall (1998) reviewed such provocative ideas of evolutionary biologists as Dawkins' "Selfish Gene" and Eldredge and Gould's "Punctuated Equilibria" (Eldredge and Gould 1972) and also relativized the meaning of adaptationism (p 95: "…organisms may not be as exquisitely fine-tuned to their environments…")

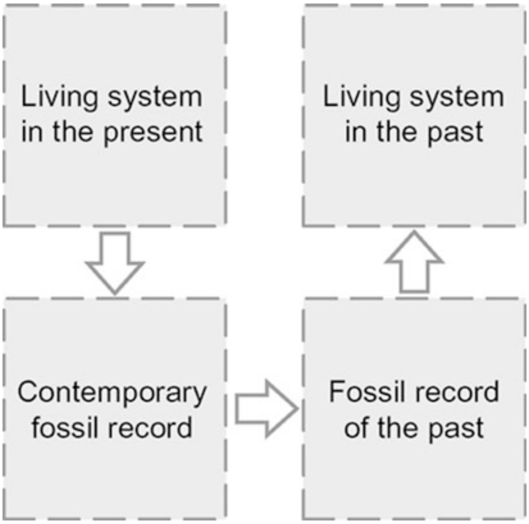

Fig. 1 Linking the past and the present. Interpreting the fossil record and reconstructing life in the past depend on the understanding of the process of transformation during fossilization. This is inferred by observations of contemporary fossil information or the way in which observable behavior in the present would be visible in the fossil record (After Foley 1987)

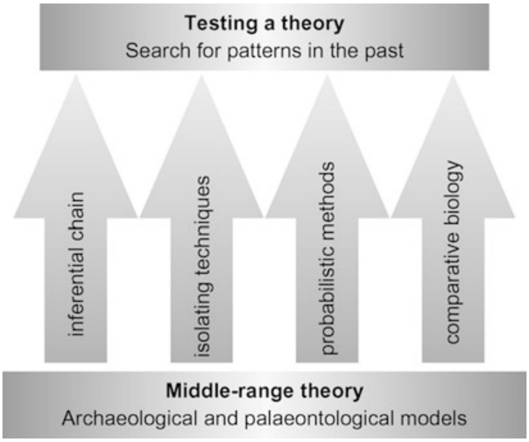
in our evolutionary thinking. Therefore, no one should forget that there exists a possibility of overstraining positivism, thus using only verified results as a basis for the interpretation of our findings. *Actio-reactio* thinking is of course essential and the *only* way of doing science in general, but the danger of storytelling in paleoecology is acute (Henke 2010). Scientists are at risk of delivering explanations for adaptations which could be true, but actually might not be (see later). It is questionable whether the equation *Bauplan : environment* = 1:1 is satisfied.

Foley (1978) linked the past and the present by invoking Binford's (1977, 1981) *middle-range theory*. This is actually an assemblage of theories that link observable aspects of the past to processes operating today and permit inferences about the conditions of geological and biological systems in the past. Such observations must be linked to observable past phenomena (i.e., an anatomical element) (Fig. 1). The connecting piece between a theory (deductions and predictions from a basis of axioms) and the data is the *model* (which describes and predicts the variation and structure of phenomena derived from theoretical principles).

Foley (1987) also points out that there are different levels of model building, depending on behavioral (predepositional) and geological (postdepositional) factors. Furthermore, identical records might be produced by different behaviors (Hill 1984; Foley 1987), so the *overlap* of different models has to be taken into consideration. Four pathways are very useful for testing a theory in order to reduce the pure reflection of contemporary ideas: (1) a careful analysis of each link in an inferential chain; (2) like Binford (1981) not following the broad trend, but rather looking for small details that might appear comparatively insignificant; (3) the isolation of processes that may result in similar results and assigning (theoretically/experimentally) the probabilities of various outcomes; and finally, (4) the comparative biological approach, which investigates patterns of interspecific and intraspecific variations that can be used to correlate biological variables (Fig. 2).

Fig. 2 Implications of the middle-range theory: a summary of pathways to the past (Modified from Foley 1987)



Ecology and Cladistics

The a priori assumption that a particular character (or character state) is the result of a particular evolutionary process may lead to far greater problems of circularity than does the incorporation of these characters into a global estimate of evolutionary history (Luckow and Bruneau 1997, p. 150). These authors infer that the exclusion of ecological information from a phylogenetic analysis when testing ecological hypotheses is not only unnecessary but also "undesirable." Luckow and Bruneau (1997) justified their arguments by concluding that character exclusion would partition the data in an arbitrary way and that discrete homology statements would get lost.

Abiotic Factors

Throughout natural history, the physical conditions of the Earth have had a strong influence on evolution, adaptive or otherwise, and consequently on human evolution (Dearing et al. 2006). Environmental changes shape the habitats and the evolutionary "fates" of living systems (see also Vrba, chapter "▶ Role of Environmental Stimuli in Hominid Origins," Vol. 3). One fundamental aim of evolutionary biology is to understand and reconstruct the interaction of physical environmental stimuli and the survival of organisms – even in human evolution (Potts 2012; Bailey et al. 2011). Wegener (2005, p. 222) wrote: "Only by summing up all fields of the geosciences may we hope to find out the "truth," this means determining a picture that integrates all known facts in the best order and which seems to represent the utmost probability; even then we have to be aware that each discovery, regardless of which scientific field it emanates from, may modify the result" (translated by the authors). Earlier acceptance of this neglected genius' appeal for an adequate scientific network might have accelerated the unraveling of the Earth's physical secrets.

Geological Influences

Volcanism

In the truest sense of the word, volcanoes put pressure on their environments. Usually eruptions have a localized but strong influence. However, tephra (ejecta, e.g., ash or pumice) and lava do have the potential to modify water and soil chemistries, thereby eliminating or modifying habitats over wide areas. Occasionally they also support the conservation of important fossil footprints.

Including sea floor and continents, about 80 % of the Earth's surface has been produced by ascending melted rock, primarily at plate boundaries. Volcanic material creates a useful (though blurred) perspective on the Earth's interior. The Earth's lithosphere also delivers nutrients, chemical resources, and minerals (Press and Siever 1995).

Feibel (1999) investigated eruptive activity in the Turkana area of northern Kenya and concluded that the higher assumed rate (38 events per 240,000 years) indicates one significant eruption per 6,300 years. Massive eruptions can also cause global impacts since they glut the atmosphere with climate affecting aerosols. Rampino and Shelf (1992) discussed the controversial idea of the Mount Toba explosion 74,000 years ago, which might have produced a sharp cooling and consequently a temporary shift to glacial conditions. Even today volcanoes are able to paralyze parts of *Homo sapiens*' "modern life" if you imagine the eruption of Iceland's Eyjafjallajökull and ash-cloud-induced air-traffic breakdown in Northern and Middle Europe in 2010.

Tectonic Aspects

Faulting within local sedimentary basins, continental plate movement, and highland formation through uplift may greatly affect terrestrial habitats (Chernet et al. 1996; Trauth et al. 2007; King and Bailey 2006). Between 16 and 12 Ma, the Eurasian and the Afro-Arabian continental plates moved and allowed an exchange of the flora and fauna, e.g., an exodus of early African apes (Potts 2003). Between 7.0 and 5.0 Ma, the Atlantic Ocean and the western end of the Mediterranean were temporarily separated as Africa drifted northward. Here, a periodic drying and flooding of the Mediterranean basin occurred and huge salinity deposits were built up. Western Eurasia dried out due to an evaporation and salinization phenomenon. Between 4.5 and 3.0 Ma, the Isthmus of Panama was formed by the contact of continental plates and the following uplift (Stanley 1995). One result was the strengthening of the conveyor belt of Atlantic Ocean currents: the North Atlantic was "watered" by the warm Gulf Stream. The initiation of ice ages in the Northern Hemisphere during the Late Pliocene can be explained by the development, over 36 Ma, of isolation of the Arctic Ocean caused by a high-salinity, warm, sinking, and returning current (Stanley 1994).

Rift Valley formation in eastern Africa and the uplift of western North America and the Tibetan Plateau are examples of drying and cooling effects. Models of general circulation show that when major air currents are divided by elevated plateaus, the air is altered due to winter cooling and summer heating, causing high- and low-pressure areas to form over landmasses far from the plateaus (Ruddiman and Kutzbach 1989). One consequence is a greater seasonal variation and also the creation of seasonal monsoons. The overall effect is a cooler and drier global climate (Ruddiman et al. 1989). Even geochemical weathering on rocks can be traced back to uplifts: enhanced monsoons, steepening river gradients, and faster erosional rates increase weathering. Raymo and Ruddiman (1992) suggested that global cooling might result from the deposition of carbon from the highlands into the ocean as well as from weathering responses. A consequence would be a reduction in carbon dioxide and its removal from the atmosphere. The heat-retaining function of carbon dioxide as a major greenhouse gas would disappear as a result. Another effect occurs on the leeward sides of uplifted regions: upland depletion of air moisture and precipitation cause rain-shadow drying, a phenomenon partly responsible for the aridification of the area to the east of the African Rift Valley compared with its western counterpart.

Another possibility is that the shapes of sedimentary basins are modified by the local impact of earthquakes. Availability of water to the local biota is obviously a very important factor, so the changes of fluvial systems by intrabasin faulting mechanisms are also a matter of paleoecological discussion.

Eastern Africa is a superb example to illustrate intracontinental rifting phenomena. During the Cenozoic, a system of continental rifts developed from the Red Sea and the Gulf of Aden in a southward direction from the Afar region of Ethiopia, which is a triple junction where three developing tectonic plates come together (Figs. 3 and 4; Table 3). Such phenomena are widespread. A former triple junction existed where Africa and northern and southern America came together. The Amazon, the Mississippi, and the Niger all represent rivers that run through "failed rifts." Afar is characterized by three spreading zones and represents a small portion of oceanic crust that has been uplifted and is now part of the continent (Stanley 1994).

Climatic Influence

Cycling Planet Earth

The Milankovitch cycles (Rowan and Reed, chapter "▶ The Paleoclimatic Record and Plio-Pleistocene Paleoenvironments," Vol. 1) are a consequence of the changing gravitational pull of other planets. Variation in solar heating, which is related to astronomical cycles that alter the orientation and shape of the Earth's orbit around the Sun, is attributed to these periodic oscillations. The distribution and strength of solar radiation change over the globe in periods of 19, 23, 41, and 100 thousand years (Hewitt 2003). How can these periods be detected? Oxygen isotopes are documented in the deep-sea record and represent measurements of the global ice volume, ocean temperature, and evaporation. Around 3.0–2.5 Ma, the amplitude and frequency of δ^{18} O oscillation changed significantly. Northern Hemisphere glaciations and greater aridity in the tropics both correspond to this pattern. Between 900 and 600 ka, the effects of 100,000-year-long cycles of glacial forming and interglacial warming came into play (Hewitt 2003).

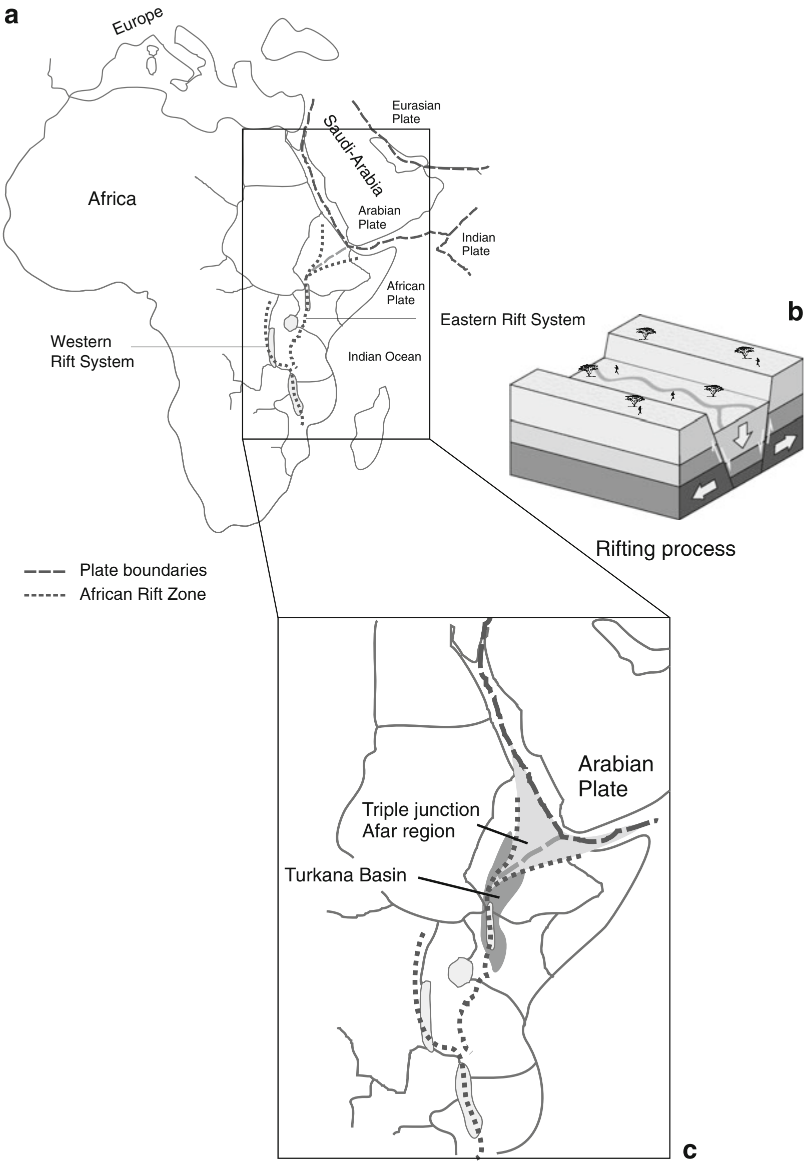


Fig. 3 African Great Rift Valley system (**a**) and rifting process (**b**) with accentuation of the Afar triangle and the Turkana basin (**c**)

The 23,000-year cycle of the Earth's rotational axis intensifies African monsoons, and the millennial-scale instability causes North Atlantic iceberg discharge. This involved huge masses of ice rafting and melting and a decrease of ocean salinity. Taylor et al. (1993) and Bond et al. (1997) traced this phenomenon back to

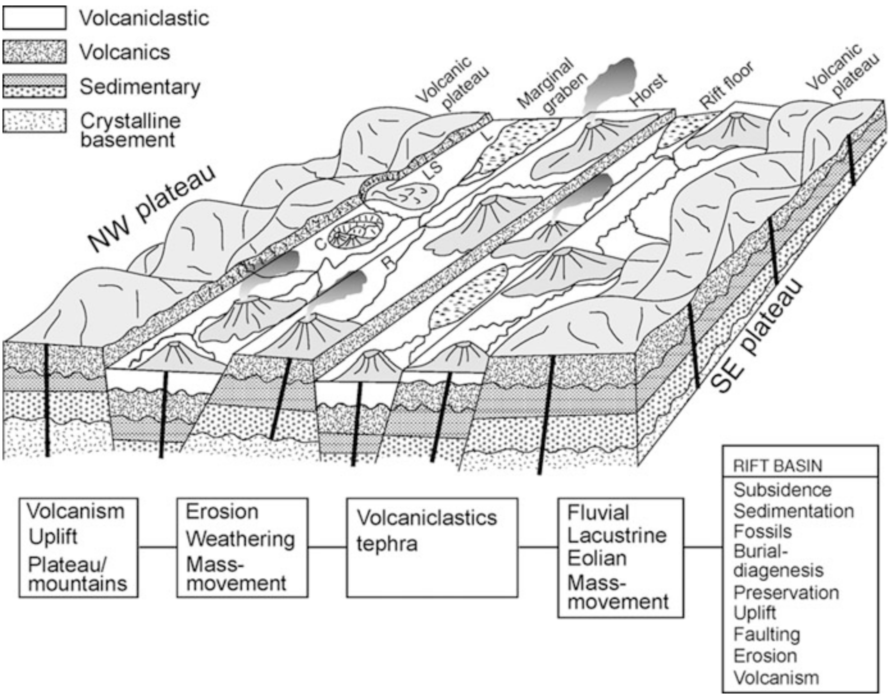

Fig. 4 Schematic representation of tectonism, volcanism, and sedimentation processes within the Ethiopian Rift System (WoldeGabriel et al. 2000)

decade- to century-scale fluctuations between near-glacial conditions and interglacial warmth. Raymo et al. (1998) and McManus et al. (1999) linked these conditions to the Late Pleistocene and Early Holocene.

Well-defined cycles are not necessarily well separated in terms of amplifying and buffer mechanisms. Their interactions show complex patterns, as Clemens et al. (1996) and Paytan et al. (1996) have demonstrated. Furthermore, Potts (2003, p. 365) stresses that "major environmental shifts occurred episodically throughout the Quaternary and did not necessarily coincide exactly with maximum changes in temperature, moisture, or any other single factor." Lister and Rawson (2003) called attention to the rise and fall of sea level, one major effect of the climatic ups and downs: over the past 600,000 years, fluctuations of up to 120 m are documented. Inundations as well as the exposure of continental shelves created new barriers or pathways. Like others Maslin and Christensen (2007) assume coherence between, on the one hand, extreme climatic variability caused by tectonic changes and orbital forcing and, on the other hand, speciation and dispersal events in human evolution. Ann Gibbons brought together several researcher's suggestions linking climatic variability to major events in human evolution like speciation or the development of modern stone tool technologies like the Acheulean (Gibbons 2013) under the title of "How a fickle climate made us human."

Table 3 The Ethiopian Rift System and some important paleoanthropological sites

Areas with paleoanthropological sites	Location within the rift	Sedimentary environments	Age of tuffs	Number of tuff beds/Ma (preserved)	Tuffs; percentage of stratigraphic section	Percentage of tuffaceous sediments in stratigraphic column	Hominid species
Shungura Usno Fejej	Omo rift	Lacustrine, fluvial, overbank	4.1–1.39 Ma	13	9	Estimated at 70	*A. afarensis*, *A. aethiopicus*, *A. boisei*, *H. habilis*, *H. erectus*
Konso-Gardula	Southern MER (Main Ethiopian Rift)	Fluvial	2.0–1.35 Ma	~4	5	95	*H. erectus*
Gademota (Middle MSA)	Central MER	Colluvium, paleosol	35–1.81 ka	3	n.d.	n.d.	*H. sapiens*
Gadeb	Eastern rift shoulder, Central MER	Lacustrine, fluvial	2.51-ca. 0.7 Ma	>2	~12	Estimated at 50	*H. erectus*

Melka Kunturè	Central MER	Fluvial	< or = 1.5 Ma	5	n.d.	n.d.	*H. erectus*
Kesem-Kebena (K-K6)	Northern MER	Lacustrine, fluvial, lacustrine	1.04–1.0 Ma	3	38	62	*H. erectus*
Middle Awash	Southern Afar	Fluvial, overbank, lacustrine	4.38–4.29 Ma	>20	5	40	*A. ramidus*, *H. erectus*, *A. garhi*
Hadar	West-central Afar	Fluvial, overbank, lacustrine	3.4–3.18 Ma	5	<5	Estimated at 40	*A. afarensis*, *H. erectus*
Gona	West-central Afar	Lacustrine, deltaic, fluvial	2.94–<2.52 Ma	>4	<5	Estimated at 40	None

Modified from WoldeGabriel et al. (2000)

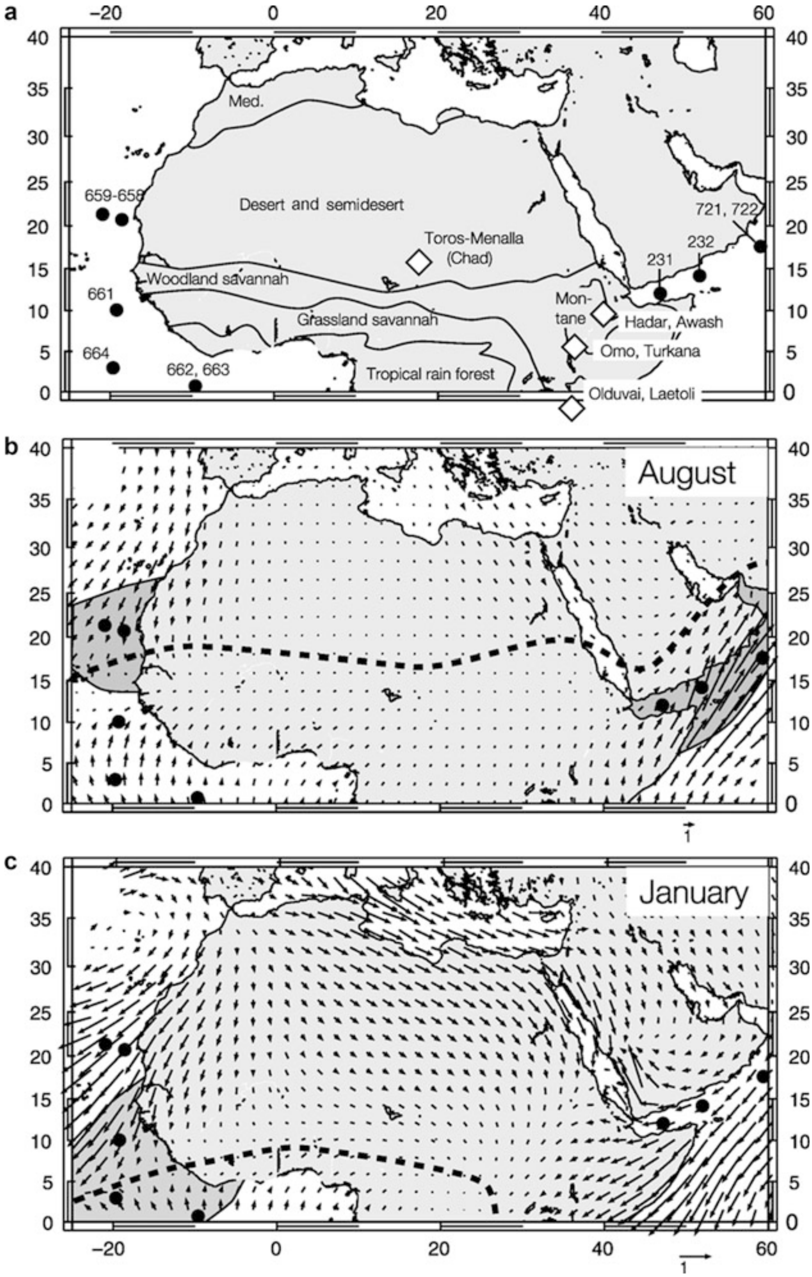

Fig. 5 (continued)

Our Planet's Oceans

The Earth's climates were much wetter and warmer before Middle Eocene times, and deciduous and evergreen forests dominated the natural scenery. Antarctica was full of temperate rain forests, and Arctic landmasses were covered with trees (Askin 1992; Denton 1999). A strong seasonality and a general lack of aridity reduced the occurrence of grasslands and deserts. Sea ice and glaciers were limited in their volume expansion (Ruddiman and Kutzbach 1991). The world's oceans were about 10 °C warmer at depth than today. Furthermore, the atmospheric temperature gradient – from the equator to the pole – was much smaller than today (Savin et al. 1975; Shackleton and Boersma 1981).

This changes when throwing a glance at the recent situation. Since the Middle Eocene, global climate has cooled down. Shackleton (1995) discussed the essential global paleoclimatic change at 2.95–2.52 Myr and the beginning of the oscillating ice ages. Over the past 0.95 Myr, each glacial maximum was on average 5 °C cooler than today and the planet was drier, e.g., much of Northern Europe was covered by tundra and Africa was drier (Denton and Hughes 1981; Denton 1999).

Another Unique Continent: Africa

deMenocal (2004) gave us a very useful overview of the African climate: as Fig. 5 demonstrates, the combination of the seasonal migration of the intertropical convergence zone and the African monsoon causes a highly seasonal range of North African rainfall. In the boreal summer, heat over the North African land surface, centered near 20° N, draws moist maritime air from the equatorial Atlantic into western and central subtropical Africa. Accordingly, woodland and grassland savannas flourish (Hastenrath 1985; Harris 1980).

Based partly on topographic rain-shadow effects, summer rainfall in East Africa is very variable. It is also related to the westerly airstream of the African monsoon (Nicholson 1993). East Africa's subtropical rivers, such as the Omo and the Nile, are drained by the summer monsoonal runoff via the capture of moisture by Ethiopian and Kenyan Highlands. On the other hand, relative to adjacent oceans, Asian and African landmasses become cooler, and a reversion of the atmospheric circulation comes about (deMenocal 2004).

Prospero and Nees (1986) showed that the changes of subtropical African summer rainfall are closely tied to West African dust export to the Atlantic. Additionally, these modifications have been linked by Giannini et al. (2003) to anomalies of the sea-surface temperature. Fig. 5b demonstrates that Indian

◄

Fig. 5 (**a**) Regional map of North Africa vegetation zones, locations of DSDP and ODP drill sites (*filled circles*), and locations of selected African mammal fossil localities (*open diamonds*). (**b**) Boreal summer (August) surface wind stress (unit vector = 1 dyn/cm^2), intertropical convergence zone (ITCZ, *heavy dashed line*) location, and boundaries of seasonal tropospheric dust plumes off NW Africa and NE Africa/Arabia. Dust plume contours were derived from haze frequency data. (**c**) Boreal winter (January) surface wind stress (unit vector = 1 dyn/cm^2), ITCZ location, and boundary of the seasonal tropospheric dust plume off NW Africa (Reprinted from deMenocal (2004), with permission from Elsevier.)

monsoon surface winds are interconnected with summer dust plumes of Arabia and Northeast Africa (Nair et al. 1989). These winds carry mineral dust to the Arabian Sea and the Gulf of Aden. The study of mineralogical and sedimentological data reveals that wind-borne detritus "from these sources comprises the dominant source of terrigenous sediment to the eastern equatorial Atlantic and the Arabian Sea" (deMenocal 2004, p. 7).

Marine Paleoclimatic Records

The last (ca.) 5 Myr, during the Late Neogene, showed progressive steplike increases in African aridity and periodical arid-humid climate cycles. This conclusion can be drawn from marine sediments accumulating off the western and eastern margins of the subtropical North African region. The isolation of the Atlantic basin via the Isthmus of Panama and the following gradual onset of high-latitude glacial cycles at 3.2–2.6 Ma seem to have influenced African climate variation patterns (Haug et al. 2001). The onset of glacial ice rafting and modest 41-kyr glacial cycles after 2.8 Myr caused Plio-Pleistocene cooling at high latitudes. Another step was a shift toward cooler conditions and, after ca. 1.6 Myr, higher-amplitude 41-kyr cycles after 1.2–0.8 Myr (Shackleton et al. 1984).

Variability of subtropical African paleoclimate: deMenocal (2004) summarized the patterns of marine sediment records of Plio-Pleistocene eolian export from West and East Africa:

- The variability of orbital-scale African climate variability persisted throughout the entire interval (and in some cases extending into the Miocene and Oligocene).
- The onset and amplification of high-latitude glacial cycles was closely linked to the onset of large-amplitude African aridity cycles.
- A gradually increasing increasing of eolian concentration and supply (flux) after 2.8 Myr.
- At 2.8 (±0.2), 1.7 (±0.1), and 1.0 (±0.2) Myr, there were steplike shifts in the amplitude and period of eolian variability.
- There is evidence for 10^4- to 10^5-year "packets" of high- and low-amplitude paleoclimatic variability which were paced by orbital eccentricity.

deMenocal (2004, p. 8) described the marine record as "a succession of wet-dry cycles with a long-term shift toward drier conditions, punctuated by step-like shifts in characteristic periodicity and amplitude." de Menocal (1995) interpreted subtropical African climate prior to 2.8 Myr as varying at the 23- to 19-kyr period, mainly as a result of Asian monsoonal variability. At 2.8 (±0.2) Ma, there was a shift toward climate variation periods longer than 41 kyr, and after 1.7 (±0.1) Myr, the cycles lengthened again, and an eolian variability shift toward longer- and larger-amplitude 100-kyr cycles after 1.0 (±0.2) Myr occurred. The onset and growth of high-latitude ice sheets and cooling of the subpolar oceans were synchronous with these shifts in the African eolian variability (Shackleton et al. 1990), and there was a coupling between high- and low-latitude climates after the glaciation onset near 2.8 Ma (deMenocal 1995).

Dupont and Leroy (1995) showed that a pollen record from site 658 documents the phenomenon of greater variability and progressively xeric vegetation after ca. 3.0 Myr and concluded that a shift toward a drier and cooler African climate occurred during glacial maxima. The pollen record correlates with oxygen isotopes, indicating that large global ice volume and deep-sea temperatures correspond to aridity. These authors conclude that a comparison of short-term fluctuations of periods before and after 2.5 Myr demonstrates "that obliquity forcing of northwestern African climate started with the first large glaciations in the Northern Hemisphere" (p. 297).

Which phenomenon is the fundamental impulse generator for African climate variability? The Plio-Pleistocene succession of sapropel layers in the Mediterranean Sea could be interpreted as a consequence of orbital precession (Hilgen 1991). Enhanced monsoonal and Nile river runoff led to increased Mediterranean stratification and reduced ventilation of the deep eastern basins (Rossignol-Strick 1985). During these humid periods, organic-rich layers were deposited. However, another stimulating factor could be a covariation of African climate with the high-latitude climate cycles at the 41- and 100-kyr periodicities, which is what marine sediments actually suggest.

deMenocal (1995, 2004, p. 10) tried to reconcile the two different points of view "by acknowledging that precession was the fundamental driver of African monsoonal climate throughout the late Neogene, but that high-latitude glacial cooling and drying effects were superimposed on this signal only after 2.8 million years."

Physical (Paleo)geography or the Beauty of Mosaics

The African continent extends virtually equidistant into both the Southern and the Northern Hemispheres. It includes about 20 % of the world's land surface and stretches 8,000 km from north to south. The configuration of the bordering oceans and landmasses has remained almost the same from the Early Pliocene up until today (O'Brien and Peters 1999).

Based on the pioneering work of Lobeck (1946); O'Brien and Peters (1999) subdivided Africa into different physiographic regions (Fig. 6). In Low Africa, during most of the Pliocene, all of the interior basins may still have lacked outlets to the sea, a condition not existing today. Prerift Africa's (Miocene-Pliocene) interior basins and associated drainage systems are nowadays etched by old deltas, strandlines, old terraces, and alluvial deposits. This might indicate (at least) seasonally expansive internal lakes, e.g., the Paleolake Congo. This was probably a perennial water body up to at least the Late Pliocene, and its eastern catchment extended to the High Interior Plateau and the volcanic highlands of the Eastern Rift Belt (O'Brien and Peters 1999).

In the Oligocene, High Africa was tectonically driven by the African swell, which was active again in the Late Pliocene and Pleistocene. Different effects have

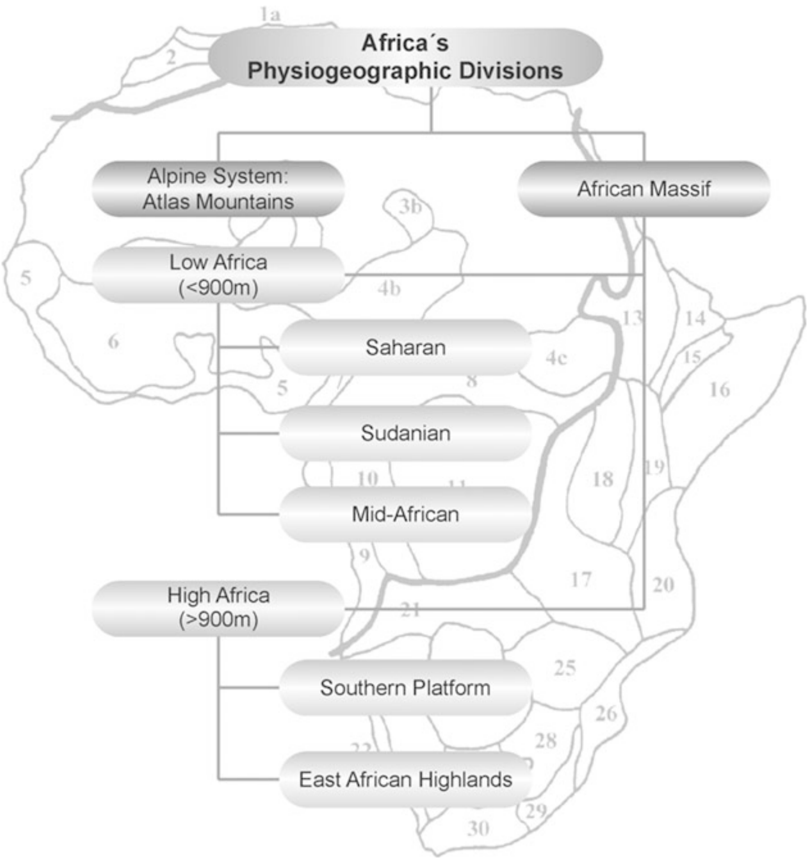

Fig. 6 Physiogeographical divisions of Africa (After O'Brien and Peters 1999)

influenced southern and eastern Africa: during the Late Pliocene, local environmental and increasing subregional fragmentation took place. During the Early as opposed to the Late Pliocene – up to 3.0 Myr – the rift grabens associated with doming were shallow and also at higher elevations than now (Brown 1995). The Ethiopian Massif was probably lower than now, while the High Eastern Interior Plateau may have been higher (Feibel 1999). Between 3.0 and 2.0 Ma, an uplift of rift shoulders by 1,000–1,500 m and a concomitant major subsidence of rift grabens occurred: (1) first in the Eastern Rift Belt areas and in the Afar region and later (2) in the Western Rift Belt, where some of the uplifted flanks rose to 4,000 and more meters above sea level (Partridge et al. 1995a, b). The eastern drainage perimeter for the Congo Basin was established by the escarpment mountains of the Western Rift Belt, which also caused a diversion of the westward drainage from the Eastern Rift Belt and the Interior Plateau, into the Sudd. The Rift Valley domain of the East African Highlands was particularly perforated by active volcanoes (O'Brien and Peters 1999).

Africa's Southern Platform was formed by subsidence events resulting in local fragmentation of the environment (exceptions: areas immediately adjacent to subsided or uplifted margins) and by broad-scale regional uplift. The Southern Platform was apparently lower in elevation than nowadays by some 200 m in the southern escarpment mountains and by as much as 1,000 m in the extreme southeast. The Transvaal, however, was somewhat higher than today (maybe by about 400 m). Furthermore, the paleolakes of the Southern Platform are of special interest for hominid ecogeography (e.g., Makarikari). The grabens of the Western and Eastern Rift belts in the East African Highlands contained intermittent rivers and lakes. Lake Malawi, however, obtained its present shape only at the end of the Pliocene (Partridge et al. 1995b; O'Brien and Peters 1999).

Biotic Factors

Together, abiotic factors build a framework for living spaces that frequently harbor more than one population (Ziegler 1992). These spaces are called *biotopes*, with their enclosed organismic communities characterized as *biocenosis*. These often include highly adapted and specialized species in numerous ecological niches; together they build the so-called ecosystems or *biomes*. The goal of paleoecologists is to reconstruct these systems or paleoenvironments based on organic and inorganic remains.

In the following section, we concentrate mainly on fossils and their interpretation and on the factors that influence them and thus have to be analyzed when reconstructing paleoenvironments. We touch on questions of *postmortem* processes, stratigraphic research, and coevolution. Due to the fact that we spotlight hominid and accordingly terrestrial evolution, we omit an extensive debate on plant fossilization and exclude aquatic ecosystems.

Fossils

A fossil is any remain or trace of any organism from all past periods. They are the key elements of paleontology and consequently of paleoanthropology and paleoecology and act as *containers* or *archives* that preserve information over a long period. Scientists who deal with fossils have to find the right *tools* to open and unravel the secrets lying within. The following paragraphs illustrate some of these "tools" and enlighten several approaches of paleoecological research.

What Happened *Antemortem* and What *Postmortem*?

It is unlikely that an organism will be preserved through time after death. Less than 1 % of all species of organisms are handed down to us (Ziegler 1992; deMenocal 2004), especially in terrestrial and tropical conditions, also in the case of hominoids (Carroll 1988; Martin 1990; Stanley 1994; Andrews 1990). Due to this, the density of relevant paleoanthropological fossils is very low – approximately one fossil per one

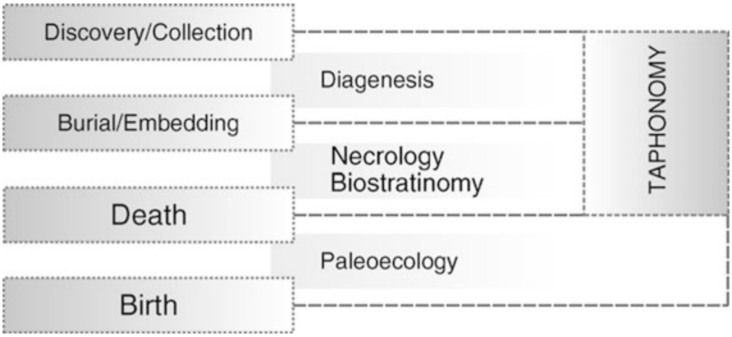

Fig. 7 Four key events in the history of a fossil and the related paleontological disciplines (After Lawrence 1968)

hundred generations – and there are a lot of gaps that affect the phylogenetic and ecological reconstructions scientists strive for (see later). Besides this, most fossils are fragmentary or incomplete and require reconstruction by means of all available methods, now including 3D reconstruction using CT, MRT, or surface scanning (Weber, chapter "▶ Virtual Anthropology and Biomechanics," Vol. 1). Additionally, researchers have to consider the limited erosion of noteworthy ancient fossil sites on the African continent, since most areas are covered with tropical forest, as well as the political and financial circumstances that impede excavations on the other hand.

Every fossil contains a great deal of information on the evolutionary history (phylogeny), physical organization (morphology), and lifestyle (ecology) of the populations the organism once belonged to. Under ideal circumstances, it is possible to extract most of this information by careful analyses of the taphonomic and diagenetic processes involved. *Taphonomy*, as a special field of paleontology, represents the description and causal analysis of all factors that influence an organism after death (necrology and biostratinomy) (Fig. 7) and subsequently all processes of embedding and fossilization (Efremov 1940; Lyman 1996; Grupe and Harbeck, chapter "▶ Taphonomic and Diagenetic Processes," Vol. 1). In contrast, *diagenesis* characterizes only the biological, physical, and chemical alteration of the mineralogical elements affecting fossil-bearing sediments and is part of taphonomy and the lowest grade of rock metamorphism (Stanley 1994; Lyman 1996; Conroy 1997).

The possibility that an organism will be fossilized after death – its transition from the bio- to the lithosphere – depends on many environmental factors (Foley 1978; Henke and Rothe 1999). With few exceptions, the soft tissue – if not eaten by predators or scavengers – undergoes the physiological processes of decomposition and decay in the first phase after death (necrology), and normally only hard materials like the teeth, bones, shells, and rarely scales and horn are suitable for being mineralized and thus fossilized. The most important participants in this process are calcium in the form of calcite and aragonite ($CaCO_3$), bone apatite ($Ca_5(OH)(PO_3)$), silicic acid-skeletal opal (SiO_2), chitin, cellulose, and scaffold proteins (spongine, creatine).

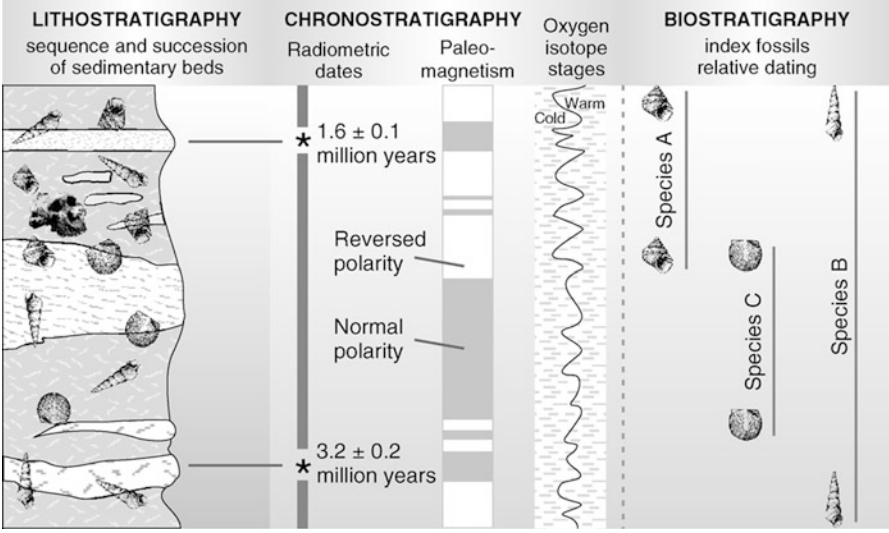

Fig. 8 Three essential components of the study of fossils in context (Adapted from Behrensmeyer 1992)

Who Are You? Where Do You Come From? What Brought You There?

The only way to reconstruct ancient ecosystems is to examine the fossil record and elucidate the internal and external influences that led to the life-forms. Following Etter (1994), there are three crucial requirements that have to be fulfilled when analyzing fossils:

1. Accurate determination and systematic classification of the collected specimen
2. Putting all investigated profiles in a temporal and stratigraphic order as precisely as possible
3. Understanding the ecological context and the specific adaptations of the organisms that enable it to live in particular environments

In brief, paleontologists and paleoanthropologists, respectively, have to study fossils in context to understand the processes occurring in interrelated evolving systems (Fig. 8).

Who?

Taxonomic classification is not only essential but also complicated and depends on whatever evolutionary theory, species concept, and taxonomic approach the researcher prefers (Delson 1990; Foley 1978; Tattersall 1992, 1996; Wood 1992, 1996; Wood and Collard 1999; Wolpoff 1999; Wheeler and Meier 2000; Sarmiento et al. 2002). All these questions go beyond the scope of this chapter and are discussed elsewhere in these volumes (Ohl, chapter "▶ Principles of Taxonomy and Classification: Current Procedures for Naming and Classifying Organisms," Vol. 1). Academics need to overcome the subject-object problem (Stadler et al. 1977; Vogel 2000) when analyzing how we "became human" or even when assembling or disassembling new genera or species – not to mention new hypotheses or theories – as soon as possible after finding new hominid remains. In the words of Eric Delson: "The paleoanthropology community must look quite Pavlovian to outsiders – we all drool predictably every time a new fossil is discovered" (Delson 1997, p. 445). Obviously, new fossil findings complicate the puzzle of primate and hominid evolution (Foley 1991; Tattersall 1992, Marks, chapter "▶ Genetics and Paleoanthropology," Vol. 1).

Since Darwin's ideas about natural selection and his groundbreaking theory of evolution via selective forces were published in 1859, much has been learned about the processes that generate species and the debate is still in progress. Using the individual specimens that constitute the fossil record, we can indirectly scrutinize ancient organic systems at definite points in time ("semaphoronts" sensu Hennig 1982). One affiliated evolutionary theory, "punctuationism" (antonym: gradualism) postulates rapid evolutionary development at the nodes of the "Tree of Life" and long periods (branches) with slow rates of evolutionary change. Associated with the latter is a crucial problem of fossil research, for the chance of finding and moreover identifying "node fossils" (once called "missing links") is significantly lower than of finding "branch fossils." Another accompanied question arises: Are "node fossils" detectable at all or are we entangled in fossils that show mosaic-like plesio- and apomorphic character stages making it nearly impossible to fix a borderline between species – even genera? However, human evolution is strongly embedded within the framework of evolutionary biology and has to be seen as a chain of adaptive radiations (Foley 2002) and extinction events.

Where and When?

One of the most important factors when reconstructing ancient ecosystems is the time dimension and thus the absolute and relative determination of age (dating). Stratigraphers subdivide sediment layers chronostratigraphically and put them in a hierarchic system (Table 4; Fig. 9). Each unit within a stratigraphic system has been defined by means of a basal Global Standard Section and Point (GSSP) by the International Commission on Stratigraphy. Absolute dating, or chronometrics, is done by direct chemical (e.g., amino acid racemization) or physical (e.g., radiometric, thermoluminescence, magnetism) analyses of the bone tissue, rocks, or fossil material in the facies (as the sum of all primary rock characteristics that incorporate inorganic (lithofacies) and organic (biofacies) elements) of interest, and different techniques attain different time depths (Conroy 1997; Wagner and Richter, chapter "▶ Chronometric Methods in Paleoanthropology," Vol. 1). Relative dating methods are tightly related to the theory of, or directly on, *stratigraphy* and the idea of marker fossils, primarily developed by Nicholas Steno, a Danish anatomist, and upgraded by William Smith (alias "strata Smith"), an eighteenth-century English engineer (Ziegler 1992; Stanley 1994; Rothe 2000). Their perceptions led to three principles of sedimentation: (1) younger deposits overlie the older ones from the bottom up; (2) in the initial state, all layers are approximately horizontal; and (3) sediments extend laterally and can be parallelized over large areas (Rothe 2000). A further important law was

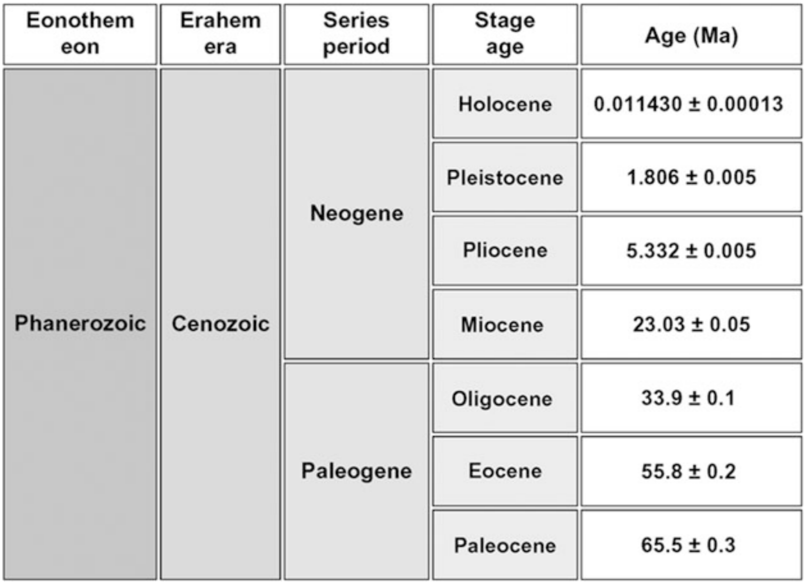
Table 4 Summary of the categories and unit terms in stratigraphic classification

Stratigraphic categories	Principal stratigraphic unit terms	Equivalent geochronological units
Lithostratigraphic	Group	*Note*: if additional ranks are needed, prefixes "sub" and "super" may be used with unit terms when appropriate, although restraint is recommended to avoid complicating the nomenclature unnecessarily
	Formation	
	Member	
	Bed(s), flow(s)	
Unconformity bounded	Synthem	
Biostratigraphic	Biozones	
	Range zones	
	Interval zones	
	Lineage zones	
	Assemblage zones	
	Abundance zones	
	Other kinds of biozones	
Magnetostratigraphic polarity	Polarity zone	
Chronostratigraphic	Eonothem	Eon
	Erathem	Era
	System	Period
	Series	Epoch
	Stage	Age
	Substage	Subage (or age)
	(Chronozones)	(Chron)
Other (informal) stratigraphic categories (mineralogical, stable isotope, environmental seismic, etc.)	-Zone (with approximate prefix)	

Murphy and Salvador (1999)

established by Johannes Walther, a German geologist and student of Ernst Haeckel, who based his inferences on the Swiss geologist Amanz Gressly's fundamental contributions on stratigraphy in the eighteenth century and stated that the vertical succession of facies reflects lateral changes in past environments (Cross and Homewood 1997). Stratigraphic research can be roughly divided in three parts that differ in materials and methods:

1. *Lithostratigraphy* deals with the sequence and succession of sedimentary beds to yield diachronic zones; only a few "key beds" are nearly isochronic (Behrensmeyer 1992; Stanley 1994).
2. *Biostratigraphy*, which is based on organismic evolution, shows overlapping zones by analyzing facies-specific marker or index fossils that can be deemed as



Eonothem eon	Erahem era	Series period	Stage age	Age (Ma)
Phanerozoic	Cenozoic	Neogene	Holocene	0.011430 ± 0.00013
			Pleistocene	1.806 ± 0.005
			Pliocene	5.332 ± 0.005
			Miocene	23.03 ± 0.05
		Paleogene	Oligocene	33.9 ± 0.1
			Eocene	55.8 ± 0.2
			Paleocene	65.5 ± 0.3

Fig. 9 Geological time scales (Dates refer to the International Commission on Stratigraphy 2004)

isochronic (Stanley 1994). Age estimations become more precise, the more closely index fossils are related (Behrensmeyer 1992). The life span of a fossil species, referred to as its “zone,” ranges from the first appearance of that species until a subsequently following species replaces it. Biostratigraphic time scales are often bound to a specific area. Both approaches offer the possibility of correlating sediments and time horizons continuously in regional areas (parastratigraphy) and worldwide (orthostratigraphy).

3. *Chronostratigraphy*, rock layers (strata) are sequenced and classified by absolute dating methods.

Christian Leopold von Buch, an eighteenth-century German geologist, popularized the term “index fossils” as a marker for the correlation of contemporary strata, based on considerations by Charles Darwin and Charles Lyell concerning the irreversibility of changing morphologies through evolutionary time. Index fossils have to meet a number of requirements: (1) worldwide distribution, (2) rapid development that means a visible short time span of one species and evident morphological differences in comparison to other species, (3) high number of individuals, and (4) high chance of being preserved (Carroll 1988; Ziegler 1992). Obviously, marine organisms (plankton and nekton) are ideally suitable as index fossils, and for that reason paleontologists often focus on aquatic micro- and nanofossils to date sediments (e.g., foraminifers, diatoms). But macrofossils are also appropriate for stratigraphic positioning; these include the teeth (Kullmer 1999) and the hard tissues of smaller multicellular species (e.g., ammonites, graptoliths, conodonta). In addition to index fossils, there are also so-called “facies fossils” that are important for the characterization of a certain milieu with particular ecological conditions; early hominids fit in here. Problems for the chronological determination of strata are produced by geomorphological events like earthquakes, volcanism, dislocations, and disconcordance on the one hand and organism-induced disturbances like bioturbation and digging on the other.

A special case in stratigraphy is sequence or cyclostratigraphy, which corresponds to the global correlation of tectonically independent eustatic sea-level fluctuations that happen synchronically in the form of transgressions (sea level raises over supratidal area) and regressions (sea level falls under the lowest tide gage) that are reflected in terms of changing communities (terrestrial/aquatic) and graphical curves. Further methods of dating involve measurements of cyclic events, e.g., seasonal temperature changes, among others: paleomagnetism, palynology (microflora and microfauna, e.g., spores, pollen, ostracods, radiolarians), dendrochronology (counting annual tree rings), dentin annulations (counting tooth dentin layers), diverse luminescence dating methods, stable isotope analysis in ice- or deep-sea cores, and microfossils (Lee-Thorp and Sponheimer, chapter “▶ Contribution of Stable Light Isotopes to Paleoenvironmental Reconstruction,” Vol. 1). Investigations of paleolimnological detritus layers are a method developed by the Swedish scientist Baron de Geer in 1878 and known as the exploration of “varves” (Swedish term that stands for “periodical recurrence”), annual laminated sediments in paleolakes. These methods all lack a link to “absolute” time, i.e., there is, with the exception of tree rings, no determination of a “null varve,” a starting point (Rothe 2000). An overview of relative and absolute dating methods is given in Table 5.

What Context?

Biotic information may be obtained from body fossils that deliver morphological insights (comparative morphology) and from trace fossils that contain ecological information in the form of organic tracks and inorganic marks (ichnology, e.g., footprints of Laetoli). In the case of body fossils, attention should be paid to the immense differences between life, death, and fossil assemblages (Fig. 10). A biocenosis simply represents all living species, i.e., the extant “community” in an ecosystem; in contrast, paleobiological remains are differentiated into autochthonous (thanatocoenosis = death or indigenous assemblages, in situ communities) and allochthonous (taphocoenosis = fossil assemblages) extinct communities. The latter may be affected by minor transport events (parautochthonous) or represent a mixture of local species and species that are brought in. Differences between life and fossil assemblages may result from “displacement” of various kinds (transport, accumulation, disarticulation, etc.), scavenging, destruction of hard materials (bio-erosion, abrasion), obliteration of specific elements (calcite vs. aragonite), etc., all of which may lead to misinterpretation in terms of taxonomy and ecological and chronological placement of fossils.

However, even in contemporary communities, it is complicated to sort out decisive external and internal factors and to show which weighting each has on specific developments in an ecological system.

Table 5 An overview of dating methods (relative and absolute, no claim for completeness)

Dating methods	Description in brief
Relative dating methods	
Cation ratio	Geographical-dependent age determination of a rock by surface analyses (positive-charged ions in the varnish that is formed on a rock), very inaccurate
Cultural affiliation	Determination of temporal levels of tool industries, ceramics, etc. made by the temporal community in a certain area
Fluorine dating	Fluorine accumulates in bone material (fluorapatite) that is deposited in groundwater-leading layers, thus providing information on the past time after burial
Obsidian hydration analysis (OHA)	Obsidian absorbs atmospheric humidity; old artifacts show a thicker "rind" of hydrate than younger ones (dependent on external factors like soil type, climate, erosion, burning, etc.)
Patination	This technique is used when multiple artifacts of the same type are found in the same area and under the same conditions; several kinds of patina are related to time
Pollen analysis	The study of chronological vegetational history by using microfossils in a target area
Rate of accumulation	Rock layers accumulate over time; thus, the deeper the layer, the older (applies also for artifacts associated with layers)
Seriation	Changes in ceramic forms over time to reconstruct consistent patterns of cultural trait change
Varve analysis	The thickness and shape of annually laminated sediments in a specific ecosystem (mostly paleolimnological) account for composition, displacement, and climate
Fossils	"Zones" of organismic remains (mostly species) are determined to classify certain strata
Absolute dating methods	
Archeomagnetism	Determination of variations (intensity, direction) in the Earth's magnetic field
Astronomical dating	Analysis of the Sun's declination at the solstices
Dendrochronology	Counting annual tree rings in order to determine the age of wood and reconstruct seasonal conditions
Electron spin resonance	Artifacts/fossils are exposed to radiation that predictably changes the magnetic field of the object (nondestructable)
Thermoluminescence dating (TL)	When reheating artifacts, the emitted light of specific crystals is proportional to the amount of radiation absorbed since the material was last heated, thus, provides a method to date pottery, hearths, fire-heated rocks, and burned minerals
Optically stimulated luminescence (OSL)	Similar to TL, it uses light to innervate vacated electrons in sediments; comparisons could be made through sediments with a known amount of added radiation
Fission track	Uranium (^{238}U and ^{235}U) radioactive elements create fission tracks by spontaneous splitting of uranium atoms and therefore exposing high amounts of energy that destroy the crystal lattice in a mineral

(*continued*)

Table 5 (continued)

Dating methods	Description in brief
Oxidizable carbon ratio (OCR)	Soil bodies are analyzed to determine the linear progression of slow humus and charcoal recycling through time with an increase in readily oxidizable carbon and a decrease in the total amount of organic carbon
Potassium-argon dating ($^{40}K/^{40}Ar$)	The measurement of the accumulation of argon in a mineral over time
Argon-argon dating ($^{39}Ar/^{40}Ar$)	Comparison of the amount of ^{40}Ar and ^{39}Ar; ^{40}Ar is a stable isotope, thus does not decrease in time, whereas ^{39}Ar is radioactive and consequently decreases over time
Radiocarbon dating (^{14}C)	Age estimation for organic materials by measuring the disintegration of radioactive ^{14}C since an organism died; data indication is given by years before present (BP), whereas "present" means exactly AD 1950
Uranium-thorium dating ($^{234}U/^{230}Th$)	Comparison which uses the properties of radioactive half-life ^{234}U and ^{230}Th and measures the equilibrium between these elements and not the accumulation of a decay product
Aluminum-beryllium dating ($^{26}Al/^{10}Be$)	The ratio between aluminum and beryllium isotopes in the mineral quartz changes under cosmogenic radiation. The specific conditions of radiation must be previously determined
Uranium-lead dating Thorium-lead dating	The ratio of radioactive uranium and thorium isotopes to lead as decay product, dating of rock material with a tremendous time depth of billions of years
Rubidium-strontium dating	Stable isotope ratio $^{87}Sr/^{86}Sr$ is measured in rock material
Racemization	Amino acids as subunits of proteins are widespread in organisms; living organisms contain only l-amino acids (turn polarized light to the left); in dead organisms l-amino acids degrade stepwise to d-amino acids (turn polarized light to the right) until the amounts are equal; thus, the ratio between both conformations provides information about the age of a sample (5,000–ca. 200,000 years depth)
^{2}H, ^{13}C, ^{15}N, ^{18}O, ^{34}S stable isotopes	These isotopes are found for several reasons in different amounts in sample materials of different kinds and could be useful for agricultural, archaeological, ecological, nutritional, geochemical, or medical research

Floras, Faunas, and a Word on Coevolution

There is – and always has been – a constrained relationship between flora and fauna. Since the first algae produced large amounts of oxygen, completely changing the atmosphere, animals and plants have had different interdependencies, though there is a comprehensive pattern of coevolution. To put it simply, coevolution or mutual selection is the process of reciprocal influence exerted by entities (mostly species) in an ecosystem (Begon et al. 1998), e.g., predator–prey or parasite–host relationships. The association of insects that need nectar and plants that require pollen transportation presents a common example. In the case of primate evolution, Sussman (1991) hypothesized that primates evolved in conjunction with the radiation of angiosperm

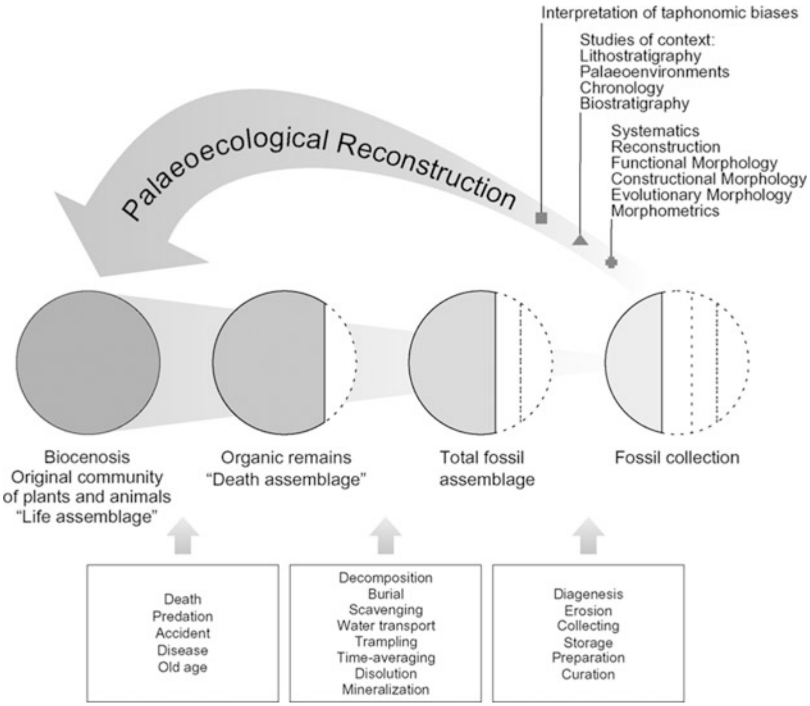


Fig. 10 The differences between life, death, and fossil assemblages related to taphonomic principles (Compiled from Lyman 1996 and Behrensmeyer 1992)

plants and developed terminal branch feeding on nectar and flowers (Bloch and Boyer 2002; Silcox et al., chapter "▶ Primate Origins and Supraordinal Relationships: Morphological Evidence," Vol. 2). "Sussman has proposed that grasping extremities and nails on the digits evolved for eating fruit on terminal branches of angiosperms" (Sargis 2002, p. 1564). Presumably, our own ancestors began to walk upright long before they developed larger brains, since monotonous coverage of the landscape by tropical forest was beginning to fail due to climatic changes from warm and wet to arid and cool conditions in the Late Miocene (Vrba 1985; Vrba, chapter "▶ Role of Environmental Stimuli in Hominid Origins," Vol. 3; Wesselmann 1995; Bobe et al. 2002; Bobe and Behrensmeyer 2004). Sussman et al. (1985) and Rayner et al. (1993) suggested that, throughout the Pliocene, australopithecines showed arboreal and bipedal tendencies in a mosaic-like habitat that was marked by significant patches of subtropical forest, large areas of grassland, and savanna of all kinds. "Upright posture, large brain, tool making, and other hominin characters as adaptations to a savanna habitat must be rethought, at least in the case of *A. africanus*" (Rayner et al. 1993, p. 228; Rowan and Reed, chapter "▶ The Paleoclimatic Record and Plio-Pleistocene Paleoenvironments," Vol. 1). In 2004 Schrenk et al. published a Pan-African so-called "open source" perspective suggesting that bipedal locomotion was developed several times at the margins of shrinking rainforest habitats during a global cooling trend in the Middle Miocene (Schrenk et al. 2004); for further discussions on the origins of bipedality, see Harcourt-Smith, chapter "▶ Origin of Bipedal Locomotion," Vol. 3 and Senut, chapter "▶ The Miocene Hominoids and the Earliest Putative Hominids," Vol. 3). King and Bailey (2006, p. 282) state that the African Rift "... offers physical protection in the form of cliffs, lava flows and topographic enclosures, and hence small-scale topographic complexity in which a relatively defenceless species can find protection from predators." The authors expand their view and suppose that rift-like complexity could not only be found in areas where human evolution took place but along the dispersal routes of early *Homo* in and beyond Africa as well. Potts (2012, p. 163) concludes in a very clear review about environmental change as "first driver" in human prehistory that "Evolutionary processes favored any response that could enhance survival in a changing world. [...] This observation makes sense in light of the environmental instability that ancient human predecessors encountered." High plasticity and adaptability seem to be among the qualities that made *Homo*. Other factors, e.g., isolation, niche boundary shifts, and small population size, could also be a spur to evolutionary "innovations" in hominids (Wolpoff 1999; Henke and Rothe 2003). Just a few steps further in our evolutionary history, and in the debate concerning early *Homo* as well, there is a huge amount of different hypotheses that aim to link environmental constraints to specific adaptations and morphological transformations (Vrba, "▶ Role of Environmental Stimuli in Hominid Origins," Vol. 3). Because of the insufficient preservation of plants in toto, caused by increased decomposition in aerobic and particularly tropical conditions, paleobotanists rely heavily on pollen, spore, and phytolith analyses (Jolly et al. 1998; Elenga et al. 2000; African Pollen Database). However, such things can be dispersed well away from their original habitat through wind and water (Andrews 1992). Density and distribution of these palynological units in sediment layers give us an idea about the allocation of specific plant families, spatial scales of retraction or expansion, and potential plant food proposed. For example, isotopic data on hominin diets have shown an involvement with C_4 grass – foods (Lee-Thorp and Sponheimer, chapter "▶ Contribution of Stable Light Isotopes to Paleoenvironmental Reconstruction," Vol. 1 and Sponheimer and Lee-Thorp, chapter "▶ Hominin Paleodiets: The Contribution of Stable Isotopes," Vol. 1). Large herbivores (e.g., gramineous, foliaceous) are bound to the availability, dispersal, and capacity of particular plants; subsequently, hypotheses about migrations of herds and "predator–prey" relationships between carnivores and early hominins may, respectively, achieve wider temporal and spatial scales. Bovids are the most common faunal element at most Neogene hominid fossil localities and are often used as indicators to understand Plio-Pleistocene hominid ecological and behavioral changes (Vrba 1995; Kappelmann et al. 1997). Besides, the strong interrelations between fossil species, phytogeography, climate, biogeography, and faunal conditions may lead to improved recognitions of "turnover pulses" in ecological networks and reflect the importance of environmental changes on faunal adaptation, selection, and evolution (Foley 1978, 1994, 1995, 1999; Potts 1998a, b; Lahr and Foley 1998; O'Brien and Peters 1999; Owen-Smith 1999; Vrba 1995, 1999; Vrba, chapter "▶ Role of Environmental Stimuli in Hominid Origins," Vol. 1; deMenocal 2004; Hernández Fernández and Vrba 2006).

Syntheses

Modifying Dobzhansky's credo (1973) we state that *Nothing in evolution makes sense except in the light of ecology*. Corresponding to this "ecolution", we try to depict cross sections in three-time horizons (early-middle-late) of hominid evolution from ca. 7 Ma until today (Fig. 11). This should provide a basis for understanding how many different viewpoints have to be captured when looking at a complex process like hominoid and hominid evolution. It does not claim to circumscribe all factors in all periods; it can only provide insights and surely leaves many perspectives unseen.

But is there an "ideal" environment that can be hypothesized for the evolution of African hominids? This and other questions are discussed in this section. Two different kinds of hypotheses can be discerned: (1) the habitat-specific and (2) the variability-selection hypothesis. The former considers faunal adaptations to a specific environment, while the latter emphasizes the importance of climatic instability as a trigger for adaptive changes.

Modern interpretations support a step-by-step development of drier, cooler, and more open conditions since the Late Miocene. Both the influence of an arid-adapted fauna on early hominid evolution at the mid-Pliocene (near 3.2–2.6 Ma) and the aridification shift (Bonnefille 1983; deMenocal 1995; Dupont and Leroy 1995) are viewed as catalysts for human evolution.

Vrba et al. (1980, 1995, 1998; Vrba, chapter "▶ Role of Environmental Stimuli in Hominid Origins," Vol. 3) are prominent advocates of the turnover-pulse hypothesis that derives from the habitat-specific hypothesis, itself a variation of the savanna hypothesis. Fundamental shifts in African climate – 2.8, 1.8, and 1.0 Ma – initiated the so-called "turnovers." These turnovers are focused bursts of biotic change. For example, between 3.0 and 2.5 Myr, many first appearances were of grazing species. This pattern links aridity and expanding grasslands to faunal changes (Vrba 1980; Bobe and Eck 2001). Graphically, the pulses are defined via clustering. Authors, such as Behrensmeyer et al. (1997) or Werdelin and Lewis (2001), do not, however, support this important view of climate-hominid evolution interaction.

To make things more complicated, bipedality may have evolved in forest or woodland habitats, not savanna (Rayner et al. 1993; Wood and Harrison 2011); and maybe it was developed even in non-hominin primates like *Oreopithecus* (Rook et al. 1999). As concerns the evolution of early tool-making hominids, mosaic zones of grass- and woodland may have stimulated our evolution (Blumenschine 1986).

On the other hand, the *variability-selection hypothesis* advocates the importance of climatic instability for introducing (1) genetic plurality, (2) natural selection, and (3) faunal innovations. Potts (1998b) suggested that many of the largest African faunal evolution events occurred when there were increases in the amplitudes of paleoclimatic variability (such as modifications in the durations and amplitudes of orbital-scale wet-dry amplitudes). Potts' (1998b, p. 82) view stresses the inconsistency of selection over long time spans and "thus departs from the prevailing

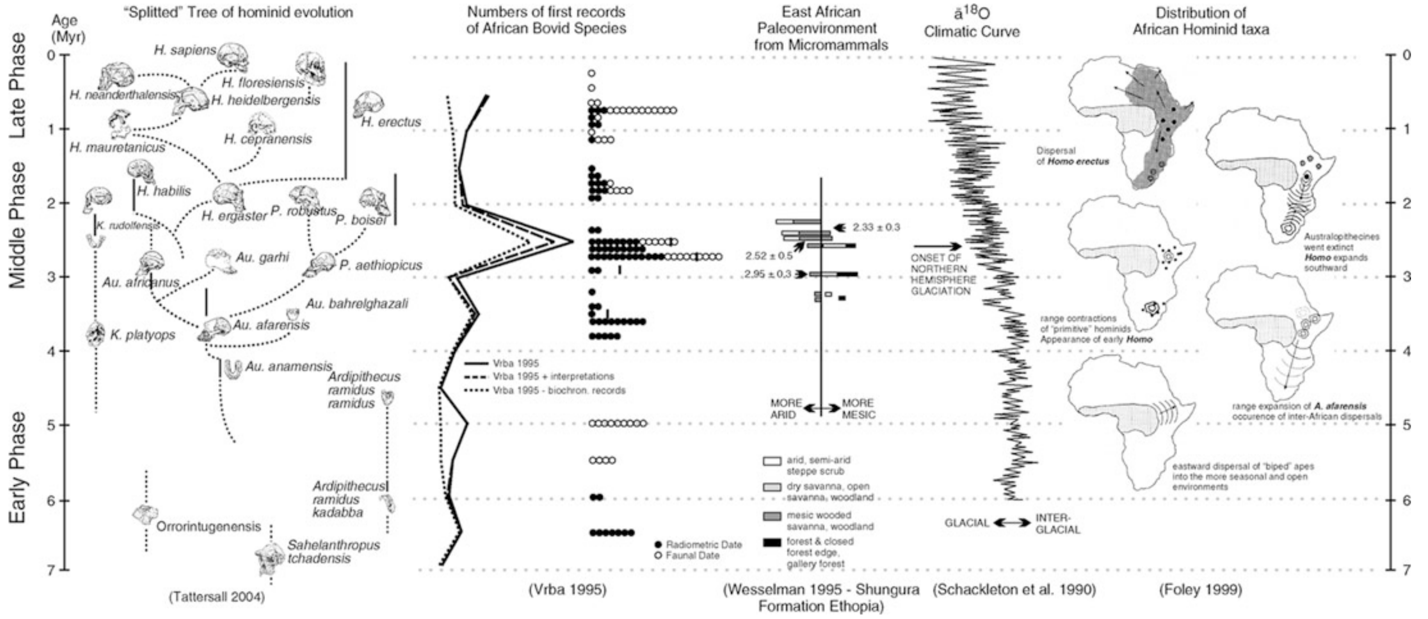

Fig. 11 (continued)

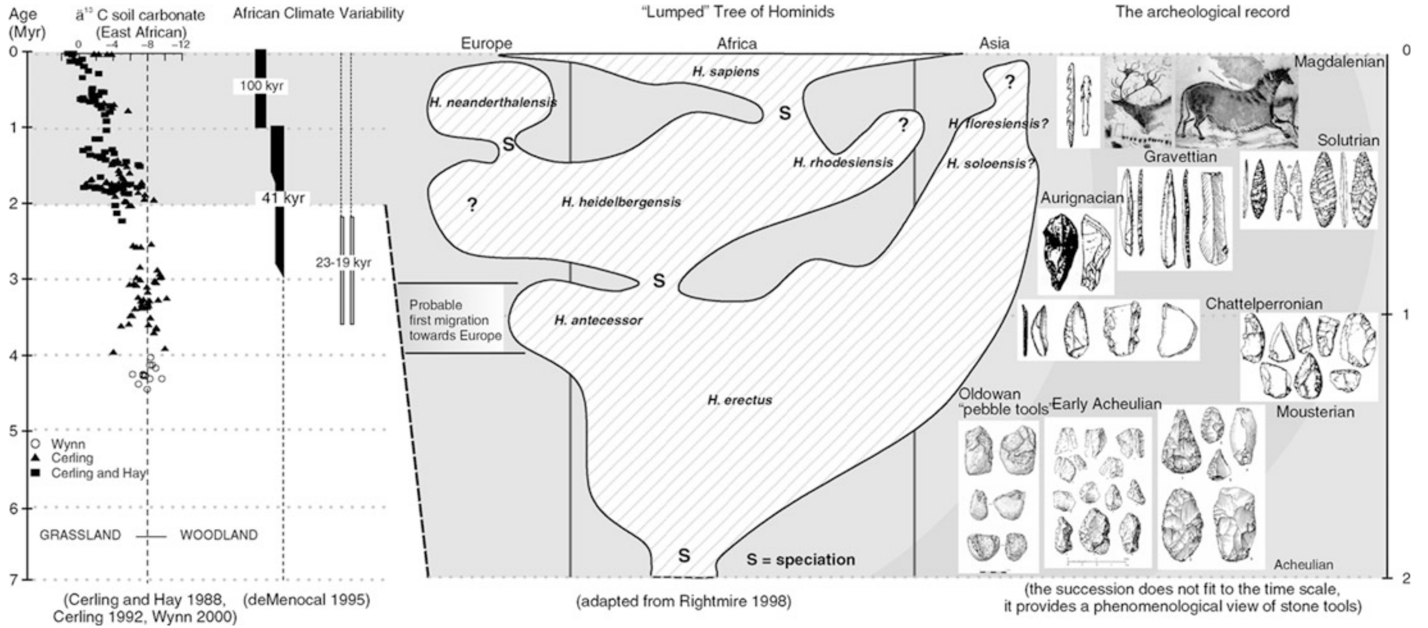

Fig. 11 Summary diagrams of paleoenvironmental data and hominid evolution, compiled from different authors. There is a clear linkage between hominid evolution, macro- and micromammal report, climatic changes, stable isotope data, and dispersals within and out of Africa. Seemingly, colder and more arid conditions combined with adaptational changes among hominids initiated several processes that led to the currently accepted patterns of biogeographical processes in hominid evolution. *Homo erectus* was the first hominin species to spread into the Old World. The taxonomic relationship between late hominin species is by no means completed. The evolution of stone tools comprises the last 2 Myr and leads to an explosion of artistic expression ca. 18 ka

paradigm of adaptive evolution via long-term directional selection." As many biologists (e. g., Sahney et al. 2010) assume a close match between an organism and its specific environment (that can be confirmed for organisms that are habitat specialists), the variability-selection model proposes that lineages experience factors over time that disrupt close connections to any specific environment – a decoupling mechanism that separates the organism from any environmental state.

Early Phase: Forerunners Among Miocene Primates

In the Late Miocene (23.8–5.3 Ma), the hominoids, including Hylobatidae and Hominidae [Ponginae/orangutans and Homininae/African great apes and *Homo*; sensu Groves (2001)], had reached their greatest abundance and diversity, and with little doubt human origins lie somewhere within this group (Conroy 1997). Niches now occupied by cercopithecoids were additionally exploited by hominoids in Africa (Fleagle 1999). The fossil records of the Early, Middle, and Late Miocene are fairly good and include Proconsulidae and Oreopithecidae as well (Godinot, chapter "▶ Fossil Record of the Primates from the Paleocene to the Oligocene"; Begun, chapter "▶ Fossil Record of Miocene Hominoids," Vol. 2; Rasmussen 2007). However, the search for the root of hominid evolution and additionally for "... the identification of hominoids among the various genera and species of fossil apes from that epoch has proved a fruitless exercise thus far" (Fleagle 1999, p. 483). Some propose *Dryopithecus* as a possible predecessor of the clade that includes great apes and humans; others suppose *Ouranopithecus* to be directly ancestral to later humans. The earliest fossils that are proposed as being probable hominid ancestors are two species of the genus *Ardipithecus* (*ramidus*/*kadabba*) 5.2–4.4 Ma from Ethiopia (White et al. 1994, 2009; Haile-Selassie 2001), *Orrorin tugenensis* ~ 6 Ma from Kenya (Senut et al. 2001), and *Sahelanthropus tchadensis* 6–7 Ma from Chad (Brunet et al. 2002). All these specimens were found in the last 20 years, probably because excavation campaigns were targeted toward the "roots' of hominids and the divergence point between apes and hominids, respectively. There is much debate about the "ape-or-human" status, the morphological features, the selection pressures, and the changes that have to be carried out on the tree of human evolution (Gibbons 2002), and of special interest here are the ecological circumstances around 7–4 Ma that these species were confronted by.

Ardipithecus is the name given to 5.8–4.4-Myr-old fossils from the Middle Awash area of Ethiopia. Haile-Selassie (2001, p. 178) declared *Ardipithecus* to be the genus that "... postdated the divergence of lineages leading to modern chimpanzees and humans." The fossils are associated with a relatively wet and wooded paleoenvironment (Haile-Selassie 2001; WoldeGabriel et al. 2001). WoldeGabriel et al. (2001, p. 175) suggested that similar habitats were found in the case of *Orrorin* (see later) and therefore that "... these findings require fundamental reassessment of models that invoke a significant role for global climatic change and/or savanna habitat in the origin of hominids." Associated vertebrate fossil assemblages indicate woodland/forest habitats and small areas of open grassland around lake margins. Among the micromammals the rarity of lagomorphs shows that open grasslands are not well sampled in the habitat of *Ardipithecus*. Moreover, closed wooded environments, where fossils are less likely to be preserved, may explain the low numbers of hominoid/hominid fossils in the Late Miocene. An eleven-paper publication in 2009 by an international team on *Ardipithecus ramidus* remains, including 110 fossil specimens and “Ardi,” a partial female skeleton comparable to the remains of “Lucy,” draws the following picture: this extinct 4.4-Myr-old species was a small-sized arboreal climber (without specializations for knuckle walking and suspension) in a tree-dominated habitat that had a nonspecialized “soft” C_3-food diet, showed minimal social aggression (reduced premolar/canine complex), and walked terrestrially as a facultative biped in a more primitive mode than *Australopithecus*. The unique compilation of traits in *Ardipithecus ramidus* perhaps helps us to develop a picture of the last common ancestor of humans and great apes. Thus, the authors concluded that a chimpanzee-like forerunner is unlikely (Science-Extra 2009).

East African *Orrorin* seems to fall somewhere between the African great apes and humans and thus “. . . accords with the East Side Story proposed by Coppens” (Senut et al. 2001, p. 142). The “East Side Story” is a construct that invokes the geomorphologically induced allopatric development of African great apes and hominids (~8 Ma) in the placement of the cradle of mankind in eastern Africa between the Great Rift Valley and the Indian Ocean (Coppens 1987, 1999; deMenocal 2004). A general trend of worldwide cooling, the extensive increase of grassland, and the retraction of tropical forests, rainforests, and wooded savannahs are perceptible ~8 Ma. At the same time, a rifting process and an uplifting of the western rift shoulder led to the appearance of a topographic borderline that placed them in the more and more arid eastern part in the rain shadow of the wetter western part (Pickford 1990). This eastern “isolation” for several million years might have been behind endemic peripatric genetic drifts and consequently the origin of hominid features (Coppens 1999). After analyzing and interpreting post-cranial morphological features, Pickford et al. (2002) conclude that *Orrorin* was a habitual biped with the ability to climb trees, and they found several apomorphic characters shared with australopithecines and *Homo* but none with *Pan* or *Gorilla* (Senut, chapter “▶ The Miocene Hominoids and the Earliest Putative Hominids,” Vol. 3). The habitat of *Orrorin* was reconstructed, from faunal remains and geological analyses of the Late Miocene Lukeino Formation in the Tugen Hills of Kenya, as a mosaic of open woodland and forests around a lake. *Orrorin* seems to be a representative of a typical “edge species” that lived on the frontier between environmental units (Sussman and Hart, chapter “▶ Modeling the Past: The Primatological Approach,” Vol. 1). Associated faunal remains stem from colobines, carnivores, and ungulates (Pickford and Senut 2001). However, the allopatric “East Side Story” is challenged by *Sahelanthropus tchadensis* – a 6–7-Myr-old hominin from western Africa.

S. tchadensis was found in Central Africa, in the western Djurab desert of Chad (Brunet et al. 2002). The locality is interesting because it lies far west to the Rift. Following the discovery of *A. bahrelghazali* in 1995, there was no further evidence for a western dispersal of hominids (Brunet et al. 1995) until *Sahelanthropus*, whose ecological circumstances are remarkable insofar as they are similar to those of the eastern fossil sites. This raises the possibility of analogizing evolutionary constraints for hominids in the eastern and western different areas. Vignaud et al. (2002) suggested that *Sahelanthropus* lived close to a vast lake with swamp areas and rivers (inferred from fish and amphibious forms) and not far from a sandy desert. As deduced from basicranial and facial structures, Brunet et al. (2002, p. 150) concluded that there are clear similarities between *Sahelanthropus* and "... later fossil hominids that were clearly bipedal." The faunal record shows animals associated with a mosaic landscape with lacustrine gallery forest, open grassland, and savanna (primates, rodents, equids, bovids, and carnivores). All of these observations led Brunet and colleagues to arrive at the conclusion that *Sahelanthropus* lived in a more mosaic-like habitat than *Ardipithecus*, *Orrorin*, and the australopiths (Blondel et al. 2010; Strait et al., chapter "▶ Analyzing Hominin Phylogeny: Cladistic Approach," Vol. 3 and Rown and Reed, chapter "▶ The Paleoclimatic Record and Plio-Pleistocene Paleoenvironments," Vol. 3).

Still, all three new genera are represented by little fossil evidence and lack intraspecific comparisons, limiting inferences facilitating taxonomic placement of these fossils into the ape or the human lineages (Brunet et al. 2002; Wolpoff et al. 2002; Wood 2002; Senut, chapter "▶ The Miocene Hominoids and the Earliest Putative Hominids," Vol. 3). In addition, for understanding the "start-up" of humanization, we also need to identify the selection pressures that triggered the evolution of bipedality and dental adaptations relating to dietary behavior shifts in changing habitats. Meanwhile, even the consensus from fossil and molecular evidence, that the human lineage diverged from that of the chimpanzees between ~6 and 8 Ma, is uncertain caused by the inconsistent calibration of the molecular clock we use as our "rearview mirror" (Stauffer et al. 2001; Gibbons 2012). Besides this, many questions linger pertaining both to the taxonomic classification of these "ape men" (Begun 2004) and the reconstruction of the paleoenvironments they lived in. "The solution is in the mantra of all paleontologists: We need more fossils!" (Begun 2004, p. 1480; Menke, "▶ The Ontogeny-Phylogeny Nexus in a Nutshell: Implications for Primatology and Paleoanthropology," Vol. 1).

Middle Phase: "Chewer" and "Thinker"

Around 2.4–2.0 Ma, the genus *Homo* first appears in the fossil record of Africa. Its definition and the establishment of a hypodigm have given rise to a labyrinth of ideas and approaches about the number of species involved (Foley 1991; Tattersall 1992; Collard and Wood, chapter "▶ Defining the Genus *Homo*," Vol. 3), morphological variability, distinctions from the australopiths, and phylogenetic relationships. Recently, the bush of hominid evolution and especially the split between *Australopithecus* and *Homo* were altered by the 1.95–1.78-Myr-"young" remains of *Australopithecus sediba* found in the Malapa cave in South Africa in 2010. Because its cranial and postcranial features showed a mosaic of primitive (australopith) and derived (*Homo*) features, *A. sediba* was identified as a transitional species and hence a potential forerunner of early *Homo*. Once more another possible ancestor of *Homo* had been found in the australopith branch (Berger et al. 2010). As might be expected, there are other ideas: (1) *A. sediba* is only a late version of *A. africanus* (Tim White and Ron Clarke in Balter 2010); (2) *A. sediba* is an early *Homo* (Donald Johanson cited by Wong 2010); and (3) *A. sediba* is a late form of australopiths that lived at the same time as early *Homo*, leaving taxonomic questions and coming back to paleoecology. Analyzing *A. sediba's* dental phytoliths, stable carbon isotopes, and dental microwear, Henry et al. (2012) infer a C_3-plant diet in a gallery forest like biome with C_4-grassland and woodland in the vicinity. The home ranges of *A. sediba* could thus have been large and comparable to that of modern savanna chimpanzees striving for C_3-fruits. The upper limb of *A. sediba* shows ape-like climbing and suspensory abilities than manipulation skills like in *Homo* (Churchill et al. 2013). Albeit the lower limb clearly shows the capability for bipedal walking, the gait mechanics seem to be different from what we knew previously in *Australopithecus*. DeSilva et al. (2013, p. 1232999-1) conclude that "… there may have been several forms of bipedalism during the Plio-Pleistocene." The crucial questions regarding the borderline between *Australopithecus* and *Homo*, and exactly which forms gave rise to genus *Homo* and which ones originated the "robust" lineage around 2.5 Ma, are still unanswered. From the ecological point of view, the crucial question is: "*Why did these two lineages split off*?" In our opinion the base of all "changes-driven" suggestions is the innate skill of organisms to adapt to environmental changes. Vrba (1988) provides an overview of general hypotheses that relate environmental changes to biotic evolution and thus provides a basis to speculate about divergence processes (Table 6).

Late Pliocene and Early Pleistocene strata contain a number of hominid fossils that obviously belonged to different morphotypes and ways of living. On the one hand, there are robust forms with large faces, huge supraorbital structures, small brains, and enormous masticatory capacities; on the other hand there have been forms with small faces, larger brains, reduced supraorbital features, and reduced size of upper and lower jaws. The latter are associated with the first 2.4-Ma-old lithic tools ("pebble tools" and "choppers") as attributed to the Oldowan industry and "handy man" *H. habilis*. It remains doubtful that australopithecines maintained the kind of Osteodontokeratic culture (bone, teeth, and horn) that Raymond Dart (1957) proposed.

The focus here lies on the outstanding trends that divide two temporally sympatric genera and morphological/evolutionary "lineages": *Paranthropus* and early *Homo*. The different ecological niches that could have been occupied by the species of both genera are limited by their basic needs as (1) large mammals, (2) terrestrial primates, (3) dwellers of tropical gallery forests/open savanna – or grassland – habitats, (4) interspecific competitors, and (5) K-strategists (Foley 1978; Henke and Rothe 1994, 1999). When reflecting on the possibilities of coping with the environment and niche separation as well as niche expansion, the encompassment of all kinds of "internal" influences like body size, population dynamics, abilities of locomotion and "thinking," life-history strategies, behavior, and social system is

Table 6 Hypotheses of how environmental changes relate to biotic evolution

Hypothesis	Description
Refugial vs. biotidal areas	Environmental changes affect two basic kinds of geographical areas differently: the biome resists in a refugium, whereas it does not in a biotidal area. Refugia are characterized by the persistence of dominant taxa (new species within these taxa may be added); in contrast, biotidal areas are shaped by the temporary appearance and disappearance of dominant taxa
Turnover pulse (local/ widespread)	Physical environmental change is required to initiate most speciations, extinctions, and distribution drift. Thus, most lineage turnover has occurred in pulses, near synchronous across diverse groups of organisms. Changes could either be widespread with independent evidence of environmental change or they are mostly local and form a largely random frequency distribution against time
Coordinated stasis hypothesis	Organismic interactions are the reason for evolutionary stasis in a community. Only radical physical changes can detach the coevolutionary bonds between the life-forms, comparable to the turnover-pulse hypothesis
Climatic/tectonic initiating cause	A particular environmental cause of turnover was global, or at least widespread, climatic change. Alternatively, the cause could be tectonic, and thus turnover signature is appropriately geographically restricted
Variability-selection hypothesis	Advocates the importance of environmental variability for introducing (1) genetic plurality, (2) natural selection, and (3) faunal innovations

Compiled after Vrba (1988), Potts (1998); see also Vrba, chapter "▶ Role of Environmental Stimuli in Hominid Origins," Vol. 3

required. Furthermore, the roles of "external" factors such as climate, biogeography, sympatric species, and predator–prey relationships have to be taken into account (Foley 1978).

About 2.0 Ma, several kinds of hominids are found in northwestern Kenya and south Ethiopia around Lake Turkana (Tattersall 2002): *Paranthropus boisei*, *P.* (*Australopithecus*) *aethiopicus*, *H.* (*Kenyanthropus*) *rudolfensis*, *H.* (*Australopithecus*) *habilis*, *H. erectus* (*ergaster*); the genera and species names in parentheses indicate that the debate about their taxonomic status is still in progress. The Turkana Basin (Fig. 3), situated in the Great Rift Valley from southern Ethiopia into northern Kenya, covers an area of about 3,600 km^2 and represents one of the richest fossiliferous areas in Africa. An exceptional breadth of "mosaic-like" geological and environmental diversity has been investigated by the Koobi Fora Research Project. It reaches from the lacustrine/fluvial sediments of the Omo River channel, with gallery forests and swamps, across thorn bush and grassy floodplains strongly influenced by seasonal flooding, to the basin margins with an arid climate and totally different sedimentation regimes (kfpr.com/prehistory_of_koobi_fora). The geological record provides volcanic tephra layers, amenable to chronometric dating, that are associated with unusually well-preserved fossils. The faunal record has a nearly gapless temporal as well as a lateral component, making it possible to reconstruct paleohabitats over large areas. The archaeological remains include Oldowan, Karari, and Acheulean tools that complement the evidence of the fossil hominins.

The Omo basin sediments, fossils, and pollens provide a wealth of information about the ecological circumstances and the temporal distribution of hominids in this region. *P. boisei* and *P. aethiopicus* are strongly adapted to drier conditions in savanna habitats with gallery forests or patchy wooden refugia. Craniodental morphology and especially microdental analyses suggest an exclusively low-quality herbivorous subsistence with sometimes coarse gramineous parts, dependent on the availability of food in a highly variable seasonal environment that is characterized by both copiousness and scarcity (Rak 1983; Foley 1987; Kay and Grine 1988; Henke and Rothe 1999). In contrast, gracile australopithecines seem to have preferred more humid habitats with large spots of forest (Coppens 2002) and were able to accommodate to substantial environmental variability and dietary shifts (Teaford and Ungar 2000; Bonnefille et al. 2004).

The most widely studied *habitat-specific hypothesis* is the savanna hypothesis. Dart (1925) already used the open savanna model as a tool to explain larger brains and bipedality in early *Homo*. This concept plausible prima facie was not confirmed by the data collected (Leakey and Hay 1979; Cerling 1992; Cerling and Hay 1988; Senut et al. 2001): bipedalism was apparently established millions of years *before* the savanna grassland expansion. Early *Homo* lived in fairly open, arid habitats, used an enlarged spectrum of food resources, and is best characterized as an opportunistic and omnivorous forager. Basic sustenance was surely provided by plant food, but the use of tools made accessible difficult-to-reach high-energy sources like edaphic storage organs (tubers and roots) (Laden and Wrangham 2005) and meat from scavenging complemented their diet (Foley 1987; Blumenschine et al. 1994). This latter is important when looking at coevolutionary processes and sympatric interdependencies between early *Homo*, herbivores, and carnivores (Turner 1984; Lewis 1997; Brantingham 1998). High-energy-density diets and unstructured feeding patterns (originated by the seasonal availability) still characterize present-day human eating behaviors, although today's nutrition is largely uncoupled from seasonal cycles (Ulijaszek 2002). Hunting, as Lee and DeVore (1968) suggested, is widely accepted as unlikely in early *Homo*; it seems that the conception of a klepto-parasite seems to characterize the real natural situation best. Comparative primatological studies of chimpanzee populations and analyses of behavioral ecology and nutrition strategies in current African hunter-gatherer tribes (Lupo 2002; Marlowe 2005) support these assumptions. Vrba (1988, p. 422) stated that "… in some respects the *Homo* lineage evolved toward a greater ecological generalization, while in contrast the 'robust' lineage(s) became more specialized on resources prevalent in more open environments."

In the Middle and Late Pleistocene, the diversity of hominids decreased drastically; the "robust" australopithecines became extinct, maybe because they were too specialized and could not adapt to the changing environmental conditions (Klein 1988); and *Homo* constituted the only remaining genus in the bottleneck of hominid evolution. The questions of how and why that happened and what processes were involved are manifold (Henke and Rothe 1999; Tattersall 2002; Rightmire 1998, chapter "▶ Later Middle Pleistocene *Homo*," Vol. 3).

Late Phase: Neanderthals and Colonizers

As one of the most discussed topics in human evolution, the Neanderthal enigma is a prominent "problem" of the late phase. d'Errico and Sánchez Goñi (2003) investigated the millennial-scale climatic variability of OIS3 in the context of Neanderthal extinction. To the extent that population models seek climate as a triggering factor for the colonization of Europe by anatomically modern humans and the Neanderthal extinction, they appear to be highly contradictory due to (1) the lack of terrestrial continuous and well-dated paleoclimatic sequences, (2) the uncertainties in the dating methods, and (3) the doubts about the cultural attribution of archaeological layers. These authors therefore reviewed the paleoclimatic OIS3 evidence from Iberia and found a fragmentary, low-resolution, and poorly interpreted record. d'Errico and Sánchez Goñi (2003) concluded that Aurignacian moderns colonized the north of Iberia and France at the onset of the H4 event. They based their results on a correlation between archaeological data from western Europe and from two images pollen-rich deep-sea cores. Their scenario favors Neanderthal populations existing in desert-steppe-like environments (made up of *Artemisia*, Chenopodiaceae, and *Ephedra* which characterize the H4 of this area), while the Aurignacian moderns were probably not interested in colonizing these arid Mediterranean biotopes. Anatomically modern humans did this only after the H4 event.

However, Finlayson et al. (2004) pointed out problems with this scenario. They admit that d'Errico and Sánchez Goñi's (2003) paper is very useful in reinforcing the data showing that climatic events worldwide became increasingly unstable during OIS3, but as inferred by Finlayson et al. (2004, p. 1208), there are problems of cause and effect: "We suggest that this is a spurious correlation, and that what is being observed is two populations responding to the same variable (or variables) in opposite directions. Since no direct proof of cause and effect between Aurignacians and Neanderthals is advanced, this must remain the most parsimonious explanation." Finally, they interpret d'Errico and Sánchez Goñi's (2003) data in the opposite way by concluding that the available information points to climate instability fragmenting Neanderthal populations and emphasizing that not a single piece of evidence exists to demonstrate competition between Moderns and Neanderthals.

Further questions that have to be answered when discussing anatomically modern humans in Eurasia, Australasia, and the New World are the following: *Why and when did the expansion happen*? *Who and how many participated and where did they arrive*? Fig. 12 provides an overview of potential migration waves and the time they probably took place. One consensus seems to crystallize from the fossil record: equipped with a stature shape and size near to ours (Turkana boy from Nariokotome), a large brain, and increased mobility; able to handle hunting

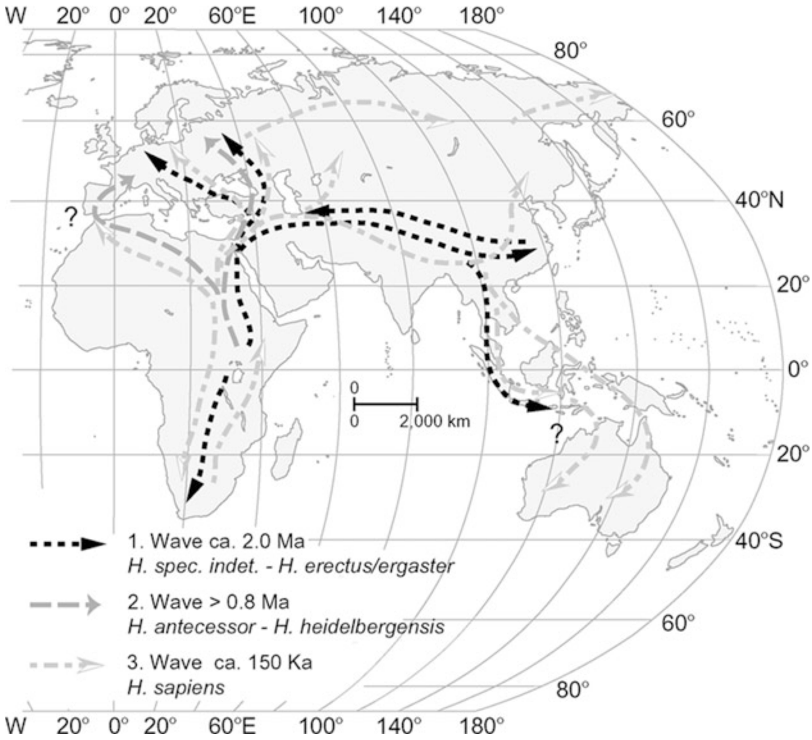

Fig. 12 Potential migration waves and migration periods of archaic *Homo* populations "Out of Africa" assumed by several paleoanthropologists (After Henke 2004)

weapons (400-ka-old spears of Schöningen/Germany) as well as fire; and being provided with a significant curiosity, *H. erectus* (*H. ergaster*) migrated far from the continent of its birth at around 1.8 Ma (Dmanisi fossils) (Gabunia et al. 2001) and conquered the Old World. Thenceforward, there are diverse models/hypotheses that try to explain dispersal patterns over the last 1.5 Myr of human evolution. The recent African origin model (RAO) holds that the biocultural transition from late archaic *H. sapiens* to anatomically modern humans was restricted to Africa, with subsequent dispersion and replacement of *H. erectus* ca. 200 ka. Another hypothesis assumes an anagenetic transition from the early hominins to *H. erectus* (earlier than 1.5 Ma), followed by dispersal. In the view of Templeton (2002), a second and a third expansion (Out of Africa "again and again") shaped the modern human gene pool. The assumption that *H. sapiens* developed independently and in parallel in several regions of the world is mainly based on Asian fossils (e.g., Zhoukoudian, upper cave) and is summarized as the "Multiregional Continuity Model," or the polyphyletic hypothesis, with gene flow maintaining some genetic homogeneity (Wolpoff 1999, 2002). The "mostly Out-of-Africa hypothesis" (Relethford 1998, 2001) is a combination of the African replacement model with the multiregional model. All these hypotheses involve questions of whether migrating hominins replaced local populations, or interbred (for further discussions, see also Bräuer, "▶ Origin of Modern Humans," Vol. 3).

Referring to the questions we formulated at the beginning of this section, we want to add a third one: *how did hominins migrate from Africa*? (Henke and Hardt 2011). In the early phase, hominids seem to have been restricted to certain African habitats (although there were relatively large numbers of "intra-African" dispersals Strait and Wood 1999); this restriction lapsed through the Pleistocene, and hominids seemed to become more eurytopic and thus became able to tolerate a wider range of conditions (Foley 1978; Vrba 1995, 1999; Lahr and Foley 1998). It is possible to see an ecological patterning in the colonization of temperate regions even when looking at the range of other species (mostly large mammals) that spread out of Africa alongside the hominids (Turner 1984; Lewis 1997; Brantingham 1998; Strait and Wood 1999). Certain characteristics of large mammals provide the capacity to exploit new environments, including (1) large body size, (2) carnivorous behavior, and (3) sociality in larger groups. Hence, scientists have to think about the general principles that encourage zoogeographic mobility (Foley 1987; Henke and Rothe 1999):

- *Carnivores* are more *eurytopic* than herbivores. Meat requires less specialized and locally restricted adaptations than plants, thus carnivores are expected to migrate faster than herbivores, which are restricted to specific plants in a specific area.
- *Exogeny*: the attribute of an organism to forage across a variety of niches, giving it higher tolerance, less specialization, increased interspecific competition.
- *Environmental physiology*: increasing body size enhances the energetic situation of an organism in terms of the relation between body weight and surface (Bergmann's rule 1847; Aiello and Wells 2002). Consequently, larger mammals are able to cope more efficiently with temperate conditions. The extremities tend to be reduced in colder environments to diminish frostbite as seen in the distal limb segments of Neanderthals (Allen's rule 1906). "There is indeed some possibility that the increase in body size associated with *Homo erectus* [...] may have at least contributed to the success of human geographical spread" (Foley 1987, p. 268).

Additionally, home range size and diet quality seem to be closely related to initial dispersals from Africa (Antón et al. 2002). Although these principles are able to account for the expansion of early hominins, certain problems related to surviving high-latitude habitats remain: (1) resource availability is highly seasonal and (2) the annual variation in day length shortens the time for foraging and other activities in winter. Favored strategies here are the extraction of resources yielding high returns and an increase in the efficiency with which resources are extracted. The former is linked to an increase in carnivory and high-energy food and the latter to increasing predatory efficiency and, especially in hominins, improved tool manufacturing and using. Additionally, producing complex and efficient stone tools demands advanced cognitive competence and accordingly constitutes an interaction between encephalization and culture (Klein 2000; Wynn 2002; Osvath and Gärdenfors 2005; Biagi, chapter "▶ Modeling the Past: The Paleoethnological Approach," Vol. 1 and Toth and Schick, chapter "▶ Overview of Paleolithic Archaeology," Vol. 3). Most likely, habitat structure and resource types were the driving forces that mainly influenced dispersals and the sequence of habitat colonization by hominids (Foley 1987).

Conclusion

Human evolution is not a "Sonderweg" (exceptional way); it strictly follows the rules of evolutionary biology and neither constitutes a special case nor determines the terminal branch end in the Tree of Life, let alone creation's crowning glory (Foley 1978, 2002). It is just the story of balanced interrelationships between environment and large mammalian genera possessing preadaptations that facilitated coping with the conditions during a specific time span. Corresponding to Foley (2002), the following key events altered the direction of radiations and dispersals in the hominid lineage:

1. *Invasion* of Africa from Asia of an ancestral lineage of Miocene primates and the outcome of African apes and potential "hominids" *Ardipithecus*, *Orrorin*, and *Sahelanthropus*.
2. *Bipedal adaptations* in australopithecines living in tree-dominated grassland-woodland mosaic habitats probably in dense gallery forest biomes and/or at the margin of the shrinking central African rainforest (taxa: *A. anamensis*, *A. afarensis*, *A. africanus*, *A. garhi*, *A. bahrelghazali*, *A. sediba*) in the Pliocene with nearly Pan-African dispersals.
3. *Megadonty and masticatory apparatus increase* as adaptation to low-quality nutrition in a mosaic-like environment in the "robust" australopithecines (taxa: *P.* (*A.*) *aethiopicus*, *P.* (*A.*) *boisei*, *P.* (*A.*) *robustus*) during the latest Pliocene and Early Pleistocene leading to an extinct backside branch.
4. *Origin and radiation of earliest Homo* is the most intriguing event of all because the phylogenetic position of the scarce fossils is extremely uncertain and variations within the group are extensive (taxa: *A.* (*H.*) *sediba*, *Kenyanthropus platyops*, *H.* (*K.*) *rudolfensis*, *H. habilis*). Nevertheless, there is a clear trend toward *brain size increase*.
5. The *diversification and dispersal* of *Homo* 1.75 Ma (taxa: *H. erectus*, *H. ergaster*) and a second radiation of later forms of *Homo* 0.5 Ma (*H. heidelbergensis*), bound to several changes in dental/cranial morphology and behavior (*carnivory*, *hunting*, *tradigenesis*), the development of technologies (*stone tools*), and the usage of *fire*.
6. Enhanced neural capabilities and improvement of lithic and hunting technologies (e.g., projectiles) in the context of interglacial/glacial cycles may have led to repeated dispersals following each other with the outcome of *H. neanderthalensis* and *H. sapiens*.

7. *Symbolic thought* (Henke in press) combined with *language* and the opening of new resources (e.g., aquatic food) characterizes the radiation and global colonization of *H. sapiens* in the last 100 kyr ago. Why and how the Neanderthals became extinct is still a matter of debate.
8. Recently, humans seem to have nearly *detached themselves from selection pressures* (except regarding their own species and some kinds of pathogens). Meanwhile, *Homo* is the large mammal species with the most individuals – there are seven billions of us now. This, however, brings with it great responsibility to safeguard "System Earth" in order to afford further evolutionary development in global ecosystems. The sheer mass of *Homo sapiens* is causing systemic changes in every sphere of the planet that are faster than ever before in the Earth's history. We are now in the Anthropocene (Zalasiewicz et al. 2011). Or, as Potts put it (2012, p. 163): "The question remains as to how human societies in the future will apply their evolved adaptability in adjusting to the rapid changes we now create."

We would like to stress that primate and consequently hominid evolution is a complex process that has to be seen from different angles and needs all of the different scientific approaches currently available.

One question remains open: *Is paleoecology an adequate window on the past*? This is answered in the affirmative but, as in any other hypothesis-based scientific field, it is also realized that without paying attention to possible pitfalls and without interpreting the results in context, there is a danger of simply telling stories. Unfortunately, there are no "laws" in ecological science such as those that exist in chemistry and physics; there are merely a lot of hypotheses that have to be tested and one concept that is close to a "law": *natural selection* (Pianka 1983). Hence, we conclude that paleoecology – when conceived with care – is an important field of evolutionary biological, and especially paleoanthropological, research. When discussing hominid evolution, and consequently our own evolutionary history, the danger of storytelling is potentially higher because fossils are rare, sample biases are high, and not least because hypotheses always stand on shaky ground when the subject is ourselves (White 2000).

Actualism may be a path that leads to "true" inferences when ecological models and model organisms are selected carefully. For example, *Pan*, as our genetically closest relative, seems to be a good model from which to derive certain inferences, but as a restricted occupant of dense and humid forest habitats with significant morphological adaptations, it might not be the first choice for reconstructing the selective pressures that affected early humans living "on the edge" between open and closed habitats (see also Susman and Hart, chapter "▶ Modeling the Past: The Primatological Approach," Vol. 1).

It is obvious that paleoecology demands a multidisciplinary approach. However, nearly all researchers are specialized in their own "scientific niches" and struggle to keep and defend them. The great challenge ought to be the creation of a "scientific biocenosis" that helps us to understand evolutionary processes in terms of all the phenomena scientists are able to examine. The "scientific environment," however, is sometimes harsh, and chilly winds wave the banner of publication quantities and impact factors. There is hope that a high adaptational species – such as ourselves –could change and improve this "habitat" to enhance the "ecology" of pure science.

Zoogeography: Primate and Early Hominin Distribution and Migration Patterns

Alan Turner and Hannah O'Regan

Contents

Abstract

Human evolution may be usefully considered as part of the evolution of the larger mammalian fauna of the Tertiary and Quaternary periods. When viewed in this way, the dispersion of the hominins, and the questions of timings and directions, can be examined in the context of movements in other mammalian groups without being treated as special case with a unique set of causes. Earliest migrations by Primates into Africa during the Oligocene and Miocene were accompanied by numerous other taxa that were capable of crossing the closing gap between

continents. While the later evolution of the Hominidae may well have taken place in Africa, the dispersion patterns of the dryopithecine apes during the early Middle Miocene into Eurasia and then back into Africa toward the Late Miocene suggest a rather wider ancestry for humans and the living African apes. Earliest movements across the Gibraltar Straits during the Pliocene and Pleistocene can be ruled out for any terrestrial mammals, and while a Late Pliocene dispersal across the opening Bab el-Mandeb region of the southern Red Sea may have been possible, such a route appears an unlikely choice for a Pleistocene gateway leaving only the Levantine route across Sinai as a plausible way out of or into Africa.

Introduction

It is a commonplace observation that species of both plants and animals have patterns of distribution, and that everything is not found everywhere (Cox and Moore 2004). In many cases, such distributions can be explained by the presence of physical or biotic barriers such as mountains, deserts, or water and the absence of suitable foods, while some clearly owe much to modern human interference. But a species may not have always been where it is found now, while another may formerly have existed in areas from which it is now absent, so that many patterns reflect processes of movement that occurred from a few tens to thousands or millions of years ago. We live on a planet that has been constantly changing as the continents have shifted and climates have altered, and it is likely that many of the patterns we observe today have been affected by such events.

Change in zoogeography over geological time, and its relationship to tectonic and climatic events, is one of the things that the fossil record can bring to providing a bigger picture of the past, although pitfalls must be overcome in the process. Identification and dating must be accurate, and while presence is clear enough from the fossils, firm evidence for absence in a region may be rather more difficult to distinguish from simple failure to look in the right place or simply to find. But the fossil record is never as good as it will become, and synthesis cannot forever be delayed on the grounds that we do not yet have enough data. As time goes on, and more evidence accumulates from more and more sites, even absence may start to be seen as a real feature of the record and attempts at synthesis of zoogeographic patterns may legitimately be made (Turner and Wood 1993).

Paleoanthropology deals with the evolution of *Homo* and our close fossil relatives, the tribe Hominini or hominins, and may be extended, according to the interests of the enquirer, to include the evolution of the Hominoidea (the superfamily that includes lesser apes, great apes, and humans) or even more widely to other primates. In the case of the Hominoidea, one of the most important issues to understand is the question of dispersions, whether of the Primates into Africa in the first place or our closer hominin fossil relatives out of Africa in the later stages of their evolution. It could be argued that the dispersals of the Hominoidea are likely to be best understood within the context of dispersals in other elements of the mammalian fauna, and here this larger context is examined, beginning with a brief discussion of the initial movement of the Primates into Africa, followed by a review of the evidence for Miocene to Early Pleistocene distributions within Africa and between Africa and Eurasia.

Early Movements of Primates into Africa

Recent molecular analyses of DNA sequences suggest that a small number of mammalian orders (the elephants, hyraxes, tenrecs, aardvarks, elephant shrews, golden moles, and the aquatic manatees or sea cows) together compose a unique group, the Afrotheria, whose members share a restricted common ancestry (Tabuce et al. 2008). The fact that the closest (sister) group to these is likely to be the South American order Xenarthra (the sloths, anteaters, and armadillos) makes sense in terms of continental separations (Asher et al. 2009). A significant absence from the Afrotheria, however, is Primates, which seem to have evolved in the Northern Hemisphere (Fleagle 1999).

The Afrotheria owe their origins as a distinctive group to the fact that the continent was long isolated after the breakup of the southern landmass of Gondwana. Africa and the southern part of the Arabian Peninsula finally docked with the Eurasian plate in the Early Miocene, around 25–18 Ma, after a northward movement from the breakup estimated at around 14° of latitude (Rögl 1999). In the process of closing with Eurasia, the eastern arm of the Tethys seaway was closed, providing a land connection. At what precise point movements across the shortening gap between Africa and Eurasia became possible for terrestrial animals is unclear, but primates are known in some numbers from the Fayum deposits of Egypt between 37 and 30 Ma, with an earlier appearance between 52 and 46 Ma suggested by material from Algeria (Tabuce et al. 2009). The implication is that some form of island hopping across the shortening gap was possible as tectonic forces buckled the floor of the Tethys and produced a series of small and no doubt short-lived areas of dry land. Following the contact between Africa and Eurasia, a transgression of the Tethys Sea southward left Africa connected to Eurasia via the southernmost part of the Arabian Peninsula across what are now the Bab el-Mandeb Straits (Tchernov 1992). Much of the later Miocene movement of faunas into and out of Africa therefore probably took place across this region, although our knowledge of the Miocene mammalian fauna of Arabia is currently very poor (Whybrow and Clements 1999).

Those same enormous forces produced by the combined northward movement of Africa and India formed the mountain chains that run from southern Europe to the Himalayas. These include the Taurus and Zagros mountains of Turkey and Iran, which have combined with the frequently harsh conditions of the Arabian Peninsula to control movements into and out of Africa (Tchernov 1992) (see also later). Toward the end of the Miocene, during the Messinian salinity crisis, tectonic processes in the westernmost region closed the portal with the Atlantic and the Mediterranean began to dry up (Kirjksman et al. 1999). During the Early Pliocene, the Mediterranean refilled, while the Red Sea widened as the Arabian plate swung away and eventually broke the Bab el-Mandeb land bridge in the Late Pliocene, part of the eastern African rifting process that continues to the present day. Although some form of land bridge therefore existed between southern Spain and northern Africa during the Messinian (Gibert et al. 2013), there is no compelling evidence for one across the Gibraltar Straits since then. Most if not all subsequent mammalian movements between Africa and Eurasia during Plio-Pleistocene times are therefore likely to have been via the Levant and perhaps Arabia (see later).

The Eocene to Oligocene primates of the Fayum were already quite diverse and numerous genera have been recognized (Seiffert et al. 2010), but their relationships to modern primates have yet to be established. Such diversity points to a well-established presence at that point, but the subsequent record of monkeys is poor until well into the Miocene, when records recommence in the rich deposits of eastern Africa where numerous remains referred to the family Victoriapithecidae occur (Jablonski and Frost 2010). Primitive apes appear in the fossil record of Africa a little later than the monkeys, and there is a reasonably good record from Late Oligocene to mid-Miocene deposits. One of the oldest specimens comes from Lothidok Hill in northern Kenya, in deposits that may be as early as 27 Ma, while others are found at a range of Early Miocene sites in Uganda and Kenya such as Rusinga Island in what is now Lake Victoria, at Koru and at Songhor in deposits dated to the period 22–17 Ma (Andrews and Humphrey 1999). These animals, belonging to the genera *Proconsul*, *Rangwapithecus*, and *Nyanzapithecus* and varying from large monkey-like up to female gorilla-like in size, are placed in the separate family Proconsulidae and best characterized as "arboreal quadrupeds" (see Begun, chapter "▶ Fossil Record of Miocene Hominoids," Vol. 2).

More advanced apes appear in a further radiation in the period 17–12 Ma, and are referred to three superfamilies – the Dendropithecoidea (Family Dendropithecidae), Proconsuloidea (subfamilies Proconsulinae, Afropithecinae and Nyanzapithecinae), and the Hominoidea (subfamilies Kenyapithecinae and Homininae) (Harrison 2010). It is at this stage that primates appear to have moved back out of Africa. Although the Afropithecinae occur in Africa and Arabia, the Kenyapithecinae are known from Kenya but mostly occur in Turkey and southeastern Europe, while members of the Homininae (tribe Dryopithecini) are European in distribution (Begun 2009). In other words, the major known fossil distribution of the early Hominoidea is outside Africa. This early dispersion from Africa may have implications for our understanding of the later origins of the Homininae, the subfamily containing the African great apes and humans (see below).

The earliest movement of the Primates into Africa may have been "accompanied" by a dispersal of the archaic predator order Creodonta, since members of the family Hyaenodontidae also first appear in Early Eocene deposits there, but further contemporary incursions of other groups are not evident. A clearer pattern emerges at the time of full contact around 20 Ma, when other immigrants from Eurasia included the first perissodactyls in the form of early rhinos, and the bizarre-looking chalicotheres, with their horse-like heads and clawed feet. More artiodactyls also made their appearances, with the incursion of the giraffoid climactocerids and first antelopes as well as primitive pigs of the genus *Nguruwe*, which must have traversed the continent since they are known from Namibia and Kenya at around 17.5 Ma

(Turner and Antón 2004). More advanced cercopithecoid monkeys replaced the earlier primates, although in situ evolution is hard to distinguish from immigration. True Carnivora entered the continent with the first appearance of cats and the amphicyonid bear-dogs as well as of mustelids (Morales et al. 1998) and, at least in North Africa, of members of the extinct cat-like family Nimravidae, although the creodonts continued to prosper as the dominant meat eaters. In the other direction, the probable dispersion of dryopithecine apes was perhaps preceded by the appearance of anthracotheres in Europe and possibly accompanied by a dispersal of monkeys of the genus *Pliopithecus*, the creodont *Hyainailouros* (Agustí and Antón 2002) and the first movement of the proboscideans from Africa (Harzhauser et al. 2007). The latter consisted of movements not of elephants proper but of the four-tusked gomphotheres and the deinotheres, the latter marked by a single pair of tusks set in the lower jaw. The subsequent history of some of the various proboscidean genera during the Miocene and Pliocene suggests a good deal of interchange with Eurasia.

On a general note, the structure of the African Early Miocene guild of larger carnivores seems to have divided into flesh-eaters among the early cats, nimravids and perhaps smaller creodonts, and bone-crunchers among the amphicyonids and larger creodonts, and by the mid-Miocene, the complexity in the guild structure of carnivores was enormous. Such a guild points to an equivalent complexity in the ecological relationships of predators and prey in Africa at this early period. The ungulates do not look particularly well adapted for speed, while the predators do not look equipped to chase anything moving particularly fast. Dog-like animals, in the form of some of the smaller hyenas of the genera *Ictitherium*, *Hyaenictitherium*, *Lycyaena*, and *Hyaenictis*, only appear much later in the Miocene (see later) and in the absence of the true dogs of the family Canidae until later still in the Pliocene it is difficult to assess the extent to which pack hunting might have been possible (Turner and Antón 2004). The larger amphicyonids are unlikely to have operated cooperatively, and would probably have taken a mixture of carrion and hunted meat. Overall, the zoogeography that can be pieced together supports interpretations of the earlier to Middle Miocene vegetation of Africa as generally quite closed (Cerling 1992; Cerling et al. 1997). It might therefore be presumed that most of the primates at that time would have found food and refuge among the closed vegetation, and as such have been fairly safe from predation, but the latest work on material from Kenya suggests that Miocene primates were preyed upon by a variety of animals (Jenkins 2011).

Zoogeographic Evidence for the Origins of the Hominidae

Africa is usually taken to be the origin point of the human lineage, and so far as the later stages of the Pliocene and Pleistocene are concerned, this is generally accepted as true beyond reasonable doubt. Nevertheless some doubts about this matter have been raised in recent years – in particular regarding the origins of *Homo erectus* (White 1995; Dennell 2004) – and it would always be unwise to assume that there are no surprises left in the fossil record. However, as discussed above, the Primates themselves did not originate in Africa, and while emphasizing their incursion during the Early Eocene may seem like an academic nicety, it is worth stressing that the intermediate period of the mid- and later Miocene witnessed emigrations and perhaps also re-immigrations.

The apes of the subfamilies Homininae and Kenyapithecinae that dispersed from Africa underwent a considerable radiation in Eurasia until the end of the Mid-Miocene, around 7–9 Ma (Andrews and Bernor 1999). In Africa, apes are scarce between perhaps 15 Ma and the very end of the Miocene (Andrews and Humphrey 1999; Leakey and Harris 2003), although fragmentary specimens are known from some 10 Ma onward (Begun 2009*)*. Interpreting such scarcity in the fossil record is always hazardous, since it may indicate no more than an absence of suitable deposits or inadequate search and recovery. But if it is a real pattern, then it is perhaps the ancestor for the later great ape and human lineage of the subfamily Homininae may be found among these Eurasian advanced hominid apes. The possibility that the European Dryopithecini make the most plausible candidates has been both proposed (Begun 1993, 2009) and questioned (Andrews 1992; Andrews and Bernor 1999) on several details of taxonomy and systematics, but Solounias et al. (1999) raised the question again in the context of understanding wider issues of the relationship between faunas of southeastern Europe and Africa. The latter authors point out that many of the savanna-dwelling mammals of Africa may well have originated in what they term the Pikermi Biome, based on the rich Late Miocene Greek locality of Pikermi. They cite somewhat longer necked and thus more advanced giraffes, rhinos of the extant genera *Diceros* and *Ceratotherium*, the false sabretoothed cat *Dinofelis* and the larger bone-smashing hyenas *Belbus beaumonti* and *Adcrocuta eximia* as offering primary evidence for such an origin, and it is indeed clear that such animals do make their first appearance in Africa in the latter part of the Miocene. Overall, by around 8 Ma, over the middle part of the Miocene, there is an evidence of considerable incursion from Eurasia generally into Africa if we add to the above list the smaller to midsized and dog-like hyenas of the genera *Protictitherium*, *Ictitherium*, *Hyaenictitherium*, *Lycyaena*, and *Hyaenictis*, the sabretoothed cat *Machairodus*, a range of mustelids, and a number of antelopes (Vrba 1995; Werdelin and Turner 1996; Turner and Antón 2004). The impetus for this movement appears to have been a major shift in climate, changing the western European vegetation from subtropical evergreen forest to more deciduous and dry woodland and provoking a turnover in mammalian fauna that Agustí et al. (1999) termed the mid-Vallesian Crisis. By around 9 Ma, the dryopithecine hominids were extinct in Western Europe, although they managed to survive until perhaps 7.5 Ma in Italy and China (Andrews and Bernor 1999). A movement of early hominid apes back into Africa is therefore entirely plausible as part of this larger pattern of dispersion.

Zoogeography of African Pliocene Hominini

Whether or not the common ancestor of later Hominidae was indeed of Eurasian dryopithecine-like morphology and origin, our African ancestors and relatives changed from being generalized apes to more sophisticated apes with tools over a period of a few million years, only becoming really recognizably human with the earliest appearance of the *H. erectus* lineage at around 1.8 Ma. This transition included shifts to an upright stance and fully bipedal walking and a massive increase in relative and absolute brain size, presumably accompanied by alterations in behavior, social interactions, and intelligence. Details of zoogeography however remain unclear.

The earliest currently known putative hominins are from the late Miocene – *Sahelanthropus tchadensis* (6–7 Ma) from Toros Menalla in the Chad Basin (Brunet et al. 2002), *Orrorin tugenensis* (6.2–5.5 Ma) from Lukeino in Kenya (Senut et al. 2001), and *Ardipithecus kadabba* (5.77–5.2 Ma) from Gona in Ethiopia (Haile-Selassie and WoldeGabriel 2009). Both *O. tugenensis* and *Ar. kadabba* have been associated with wooded environments with a nearby water source, but the Chad Basin paleoenvironment appears to have been more of a mosaic association of lake-side gallery forest, wooded savanna, and open grasslands (Vignaud et al. 2002), and the precise preference of the primate is hard to determine (see Strait et al., chapter "▶ Analyzing Hominin Phylogeny: Cladistic Approach," Vol. 3 and Rowan and Reed, chapter "▶ The Paleoclimatic Record and Plio-Pleistocene Paleoenvironments," Vol. 1).

According to interpretations of the Early Pliocene material referred to *Ardipithecus ramidus*, first found in 4.4 Ma deposits of the Middle Awash Valley in Ethiopia (White et al. 1994, 1995), an attachment to a woodland habitat may have persisted until close to 4.0 Ma (WoldeGabriel et al. 1994). Material also referred to *Ar. ramidus* from 4.5 to 4.3 Ma sediments to the west of the Awash at As Duma (Semaw et al. 2005) is also said to be associated with moderate rainfall grassland and woodland/grassland, based on paleosols, soil carbonates, and faunal elements. However, stable carbon isotope values for ungulate dental enamels at the Gona *Ardipithecus* sites suggest a significant component of C_4 grasses in the diet (Levin et al. 2008), and we should beware of the dangers of a small number of early hominin localities misleading us about habitat preferences and true distributions.

We do know that the physical and biotic environment within which the hominins were evolving was itself undergoing significant changes. Rifting, volcanic activity, and uplift were continuing to change the topography of eastern and southern Africa as they had throughout the Miocene (Pritchard 1979; Adams et al. 1996), and as a result of these changes and their interaction with climatic events, the vegetation was opening out to provide the distribution and huge mosaic of habitats existing there today. Such physical and biotic changes underlie the distributions of the living African mammal fauna (Grubb 1999; Grubb et al. 1999) and must have had a major bearing on the zoogeography of the past (Turner 1995). Clearly, more open vegetation not only developed during the Pliocene but also became an attractive habitat for predators and in all probability early hominins (Turner and Antón 1999). The development of stone-tool technology can now be traced back in Africa to around 2.6 Ma at Gona in Ethiopia, and similarly dated stone-tool cut-marked bones have also been reported from Bouri in Ethiopia (Semaw et al. 2003). More recently, bones with damage interpreted as hominin-inflicted and dating from approximately 3.9 Ma have been reported from Dikika, Ethiopia (McPherron et al. 2010);

however, these have not been widely accepted (see Dominguez-Rodrigo et al. 2011 and references therein). What happened in terms of hominin development before such lithic technology was developed, either to assist or to motivate the move to more open terrain, is unclear.

An analysis of the zoogeography of African Pliocene hominins within the larger context of distributions in the rest of the Plio-Pleistocene large-mammal fauna was undertaken by Turner and Wood (1993), prior to the more recent discoveries referred to above but based on a larger body of hominin species and known distributions. The evidence available then, as now, suggested that the genus *Australopithecus* was apparently geographically split, and represented by *A. afarensis* in eastern Africa and *A. africanus* in the south. The genus *Paranthropus*, taken by Turner and Wood (1993) to be monophyletic, was considered to be represented by *P. robustus* and perhaps *P. crassidens* in the south and by *P. aethiopicus* and *P. boisei* in the east. More recent discoveries have extended the range of named hominin taxa in the eastern region but done little to alter that picture of regional distributions, although Bromage and Schrenk (1995) have extended the range of *P. boisei* southward to Malawi. The most primitive australopithecine species, *A. anamensis*, dating to approximately 3.9–4.2 Ma has been identified in both Kenya (Leakey et al. 1995) and Ethiopia (White et al. 2006), while another, *A. bahrelghazali*, has been recognized at Koro Toro in Chad in deposits of slightly later age (Brunet et al. 1996). A third species, *A. garhi*, has been identified in deposits of the Middle Awash Valley (Asfaw et al. 1999), and a fourth, placed in a new genus as *Kenyanthropus platyops* (Leakey et al. 2001), has been identified from deposits dated to 3.5 Ma at West Turkana. The newest (and latest) species of *Australopithecus* – *A. sediba* – has recently been recognized and dated to 1.97 Ma at Malapa in South Africa (Pickering et al. 2011).

In the case of the genus *Homo*, assessing the geographic distribution of species is made more difficult by the increasingly evident fact that the taxonomy is more complicated than has previously been assumed. *Homo* is conventionally considered to be evident in Africa back to about 2.5 Ma, first represented in eastern Africa by the species *H. habilis* and *H. rudolfensis*, although the latter has also been identified in Malawi by Bromage and Schrenk (1995). The fact that stone tools appear in the archaeological record at about the same time has led to speculations about the relationship between evolutionary change and the development of tool-making abilities. However, it has long been apparent that the earliest taxa assigned to the genus *Homo* are a rather heterogeneous group (Wood 1991, 1992), and it has been argued that they could be removed from *Homo* altogether, in a scheme leaving *H. erectus sensu lato* as the earliest clear member of the genus (Wood and Collard 1999; see also Wood and Baker (2011), Schrenk et al., chapter "▶ The Earliest Putative *Homo* Fossils," Vol. 3, Baab, chapter "▶ Defining *Homo erectus*," Vol. 3, and Tattersall, chapter "▶ *Homo ergaster* and Its Contemporaries," Vol. 3). This would place the first evidence of our genus within the Olduvai Event (1.95–1.77 Ma) and sometime after the earliest appearance of stone tools, and it is this seemingly abrupt appearance of *H. erectus* that has led to suggestions of a possible origin outside Africa (White 1995; Dennell 2004).

Of course, tool making by hominins of other genera is neither improbable nor implausible. Chimpanzees both make and use tools, albeit primitive ones that satisfy any sensible definition of such behavior, and it may be that a variety of evolutionary solutions that included some elements of manufacture and use of technology were developing among the African Pliocene hominins (Turner and Antón 2004). While our own lineage moved toward greater ecological generalization coupled to an emphasis on stone-tool technology and an increase in brain size, members of the genus *Paranthropus* appear to have developed larger jaws and teeth in order to cope with their food (see Rowan and Reed, chapter "▶ The Paleoclimatic Record and Plio-Pleistocene Paleoenvironments," Vol. 1). At least one hominin species traditionally referred to *Homo*, the east African *H. rudolfensis*, appears to have followed the same path as the paranthropines between 2.5 and 1.8 Ma with enlarged teeth but with a relatively large brain as well. If the *H. rudolfensis* material is indeed to be linked to the earlier *K. platyops* and referred to that genus, as suggested by Leakey et al. (2001), we may then very well have evidence of a separate lineage within which brains and teeth both developed. We may therefore identify at least three different evolutionary developments within Pliocene hominins, all of which enjoyed a considerable measure of success.

Whatever the lineages involved, making sense of the zoogeography of Pliocene hominins is difficult. The record presents a complex series of morphologies and proposed taxa, and interpretations of identity, relationship, and adaptations of the various species, leave alone distributions, are impeded by the fragmentary state of much of the material and the fact that several taxa or putative taxa are represented by single specimens or localities. This underscores the value of looking at distributions within the rest of the fauna in order to see whether patterns that may appear to be present in the hominins make sense in terms of larger-scale patterning. The investigation by Turner and Wood (1993) extended to include just such a larger patterning in eastern versus southern African taxa and concluded that there was evidence for a high degree of regional differentiation in some families, particularly the Bovidae, coupled with evidence for significant dispersals in others. Among the Primates, the papionin monkeys appeared to show the most evidence for dispersals, and overall, it was apparent that regional isolation was not a matter of rigid demarcation. The implications of this for our understanding of hominin biogeography are that regionally restricted taxa would be a plausible interpretation of the material to hand, but that movements between regions are likely to have occurred and that identified genera such as *Australopithecus* and *Paranthropus* with differing species in each regions are indeed likely to be monophyletic. If monophyly is a correct interpretation, then a localized origin with subsequent dispersals is likely to have been the dominant pattern (Turner and Paterson 1991; Turner 1999a).

The known distribution of Pliocene and perhaps Late Miocene hominin remains now stretches from Chad down through eastern Africa to South Africa, perhaps even from the Atlantic coast of the western Sahel down to the Cape as Brunet et al. (1995) argued, and any reasonable interpretation of that pattern would recognize it as a minimal statement of range. But how much the gaps in between known localities were filled in, or the limits of distribution extended, remains unknown. Artifactual evidence from northwestern Africa may indicate the presence of hominins with Oldowan tools as early as the Olduvai event (Sahnouni and van der Made 2009), but the best evidence appears to date from around 1.0 Ma (Raynal et al. 2001). Dennell (2004) has even suggested that if Pliocene hominins were in Chad some 2,500 km west of the Rift Valley by 3.5 Ma then why not as far to the north or east by the same period? This, of course, would place them in southwestern Asia.

Out of Africa

The number, timing, and direction of earliest hominin dispersals from Africa have long been a major point of discussion, and opinions on these topics remain varied and contentious (Rolland 1998; Turner 1999b; Bar-Yosef and Belfer-Cohen 2001; Strauss 2001; Villa 2001; Dennell 2004, 2009; Abbate and Sagri 2012). Early Pleistocene assemblages from ‘Ubeidiya in Israel dated to around 1.5 Ma (Belmaker et al. 2002), perhaps Pakistan by 1.8 Ma (Dennell 2004), Iberia by 1.4 Ma (Oms et al. 2000; Toro-Moyano et al. 2013) and human material from Dmanisi in Georgia dated around 1.8 Ma (Lordkipanidze et al. 2013) set a minimal date for the original movement. Dispersals to eastern parts of Asia remain more contentious (see Dennell (2009) for review), with the best evidence so far from 1.66 Ma deposits with stone implements and what is interpreted as stone-tool processing of animal carcasses at Majuangou in the Nihewan Basin of northern China (Zhu et al. 2004). The stone tools resemble primitive Oldowan items found in African deposits, and the authors argue for a significant and flourishing early dispersion from Africa, although the rest of the mammalian fauna has no clear African elements. Hominin occupation appears to have been more extensive and intensive in Europe in particular and Eurasia in general after 0.5 Ma with a long tail of more sporadic appearances back into the Early Pleistocene (Turner 1999b; Roebroeks 2001), although Martínez et al. (2010) suggested that occupation in Iberia *may* have been continuous from the latest Early Pleistocene. But which route, or routes, was used? Several have been proposed – land across Sinai and the Levant, across the Bab el-Mandeb Straits at the south of the Red Sea and then across the Arabian Peninsula proper, or by the Gibraltar Straits? Here the evidence is reviewed from a faunal perspective, but see Abbate and Sagri (2012) for further information on the geomorphology.

Gibraltar

Although the evidence available points to some part of the Arabian Peninsula as the most probable route for Plio-Pleistocene hominin dispersions, a route across the Gibraltar Straits has frequently been proposed. For example, Rolland (1998) argued for a reduction of the seaway through the Straits to 8 km during glacial maxima, without any increase in surface current and for sweepstake-like movements, especially during OI Stages 12 and 16. Flemming et al. (2003) argued that the Strait itself would not have narrowed significantly during sea-level falls, although they pointed out that now submerged areas to the west of the Strait would have formed substantial islands that might have provided "stepping stones." Strauss (2001, p. 99) offered a thoughtful analysis of the issue but concludes that the record for human contacts is "at best spotty and ambiguous." As far as other routes across the Mediterranean are concerned, particularly between Tunisia and Sicily, Flemming et al. (2003) reached no conclusion, and it is not evident that such possible routes have any strong scientific support. Villa (2001) provides a useful summary of some of the arguments and rejects the idea of such routes.

As summarized elsewhere (O'Regan et al. 2006), among the extant and Holocene terrestrial mammals present in North Africa and Iberia, such as wild boar (*Sus scrofa*), red deer (*Cervus elephas*), otter (*Lutra lutra*), and the red fox (*Vulpes vulpes*), there are none that are not also present in the Levant. This suggests that these animals took a circum-Mediterranean route rather than crossing the Gibraltar Straits (Dobson 1998), although of course, the possibility of some individual animals swimming across cannot be completely ruled out. Some bat species are found on both sides of the Straits and further eastward in Europe but are not recorded in the Levant or elsewhere in North Africa, which could imply dispersion across the Gibraltar Straits (Dobson and Wright 2000). However, the extent to which recent human interference has played a part remains a concern, and of the 17 terrestrial mammal species inhabiting North Africa today only four are considered to have a natural circum-Mediterranean distribution, whereas the rest are thought to be recent introductions (Dobson 1998). Clearly, if populations of *H. sapiens* were capable of dispersing over substantial bodies of water to reach Australia in the Late Pleistocene (Bowler et al. 2003), then it is also possible that they may have been moving around the Mediterranean and transporting animals prior to the Holocene, a point stressed by Strauss (2001). However, the Gibraltar Straits cannot be shown convincingly to have been the scene of natural Pliocene, Pleistocene, or even Holocene movements of terrestrial mammals (with the possible exception of the hippopotamus (O'Regan 2008)) and thus the Arabian Peninsula remains the only established route of a two-way movement between continents.

Arabia

In contrast, the possibility of hominin dispersions through the Arabian Peninsula and the Levant, either across the Sinai Peninsula or the Bab el-Mandeb Straits at the south of the Red Sea, is indicated by the mixed Afro-Eurasian nature of the fauna of the region since the later part of the Pliocene and in particular by the Early Pleistocene deposits at 'Ubeidiya in Israel (Tchernov 1992; Belmaker et al. 2002; Belmaker 2010a). Later Pliocene African elements, chiefly bovids and giraffids, are known to the north of the Taurus-Zagros mountain chain that borders the northern boundaries of the Arabian Peninsula at localities such as Kuabebi in the Caucasus and Wolacks in Greece (Sickenberg 1967), the Oltet Valley in Romania

(Radulesco and Samson 1990), and Huélago in southern Spain (Alberdi et al. 2001). However, many of these taxa have now been reinterpreted as Miocene relicts rather than African immigrants, leaving relatively little evidence for Late Pliocene and Early Pleistocene African dispersals (Agustí et al. 2009; Agustí and Lordkipanidze 2011). Reviews of faunal dispersal both into and out of Africa between 3.0 and 0.5 Ma can be found in O'Regan et al. (2011) and Martinez-Navarro (2010).

The evidence for African faunal elements at Dmanisi has recently been reviewed and largely discounted by Agustí and Lordkipanidze (2011); while at 'Ubeidiya the African faunal affinities were based on an undetermined giraffid, the bovids *Pelorovis oldowayensis* and *Oryx* sp., the hippo *Hippopotamus gorgops*, the suid *Kolpochoerus olduvaiensis*, and a number of carnivores including the spotted hyaena, *Crocuta crocuta* and possibly the honey badger cf. *Mellivora* sp. (Tchernov 1992; Belmaker 2010). The Acheulean industry at 'Ubeidiya is unknown at Dmanisi and appears to have developed in Africa at a slightly later date. Other Early Pleistocene localities in Europe have relatively few African species. Much has been made of the appearance of the cercopithecine *Theropithecus* cf. *T. oswaldi* at Cueva Victoria in southeastern Spain (Gibert et al. 1995), and possibly at Pirro Nord in Italy (Rook et al. 2004) and 'Ubeidiya (Belmaker 2010b), and of the African machairodont cat, *Megantereon whitei*, at Venta Micena, Dmanisi and the Greek locality of Apollonia (Martínez-Navarro and Palmqvist 1995, 1996; Palmqvist et al. 2007). The *Hippopotamus*, is also present at several Early Pleistocene sites such as 'Ubeidiya and Venta Micena (O'Regan et al. 2006, 2011).

Overall, the suggestions of possible hominin dispersions into Eurasia during the very earliest Pleistocene that appear in the literature from time to time (Bonifay and Vandermeersch 1991; Boitel et al. 1996), while unsupported by critical assessments of the evidence within Eurasia, cannot be dismissed a priori as impossible or even unlikely. These conclusions parallel some of those reached by Mithen and Reed (2002) in their computer simulation of dispersals and stressed elsewhere (Dennell 1998, 2004). If recent arguments summarized earlier about the status of later Pliocene species referred to the genus *Homo* are correct, then clearly the earliest hominin to have moved out of Africa would not have been a member of our own genus. However, whether such a view offers support for an extra-African origin for *H. erectus* remains unclear, particularly as the latest data from Dmanisi appear to demonstrate that the cranio-dental morphological variability seen in *Homo erectus*, *H. ergaster*, and *H. georgicus* are all present within the specimens from this single locality (Lordkipanidze et al. 2013; see also Baab, chapter "▶ Defining *Homo erectus*," Vol. 3 and Tattersall, chapter "▶ *Homo ergaster* and Its Contemporaries," Vol. 3).

Precise Routes

If Arabia is indeed the only plausible route out of Africa for terrestrial mammals during the Plio-Pleistocene, it remains difficult to judge the relative contributions of the Sinai versus the Bab el-Mandeb as gateways. While knowledge of the Middle Paleolithic or later Middle Pleistocene hominin occupation of Arabia is rapidly improving (e.g., Crassard et al. 2013), there is still a relative paucity of evidence for Lower Paleolithic occupation (Petraglia and Alsharekh 2004). However, as Petraglia (2003) also showed, both Oldowan and Acheulean assemblages are known, and the eastern side of the Bab el-Mandeb Straits in particular appears to have been occupied by hominins with this technology. Unfortunately, the absence of good chronological control remains a major obstacle to assess the pattern of lithic assemblage distribution.

As Petraglia and Alsharekh (2004) show, while movement across Sinai offers the possibility of movement along the Levant and then perhaps south into Northern Arabia either along the eastern Red Sea Coast or inland behind the highlands of the Hejaz Asir, movement across Bab el-Mandeb confronts any dispersing population directly with the highlands. These would tend to restrict movement to the coastal strips, north along the eastern Red Sea Coast or east along the Arabian Sea Coast. While annual rainfall today in the Hejaz Asir or in the Oman Mountains at the easternmost corner of the Peninsula can reach well over 100 mm, much of the southeastern portion, the Rub Al Khalil or Empty Quarter, may have no more than 50 mm with temperatures that exceed 50 °C (Glennie and Singhvi 2002). The fact that Lower and Middle Paleolithic occupation did occur means of course that conditions were sometimes favorable, and substantial river systems appear to have existed certainly by MIS 5 (Crassard et al. 2013), but lack of evidence hampers interpretation of the earliest hominin dispersals. Little is known of the Plio-Pleistocene fauna of Arabia, which is even more sparsely represented than that of the Miocene. The sole exceptions are the small assemblages from An Nafud in northern Saudi Arabia, thought to be of Early Pleistocene age (Thomas et al. 1998) and which, with spotted hyaena, hexaprotodont hippo, horse, elephant (cf. *Elephas recki*), several bovids including a species of *Pelorovis* as well as crocodile and fish, are of distinctly African stamp. The range of species implies good grassland and standing water in the vicinity, an interpretation supported by isotopic analyses of herbivore teeth.

However, as Glennie and Singhvi (2002) also point out, increased aridity is indicated during glacial periods, beyond even that seen today despite the fact that temperatures may have averaged somewhat lower, and this factor presumably played a large part in determining the extent to which mammals, including early hominins, could maintain any occupation throughout the Pleistocene. Current data indicate that these periods of aridity are related to the deposition of Aeolian sands over at least the last 0.2 Ma (Preusser 2009). Glacial periods with related sea-level changes are of course precisely the point at which the Bab el-Mandeb crossing is likely to have been at its most obvious and navigable to early hominins (Rohling et al. 1998; Cachel and Harris 1998), so that the easiest and most attractive access by that route is likely to have been at a point when conditions in southern Arabia, and for that matter on the corresponding coastal area of Africa, are likely to have been least appealing. Taken overall, the Bab el-Mandeb Straits do not seem likely to have offered a likely gateway out of Africa for terrestrial mammals during the Lower and Middle Pleistocene, suggesting that movement across Sinai and then northward along the Levant, southward into Arabia, or eastward and beyond is the most plausible route. However, movement across the Bab el-Mandeb during the later Pliocene, before the Straits had fully formed, and thus before the crossing into Arabia was dependent on sea-level fall, may have been an entirely different matter, as previously pointed out (Turner 1999b). The importance of the Afar region of Africa to the south and west of Bab el-Mandeb as an area of attractive resources for mammals, including hominins, following rivers into the developing depression as rifting progressed from Miocene times onward was highlighted by Kalb (1995, p. 366), who stressed "the step-by-step process of animal migrations into and dispersal across inter-continental areas prior to complete plate separation."

Conclusions

It seems clear that the wider context of movements between Africa and Eurasia throws useful light on the patterns of dispersion within Primates in general and Hominoidea in particular so that changes in primate distribution can be examined without having to treat them as a special case. In the earliest stages of the Oligocene and Early Miocene, we see that movements into Africa are accompanied by a range of other taxa. If dryopithecine apes first moved back into Europe during the Mid-Miocene and then back again into Africa toward the end of that epoch, then they did so as part of a much wider dispersal across a range of mammalian orders.

Current knowledge of Pliocene hominins is at best incomplete, and while recent discoveries have extended the range of named species, they have done little to clarify the likely relationships between those taxa or the true nature of distributions. With the greater number of putative taxa now available, it will require some considerable time and quite a few more discoveries before real sense can be made of the patterns. However, as far as movement out of Africa by hominins is concerned, a number of points can be made. The Gibraltar Straits are unlikely to have been the site of any Pliocene or Pleistocene gateway for terrestrial mammals, and while movement across the Bab el-Mandeb region before the Red Sea opened fully toward the end of the Pliocene may have been possible, dispersal across the Straits once the glacial and interglacial cycle got underway seems to us unlikely. Sinai and the Levant, the scene of a two-way faunal movement between continents during the latest Pliocene and earliest Pleistocene, remains the only established route. Moreover, the diversity of elements using that gateway points to the relatively hospitable nature of the area in the Earliest Pleistocene, so that suggestions of possible hominin dispersions into Eurasia during this period are not inherently implausible. However, how long any dispersing populations were able to maintain their extended range is entirely another question. Early hominin movements into Arabia and the Levant may have been sporadic, and probably tenuous and subsequent movements out into Eurasia proper were probably even more so.
