The Paleodemography of Extinct Hominin Populations

Janet Monge and Alan Mann

Contents

Abstract

Paleodemography is the study of past population structure. The demographic structure of the population is both the outcome of evolutionary processes operating on groups of individuals and the basis on which future evolutionary forces can potentially operate. This review is concerned with a critical evaluation of paleodemographic studies of the hominin lineage prior to the development of agriculture. Because of the potential this research has for the generation of data about birth spacing, mortality, lifespan, sex ratio, patterns of fertility, and maturation, the study of the demography of earlier human populations has attracted much attention. Very limited and fragmentary sample sizes, however, combined with many uncertainties about depositional patterns, have led to major

difficulties in the development of generally accepted hypotheses. Because of the nature of the preservation of skeletal materials, oftentimes past population structure has been modeled on known living populations. In the remote past, for example, at the inception of the human lineage, the choice of comparative living samples from which to derive models is problematic. Are the data from chimpanzees or modern humans more appropriate in these reconstructions? Or are the past and extinct populations completely different from any other population model constructed from living species?

Since many population parameters are based on life history variables, and vice versa, the assessment of population parameters in the past must be based on an effective evaluation of those key features that influence virtually every aspect of population structure: mortality, fertility, and longevity, to name just a few. Published reevaluations of a number of widely accepted concepts, such as the simple association of life history variables with structures like gross body or brain size, have made these earlier studies increasingly untenable. Further, recently collected data on modern humans and free ranging chimpanzees has cast doubt on the idea that these two primates experience dramatically different timing in their maturation and lifespan events. Other life history parameters of extinct populations, however, such as life expectancy, age at maturation and age at weaning may be retrievable.

While there are many useful variables of past population structure that can be analyzed, most social/cultural parameters (see Layton et al. 2012) cannot be retrieved from the earliest phases of human evolutionary history. These include settlement size and household size and especially changes in population size over time, growth, decline, and even population collapse.

Introduction

Demography is the study of population structure, its size, composition, and related features such as sex, age, geographic distribution, and other environmental, social, and cultural factors. The successful application of demographic studies in modern human societies relies on the accumulation of data on all members of a population or, more commonly, on a calculated sampling of the population (Yaukey and Anderton 2001). In contrast, paleodemography has been characterized as the field of inquiry that attempts to identify demographic parameters from past populations derived from archaeological contexts (Hoppa 2002, p. 9) (Bocquet-Appel 2010) and is primarily based on the analysis of human skeletal materials. The preservation of human skeletons in contexts of even the relatively recent prehistoric past, where agriculture and permanent settlement are present, is variable and dependent on environmental conditions such as soil type and pH, climate, and destructive geological events. Additionally, cultural factors, such as cremation, cannibalism, mass burials, indifference to the disposition of dead infants, and many other behavioral factors, also dramatically influence the preservation of human bones. This chapter is limited to an examination of the paleodemography of our earlier ancestors, prior to the development of agriculture.

Reconstructing population structure from this more distant past is much more problematic. Some recent notable technical advances include the modeling of life tables for preindustrial human populations, predicting mortality patterns (Seguy et al. 2010) and, in the analysis of the skeletal series at Libben, exploring the fertility patterns in a nonagricultural village (Meindl et al. 2010).

Population size, although strictly not a demographic parameter without other information about the structure of the population, has been used to understand factors like extinction in previous hominin populations using archaeological site samples from Western Europe (Mellars and French 2011; critiqued by Dogandzic and McPherron 2013) and to explain the genetic structure of modern human populations (Hawks 2010).

Preagricultural hominins, it has been postulated, relied on a subsistence base founded on the gathering and collecting of wild foods, insects and small vertebrates, and the hunting of larger animals. Scattered and seasonally available food sources meant that for the most part, these peoples did not have permanent settlements. Rather, they established temporary camps, exploiting the local resources and moving on when these were depleted. The duration of a stay at a particular locale was dependent on the season, abundance of resources, size of the group, and other variables. The groups were small in size (Weiss 1973) often no larger than 30–50 individuals. Based on modern ethnographic examples (i.e., Lee and Devore 1968), groups were probably seasonally variable in membership. Temporary encampments and continuous movements imply that deaths would have occurred at different places and that, except for unusual circumstances, we should not expect to find remains of a number of individuals at a specific locale. The expectation is that many deaths will occur during movements and the body left or interred, along the route. Further, deaths would have been seasonal, occurring during those times of the year when resources were scarcest; this implies that hominin remains are more likely to be found at some locales and not others. These generalizations about early members of the human lineage, however, are overwhelmingly based on the anthropological study of living gatherers and hunters, and the accuracy of these observations when applied to earlier, now extinct humans, is uncertain (chapter "▶ Modeling the Past: The Primatological Approach," Vol. 1). Layton et al. (2012) make the argument that the basic life and demographic parameters of a gatherer/hunter society were achieved by the time frame of *Homo heidelbergensis* (viewed by some as archaic *Homo sapien*s). There is, for example, no certainty that all earlier hominins actually were gatherer/hunters; they may have been more specialized in dietary choice and habitat and thus were organized in a different but unknown fashion. As there are periods in the hominin fossil record which suggest that multiple hominin species coexisted, perhaps in geographically close proximity, it remains possible that early hominin demography was based on very different adaptive patterns. Further, prior to about 115 Ka, the sample of hominin skeleton bones available for study is very small. Only after this time did the introduction of the deliberate burial of the dead result in many more bodies being preserved, and numbers of more or less complete skeletons excavated. Finally, the study of the earliest known members of the hominin lineage, mainly early members of the genus *Homo* and still earlier species of the genus *Australopithecus*, is fraught with difficulty (for the moment, fossil samples of the very earliest identified hominins, *Sahelanthropus* and *Orrorin*, are much too few even to be considered here). The *Ardipithecus ramidus* sample, while quite extensive (see collected papers in *Science 326*, 2009), remains relatively unknown from the perspective of demography. Bones of these creatures are discovered in very different circumstances than later hominins. These early remains are usually broken and very fragmentary; multiple bones from the same individual are rarely discovered. The deposits in which they have been preserved have been formed by long-term geological processes; and they are not directly associated with archaeological accumulations. The reconstruction of the taphonomic circumstances that led to the hominin bones being deposited in the geological sediments in which they were found is complex and often ends with uncertain results. However, survivorship curves have been developed recently on the dinosaur species *Albertosaurus sarcophagus* by Steinsaltz and Orzack (2011), an approach that might hold some promise in the analysis of fossil hominins in deep evolutionary time.

The study of general paleodemographic variables is therefore limited by the recovered skeletal and fossil samples and their contexts. These do not yield valid population samples for the construction of the sort of demographic profiles possible in the study of extant humans. Thus, the techniques of analysis and the modeling of data accumulated on these skeletal samples, even under the best of circumstances, can provide only the most preliminary and shadowy details about population structure and basic life history variables.

Basic Parameters of Paleodemographic Study

Estimation of the Age at Death of Skeletal Remains

A demographic study of a skeletal sample begins with the assessment of both the age-at-death and sex distribution of the skeletal material. These data are absolutely essential for the construction of other population statistics. Aging and sexing of skeletal samples of living humans has been the subject of extensive research focused on the development of techniques that can yield results with a high degree of accuracy. The problems associated with aging and sexing and the ways in which the resultant data have been modeled have been summarized by Hoppa and Vaupel (2002). When the sample is of nonmodern skeletal materials (e.g., Neanderthals or australopithecines), the criteria for judging these factors are far from certain. Establishing the age at death of a skeleton relies on knowledge of the life history of the species concerned and of the biological pathways within which these hominins grew and matured. There remains uncertainty and debate about the timing of maturational events in the dentition or the skeleton and about whether models based on living humans or chimpanzees provide greater accuracy. Recent considerations of the variation in growth that characterizes chimpanzees and living humans add a further complication to these estimations (Zihlman et al. 2004;

Smith and Boesch 2010; Monge and Mann 2006). In their summation of the *Ardipithecus ramidus* materials, White et al. (2009) argue that the anatomical features of these primates indicate that "the last common ancestors of humans and the African apes were not chimpanzee-like and that both hominids [hominins in this review] and extant African apes are each highly specialized, but through very different evolutionary pathways" (White et al. 2009, p. 64). If this conclusion is confirmed by additional research, the use of chimpanzee biology in reconstructing early hominin lifeway patterns will need to be seriously reconsidered.

Although they are often considered together as part of a single aspect of paleodemography, it is our contention that potential life variables, including lifespan (often referred to as the study of life history), should be dealt with separately from a consideration of the achievement of this life potential (which is often viewed as a central focus of paleodemographic studies). Potential lifespan is an evolutionary biological phenomenon (with important implications for the evolution of culture) whereas achievement of that life potential represents the complex interaction of biology and culture. Carey and Judge (2001) aptly summarized this dichotomy when they observed that modern humans probably achieve a level of life potential far earlier than this potential can be routinely achieved. Through biomedicine, diet, sanitation, insect control, and other cultural appliances, modern societies have been attempting to reconcile these two elements: to make life potential and individual lifespan the same phenomenon, not just for a favored few but for all humans. In reality, while all living human populations have the potential for the same potential life expectancy (Carey and Judge 2001), most people do not achieve this. Comparisons of differences between populations are one way to analyze the contributions and adequacy of cultural mechanisms to achieve this potential and are of possible use in paleodemography. For example, using a sample of 768 dental individuals spanning the course of most of human evolution, Caspari and Lee (2004) have argued that increased cultural complexity was primarily responsible for the increases in lifespan during the course of the latter phases of human evolution.

When and under what circumstances members of the human lineage achieved a modern humanlike potential life expectancy is a matter of some debate. This includes debates on all phases of life history, from infancy through childhood and adolescence to adulthood. More fundamentally, even statements that the potential of life expectancy in humans is double of that in chimpanzees must now be questioned, especially the statement that potential lifespan in humans is double that of chimpanzees. Maximum age for humans is frequently quoted as 90–100 years, and 50 years for chimps (Sacher 1975; Hawkes et al. 1998; Bogin 1999). However, our knowledge of the lifespans of chimpanzees is presently limited to a few known-age captive animals and is hampered by the paucity of field observations of wild chimpanzees, even though some have been observed for 40–50 years. Cheeta, the chimpanzee who was featured (in all likelihood) in the Tarzan movies, died in 2011 at the age of 80 (or so it was claimed).

The chimpanzees of Mahale have been studied for 34 years and are now providing a limited demographic data set that suggests death among older animals occurs between 31 and 48 years (Nishida et al. 2003). This is not radically different from the profiles of average age at death in many pre-1900 human populations and for what has been estimated for most of human history (Gage 2000; but see also Ascádi and Nemeskéri 1970, and see Robb 2007 for a discussion of the age at death in preindustrial France). The Mahale chimpanzee study also reports that approximately 25 % of older females had a postreproductive lifespan. This phenomenon, the equivalent of postmenopausal human females, has traditionally been cited as a uniquely human life history event. From these observational data, it is clear that this postreproductive phenomenon can no longer be considered a unique event in human life history; theories that have been associated with this pattern, e.g., the grandmother hypothesis, must be reconsidered in light of this data (Alvarez 2000; Hawkes 2003; Levitis et al. 2013), although it is possible that the extent of these postreproductive years might be greater in humans (Blurton Jones et al. 2002).

Since the process of aging causes an exponential increase in virtually all pathologies (Harrison and Roderick 1997), evolutionary selection for increased longevity must target the genes responsible for aging and not focus exclusively on a reduction in fatalities associated with pathological conditions. In baboons, longevity has a reasonably strong genetic component (Martin et al. 2002), and it is possible that chimpanzees and humans have the same potential for longevity; via cultural mechanisms, humans have reduced the cumulative effect of pathological conditions directly associated with aging. Vaupel et al. (1998) have provided a more detailed discussion of the effect of increases in longevity on human demography.

The causes of death in past populations are also difficult to determine. Nishida et al. (2003) have calculated that in the Mahale chimpanzees, just under half of deaths are caused by disease. This appears to exclude general causes associated with death by senescence. In a study of a population of chimpanzees in Guinea Bissau, Sugiyama (2004b) reported that under conditions of ecological stress, in this case deforestation, specific subsets of the group were more likely to die: infants (0–3 years of age), juveniles (4–7 years), and active adolescents (8–11 years).

Mortality profiles of five gatherer/hunter groups are presented in Hill et al. (2007). The primary cause of death reported for the Hadza, a gatherer/hunter group in Tanzania, between the years 1985 and 1997 (Blurton Jones et al. 2002), appears to be disease, here also excluding death associated with the state of just being old. Sugiyama (2004a) has reported on the extent of injury in a forager-horticultural group, the Shiwiar (Ecuador). The results of 678 injuries suffered by 40 individuals indicate that trauma is likely, in fact, common at all stages of life and that without group provisioning, the effects of these injuries would range from debilitating to lethal. If the same sorts of patterns existed in the past (Martin and Frayer 1997), it is reasonable to suggest that provisioning may have played a role in the social system of earlier hominin taxa. Berger and Trinkaus (1995) reported on the incidence and anatomical position of bone fractures in Neanderthals. The position and frequency indicated that the Neanderthals were living a challenging lifestyle with a preponderance of injuries on the upper part of the body. The Krapina Neanderthal collection also shows a significant number of nonlethal injuries

(Kricun et al. 1999), some of which appear to have demanded provisioning of some sort, for example, the Krapina 34.7 parietal in which a large cranial depression shows a considerable amount of posttrauma healing (Mann and Monge 2006). Indeed, death from trauma may have been the main cause of death in earlier hominins. It is, however, extremely difficult to identify signs of disease in earlier hominins because few diseases leave any sign of abnormal bone change (Roberts and Manchester 2007). Further, before the advent of plant and animal domestication, most of the pathologies that have killed millions of modern humans were not a part of the environmental stressors earlier hominins were exposed to. Diseases such as tuberculosis, influenza, rhinoviruses (common cold), bubonic plague, typhus, cholera, polio, typhoid, pertussis, and diphtheria are the result of human settlement after agriculture and the close associations that developed with domestic animals (Crawford 2007).

Except for the widespread signs of bacterial infection on the Middle Pleistocene Kabwe specimen from Zambia, virtually nothing is known about the cause of death in fossil hominins. Similarly, almost nothing is known about the cause of death in most recent human archaeological samples (see, e.g., a description of paleopathology in Lovell 2000). Pettitt (2000) argued, using the oldest aged Neanderthal skeletons, primarily Shanidar I and La Ferrassie 1, that life was difficult in the past and that death primarily resulted from repeated sustained trauma. He based this conclusion on the general robusticity of the Neanderthal skeleton, including dense bones and strong muscle markings which suggested that the body was repeatedly challenged in life. In contrast, X-ray analysis of the entire fossil skeletal sample from the site of Krapina (Kricun et al. 1999) concluded that the skeletons are of healthy individuals, with the dense bone structure indicative of an active lifestyle.

On the basis of assemblages of bones showing a lack of representation of very young and old individuals, Bocquet-Appel and Arsuaga (1999) have argued that at the two largest hominin fossil sites in Europe, Krapina, and Atapuerca (SH), the hominin accumulations were the result of a catastrophe. Cannibalism has been considered a possible cause for the accumulation at Krapina (White 2000); that at Atapuerca (SH) has been attributed to trapping of hominins by bears (but see also Bermudez de Castro and Nicolas 1997). The age distribution at these sites, with an overabundance of adolescents and young adults, fits the paleodemographic profile of skeletal materials caught in a catastrophic event (Paine 2000). The death profile of many catastrophes, for example, the tsunami in the Indian Ocean at the end of 2004, often illustrates the overwhelming overabundance of children including adolescents in the death assemblage; estimates calculate that at least one-third of the deaths in South East Asia were of children.

Carnivore activity is considered a possibly significant contributor to the australopithecine fossil assemblages in the South African dolomite caves (Brain 1981). In this instance, the preponderance of young (but not infant) individuals might be most reasonably explained by differential predation of the young, something that is documented for African ground-dwelling baboons (Mann 1975). Some sort of catastrophic event may apply to the proposed simultaneous death assemblage in the A.L. 333 site at Hadar, Ethiopia.

In a series of papers, Bocquet-Appel and colleagues beginning in 1982 (Bocquet-Appel 2010) have emphasized the difficulties of achieving dependable paleodemographic parameters from the aging of skeletons. He has argued that no matter how they are modeled, population profiles can only incompletely represent the living group from which they derived and only in one small slice in time. Further, considering the small, nonrandom sample sizes that are the usual subject of study, if the population from which the skeletons derive is in the process of demographic change, for example, in a general or even brief trend of population increase, then the resulting death assemblage is likely to show a preponderance of young individuals relative to the number of adults. The same pattern can also be explained by a general increase in population in-migration. Thus, without large sample sizes covering a longer time period, it would appear inappropriate to propose any broad generalizations.

Because of the nature of the fossil record, the bulk of efforts at aging concentrate on the dentition, the most likely element to preserve, although other parts of skeletal anatomy have also been used to age fossil skeletal elements.

In forensic anthropology, the determination of as precise an age at death as possible is crucial for individual identification. In paleodemography, this level of accuracy is not required and the use of life table modeling is considered to be effective. Nevertheless, derived age structure must be used to model the population appropriately in the first place, with the assumption that age-at-death differences in populations form an inherently interesting question. In human evolutionary studies, the age-at-death distribution question is an interesting one since it allows us to attempt to understand evolutionary process from the perspective of mortality.

One of the major critiques of paleodemography discussed by Bocquet-Appel and Masset (1996) involved the assumptions made in the process of aging a skeleton. This initiated a debate evaluating the criteria employed in the estimation of the age at death of skeletal samples (Bocquet-Appel 2010; Van Gerven and Aremelagos 1983; Greene et al. 1986; Konigsberg and Frankenberg 1994). Discussion focused on the use of aging standards based on the biases already present in the reference samples, to such an extent that the resulting aging profiles mimicked the age distribution of the reference sample. Bocquet-Appel and Masset's (1982) principal concerns about the limitations of paleodemographic studies include the assumptions that the populations from which the skeletons derived were stable, life history patterns were the same throughout human evolution, and mortality patterns in the past can be understood using recent human and primate populations. Many of these same points were made by Howell (1982) on a paleodemographic study of the Native American Libben Site, Ohio (Lovejoy et al. 1977). A review by Milner et al. (2000) evaluates the issues first raised by Bocquet-Appel and Masset (1982).

These discussions require critical appraisal of the published literature on the estimation of the age at death of the skeleton (for comprehensive reviews, see Katzenberg and Saunders 2000; White 2000; Hoppa and Vaupel 2002), and some skeletal biologists have advocated for the use of functional life history stages rather than age categories within the paleodemographic analysis of skeletal samples (Roksandic and Armstrong 2011). In many cases, these standards have been developed in the USA on the Hamann-Todd Osteological Collection (curated at the Cleveland Museum of Natural History, 1 Wade Oval Drive, Cleveland, Ohio 44106) and the Terry Collection (curated at the Department of Anthropology, Smithsonian Institution, Museum of Natural History, Washington DC 20013), both reference collections of known age- and sex-at-death individuals.

Early research that presented models of the lifespan of fossil hominins, summarized by Ascádi and Nemeskéri (1970), examined a variety of fossil hominin materials from Europe and Asia. Later, more elaborate discussions (Mann 1968, 1975; McKinley 1971) focused on the large fossil collection of *Australopithecus robustus* from the Swartkrans site in South Africa. On the basis of observed similarities in the pattern of dental development among the significant sample of immature individuals in the Swartkrans fossil collection to that established for modern humans, Mann argued that these early hominins matured in the prolonged period then thought to be unique to *Homo sapiens*. This conclusion was criticized by Sacher (1975, 1978), whose research on the correlation between brain size and longevity suggested that the life history trajectory of the small-brained robust australopithecines was more apelike than humanlike. Smith (1989) expanded on this work, arguing for a strong correlation between dental development and brain size. More recent data on primate biology has made some of Smith's conclusions untenable. For example, factoring in variations in diet, Godfrey et al. (2001) have shown that cranial capacity alone is an insufficient predictor of dental development within primate taxa. Although not frequently quoted in anthropological reviews of life history, Carey and Judge (2001), using a large longevity sample, have shown that brain size is only one of a number of central aspects of life history. Gage (1998) has also pointed out that in order to extrapolate to primate life history, more information is needed on patterns of variation, especially environmentally induced variation. Finally, in this context, Leigh (2004) has shown that in primates, brain growth is an extremely complicated phenomenon and that adult brain size alone is not well associated with dental maturation or with the length of the juvenile growth period (and see Braga and Heuze 2007).

Age profiles of more recent fossil hominin accumulations are not very different from those of living peoples, for example, the skeletal series of Natufians (the pre- or incipient agricultural groups of the Levant) analyzed by Karasik et al. (2000). In this study, using a traditional comparative series as the standard, the mean age at death was 31.5 years; in contrast, applying aging standards derived from local Sinai Bedouins produced a mean age at death of 36.5 years. Very few individuals were placed in the older adult category of 45–50 years of age. Unfortunately, the fossil record of earlier phases of human evolution, with fragmentary, incomplete bones of few individuals generally deriving from many generations, cannot be subjected to this sort of critical comparative study.

Probably the best studied fossil assemblages for which paleodemographic profiles have been developed are those from Krapina and Atapuerca (SH). Each site contains a large number of individuals: for Krapina, between 75 and 92 (Wolpoff 1999), and at Atapuerca, a minimum of 32 individuals (Bermudez de Castro and Nicolas 1997). As mentioned previously, both sites have been interpreted as possessing assemblages indicative of a catastrophic event. This idea for the accumulation of the sample at Krapina was supported by White (2000) and Trinkaus (1985) but criticized by Russell (1987a, b). At Atapuerca, Bermudez de Castro and Nicolas (1997) have argued against the possible catastrophic event proposed by Bocquet-Appel and Arsuaga (1999). Age estimations based on tooth development and emergence and occlusal wear, the elements usually examined in deriving age-at-death determinations in fossil hominins, resulted in a relatively low average age at death at both sites. Profiles from both Atapuerca and Krapina reveal an age-at-death distribution with high adolescent and young adult mortality and a death of older individuals. In an extensive examination of Neanderthal paleodemography, using 206 European and Middle Eastern Neanderthal remains and comparisons to 11 modern human populations including gathering and hunting peoples, agricultural peoples, and archaeological collections, Trinkaus (1995) concluded that Neanderthal populations were under extensive environmental stress that resulted in a unique population profile. The elements of this profile included high levels of infant mortality extending into young adulthood, with few or no individuals surviving into older age categories (+40 years). This latter feature of the Neanderthal mortality profile is unique among all the modern human populations used in his analysis, including archaeological samples. Trinkaus (1995) considers other explanations for this mortality pattern and attempts to minimize the effect of the Krapina and Vindija samples on the resultant profile. These two Croatian sites account for the bulk of adolescent specimens in the overall Neanderthal sample, emphasizing the possibility of alternative explanations for the unusual mortality profiles represented at these sites.

If the Middle Pleistocene Atapuerca (SH) site and the Late Pleistocene analyses by Trinkaus (1995) for Neanderthals are acceptable, using life tables from modern human populations it would not appear possible for these extinct hominins to replace their numbers in each subsequent generation. In another study, Trinkaus and Thompson (1987) concluded that there were no older individuals in Neanderthal populations. This leaves us in the perplexing situation of having to explain why, if these death assemblages are representative of living populations, these hominins did not become extinct after just a few generations. Clearly something is wrong with these analyses. In this context, Ogilvie et al. (1989) concluded that dental enamel hypoplasia indicates that Neanderthals sustained continuing stress from weaning to adulthood, resulting from an inadequacy of foraging technique. One major problem with this analysis is the “osteological paradox” (Wood et al. 1994) in which high frequencies of stress indicators on the skeleton are actually an indication of the adequacy of cultural and/or biological mechanisms in the individuals and populations at risk, in buffering the negative environmental effects.

For Middle and Upper Pleistocene hominin samples, such as those from Atapuerca (SH) and the European Neanderthals, it might be possible to use life history parameters that have been described for modern humans (but see Dean et al. 1986; Bermudez de Castro et al. 2001; Ramirez Rozzi and Bermudez de Castro 2004). For earlier hominins, the issue is very controversial. Caspari and Lee (2004) attempted to circumvent the problems associated with life history differences in human evolution by using dental attributes to grossly divide the hominin fossil record (including members of *Australopithecus*) into younger and older age categories, pointing out that this division will reasonably apply to all the taxa, regardless of possible differences in growth and development.

Determining the Sex of Skeletal Materials

There are also significant limitations in the identification of the sex of a skeleton. How applicable to extinct hominins are the anatomical criteria developed on modern human samples for determining the sex of individual specimens? In general, the sex determination of earlier hominins is based on the anatomy of the os coxae and on comparisons of the level of robusticity of the preserved postcranial bones in the sample. In the case of pelvic bones, unambiguous identification is often impossible, even when the bones are relatively complete and undistorted (Rosenberg 1988). Gracilization related to evolutionary change in fossil samples over time can confound the recognition of sex differences based on skeletal robusticity. For example, the locus H mandible from the Lower Cave, Zhoukoudian, has been identified as a female in comparison with other mandibular specimens. However, it is possible that this Locus was deposited later in time than the other fossil bearing loci, and the more gracile nature of this fossil may be indicative of a male from a later time (Mann 1981).

The clear implication of these problems is that the recognition of sexual dimorphism within an extinct hominin species can be very difficult. Plavcan and Cope (2001) have attempted to determine the validity of species in the fossil record using metric criteria and sample variation. Other researchers have also examined this problem (Lockwood et al. 1996, 2000; Rehg and Leigh 1999), and much of this literature has recently been reviewed by Scott and Lockwood (2004). More broadly, Plavcan (2001) has reviewed the pattern of sexual dimorphism in primates. These studies consider the evidence for the presence of a range of variation that can be reasonably accommodated within a valid species; within such metrically defined species, sex differences are established along the continuum. Ultimately, however, since sample sizes of earlier hominins are very small, both sexes are often collapsed into one. As a consequence of this, the determination of sex in hominin fossil paleodemography has attracted less attention than the establishment of criteria associated with aging.

However, the identification of the sex of fossil skeletal materials can yield significant data on population structure. This is because knowledge of female mortality is crucial to understanding patterns of fertility. Using comparative data from chimpanzees and modern humans groups, Lovejoy (1981) hypothesized a demographic transition at the origin of the hominin lineage, primarily based on decreasing birth intervals. Dall and Boyd (2004) have suggested that lactation in mammals probably evolved as a way to minimize the impact of fluctuations in food resources. Austin et al. (2013) assessed weaning patterns in a sample of modern human and macaque children as a comparative sample to a juvenile Neanderthal specimen. A demographic shift in age at weaning to the time frame of the early evolution of the genus *Homo* is proposed by Kennedy (2005). Thus, a decrease in time spent in lactation and its subsequent effect on birth interval may have been associated with a relatively more consistent food supply in human evolution. Birth interval, age at menarche, and age at first birth (first parity) are highly variable in both chimpanzees and humans (Eveleth and Tanner 1990). Sugiyama (2004b) summarized data on chimpanzees which showed that captive animals display reduced times in each of those categories associated with fertility; in contrast, fertility patterns among wild chimpanzees are quite varied.

Although sexing the skeleton is relatively easy in strongly dimorphic species, the process in modern human populations is much more difficult. Populations and species have varied degrees of dimorphism, and it can be expressed in different ways. White (2000), in a summary of the techniques used to sex the skeleton in recent archaeological populations, recommends seriating the specimens and then determining the most appropriate features within that population to use as sexing criteria. Both White (2000) and Meindl and Russell (1998) provide detailed reviews of the extensive literature on the identification of the sex of skeletal materials. A somewhat different review of the pre-1980 literature is provided in the summary of the Workshop of European Anthropological Association, published in the Journal of Human Evolution (1980).

In earlier, nonmodern hominins, the presence and extent of dimorphism is difficult to understand and quantify. Frayer and Wolpoff (1985) described various models for the identification and comprehension of sexual dimorphism in human evolution. More recent research has generated new models for understanding the context of dimorphism across the hominin lineage and among vertebrates in general. For example, if late secondary sex characteristics are primarily influenced by the production of testosterone, then an understanding of reduced dimorphism in hominins might be explained by a selection model directed toward a decrease in testosterone production or changes in its target cells. Thus, the immune suppression effect of testosterone production is reduced, influencing longevity, and the role of fathers in caregiving might have increased as male–male competition based on testosterone levels was reduced (Wingfield et al. 1997). This is a plausible explanation for reduction of sexual dimorphism and provides an explanation for the evolutionary role of monogamy in human evolution.

In general, however, the study of the regulation and evolution of sexually dimorphic characteristics from a physiological and genetic perspective is just beginning. It is reasonable to infer that some combination of hormonal and genetic factors plays an important role. For example, Skuse (1999) proposed a mechanism of genomic imprinting of the X chromosome as a possible mechanism, and Haqq and Donahoe (1998) reviewed the literature on individuals diagnosed with sexual ambiguity to construct a more holistic model of the factors contributing to the attribution of sex. Significant differences exist in the brains of human males and females, and sex differences are present in many biological systems (Maguire et al. 1999; Goldstein et al. 2001; Allen et al. 2003; Dubb et al. 2003; Raz et al. 2004;

Shah et al. 2004; Vawter et al. 2004). Bolnick and Doebeli (2003) proposed a possible role of sexual selection and sexual dimorphism under conditions of ecological destabilization. The multiple outcomes of this theoretical model seem to indicate that there is a conflict between speciation and dimorphism, i.e., sexual selection for increased dimorphism reduces the possibility of speciation. In this model, under conditions of changing ecological landscapes during the course of human evolution, some species undergo an adaptive speciation while others evolve alternatives to speciation, including an increase in sexual dimorphism. This may be a useful explanatory factor in the differing levels of sexual dimorphism observed in hominin taxa.

For the most part, although sexing is critical to almost all types of skeletal analysis, our ability to apply this to extinct members of the hominin lineage is difficult. Since the number of skeletons present in any analysis of the life history or paleodemography of fossil hominin samples is so small, it makes sense to pool both the male and female skeletons and consider them as a single sample.

Among the confounding difficulties which have led to the pooling of samples is the inability to distinguish dimorphic characteristics among the earliest hominins (including *Australopithecus*). Numerous arguments focused on the evolution of sex differences in the pelvis and in other features related to dimorphism (i.e., female vs. male stature). Assuming the obstetrical dilemma in human evolution, and without knowledge as to the exact time frame when this would have occurred in human biological history, research has pointed to possible evolutionary mechanisms responsible for these differences including sexual selection for more fecund female mates. Guegan et al. (2000) presented data on populations in 38 countries to show that stature dimorphism in females in modern populations could be correlated with complications associated with pregnancy and the birthing process. Nettle (2002) has shown that female height is correlated with reproductive success but that maximum success occurred in females who were below the mean for height. Integrating the data from both of these studies suggests that over time, female height may be more conservative than male height. Thus, differences in dimorphism in human evolution may be related in large measure to variations in males, with female biology remaining somewhat stable. Studies of living humans appear to show that females are less vulnerable to environmental influences on growth processes than males (Stini 1985).

Sexual selection has also been implicated in the evolution of body dimorphism. For example, Pawlowski and Grabarczyk (2003) have argued that the low center of gravity in females, manifest after puberty and adaptive for both pregnancy and the carrying of infants, is the result of sexual selection by males for this specific female body form.

The os coxa is the single most dimorphic feature of humans and, according to Tague and Lovejoy (1986), probably has been for at least the last few million years. The anatomy of the known sample of hominin pelvic bones appears to be related to the conflicting needs of both efficient bipedality and the problems associated with birthing relatively large-brained babies with broad shoulders. It appears that some of the dimorphism present in adult pelvises might actually be present in utero

(Holcomb and Konigsberg 1995). In addition, it is possible that geographic population affects the expression of sexual dimorphism in the pelvis (Patriquin et al. 2003). In modern populations, the accuracy of the assignation of sex using the pelvis is close to 95 % (Murail et al. 1999; Bruzek 2002). According to Leutenegger (1982), all primate females possess a greater ischiopubic index than males do.

Although biases exist in the determination of sex based on features of the skull, there appear to be differential differences between the preservation of female versus male skeletons (Walker et al. 1988). There is a tendency to identify older female skulls as male (see Henke 1974). This is no doubt a direct consequence that the skull becomes more “masculine” as it ages (Meindl et al. 1985); it is difficult, however, to know if this bias applies to fossil hominin studies. Susanne et al. (1985) present data on age changes in cephalic dimensions.

The distinctive features of the male and female os coxae are universal in living humans (and probably most extinct species as well), although there might be some variation in the degree of expression of the differences within these populations. The same, however, does not apply to other characteristics used in sexing the skeleton. Thus, in concert with the techniques applied to determining the age at death of a skeleton, sexing techniques must be population specific. This can be accomplished either through analysis based on the data accumulated on a reference sample of known sex (Steyn and Iscan 1997; Graw et al. 1999; Mall et al. 2000; Asala 2001; Schiwy-Bochat 2001; Pettenati-Soubayroux et al. 2002; Bidmos and Asala 2004) or through seriation of a group of unknown specimens (White 2000) and the application of a variety of statistical techniques to the data. Safont et al. (2000) have employed this method on a modern human sample. Since it can generally be assumed that an unknown sample contains both male and female skeletons, it is reasonable to sort the skeletal elements into male and female categories.

In fossil hominin studies, in contrast, because it is not possible to derive a set of metric or nonmetric characteristics associated with sex (or age for that matter) on an applicable reference sample, it is necessary to derive a set a parameters that best describes (statistically or with other methods) the variation in the sample being examined. Depending on its place in the hominin timescale, comparisons can be made to hominoids, especially chimpanzees, or to living human populations.

An example of this type of analysis was that of Reno et al. (2003) on a fossil sample from Afar Locality (A.L.) 333 and assigned to *A. afarensis* (see also the commentary by Larson 2003). Since the A.L. 333 locale is considered on geological grounds to be a simultaneous death assemblage, it was assumed that the fossil sample represented males and females of the same species. Simulations were undertaken to compare the Afar fossils to modern humans, chimpanzees, and gorillas. Using measurements of postcranial elements, *A. afarensis* was found to be closest to *H. sapiens* in degree of sexual dimorphism (with *H. sapiens* intermediate between the monomorphism of chimps and the extreme dimorphism of *Gorilla* in postcranial dimensions). These researchers also question the simple extrapolation of dimorphism to social categories in primates. They emphasized the striking dissimilarity in sexual dimorphism between canine tooth maturation in chimpanzees and their almost negligible postcranial dimorphism. They conclude that *A. afarensis* possessed a very distinct pattern from polygamous chimpanzees. In this analysis, monogamy is probably the most likely pattern of social organization among these early fossil hominins. Richmond and Jungers (1995) and Lockwood et al. (1996, 2000) have also investigated the pattern of sexual dimorphism in *A. afarensis*. Examinations of sexual dimorphism have been performed on *A. (P.) boisei* specimens (Silverman et al. 2001), face dimorphism in *A. africanus* (Lockwood 1999), sexual dimorphism in *Australopithecus* (*P.) robustus* and early *Homo* (Susman et al. 2001), and the mandibular metrics of a comparative sample of *H. sapiens*, *Pan troglodytes*, *Pongo pygmaeus pygmaeus*, and *Gorilla gorilla gorilla* (Humphrey et al. 1999).

One of the most extensive investigations of sex assignation in a specific sample was undertaken by Bermudez de Castro and Nicolas (1997) on the fossil materials from the Spanish site of Atapuerca (SH). A total sample of 32 individuals was examined, with a 1:1 sex ratio derived from the specimens that could be sexed. They report an overrepresentation of females in the age category between 16 and 20 years. This may be a reflection of a high female mortality in early child bearing years. Additional studies on this collection have been done by Rosas et al. (2002) and Bermudez de Castro et al. (2001), who examined the level of sexual dimorphism in the sample as revealed in mandibular and dental measurements, respectively. Bermudez de Castro et al. (2001) concluded that the dentition showed greater sexual dimorphism than that found in modern humans. In the mandible, sexual dimorphic patterns were present but differed from those in modern humans. Arsuaga et al. (1997) looked at body size and cranial capacity dimorphism, reporting a degree of dimorphism similar to other Middle Pleistocene hominins and modern humans.

Wolpoff (1999) noted that sexual dimorphic characteristics, including overall cranial size and capacity, vault thickness, superstructures and toruses (mastoid process, sagittal keel, nuchal torus), forehead curvature, and functionally related features of facial size and robustness, vary in expression in recent human geographic populations and are a reflection of the hominin evolutionary past in each region. On the basis of these observations, Wolpoff (1999) identified male and female sex differences in an extensive sample of Middle and Upper Pleistocene hominins. Weidenreich's (1935, 1943) detailed studies of the morphology of the *H. erectus* sample from Zhoukoudian suggested a relatively low level of sexual dimorphism, a conclusion that was also found by Mann (1981), who studied the virtually complete Zhoukoudian cast collection.

Other studies of the application of techniques of sexing to fossil hominin materials include the work of Coqueugniot et al. (2000) as well as the application of mandibular ramus posterior flexure to a sample of Neanderthals and early modern humans (Loth and Henneberg 1996), dimorphism in chin morphology in the specimens from Klasies River Mouth (Lam et al. 1996), and an analysis of the Kebara 2 pelvis using various bony dimensions (Tague 1992). Finally, Trinkaus (1980) employed indices of robusticity of postcranial elements to show that European and Near Eastern Neanderthal limb bones show the same degree of sexual dimorphism as modern humans in this feature. In a recent article by Lordkipanidze et al. (2013), the sample of 5 crania from the 1.8-million-year-old site of Dmanisi was divided into male and female based on robusticity of cranial elements.

Other Paleodemographic Parameters

Life History

Life history variables (chapters "▶ Primate Life Histories," Vol. 2 and "▶ Estimation of Basic Life History Data of Fossil Hominoids," Vol. 1), including brain and body size, neonatal weight, length of gestation, lifespan, age of sexual maturation, and age of weaning, are all correlated to each other; various theories have been proposed to explain the evolutionary mechanisms through which this occurs. Using data on living primates, Harvey and Clutton-Brock (1985) noted that the distinctive features of this mammalian order are large brains, prolonged maturation, and long lifespans. Understanding the relationships of these variables to each other from an evolutionary perspective has been the subject of numerous projects and debates (Borries et al. 2013). Pereira (1993) has summarized this work, including a discussion of allometric or correlation analysis. Heterochrony has also been used to explain life history developmental processes that may have characterized human evolution (Gould 1977; Minugh-Purvis and McNamara 2002). The usefulness of heterochrony has been critically evaluated by Godfrey and Sutherland (1996) and Shea (1989).

Gage (1998) compiled all known mortality and fertility data on a broad group of primates. He concluded that a comparison of human and chimpanzees life histories indicates that delayed maturation is a characteristic of humans, whereas an extension of the overall time frame of reproduction, along with an increase in the calculated rate of aging, appears characteristic of chimpanzees. Chimpanzee character state of life history is evolutionarily derived and thus does not make a useful model for understanding the last common ancestor of chimpanzees and humans (see discussions in Duda and Zrzavy 2013). Although this observation must be kept in mind, chimpanzees are our closest living relative; the use of the growing body of literature on chimpanzee studies, especially in the wild, can reasonably provide a point of comparison not only to living humans but also to extinct members of the human lineage. The human life history pattern as described by Smith and Tompkins (1995, p. 260) is that "humans take about twice as long to erupt teeth, twice as long to reach adulthood, and live about twice as long as great apes." This probably represents an overstatement of the unique position of humans within the Primate Order. For example, the work of Zihlman et al. (2004) shows that wild chimpanzees take upward of 3 years longer to mature than animals in captivity. Using M1 eruption times as a proxy for other maturational events, chimpanzees now appear to overlap the range of modern humans. Recent work on sexual maturation of chimpanzees in the wild shows that some groups do not mature until 14 years of age (Sugiyama 2004b).

A comprehensive description of life history in mammals was analyzed using an energetics model by Hill and Kaplan (1999), and an evolutionary model of longevity increases was presented by Carey and Judge (2001). Using game theory, Brommer (2000) also discussed the evolution of life history using the evolutionary concept of fitness. Using seven anthropoid primate species, Leigh (2004) has shown that life history among the primates cannot be related solely to brain size but more specifically to the point in life history in which brain growth occurs. The correlation of diet to primate life history has been addressed by Godfrey et al. (2001) and Kaplan et al. (2000). Day et al. (2002) associated life history variables across various species of animals with the level of predator pressure. Bolnick and Doebeli (2003) have also proposed that species confronted with ecological instability adapt in a number of ways, including changes in sexual dimorphism, speciation, or an alteration of ontogenetic processes that reduces the influence of the destabilizing ecological events. It is possible that some and all combinations of these outcomes have occurred in human evolution. Of critical importance is the plausible role of ontogenetic changes as an adaptive feature in at least some species in human evolution. If, for example, *A. afarensis* does indeed show little sexual dimorphism and, by extrapolation from primate models, this indicates a pattern of monogamy among these hominins, then it is indeed possible that altricial young were also part of this pattern, further supporting Lovejoy's (1981) hypothesis.

Since life history theory is built on the foundation of living animals, it becomes a challenge to integrate fossil hominin species into these analyses. It has been argued that correlations of brain and body size to life history variables supersede any possible analysis of the fossil materials and that all data must be interpreted in this context. Certainly, evolutionary events have produced unique combinations of life history features in the past; and if it is possible to integrate these into the correlation studies, it might serve to more fully represent the life history of hominins across time and space. There appears to be no consensus as to when in the course of hominin evolution modern humanlike life histories evolved. Various perspectives on the evolution of life history have been presented (Smith and Tompkins 1995; Tillier 1995; Bogin 1999; Minugh-Purvis and McNamara 2002; Thompson et al. 2003). More recently Robson and Wood (2008) presented a synthesis of life history data from the fossil record of human evolution and concluded that in the time frame of *Homo heidelbergensis* (viewed by some as archaic *Homo sapiens*), the basic life history parameters similar to modern humans were attained.

In order to reconstruct the life history patterns of earlier hominins, most research has concentrated on the examination of those biological patterns that may yield data documenting rates of maturation. Overwhelmingly, this has meant focusing on the developing dentition with the assumption that the maturation of dental hard tissues and the sequential eruption of the teeth are under strong genetic control, with a minimum of possible environmental influence. Unlike bone, which is subject to remodeling throughout life, dental enamel appears to be relatively stable, preserving the initial structures. Most research on the maturation patterns of earlier hominins focuses either on the pattern and sequential eruption of the developing dentition or on the examination of dental microstructures as time-dependent features. Comparisons between fossil hominins are most usually made to the living great apes, especially chimpanzees, and to modern humans.

Patterns of Maturation

Chimpanzees and humans are characterized by different life history strategies; this should be apparent in the dental calcification and eruption schedules of the two species. What if any pattern differences have been described? The most prominent is that chimpanzees have an accelerated development and eruption of the M1 especially in relationship to the development of I1 (Smith 1994, 2000; critique by Mann et al. 1990). It has also been observed that chimpanzees have a time overlap in the calcification schedule of the molar sequence (Anemone 2002). And finally, chimpanzees have a significant difference in the pattern of calcification and eruption of the permanent canines. Since this tooth is so functionally and anatomically distinct from that of humans, the canine is probably not a good indicator of life history pattern differences (Lampl et al. 1993).

Various models have been used to explain these differences. These include differences in life history (see, e.g., Smith 2000 and the critique by Lampl et al. 2000), but other explanations have been proposed (Simpson et al. 1990; Simpson and Kunos 1998).

Many scholars have undertaken general discussions of how dental development of fossil hominin samples can be understood as part of life history (Bogin 1999; Smith and Tompkins 1995; Bogin and Smith 1996; Kuykendall 2003). Discussions of life history in the early phases of human evolution have been extensively discussed (Dean 1985; Smith 1994; Conroy and Vannier 1989; Mann et al. 1987; Conroy 1988; Mann 1988; Wolpoff et al. 1988; Conroy and Kuykendall 1995; Smith and Tompkins 1995; Clegg and Aiello 1999; Dean et al. 2001; Moggi-Cecchi 2001). Many investigations have also focused on the later phases of human evolution (summarized in Robson and Wood 2008).

Dental Microstructure

Some researchers have maintained that dental enamel and dentin microstructures are useful tools for the reconstruction of the timing of dental development. Dental microstructure is a hard tissue relic of the ontogenetic processes that govern tooth growth (Ramirez Rozzi and Bermudez de Castro 2004; Guatelli-Steinberg et al. 2005). Conversely, it is also possible that these structures reflect a microworld of minianatomical detail that may or may not be useful in the timing of dental development or the reconstruction of phylogenetic relationships.

Bromage and Dean (1985) presented data to support the idea that the timing of tooth development in fossil hominins could be estimated using microstructural details of enamel. Since then there has been much debate about the applicability of these hard tissues to understanding of the times of maturational events in earlier hominins (Dean and Reid 2001; Moggi-Cecchi 2001; Ramirez Rozzi and Bermudez de Castro 2004; Guatelli-Steinberg et al. 2005; Monge et al. 2006; Smith et al. 2010).

Finally, growth and development studies have been undertaken on the femur (Tardieu 1998) and pelvis (Berge 1995) of fossil hominins. In both these studies, although a humanlike pattern of growth best describes all members of the genus *Homo*, australopithecine-grade hominins probably had growth trajectories similar to those in chimpanzees.

What can be concluded from this diverse body of research? Even where a virtually complete skeleton of a youngster (KNM-WT 15000) has been recovered, it has been difficult to reach a consensus about its rate of maturation and its age at death (Clegg and Aiello 1999). The diversity of research on the patterns of maturation in earlier hominins is well illustrated in the edited volume, Patterns of Growth and Development in the Genus *Homo* (Thompson et al. 2003). Thus, it remains very difficult to compare the work presented by one researcher with that of another because the fossil samples and the techniques of analysis that are employed are often so different.

However, and with some reservations, the research results appear to support the general recognition that, by the appearance of members of the genus *Homo*, there was a maturational shift to a more modern humanlike pattern, although that pattern might be manifested in slightly different ways in individual species within *Homo*. If this cautious conclusion continues to be supported by additional data, it will justify the use of the growth and development patterns of modern humans as reference data and for use in modeling population parameters within paleodemographic reconstructions. What sorts of patterns characterized the maturation of the still earlier members of the hominin lineage remains uncertain. However, recent information documenting significant variation in maturational events in both modern humans and chimpanzees suggests that the traditional notion of a uniquely human prolonged period of maturation may have to be reconsidered.

Conclusions

1. The paleodemography of extinct hominin taxa has not produced a corpus of dependable data, and it remains possible that reasonable population-based demographic parameters from fossil assemblages will remain unattainable into the foreseeable future. The use of modeling from archaeological samples holds more promise in an application to the more distant past to capture demographic parameters in long extinct populations in the hominin lineage (Konigsberg and Frankenberg 2013).
2. In contrast, life history reconstruction, establishing some basic parameters associated with demographic analysis, is a more achievable goal. Among these parameters are potential life expectancy, time of maturation, and age at weaning. The accumulation of additional information on living primates has made the simple association of life history variables with gross size variables (e.g., brain size and body size) increasingly untenable.
3. The larger the database on captive and wild chimpanzees, the more difficult it becomes to clearly distinguish their life history variables from those of living

humans. This will certainly affect our interpretations of life history and extrapolations to demographic features that characterize fossil hominin species. Similarly, the more knowledge we have of the extent of modern human variation and plasticity, the more difficult it becomes to specifically categorize unique autapomorphic features of human life history.

4. Culture (in conjunction with significant developmental plasticity) may be more important as regard understanding human life history than biology, especially in variations in the expression of features such as longevity and age at weaning, and perhaps even maturation rates, general reduction in the age of first menstruation, and others. Such factors may better explain the large ranges of variation that have been observed in both humans and chimpanzees.

In sum, we know very little of the demography including all aspects of population parameters of earlier members of the hominin lineage, and much that appears to be understood requires reevaluation on the basis of newly acquired data from nonhuman primates and the increasing comprehension of the range of variation characterizing human growth and maturation.

Hominin Paleodiets: The Contribution of Stable Isotopes

Matt Sponheimer and Julia Lee-Thorp

Contents

Abstract

Stable isotope ratio analysis is now regularly used to investigate early hominin diets based upon the principle that 'you are what you eat'. Analysis of collagen from Neanderthals and anatomically modern humans prior to 20 Ka has shown them to be significantly enriched in ^{15}N compared to contemporaneous carnivores and herbivores. This suggests that much of their dietary protein, although not necessarily their dietary energy, came from animal foods. Carbon isotope

analysis of the enamel mineral of southern African australopiths and early *Homo* has revealed that these taxa consumed $\sim$30 % C$_4$ foods such as tropical grasses, sedges, or animals that ate these foods. Moreover, the australopiths are characterized by remarkably variable δ^{13}C values. Chimpanzees, in contrast, are nearly pure C$_3$ consumers even in environments with abundant C$_4$ vegetation. These data suggest that when confronted with increasingly open areas, chimpanzees continue to exploit the foods that are most abundant in forest environments, whereas southern African australopiths utilized novel C$_4$ resources in addition to forest foods. However, new data from eastern and central Africa show that not all australopiths follow this pattern. The earliest australopiths had nearly pure C$_3$ diets, but by about 2 Ma others ate predominantly C$_4$ vegetation. It also appears that increased masticatory robusticity in the australopiths is associated with greater C$_4$ consumption.

Introduction

The nature of early hominin diets has been the subject of lively debate and not without good reason (e.g., Dart 1957; Robinson 1954; Jolly 1970; Brain 1981; Binford 1981; Grine and Kay 1988; Sillen 1992; Stiner 1994; Lee-Thorp et al. 1994; Sponheimer and Lee-Thorp 1999; Richards et al. 2000; Speth and Tchernov 2001). Most large primates spend at least 50 % of their waking hours searching for or consuming food (e.g., Altmann and Altman 1970; Teleki 1981; Goodall 1986; see chapters "▶ Evolutionary Biology of Ape and Monkey Feeding and Nutrition," "▶ Great Ape Social Systems," and "▶ The Biotic Environments of the Late Miocene Hominoids Vol. 2). Thus, if we seek to know what "a day in the life" of our ancestors was like, understanding what they ate would represent an enormous step in that direction (see chapter "▶ Dental Adaptations of African Apes," Vol. 2). Furthermore, diet is considered among the most important factors underlying behavioral and ecological differences among extant primates (Ungar 1998; Fleagle 1999), and thus the story of our ancestors' evolving diets is likely to be intertwined with that of how our species, *Homo sapiens*, came to be. We can glean paleodietary information from many sources (see chapter "▶ Role of Environmental Stimuli in Hominid Origins," Vol. 3). Archaeological evidence in the form of stone tools and butchered animal bones is one source of dietary information, which tells us about the kinds of animals that hominins utilized as well as their procurement strategies (e.g., Binford 1981; Brain 1981; Blumenschine 1987; Stiner 1994; Speth and Tchernov 2001). Yet, such evidence tends to overemphasize the importance of animal foods at the expense of plant foods that make up the bulk of most primate diets (e.g., Lee 1979; Eaton and Konner 1985; Milton 2002). Moreover, the first potential hominins (Senut et al. 2001; Brunet et al. 2002; Haile-Selassie et al. 2004) precede the earliest archaeological traces by millions of years (Semaw et al. 1997; de Heinzelin et al. 1999), and thus the archaeological record remains silent with regard to the diets of the earliest hominins (see chapters "▶ Modeling the Past: Archaeology," Vol. 1 and "▶ Overview of Paleolithic Archaeology," Vol. 3).

As a result, paleoanthropologists have had to look for other sources of paleodietary information. Dental allometry/morphology and microwear have received much attention and provided important insights into the diets of our ancestors (see chapters "▶ Hominoid Cranial Diversity and Adaptation" and "▶ Dental Adaptations of African Apes," Vol. 2; Robinson 1954; Grine 1981, 1986; Grine and Kay 1988; Ungar and Grine 1991; Teaford et al. 2002; Ungar 2004). Still, these techniques have limitations. For instance, the relatively large incisors and bunodont molars of modern *Papio* suggest a frugivorous diet (Hylander 1975; Fleagle 1999; Ungar 1998), and yet many *Papio* populations consume large quantities of grasses, for which they have no apparent dental specializations (Altmann and Altman 1970; Harding 1976; Dunbar 1983; Strum 1987). Ungar (2004) has also argued that the dental morphology of extant apes and early hominins may tell us more about their fallback foods than it does about their "typical" diets. Dental microwear, in turn, reveals a great deal about the mechanical properties of a primate's food. Primates that eat hard, brittle foods, such as gray-cheeked mangabeys (*Lophocebus albigena*), have relatively more microscopic pitting on their molars than do those that eat more pliant, tough foods like mountain gorillas (*Gorilla gorilla beringei*) (Grine and Kay 1988; Ungar 1998). However, microwear is quickly obliterated and therefore provides dietary information for a few brief days, which may or may not be representative of an individual's "average" diet. In addition, soft foods, such as animal flesh, may not always produce recognizable microwear signatures. Thus, even with these important techniques in our paleodietary arsenal, a great deal about the diets of early hominins remains unknown.

Consequently, new paleodietary techniques have emerged in recent years, one of the most important of which is stable isotope analysis. The idea behind this technique is that "you are what you eat." In other words, the isotopic composition of one's food is ultimately traceable in one's tissues. Thus, stable isotope analysis provides a direct chemical means of investigating the diets of modern and fossil primates. In this paper, we address the contribution of stable isotope analysis to our understanding of early hominin diets. The paper is divided roughly into two sections: stable isotope analysis of bone and dentine collagen, which has been used to investigate the diets of our close cousins the Neanderthals and early modern humans (Bocherens et al. 1991, 1999, 2001, 2005; Fizet et al. 1995; Richards et al. 2000, 2001; Pettitt et al. 2003; Schulting et al. 2005), and stable isotope analysis of enamel apatite, which has shed much light on the diets of the South African australopiths and early *Homo* (see chapters "▶ Analyzing Hominin Phylogeny: Cladistic Approach," "▶ The Species and Diversity of Australopiths," and "▶ The Earliest Putative *Homo* Fossils," Vol. 3; Lee-Thorp et al. 1994, 2000; Sponheimer and Lee-Thorp 1999, 2003; van der Merwe et al. 2003; Sponheimer et al. 2005a). We proceed in this reverse chronological order in an effort to trace the general development of paleodietary stable isotope studies: collagen was first utilized in 1977 with enamel apatite studies appearing a decade later. In addition,

the temporally and geographically restricted discussion herein (i.e., the emphasis on European Neanderthals and South African australopiths) is more a reflection of the limited degree to which stable isotopes have been used to investigate the diets of Plio-Pleistocene hominins, than selective presentation on our part. The only data we have excluded for the purpose of this paper are for specimens younger than 20 Ka. The stable isotope data for all older hominins, which we are aware of at least, are discussed herein and can be found in Tables 1 and 2.

Collagen

The first paleodietary study using stable isotopes sought to document maize consumption among Native American populations in New York State (Vogel and van der Merwe 1977). This application was made possible by differences in the photosynthetic pathways of plants. Tropical grasses, such as maize, use C_4

photosynthesis, while virtually all other potential plant foods in New York State use C_3 photosynthesis. The C_3 photosynthetic pathway discriminates markedly against ^{13}C, and as a consequence, C_3 plants have very depleted $^{13}C/^{12}C$ ratios. In contrast, plants that utilize the C_4 photosynthetic pathway discriminate less against ^{13}C and

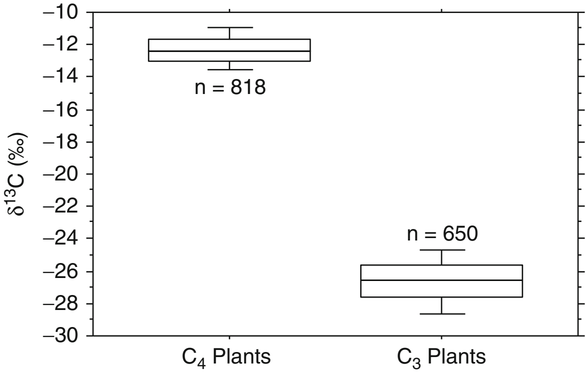

Fig. 1 $^{13}C/^{12}C$ ratios of plants using C_3 (trees, bushes, shrubs, and forbs) and C_4 photosynthesis (grasses and some sedges) in Kruger National Park, South Africa. The boxes represent the 25th–75th percentiles (with the medians as *horizontal lines*), and the whiskers show the 10th–90th percentiles. The carbon isotope compositions of plants using these different photosynthetic pathways are highly distinct. Maize is a tropical grass that uses C_4 photosynthesis, and thus it has a very different carbon isotope composition than other foods that were consumed by Native Americans in New York State (Vogel and van der Merwe 1977)

are consequently relatively enriched in ^{13}C (Smith and Epstein 1971; Fig. 1). These distinct isotopic signatures are passed down into the tissues of individuals that eat these plants. Thus, individuals who eat large quantities of C_4 plants like maize will be relatively enriched in ^{13}C compared to those who eat only C_3 vegetation (see chapters "▶ Role of Environmental Stimuli in Hominid Origins," "▶ Origins of Homininae and Putative Selection Pressures Acting on the Early Hominins," "▶ Analyzing Hominin Phylogeny: Cladistic Approach," and "▶ The Species and Diversity of Australopiths," Vol. 3). Vogel and van der Merwe (1977) analyzed the bone collagen of individuals ranging in age from ~4,000 B.P. to ~500 B.P. They saw little evidence of maize consumption among the oldest individuals but found that maize had become a very important dietary resource by about 1,000 B.P. – sometimes representing up to 50 % of an individual's diet. This study paved the way for a plethora of innovative applications in the following decades which relied on stable isotope abundances in bone collagen (see chapter "▶ Taphonomic and Diagenetic Processes," Vol. 1); however, since collagen is rarely preserved for more than 10,000 years, these investigations were largely confined to the recent past. Yet, it has been shown that, under the right conditions, bone collagen can survive for 200,000 years or more (Jones et al. 2001). Thus, it has proven possible to analyze the bone collagen of late Pleistocene hominins in certain cases.

Collagen: Methodological Considerations

Before proceeding to the hominin data, we will briefly discuss a few relevant methodological considerations. Much has changed since the early days of stable isotope analysis. Today, only small samples are required for analysis, and automation has led to significantly increased sample throughput in labs around the world. Nevertheless, the basic procedures have remained largely the same, even though the protocols vary somewhat from lab to lab. Here, we briefly summarize the operational protocols of the labs that have analyzed the collagen of early hominins. One must keep in mind, however, that this is meant to be a general summary, not an exhaustive step by step explication of analytical procedures.

After surface cleaning, bone or dentine samples are demineralized in diluted HCl (0.5–1.0 M) for periods ranging from 20 min to 5 days. Performing this step at low temperature (5 °C) is one recent innovation that allows collagen to be extracted from very old, fragile samples (Richards and Hedges 1999; Jones et al. 2001). The insoluble residue may then be soaked in 0.125 N NaOH to remove contaminating humic acids; but as this leads to collagen solubilization and decreased extraction yields, it is no longer favored. Fortunately, neglecting this step appears to have little effect on the resulting stable isotope ratios (Bocherens et al. 1999). The residue is then often gelatinized in weak HCl at 75–100 °, filtered, and freeze-dried. A small (~1 mg) sample of this purified collagen is then combusted in an elemental analyzer, and the resultant CO_2 and N_2 gases are analyzed for $^{13}C/^{12}C$ and $^{15}N/^{14}N$ abundances in a stable isotope ratio mass spectrometer. Stable light isotope ratios are expressed as δ values in parts per thousand (‰) relative to international standards, which are PDB (a marine carbonate) and atmospheric N_2 for carbon and nitrogen, respectively. Standard deviations of replicate measurements are generally about ±0.1 ‰ for carbon and ±0.2 ‰ for nitrogen. Importantly, collagen degradation is known to alter stable isotope ratios significantly. To produce reliable results, collagen must generally have a carbon/nitrogen ratio between 2.9 and 3.6, with carbon and nitrogen percentages of at least 15 % and 5 %, respectively (Ambrose 1990).

Our understanding of the relationship between dietary $\delta^{13}C$ and collagen $\delta^{13}C$ has improved significantly since the first use of stable isotopes for paleodietary reconstruction. Experimental studies of rodents on controlled diets have shown that collagen $\delta^{13}C$ is enriched by about +5 ‰ relative to dietary protein (Ambrose and Norr 1993; Tieszen and Fagre 1993), as dietary amino acids are preferentially utilized for tissue synthesis. In contrast, carbon from dietary carbohydrate and lipid makes much less of a contribution to bone collagen (or indeed hair, muscle, etc.). Consequently, bone collagen $\delta^{13}C$ (and $\delta^{15}N$) tells you more about the protein component of an individual's diet than it does about their "whole" or "bulk" diet. This is significant, as animal foods, which are high in protein, will be overrepresented in bone collagen at the expense of low-protein vegetable foods. This bias must be borne in mind when interpreting collagen stable isotope data.

The Neanderthals

Bocherens et al. (1991) performed the first stable isotope analysis of a Neanderthal and associated fauna from the site of Marillac in France. This study demonstrated that enough collagen could be extracted from bones more than 40,000 years old and paved the way for subsequent analyses of Neanderthals from Marillac and Saint-Césaire (Fizet et al. 1995; Bocherens et al. 2005); Scladina Cave, Awirs Cave, and Betche-al-Roche Cave in Belgium (Bocherens et al. 1999, 2001), and Vindija Cave in Croatia (Richards et al. 2000). Virtually all native European plants use the C_3 photosynthetic pathway. As a result, these plants have similar carbon isotope compositions, although those in densely wooded environments are somewhat depleted in ^{13}C due to the canopy effect (Vogel 1978; van der Merwe 1989). Thus, not surprisingly, carbon isotopes revealed little about the diets of Neanderthals, save for the possibility that they utilized few food resources from closed environments (Bocherens et al. 1999; Richards et al. 2000).

The nitrogen isotopes in Neanderthal bone collagen, however, proved more revealing. Nitrogen isotopes ratios ($^{15}N/^{14}N$) are known to increase by about 3 ‰ up every step in the food chain (e.g., Minagawa and Wada 1984; Schoeninger and DeNiro 1984; Ambrose and DeNiro 1986). Thus, within a hypothetical food web, if plants have $\delta^{15}N$ values of 0 ‰, herbivores like reindeers have $\delta^{15}N$ values of about 3 ‰, while carnivores such as wolves have $\delta^{15}N$ values of about 6 ‰. And although nitrogen isotope distributions in food webs are more complicated than this hypothetical example suggests – due to heterogeneity in plant $\delta^{15}N$ and the disparate physiological adaptations and requirements of mammals (Ambrose and DeNiro 1986; Sealy et al. 1987; Sponheimer et al. 2003a) – the general pattern has been shown to be robust in both terrestrial and marine ecosystems. Thus, analysis of nitrogen isotopes in bone collagen can potentially reveal the trophic level at which a hominin was feeding. This is relevant for investigating Neanderthal diets, as their degree of carnivory and manner of carcass acquisition (hunting or scavenging) have been the subject of considerable debate (e.g., Binford 1981; Mellars 1989; Stiner 1994; Speth and Tchernov 2001; see chapter "▶ Neanderthals and Their Contemporaries," Vol. 3).

Intriguingly, all published studies have shown that Neanderthals have very high $\delta^{15}N$, well above that of contemporaneous herbivores such as horses (*Equus caballus*), reindeer (*Rangifer tarandus*), and bison (*Bison priscus*) and similar to that of carnivorous wolves (*Canis lupus*), hyenas (*Crocuta spelaea*), and lions (*Panthera spelaea*) (Bocherens et al. 1991, 1997, 2001, 2005; Fizet et al. 1995; Richards et al. 2000). Indeed, analysis of variance and Fisher's PLSD test of the combined datasets show that Neanderthal $\delta^{15}N$ ($x = 10.9$ ‰, s.d. = 1.1, $n = 12$) is not only significantly higher than herbivore $\delta^{15}N$ ($x = 5.8$ ‰, s.d. = 1.6, $n = 132$) ($P < 0.001$) but also slightly higher than carnivore $\delta^{15}N$ ($x = 9.7$ ‰, s.d. = 1.1, $n = 26$) ($P = 0.02$) (Fig. 2). We should note that the combined dataset contains specimens that accumulated over ~70,000 years and in locations throughout Europe and that such temporal and spatial mixing increases intrataxonomic variability making statistically significant differences between taxa less likely. For instance, Stevens and Hedges (2004) found that European horse (*Equus* spp.) $\delta^{15}N$ fluctuated by at least 4 ‰ over the last 40,000 years due to glacially mediated changes in the nitrogen cycle. Hence, it is particularly striking that significant differences are found between Neanderthals, herbivores, and carnivores without controlling for temporal and spatial variation. In general, the $\delta^{15}N$ data appear to

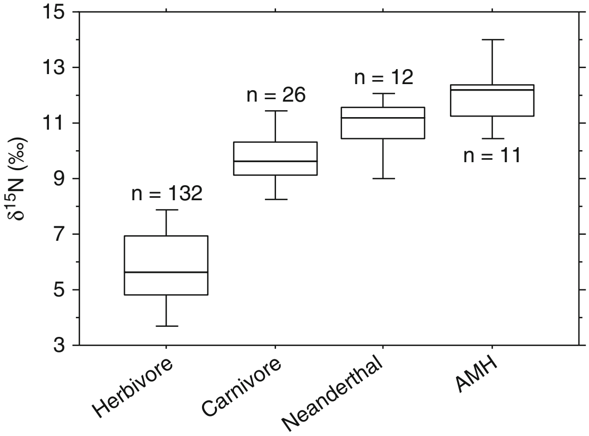

Fig. 2 $\delta^{15}N$ of Neanderthals, mid-Upper Paleolithic humans, herbivores, and carnivores. The boxes represent the 25th–75th percentiles (with the medians as *horizontal lines*) and the whiskers show the 10th–90th percentiles

suggest that Neanderthals received much of their dietary protein from animal foods (Richards et al. 2000). Enrichment in ^{15}N compared to (other) carnivores *may* suggest a dependence on herbivores with relatively high $\delta^{15}N$ such as mammoths (*Mammuthus primigenius*) or even the consumption of omnivorous bears (*Ursus* spp.) (Richards et al. 2000; Bocherens et al. 2001, 2005). While the interpretation of these data remains difficult, it is clear that Neanderthal diets were distinct from those of contemporary herbivorous fauna.

This leads inexorably to the question, "Were Neanderthal diets distinct from those of their hominin contemporaries?" (see chapter "▶ Neanderthals and Their Contemporaries," Vol. 3). While it has not yet been possible to compare the stable isotope compositions of Neanderthals and contemporaneous anatomically modern humans (AMH), Richards et al. (2001) were able to analyze nine near contemporaries from the mid-Upper Paleolithic (~28–20 Ka) at Brno-Francouzská and Dolní Věstonice (Czech Republic); Kostenki, Mal'ta, and Sunghir (Russia); and Paviland (Great Britain). They compared these anatomically modern humans to the five Neanderthals that had been published at the time and argued that the modern humans were even more elevated in $\delta^{15}N$ ($x = 12.0$ ‰, s.d. $= 1.6$, $n = 9$). This suggested that anatomically modern humans were also highly dependent on animal foods. Richards et al. (2001) argued, however, that even the consumption of high $\delta^{15}N$ herbivores like mammoth would not be sufficient to account for the extremely elevated $\delta^{15}N$ of these AMH. Instead, they suggested that these humans had begun to diversify their resource base to include freshwater aquatic resources such as fish and waterfowl, which can be more enriched in ^{15}N than terrestrial resources (Dufour et al. 1999; Katzenberg and Weber 1999). This suggestion was rather surprising, as there is little direct archaeological evidence for exploitation of such foods at this time, although such evidence becomes abundant by the late Upper Paleolithic. Yet, with the subsequent publication of seven new Neanderthal specimens (Bocherens et al. 2001, 2005) and two more mid-Upper Paleolithic humans (Pettitt et al. 2003; Schulting et al. 2005), there is no longer any statistically significant difference in the $\delta^{15}N$ of AMH

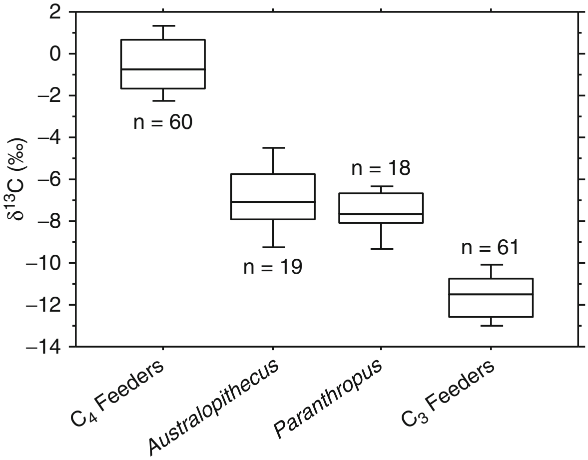

Fig. 3 $\delta^{13}C$ for australopiths, C_3 plant consumers (browsing/frugivorous bovids and giraffids) and C_4 plant consumers (grazing bovids and equids). The boxes represent the 25th–75th percentiles (with the medians as *horizontal lines*) and the whiskers show the 10th–90th percentiles. Given the size of this dataset, there can be no doubt that australopith $\delta^{13}C$ is highly distinct from that of associated browser/frugivores (This figure was produced using data available in 2006. The fully updated dataset is available in Sponheimer et al. (2013))

($x = 11.8$ ‰, s.d $= 1.6$, $n = 11$) and Neanderthals ($P = 0.06$ t-test; $P = 0.09$ Mann-Whitney U) (Fig. 3; Table 1). There is, however, a small but significant difference in the $\delta^{13}C$ of AMH ($x = -18.7$ ‰, s.d. $= 0.5$, $n = 11$) and Neanderthals ($x = -20.0$ ‰, s.d. $= 0.8$, $n = 12$) ($P < 0.01$ t-test and Mann-Whitney U), although the meaning of this difference is unclear. A greater reliance on open area resources such as ^{13}C-enriched reindeer by AMH is one of many possible explanations. More salient from the perspective of dietary breadth, Levene's test reveals no significant differences in the isotopic variability of Neanderthals and AMH ($\delta^{13}C$, $P = 0.23$; $\delta^{15}N$, $P = 0.61$), and thus there is little isotopic support for utilization of novel resources or greater resource breadth in AMH prior to 20 Ka.

These stable isotope studies are an important complement to traditional archaeological paleodietary studies, as they represent a direct measure of the foods that an individual ate that is independent of the taphonomic biases that bedevil faunal analyses (Lyman 1994). Nevertheless, interpretation of these stable isotope data is not straightforward, and there remain a number of important unanswered questions. For instance, why are both hominins enriched by more than 5 ‰ compared to associated herbivores when an enrichment of about 3 ‰ would be expected for a carnivore? Stated otherwise, why is their $\delta^{15}N$ significantly higher than that of associated carnivores? As discussed earlier, this may be partially, but not satisfactorily, explained by the consumption of herbivores with unusually high $\delta^{15}N$ such as mammoths or even by the consumption of omnivores and/or aquatic resources. Another possibility, however, is that there is some physiological explanation for their extremely high $\delta^{15}N$. Experimental studies have shown that when herbivores are fed diets with crude protein contents that are much greater than their nutritional requirements, their diet-tissue spacing can become much greater than 3 ‰ (Sponheimer et al. 2003a). This implies that if the prevailing environment forced Neanderthals to consume high-protein diets that considerably exceeded their crude protein requirements, their diet-tissue spacing might have exceeded 3 ‰, thus artificially increasing their $\delta^{15}N$ compared to other taxa. On the other hand, committed carnivores generally have smaller diet-tissue spacing than herbivores (Robbins et al. 2005). Regardless, the anomalously high $\delta^{15}N$ of mammoths and low $\delta^{15}N$ of cave bears (Bocherens et al. 1997; Ambrose 1998) may also hint at the importance of physiological adaptations in determining an organism's nitrogen isotope composition.

It is worth noting that while such interpretive difficulties exist, they do not diminish the significance of these studies. Even if the Neanderthals did have artificially increased diet-tissue spacing due to a high-protein intake, it might erase their distinctiveness from other carnivores, but would certainly not make them look herbivorous.

Enamel Apatite

Older hominin material is not amenable to this form of analysis as bone collagen is rarely preserved from beyond the late Pleistocene (Jones et al. 2001). However, the carbon isotopes in the bone's mineral component (a biological apatite) can also be used as dietary proxies (Sullivan and Krueger 1981, 1983; Lee-Thorp and van der Merwe 1987). But even though bone mineral clearly persists beyond bone collagen, it can be altered postmortem, often resulting in the loss of the biogenic dietary signal (Schoeninger and DeNiro 1982; Lee-Thorp and van der Merwe 1987; Lee-Thorp 2002). This is due to the bone's high organic content, porosity, and small crystal size, which make it susceptible to dissolution/reprecipitation phenomena and facilitate the incorporation of diagenetic carbonate ions (e.g., LeGeros 1991; Lee-Thorp 2002; Lee-Thorp and Sponheimer 2003). Thus, bioapatite paleodietary studies were forestalled until Lee-Thorp and van der Merwe (1987) showed that dental enamel from ancient fauna with well-understood diets retained its biogenic isotope signal. For example, they showed that fossil equids, like their modern counterparts, had C_4-dominated signatures, while fossil tragelaphines had C_3-dominated signatures like their modern descendants. Since then, numerous empirical and theoretical studies have substantiated this finding (e.g., Lee-Thorp et al. 1989a; Wang and Cerling 1994; Sponheimer and Lee-Thorp 1999b; Hoppe et al. 2003; Lee-Thorp and Sponheimer 2003; Trickett et al. 2003). The enamel's resistance to diagenetic phenomena is conferred by its virtually organic-free and highly-crystalline state (LeGeros 1991), which renders it effectively "prefossilized." Thus, tooth enamel offered the possibility of investigating the diets of early Pleistocene and even Pliocene hominins.

Enamel Bioapatite: Methodological Considerations

For the reasons outlined above, only tooth enamel is sampled for stable isotope analysis of hominin and non-hominin specimens that are millions of years old. Initially, a sample of 200–400 mg was needed (about half of a baboon's molar), but advances in mass spectrometry have reduced the necessary sample size to a few milligrams (Lee-Thorp et al. 1997; Sponheimer 1999). As a result, it has become possible to sample teeth while producing little to no readily observable damage. As a result, more teeth have become available for analysis.

We will now give an overview of the recent sampling and pretreatment protocols, which are modified after Lee-Thorp et al. (1997) and Sponheimer (1999). Specimens are given a careful visual inspection prior to sampling, and those that are heavily stained or have mineral inclusions in the potential sampling areas are excluded from analysis. Generally, only permanent dentition is sampled, with a heavy emphasis on late-forming teeth such as M_2s and M_3s. Powdered enamel samples are acquired (usually from a tooth's buccal surface) using a low-speed rotary drill with a diamond-tipped burr. However, most of the recently sampled hominin teeth had been previously fractured, which allowed sampling between the occlusal surface and the enamel-dentine junction so as to avoid damage to the external surface of the teeth. Although only small samples are taken (~2 mg), we generally attempt to sample over as extensive an area as is possible, so as to obtain enamel formed over a considerable period of time. The enamel powder is soaked for about 10 min in 1.5 % sodium hypochlorite to remove organic contaminants and then rinsed to neutrality. The remaining enamel powder is then pretreated with 0.1 M acetic acid for ~10 min to remove diagenetic carbonates, rinsed to neutrality, and freeze-dried. It is worth noting that these pretreatment protocols can vary from lab to lab, and even within labs over time. As different pretreatments can lead to small but significant differences in a sample's stable isotope composition (especially oxygen), one must compare stable isotope values for the teeth analyzed following different protocols with caution. Finally, each sample is placed in an individual reaction vessel and analyzed for $^{13}C/^{12}C$ and $^{18}O/^{16}O$ using an autocarbonate device coupled to a stable isotope ratio mass spectrometer. Carbon and oxygen isotope ratios are expressed as δ (^{13}C, ^{18}O) values in parts per thousand (‰) relative to the PDB standard. The standard deviation of replicate measurements is typically 0.1 ‰ and 0.2 ‰ for $\delta^{13}C$ and $\delta^{18}O$, respectively. Oxygen isotopes do provide ecological information (Kohn et al. 1996; Sponheimer and Lee-Thorp 1999c; Sponheimer and Lee-Thorp 2001), although they are much better known as paleoclimatic proxies (e.g., Prentice and Denton 1988; Ayliffe and Chivas 1990). For this reason, and because of space constraints, we will not discuss them as paleoecological indicators here.

The relationship between dietary $\delta^{13}C$ and enamel apatite $\delta^{13}C$ has been well-studied. Unlike collagen, apatite tends to reflect the $\delta^{13}C$ of the "whole" or "bulk" diet, and not just the protein component (Ambrose and Norr 1993; Tieszen and Fagre 1993). Thus, apatite and bone collagen $\delta^{13}C$ provide different perspectives on an individual's diet. Indeed, if one wanted to obtain the most complete picture of an individual's diet, one should analyze both collagen and apatite, although this rarely happens in practice. Most important for our purposes here, however, is that enamel apatite provides a good average dietary signal and will equally reflect the consumption of vegetable and animal foods. Interestingly, however, it is evident that the relationship between dietary $\delta^{13}C$ and apatite $\delta^{13}C$ is not constant. Rodent apatite tends to be enriched by about +10 ‰ compared to diet (Ambrose and Norr 1993; Tieszen and Fagre 1993), while large mammal apatite is enriched by about +13 ‰ (Lee-Thorp et al. 1989b; Cerling and Harris 1999; Passey et al. 2005). These differences must be borne in mind when comparing rodent and non-rodent $\delta^{13}C$ but are of little significance for the present discussion.

The South African Australopiths and Early *Homo*

As in the initial bone collagen study by Vogel and van der Merwe (1977), the South African australopith studies were based upon the distinct isotopic signatures of C_3 (trees, bushes, shrubs, and forbs) and C_4 plants (tropical grasses and some sedges). In the early 1990s, it was generally believed that *Australopithecus africanus* had a diet that of fleshy fruits and leaves, much like the modern chimpanzee (*Pan troglodytes*), while *Paranthropus robustus* consumed smaller, harder foods such as nuts (Grine 1981, 1986; Grine and Kay 1988; Ungar and Grine 1991). As these are all C_3 foods, one would then expect that *Australopithecus* and *Paranthropus* would have $\delta^{13}C$ values indistinguishable from those of C_3 browsers and frugivores. Several studies have shown, however, that the $\delta^{13}C$ of both australopiths is very distinct from that of their C_3-consuming coevals (Lee-Thorp et al. 1994, 2000; Sponheimer and Lee-Thorp 1999a; van der Merwe et al. 2003; Sponheimer et al. 2005a).

Figure 3 shows the combined australopith dataset from Makapansgat, Sterkfontein, Kromdraai, and Swartkrans. Analysis of variance and Fisher's PLSD test show that both *Australopithecus* ($x = -7.1$ ‰, s.d. = 1.8, $n = 19$) and *Paranthropus* ($x = -7.6$ ‰, s.d. = 1.1, $n = 18$) are strongly different from contemporaneous C_3 ($x = -11.5$ ‰, s.d. = 1.3, $n = 61$) and C_4 consumers ($x = -0.6$ ‰, s.d. = 1.8, $n = 60$) ($P < 0.0001$), but cannot be distinguished from each other. This distinction between the hominins and other fauna cannot be ascribed to diagenesis, as there is no evidence that browser or grazer $\delta^{13}C$ has been altered, and diagenesis should affect hominins and non-hominin fauna alike. If we take the mean $\delta^{13}C$ of C_4- and C_3-consuming herbivores as indicative of pure C_4 and C_3 diets, respectively, this would indicate diets of about 35–40 % C_4 vegetation for both *Australopithecus* and *Paranthropus*. Thus, both were eating considerable quantities of C_4 resources, possibly grasses, sedges, or animals that ate these plants. None of these possibilities were expected, as extant apes are not known to consume these foods to a significant degree (see chapter "▶ Great Ape Social Systems," Vol. 2; Goodall 1986; McGrew et al. 1982). Indeed, even in environments where C_4 foods are readily available, chimpanzee $\delta^{13}C$ does not indicate any C_4 consumption

(Schoeninger et al. 1999; Carter 2001). This suggests a fundamental niche difference between the australopiths and extant apes, which is not so surprising given the vast differences in their craniodental morphology (Grine 1981; Kay 1985; Teaford et al. 2002; Ungar 2004).

It is worth noting that the evidence of extensive C_4 consumption was not the only surprise in the australopith dataset. Indeed, hominin $\delta^{13}C$ turned out to be more variable than virtually all modern and fossil taxa that have been analyzed in South Africa (Lee-Thorp et al. 1994, 2000; Sponheimer et al. 1999, 2001, 2003b; Codron 2003; van der Merwe et al. 2003). There is considerable evidence that South African australopith habitats became more open between ~3.0 Ma and ~1.7 Ma (Vrba 1980, 1985; Reed 1997; Luyt and Lee-Thorp 2003), and it might be argued that this environmental change forced the australopiths to modify their diets over time, leading to their unusually variable $\delta^{13}C$. Yet, linear regression demonstrates that there is no relationship between hominin $\delta^{13}C$ and time ($P = 0.63$, $R^2 = 0.01$; Fig. 4) and there are no significant differences in hominin $\delta^{13}C$ between 3.0 Ma Makapansgat Member 3, 2.5 Ma Sterkfontein Member 4, and 1.8 Ma Swartkrans Member 1 (ANOVA, $P = 0.14$). Indeed, what is most striking about these data is the lack of change in hominin $\delta^{13}C$ in the face of pronounced environmental change. Somewhat paradoxically, however, within any given time period (Member), hominin $\delta^{13}C$ is highly variable. This might simply indicate that the australopiths were extremely opportunistic primates with wide habitat tolerances that always inhabited a similarly wide range of microhabitats. This would be consistent with Wood and Strait's (2004) recent suggestion that early hominins were eurytopic rather than ecological specialists.

In the case of *A. africanus*, the variability is so great that one might be excused for asking if there are not two ecologically distinct taxa presently commingled within its hypodigm (see chapters "▶ Analyzing Hominin Phylogeny: Cladistic Approach" and "▶ The Species and Diversity of Australopiths," Vol. 3). In fact, if one includes the numbers for the three teeth (STW 236, STW 213i, STW 207) that are possibly, but not definitively, attributed to *A. africanus* (van der Merwe et al. 2003), then this taxon would range from nearly pure C_3 to nearly pure C_4

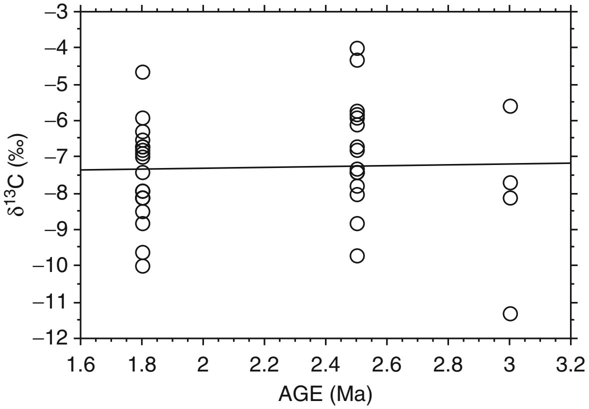

Fig. 4 $\delta^{13}C$ of South African hominins through time. No temporal trend is evident, despite abundant evidence that South African hominin environments changed during this time

diets. Stated otherwise, the range of $\delta^{13}C$ within *A. africanus* (−1.8 to −11.3 ‰) would be nearly as great as the entire range for ecologically disparate *Papio* and *Theropithecus* combined (+0.4 to −12.6 ‰) (Lee-Thorp et al. 1989). In and of themselves, stable isotopes cannot address the question of *A. africanus* unity; but numerous researchers have suggested that *A. africanus* might demonstrate more morphological variability than would be expected for a single taxon (Kimbel and White 1988; Clarke 1994; Lockwood 1997; Moggi-Cecchi et al. 1998). Hence, the possibility of two taxa, one subsisting largely on C_4 foods and the other on C_3 foods, cannot be dismissed. Further work addressing this hypothesis is warranted, but for the time being, we continue to work under the assumption that the specimens currently assigned to *A. africanus* represent a single species.

In short, both South African australopiths consumed about 35–40 % C_4 vegetation and have highly variable carbon isotope compositions. But how does this compare with early *Homo*? Lee-Thorp et al. (2000) tested for isotopic differences between *Paranthropus* and rarer early *Homo* specimens from Member 1 at Swartkrans. They assumed that if *Homo* consumed more animal foods, as was widely held, then its $\delta^{13}C$ values should be enriched compared to the australopiths because many savanna animals eat C_4 grasses. Surprisingly, though, *Homo* $\delta^{13}C$ was very similar to that of the australopiths, and the results must be interpreted in a similar way: roughly 25 % early *Homo*'s diet came from C_4 sources that included C_4 grasses, C_4 sedges, C_4 animal products, or some combination of these foods (see chapters "▶ The Earliest Putative *Homo* Fossils" and "▶ Defining the Genus *Homo*," Vol. 3; Lee-Thorp et al. 2000). However, only three *Homo* specimens from one site have been analyzed and published, and thus comparisons with the more numerous australopith data must be viewed with caution.

What C_4 Foods?

Which C_4 foods did the South African australopiths utilize? This question is quite significant, as the use of these different resources might have a variety of physiological, social, and behavioral implications. For instance, if australopiths had a grass-based diet similar to the modern gelada baboon (*Theropithecus gelada*), this would almost certainly indicate that their diets were less nutrient dense than those of modern apes, possibly placing important limitations on burgeoning hominin brains and sociality (Aiello and Wheeler 1995; Milton 1999). The converse that australopiths ate diets rich in animal foods would indicate a leap in dietary quality over modern apes. This could have been a crucial step toward hominin encephalization, the development of stone tool industries, and increased social complexity (Milton 1999). Similarly, it has been suggested that consuming the underground storage organs of plants like C_4 sedges would represent an increase in dietary quality over that of extant great apes because they are lower in dietary fiber than ape fallback foods (Conklin-Brittain et al. 2002). We will now discuss the evidence for the consumption of C_4 grasses, C_4 sedges, and animal foods in turn.

The Case for Grasses

Some researchers noted that the robust craniodental anatomy of the australopiths might have been an adaptation for eating grass seeds and roots as do modern gelada baboons (*Theropithecus gelada*) (Jolly 1970; Wolpoff 1973). A dental microwear study of modern geladas showed that their molar microwear is dominated by scratches with little evidence of pitting (Teaford 1992), however, which is quite unlike the heavily pitted molars of the australopiths (Grine 1986; Grine and Kay 1988). This result is hardly surprising, though, as it would seem unlikely that relatively large-brained hominins could be sustained on gelada-like diet (high in fiber, low in protein and long-chain polyunsaturated fatty acids) without supplementation with higher-quality foods. Furthermore, the stable isotope results do not indicate a pure C_4 diet, but rather one in which C_4 foods are very important, but not exclusive. Therefore, even if the C_4 component did originate from grasses, one would not expect australopiths to have *Theropithecus*-like microwear.

One might expect, however, that australopiths and savanna baboon populations that consume large quantities of grass seasonally would show similarities in dental microwear (Altmann and Altman 1970; Harding 1976; Dunbar 1983; Strum 1987), and indeed two recent studies of *Papio* molar microwear noted a more australopith-like frequency of pitting than was found in *Theropithecus* (Daegling and Grine 1999; Nystrom et al. 2004). In addition, a recent elemental analysis of australopith tooth enamel showed that while *Australopithecus*, and to a lesser extent *Paranthropus*, had higher Sr/Ca ratios than carnivores, browsers, and papionins, their Sr/Ca was quite similar to grazers. In fact, the unusual combination of high Sr/Ca and low Ba/Ca in *Australopithecus* has only been found in modern fauna that heavily utilize the underground portions of grasses such as warthogs (*Phacochoerus africanus*) and African mole rats (*Cryptomys hottentotus*) (Sponheimer et al. 2005b). These elemental data are still preliminary and certainly cannot be used to state affirmatively that early hominins consumed grasses. Nevertheless, they are entirely consistent with the possibility and suggest avenues for future research.

The Case for Sedges

Sedges have also received attention as a potential C_4 food for australopiths. Conklin-Brittain et al. (2002) argued that a trend toward desiccation in the Pliocene eroded forests and ultimately forced australopiths into new, more open habitats (see chapters "▶ Role of Environmental Stimuli in Hominid Origins," Vol. 3, "▶ Zoo geography: Primate and Early Hominin Distribution and Migration Patterns," Vol. 1, and "▶ Evolutionary Biology of Ape and Monkey Feeding and Nutrition," Vol. 2). Although the degree, manner, and timing of this deterioration are a matter of some debate, the fact that it occurred is not (Vrba 1985; DeMenocal 1995; Feibel 1997). Conklin-Brittain et al. (2002) reasoned that this loss of forest habitat forced australopiths into environments that were most similar to their ancestral forest homes, namely, wetlands, swamps, and river margins. Sedges are readily available in these environments and have been argued to be among the possible sources of the C_4 signal in australopiths (Sponheimer and Lee-Thorp 1999a; Conklin-Brittain et al. 2002). Some sedges have underground storage organs that have protein levels equal to those of most chimpanzee foods (9 % crude protein), but much lower fiber levels (16 % fiber) than foods consumed by chimpanzees (33 %) (Conklin-Brittain et al. 2002). Thus, the regular inclusion of sedges in australopith diets might represent an increase in dietary quality over extant great apes. Equally important, the underground portions of sedges would be relatively inaccessible to most mammals, yet readily accessible to hominins with crude-digging implements (Hatley and Kappelman 1980), making sedges a high-quality resource for which there is very little competition. Such foods might have been particularly important during the dry season when other preferred dietary resources were scarce. Moreover, there is evidence of humans and other primates consuming sedges. Modern humans have consumed sedges like *Cyperus esculentus* and *C. papyrus* for thousands of years (Tackholm and Drar 1973; Defelice 2002). Western lowland gorillas (*Gorilla gorilla gorilla*) have also been observed consuming the pith of sedges, although in small quantities (see chapter "▶ Great Ape Social Systems," Vol. 2; Doran and McNeilage 1998). Finally, *Australopithecus*' high Sr/Ca is consistent with the consumption of sedge USOs (Sillen et al. 1995; Sponheimer et al. 2005b), although as previously mentioned this is also consistent with the consumption of grass USOs.

But how likely is it that the observed C_4 signal in early hominins was derived from C_4 sedges? Although 33 % of the world's sedges use the C_4 photosynthetic pathway (Sage et al. 1999), it is incorrect to assume that all or even most sedges available to australopiths would have utilized the C_4 pathway. Although 65 % of Kenyan sedges reportedly use C_4 photosynthesis (Hesla et al. 1982), only 35 % do in South Africa (Stock et al. 2004). More to the point, a study of sedges in riverine habitats similar to those inhabited by australopiths found that only 28 % use C_4 photosynthesis (Sponheimer et al. 2005a). Thus, unless the South African australopiths deliberately sought out C_4 sedges or the distribution of sedges was markedly different during the Pliocene, the australopiths would have had to have had a diet of 100 % sedges to come close to producing the observed 35–40 % C_4 signal. A slightly more probable scenario than this extreme sedge specialization is that the australopiths deliberately sought out C_4 sedges with particularly well-developed rootstocks such as *Cyperus papyrus*, and thus a diet of 35–40 % sedges would have been sufficient to explain the australopith carbon isotope values. Yet, this too is unlikely, for although these highly edible sedges are common in extensive perennial wetlands like the Okavango Delta, they are rare in the woodland/bushland habitats that were inhabited by australopiths (Reed 1997; Peters and Vogel 2005).

All told, the available data suggest that even if sedges did constitute an important resource for early hominins, they were likely supplemented with other C_4 foods. Alternatively, if other C_4 foods were not consumed, australopiths would have had to have been true sedge specialists to account for the strong C_4 signatures observed in most specimens. It is worth noting, however, that some early hominin habitats in East Africa such as the wetlands of the Eastern Lacustrine Plain at Olduvai Gorge (Hay 1976; Deocampo et al. 2002) might have been better sources of edible C_4 sedges, and Puech et al. (1986) have also suggested that the dental microwear of early East African hominins is consistent with the consumption of such foods (see below for isotopic analysis of eastern African hominins).

The Case for Animal Foods

Animal foods can mean many different things including large and small vertebrates, invertebrates, and even bird's eggs. These foods can also be acquired in a variety of ways including active hunting of large games, passive scavenging, and gathering of insects and eggs (see chapters "▶ The Hunting Behavior and Carnivory of Wild Chimpanzees" and "▶ Cooperation, Coalition, Alliances," Vol. 2). Although chimpanzees are known to hunt a variety of small vertebrates such as red colobus monkeys (*Piliocolobus badius*) and blue duiker (*Cephalophus monticola*), these are pure C_3 consumers (Teleki 1981; Goodall 1986). Therefore, intake of these foods could not contribute to the C_4 component of australopith diets. More likely sources of the reported C_4 signal include small grass-eating taxa such as hyraxes (*Procavia* spp.) and cane rats (*Thryonomys swinderianus*). The young of larger species would also be tempting targets. For instance, the young of antelope like reedbuck (*Redunca arundinum*) lies hidden and largely helpless for the first several months of life, making them an easy prey for enterprising hominins.

Arthropods are also potential C_4 foods. Baboons are known to eat grass-eating grasshoppers (Acrididae) almost exclusively during temporary gluts (Hamilton 1987). Grass-eating termites represent another intriguing possibility, particularly given recent studies suggesting that bone tools from Swartkrans were used to extract termites from mounds (Backwell and D'Errico 2001). Stable isotope studies of termites in African savanna environments have shown that they could have contributed to the australopiths' ^{13}C-enrichment (Boutton et al. 1983; Sponheimer et al. 2005a). While termites range from nearly pure C_3 to pure C_4 consumers, the vast majority of savanna termites, even in densely wooded riverine microhabitats, consume significant proportions of C_4 foods. In fact, termites throughout Kruger National Park eat 35 % C_4 vegetation on average (Sponheimer et al. 2005a; Fig. 5). Thus, termite consumption by australopiths in woodland savanna and even in riverine forest would be expected to impart some C_4 carbon to consumers. On the other hand, the fact that so few termites have a pure C_4 signal makes it unlikely that termite consumption alone was the source of the strong C_4 signal of australopiths, because it would require a diet of nearly 100 % termites.

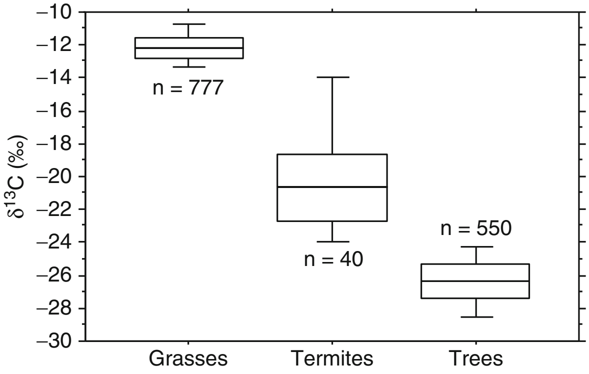

Fig. 5 δ^{13}C for termites, trees, and grasses in Kruger National Park. The boxes represent the 25th–75th percentiles (with the medians as a *horizontal line*) and the whiskers show the 10th–90th percentiles. Note that while termites have highly variable carbon isotope compositions, the vast majority of specimens have mixed C_3/C_4 signatures

Alternatively, if the hominins selectively preyed upon grass-specialist harvester termites (*Trinervitermes*, *Hodotermes*) with virtually pure C_4 diets, a diet of about 35–40 % termites would be sufficient to produce the observed hominin carbon isotope ratios. This scenario, however, is highly unlikely because these C_4 termites are much less common than those with mixed C_3/C_4 diets in woodlands today; and while harvester termites are more abundant in open grasslands and during acute droughts (Braack and Kryger 2003), there is no reason to believe that australopiths frequented such open environments or that drought conditions were so preponderant (see chapters "▶ Role of Environmental Stimuli in Hominid Origins," Vol. 3 and "▶ The Paleoclimatic Record and Plio-Pleistocene Paleoenvironments," Vol. 1). Moreover, while *Trinervitermes* builds highly visible aboveground nests (mounds), *Hodotermes* does not, making it much less conspicuous on the landscape (Carruthers 1997; Stuart and Stuart 2000). Thus, it is possible and even likely that termites contributed in some way to the unusual $\delta^{13}C$ values of australopiths, but other C_4 resources were almost certainly consumed in considerable quantities.

It has been suggested that hominid dental anatomy was not well suited for the processing of animal foods (Teaford et al. 2002), but this observation only pertains to a limited class of animal foods. A great many animal foods require little, if any, oral processing. Termites, grasshoppers, ants, grubs, eggs, and a variety of other insect delicacies may be consumed whole, and even small vertebrates can be swallowed whole or in a few pieces (Smithers 1983). Brains, marrow, and other soft tissues can also be consumed without oral processing. In addition, no experiments have been conducted to investigate the actual oral and/or preoral processing necessary to consume the muscle tissue of small vertebrates. Thus, it seems unwise to unduly limit the potential foods for australopiths until such studies have been undertaken. Furthermore, the consumption of animal foods is common among mammals without seemingly appropriate dentition. One obvious example is the aardwolf (*Proteles cristatus*) which consumes hundreds of thousands of termites per night with largely nonfunctional, obsolescent dentition (Smithers 1983). In some cases, this apparent disjunction between dental morphology and trophic behavior might result from the dentition being adapted for others, more mechanically challenging foods in an animal's diet. For example, capuchin monkeys (*Cebus apella*) have large, bunodont dentition with thick enamel adapted for consuming fruits and hard nuts. Nonetheless, up to 50 % of capuchin diets can come from animal foods, although the average is closer to 25 % (Fleagle 1999; Rosenberger and Kinzey 1976; Rosenberger 1992). Similarly, Ungar (2004) has argued that among hominoids, differences in dental morphology primarily reflect their multifarious fallback foods, rather than their preferred foods during times of plenty.

What Does It Mean?

All told, we still cannot be certain which C_4 resources were utilized by South African australopiths. Grass roots, grasshoppers, bird's eggs, lizards, rodents, and young antelopes might have been important C_4 resources, particularly during the dry season when little other food was readily available. Succulent plants like euphorbias (Euphorbiaceae) and aloes (Aloaceae) (which are rare in most woodlands but have $\delta^{13}C$ values that are sometimes indistinguishable from those of C_4 grasses) are also possibilities; for although they are often poisonous to humans (and presumably chimpanzees), they are occasionally utilized by baboons and humans (Codron 2003; Peters and Vogel 2005). Further work on dental microwear and morphology, elemental analysis, and the potential availability and nutritional properties of foods may make it possible to identify these C_4 resources with greater confidence. At present, however, it seems likely that australopiths utilized a wide variety of these foods.

Despite this uncertainty, we should not lose sight of the most significant aspect of these stable isotope data, namely, that australopiths increased their dietary breadth compared to extant apes by consuming novel C_4 resources, *regardless* of what these resources were (see chapter "▶ Role of Environmental Stimuli in Hominid Origins," Vol. 3). Similar evidence for increased dietary breadth is also evident in their thicker enamel, larger postcanine dentition, and greater mandibular corpus robusticity, all of which point to the consumption of hard objects beyond the capabilities of extant apes (Teaford et al. 2002). Thus, the fundamental trophic difference between australopiths and extant apes might be that when confronted with increasingly open areas, apes continue to exploit the foods that are most abundant in forest environments (McGrew et al. 1982), whereas australopiths utilized novel C_4 resources in addition to forest foods. There would have been a number of advantages to such a dietary strategy. It would have allowed australopiths to survive and even thrive in a much greater variety of habitats than do modern great apes, potentially allowing expansion of their range. Similarly, the increased dietary breadth could have buffered australopiths against climatic change and habitat loss. Another implication of increased dietary flexibility might be decreased foraging time and mobility, allowing for increased social interaction and possibly greater social complexity. This flexibility could also have increased dietary quality over that of extant apes by adding low-fiber underground storage organs and protein- and lipid-rich animal foods to australopith menus. This might have been an important step leading to greater encephalization and development of the genus *Homo* (see chapter "▶ Evolution of the Primate Brain," Vol. 2; Aiello and Wheeler 1995; Milton 1999; Conklin-Brittain et al. 2002).

If increased dietary breadth was a fundamental australopith adaptation, what are we to make of the later robust australopiths in which the dental adaptations reached their most specialized form? They are believed to have been specialist hard object feeders that were eventually replaced by our *Homo* forebears who, for the first time, had regular access to higher quality animal foods (Aiello and Wheeler 1995; Milton 1999). An alternative explanation, however, is that the robust australopithecines were the quintessence of the trend towards dietary diversity because they could access the foods of their progenitors as well as harder foods. One might then argue that they were supplanted by *Homo* not because they ate different kinds of foods, but because *Homo* was more efficient at procuring these resources due to increased use of extra-oral processing (e.g., stone tools) and greater planning depth. It is believed, for instance, that early *Homo* increased access to bone marrow from scavenged or hunted carcasses of medium to large mammals by using stone tools (e.g., Blumenschine 1987), whereas there is a debate as to whether or not robust australopiths utilized such technology (e.g., Leakey et al. 1964; Susman 1988; Semaw et al. 1997; de Heinzelin et al. 1999). Furthermore, where australopiths may have eaten antelope lambs only when they stumbled upon them, *Homo* may have had superior planning depth and followed female antelopes back to their young, capturing them only when the mother left once more.

New Data from Beyond South Africa

For nearly 15 years, carbon isotope analysis had only been undertaken on South African early hominins, but now studies have been completed on both central and eastern African hominin specimens (van der Merwe et al. 2008; White et al. 2009; Cerling et al. 2011, 2013; Lee-Thorp et al. 2012; Wynn et al. 2013; Fig. 6). These new data have dramatically increased our understanding of the taxonomic, regional, and temporal dimensions of early hominin diet (data available at http://dx.doi.org/10.6084/m9.figshare.710649; Sponheimer et al. 2013).

For instance, it now appears that before 4 Ma, eastern African hominins had carbon isotope compositions indicating primarily C_3 consumption (White et al. 2009; Cerling et al. 2013). It also appears that by about 3.5 Ma, C_4 food consumption became significant, if highly varied, within eastern African taxa such as *A. afarensis* and *Kenyanthropus platyops* (Cerling et al. 2013; Wynn et al. 2013).

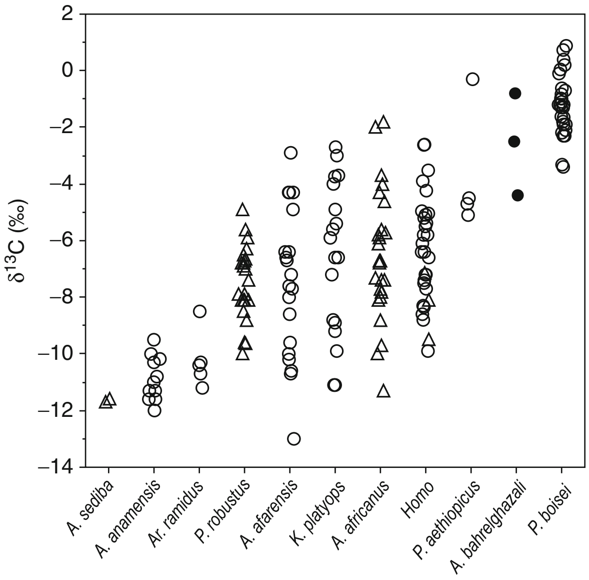

Fig. 6 Early hominin taxa from southern Africa (*open triangles*), eastern Africa (*open circles*), and central Africa (*closed circles*) arranged from lowest to highest $\delta^{13}C$ values

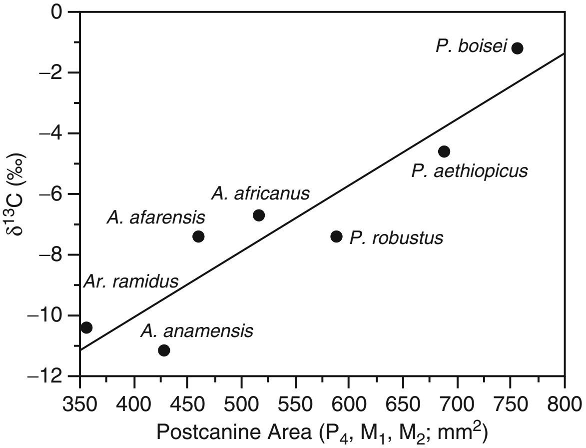
Fig. 7 Linear regression showing that australopith postcanine area predicts $\delta^{13}C$ values ($r^2 = 0.86$, $t(5) = 5.50$, $P < 0.01$). The relationship between $\delta^{13}C$ values and mandibular cross-sectional area at M1 is not shown (see Sponheimer et al. 2013)



There is also strong evidence for regional differences. Most notably, *P. robustus* in southern Africa and *P. boisei* in eastern Africa, despite their marked morphological similarities, have highly different $d^{13}C$ values ($P < 0.001$), suggesting that the latter had a diet dominated by C_4 (or less likely CAM) vegetation (van der Merwe et al. 2008; Cerling et al. 2011). Concomitantly, there is now strong isotopic evidence of niche differentiation between *Homo* and *Paranthropus* in eastern Africa, which contrasts with the broadly similar $\delta^{13}C$ values of these genera in southern Africa (Lee-Thorp et al. 2000). Preliminary observations also suggest a relationship between masticatory morphology and australopith carbon isotope compositions, with postcanine tooth size and mandibular cross-sectional area at M_1 both increasing as do $\delta^{13}C$ values (Sponheimer et al. 2013; Fig. 7). This could indicate that C_4 food consumption was among the driving forces behind the trend toward masticatory robusticity within the australopiths.

Given this, it is surprising that evidence for environmentally driven changes in australopiths $\delta^{13}C$ values remains equivocal. The transition to significant C_4 consumption at about 3.5 Ma is not obviously related to increased availability of C_4 grass (Sponheimer et al. 2013), and changes in the habitat of *A. afarensis* are not clearly reflected in its $\delta^{13}C$ values (Wynn et al. 2013). It remains possible that an environmental signal has become obscured by the poor temporal and environmental resolution of the existing hominin fossil record and that climatic/environmental change at precessional or shorter time scales did drive hominin $\delta^{13}C$ values (Hopley and Maslin 2010), but this cannot be tested at present. We note, however, that even if changes in the abundance of C_4 grass did not influence hominin $\delta^{13}C$ values, it remains possible that other environmental parameters such as tree or mammalian diversity did (Sponheimer et al. 2013).

As to what C_4 resources hominins post 4 Ma ate, it should be remembered that "early hominin diet" or even "australopith diet" is chimerical given that the available carbon isotope data now span more than three million years, 11 species, and major differences in masticatory anatomy and associated archaeology (see chapters "▶ Analyzing Hominin Phylogeny: Cladistic Approach" and

"▶ The Species and Diversity of Australopiths," Vol. 3; Sponheimer et al. 2013). Given this, and the likely corollary of marked diversity of early hominin diets, it is not only plausible but probable that C_4 food acquisition and consumption differed among hominin species within a broad region like eastern Africa. For instance, given *Paranthropus boisei*'s high $\delta^{13}C$ values, thick, robust mandibles, low-cusped cheek teeth, and diminutive incisors and canines, it is improbable that its major C_4 dietary input was meat. Even savanna carnivores may not attain such high $\delta^{13}C$ values (Codron et al. 2007). It is, therefore, most parsimonious to ascribe the preponderance of its C_4 "signal" to the direct consumption of C_4 plant foods like grasses or sedges. As to what parts of these plants were consumed, given the discussion earlier in this manuscript, we are a long way from knowing. The situation for contemporaneous *Homo* might be different, though. Its dental morphology (Ungar 2004), the general belief that it produced (rather than *Paranthropus*), the majority of its associated archaeological record (Leakey et al. 1964), and arguments derived from energetics (Aiello and Wheeler 1995) are consistent with *Homo* having consumed greater amounts of animal protein from which it might have derived its C_4 carbon.

Conclusion

Stable isotope studies have made an important contribution to our understanding of early hominin diets. In the case of Neanderthals, stable isotopes strongly support the contention that they were highly carnivorous, primary predators. As for the australopiths, stable isotopes suggest that they broadened the ancestral ape resource base to include C_4 foods, which coupled with bipedalism, and allowed them to pioneer increasingly open and seasonal environments. Yet, as is the case with all paleodietary techniques, stable isotopes leave a great many important questions unresolved. Particularly important are the equifinality problems that are common in stable isotope studies. In other words, many different diets can lead to the same stable isotope signature. For instance, carbon isotopes often cannot distinguish between diets as different as folivory, frugivory, and carnivory. And although some progress has been made using oxygen isotopes to break such equifinalities (Sponheimer and Lee-Thorp 1999c; Carter 2001), there is little reason to believe that this problem can be circumvented entirely by relying on stable isotopes. In the end, stable isotopes are one tool among many, all of which provide a slightly different window into the diets of our ancestors. Thus, where stable isotopes cannot determine the favored prey of Neanderthals, faunal analysis has much to contribute (Speth and Tchernov 2001), and when carbon isotopes remain silent on the topic of australopith fallback foods, dental morphology may jump into the fray (Ungar 2004). Thus, stable isotopes will prove most informative when pursued as part of a larger, integrated paleodietary investigation.

That being said, stable isotopes themselves still have a great deal to tell us about the diets of our ancestors. To date, only Pliocene and early Pleistocene African hominins, Neanderthals, and AMH have been analyzed for stable isotopes to any significant extent, leaving the entire continents and large periods of time virtually unexplored. Future stable isotope studies will surely bridge these gaps, and in so doing greatly increase our knowledge of early hominin diets. Yet, we should not be satisfied to merely work our way through previously neglected or unattainable material, but should seek to push the limits of the technique itself. Improving our knowledge of the stable isotope compositions of modern plants and mammals, investigating how physiology affects diet-tissue spacing, and refining organic extraction techniques so that nitrogen isotopes can be analyzed for a wider variety of taxa will not only improve our ability to reconstruct paleodiets but will also enable us to address questions in ways that were previously unimaginable. Hopefully, such actualistic and experimental work will serve to hone this already exciting paleodietary tool.

Estimation of Basic Life History Data of Fossil Hominoids

Helmut Hemmer

Contents

Abstract

Relationships between the life cycle and body mass, brain mass, and relative brain size of extant primates can be used to estimate life history parameters of extinct species. Methods to predict these key variables from available cranial and postcranial materials of fossil hominoids, especially hominids, are compiled and evaluated. The use of different concepts of scaling relative brain size is discussed. Brain mass and constant of cephalization data were used as the source material for the estimation of the age at eruption of the first lower molar, the age at female sexual maturity, the age at first breeding, and the maximum life span. Such data support the interpretation of the Late Miocene *Sahelanthropus tchadensis* as a taxon possibly related to the hominid stem species near the splitting of chimpanzee and hominid lines; confirm the fundamental nature of the australopithecines as progressive apes, not as humans; and support the view of a close relationship of the Early Pleistocene *Homo* paleopopulation of Dmanisi (Georgia) to the earliest Pleistocene African *Homo* populations.

Introduction

Fossil bones are the material of classic osteological studies as a base of systematic and phylogenetic conclusions as well as the understanding of functional correlations of morphological structures. They also bear information that may be used for a two-step computing procedure to estimate fundamental life history and ecological and behavioral data that open a progressive level of insight into ecological relations.

Life history study is understood as an approach in evolutionary biology, identifying ontogenetic variables and then asking what impact those variables have on population size and composition. Relationships between the life cycle and anatomical variables, such as body size and brain size, are of particular interest because they can be used to estimate life history parameters of extinct species (Hemmer 1974, 2003; Gingerich et al. 1982; De Rousseau 1990; Harvey 1990; Smith and Tompkins 1995), even if there are also life history components independent of brain and body size (Harvey and Read 1988).

The first step of such life history data calculation is the estimation of body mass as a key variable, supported by the estimation of brain mass, from available fossil remains. The second step then takes advantage of the first-level results to look for estimates of parameters of the individual's life cycle, such as the age at first reproduction or the maximum life span. How this subsequently affects higher levels of organization as, e.g., ecological aspects or population growth and evolution, is an additional step of life history consideration (De Rousseau 1990; Hemmer 2003; Kappeler et al. 2003). This chapter focuses on the way to evaluate such basic information concealed in fossil bones, to look for hominoid, especially hominid, life history aspects. It does not deal with life history correlates as left by the processes of growth, with "osteobiographic" techniques (Boyde 1990; Bromage 1990).

Life History Correlations

Basic primate life history dimensions were found to correlate with body mass (Harvey and Clutton-Brock 1985; Harvey et al. 1987; Lee and Kappeler 2003; Table 1), with absolute brain size (Sacher 1975; Harvey et al. 1987; Smith 1989; Smith et al. 1995; Deaner et al. 2003), and with relative brain size (Hemmer 1974). Brain size is more closely correlated with several life history variables, such as the age at sexual maturity or at first breeding, than is body size (Harvey et al. 1987). Unfortunately, data compilation in landmark publications (Harvey and Clutton-Brock 1985; Harvey et al. 1987) was confounded by conversion of cranial capacity with brain mass using a relationship 1 $cm^3 = 1$ g (Smith et al. 1995). Other studies were based on either cranial capacity or brain mass (Sacher 1975; Smith et al. 1995; Table 2). The factor related to brain size was considered to be maturation rate as a whole rather than any one of its aspects (Smith 1989). There is an extremely high correlation of the age at eruption of the first lower molar, as a rather stable marker of growth with relatively low variance, and brain size ($r = 0.98$). When the effect of

Age at first breeding, female (AFB)	0.92	$\log AFB = 0.44 \log FBM + 1.638$
Interbirth interval (IBI)	0.86	$\log IBI = 0.37 \log FBM + 1.464$
Life span (LS)	0.78	$\log LS = 0.29 \log FBM + 2.893\ 1$

Harvey and Clutton-Brock (1985, Tables 4 and 5) or Harvey et al. (1987, Tables 16.3 and 16.4); correlation coefficients based not on the species but on the subfamily level

Table 2 Relationships between life history variables and brain size in anthropoid primates

Life history variable	*r*	Equation	Source and sample
M_1 eruption age (years) (M_1EA)	0.98	$\ln M_1EA = 0.582 \ln CrC - 2.405$	Smith et al. (1995): 14 anthropoid species
Life span (years) (LS)	0.835	$\log LS = 0.379 \log BrM + 0.640$	Sacher (1975): 43 anthropoid species

CC cranial capacity (cm^3), *BrM* brain mass (g)

body mass is held constant in multiple regression, the partial correlation of M_1 eruption and adult brain size remains $r = 0.90$ (Smith 1989).

The use of relative brain size (constant of cephalization; see later) instead of absolute brain mass or cranial capacity in life history correlations (Hemmer 1974) eliminates the influence of body size and allows for some further improvement of the correlation coefficient with most variables. Allometric formulas that may be used as predictor equations for the estimation of life history data in fossil hominoid primates were calculated for the present contribution based on brain mass (brain and body mass data, Bauchot and Stephan (1969); life history data, Harvey and Clutton-Brock (1985)) to avoid the former 1:1 confusion with cranial capacity data. The results for the relationship of body size, brain size, and coefficient of cephalization with the life history corner-stages age at sexual maturity, age at first reproduction, and maximum life span (data taken from the compilation of Harvey and Clutton-Brock (1985): Table 1), as well as age at first lower molar eruption and at completion of the dentition [data taken from Smith (1989), with modifications by Smith et al. (1995)], are listed in Tables 3 and 4 and illustrated in Figs. 1 and 2.

Estimating Body Mass

Body size cannot be measured directly being an abstract concept not a concrete parameter. Size may variously be recorded, e.g., as head-body length or height at the withers in quadruped mammals or as stature in hominids, but for general use

Table 3 New life history variable allometries in anthropoid primates

Life history variable	*r*	*n*	Equation	Reliability for prediction in hominid evolution

Reliability for prediction in hominid evolution defined on the basis of the prediction error (PE, %) of the estimation for *Homo sapiens*; PE = (observed − predicted)/predicted × 100: $\text{PE} \leq 1$ %, very useful; $\text{PE} > 1 \leq 5$ %, useful; $\text{PE} > 5 \leq 10$ %, still useful; $\text{PE} > 10 \leq 20$ %, less useful; $\text{PE} > 20$ %, useless. Data for BM and BrM based on Bauchot and Stephan (1969); for CC, Hemmer (1971); for ASMF, ASMM, AFB, and LS, Harvey and Clutton-Brock (1985); and for AME and ACD, Smith (1989), with modifications by Smith et al. (1995)

BM body mass, *BrM* brain mass, *CC* constant of cephalization, *LSR* least-squares regression, *RMA* reduced major axis

body mass undoubtedly is the most reliable measure and the size variable of choice (Gingerich et al. 1982; Jungers 1988; Ruff and Walker 1993; Aiello and Wood 1994; Hemmer 2004). Skeletal predictors may allow to estimate body mass on principle on the base of dentition (Table 5), skull (Table 6), and postcranial elements (Tables 7 and 8).

There exists no direct biomechanical relationship between tooth and cranial variables and body mass (Jungers 1988), but such dimensions nevertheless depend on a general factor of size. Dentition measurements may allow us to predict a genetically programmed frame of body size than the real size an individual reached during its ontogeny. Allometric relationships between tooth size and body mass

Table 4 New life history variable allometries in hominoid primates

Life history variable	*r*	*n*	Equation	Reliability for prediction in hominid evolution
Age at first breeding, female (months) (AFB)	0.837	5	log AFB = 0.268 log BrM + 1.450 (LSR)	Useless, no significant correlation

			log AFB = 0.405 log CC + 1.524 (RMA)	6 %, still useful
Life span (years) (LS)	0.913	5	log LS = 0.296 log BrM + 0.888 (LSR)	8 %, still useful
			log LS = 0.324 log BrM + 0.814 (RMA)	4 %, useful
	0.950	5	log LS = 0.389 log CC + 1.059 (LSR)	<1 %, very useful
			log LS = 0.410 log CC + 1.027 (RMA)	2 %, useful

have been used to reach the goal of body mass estimation in extinct nongeneralized primates (Gingerich et al. 1982; Martin 1990; see discussion in Jungers 1990). This approach depends on what evolutionary grade of primate species is used to predict body mass (Conroy 1987), and would be a hazardous venture insofar as hominid evolution is concerned, in view of considerable changes of the relative size of the masticatory apparatus (Wolpoff 1973; Jungers 1988). The introduction of taxon-specific conversion factors (prediction by tooth size related to prediction by cranial or postcranial dimensions) may help to overcome that problem (as used in felid body mass prediction by Hemmer (2001, 2004)). It must also always be taken in mind that dentition-based body mass estimates cannot present real individual life weights but merely provide some idea about a statistic mean to be awaited at a given linear predictor measure within a population in question.

Cranial dimensions should depend more closely than tooth dimensions on individual ontogenetic body size modeling. They allow us to predict some "normal mass" of an individual. Cranial dimensions prove in that generalized function in some cases to be nearly as good or even better mass predictors as are some of the best postcranial ones (Aiello and Wood 1994; Kappelman 1996). Nevertheless, cranial dimensions may also considerably mislead on the other hand. Comparing the average body mass estimated at the base of seven cranial predictors to the actual body mass of the respective species, the average prediction error (PE) was found to be ±32.3 %, ranging from 0.5 % to 79.3 % (Martin 1990).

In limb bones, the genetic influences are supplemented by loading-related stimuli to a higher extant. They give evidence of an individual's muscular strength and

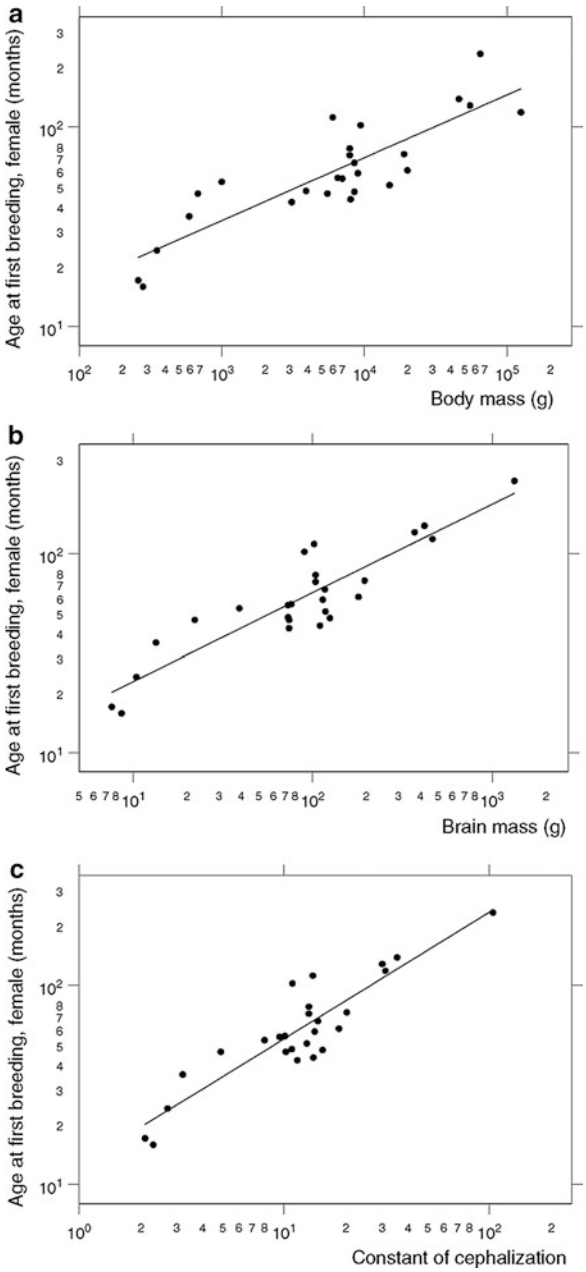

Fig. 1 Bivariate log–log plots (*lines*: least-squares regressions) of female age at first breeding (Data by Harvey and Clutton-Brock (1985), Table 1) against body mass ($r = 0.856$), brain mass ($r = 0.898$) (Both data sets by Bauchot and Stephan (1969)), and constant of cephalization ($r = 0.902$) (Data by Hemmer (1971), based on the respective sets of body mass and brain mass)

development (Lanyon 1990). Just here is a crucial point in hominoid evolution, where quadrupedal gait changed to bipedal gait, or vice versa. Just skeletal structures that bear a direct functional relationship to body mass are to await to mislead in body mass estimation when the pattern of movement and the strains involved changed in that

way. Predictor equations calculated for femoral diaphyseal diameters or circumferences, as well as for femoral articular dimensions (Jungers 1988, 1990; Kappelman 1996), and also for cross-sectional geometrical data, such as cortical area or area moments of inertia (Ruff 1990), lose their utility when developed with quadrupedal hominoids but are used for mass estimation in bipedal hominids [for convincing illustration of these issues, see Figs. 8.5, 8.7, and 8.8 in Ruff (1990) comparing femoral dimension allometric lines for *Homo sapiens* with those for pongids or nonhuman primates in general]. Mass estimates based on femoral dimensions of a bipedal hominoid using predictor equations developed with a nonhuman hominoid sample should thus be awaited not to meet the real values (44 % and 30 % overestimates for human males and females with a catarrhine femoral head diameter

regression (Kappelman 1996)). Femur-based estimates gained with the use of equations calculated with hominoids including man should be shifted somewhat more in the direction of the true values but still differ from them. In the case of using pure *Homo sapiens*-based predictor equations for body mass estimation in early hominids, caution needs to be exercised too, as all fossil hominids seem to have been characterized by considerable skeletal robusticity with thick long-bone cortices (Jungers 1988; McHenry 1992; Ruff and Walker 1993; Ruff et al. 1997).

If the fossil record of single *Homo* skeletons is complete enough to know the body height (stature) and width (bi-iliac breadth), relatively accurate body mass estimations will be possible based on these dimensions (Ruff and Walker 1993; Ruff et al. 1997; Table 8), provided that there are no basic differences in body proportions.

A crude approach to body mass of fossil hominoids other than simple comparisons among hominoid skeletons (for compilation of earlier trials of that type, see Suzman (1980)) may be done on the basis of close correlations of some cranial and postcranial dimensions with partial skeletal mass to represent body size (Steudel 1980). This procedure allows to compare fossils with the body mass of large, slightly larger than average, average, slightly smaller than average, or small male or female actual ape species. Approaches to body mass estimation in early hominids by a prediction of body height on the basis of postcranial elements and the subsequent use of a body height to body weight ratio (Wolpoff 1973) must meet the requirements of the same stature class, for which the ratio was calculated, and of the same limb-to-body proportions. Finally, another simplified attempt to estimate body mass of early hominids exclusively at the base of the cube of limb bone length or the square of diameter percentage deviations from a *Homo sapiens* standard skeleton (Krantz 1977) may not result in much more trustful body mass estimates than heavier, much heavier,

LSR least-squares regression, *RMA* reduced major axis

Table 8 Body mass prediction based on stature and bi-iliac breadth

Equation	r	Source and sample
BM = 0.413 ST + 2.892 BI − 84.8	0.941	Ruff and Walker (1993): 21 males, worldwide adult population
BM = 0.498 ST + 1.877 BI − 74.6	0.965	Ruff and Walker (1993): 306 male Karkar Islanders, 8–67 years
BM = 0.373 ST + 3.033 BI − 82.5	0.90	Ruff et al. (1997): males

Only samples with $r \geq 0.90$ were selected
BM body mass (kg), *ST* stature (cm), *BI* bi-iliac breadth (cm): before applying these formulas, skeletal bi-iliac breadth is converted to living bi-iliac breadth using the equation living BI = 1.17 skeletal BI − 3 (Ruff et al. 1997)

lighter, or much lighter compared to the standard, as such a procedure neglects size-dependent allometric shifts and evolutionary changes in body proportions.

It should always be kept in mind that body mass estimates resulting from either cranial or postcranial variables are subject to considerable error (Jungers 1990; Martin 1990; Ruff and Walker 1993; Aiello and Wood 1994; Kappelman 1996). Given this fact (Table 5) and the use of equations based on highly correlating samples ($r \geq 0.95$; the correlation coefficient depends on the overall size variability and allows for higher values in all primate samples than in taxon-specific samples, but the latter otherwise may have a higher misleading potential for predicting equations used for extinct species), different available line-fitting techniques to create predicting equations (least-squares regression, reduced major axis, major axis) and the partial availability of correction factors to compensate for bias, introduced when a body mass estimate derived in logarithmic units is detransformed back to arithmetic units (Smith 1993), as well as many other issues around estimation of body mass in paleontology

(Smith 2002), may not really merit that high attention for practical use as sometimes postulated (Gingerich et al. 1982; McHenry 1992; Hartwig- Scherer 1993; Aiello and Wood 1994; Kappelman 1996). Individual body mass estimates of fossil specimens of course may be calculated that are mathematically quite correct, even to the nearest 100 g, for further statistical use; but nevertheless, it is biologically wise to list them not in that accurate form but as roughly rounded values. To give a comparable example, rounding to the nearest kilogram was proposed for body mass prediction in fossil cats only for specimens weighing less than 20 kg; rounding to the nearest 5 kg, for the range between 20 and 50 kg; and rounding to the nearest 10 kg, for specimens weighing more than 50 kg (Hemmer 2004).

Estimating Brain Mass

Cranial capacities measured in cm^3 are not the same as brain masses measured in g. In primates, the general relationship will be cranial capacity > brain mass > brain volume (Smith et al. 1995). Unfortunately, this is not always done in comparative publications [e.g., cranial capacities labeled brain mass in Table 1 of Harvey and Clutton-Brock (1985), identical with Table 15.1 of Harvey et al. (1987); see Smith et al. 1995]. There is also no stable relationship between brain mass and cranial capacity [e.g., 1/1.05 as used for humans by different authors (Smith et al. 1995) or 1/1.14 as used by Hartwig-Scherer (1993), following Count (1947)] over the whole range of brain size variability. The repeatedly found allometric exponent of 1.02 (Martin (1990), for primates; Röhrs and Ebinger (2001), for mammals other than primates) does not mean an isometric relationship between the two variables at correlation coefficients as high as 0.995–0.997 (Table 9). Therefore, all comparative work using brain size should either center on cranial capacities or brain masses. Calculations of relative brain size (cephalization, encephalization quotient) based on body mass clearly should proceed with brain mass. Unfortunately, the available predictive equations for primates or mammals in general give quite differing brain mass values (Table 10). The primate cranial capacity brain mass conversion formula (Martin 1990) is retained here, since it produces neither clearly excessive values in the upper (*Homo sapiens*) range in view of such conversion data as presented by earlier authors [compilation in Martin and Saller (1959)] nor nonsense values in the lower range, whereby brain volumes would become just larger than cranial capacities (as produced with the use of the formula of Ruff et al. (1997)).

It should be noted that there are some pitfalls in the determination of the cranial capacity as basis for brain mass estimation. The usual method of packing the cranial cavity with small rounded particles as lead shot, mustard seed or millet grain, and other comparable materials is limited by the need to condense the fill both in the skull and in the measuring cylinder in the same way. The method closing the foramina before packing the cranial cavity may also influence the result. A good standardized practice is needed to achieve a tolerable accuracy with this volumetric approach, and it may be combined with a weighing procedure (Smith et al. 1995). Measurements obtained by the packing method may surpass the volume of artificial

Table 9 Interspecific allometric relationship of cranial capacity and brain mass in primates and in mammals other than primates

Sample	Allometric equation	r	Authors	Formula converted for mass estimation
33 primate species	$CrC = 0.94\ BrM^{1.02}$	0.996	Martin (1990, p 363 + Fig. 8.4)	$\log BrM = 0.98 \log CrC + 0.0246$
27 primate species	–	0.995	Ruff et al. (1997)	$\log BrM = 0.976 \log CrC + 0.0596$
17 mammal species	$CrC = 0.96\ BrM^{1.02}$	0.997	Röhrs and Ebinger (2001)*	$\log BrM = 0.98 \log CrC + 0.0168$

BrM brain mass, *CrC* cranial capacity (cm^3)

[a] The authors present this equation as $\log CrC = -0.0015 + 1.02 \log BrV$ (BrV = brain volume) and add the equation BrV = BrM:1.036

Table 10 Cranial capacity-based brain mass estimates (g) by the use of different equations (Table 9)

Cranial capacity (cm^3)	Brain mass estimated by the primate formula of Martin (1990)	Brain mass estimated by the primate formula of Ruff et al. (1997)	Brain mass estimated by the mammalian formula of Röhrs and Ebinger (2001)
50	49	52	48
100	97	103	95
500	467	494	459
1,000	922	972	905
1,500	1,371	1,444	1,347

endocasts (Martin 1990, Table 8.5: 10–11 % in the Eocene lemuroid primate *Adapis parisiensis*). The estimation of endocranial volume by double graphic integration derived from X-ray pictures may result in substantially diverging values (Martin 1990, Table 8.5: 10–12 % less than the artificial endocast in *Adapis parisiensis*). An assessment of cranial capacity in fossil primates also may be done by the use of linear cranial dimensions (Martin 1990; Table 11).

Calculating Relative Brain Size

There are four main concepts of scaling relative brain size in primates (McHenry 1976). The constant of cephalization (CC) (Hemmer 1971) was developed on the base of a common mammalian intraspecific allometric exponent around 0.23 [$BrM = CC \times BM^{0.23}$; BrM = brain mass (g), BM = body mass (g)]. The index of progression (IP) (Bauchot and Stephan 1966, 1969) gives the ratio of actual brain mass to brain mass predicted on the basis of an interspecific basal insectivore allometric equation with an exponent of 0.63. [The index of cranial capacity (ICC)

Table 11 Estimation of cranial capacity (CrC) (cm^3) by linear dimensions in primates (Martin 1990: Table 8.10)

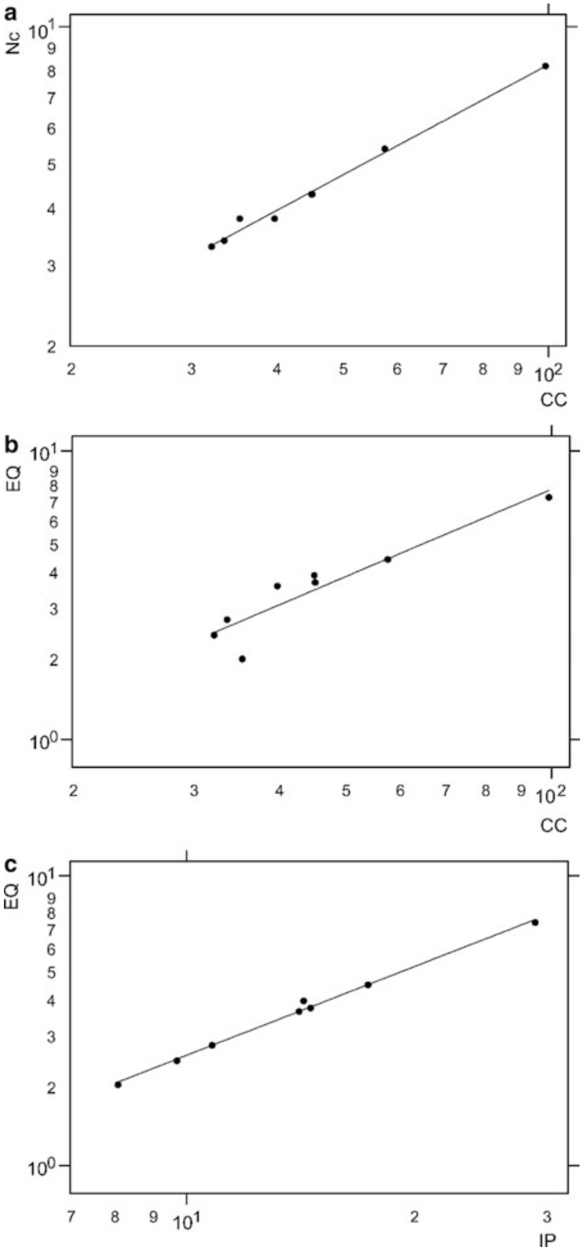
Dimension (mm)	*r*	Equation
Braincase width (CW)	0.99	$\log CrC = 3.24 \log CW - 3.75$
Braincase height (CH)	0.98	$\log CrC = 2.91 \log CH - 2.91$
Braincase length (CL)	0.98	$\log CrC = 3.28 \log CL - 4.37$
Sum CW + CH + CL (SU)	0.995	$\log CrC = 3.12 \log SU - 5.18$
Product CW × CH × CL (PR)	0.995	$\log CrC = 1.02 \log PR - 3.54$

The formulas are based on the major axis, and the cranial capacities were determined by packing the cranial cavity with sintered glass particles

as introduced by Martin (1990) follows just the same lines as the index of progression.] The encephalization quotient (EQ) (Jerison 1973) is also the ratio of actual to predicted brain mass, the latter based on an interspecific mammalian allometry (predicted brain mass $= 0.12\ BM^{2/3}$). The extra-neuron count (Nc) (Jerison 1973) "is a numerical measure of progressiveness in brain development beyond the level required by increasing body size" (Jerison 1973). The results of the CC and Nc methods perfectly correlate on the one hand as do the results of the IP and EQ methods on the other (Fig. 3). This reduces the issues on principle to the choice of either the intraspecific (CC and Nc methods) or the interspecific (IP and EQ) type of brain to body mass allometries.

EQ has been widely used in the last three decades by the overwhelming majority of authors (Hartwig-Scherer 1993; Kappelman 1996; Ruff et al. 1997; McHenry and Coffing 2000). The results of EQ calculations vary depending on which of the different equations is selected (Kappelman 1996) [allometric exponents varying from 0.60 (Old World simian EQ: Martin 1990) or 0.67 (Jerison 1973) close to 0.75 (0.74–0.76) (Martin 1990; Hartwig-Scherer 1993; Ruff et al. 1997; McHenry and Coffing 2000)]. Nevertheless, some writers have begun to feel uncomfortable about the EQ method (McHenry 1988; Kappelman 1996; Arsuaga et al. 1999; Rightmire 2004). A negative allometric relationship between body size and EQ was raised, but the reasons were assumed to be unclear (Kappelman 1996). EQ being a function of body mass predicted for individuals using an interspecific equation, the comparison of EQ values determined for fossils was considered to be misleading (Rightmire 2004). Similarly, the EQ was not felt to be meaningful when closely related species with widely differing body mass are compared (Arsuaga et al. 1999). Curious EQ results like a position of *Miopithecus talapoin* above all nonhuman hominoids, the gorilla ranging below all cercopithecines (Hemmer 1971; Table 2), or *Cebus albifrons* lying between *Homo erectus* and *Homo sapiens* (Hartwig-Scherer 1993, Fig. 6) also indicate that this procedure may be seriously biologically inadequate. All such problems disappear when the CC intraspecific approach is followed instead of the EQ interspecific method (Hemmer 1971). As a by-effect of the low intraspecific allometric exponent, the influence of differences in body mass predictions on EQ calculations (Conroy 1987) is less profound with the CC method.

Fig. 3 Bivariate log-log plots (*lines*: least-squares regressions) to demonstrate the mutual relationship of the main methods to scale relative brain size (Data from McHenry (1976), Table 2; hominoid primates). (**a**) Extra-neuron count (*Nc*) (Jerison 1973) against constant of cephalization (*CC*) (Hemmer 1971) ($r = 0.997$). (**b**) Encephalization quotient (*EQ*) (Jerison 1973) against constant of cephalization (*CC*) $r = 0.971$). (**c**) Encephalization quotient (*EQ*) against index of progression (*IP*) (Bauchot and Stephan 1966) ($r = 0.998$)



Life History Data Estimations in Fossil Hominids

The final approach to life history data estimation in fossil hominoids, especially in fossil hominids, is a story of reliability of the prediction equations to be used. There is a wide variability in the results of body mass estimation obtained on the basis of different species samples used to create the equations, on the basis of different dimensions, and using different line-fitting techniques (Table 12). The availability of several parts of a single skeleton, as, e.g., in the female *Australopithecus afarensis* AL 288-1 specimen, allows for many independent estimates, which group together centrally to resemble a normal distribution, to give a clear and conclusive view of the most probable body mass of that individual and to allow easy recognition of outsider values (Fig. 4). In the AL 288-1 case, the peak of the density curve (made up of 54 estimates) is found near 29 kg, and the mean and the median range near 30 kg, allowing for a consistent estimation of body mass roughly around 30 kg, as also found in earlier studies (Jungers 1988, 1990; McHenry 1992). The existence of such a key specimen also allows us to judge empirically which predictors may be more useful and which should be excluded from the estimation process for a taxon for which neither humans nor African apes are completely adequate models (Hartwig-Scherer 1993). For AL 288-1, dimensions of the humerus and radius heads and the elbow joint (McHenry 1992) produce clearly estimates that are too small based on general hominoid allometries as does the size of the sacral body (McHenry 1992). On the other hand, very large estimates result from the circumference of the humerus based on *Homo sapiens* allometry and from the circumference of the tibia based on an African ape allometry (Hartwig-Scherer 1993), while the dentition provides an outsider value (Jungers 1988).

The availability of well-founded body mass estimates based on postcranial predictors allows us to determine which cranial predictors compare in reliability with them for *Australopithecus* and early *Homo* as well. Orbital height was extracted as the cranial variable which produces body mass estimates that are most in line with postcranially generated estimates (Aiello and Wood 1994). This may be supplemented by estimates based on a computer digitizing measurement of the orbital area (Kappelman 1996).

Published body mass estimates based on these cranial dimensions were used together with most relevant postcranially predicted data to extract rounded mean body mass for *Australopithecus* and *Homo* paleopopulations and to calculate in each case the CC with rounded mean brain mass converted from mean cranial capacity (Tables 13 and 14). These brain mass and CC data were then used as the source material for the estimation of life history traits. The evaluation of the reliability of the life history trait predictor equations (Tables 3 and 4) was done empirically based on the PE of the estimation of *Homo sapiens* [PE $=$ (observed $-$ predicted)/predicted $\times$ 100]. Only equations with a PE ≤ 5 % were considered to be useful for the life history estimation in fossil hominids. It must never be forgotten that most of the actually observed primate life history dimensions are subject to enormous variability produced by diverse ecological factors. Any prediction for extinct populations will be subject to this variability too.

Table 15 Estimations of life history data in ***Sahelanthropus***, ***Australopithecus***, and ***Homo*** fossil samples

Taxon	Age at eruption of the first lower molar (years)	Age at sexual maturity, female (years)	Age at first breeding, female (years)	Maximum life span (years)
Gorilla gorilla	–	6.5	9.9	39.3
Pan troglodytes	3.15	9.8	11.5	44.5
Sahelanthropus tchadensis	≥2¼ ≤2½	≥6 ≤8	≥8 ≤10	≥38 ≤ 44
Australopithecus afarensis	2¾	8	10½	45
Australopithecus africanus	3	8½	11	46
Australopithecus boisei	3	9	11½	48
Australopithecus robustus	3	9	11½	49
Homo sp. *habilis*	3¼–3½	9½–10	12–12½	50–51
Homo sp. *rudolfensis*	3¾	11	14	55
Homo sp. *georgicus*	3½	10–10½	13	51–54
Homo sp. *ergaster*	4¼	12	15	57
Homo sp. *erectus*	4½	13	16	60
Archaic *Homo sapiens*, Europe	5	14½	18	65
Homo sapiens, Neanderthals	5¾	16	19½	69
Homo sapiens, observed values	5.4	16.5	19.3	70

Age at eruption of the first lower molar rounded to the next ¼ years, age at sexual maturity and at first breeding rounded to the next ½ year, and maximum life span rounded to the next year. All estimations based on the predictor equations evaluated as useful or very useful (Tables 3 and 4) (mean predicted value, if more than one equation per dimension meets the criteria). The actual observed *Gorilla gorilla*, *Pan troglodytes*, and *Homo sapiens* values are those used for the calculations of the predictor equations [Published by Smith et al. (1995) (molar eruption) and Harvey and Clutton-Brock (1985)]

Nevertheless, the results then obtained confirm, correct, and supplement the earlier [Hemmer (1974) on the age at sexual maturity, at first breeding, and at teeth eruption in *Australopithecus*] and later calculations [Smith and Tompkins (1995) on first permanent molar eruption]. At the same time, they are supported by results of osteobiographic techniques. *Australopithecus* (*afarensis*, *africanus*, *robustus*) and early *Homo* specimens, aged at something like 3–3.5 years on the basis of incisor crowns with little or no root development, had first permanent molars coming into occlusion (Bromage 1990) just as predicted with first lower molar eruption at around 3 years (Table 15). The estimation of life history data confirms the fundamental nature of the australopithecines as progressive apes, not as humans, the early *Australopithecus afarensis* ranging within the modern African ape life history dimensions.

Some important new fossil taxa discovered in the last years are included in the selected samples of life history data presentation (Table 15). The interpretation of the Late Miocene *Sahelanthropus tchadensis* (Brunet et al. 2002), as a taxon possibly related to the hominid stem species near the splitting of chimpanzee and hominid lines (Brunet et al. 2002; Wood 2002), may be supported by the estimation of life history dimensions that indicate an earlier evolutionary stage than all *Australopithecus* and *Homo* paleopopulations on the one hand and then the chimpanzee on the other. The Early Pleistocene (Upper Villafranchian) *Homo* paleopopulation of Dmanisi (Georgia) (*Homo georgicus*; Gabounia et al. 2002) has been interpreted as more closely related to the earliest Pleistocene *habilis* and *rudolfensis* than to the Later Early Pleistocene *ergaster* and *erectus* (Gabunia et al. 2000; Gabounia et al. 2002; Vekua et al. 2002). The life history estimates clearly support this view. The so-called *Homo floresiensis* (Brown et al. 2004) is not integrated here, as this specimen obviously neither represents a new species nor an enigmatic branch of hominid evolution, but is just a classic microcephalic *Homo sapiens* individual, sharing the characteristic syndrome of pygmy size, very small (chimpanzee sized) brain, and considerably aberrant skull allometries (Hemmer 1967). Perhaps this fossil may be interesting as an example of the survival of handicapped people in a Paleolithic culture. It may also help to understand the dysregulation leading to microcephalic development as a possible key to an intrinsic relationship of brain, maturation, and life history.

Conclusion

Relationships between the life cycle and body mass, brain mass, and relative brain size of extant primates can be used to estimate life history parameters of extinct species. Methods to predict the key variables body mass and brain mass from available cranial and postcranial materials of fossil hominoids, especially hominids, are compiled and evaluated. The final approach to life history data estimation in fossil hominoids, especially in fossil hominids, is a story of reliability of the prediction equations to be used. There is a wide variability in the results of body mass estimation obtained on the basis of different species samples used to create the equations, on the basis of different dimensions, and using different line-fitting techniques. The availability of several parts of a single skeleton allows for many independent estimates, which group together centrally to resemble a normal distribution, to give a clear and conclusive view of the most probable body mass of an individual and to allow easy recognition of outsider values and thereby of less useful predictor equations. The use of relative brain size instead of absolute brain mass or cranial capacity in life history correlations eliminates the influence of body size and allows for some further improvement of the correlation coefficient with most life history variables. Convincing estimates of corner stages of life history, the age at eruption of the first lower molar, the age at female sexual maturity, the age at first breeding, and the maximum life span, may be reached by this procedure. This is demonstrated for some key fossils, such data supporting their phylogenetic interpretation resulting from comparative morphological studies.

Genetics and Paleoanthropology

Jonathan Marks

Contents

Abstract

The training and the nature of their data often lead geneticists and paleontologists to conceptualize evolution in different ways. This chapter looks at two basic evolutionary concepts – adaptation and phylogeny – and shows how scholars trained in those fields have utilized them differently. As the works of genetics and paleontology converge, notably with ancient DNA studies, we also find new complexities in homology, relatedness, and speciation.

Introduction

In 1917, the paleontologist William King Gregory framed the apparent conflict between genetics and paleontology in terms of two key issues: adaptation and phylogeny. Prominent geneticists, notably William Bateson and Thomas Hunt Morgan, had argued, first, that adaptation was a teleological mirage and, second,

that phylogenetic inferences should take a back seat to genetic, mechanistic studies. Gregory, on the other hand, challenged his readers to doubt that cetaceans are adapted for swimming or horses for galloping – far from being a mirage, adaptation was a crucial aspect of evolution. Moreover, the talk of studying genetic processes before and instead of evolutionary products was not only crassly self-interested but intellectually pernicious: "…the time for developing phylogenetic conclusions and for revising comparative anatomy and classification is always *now*, as fast as the evidence can be gathered and analyzed" (Gregory 1917, p. 635).

Differing Views of Adaptation

The exchange between the anatomist and geneticists a century ago perhaps surprisingly is still resonant today, having been reframed by molecular biologists in the 1960s. Adaptation is the apparent fit between an organism and its environment. Aristotle believed it was the result of species simply having been built that way. Many centuries later, Darwin argued that it was rather the result of a long-term bias in the survival and reproduction of organisms that differed slightly from the average, in the direction of a better fit. In other words, adaptation is the result of history, rather than of miracle. Nevertheless, there was tension even in the first generation of evolutionary biology in the Victorian era. Herbert Spencer convinced Darwin that his phrase "survival of the fittest" was effectively synonymous with Darwin's own "natural selection." Darwin agreed, in *The Variation of Animals and Plants Under Domestication*: "This preservation, during the battle for life, of varieties which possess any advantage in structure, constitution, or instinct, I have called Natural Selection; and Mr. Herbert Spencer has well expressed the same idea by the Survival of the Fittest" (Darwin 1868, p. 6).

Yet there is a crucial difference between the two phrases. If only Spencer's "fittest" survive, then the descendant populations can be expected to be very fine-tuned to the environment, since they were not merely fitter, but fittest. The pores of the sieve, so to speak, would have been very small. Natural selection, on the other hand, makes no claim as to the relative size of the pores. Under extraordinary circumstances, only the fittest may survive, but it is primarily simply the fitter that survive. That necessarily implies a bit more tolerable unfitness between the organism and its environment than we might expect if only the fittest were surviving.

Through the mid-twentieth century, evolutionary theory had achieved a compromise whereby adaptation was generally seen as a result of the successive accumulation of beneficial genetic mutations (Fisher 1930). In parallel, the population geneticist Sewall Wright (1931) modeled how transient maladaptation might lead to even higher states of adaptation or how alternative states of adaptation could coexist, either from different combinations of alleles or from different alleles of equivalent survival value. This work influenced Dobzhansky's (1937, 1955) ideas that saw evolution as driven not so much by the fixation of superior alleles, but by the production of superior heterozygous genotypes, yielding populations in states of transient or stable polymorphism. Wright's work was also later developed by his student Motoo Kimura, who founded a Japanese school of population genetics, rooted in the study of genetic variations of equivalent selective value, or "neutral mutations" (Kimura 1968, 1983).

Concurrently, the earliest empirical studies of molecular genetic variation were showing that the detectable genetic differences between species were difficult to reconcile with a view of evolution that envisioned the sequential selection of slightly favorable mutations. For a notable example, human diabetes was found to be treatable by injections of insulin derived from a cow or pig pancreas, despite the fact that there are some structural differences among the hormone molecules. Far from being precisely attuned to cow physiology, the bovine insulin molecule works well in humans, which in turn seems to imply a great deal of "slop" in the genetic system. Discoveries such as these suggested empirically that the genetic study of evolution might best proceed in the absence of presuppositions about adaptation, that is to say, as "non-Darwinian evolution" (King and Jukes 1969).

The molecular biologist François Jacob (1977) famously argued that evolution acted not like an engineer, but like a tinkerer, drawing inspiration from the anthropologist Claude Lévi-Strauss's (1962) work on mythology. The storyteller, said Lévi-Strauss, does not compose an optimal story from scratch, but rather cobbles together available motifs and suitable themes and consequently relates a story that is familiar and resonant to its audience. In a similar fashion, argued Jacob, nature works with genetic systems that are passably functional, often redundant but, most of all, suboptimal, and transforms them into other novel systems with those properties. Thus, the metaphor of evolution as an engineer fails before the metaphor of evolution as *bricoleur*, or tinkerer.

This basic difference between the way geneticists and anatomists see adaptation is rooted in the nature of their subjects. Bodies are what adapt. They may do so genetically, over the course of many thousands of years. They also do so developmentally (and irreversibly): The body grows in certain characteristic ways in response to hypoxia or oxygen stress, for example. And they adapt as well physiologically (and reversibly), as in tanning or shivering or callousing under the stimulation of ultraviolet light or cold or abrasion. The point is that the fit between an organism and an environment is an ongoing, dynamic one (Lasker 1969). To survive is to adapt; consequently, if you study bodies, you are necessarily struck by the fit between what an organism looks like and how it lives. To study evolution, then, you are studying the transition from one adapted state to another; consequently, the anatomist focuses on the particular physical differences among species and explains them in terms of the adaptive differences between the species. The similarities require no explanation; one queries not the choice to remain on four legs, made by myriad primate species, but the change to two-legged locomotion. One does not query the retention of body hair in all other primates, but its reduction in one lineage. It is obviously good to be able to speak, but all the species that cannot speak seem to make do. The anatomist thus anticipates stability, which requires no explanation, and interrogates change, which does require an explanation, in terms of Darwinian directional selection.

A genetic comparison, however, works nearly the opposite way. The geneticist anticipates change (due to the constant fixation of new, nearly neutral mutations) and interrogates stability, for it implies constraints on the ubiquitous pressure to change. Consequently, when examining genomes of different species, we will expect to find differences, and we explain sequences that are "too similar" as being constrained by selection, because they are more functionally important than other sections of DNA, where differences are accumulating. This is precisely how the homeobox, a DNA regulatory sequence involved in the early development of the embryo, was discovered in the 1980s. How could anything in the DNA of flies and mice *not* be different (Gehring 1993)?

Consequently, where an anatomist can see adaptation, and inferentially the invisible hand of natural selection, a geneticist can see slop and wiggle room, produced by randomness and historical accident. The patterns they see, the questions they ask, and the explanations they invoke differ correspondingly. The geneticist sees a genome in which most DNA changes are neither good nor bad, mutation is a constant but light pressure on the integrity of the system, and most DNA sequences are consequently expected to change, indeed to degrade, with some degree of regularity. In fact, the regularity is so much of an expectation that the amount of detectable genetic difference between two species is generally taken not as an indication of how differently adapted they have become, but as a chronological meter of how long ago their gene pools separated. When we compare humans and chimpanzees genetically, for example, we see far more readily how similar their genomes are, not how behaviorally, ecologically, demographically, and cognitively different they are (Marks 2002). The DNA sequences of two animals that have recently become differently adapted are expected to be very similar, except for the constant pressure of mutation and for the very rare "really good" mutation that actually translates into a physical benefit. Consequently, if we study the human genome in a comparative context, we are more struck by what we do not see than we are by what we do see. We do not see the weight-bearing feet; there are no feet in the genome. Nor are there tans, nor shivers, nor callouses. There are genes there, not bodies, and it has proven remarkably difficult to match up human genes to human adaptations in any but a small handful of cases. Indeed, it is hard to find adaptation at all reliably in the genome (Graur and Li 2000; Graur et al. 2013).

We have known for a long time that although the DNA (or genotype) somehow encodes the body (or phenotype), the genetic elements do not correspond to the body parts in any simple way. This was known to an earlier generation as the "unit-character" problem (Castle 1930). Bodies adapt, because they actually interact with environments; and genomes do not, at least not directly. Moreover, the units of the genome do not map on to the units of the body. We have genes, units of hereditary instruction; and we have elbows, units of the arm – but we do not have "elbow genes." In fact, long after the completion of the Human Genome Project, we still know remarkably little about the production of a 4-dimensional (space-filling and maturing) body from a 1-dimensional set of instructions (the DNA sequence).

It is hard to overstate the implications of these divergent ways of approaching evolutionary data. Geneticists can see animals that look very similar, but whose genomes are scrambled – for example, gibbons and siamangs. Gibbon cells have 22 pairs of chromosomes, and siamang cells have 25. But that overstates their similarities, for most of the siamang chromosomes cannot even be identified in their gibbon counterparts, because so many rearrangements have arisen between them. (Homologous human and chimpanzee chromosomes, by contrast, can be readily matched up and identified almost perfectly.) Yet a gibbon sperm with 22 chromosomes can fertilize a siamang egg with 25 chromosomes and produce a living hybrid "siabon" (Myers and Shafer 1979). It is hard to avoid the conclusion that shuffling the genes around, while leaving them fairly intact, simply does not interrupt the production of gibbon bodies from their DNA sequences (Godfrey and Marks 1991). It is a system that cries of slop, not of precision.

The best-known cases of human genetic adaptations to environmental pressure are those to malaria, incorporating a range of blood diseases and other genetic variants, including sickle-cell anemia and thalassemia. But human populations more commonly have their own nonadaptive idiosyncrasies, notably elevated risks of other genetic diseases. These are accidental, not adaptive, for example, porphyria variegata among white Dutch South Africans, the genetic legacy of a seventeenth-century settler (Dean 1971).

Along the lines of sickle-cell anemia, the prevalence of Tay-Sachs disease in the gene pool of Ashkenazi Jews has been suggested to be a genetic adaptation. Carriers, in this framework, have been suggested to be more resistant to tuberculosis (Myrianthopoulos and Aronson 1966) or a bit smarter than noncarriers (Cochran et al. 2006). Nevertheless, it is unclear from the population genetics whether selection has operated at all, with over 80 % of the Tay-Sachs alleles in Ashkenazi Jews being identical, suggestive of a strong "founder effect" (Frisch et al. 2004). Indeed, the higher prevalence of the disease in French Canadians and Cajuns is interpreted in precisely this way. Cystic fibrosis, more common in northern Europeans than in other populations, has been associated with resistance to many different diseases, all plausible, but none established (Valles 2010). While the existence of many alleles causing cystic fibrosis is consistent with an inference of selection, the preponderance of a single one – ΔF508, comprising locally between 40 % and 80 % of the CF alleles in Europe – suggests the complex interplay of stochastic and deterministic forces (Bobadilla et al. 2002).

The point is that we ought to be able to distinguish between these alternative explanations, selection (leading to adaptation) or drift (leading to nonadaptation). But usually, even with the finest-grained genetic data, we cannot. Usually the best we can do is to show that some feature of the genome is more uniform and less divergent than we think it ought to be, and speculate about the reason that its patterns of difference might be so unexpected. This is based on mathematical algorithms that often produce high proportions of false-positive results, however.

In some cases, DNA sequences that are too different can be identified, but the adaptive story behind them may be thin and insubstantial. The gene called FOXP2 impairs cognitive linguistic competence when mutated. Three coding-sequence mutations differentiate the human gene from the mouse gene, two of which occurred recently in human evolution, because even the chimpanzee lacks them.

It is certainly a gene involved in language, but is it a language gene? After all, rhesus monkeys and chimpanzees have the same coding sequence, but have quite different vocalizations and cognitive properties. The orangutan has a unique coding-sequence mutation, but no obvious special communicative faculties. And one of the unique human mutations arose in parallel in Carnivora (Enard et al. 2002; Fisher and Scharff 2009). So one can make a strong case for this gene being nebulously "involved" in cognitive linguistic function, but a considerably weaker case for this gene to be a selectively driven master human language gene, as it has often been represented. The problem is that selection occurs on phenotypes, and genotypic data are difficult to translate phenotypically; to think of FOXP2 as a master language gene is to fall into the trap of unit characters.

Students of human evolution have repeatedly pointed out that it is unwise to assume that any particular feature is an adaptation, specifically arisen by natural selection, regardless of how useful it seems today, in the absence of strong supporting evidence (Hooton 1930; Washburn 1963; Gould and Lewontin 1979). Use does not explain origin, since any trait may have multiple uses, which may assume different degrees of importance in particular contexts. This is readily visible in cultural evolution, where (despite the limitations of the analogy to organic evolution) origins are often known and can easily be shown to be different from later primary uses – for example, gunpowder for entertainment and the Internet as a means of decentralizing computers in the event of nuclear attack. The features indeed found new uses, but to attempt to infer their origins from their predominant modern uses would be highly misleading.

Many centuries ago, Aristotle explained adaptation by reference to a saw (Ogle 1882). A saw is made for a particular reason, to cut wood, and that reason is its purpose for existence. It would be ridiculous to imagine making a saw, trying to figure out what to do with it, and then serendipitously discovering that it was useful for cutting wood. But Aristotle's saw was a carefully chosen cultural feature. If he had chosen something as mundane as clothing, whose purposes include warmth, concealing taboo body parts, aesthetics, physical protection, comfort, and the communication of a social identity, his error would have been obvious. Old features have multiple uses; some of them may be new and they may affect our perception of what the feature is primarily used for, which may be quite different from how it got started. The point is that living organisms can be surprisingly good at making do with what they have. We know of ways that adaptive, nonadaptive, and even maladaptive features can evolve genetically. The choice of whether to see crafted machinery in nature, or *bricolage*, that is to say, genetic elements cobbled together into a stable functional state, as modern molecular geneticists do, is neither right nor wrong. They are divergent approaches that can both be reconciled to evidences of the history of life.

We can study what a feature does, and we can study how it got there, but to ask what it is *for* is to decorate the scientific question with metaphysical accessories. To ask what it is for is to assume that there is a reason for it – a deterministic narrative incorporating a selective regime for the feature and a particular optimal solution to a problem. But actually, there may be no reasons for some things, just naturalistic causes and uses, and much random noise; life may be more like clothes than like saws.

Genetics and Phylogeny

Gregory's (1917) other conflict between genetics and paleontology concerned prioritizing evolutionary processes, which geneticists studied, over evolutionary products and patterns, which anatomists studied. In fact, however, biochemical research was already proceeding on issues of systematics and phylogeny. The study of animal relations by the study of their blood reactions was known as "systematic serology," pioneered by G. H. F. Nuttall (1902, 1904). In the context of comparing serological reactions among many vertebrate species, Nuttall found that lemur blood did not react discernibly with human and suggested that lemurs might not really be primates. This conclusion was dismissed by the anatomist Solly Zuckerman (1933), but defended by the serologist Alan Boyden (1942). So what had actually failed – the lemurs or the test? Zuckerman found that tarsiers failed the blood reaction test too, and since they are more obviously primates than lemurs are, it stood to reason that the test was a failure, not the prosimians.

Systematic serology did yield an interesting result, however. According to the work of Christian von Krogh (1937), human and chimpanzee blood seemed more similar to one another than either was to orangutan blood, as had indeed been articulated even earlier by Guyer (1925). This conclusion was reiterated in the most popular mid-century text of physical anthropology: "The weak similarity of the orang to other species suggests a lengthy process of separate development for this animal and its early branching off from the stock of chimpanzee and man" (Hooton 1946, p. 45). When the claim was rearticulated by Morris Goodman a generation later (1963), it came with a call to reclassify the apes on phylogenetic grounds. This claim was roundly rejected, however, as zoological classifications were built from the negotiation between ancestry and adaptation (Gregory 1910; Simpson 1945, 1961; Mayr 1969). Even more senior systematic serologists found the claim more brash than insightful (Hagen 2009). To construct a classification solely based on ancestry was not considered to be a scientifically valuable enterprise, until the popularity of cladistics some years later.

In the mid-1960s Allan Wilson and Vincent Sarich, following on the suggestion by Zuckerkandl and Pauling (1965), were able to quantify the data of systematic serology and found that the amount of serological difference between two species, which was an estimate of the genetic difference, appeared to be related simply to the time since the two species diverged, not related to any adaptive differences between them. In other words, the "immunological distance" between an orangutan and a baboon was very similar to the distance between a human and a baboon, reflecting the time since a common ancestor of human and orangutan diverged from the baboon, and *not* reflecting the fact that humans are brainy, fatty, cooperative, hairless, sweaty, and bipedal. When applied to the divergence of human and chimpanzee, the two species appeared to have separated rather less than 5 million years ago, much more recently than the fossil record seemed to suggest (Sarich and Wilson 1967a, b). The fossil evidence had been over-interpreted, and the two conclusions of Sarich and Wilson have held up remarkably well. Molecular evolution does proceed in a "clocklike" fashion, and the relationships between humans and the African apes are sufficiently close as to suggest that they diverged from one another only in the latest Miocene, perhaps 6–8 million years ago.

This argument was built upon temporal inferences, not directly upon phylogenetic inferences. With the advent of protein and later DNA data, it became possible to reconstruct species divergences from cellular or genetic information, just as one might use dental or anatomical information. The two manners of utilizing these data mirrored the ways that biologists generally were considering phylogeny, using quantitative distance methods in the 1970s (Sokal and Sneath 1963) and qualitative trait distributions in the 1980s (Eldredge and Cracraft 1980) and later combining them.

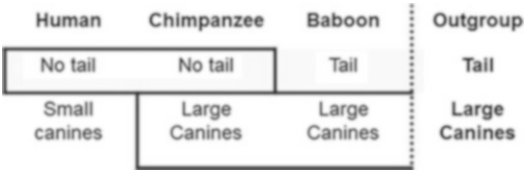
However, it is not the case that molecular-based inferences are necessarily more reliable than anatomically based phylogenies. Genomes and bodies do not map on to one another well, as previously noted, and their evolution, while tracking the same history, nevertheless involves different processes and inferential methods. Organisms cannot be epistemologically reduced to their genomes (despite the old hype on behalf of the Human Genome Project). To use a crude example, the chemistry of DNA statistically compels your genome to match that of a cantaloupe, on the average, once in every four sites randomly, since a DNA sequence is composed of only four bases. Thus, the same DNA sequence measurement that may seem so overwhelming when applied to the chimpanzee (over 98 % base-for-base match to a human) seems underwhelming when applied to the cantaloupe (about 25 % base-for-base match). There is, after all, no significant biological sense in which you could reasonably consider yourself to be one-quarter cantaloupe – except by DNA comparison!

The patterns of human evolution as recorded and analyzed in the genes and as recorded and analyzed in the body obviously have to be similar, since they are recording the same events of biological history. Ideally, genetic and anatomical data ought to provide independent tests of phylogenetic hypotheses; in practice, however, the testing is often one sided. As early as 1964, the paleontologist George Gaylord Simpson identified the problem as "semicircular reasoning": "[A]greement between the two has been taken as the requisite validation of the molecular approach to phylogeny, but nonagreement has been taken as evidence of the greater reliability of the molecular method" (Simpson 1964, p. 1535).

The problem is not that one is better than the other; it is that they each have their own sets of assumptions and methods, and when their products don't match, they both have to bear close scrutiny.

Distance methods have the advantage of being able to incorporate large classes of data, but they reveal patterns of similarity and difference, not evolutionary divergences, and can only be related to evolutionary divergences when assumptions are made about the rates and modes of change. Cladistic methods work by taking two character states distributed across three taxa (say, tail/no-tail

Fig. 1 Distribution of two characters, each with two character states, across three catarrhine taxa and a platyrrhine outgroup



or large canines/small canines across baboons, chimpanzees, and humans) and asking which two of the three taxa are likely to be closest relatives, on the basis of that distribution. By establishing the ancestral condition in an outgroup (large canines and tail in a platyrrhine monkey), it follows that evolution proceeded away from that condition, and thus the relevant changes involved losing the tail in an ancestor of humans and chimps and reducing the canines in an ancestor of humans. Thus, sharing "no-tail" links humans and chimps as close relatives, for the tail was lost in a common ancestor of human and chimp; but sharing "large canines" does *not* link baboon and chimp as close relatives, for the evolutionary event that occurred among the three taxa under consideration was reduction of the canines in the human lineage (Fig. 1). Sharing large canine teeth simply marks two of many lineages in which an evolutionary change did not occur.

We can draw those inferences because our assumption holds that levels of homoplasy (parallel acquisition) are low relative to synapomorphy (sharing features by virtue of recent common ancestry). So if "having four limbs" arose independently in lizards, cows, baboons, and people, or if hairy skin arose independently in cows, baboons, and people, there would be a problem in deriving those animals from a single, unique four-legged ancestor or hairy ancestor, respectively. But it does seem, given the anatomical and fossil data, that growing four limbs or body hair is a sufficiently rare occurrence that it is a good marker of common ancestry and unlikely to have emerged independently in more than one of the lineages in question.

On the other hand, the possession of, say, a G at a random place in the genome is not quite such a rare event. Not only is mutation a constant pressure on the genome, but there are only three things for a G to mutate to (A, T, or C, although more likely A, because it is about the same molecular size as G). What that means is that the theory behind phylogenetic reconstruction necessarily has to be a bit different for DNA sequences than it is for body parts. Generally, that entails quantifying the amount of genomic differences (since there may be millions of them in a genomic comparison) and deciding that the tree that takes the smallest number of inferred mutational changes – the most "parsimonious" tree – is the best tree, that is to say, the one that most accurately encodes the history of the species.

There are important, often uninterrogated, assumptions that go into such comparisons. Often these create problems for understanding homology in the genome, which may be far more problematic that it is anatomically (Thornton and DeSalle 2000).

In addition to nucleotide substitutions, which are most amenable to quantitative treatment, there are insertions and deletions (indels), which are rarer, as well as movable elements, variable number of tandem repeats (VNTRs), and cellular mutational processes by which one DNA sequence can be used as a template to "correct" the DNA sequence adjacent to it. It is not uncommon to find, for example, that a sequence of AAA might be homologous to a sequence of AAAAAAA in another species. Does this represent five one-base indels or one five-base indel? The question is consequential to the extent that one is fundamentally attempting to establish the amount of genetic change that has occurred between the two species in question.

This becomes more problematic with more distant comparisons. The molecular evolutionist is trying to infer the number of evolutionary changes that have occurred from the number of evolutionary differences that are observable. Observing an A in one species and a G in another may lead to the inference of a single mutation having occurred (say, A to G), but there is a small probability that it actually represents two mutations: A to C and then to G. The more distant the relations, or the more rapidly the particular bit of DNA evolves, the greater the likelihood that the number of observed differences underestimates the actual number of evolutionary changes. By making certain assumptions about the rates and modes of evolution, one can computationally adjust for the discrepancy, but this introduces the problem of a gap between observations and evolutionary inferences. There are several ways of correcting that mathematically, but they leave large uncertainties in the phylogenetic results. The problem is an inherent contradiction in the reasoning: One is choosing the most parsimonious solution in a system that is intrinsically unparsimonious. Statistics can never fully compensate for problematic epistemology. Indeed, this can lead to absurdities, such as "the [genomic] difference between galago and human . . . is about 170 %" (Doan 2003), as if two entities could reasonably be judged as 170 % different from one another. Rather, it means that one is inferring two mutations to have occurred, one of which is invisible, nearly every time one sees a single difference between the two DNA sequences.

Other genetic traits, such as the presence or absence of mobile particular genetic elements, may be more useful for cladistic inferences (Xing et al. 2007). In practice, most of the time phylogenetic trees derived from DNA are concordant with those derived from anatomy. But, as Simpson (1964) queried, in the rare cases where they do not concord, how do we know which tree to trust? For example, some genetic studies locate the proboscideans (including elephants) as especially closely related to the carnivores and artiodactyls, among the mammals. Most other analyses place the elephants as no closer to the dogs and cows than are rodents or monkeys (Dolgin 2012). What to believe? In short, we are obliged to view any analysis of genetic data as valuable, but accompanied by its own set of methodological limitations, and sometimes yielding incorrect inferences (Penny 2013). Where genetic analysis had once suggested a very ancient divergence for the modern mammalian orders (Hedges et al. 1996), that inference is now roundly rejected (O'Leary et al. 2013).

Where genetic data once revealed human races (Boyd 1963), now they do not (Madrigal and Barbujani 2007).

Fossil DNA

A suite of osteological traits is used to diagnose Neanderthals and to distinguish them from anatomically modern humans. As anyone who teaches undergraduates can attest, these features are sufficiently subtle that they need to be carefully pointed out to students, for they are actually obvious only to specialists. When genomics researchers were able to sequence the DNA from Neanderthals, they reinforced the conclusion that Neanderthals were subtly, yet distinctively and diagnosably, different from modern humans. Shortly thereafter, geneticists sequenced the DNA from a 50,000-year-old finger bone found in a Siberian cave. The DNA from this site, called Denisova, has yielded several odd results. First, the mitochondrial DNA (mtDNA) seemed to suggest that it was distinct from both human and Neanderthal DNA (Krause et al. 2010). Second, the nuclear or genomic DNA seemed to show it to be a divergent variant of Neanderthal DNA (Reich et al. 2010). Third, the Denisovan genomic DNA seems to have more similarity to the DNA of modern Oceanic peoples, such as New Guineans, than to other modern humans, including Siberians (Reich et al. 2011). And fourth, the DNA from a toe bone in the same stratum is more like the DNA of Neanderthals than like the finger bone (Prüfer et al. 2014).

These results are highly paradoxical and are difficult to make sense of, particularly the geographical problem of imagining Middle Pleistocene Siberians to stand in a special relation of ancestry or kinship to Melanesians of today (Hawks 2013). To make sense of these data, we have to bear in mind that Neanderthals are defined anatomically, but Denisovans are only known genetically (two teeth and a toe bone have since been discovered at the same site, none diagnostic), and their relationship to one another is obscure at best. Based solely on the Denisova sample, it is certainly a reification to imagine a population of "Denisovans" stretching across Asia. Further, the human gene pool is notably depauperate in genetic diversity, being perhaps 5–10× less variable than the gene pools of chimpanzees and gorillas, who are, of course, far less numerous and far less geographically cosmopolitan than humans are (Kaessmann et al. 2001). We do not know precisely how or when our ancestors became so genetically homogeneous, or the nature of the "lost" genetic diversity, or even how that fact might affect the interpretation of these comparisons. Finally, the special genetic similarity of modern humans to 50,000-year-old Siberians may be illusory, since mathematical models have indicated that, in relation to the present human population, the ancestral human gene pool demographically collapses by about 10,000 years ago (Rohde et al. 2004). In other words, anyone alive 10,000 years ago was a common ancestor of all living people or of no living people. The meaning of shared DNA segments between particular modern populations and Siberians of 50,000 years ago would thus be unclear and certainly far removed from ordinary notions of descent and relatedness.

Trees and Rhizomes

The cultural aspects of ancestry, even in evolution, emerge in interesting ways. Since the cessation of gene flow classically implies a new species and a new evolving lineage, it has traditionally been assumed that, above species level, gene pools can only diverge from one another, since they can't get more similar through gene flow or interbreeding. Consequently the most famous image of evolution is as a tree, its branches ever diverging from one another. This produces our classical scientific notions of descent and relatedness, which are those being applied to the relations of Neanderthals, humans, and "Denisovans" with such curious results.

That is an image for macroevolution, however. For microevolution, we must look to another part of the tree – to its root system. Roots, unlike branches, are not always separating from one another. Roots may often fuse with one another and create a connected network whose individual branches may be very difficult to delineate (Arnold 2008). They are like populations of organisms, evolving somewhat separately, but connected by gene flow, and never entirely distinct. Tree-building algorithms may be inadequate to the task of reconstructing relatedness among entities that not are related to one another as branches of a tree (Templeton 1998).

Likewise, the genetic relationships among humans, chimpanzees, and gorillas were known by the 1980s to be (a) very close and (b) phylogenetically ambiguous. To the extent that a pairwise "resolution" of the three-way divergence could be established, it invariably was accompanied by a high degree of uncertainty. Consequently, the relations among the three living genera were often rendered as a three-way split, or "trichotomy." The introduction of DNA sequence analysis finds the human and chimpanzee to be consistently closer than either is to the gorilla, but with a high amount of discordant data (Chen and Li 2001). These are generally interpreted to be the results of (1) parallel mutation (Goidts et al. 2005; Marques-Bonet et al. 2009); (2) complex segregation of ancestral polymorphisms, or incomplete lineage sorting (Prüfer et al. 2012); and (3) backcrossing or trans-specific hybridization (Patterson et al. 2006). Significantly, however, although it can be rendered compatible, this tree is discordant from the tree one would derive from solely anatomical evidence (e.g., Collard and Wood 2000).

Rather than trying to explain away a large amount of discordance, it may be more useful to reconsider the underlying evolutionary model. The paleontological view of speciation that is most compatible with cladistics and punctuated equilibria sees speciation occurring at a geological instant, as an "event." But a consideration of reproductive and population genetics necessitates seeing speciation as a "process."

Another wrinkle in tree making is the fact that anatomies are canalized, that is to say, they are generally uniform in spite of underlying genetic variation. But the underlying genetic variation is there, and may be more difficult to sort, if one looks at the DNA rather than at the body, because there is so much DNA. For example, we find that mammals have hairy skin; we don't find polymorphism, such that some mammals have hairy skin and others have feathers. On the other hand, polymorphism is far more common for genetic characters (A, G, C, and T), and some of it gets sorted into descendant lineages in discordant ways. How much? That depends on the specific genetic regions, the demographic histories of the species, and the genetic structure of the extinct ancestors, which may be simply unknowable.

Here is a relevant, simple scenario for the early ancestry of humans. Suppose an ancient, late Miocene chimpanzee-like population of animals, widely distributed across central Africa, gave rise to a group of gorilla-like creatures in the western part of its range and, around the same time, to a group of humanlike creatures in the eastern part of its range. Then the humanlike creatures expanded their numbers at the expense of the gorilla-like and the remaining chimp-like creatures. Then a few million years later, one tries to compare the genomes of one or two specimens of each and demands to know which two of the three species are the closest relatives. One would probably find a lot of phylogenetic discordance, many features that appear to link humans to the ancestral proto-chimps, and many features that appear to link gorillas to the ancestral proto-chimps. One probably would not find much that appears to link humans specifically to gorillas, because they would not stand in an especially intimate phylogenetic relationship to one another.

And although one could force all three genera into a mold that shows them as having experienced two consecutive binary splits, that would not reflect the actual demographic and phylogenetic history – it would be simply imposing a historical model upon the data, rather than extracting it.

And that is indeed essentially what one finds. Chimpanzees are closely related to humans and also closely related to gorillas, although that latter fact has tended to get lost in simplistic renderings of our phylogenetic history. One recent high-tech genomic study was so committed to binary splits that it depicted gorillas “splitting” at 5.95 million years ago, and then chimps and humans “splitting” from one another at 3.7 million years ago – but also imagined a strain of gorillas returning to sodomize their chimpanzee cousins (Scally et al. 2012). The reason for this creative phylogenetic scenario is that fully 30 % of the DNA sites that could be used to link two of the three genera actually linked the “wrong” two – that is to say, they linked chimpanzees to gorillas, rather than to humans. This is only a problem, though, if one is constrained by the bifurcating tree as a metaphor for the evolution of species. If, instead, we conceive of speciation as a process (rather than as an event), of population differentiation as a microevolutionary demographic phenomenon, and of the bifurcating tree as an inapplicable metaphor, we might come closer to the actual history that is embedded in the genetic data. That history would be one of populations becoming differentiated, but incompletely separated, and significantly long periods of gene flow, without an actual pair of closest relatives and lots of “wrong” data (Fig. 2).

A three-way split or more, in a fragmented habitat, over a short span of geological time, might describe late African ape evolution more accurately. That may be a major source of phylogenetic ambiguity: In other words, trying to force evolution into dichotomous molds, to make bifurcating trees, may be a variant of the old square-peg/round-hole problem (Fig. 3).

Fig. 2 Divergences of human, chimpanzee, and gorilla, with trans-specific introgression, after Scally et al. (2012)

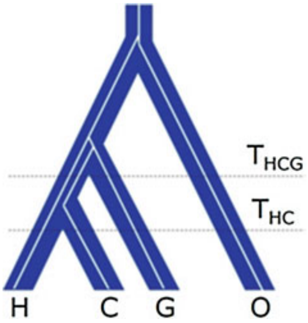


Fig. 3 Relations of human, chimpanzee, and gorilla depicted as incomplete speciation over a significant period of time, incorporating geographic, demographic, and population genetic complexity

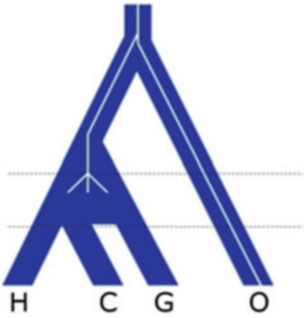

The tree metaphor is of course broadly applicable in understanding the history of life, as Darwin and Haeckel appreciated, but it is breaking down in diverse areas. We now know there to be horizontal exchanges of genetic information between species, with viruses as vectors. Near the root of the tree of life – that is to say, as we try to reconstruct the origin of life and its primary "branches" – it turns out that the branches emerge not from a trunk, but from a web. That is probably because life emerged before species did, and the tree metaphor only really applies to well-formed species.

Consequently, below the species level, the phylogenetic issues are much more vexing. The species that most directly concerns us, *Homo sapiens*, has many formal divisions, but they are culturally based; and it has biological diversity that does not sort us into meaningful natural divisions. The categories "French" or "Latino" or "Lutheran" are meaningful without being natural or biological; and the categories "albino" or "over 6′3″ tall" or "toddler" are natural while only being narrowly meaningful.

One could certainly ask whether the French are genetically more closely related to the English or the Swiss, but of course since those are political categories, the answer one gets will depend crucially on who represents the French, the English, and the Swiss in the study. So it is a foolish question, rather like asking whether architects are genetically more closely related to doctors or to air traffic controllers. The concept of relatedness is here consequently a biocultural concept, not a strictly natural one, because the categories of people being compared are not natural categories of people.

While once again, computers can be programmed to deliver bifurcating trees of human populations based on their genes, as geneticists armed with computers have realized since the 1960s. There are two problems with this. First, one does not need a computer or a geneticist to determine that a Swede and a Dane are more closely related to one another than either is to a Navajo. People from nearby are invariably more similar and more closely related than people from far away. And second, gene flow – the horizontal contact between populations that accompanies their vertical descent – means that the image that most accurately represents the metaphoric structure of the human species is the rhizome or trellis or capillary system (Wolpoff and Caspari 2000). In other words, closely related peoples are not really representable in a treelike fashion, because they have never really diverged, even though they may be statistically slightly different from one another. The classic physical anthropologists of the mid-twentieth century knew that and struggled with representing it (Hooton 1946).

Today, geneticists still sometimes reduce human population histories to a series of splits, as their computer programs often require that simplistic assumption. The interesting question, though, is not whether "for example, the Irish are more closely related to the Spaniards or to the Swedes" (as a respected population genetics website naively queries –http://hsblogs.stanford.edu/morrison/2011/03/10/human-genome-diversity-project-frequently-asked-questions/, accessed 10 October 2013), but rather how to conceptualize and represent the relationships among human populations as microevolutionary, not macroevolutionary and treelike.

Conclusion

Scholars trained in genetics and in anatomy often see evolutionary comparisons in quite different ways. They may differ in the ways that they invoke adaptation, natural selection, and speciation. In fact, even with the finest-grained genetic data, it may be difficult to distinguish the "invisible hand" of selection from the stochasticity of genetic drift. Genetics nevertheless carries a great deal of cultural authority, particularly in the wake of the Human Genome Project, so it is easy to overlook the limitations of genetic comparisons, particularly when the limitations of the fossil record are so familiar. History shows, however, that there are always learning curves and missteps in the application of genetic technologies to questions of human evolution. Anatomical and genetic techniques each have their own set of strengths and weaknesses, which may need to be carefully evaluated when they produce apparently discordant results. One of the more difficult issues in contemporaryevolutionary theory involves the imposition of a dendritic, or treelike, model upon evolutionary histories that may be more complex, thus concealing that complexity.

Acknowledgments This chapter was written during my tenure as a Templeton Fellow at the Notre Dame Institute for Advanced Study, for whose support I am very grateful.

Abstract

Ancient DNA research, defined as the retrieval and analysis of DNA sequences from various degraded biological source materials, has promoted many biological and medical research fields during the last three decades. In particular, historical anthropology and paleoanthropology stand to benefit from direct access to back-dating genetic data, as has already been shown through

applications ranging from individual identification to reconstruction of kinship and marriage patterns to human phylogeny. The DNA-based prerequisites and basic methodological strategies for access to the various types of information are explained, as well as the characteristics of ancient DNA that limit the different approaches. Major restrictions arise from the degradation of ancient DNA down to fragment sizes of only a few hundred base pairs or less. This fact links ancient DNA analysis to either the PCR technique or to Next Generation Sequencing (NGS) approaches, both of which make it possible to deduce genetic information from degraded nucleic acids. Futhermore, ancient DNA extracts regularly consist of only a few intact target sequences, which may harbor sequence deviations due to the degradation process. Both these factors make the analysis vulnerable to the generation of non-authentic results. These pitfalls of ancient DNA analysis are explained and discussed in detail, with reference to the most recent relevant literature. Wherever available, suggestions for strategies to overcome commonly experienced obstacles in ancient DNA analysis are highlighted and evaluated.

Introduction

Today, the analysis of ancient degraded DNA, extracted from forensic evidence samples and archaeological specimens hundreds and thousands of years old, is common practice. It was the coincidence of two events, three decades ago, that enabled this remarkable and comparatively rapid development. On the one hand, there were the first reports on the retrieval of ancient DNA from a specimen of an extinct quagga more than 100 years old (Higuchi et al. 1984) and a specimen of an Egyptian mummy 2,400 years old (Pääbo 1984) that electrified many scholars working on historic and prehistoric biological sample materials. On the other hand, PCR was invented, enabling the enzymatic amplification of short specific DNA sequences (Saiki et al. 1985), which proved to be a true breakthrough to a new level of information for any biological and medical discipline. Only through the PCR technique did ancient DNA research, defined as the retrieval and analysis of degraded DNA sequences from forensic evidence, museum specimens, archaeological finds, fossil remains, and any other degraded traces of DNA, become viable.

In the context of population genetics, it is generally possible with the help of model calculations to deduce former states from present day genetic patterns (Barbujani and Bertorelle 2001; Cann 2001). However, these approaches may suffer from heuristic assumptions that fail to prove their applicability. Biases may be caused by, e.g., unknown bottleneck situations, unknown selective forces, or the unreliability of the molecular clock model. Therefore, direct access to historic and prehistoric genetic patterns has been a desideratum ever since ancient mitochondrial and nuclear DNA (nDNA) proved to be approachable through PCR (Hagelberg et al. 1989; Hummel and Herrmann 1991; Jeffreys et al. 1992; Gill et al. 1994).

In the early days of ancient DNA research, the common aspect for scholars from different scientific backgrounds was the fact that their investigations dealt with a demanding sample material (Herrmann and Hummel 1993). However, within a short time, the field has diversified, and thousands of manuscripts that can claim to be ancient DNA research work have now been published. Among the various scientific contexts are, for example, epidemiology and public health (for reviews see, e.g., Zink et al. 2002; Greenblatt et al. 2003; Drancourt and Raoult 2005), nutritional sciences and food technology (Miraglia et al. 2004; Kato et al. 2005; Teletchea et al. 2005), histopathology and laboratory medicine (Leiva et al. 2003; Mariappan et al. 2005; Paik et al. 2005), forensic sciences (Iwamura et al. 2004; Valenstein and Sirota 2004; Budowle et al. 2005; Carracedo and Sanchez-Diz 2005; Sipoli Marques et al. 2005; Tamaki and Jeffreys 2005), human evolution (Cavalli-Sforza and Feldman 2003; Kaessmann and Pääbo 2004), paleobotany (Gugerli et al. 2005), and historical anthropology (Keyser-Tracqui et al. 2003; Hummel 2003a, Haak et al. 2008). Although the underlying scientific questions have significantly diversified since the beginning of the new millennium, a common theme for discussion remains, namely, the question of the authenticity of ancient DNA results. This discussion was prompted by a list of criteria (Cooper and Poinar 2000) which – according to the authors – ought to be adhered to in any ancient DNA analysis. However, it was obvious that these criteria concerned themselves only with rather general types of difficulties encountered in the analysis of ancient mitochondrial DNA (mtDNA), in particular where only few or single specimens were available, and should be replaced by a sensible experimental design focused on the actual concerns of each individual investigation (Hummel 2003a, b, Gilbert et al. 2005, Bandelt 2005).

At present this long-lasting debate has fallen silent, which is most likely owed to the fact that new technologies involving whole genome sequencing entered the scientific scene a few years ago – technologies which rapidly turned out to be particularly promising for all kinds of evolutionary biology questions (for reviews see, e.g., Huynen et al. 2012, Rizzi et al. 2012, Disotell 2012). In the case of hominid evolution, this means that the effort to answer questions concerning the co-existence of Neanderthals and anatomically modern *Homo sapiens* from comparatively short parts of the mitochondrial genome (Krings et al. 1997, 2000; Ovchinnikov et al. 2000; Caramelli et al. 2003, 2006; Beauval et al. 2005; Lalueza-Fox et al. 2006; Orlando et al. 2006), which earlier had to be PCR-based, will soon be on firmer ground. This will be achieved as soon as complete genomes of Neanderthals (Green et al. 2010), Denisovan (Krause et al. 2010a), and anatomically modern human individuals (Krause et al. 2010b) have become more numerous. Some caution is called for, however: the initial studies of the so-called Neanderthal genome project (Green et al. 2006, Noonan et al. 2006) were soon controversial, since they revealed inconsistencies most likely due to modern human DNA contamination (Wall and Kim 2007). This case demonstrated that a contamination hazard exists whenever the species under investigation is close to or identical to the investigators. Next Generation Sequencing (NGS) technologies are designed not to exponentially amplify short fragments but to sequence the extracted DNA sequences, but this does not eliminate the hazard. Therefore, independent of whether PCR or NGS technologies are being employed, experimenters must take care to adhere to the basic guidelines for contamination prevention during all steps of DNA sample preparation. Beyond that, it seems of course reasonable to adapt the experimental design as closely as possible to the scientific question at hand.

Ancient DNA Sources and Characteristics

Genetic information may be preserved in any type of biomaterial which at some point contained cells. In the average animal cell, basically the entire genetic information characterizing the respective individual is coded in the diploid set of chromosomes and hundreds to thousands of mitochondrial genomes. In plants, the chloroplasts also contribute to the genomic information. However, already in the living organism, cell organelles may suffer from normal processes of partial or complete degradation e.g., the decline of the nucleus in keratinous cells of hair and nails during growth. And whereas in plants, seeds are already designed by nature to preserve genetic information through time, a similar situation is not given in animals. However, even in animals, skeletal materials – such as bone and teeth – harbor cells in a more or less intact state of preservation through the ages. Within those tissues that are characterized by a high content of inorganic material and by high density, several different cell types are DNA sources: osteoblasts, osteoclasts, and osteocytes, which are responsible for bone remodeling and homeostasis, as well as all types of blood cells found in the Haversian canals. Aside from the cells representing the genotype of the organism whose skeletal remains were found, cells of pathogens that at some point entered the blood stream may also be preserved.

Typically, the majority of ancient DNA is degraded down to fragments smaller than 200 base pairs (bp) in length. This can reproducibly be shown through multiplex approaches (Fig. 1) which simultaneously amplify DNA fragments of different lengths ranging from 100 to 350 bp.

The typical signal patterns observable in electropherograms of multiplex amplifications indicate comparatively high yields of DNA fragments smaller than 200 bp and lesser yields of larger fragments. These patterns are not dependent on possibly varying amplification efficiencies of the different primers, or preferential amplification of shorter fragments, but entirely reflect the relative amounts of the target sequences. This should be considered when choosing and optimizing PCR parameters.

DNA Degradation

Whether the genetic information of an organism will be preserved just for days and weeks or for hundreds and thousands of years depends on many chemical and biological factors; these factors are interconnected in a highly complex manner and are, therefore, hardly understood and almost impossible to predict. In light of the cumulative empirical findings of many researchers and a small number of systematic studies (Burger et al. 1999; Caputo et al. 2011), certain factors favoring the

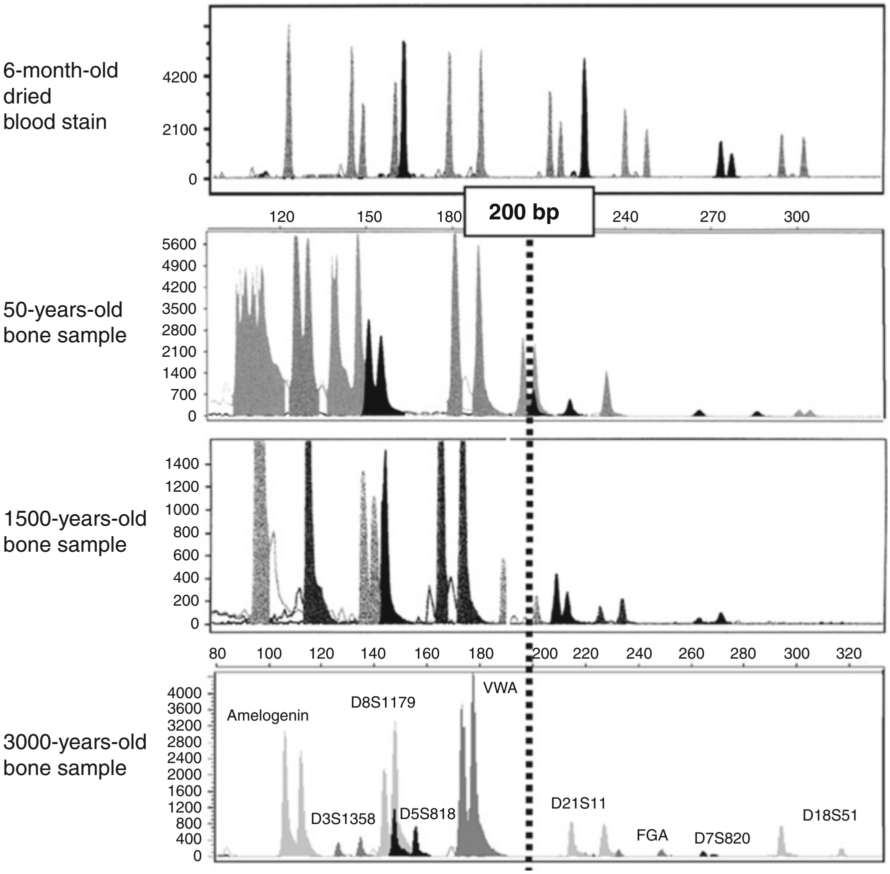

Fig. 1 Electropherograms of 40-cycle STR multiplex amplifications reveal characteristic differences in signal intensities depending on the length of the amplified fragment. The peaks reflect the typical degradation patterns of ancient DNA. While such pattern is only weakly present in 6-month-old dried blood stains, analyses of forensic and archaeological bone specimens reveal the patterns clearly. For the choice of amplification parameters, it may therefore be recommendable to work with varying cycle numbers, in order to enable proper detection and allele determination of amplification products of different lengths

preservation of partly intact DNA seem undisputedly clear: low temperatures and the absence of humidity, accompanied by a neutral or slightly basic pH value. In general, however, only very few studies have investigated the link between characteristics of the sample material and DNA preservation (Ottoni et al. 2009; Sosa et al. 2013).

Immediately after death, favorable conditions are best realized in bones and teeth, due to their high mineral content. When the environment of the decomposing body provides an optimal situation for preservation, the enzymatically driven autolytic decay is soon stopped; at the same time, the subsequent decomposition of remaining tissues through microfauna, bacteria, and fungi is less likely to take place effectively. The result is a mummification of the cells which, once it has occurred, may well last for thousands of years. The DNA within the mummified cells is now protected from the initial, main destructive processes: hydrolysis and the activity of exonucleases and endonucleases. The DNA will still suffer from a certain amount of destruction (e.g., oxidative damage), but much less so than in the course of early decay.

As a matter of fact, the mere preservation of macromorphologically intact skeletal material indicates pH values also favoring DNA preservation. If prehistoric pH values had been as acidic as was claimed in a paper (Lindahl 1993) that was often cited in the context of DNA degradation, the bone mineral of interest would have been turned into water-soluble brushite and thus would no longer have existed.

Further, a more or less intact micromorphology that can be assessed by histological techniques indicates the absence of microorganisms, which is also favorable to DNA preservation.

Finally, empirical findings indicate that preservation of DNA seems to be favored not only by the density of the bony material (compact versus spongeous bone) but also, possibly even more so, by location in a distal anatomical region, i.e., far from the torso with its large amounts of soft tissues. If these findings prove to be reproducible, this would result in enormously helpful guidance in the decision how to sample a skeleton. It would also indicate that the very early autolytic processes of body decay are possibly greatly underestimated as a factor in DNA degradation and long-term DNA preservation.

Information from the Genome

All genetic information in a cell is part of the so-called genome, regardless of its informational value, what type of cell organelle it originates from, and its mode of inheritance. In animal cells, the genome regularly consists of two types of DNA which differ from each other in many respects: chromosomal DNA, also known as nuclear DNA (nDNA), and mitochondrial DNA (mtDNA). While nDNA is organized in the form of densely packed chromosomes that are located within the nucleus of a cell, mtDNA is organized in up to ten identical plasmid-like rings within each mitochondrion of the cell. There is only a single nucleus in each cell, but there are many mitochondria per cell; depending on the intensity of the metabolic turnover of the specific tissue, there may be up to thousands.

Both types of DNA, mitochondrial and nuclear, consist of coding and noncoding regions. The coding regions, also called genes, determine protein synthesis, i.e., they are expressed through the phenotype of an individual, which includes visible features as well as invisible ones (with the latter including, e.g., immunological characteristics). However, until now, it has been the noncoding regions of mtDNA and nDNA that have been the focus of ancient DNA research. This is due to the fact that noncoding regions allow a high degree of sequence and length polymorphism, which are the basis for identifying and reconstructing kinship from the phylogenetic to the genealogical level (Budowle et al. 2003; Pakendorf and Stoneking 2005; Rowold and Herrera 2005).

What Does Mitochondrial DNA Tell Us?

Mitochondrial DNA is most suitable for estimating the time of divergence of two or more populations and, for example, for reconstructing migration patterns. This is due to its nonrecombinant mode of inheritance, which implies that all differences found in the mitochondrial sequence are the result of mutation events thought to occur at a constant rate, set by a "molecular clock." Since the sequence divergence of mtDNA represents a measure of time in this sense, it can also be easily understood why it is in principle possible to investigate present-day populations in order to reconstruct events far back in time. Depending on the choice of sequence that is analyzed, it may be feasible to discriminate individuals on the species or subspecies level, or to assign the maternal lineage to a certain population.

Factors that are thought to perhaps affect the precision of the molecular clock are changes in the amount of natural irradiation, e.g., due to volcanic eruptions, and the number and likelihood of back mutations, particularly at so-called mutational hot spots of the mitochondrial sequence. Other caveats that must be considered in the analysis of ancient mtDNA are the possibility of sequence-specific pseudo-mutations due to DNA degradation, nuclear insertions, and the particular high background of contamination through mtDNA – all of which may threaten the authenticity of the results.

Inheritance of the Mitochondrial Genome

The mitochondrial genome is inherited maternally, lacking recombination and therefore representing a so-called haplotype. This is due to the fact that each female oocyte possesses a full set of mitochondria, whereas a sperm needs just a few to generate energy for movement. For quite some time it was thought that the mitochondria of the sperm did not enter the oocyte at all, but there now is evidence that male mitochondria do enter but are identified as foreign and destroyed by the oocyte. If this latter process is not effective, the result is a so-called heteroplasmy; that is, two different sequences with their particular sequence deviations are represented in an individual's mtDNA. Heteroplasmy may also derive from replication errors during cell duplication, a phenomenon particularly often observed and well known from certain C-stretches of the hypervariable regions (Malik et al. 2002). In ancient DNA analysis, it may be challenging to distinguish between true heteroplasmy and an artifactual signal that may occur due to various reasons.

Sequence Polymorphisms

Mitochondrial DNA reveals a comparatively high density of genes. In humans, as many as 37 genes are represented within the total length of 16,569 bp of a single mtDNA genome. Most of these genes are involved in the metabolic turnover of the cell. Due to the nature of a gene, which codes for the synthesis of proteins, only very limited sequence deviations are possible without disrupting function. However, there are two regions within the human and animal mitochondrial genome, so-called D-loops, which are noncoding, i.e., not involved in protein synthesis. One of the D-loops, spanning almost 1,000 bp at the nomenclatoric origin of the mtDNA, is also known as the *hypervariable region* (HVR), because it reveals comparatively extensive sequence polymorphism. Besides base exchanges, there may also be base deletions and base insertions. The sequences of two randomly chosen individuals from a population differ on average at eight nucleotide positions within the HVR. The experimental design in ancient DNA analysis from prehistoric specimens must consider possible further deviations that may lead to mismatches in the primer binding sites, thereby causing amplification failure.

Cambridge Reference Sequence

In order to describe deviations unambiguously, the international scientific community has agreed to refer to a certain reference sequence. This sequence is either known as the Cambridge reference sequence (CRS) or the Anderson reference sequence. It represents the entire sequence of a human mitochondrial genome – the first that was ever analyzed entirely (Anderson et al. 1981). However, the originally published sequence was revealed to contain some rare polymorphism and sequencing errors (Andrews et al. 1999). The sequence belongs to an individual of haplogroup H, which is the major haplogroup in individuals of European descent. Since in phylogenetic terms this means that it is a comparatively young sequence pattern, there are fairly many nucleotide positions in the human mtDNA that are different from the CRS in all other haplogroups found worldwide. Moreover, the CRS mtDNA reveals two comparatively rare deletions in C-stretch regions of the HVR II, which means that the length of the average human mitochondrial genome is 16,570 or 16,571 bp, respectively.

Haplotypes, Maternal Lineages, and Haplogroups

The actual base sequence in the HVR of an individual is named a haplotype and represents the pattern specific to a maternal lineage. All individuals sharing this haplotype are members of the same maternal lineage, i.e., they are directly related in a genealogical sense, which is most likely when the haplotype is rare or even unique. Alternatively, they are at least closely related in a population genetic sense; that is the situation when many people who are not known to belong to the same genealogical family share this haplotype.

The sequence differences found worldwide in the highly polymorphic HVRs of the mitochondrial genome are divided into more than 20 haplogroups consisting of further subgroups. Those groups are clusters of sequences revealing high intragroup similarities. In general, the assignment of a sequence to a certain haplogroup depends on actual bases that are present at certain key nucleotide positions. While more than 95 % of individuals of European descent can be ascribed to one of seven major haplogroups (Richards et al. 1998), a similar percentage of Native Americans are ascribed to four haplogroups (Torroni et al. 1993). Particularly within highly branched ancient haplogroups, a further division into subgroups is common. These subgroups are defined, in turn, through an additional base pattern at further nucleotide positions that is shared by all representatives of the subgroup. Since ancient DNA is suspected to promote the generation of pseudo-polymorphisms due to degradation artifacts, sequence interpretation and any deductions with respect to phylogeny and migration based on the occurrence of rare or novel haplotypes must proceed with care. At least this holds true for PCR-based analyses; results from NGS analyses seem to be less prone to artifacts of this kind.

Phylogeny and Migration

The age and spread of haplogroups enable us to draw conclusions with respect to questions of human phylogeny and worldwide migration pattern (Soares et al. 2010; Oppenheimer 2012). The age of a haplogroup is basically deduced from its heterogeneity, i.e., the degree of sequence variation within the group. Basically, haplogroups that are more widespread and reveal more different branches and subgroups are older than those that are comparatively homogeneous (Fig. 2) (Brotherton et al. 2013).

In this manner, it is also possible to determine the regional origin and migration patterns of a haplogroup that is represented over a geographically widespread area. At the place or region where representatives of the haplogroup originated, the sequence diversity is expected to be higher than in any other region where the haplogroup is found (Watson et al. 1997).

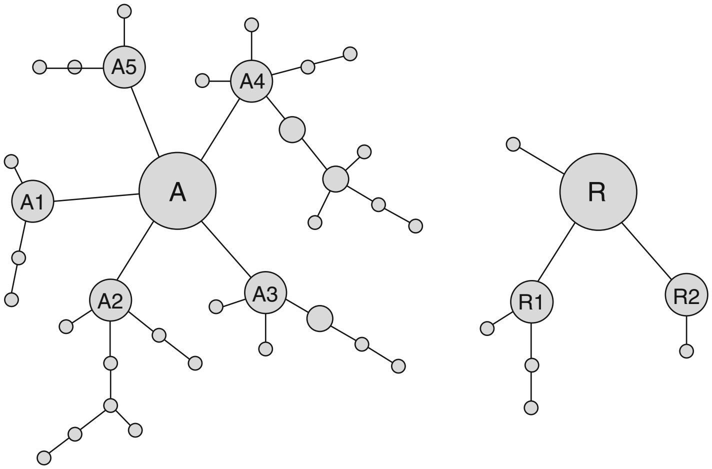

Fig. 2 The degree of heterogeneity of a haplogroup enables us to deduce the age and the geographical origin of the haplogroup. Ancient haplogroups (A) reveal more diversification, including the manifestation of subgroups, while more recent haplogroups (R) are comparatively homogeneous. Each *dot* in this type of depiction represents a single haplotype, each line connecting the *dots* a one-base-pair difference. The sizes of the *dots* correspond to the number of individuals revealing the particular haplotype

What Does Chromosomal DNA Tell Us?

The analysis of chromosomal DNA sequences allows access to the unique genetic pattern of an individual. This pattern is represented by the specific combination of single polymorphic genetic traits, which characterize the individual on a level that enables identification. The number of genetic traits that must be observed to enable identification depends on the degree of polymorphism that is recorded for the observed traits. Most common for identification purposes in the context of, e.g., the reconstruction of genealogical kinship are so-called short tandem repeats (STRs). These markers reveal a comparatively high degree of polymorphism: on average 5–15 alleles of varying lengths are present in a population for each STR. These markers are also suitable for population genetic purposes, although data from many individuals are necessary in order to enable conclusions with respect to phylogeny and migration.

Another target are single nucleotide polymorphisms (SNPs), which are usually biallelic markers revealing a sequence polymorphism at a certain nucleotide position. Unlike STRs, they are not investigated to reconstruct kinship, although this would be possible in principle, but in order to determine, e.g., the immunological properties of an individual. Since the immunological properties of a population are subject to strong selective forces, due to the presence of pathogens influencing morbidity and mortality rates, regional and/or diachronic changes in the allelic frequencies of SNPs allow us to draw conclusions on subjects such as the spread of epidemics or pandemics and everyday living conditions.

In ancient DNA analysis, the accessibility of chromosomal markers is restricted, because of the comparatively low numbers of genomes originally present in a given sample volume. However, optimizations of DNA extraction protocols may compensate for this disadvantage. Once nDNA has been successfully extracted, the analysis of nuclear markers is much less prone to erroneous results due to contamination, given a careful experimental design.

Inheritance of the Chromosomal Genome

The chromosomal genome of an individual represents a novel and unique recombination of its parental organisms. Both parents contribute a so-called haploid set of chromosomes, which are randomly selected from their own diploid chromosomal sets. Therefore, each locus under investigation reveals a maternal and a paternal allele. In the analysis of coding regions, the genotypic level may often be determined without difficulties, but this does not necessarily hold true for the phenotypic level. Gene expression and suppression must be known in order to allow conclusions to be drawn from the genotype of an individual to its phenotype. In ancient DNA analysis, a particular situation that is suspected to be involved in many diseases remains a challenge: the phenomenon of compound heterozygosity. Compound heterozygosity describes a situation where two (or more) mutations, distant from each other on the same chromosome and responsible for a certain morbidity risk, have to be present in a heterozygous state, but one mutation must be located on the maternal, the other on the paternal allele. In ancient DNA with its highly fragmented target sequences, compound heterozygosity cannot be discriminated from a heterozygous state where both markers are mutated either on the maternal or the paternal allele.

Length Polymorphisms and Sequence Polymorphisms

Chromosomal DNA consists of coding and noncoding sequences. From the Human Genome Project it is known that the bulk of DNA is noncoding DNA, sometimes called junk DNA. About 20–30 % of this noncoding DNA consists of tandem repeated sequences. Some of them, the STRs (cf. above), are particularly interesting, since a set of them enables the genetic identification of an individual. Their alleles reveal a length polymorphism which is a function of the number of repetitions of the core unit. In fact, STRs are often identical (e.g., CA_n or $AGAT_n$), but the unique nature of the neighboring sequences enables us to specifically target a certain STR locus. Other than sequence polymorphisms, the variations in fragment length are not suspected to suffer from specific DNA degradation leading to a result that, although reproducible, is still erroneous. However, ancient DNA analysis must be carried out carefully, because STR amplifications also reveal typical so-called stutter artifacts. Since stutter bands occur stochastically, the artifact can be overcome through multiple analyses. Further, the occurrence of this typical artifact can be minimized through optimization of DNA extraction and a sophisticated choice of PCR parameters. Multiple analyses also prevent erroneous homozygous results, which may occur due to so-called allelic dropout when only a small number of intact target sequences are present.

The analysis in ancient DNA of SNPs, which are spread throughout the genome, basically has to deal with the same pitfalls that are suspected to affect the analysis of mitochondrial sequence polymorphisms. Although the risk of non-authentic results due to contamination is much lower than in the analysis of mtDNA and, moreover, can efficiently be monitored through suitable experimental design, the risk of false results due to specific degradation patterns must be considered in the same way as in mtDNA analysis.

Genetic Fingerprints and Identification

The specific allele combinations from analysis sets consisting of 5–15 STRs are also known as genetic fingerprints. As the name implies, the specific allele combinations have an identifying character. Genetic fingerprints are suitable for genealogical kinship reconstruction and for the identification and the assignment of skeletal elements.

In order to be suitable for genetic fingerprinting, the STRs combined in a set have to fulfill two major prerequisites: first, they must be located on different chromosomes in order to avoid haplotypes and to ensure a recombinant mode of inheritance. Second, they must not be linked to genes, in order to avoid the force of possible selective pressure, which would be indicated by strong deviations from a Gaussian allele distribution. If these criteria are fulfilled, the degree to which the value of the so-called matching probability (P_m) can be determined depends on the total number of STRs investigated and on their respective allele frequencies in a given population. The P_m is defined as the likelihood that a second, nonrelated individual reveals the respective allele combination just by chance. Typical P_m values for commercially available and customer-designed sets consisting of 9–15 STRs range from 10^{-10} to 10^{-24}. Of course, these impressive values apply to ideal populations only (panmictic, no selective pressure, etc.). However, the situation in real, possibly even inbred, populations can be simulated approximately when calculating the likelihood that a given set of parents will give birth to two children revealing the same genetic fingerprint. If 10 STRs are observed, the likelihood of this event ranges from 10^{-5} to 10^{-7}. These values indicate that individuals from an inbred population with a limited gene pool are still sufficiently discriminated.

The identifying properties of genetic fingerprints also indicate that STR typing is more suitable than any other strategy to the identification of possible contaminations from a wide spectrum of sources.

Reconstructing Kinship and Paternity Testing

The reconstruction of kinship in a (pre-)historic skeletal series requires a different strategy than if it were a living population. Whereas in a living population, the ages of the individuals help to discriminate a priori the parental generation from the potential descendants, this information is not available in a skeletal series. It is theoretically possible to find the skeletal remains of an individual who died in early adulthood but who fathered an individual who reached the senile age class. Although individuals who are related vertically at first degree share an allele for each observed genetic marker, it is not feasible to deduce from genetic markers who is the parent and who is the offspring. Therefore, infant individuals who have not reached reproductive age play a key role in the reconstruction of kinship (Fig. 3).

If two individuals – infant and adult – are found to share exactly one allele at each observed locus, a paternity (or maternity) test can be constructed as a deficiency case (i.e., one parent missing). If the allelic genotype of a second adult individual of the opposite sex suggests that this may be the missing parent, the likelihood of parentage for both assumed parents is calculated in the manner of two independent trio cases (Brenner and Morris 1990; Chakraborty and Jin 1993). This means that, e.g., in a first step the child-mother dyad is taken as fixed, enabling us to calculate the paternity index for the male individual, and then, in an analogous way, the maternity index is calculated.

In particular, if individuals from a larger burial site are investigated with respect to their genealogical relatedness, the initial search for possible child-parent dyads is facilitated by mitochondrial and Y-chromosomal haplotyping. This strategy permits the assignment of individuals to family lineages. Analogous to autosomal genetic fingerprinting, Y-haplotyping is carried out through STR allele amplifications at the Y-chromosome.

Immunogenetics and Epidemiology: Towards Phenotype

The analysis of nuclear genetic markers that are known to be linked to the immunological properties of an individual is comparatively new. Usually these properties are represented through SNPs, which cause changes in the amino acid

mt J	---

Fig. 3 If two individuals are found to share an allele for each STR system (=STR 1, STR 2, and STR 3), they may be parent and child. (**a**) From the STR typing and the Y-Haplotype (=Y1), it cannot yet be deduced who is the father and who is the son. (**b**) A morphological or histological age determination not only solves this problem but, moreover, enables us to predict the genotype of the mother, who is still missing. (**c**) If a female individual is found who reveals the respective STR alleles as well as the appropriate mitochondrial haplotype (=mt J), she can be assumed to be the mother. The likelihood of parentage can now be calculated based on the allele frequencies of the investigated STRs

chain, thereby changing protein synthesis. Many of these markers are directly linked to the susceptibility of an individual to bacterial and viral infections and, as a consequence, to his or her susceptibility to certain cancerous growths. These markers are also of interest in the context of heterogeneous reactions of individuals to pharmacological treatments.

The allele frequencies of such markers exhibit considerable deviations worldwide, suggesting that they are subject to selective pressures, as well as genetic drift and bottleneck situations. It is striking that particular European populations or individuals of European descent often reveal allele distributions that deviate strongly from all other human populations worldwide. Not surprisingly, this is interpreted as a result of Europe's unique epidemiological history during the past centuries, and to the selective forces that are linked to epidemic and pandemic infectious disease events (Scott and Duncan 2001).

Many theories and hypotheses that claim to be able to name a particular historic epidemic event bearing responsibility for a certain uncommon allelic distribution are based on more or less thorough linkage studies carried out on modern populations (Stephens et al. 1998; Rannala and Bertorelle 2001). However, some must be classified as mere speculations (Altschuler 2000). In any case, all such studies lack direct proof. Therefore, direct access to historic and prehistoric genotypes will be invaluable. In particular, skeletal series that are known to be linked to epidemics or pandemics can play an important role as genetic archives. However, since the burial sites of skeletal series are often mass graves (e.g., of plague victims), the significant possibility of ancient cross-contaminations due to the special conditions of burials must be borne in mind when setting up the experimental design.

Authenticity

The authenticity of a PCR-based ancient DNA analysis result must be tested in two ways: first, one must exclude the possibility that contamination is responsible for the outcome of the analysis; and second, it must be proved that the result indeed represents the authentic genotype of the (pre-)historic individual sampled, and is not biased due to DNA degradation or analytic artifacts. Depending on the scientific question, the actual sequence that is under investigation, the number of individuals investigated, and, finally, the origin of the samples, proving the authenticity of ancient DNA analysis results may require unique experimental design strategies.

A comparison of PCR with NGS technology suggests that proofs of authenticity may be much more easily brought about for the latter, since NGS technology is not based on exponential amplification. However, if contaminating sequences are of the same species and outnumber the endogenous sequences of the investigated sample, the common strategy to identify contaminating sequences by their minor number is prone to fail with NGS as well.

Contaminations

Since ancient samples usually consist of very few DNA targets, even minor contaminations may cause false results, at least in PCR-based analyses. Contaminations may originate from various sources and may reveal various degrees of degradation. Therefore, there is no simple strategy for how to avoid and detect them.

Basically, we can distinguish four ways in which contaminations may enter the analysis:

- Cross-contamination between the ancient sample materials
- Contaminations of the sample material by former or current investigators

- Contaminations in laboratory reagents and disposable material
- Contaminations of either sample materials or reagents by amplification product carryover from earlier PCR analyses

Cross-Contamination

Cross-contamination of the sample material may in principle happen at any time. However, two situations in particular are suspected to increase the risk of sample cross-contamination: burials at a non-individual site (e.g., mass graves) and the laboratory processing of the samples (e.g., transfer of sample material through unclean laboratory devices or handling mistakes). Cross-contaminations are particularly hard to detect, since all sequences involved would reveal a degradation pattern as expected for ancient DNA. Further, their occurrence cannot be detected through use of the classical set of negative control samples, which includes no-template controls and extraction blanks. A possible cross-contamination event must therefore be detectable in the analysis result itself, as would be the case, for example, if amplification of DNA fragments showed up three or four alleles instead of one or two, clearly indicate the presence of material from a second individual.

Contamination by Investigators

This type of contamination may in principle happen anytime a sample is handled. What the contamination pattern looks like depends on the amount of contaminating cells and on whether the contamination happened recently or decades ago. It may vary from comparatively easily identified, fully intact DNA profiles to a hard-to-recognize type which resembles the typical cross-contamination. As in the case of cross-contaminations, negative control sample sets are not suitable for monitoring this type of contamination. Again, the analysis result itself must reveal indications of the problem. Unlike the case of a classical cross-contamination, contamination by an investigator is most likely (but not necessarily) a superficial one. Therefore, thorough removal of the sample surfaces minimizes the risk of this contamination type. This applies to both PCR-based analyses and NGS-based analyses.

Contaminations in Laboratory Reagents and Disposables

Laboratory reagents may already be contaminated when purchased (e.g., primers, reaction mixes), or they may become contaminated through handling by the investigators. In both cases, the degradation patterns of the contaminating DNA and the amount of contamination may vary strongly. If premixed PCR reaction components are used, particularly bovine serum albumine (BSA), which is a component enhancing the *Taq* DNA polymerase, may cause severe problems, due to residues of bovine DNA. This can be shown through cytochrome *b* sequence amplifications that indicate the species. However, this type of contamination can be monitored through suitable sets of negative controls. Ideally, the analysis result from the sample material itself will also provide information indicating possible contaminations.

The situation is completely different where disposable laboratory materials are concerned. PCR reaction tubes turn out to be regularly contaminated right from the production process, with human DNA prevailing (Hauswirth 1994; Schmidt et al. 1995, Gill et al. 2010), although DNA of bovine origin has also been found (Hummel 2003a). The percentage of reaction tubes that suffer from contamination varies depending on the supplier, the brand, and the actual lot. The vast majority of these contaminations are of mitochondrial origin. The reason for this lies in the nature of the production process, which very often includes autoclaving steps. If there are just a few reaction tubes containing cellular contaminations at this stage of the manufacturing process, these cells will become lysated by the autoclaving temperature and, as a result, hundreds of thousands of mitochondrial genomes are distributed more or less uniformly. Typically, the number of tubes that show specific signals of mtDNA after 40 amplification cycles varies between 20 % and 80 % if fragments of less than about 150 bp are amplified. The reason why autoclaving is still part of the manufacturing process, even in so-called high-performance (e.g., "PCR clean," "DNA free") and high-price brands, is that this allows producers to guarantee that they are staying below a certificated level of DNA for each tube in the lot, without having to invest in the cost of a truly DNA-free manufacturing process.

All kinds of treatments applied to amplification reaction tubes (e.g., UV treatment, bleaching, rinsing with and without ultrasonic treatment) are inefficient in the sense that they cannot overcome the problem. At best, a more or less sizable reduction in the number of tubes revealing contaminations can be achieved. Since the contaminating mtDNA in reaction tubes consists of just a few targets per tube, and because it is typically just as degraded as ancient DNA, it is usually not even noticed in modern DNA applications. For ancient mtDNA applications, however, which may also start from just a few intact targets, it is the most severe contamination problem of all, since it is unavoidable and may be hard to detect. Typical sets of two or three negative controls in a PCR set-up are uninformative, simply due to their small number. If they stay blank, this is not necessarily representative of the tubes in which the samples were processed. Then again, if the negative controls do reveal signals, these cannot either be assumed to apply to the tubes in which the samples were analyzed.

A way to improve the situation in mtDNA analysis is through numerous reproductions of the analysis, ideally amplifying only fragment lengths considerably greater than 200 bp. In order not to have to discard too many analysis results which reveal ambiguous signal patterns and are suspected of deriving from a mixture of precontaminating tube DNA and ancient sample DNA, researchers are advised to carry out checks with at least 30 negative controls each time a new lot of reaction tubes is in use.

Further, depending on the target sequence and the number of samples intended to be analyzed, it may be preferable to choose a NGS-based approach for the analysis of mitochondrial genomes.

Another option, although extremely laborious and inconvenient, is the use of glass tubes for PCR amplifications, manufactured from high-temperature-resistant glass. These can be reused after being tempered for a couple of hours at 600 °C at least. It may be necessary to elongate the steps of the amplification cycle for efficient reactions carried out in glass tubes; however, if tempering has been done these reactions will be positively free of contamination.

Contamination Through Product Carryover from Earlier PCR

Product carryover, although a disaster if it occurs, is not a particular threat to ancient DNA analysis. This is because it is comparatively easy to detect and easy to prevent if some basic rules are strictly followed. Product carryover would block the easy and low-cycle amplificability of a certain marker, while other markers of similar fragment length would not yet be amplifiable. Also, as long as more than a single sample is contaminated (which is extremely likely in the case of product carryover), a series of samples would reveal identical analysis results if, e.g., an extraction buffer was contaminated. If product carryover found its way into a PCR reagent, the entire set of negative controls would all show signals, thus reacting in exactly the same way the samples do.

A method to efficiently prevent product carryover contaminations, which is practiced in almost every ancient DNA laboratory, is the strict separation of pre- and post-PCR areas, including strict dedication of all equipment, such as pipettes, centrifuges, deep freezers, and so on.

Degradation and Analysis Artifacts

Ancient DNA results may also be non-authentic due to degradation and analysis artifacts. That is to say, even though it was the authentic ancient DNA that was analyzed, the original sequential order of bases or the original fragment lengths may have been biased. If one counted up the number of publications that report degradation phenomena, one might believe that non-authenticity due to degradation artifacts is a critical point almost exclusively with respect to the base sequence, rather than fragment length (Gilbert et al. 2003; Binladen et al. 2006). This reporting pattern, however, most likely reflects a bias as well, since only very few ancient DNA working groups have long-standing experience with fragment length analysis, which is mainly linked to autosomal and Y-chromosomal STR typing (Keyser-Tracqui et al. 2003; Hummel et al. 2000; Hummel 2003a). The bulk of the discussion of typical fragment length artifacts is taking place in the forensic sciences context, where STR typing of degraded DNA samples has been routine for many years (Butler 2005).

Non-authenticity of the Base Sequence

Base degradation is one of the major reasons why the analysis even of authentic ancient DNA may nevertheless reveal erroneous results. The most numerously occurring artifacts are reported to be the transition C > T/G > A and A > G/T > C; others have been observed much more rarely or not at all (C > G/G > C), at least not in nDNA (Binladen et al. 2006). Another important aspect is the question of whether mtDNA and nDNA are affected to the same extent in this. Although nDNA is thought less likely to suffer from degradation artifacts, owing to the protection the nucleic acid sequence receives from histones, an investigation by Binladen et al. (2006) could not detect major differences. Due to its obvious relevance, the C > T transition is most often discussed with respect to the cause of the artifact (cytosine may degrade to an apparent uracil, of which the complementary base is an adenine, which in turn would lead to the introduction of a thymine during the next elongation phase), its likelihood of occurrence, and available methods to overcome the artifact. One common strategy to prevent the amplification of DNA fragments containing apparent uracils is an enzymatic treatment of the DNA extract prior to amplification (Haak et al. 2005). This strategy claims to destroy all DNA fragments that contain uracil-like degraded cytosines – but it may result in total destruction of all potential target DNA sequences for the intended amplification. Further, transitions others than the C > T transition are not affected by this approach.

Therefore, other strategies to overcome generation of non-authentic PCR-based results due to DNA degradation would be preferable, if available. These could be valid strategies for DNA repair or unbalanced initial PCR employing a single primer that results in a linear amplification of one strand only. Furthermore, in cases where the sample itself does not represent a mixture of DNA from different individuals, a combination of cloning strategies – which often suffer from too few clones being analyzed (Bower et al. 2005) – and direct sequencing could be informative.

Another way to monitor and evaluate analysis results that are suspected to be biased by degradation artifacts could be the implementation of cross-checks through amplification of further loci which basically provide the same information, or at least parts of this information. In the case of mtDNA haplotyping, a suitable option might be the analysis of SNP markers on the mtDNA genome, which are known to be linked to haplogroups (Torroni et al. 1992). In the case of nuclear SNPs, the targeted loci for cross-checks might be additional polymorphic sites which are also known to be linked to certain genes, although possibly with a lower linkage rate.

Non-authenticity of Fragment Lengths

Typical fragment length artifacts are so-called stutter bands and allelic dropout. Both of these kinds of artifacts, which occur in the course of STR amplifications, are well known and extensively discussed in the ancient DNA and forensic literature (Butler 2005; Hummel 2003a). Unlike sequence degradation, allelic dropout and stutter artifacts are not a direct degradation phenomenon but rather an indirect one, since the likelihood that they prevail in the data, leading to an inaccurate analysis, depends on the number of intact targets that are submitted to amplification. Although a reduced number of intact targets is characteristic for ancient DNA extracts, these artifacts can occur during amplification of modern intact DNA as well, if there are few targets throughout the first amplification cycles. But even when very few targets are submitted to the reaction, the generation of fragment length artifacts constitutes a stochastic event that is – except in the case of base degradation – not due to alterations of the target but an amplification artifact. Consequently, mere multiple repetition of the analysis will allow the experimenter to evaluate the authenticity of a result, on the basis of reproducibility. Moreover, strategies are available to lower the tendency of the amplification reaction to create these types of artifacts. The most obvious one is to optimize the DNA extraction, in order to increase the number of targets. This helps in particular to avoid allelic dropout. In order to minimize the generation of stutter bands, relaxation of the elongation temperature has proved to be successful. However, since *Taq* DNA polymerase activity is damped down by a lowering of the temperature, the time allowed for elongation should be correspondingly prolonged.

In any case, the fact that STR amplifications are regularly carried out in multiplex approaches means that cross-checks are already built into the analysis, since the evaluation of authenticity is clearly simplified when based on the patterns of the entire set of amplified loci (Fig. 4).

Basic Strategies in Experimental Design

There is no general strategy for how to carry out an ancient DNA analysis; the most decisive factors for the experimental set-up are the sample material itself, the underlying scientific question, and the properties of the DNA sequence in focus. These factors should be considered in making decisions on the need for pre-experiments (e.g., checks for contamination rates in amplification tubes), the choice of appropriate sets of negative and positive controls, and the design of the amplification and analysis strategy. The final experimental strategy ideally combines two aims: maximizing the likelihood of a result, and maximizing the likelihood that this result can positively be proved to be authentic (Fig. 4).

Authentic results are achieved through entirely different strategies depending on, for example, whether human or animal DNA is under investigation, whether a single sample or series of samples are analyzed, whether mitochondrial or nDNA is the target, and whether base sequences or fragment lengths carry the desired information. It is unhelpful, therefore, to focus overly on abstract criteria for ancient DNA analysis per se, such as have been proposed in the past (Cooper and Poinar 2000). These broad criteria do not refer to any specifics of the research context; an experimental design following these published regulations would only directly meet the demands of the analysis of human mitochondrial HVR DNA from a single sample. But even for that particular scenario, observance of these standard criteria and regulations would not, in itself, result in full proof of authenticity, since cross-contaminations and contaminations by earlier investigators could never be ruled out.

Sample Preparation

The preparation of ancient DNA samples has to be devoted to two main objectives:

- Removal of possible contaminations
- Optimal preparation of the sample for DNA extraction and further amplification reactions in subsequent analytic procedures

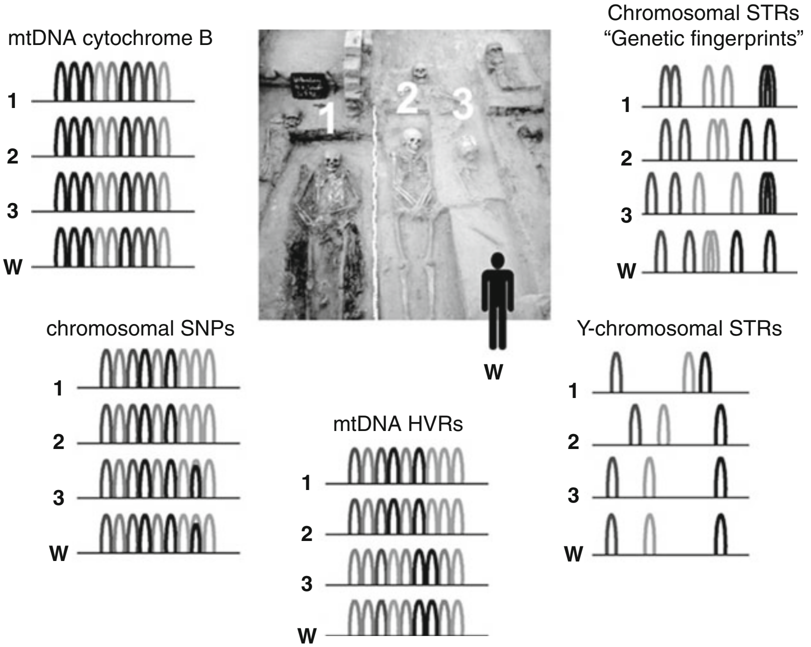

Fig. 4 Authentification power of genetic fingerprinting. The analysis strategy should consider the number of individuals that are being investigated, the number of people who worked on the sample material, and the underlying scientific question, including the sequence of interest, as shown in this example. Given that three skeletons (1–3) are being investigated and one person (W) is working on the samples, the analysis of different genetic markers may potentially have different results, therefore requiring different sets of control samples and cross-experiments. If, for example, a cytochrome *b* fragment is amplified, all samples, including ones from W, would reveal the same base sequence, and there would be no proof that W did not contaminate the samples. If a nuclear SNP is investigated, e.g., samples 1 and 2 may be homozygous, but sample 3 and W heterozygous. Again, the results do not exclude the possibility that samples 1 and 2 are cross-contaminated, or that W may have contaminated sample 3. The same may hold true for the investigation of mitochondrial HVRs. In the given example, analysis of the Y-chromosomal haplotypes can exclude cross-contamination between samples 1 and 2. However, only the investigation of autosomal STRs that represent individual genetic fingerprints enables us to prove that no contamination events are responsible for the ancient DNA results. While in all analyses except genetic fingerprinting, even extended sets of negative controls are not able to rule out direct contamination of sample 3 by W, autosomal STR typing would not even need a negative control to exclude contamination events such as carryover, contamination through laboratory personnel, and cross-contamination

Where superficial contaminations are concerned – i.e., most commonly, contaminations by present or former investigators – the first objective is achieved by thoroughly removing the surface of the sample. Further possible contaminations may also be removed by rinsing the sample surface with a strong oxidative reagent such as, e.g., household bleach. How the second objective is achieved depends on the sample material. However, in general, any increase in surface area through, e.g., crushing of the sample prior to chemical treatment has proven to improve later analysis results. Further, depending on the actually chosen extraction technique, factors such as centrifugation forces and the relation of the sample material to incubation buffers and reagents are also crucial. We recommend the development of a standard protocol with respect to given sample properties before valuable sample material is processed.

Optimizing DNA Extraction

Optimal DNA extraction protocols are obviously a highly individual matter, dependent as they are on the exact biochemical state and composition of the sample material. However, standard protocols offer a valuable starting point. The basic aims of standard protocols are:

- Maximization of the amount of DNA
- Minimization of DNA degradation in the course of the extraction procedure
- Minimization of the presence of inhibiting substance residues in the DNA extract

At present, these goals seem best achieved through automated DNA extraction using magnetic beads, although the amount of DNA in the extracts lags somewhat behind what, e.g., phenol-chloroform procedures will accomplish. However, the advantage of the DNA extracts being practically free of inhibitors, as can be demonstrated through real-time PCR, may outbalance the possible loss of DNA. In case the sample material consists of very little intact target DNA and only minor amounts of inhibiting components, other strategies – such as retention of the DNA on silica-coated membranes – may be superior with respect to optimum DNA yield. In general, the use of any type of automation at this stage of sample processing is advantageous, since it minimizes the handling of the samples and thus the risk of contamination.

Amplification Strategies

In general, there is no optimal amplification strategy; instead, the basic experimental design must be deduced from the scientific question and the sequence of interest (Fig. 4). However, there are some key aspects which should be considered.

First, the more the investigated sequence is characterized by polymorphisms, the fewer cross-checking experiments are necessary. Ideally, the amplification result will be “individual,” in the sense of identifying a unique individual, since this enables an efficient check for any type of possible contamination. If, for example, nuclear STR typing is carried out, only a minimum of negative controls are necessary. It may be advisable to deviate from classical amplification parameters, in particular concerning the elongation temperature. A decrease in the elongation temperature, or a shift to a two-step PCR consisting of a denaturing phase and a prolonged annealing phase only, may result in a remarkable decrease in stutter bands, which are an STR-specific amplification artifact encountered even in modern DNA amplifications (cf. above).

Second, in case the markers of interest are polymorphic but far from revealing results specific to an individual – as would hold for any type of biallelic SNPs or short deletions – the aim should be to link the analytic result to another, identifying one. This is realized through integration of the primers for, e.g., the SNP amplification to a multiplex assay designed for STR-based genetic fingerprinting. This approach has proved successful for nuclear markers (Bramanti et al. 2000; Fulge 2005; Hummel et al. 2005; Puder 2005), although it may require multistage fragment-length determinations, including a restriction fragment length polymorphism (RFLP) analysis. If the biallelic markers are multiplexed with nuclear STRs, only a minimum set of negative controls is necessary.

Third, the amplification of mtDNA, which is regularly represented in ancient DNA extracts by a greater number of intact targets, is hard to carry out using the same technique as for the amplification of nDNA. One reason lies in the different demands for optimal amplification cycles. Moreover, the aim of mtDNA investigations is usually a sequence analysis, which, for technical reasons, cannot be combined with STR typing. We highly recommend re-checks of contamination rates for different brands of amplification tubes. These should be carried out with the primers that are intended for the actual investigation, using high cycle numbers (>45). If possible, the primers should reveal sensible mismatches against species that are not intended to be amplified but are suspected to be present as contaminating targets (humans, working animals). It may be necessary to launch experiments that check sequence-specific degradation patterns. Although mtDNA is regularly represented by more targets than chromosomal DNA in an ancient DNA extract, the particulars of the situation with respect to degradation pattern and contaminations in amplification tubes will significantly complicate the proof of authenticity. Due to these facts and the non-individual character of the polymorphisms, even in the HVRs of mtDNA well-adapted sets of control samples are necessary, since typical sets of negative controls do not apply.

Enhancing Specificity and Sensitivity of a PCR

The specificity of a PCR, i.e., the exclusive amplification of the targeted sequence, is a basic prerequisite for success, in particular if the subsequent analysis includes a so-called Taq cycle sequencing reaction. PCR specificity can be challenging to achieve. However, any other type of ancient DNA analysis also suffers from the generation of unspecific by-products. This holds true even if no confusion with the target sequences is possible, due to, e.g., entirely different fragment lengths. The reason is that sensitivity decreases as soon as by-products, including primer dimers, are generated in the amplification reaction, since the resources for the reaction (Taq polymerase activity, primers, dNTPs, and buffer) may be exhausted sooner in this competitive situation. The consequence is that the target product, though present, may not reach the detection limit, because the by-reaction has already led to attainment of the amplification plateau.

Although optimization of the annealing temperature positively influences the specificity of the amplification reaction, even this step may not result in a highly specific reaction, or may compromise the reaction efficiency, if the annealing temperature approaches the melting temperature of the primers.

A particularly effective means to increase the specificity and therefore the sensitivity of the reaction is given through primer design. The criteria for a good primer design can be summarized as follows.

- Primers should reveal a minimum length of 20 bp if possible, preferably 23–30 bp.
- The binding energy of the 5′-end must increase that of the 3′-end in order to enable elongation only if the entire primer matches.
- 3′-end primer dimers and hairpin formation must be strictly avoided, since these formations will be elongated and cause generation of by-products.
- Primers should not reveal possible mismatches to the intended target caused by sequence polymorphism within at least 3 bp from the 3′-end.

If a primer pair meets these criteria, the amplification product increases considerably in quality and quantity. Further improvement in reaction efficiency can then be achieved through a step-wise decrease of the annealing temperature. Especially if only a very few intact DNA targets have been extracted from the sample material, this measure is likely to constitute the difference between an amplification failure, on the one hand, and a weak amplification product ready for further analysis, on the other.

Conclusion

Over the last two decades ancient DNA analysis has evolved from an enthusiastically publicized yet controversial technique revealing some spectacular results to a sound practice generating biological data that help explain the past. For quite some time this positive development was not foreseeable, because the high sensitivity of the PCR technique is both its greatest advantage and its most significant drawback. The discussion was dominated by the question how to fully authenticate PCR results and how to optimize experimental strategies.

We are now witnessing the early stages of the development of Next Generation Sequencing (NGS) approaches, which give access to entire genome information. The coming years will prove how well these very promising alternatives to PCR will come through their own teething troubles.

Modeling the Past: The Primatological Approach

Robert W. Sussman and Donna Hart

Contents

Abstract

Many models have been developed to depict the behavior and ecology of our earliest relatives. However, the Man the Hunter model has been the most widely accepted way of viewing human evolution. This theory gained ground in the mid-twentieth century and has been recycled ever since under various guises in the scientific and popular literature. Many human traits, such as bipedalism, monogamy, territoriality, tool use, technological invention, male aggression, group living, and sociality, are often linked to this perspective. Although theories and associations of human aggressive hunters abound, they are rarely based

on the two evidentiary approaches that shed light on early hominin ecology and behavior – living primate models and the fossil record. Here, an outline is given on a methodology of reconstructing early human behavior by using both the fossil record and extant primate ecology and behavior. Data on early human fossils, on modern primates living in similar habitats to our earliest ancestors, and on rates of predation both today and in the distant past indicate that Man the Hunted may be a more accurate descriptor of our earliest relatives. Here evidence for the Man the Hunted theory, some of the behavioral patterns that were needed to protect our earliest ancestors from predation, and how this may lead to a new perspective on certain aspects of human nature are described.

Introduction

In the early 1950s, the once thought missing link to our earliest human ancestor, the Piltdown Man, was confirmed to be fake (Weiner et al. 1953), and most scientists were beginning to believe that australopithecines were indeed hominins. It was becoming obvious that our earliest ancestors were small brained and probably more like nonhuman primates than modern humans in much of their behavior and ecology. The idea that there was a major "gap" between ancestral humans and nonhuman primates was no longer considered tenable, and the continuity between ourselves and our ancestors was emphasized. This stimulated scientists to begin thinking about using the living primates as potential models for the reconstruction of the behavior and ecology of our earliest ancestors. One of the first attempts at this was by Bartholomew and Birdsell (1953). Since then many models have been proposed.

Reconstructing the Behavior of the Earliest Hominins

There has been much debate about which type of model might best be employed in reconstructing the evolution of early human behavior. Tooby and DeVore (1987) describe three different types of models that have been used. The first is what they designate as referential models. In this case, a living species is used as a literal model for an extinct taxon (the referent species). For example, chimpanzees often are seen as the best referents for early hominins (e.g., Stanford 1999; McGrew 2010). Second is the conceptual model, in which a mosaic of morphological or behavioral traits is seen as a broad analogue to reconstruct early hominin species. As an example, one living primate species might be used to reconstruct the diet and another to reconstruct the social behavior. Tooby and DeVore label the third type as strategic modeling. In this case, it is assumed that species in the past were subject to the same fundamental evolutionary laws and ecological forces as species are today. Although no present species will correspond precisely to any past species, the principles that produced the characteristics of living species will correspond exactly to the principles that produced the characteristics of the species living long ago.

There has been a great deal of disagreement as to which of these three types of models might produce the best results (e.g., Kinzey 1987; Potts 1999; Stanford 1999; Jolly 2001; Elton 2006; Sayers and Lovejoy 2008; McGrew 2010; Van Reybrouck 2012) or even whether labeling these models diminishes their usefulness. In the model presented in this paper, there is an attempt to use all of the above in what is considered a logical and appropriate manner but always taking into account whether any particular aspect of our model is inconsistent with the evidence presented in the fossil record. This brings up the question of what kinds of evidence should be used, and in what manner, in attempts to reconstruct the behavior and ecology of our earliest ancestors.

The most important evidence is the fossils of hominins themselves; careful examination and understanding of the actual skeletal remains of the creatures. However, useful evidence would also include other fossil materials (such as tools or footprints) left by our earliest relatives and clues about the environment in which they lived (such as fauna, flora, or water sources). While fossils provide the most important data for an accurate reconstruction, many current theories of early hominin behavior fall short in their critical examination of the fossil evidence. In fact, they are often virtually fossil-free.

Besides fossils, any other types of secondary evidence used in reconstructions are less reliable but, nonetheless, offer insights. These should be ranked in the following order as far as applicability to reconstructing early hominin lifestyles: (1) The behavior of nonhuman primates living under similar ecological conditions to those of our earliest ancestors (e.g., Elton 2006). It is best to keep timing in mind with this approach. Forests change and so do climates and so do species, as well. Hominins likely began as edge species (living in a mixture of wetlands and grasslands) but moved out onto more open savanna about 2.5 mya (Reed and Eck 1997; Reed 2008). (2) The behavior of our genetically closest primate relatives, such as chimpanzees, bonobos, and gorillas (e.g., McGrew 2010). However, lumping all the great apes together as one analogue when they are so diverse is dangerous, although some characteristics may remain conservative within a taxonomic group. For example, monogamous pair bonds among the lesser apes or gibbons, or upright posture among the apes, might be considered phylogenetically conservative traits shared by all or most species within a taxon. (3) Characteristics shared by certain (or all) modern humans that might also be similar to our earliest ancestors. Modern foragers, however, are just as advanced and evolved within their own culture and environment as any Western urban dwellers. The least confident recommendation is (4) the behavior of other animal species that might be living under similar conditions or that share some aspects of the lifestyle of early humans, such as certain carnivore or prey species. However, a cat is still a carnivore even if it eats some grass; early hominins included a few vertebrates in their diet, but they cannot legitimately be compared to obligate meat eaters.

In using any of these types of secondary evidence, it is necessary to be extremely careful (because in many cases, similar-looking behaviors are not the same); we can end up comparing apples with oranges, lions with hominins, or even strangler figs with purse snatchers! (Yes, the analogy of invasive rainforest fig trees to purse snatching muggers has been made in the sociobiological literature (Ghiglieri 1999).) Obviously, words with loaded meaning for humans – war, rape, murder, infanticide, and genocide to name a few – must be used with extreme caution when referring to the activities of nonhuman species. In this regard Jonathan Marks (2002, p. 104) warns against "... a science of metaphorical, not of biological, connections."

One cannot, therefore, necessarily impute correlation between human ancestors and data based on extant carnivores, modern human foragers, or great apes. For example, even the concept of hunting in chimps and humans is quite different. Present-day human hunters purposely search for animal prey, but chimpanzees do not: "Instead, they forage for plant foods and eat prey animals opportunistically in the course of looking for fruits and leaves" (Stanford 1999, p. 48). Furthermore, reconstructions must always be compatible with the actual fossil data – the fossils are real but the models we construct are hypothetical and must constantly be tested and reconfirmed. Lastly, when attempting to construct models of our early ancestors' behavior, it is necessary to be precise about timing (Tattersall 2010). If one says our earliest human ancestors (those who lived seven million years ago) behaved in a certain way, we cannot use fossil evidence from two million years ago, nor can we confuse those creatures from two million years ago with those who existed 500,000 years ago. As a case in point about timing, one poses the question: Could hunting have occurred without tools? The first evidence of stone tools comes from around 2.6 million years ago (Semaw 2000). The earliest hominin fossils, however, date from almost seven million years ago (Brunet et al. 2002), at least four million years before the first stone tools.

The most popular and currently accepted theory of human evolution is the Man the Hunter model. In seeking to understand why this model is so captivating and easily adopted as the paradigm for human evolution, it is instructive to remember that the first hominin fossils to be found in the nineteenth century were European specimens well under 100,000 years in age, and most of the artifacts found with them were finely crafted spearpoints or tools used for slaughtering animals. The Paleolithic cave paintings in Europe also depicted a metaphysical connection between humans and hunting. Nevertheless, when one looks at the fossil evidence, hunting came quite late to our human family. Interpretations of hominin behavior, therefore, should be conservative and cautious, as stated by Klein (1999, p. 306): "... the mere presence of animal bones at archaeological sites does not prove that hominins were killing animals or even necessarily exploiting meat. Indeed, as was the case in the earlier South African sites, the hominin remains themselves may have been the meal refuse of large carnivores."

The diversity of large carnivores was extensive in the African paleo-past. Many groups of carnivores that are now extinct (such as the huge short-faced bear, *Agriotherium africanum*) may have preyed on hominins between 6 and 3.5 mya. Then at about 3.5 million years, new carnivores evolved to join the previous groups, meaning that as many as eight to ten different species of saber-toothed cats, false saber-toothed cats, conical-toothed cats, giant hyenas, and large wolflike canids were roaming the same African sites where hominin fossils have been found (Treves and Palmqvist 2007) (see Fig. 1).

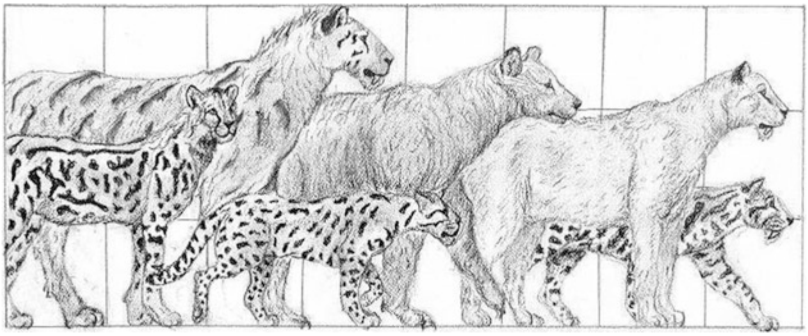

Fig. 1 (*Large Plio-Pleistocene predators*). Relative sizes of fossil cats and bears from the time period 8.5 million to 1 million years ago. Each *square* approximates 20 in. on each side; three *squares* equals 5 ft. From *left* to *right*: giant cheetah (*Acinonyx*); saber-toothed cat (*Machairodus*); ancestral leopard (*Paramachairodus*); bear (*Indarctos*); saber-toothed cat (*Homotherium*); saber-toothed cat (*Megantereon*) (C. Rudloff, redrawn from Turner 1997)

The transition to hunting as a dominant way of life does not appear to have started until after the appearance of our own genus, *Homo*, and may not have even begun with the earliest members of our genus. *Homo erectus* has been given credit in the past for existing as a large animal hunter, and dates as far back as 1.75 mya have been hypothesized for such a lifestyle. But if you take a conservative approach to this subject – looking only at facts and fossils and not imaginative speculations – the first indications of hunting are amazingly recent. In fact, according to some paleontologists, the first unequivocal evidence of large-scale, systematic hunting by humans is available from paleoarchaeological sites possibly only 60,000–80,000 years old (Binford 1992; Klein 1999). The earliest hominin fossils are 6–7 million years before the first factual evidence of systematic human hunting.

No hard archaeological evidence, in other words no fossil evidence of tools designed for hunting, exists earlier in time than a finely shaped wooden spear excavated at Schöningen, Germany, dated at approximately 400,000 years of age (Dennell 1997; Thieme 1997). The famous Torralba and Ambrona sites in Spain, dated at 500,000 years ago, contain huge numbers of large mammal bones. They were thought to represent unquestionable evidence of megafauna killed by Pleistocene hunters. Now these two sites are being reconsidered in light of better archaeological analysis. Elephant bones at these sites could just as likely represent natural deaths or carnivore kills as they do the remains of human hunting (Klein 1999; Klein et al. 2007). Further, no hominins were large-scale hunters before they had the use of fire (because of their dentition and alimentary tract, points we will elucidate below), although insects, small vertebrates, lizards, and birds likely were eaten opportunistically. The best evidence for the controlled use of fire appears approximately 800,000 years ago in Israel (Goren-Inbar et al. 2004). Klein (1999, p. 160) states: “The assumption of consistent hunting has been challenged, especially by archaeologists who argue that the evidence does not prove the hunting hypothesis . . . it is crucial to remember (although not as exciting) that probably the majority of calories [came] from gathering plant foods."

Dentition and Diet

Whether *Homo erectus* or any other hominin before 800,000 years ago regularly hunted or scavenged may be a moot question. Hunting would only be an activity undertaken if early hunters could eat what they killed, and to eat raw meat, it is necessary to have teeth capable of masticating and processing meat.

Obviously, Man the Hunter models of human evolution assume that a significant portion of our earliest ancestors' diets must have come from killing and eating meat from relatively large mammals. By comparing the characteristics of the dental and jaw morphology of various living primates with those of fossils, one can make inferences about the diets of early hominins. Teaford and Ungar (2000, see also, Ungar 2011) carried out just such a comparison in an attempt to reconstruct the early hominin diet. Using such features as tooth size, tooth shape, enamel structure, dental microwear, and jaw biomechanics, they found that the earliest humans had a unique combination of dental characteristics and a diet different from modern apes or modern humans. Ungar (2004) extended this analysis by examining occlusal slope and relief of the lower molars.

Australopithecus afarensis is characterized by jawbones that are thick, with relatively small incisors and canines in relation to molars. The molars, by comparison with other primates, are huge, flat, and blunt, show less slope and relief, and lack the long shearing crests necessary to mince flesh. *A. afarensis* also had larger front molars than back molars. The dental enamel is thick, and microwear on the teeth is a mosaic of gorilla-like fine wear striations (indicating leaf eating) and baboon-like pits and microflakes (indicating fruits, seeds, and tubers in the diet). These definitive pieces of evidence coming from fossil dentition all point away from meat eating.

In studies of mid- to large-sized primates, such as macaques, baboons, chimpanzees, and modern human foragers, in which the amount of time spent obtaining animal protein has been quantified, the total is very low, usually making up less than 5 % of time spent feeding (Garber 1987; Sussman 1999). Given these facts, it is hypothesized that early humans were able to exploit a wide range of dietary resources, including hard, brittle foods (tough fruits, nuts, seeds, and pods) as well as soft, weak foods (ripe fruits, young leaves and herbs, flowers, and buds). They may also have been able to eat abrasive objects, including gritty plant parts, such as grass seeds, roots, rhizomes, and underground tubers. As stated by Teaford and Ungar (2000, p. 13508–13509): "this ability to eat both hard and soft foods, plus abrasive and nonabrasive foods, would have left early hominins particularly well suited for life in a variety of habitats, ranging from gallery forest to open savanna." Dental morphology indicates that the earliest hominins would have had difficulty breaking down tough pliant plant foods, such as soft, fibrous seed coats and the veins and stems of mature leaves, although these foods may have been eaten occasionally (Ungar 2011). Interestingly, Teaford and Ungar (2000) stress that another tough pliant food that our early ancestors would have had difficulty processing was meat! They state (2000, p. 13509): “the early hominids were not dentally preadapted to eat meat – they simply did not have the sharp, reciprocally concave shearing blades necessary to retain and cut such foods.”

Both modern chimpanzees and humans have an alimentary track that is neither specialized for eating leaves nor animal protein but instead is more generalized, similar to the majority of primates who are omnivorous and eat a mixture of food types (Chivers and Hladik 1980, 1984; Martin et al. 1985; Martin 1990; Price et al. 2012). Modern humans, especially in Western cultures, think of themselves as meat eaters. For Americans and a whole spectrum of other cultures, meat defines that ephemeral status of wealth and ease for which we strive. Because they, themselves, were rooted in these cultural stereotypes, anthropologists egregiously misnamed the modern forager cultures as hunters and gatherers and initially emphasized only the contributions of male hunters. Nevertheless, more than two-thirds of modern-day foragers’ food comes from women gathering plant foods and, in the process, opportunistically capturing small mammals and reptiles. Less than one-third of the diet (the meat portion brought in through dedicated hunting by men) serves to supplement their foraged nutritional intake, except in cold climates or where fishing is prevalent (Marlowe 2005). Yet, meat can have significance far beyond its mathematical contribution.

Modern dietary concerns in industrial societies revolve around the amounts of both fat and red meat that are consumed by the average person. By the latter portion of the twentieth century, there was a full-blown red alert from the medical community warning that meat should be ingested in limited quantities. “Diseases of affluence” caused by high-protein, high-fat diets include raised cholesterol levels, high blood pressure, heart disease, stroke, breast cancer, colon cancer, and diabetes – all correlated to a diet exorbitantly rich in red meat. With colon cancer, in particular, startling data are available: Daily red-meat eaters are two and one-half times more likely to develop this cancer as are people adhering to a mostly vegetarian diet (Willett et al. 1990). T. Colin Campbell, who compared Chinese rural villagers (eating a traditional diet low in meat) and their urban compatriots (eating more meat), states: “We’re basically a vegetarian species and should be eating a wide variety of plant foods and minimizing our intake of animal foods” (Brody 1990, p. C2). In his Chinese study, Campbell even found that individuals following a low-fat, low-meat diet suffered less anemia and osteoporosis (conditions commonly associated with food *low* in animal products) than individuals higher on the meat-consuming ladder (Campbell and Campbell 2005).

Lastly, no hominins hunted on a large scale before the advent of controlled fire. Again, early humans just did not have the dentition nor the digestive tract of a carnivore. Our anatomy and physiology did not particularly suit us for digesting meat until the mastery of cooking solved the problem. Our intestinal tract is short, and predigestion by fire had to precede any major meat eating (although humans still require certain nutrients that are not obtainable from a meat diet). As stated above, the oldest known hearths with good evidence for controlled use of fire are around 800,000 years old.

Locomotion

By far the best known of early australopithecine species is *A. afarensis*, with many fossil remains dating from between 3.7 and 2.9 mya and possibly as far back as 5 mya. Collections have yielded close to 400 specimens in many East African sites (Kimbel and Delezene 2009). Specimens include the famous Lucy (dated at 3.2 mya), which is the most complete adult skeleton from this time period, and fossil footprints from Laetoli, Tanzania, ash deposits (dated at 3.6 mya). Furthermore, most hypotheses concerning human evolution position *A. afarensis* as a possible pivotal species from which all other later hominins, including *Homo*, evolved (Fleagle 1999; Tattersall 2010; Conroy and Pontzer 2012). Given the above facts, *A. afarensis* is seen as a good species to examine when attempting to reconstruct the appearance and behavior of one of our early human ancestors.

Terrestrial bipedalism is a hallmark of the whole fossil hominin family. This mode of locomotion can be inferred from fossil specimens nearly seven million years old (Galik et al. 2004). It appeared long before the vast growth of open grasslands in Africa and before the expansion of human brain size and recognizable stone tool making. Besides the fossilized bones, direct evidence of early bipedalism comes from the footprints at Laetoli where two hominins were walking together in soft ash almost 4 mya (see Fig. 2) – prints that are remarkably like modern human footprints (White 1980; Tuttle 1985; Day 1985; Feibel et al. 1996). However, looking at the skeletal evidence, the locomotion of these early hominins was not exactly identical to ours. In fact *A. afarensis* seems to have been a primate equally at home in the trees or on the ground indicated by a number of factors. First, the limb proportions are different from anatomically modern humans. The arms are similar in proportion to modern humans, but the legs are relatively much shorter (i.e., more apelike), and this implies the use of suspensory locomotion in the trees (Kimbel et al. 1994). Other aspects of the upper limbs also retain a number of features indicating an ability to move easily in the trees. The wrist and hand bones are quite chimpanzee-like; the finger and toe bones are slender and curved as in apes, giving *A. afarensis* grasping capabilities compatible with suspensory behaviors; the toe bones are relatively longer and more curved than in *Homo sapiens*. The joints of the hands and feet and the overall proportions of the foot bones all reinforce evidence for climbing adaptations and arboreal activity. Nevertheless, the relative thumb length of these hominins is closer to that of modern humans than it is to chimpanzees (Susman et al. 1984; Smith 1995; Corkern 1997; Alba et al. 2003; Conroy and Pontzer 2012).

The pelvis and lower limbs of *A. afarensis* are a mixture of humanlike and apelike features. These anatomical components and the shorter leg length indicate that *A. afarensis* may have used less energy while walking, whereas transition speeds from walking to running may have been lower with slower running speeds

Fig. 2 (*Australopithecines walking at Laetoli*). Reconstruction of two *Australopithecus afarensis*; successes or added advantages of bipedal locomotion were simply by-products of a preadaptation to upright posture (Used by permission of American Museum of Natural History, AMNH Library 4936[2])

than modern longer-legged humans (Steudel-Numbers 2003; but see Conroy and Pontzer 2012). Overall, Rak (1991, p. 283) summarizes: “Although clearly bipedal and highly terrestrial, Lucy evidently achieved this mode of locomotion through a solution of her own.”

A propensity to question the efficiency of primate locomotion is not new to anthropology. It was also once thought that the diminutive Neotropical marmosets and tamarins were restricted in their ability to move on small branches because they have claws instead of the standard primate nails on their hands and feet. However, it has subsequently been proven that claws do not restrict callitrichid locomotion on thin branches; indeed, their claws also enable them to utilize large trunks much like squirrels do. Claws allow them to be more versatile, and they can use a wider range of arboreal habitats than most other new-world monkeys (Garber 1984; Sussman and Kinzey 1984). It appears that the combination of skeletal characteristics found in *A. afarensis* enabled these hominins to be versatile in a similar way. They were able to use the ground and the trees equally and successfully for a very long time. These early hominins were well adapted to their environment and not in the least inhibited by switching back and forth from bipedalism on the ground to quadrupedalism in the trees.

There are at least seven different “models” that have been proposed to account for bipedalism as a hominin adaptive strategy: the *tool using and making* model

(Darwin 1874; Washburn 1960; Sinclair et al. 1986), the *carrying* model (Hewes 1961, 1964; Lovejoy 1981), the *vigilance* model (Dart and Craig 1959; Day 1986), the *heat dissipation* model (Wheeler 1984, 1991), the *energy efficiency* model (Rodman and McHenry 1980; Steudel 1994), the *display* model (Jablonski and Chaplin 1993), and the *foraging* model (Hunt 1994). Each one of the models has some merit, but none of the theories seem to be a strong enough catalyst for switching to a new mode of locomotion. Furthermore, there are many other primates who spend most of their time on the ground, and none of these has developed bipedalism, even though each of the theorized advantages presumably also would have accrued to them.

It is difficult to separate consequence from causation. It cannot be concluded that any of the seven suggested models caused hominins to become bipedal. None of the theories may be causative; instead, all the theoretical "causes" may be results of a primate preadaptation to being bipedal. All the great apes are preadapted to bipedality. When our ancestors came down from the trees, bipedalism was possible because of body proportions and suspensory adaptations – longer arms and shorter legs that allow gibbons, orangutans, and chimpanzees to hang from trees and forage for fruit. All apes have varying capacities for erect posture and are able to walk upright for short periods of time; bonobos, especially, will stride upright with humanlike posture. However, when the earliest hominins began using the ground for a major portion of their activities, their body proportions were more suited for bipedalism than for other forms of locomotion, i.e., quadrupedalism or knuckle-walking. As stated by Fleagle (1999, p. 528):

> Although it is important to see early hominins in the context of hominin evolution, it is equally important to realize that in the same way that they were not little people, they also were not just bipedal chimps, but the beginning of a new radiation of very different hominoids. It is this uniqueness that makes reconstructing hominid origins so difficult. Thus although early hominids and their bipedal adaptations are certainly derived from an African apelike ancestry, human bipedalism is morphologically and physiologically different from the occasional facultative bipedal behaviors occasionally seen in other primates. The morphological and behavioral commitment to bipedalism that characterized early hominids suggests unique ecological and historical circumstances as well.

Some species of primates are intrinsically adapted to edge habitats and, therefore, are able to take advantage of changing environments. It is hypothesized that the earliest hominins were edge species (see below) and that they exploited a terrestrial habitat due to a developing mosaic environment that included climate change. Rather than seeking the factors that *caused* early human ancestors to become bipedal, it is proposed that it was a preadaptation that already existed and it was efficient in a new habitat; the successes or added advantages were simply a by-product. Tattersall (2003) has arrived at a similar conclusion regarding bipedality.

Besides bipedalism and limb use, there are also solid conjectures of what our earliest ancestors were like as far as body build, height, weight, and brain capacity.

From various *A. afarensis* specimens and by examining the skeleton of Lucy, it seems there was a considerable size difference between males and females

(Kimbel and Delezene 2009). Although the canines of both sexes were relatively small and not at all dagger-like, they were larger and longer in the males than in the females. The range of body size for *A. afarensis* individuals is estimated to be 30–45 kg (Fleagle 1999). The height of the adults has been estimated at 1.0–1.7 m (Klein 1999). Lucy stood slightly over 1 m tall and weighed around 30 kg (she was definitely on the small side) (Conroy and Pontzer 2012). If these weights are accurate, we can extrapolate that female *A. afarensis* were the size of male baboons and males were the size of female chimpanzees.

The cranial capacity of these hominins is estimated at 400–500 cm^3 – about the size of a modern chimpanzee but twice as large as Miocene fossil apes. On average, australopithecines and modern chimpanzees have brains that are two to three times larger than similarly sized mammals, whereas modern human brain size is six to seven times larger than other mammals.

Looking at brain size relative to body size, using the encephalization quotient as a measurement, the brain of *A. afarensis* was slightly larger in relation to its body than that of modern chimpanzees ($EQ = 2.4$ for *A. afarensis* versus 2.0 for chimpanzees) (Boaz 1997). Thus, our ancestors were mid- to relatively large-sized primates with brains that were slightly larger than any nonhuman primate, although only a fraction bigger than modern chimpanzees.

There are many speculations about the external appearance of australopithecines. Johanson and Edey (1981) added some details to the portrait of a living Lucy. They pictured her and her kin as small but extremely powerful – their bones were robust for their size, and they were probably heavily muscled. Their arms were longer in proportion to their legs and trunk than modern humans. Their hands were like ours, but their fingers were curled more when in a relaxed position. Heads were more apelike than humanlike with prognathic jaws and no chin. They may have possessed more body hair in comparison to modern humans. While hair color cannot be guessed at from the fossil remains nor can the color of the skin, living in tropical Africa, *A. afarensis* likely possessed darkly pigmented skin with sun-protective melanin (Jablonski 2012).

Habitat of Our Earliest Ancestor

Although many early theories on the evolution of our earliest ancestors stress the importance of arid, savanna environments, these do not seem to be the primary habitats, according to the fossil record, until after 2 mya. The African climate was becoming more arid in the time between 12 and 5 mya, and equatorial forests were undoubtedly shrinking (Segalen et al. 2007; Conroy and Pontzer 2012). However, the process that led to this climatic phenomenon also greatly enlarged areas of transitional zones between forest and adjacent savanna. Closed woodland forests were still widespread in East Africa 3.5 mya, whereas the proportion of dry shrub to grassland habitats began to increase around 1.8 mya (deMenocal and Bloemendal 1995; Shackleton 1995).

It is in these transitional zones that the behavioral and anatomical changes were initiated in early hominin evolution. The flora and fauna remains that are found in association with fossil hominins of this time period indicate a mixed, mosaic environment – mosaic in the sense that it was ecologically diverse and subject to seasonal and yearly changes in vegetation (Potts 1996; Wolpoff 1998; Kimbel and Delezene 2009; Conroy and Pontzer 2012). These environments were wetter than those in which later fossil hominins are found, and most fossil sites of this early time period contained some type of water source, such as rivers and lakes (White et al. 1994; WoldeGabriel et al. 1994, 2001; Reed 1997, 2008; Campisano and Feibel 2007; Wrangham et al. 2009). For example, at Hadar, Ethiopia, the mammalian faunal remains suggest that a lake existed, surrounded by marshy environments fed by rivers flowing off the Ethiopian escarpment; thus, a mosaic of habitats existed at Hadar consisting of closed and open woodland, bushland, and grassland (Reed 2008; Conroy and Pontzer 2012).

The earliest hominins appear to be associated with variegated fringe environments or edges between forest and grassland. These habitats usually contain animal and plant species of both the forest and the grassland, as well as species unique to the borders between the two. The species adapted to these transitional habitats are often referred to as *edge* species or *eurytopic* (i.e., adapted to a wide range of habitats) (Kimbel and Delezene 2009). During these earliest times, it appears that hominins began to take advantage of the growing fringe environments, lessening competition with their sibling ape species which were better adapted to exploit the dense forest and thus partitioning the niche occupied by the parent species of both apes and hominins into two narrower and less overlapping adaptive zones (Klein 1999; LeeThorp et al. 2003; Reed 2008; Conroy and Pontzer 2012). From available evidence it is speculated that our early ancestors were able to exploit a great variety of food resources but were mainly fruit eaters, probably supplementing this diet with some young leaves and other plant parts, social insects, and a small amount of opportunistically captured small vertebrate prey – lizards, small snakes, birds, and mammals. They also likely exploited some freshwater and marine resources (Cunnane and Stewart 2010).

Several other species of primates are intrinsically adapted to edge habitats and are also able to take advantage of changing environments. Ring-tailed lemurs in Madagascar, African baboons, and vervet monkeys, some Asian macaques and langurs, and, to some extent, Neotropical capuchin monkeys are nonhuman primate examples. These, not coincidentally, are some of the most common and numerous of all living primates other than humans. The macaque genus, for example, has the widest geographical distribution of any nonhuman primate in Asia. Many macaque species in Asia are endangered, but the ones that have the healthiest populations (e.g., long-tailed macaques, *Macaca fascicularis*, and rhesus macaques, *M. mulatta*) are edge adapted.

Certain ecological niches may breed certain behavioral repertoires. Many argue that the closer the DNA comparison, the more similar the behaviors between two related species. In that case, chimps and bonobos might be the best prototype for early human ancestors. However, if ecology is paramount, then chimps and bonobos may be less suitable prototypes (although some traits between these close relatives may still be important and phylogenetically conservative) and edge species may be the best models for early humans.

Nearly 40 years ago, Robin Fox (1967, p. 419) declared:

> But the problem of taking the great apes as models lies in the fact of their forest ecologies. Most modern students of primate evolution agree that we should pay close attention to ecology in order to understand the selection pressures at work on the evolving primate lines. This has been shown to be crucial in understanding . . . evolution.

Even if one were to learn everything about the hominin-ape common ancestor, many of the most crucial questions about distinctively hominin evolution would remain unanswered. Although there is a fairly impressive record of human fossils during the period of 7–2 mya, there is a lack of chimpanzee fossils at these early sites. It seems likely, therefore, that chimpanzee ancestors did not inhabit these fringe environments and were likely restricted to more wet, closed forest ecosystems – areas where fossils are less likely to be preserved (Stewart 2010). Some populations of chimpanzees moved into more mosaic, open habitats relatively recently, long after humans had moved into more arid environments. Furthermore, modern chimpanzees do not live in habitats in which modern humans lived in the past or are found today. The historical geographic range of chimpanzees is quite restricted, probably more restricted than even that of early humans before leaving Africa.

To date, the best primate models to use as a basis for extrapolation about behavioral characteristics of our earliest ancestors are modern primate species living in similar edge habitats. Macaques can be extremely good colonizers of edge habitats. The macaque genus spread throughout Asia before humans reached that continent (Delson 1980). By the time *Homo erectus* arrived in Asia 1.8 mya, most hominins were no longer edge species (our more recent ancestors were exploiting more open habitats by this date (Tattersall 2010)), so hominins likely did not displace the macaques. True “weed” species, it is proposed that the macaques are excellent models for reconstructing how our early ancestors may have lived. However, even if macaques are used here, many of the features of the behavior and ecology of these monkeys are very similar to that of other primates living in similar habitats. It is these shared characteristics that make this such a strong model. After all, ultimately, it is the environment in which species find themselves that determines many of their evolutionary adaptations.

The Macaque Model

Long-tailed macaques (*M. fascicularis*) are small edge species that spend a good proportion of time both in the trees and on the ground (see Fig. 3). They are omnivorous and very versatile in their locomotion, although mainly quadrupedal. The most widespread of any Southeast Asian monkey, they occur from Burma through Malaysia and Thailand to Vietnam, while offshore populations are found on Java, Borneo, and numerous smaller islands as far east as the Philippines and Timor. Throughout this area, broadleaf evergreen and other forest types are interspersed with secondary and disturbed habitats, and it is the latter that long-tailed

Fig. 3 (*Long-tailed macaque*). The ecology and social organization of the long-tailed macaque may offer an excellent model of how our early ancestors lived (R. W. Sussman)

macaques prefer. Virtually all of the studies of this species make note that they are most commonly found in secondary forest habitat, preferably near water (Sussman et al. 2011). The success of the long-tailed macaque throughout its extensive Asian distribution is widely credited to its being an "adaptable opportunist" (Mackinnon and Mackinnon 1980, p. 187). Researchers emphasize that these monkeys are extremely adaptable and able to flourish in highly disturbed land.

There is a sizable long-tailed macaque population on the island of Mauritius in the southwest Indian Ocean (Sussman and Tattersall 1981, 1986). Although the original transport of the species from Asia to Mauritius is totally undocumented, it is likely they were onboard the ships when the Portuguese first reached the island and were inadvertently or purposely introduced to the primate-deficient ecosystem. Cited from the first studies as an assertive colonizer of new habitat, the small number of original immigrants had increased to 40,000 animals (before recent exportation of macaques for medical research) – successfully living up to their reputation as colonizers of disturbed and varied habitats (Sussman and Tattersall 1986; Sussman et al. 2011).

Long-tailed macaques are slender, active monkeys; average weight is 4–5 kg for females and 6–7.75 kg for males (Jamieson 1998). Long-tailed macaque society is organized around matrilineal hierarchies. There are always one or two dominant males visible within the group, as well as some lower-ranking adult males, plus the adolescent and subadult male offspring of the females. At sexual maturity males migrate to a new group. Female offspring are philopatric, mating with unrelated males who join their troop (Jamieson 1998).

Many of the Man the Hunter models ignore or minimize the role of females in human evolution. In many terrestrial and edge-adapted nonhuman primate species, such as long-tailed macaques and baboons, females are the core of society, remaining with their female relatives from birth to old age. Each matriline consists of several generations and can be placed in a dominance hierarchy. Highly social females inherit the rank of their mothers, so the troop organization remains relatively stable over time.

Man the Hunter scenarios typically depict male hunters as leaders, innovators, tool makers, and tool users. Since these aspects of gender specificity may never be revealed in the fossil record, it may be justifiable to construct theories based on the behavior of our primate relatives. When Japanese macaques were first studied in the wild, it was the young females who started innovative behaviors such as new ways of processing food (Kawai 1958). Chimpanzee tools are made primarily by females and used mainly in gathering activities such as nut cracking and termite fishing; it is also the female chimpanzees who teach the next generation how to use these tools (Boesch and Boesch-Achermann 2000; Sanz 2004). Furthermore, in most primates, females are the repositories of group knowledge concerning home ranges and scarce resources. Group knowledge and traditions are passed on from mother to offspring, and stability of the group, both in the present and over time, is often accomplished through female associations (Zihlman 1997).

In most primates adapted to edge environments, it is the males who migrate. However, in the closest genetic relatives of humans, the gorillas, chimpanzees, and bonobos, females normally change groups when they mature. This appears to be a phylogenetically conservative characteristic among hominoids which makes it possible that among our earliest ancestors, females, not males, migrated between groups. However, most modern human foragers are multilocal, with individuals residing with their maternal relatives at times and with their paternal relatives at other times or sometimes with neither (Marlowe 2005).

The ability of edge species to exploit a wide variety of environments is accompanied by a substantial flexibility of behavior. Long-tailed macaques appear to be primarily arboreal where suitable vegetation exists, but they come to the ground along riverbanks, seashores, and in open areas – and in some portions of their recently colonized range, such as Mauritius, they are highly terrestrial (Sussman and Tattersall 1981). They are eclectic omnivores with a distinct preference for fruit. But the variety of habitat they exploit is reflected in a wide selection of food items – besides fruit, they feed on leaves, grasses, seeds, flowers, buds, shoots, mushrooms, water plants, gum, sap, bark, insects, snails, shellfish, bird eggs, and small vertebrates (Sussman and Tattersall 1981; Yeager 1996; Sussman et al. 2011). Human-disturbed habitat or proximity to human settlements is not avoided; rather, they tend to live commensally with humans throughout their range, which results in crop raiding of sugar cane, rice, cassava, and taro fields.

Long-tailed macaques live in large multi-male, multi-female groups of up to 80 individuals, although in some areas groups are much smaller. They show distinct flexibility in structure; the large basic social unit tends to split up into smaller subgroups for daytime foraging activities (Jamieson 1998; Sussman et al. 2011). Subgroups may be all males, but most often consist of adult males accompanying females and their young offspring. The number and size of subgroups tend to vary with the season and resource availability (Jamieson 1998). The entire troop reforms each evening and returns to the same sleeping site each night, usually on the edge of a water source. Because of their unique behavior of returning to a home base each night, long-tailed macaques have been labeled a "refuging" species.

Fossils and Living Primates

Looking at the fossil evidence, it is apparent that human ancestors, living between 7 and 2.5 mya, were intermediate-sized primates, not smaller than male baboons or larger than female chimpanzees. Given their relative brain size, they were at least as clever as the great apes of today. They had diverse locomotor abilities, exploiting both terrestrial and arboreal habitats. They used climbing and suspensory postures when traveling in the trees and were bipedal when on the ground. It is believed that their bipedalism was a preadaptation, but walking on two feet freed the arms and hands and proved to be advantageous in a number of ways.

Given their relatively small size and small canines, there is no reason to think that our early ancestors were any *less* vulnerable to predation than are modern monkeys – some of which have yearly predation rates generally comparable to gazelles, antelopes, or deer living in similar environments (Hart 2000; Hart and Sussman 2009). Indeed, edge species can be *highly* vulnerable to predation and because of this usually live in relatively large social groups with many adult males and adult females; adult males often serve as sentinels and provide protection against predators (Hart and Sussman 2009). Because a primate group with only one male and ten females can have the same reproductive output as a group with ten males and ten females, often the male role in primate groups is to act as a first line of defense. If he gets eaten there are other males to take his place, but if a sexually mature female gets eaten, then she and all her potential offspring (and living dependent infants) are lost.

Like long-tailed macaques, our human ancestors may have lived in multi-male, multi-female groups of variable size that were able to split up depending on the availability of food and reform each evening at home base refuges. However, certain facts such as the exact size of the groups and subgroups, whether males or females migrated from the group when they reached sexual maturity, and the internal structure of the group (whether matrilineal or formed along male kinship lines) would be impossible to determine accurately. Indications of these social parameters cannot be found in the fossil record and are quite variable even in closely related living primates.

In sum, the best archetype of early humans may be a multi-male, group-living, mid-sized, omnivorous, quite vulnerable creature living in an edge habitat near a large water source. These hominins may well have been a refuging species returning to the same well-protected sleeping site each night. (Most modern foragers are considered central place foragers, focusing their activities around a principal location, as are many birds, social carnivores, and primates (Marlowe 2005).) These creatures were adept at using both the trees and the ground, but when they exploited the terrestrial niche, they had upright posture and were bipedal. They depended mainly on fruit, including both soft fruits and some that were quite brittle or hard, but also ate herbs, grasses, and seeds and gritty foods such as roots, rhizomes, and tubers. A very small proportion of their diet was made up of animal protein, mainly social insects (ants and termites) and, occasionally, small vertebrates captured opportunistically. These early humans did not regularly hunt for meat and could neither process it dentally nor in their digestive tracts.

Like all other primates and especially ground-living and edge species, these early humans were very vulnerable to predators, and this trait did not diminish greatly over time (Hart and Sussman 2009). Fossil evidence to this effect exists from Ethiopia and South Africa, from the Zhoukoudian cave in China, from European sites such as the skulls uncovered at Dmanisi in the Republic of Georgia, and from Olorgesailie and Tugen Hills, Kenya (see Table 1).

Man the Hunted

Given that the earliest hominin ancestors were medium-sized primates who did not have any inherent weapons to fight off the many predators that lived at that time – and given that they lived in edge environments which incorporate open areas and wooded forests near rivers – then, like other primates, they were vulnerable to predation. Because of this it is hypothesized that rates of predation were just as high in our early ancestors as they are in modern species of primates and that our origins are those of a *hunted* species (Hart and Sussman 2009) (see Fig. 4).

Protection from predation is one of the most important aspects of group living, and it is believed this was true of our earliest ancestors. Based on the long-tailed macaque model, social groups of early hominins may have been organized in a way that allowed efficient exploitation of a highly variable and changing environment and also protected its members of the group from predators. If the human lineage started out as Man the Hunted, it is proposed that a number of strategies for protection from predators are based on the behavior and social organization we observe in long-tailed macaques.

- Relatively large groups of 25–75 individuals: Since safety lies in numbers, one of the main reasons all diurnal primates live in groups is predator protection which provides more eyes and ears alert to presence of predators as a first line of defense. In his research on modern human foragers, Marlowe (2005) found that the median group size is 30 individuals.

Table 1 Hominin fossils

Fossil	Site	Approximate age	Evidence	Assumed predator	References
Orrorin tugenensis	Tugen Hills, Kenya	6 mya	Tooth marks on several bones	Leopard-like carnivore	Senut 2001
Ardipithecus ramidus	Aramis, Ethiopia	4.4 mya	Tooth marks on cranial and postcranial elements	Carnivore	WoldeGabriel et al. 1994
Australopithecus africanus	Taung Quarry, South Africa	2.5 mya	Punctures and incisions at base of eye sockets; talon rakings on cranium	Extinct raptor (*Stephanoaetus* spp.)	Berger and Clarke 1995; McGraw et al. 2006
Homo erectus	Dmanisi, Rep. of Georgia	1.8–1.7 mya	Canine tooth indentations on cranium; gnaw marks on mandible	Saber-toothed cat	Gabunia et al. 2000; Gore 2002; Wong 2003
Paranthropus robustus	Swartkrans, South Africa	1.8–1.5 mya	Canine tooth indentations at base of cranium	Fossil leopard (*Panthera* spp.)	Brain 1981
Homo?	Orce, Spain	1.6 mya	Cranium fragment excavated from fossil hyena den	Short-faced hyena (*Pachycrocuta brevirostris*)	Borja et al. 1997
Homo?	Olorgesailie, Kenya	900,000 ya	Bitemarks on the left browridge	Carnivore	Fox 2004; Small 2005
Homo erectus	Zhoukoudian, China	450,000 ya	Crushing of facial bones, maxilla, and mandible; enlargement of foramen magnum	Short-faced hyena (*Pachycrocuta brevirostris*)	Boaz et al. 2000; Boaz and Ciochon 2001; Boaz et al. 2004
Archaic *Homo sapiens* (*"helmei"*)	Florisbad, South Africa	260,000 ya	Canine tooth depression on forehead	Hyena	Deacon and Deacon 1999
Homo neanderthalensis	Mt. Cicero, Italy	50,000 ya	Fractures on cranium; enlargement of foramen magnum; gnaw marks on mandible	Hyena	Bahn 2005

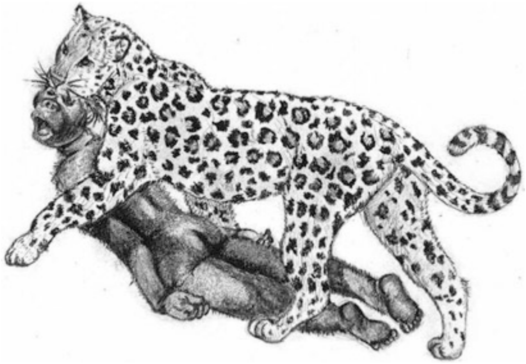

Fig. 4 (*Leopard capturing australopithecine*). Fossil evidence from South Africa documents predation by leopards on our early ancestors (C. Rudloff, redrawn from Brain 1981)

- Versatile locomotion that exploits both arboreal and terrestrial milieus: The major advantage of agility in the use of diverse habitats is safety in trees and dense underbrush. An added advantage of upright posture is the ability to scan for predators.
- Flexible social organization: For example, gathering scarce resources in small groups but reuniting as a larger group when predation requires strength in numbers allows small groups to quickly disperse and hide while large groups can mob and intimidate predators. Again, modern human foragers fit this pattern of flexibility (Marlowe 2005).
- Multi-male social structure: This demographic feature provides more male protection both when traveling through open areas and when the group settles in evening or midday. When large groups break into subgroups, females and young are accompanied by one or more large males.
- Males as sentinels: Males are usually larger in these species. Upright posture adds to the appearance of large size and also allows for better vigilance, as well as waving arms, brandishing sticks, and throwing stones. Males mob or attack predators since they are the more expendable sex.
- Careful selection of sleeping sites: Refuging species bring the whole group together at night in a safe area. During daytime rest periods, staying in very dense vegetation is essential. Males should stay on high alert during these inactive periods and when the group is on the move.
- Stay one step ahead of predators: Intelligence endows primates with the ability to monitor the environment, communicate with other group members, and implement effective anti-predator defenses (Hart and Sussman 2009).

Reconstruction of the behavior and ecology of our earliest hominin ancestor reflects the pervasive influence of large ferocious predatory animals throughout human evolution. Many circumstances have been proposed as a catalyst for the evolution of the human species – competition for resources, intellectual capacity, male-male conflicts, and hunting. But looking at our primate relatives and the fossil record, it is believed that predation pressure was one of the most critical components in shaping the evolution of our earliest ancestors.

Conclusion

While many models have been developed to depict the behavior and ecology of our earliest relatives, the Man the Hunter model has been the most widely accepted view of human evolution. Many human traits, such as bipedalism, tools, and fire, are often linked to this Man the Hunter perspective. Theories of human aggressive hunters abound but are rarely based on evidentiary approaches. Here, using a methodology based on the fossil record and extant primate ecology and behavior, data on fossil humans, on modern primates, and on rates of predation indicate that Man the Hunted may be the most accurate descriptor of our earliest relatives.

Modeling the Past: The Paleoethnological Approach

Paolo Biagi

Contents

Abstract

This chapter considers the earliest Paleolithic, Oldowan (Mode 1), and Acheulean (Mode 2) cultures of the Old Continent and the traces left by the earliest hominids since their departure from Africa. According to the most recent archaeological data, they seem to have followed two main dispersal routes across the Arabian Peninsula toward the Levant, to the north, and the Indian subcontinent, to the east. According to recent discoveries at Dmanisi in the Caucasus, the first Paleolithic settlement of Europe is dated to some 1.75 Myr ago, which indicates that the first "out of Africa" took place at least slightly before this date. The data available for Western Europe show that the first Paleolithic sites can be attributed to the period slightly before 1.0 Myr ago. The first well-defined "structural remains" so far discovered in Europe are those of Isernia La Pineta in Southern Italy, where a semicircular artificial platform

made of stone boulders and animal bones has been excavated. The first hand-thrown hunting weapons come from the site of Schöningen in north Germany, where the first occurrence of wooden spears, more than 2 m long, has been recorded from a site attributed to some 0.37 Myr ago. Slightly later began the regular control of fire. Although most of the archaeological finds of these ages consist of chipped stone artifacts, indications of art seem to be already present in the Acheulean of Africa and the Indian subcontinent.

Introduction

The aim of this chapter is to review the current evidence for the paleoethnology of the early hominids who inhabited the Old World from the time of their appearance up to the end of the Middle Pleistocene. Although the data presently available are not abundant, there is no doubt that they are of key importance for the understanding of early hominid behavior and lifestyles. The evidence is limited in most cases to stone tools and their contexts (Clark 1968, p. 277), almost exclusively due to natural and environmental factors both *physical and biological* (Stiles 1998, p. 134; McNabb 2009).

Given that the term paleoethnology rarely occurs in the Anglo-Saxon literature, while it is, or better was, more common in several European countries, it may be useful to review the meaning of this term and how it originated. It derives from the Greek palaiòs èthnos lògos (study of ancient populations) and was first used in France around the middle of the nineteenth century, and immediately afterward in Italy when prehistoric studies began to flourish, mainly in the Po Valley region of Emilia. The term paleoethnology (Pigorini 1866; Regazzoni 1885) was formally adopted during a congress exclusively devoted to the new science (“scienza nuova”) held in La Spezia on September 20, 1865, by the Italian Society of Natural Sciences (Tarantini 2012, p. 30). At this meeting, the French engineer Gabriel de Mortillet proposed the foundation of an International Paleoethnological Congress that was enthusiastically accepted by all delegates. A few years later, in 1875, Luigi Pigorini (Guidi 1987), Gaetano Chierici (Magnani 2007), and Pellegrino von Strobel (von Strobel 1998) founded a new journal in Parma, “Bullettino di Paletnologia Italiana,” the first to exclusively deal with prehistoric archaeology”.

In those years, the term paleoethnology was preferred to that of prehistoric archaeology because it was more strictly connected with the ethnographic discoveries under way in the Americas, Africa, and Asia (Figuier 1870, p. 415; Lubbock 1870) and favored analogy studies (Hodder 1982, p. 12) between the prehistoric finds recovered from excavations in European prehistoric sites and those still in use among the native communities of the above continents (Desittere 1988). In this respect, it is important to remark that even Boucher de Perthes (1864), the famous discoverer of Abbeville and the first Early Paleolithic hand axes in continental Europe (Prestwich 1860; Lamdin-Whymark 2009, p. 49), had a collection of flint tools from not only Europe but also Asia and Africa (Gowlett 2009, p. 18). This is the reason why paleoethnology courses are still delivered in the Italian university, due to the long tradition that goes back to the earliest prehistoric studies of the mid-nineteenth century.

Reverting to the early stone tool assemblages of the first hominids, they are often associated with alluvial sedimentary processes (Isaac 1967) related to the geographic and geomorphologic location and distribution of the (sometimes ephemeral) sites (Brown 1997, p. 150) that in many cases are limited to the stone tools themselves and possibly to organogenic tools and the faunal remains derived from hunting and scavenging activities (Conard 2007). Nevertheless, the excavations carried out during the last 50 years, and the study of the settlement structures and tool assemblages of the Early Paleolithic sites of the Old World, "have shown that it is quite possible to find sealed occupation sites that have suffered little or no natural disturbance before or after burial" (Clark 1968, p. 276).

As far as the remains of material culture and their chronotypological characteristics are concerned, this chapter deals almost exclusively with Mode 1 (Oldowan) and Mode 2 (Acheulean) complexes (Clark 1994; Toth and Schick 2007). Tools belonging to these two "modes" have been collected from a great number of sites, which are distributed between East Africa and the Indian subcontinent in the southeast and Europe in the northwest (Movius 1948, p. 409; Otte 2000, p. 111).

Out of Africa

Much has been published dealing with the spread of the first hominids and the radiometric dating(s) of the "out of Africa" dispersal(s) (Chauhan 2005; Petraglia 2007; Rightmire 2007). Nevertheless, many questions are still unresolved, since "the triggers for the movement of humans out of Africa are not well known" (Bar-Yosef and Belfer-Cohen 2000, p. 81). Stone tool technotypological variability, between Africa and Asia, for instance, would suggest a series of cultural complexities (Braun et al. 2010). The chronology is also very variable and badly known, in India for instance (see Chauhan 2010 contra Gaillard et al. 2010). This state of affairs results from the absence or scarcity of reliable data from some of the key territories that hominids must undoubtedly have crossed to reach Eurasia (see, for instance, Petraglia 2003, Fig. 12).

This is the case for Arabia, from which little information is currently available, especially from the southern portions of the peninsula, more precisely Yemen (Dhofar) and Oman, which were most probably reached by the Afar Depression across the dried Red Sea strait (Cachel and Harris 2007, p. 120). Effectively, the Early Paleolithic sites discovered in these countries come from a few, restricted areas where intensive surveys and excavations have been carried out in the last two decades (Whalen and Pease 1991; Cremaschi and Negrino 2002; Whalen et al. 2002; Whalen and Fritz 2004; Amirkhanov 2006). Even though many of them are represented by surface finds, the Soviet-Yemeni Archeological Mission excavated thick sequences in some caves of southeast Yemen, close to the Dhofar border. This led to the discovery of stratified complexes, which Amirkhanov (1994, p. 218) attributed to the pre-Acheulean (Oldowan: Mode 1) and Acheulean (Mode 2) periods. In this context, the only tool bearing evident traces of use, from the lowermost layers of Al-Guza Cave in Yemen (Amirkhanov 2006, p. 91), is of unique importance. This is the only pre-Acheulean worn chopper so far known from the entire south Arabian Peninsula.

Although the Early Paleolithic sites so far discovered in this region are few, south Arabia is claimed to represent one of the key routes followed by the first hominids once they started to move out of Africa, initially moving along the coast of the peninsula, to reach its interior slightly later (Rose and Petraglia 2009, p. 6), moving to the central territories of the Indian subcontinent, undoubtedly earlier than 1.0 Myr ago (Bar-Yosef and Belfer-Cohen 2000, p. 82). A second route is said to have been followed "across the Sinai into western Asia . . . although this has not been adequately detailed to date" (Bar-Yosef 1994, p. 237; Petraglia 2003, pp. 168–169), where the oldest site known to date is located at 'Ubeidiya (Stekelis et al. 1969; Bar-Yosef 1995, p. 250) (Fig. 1).

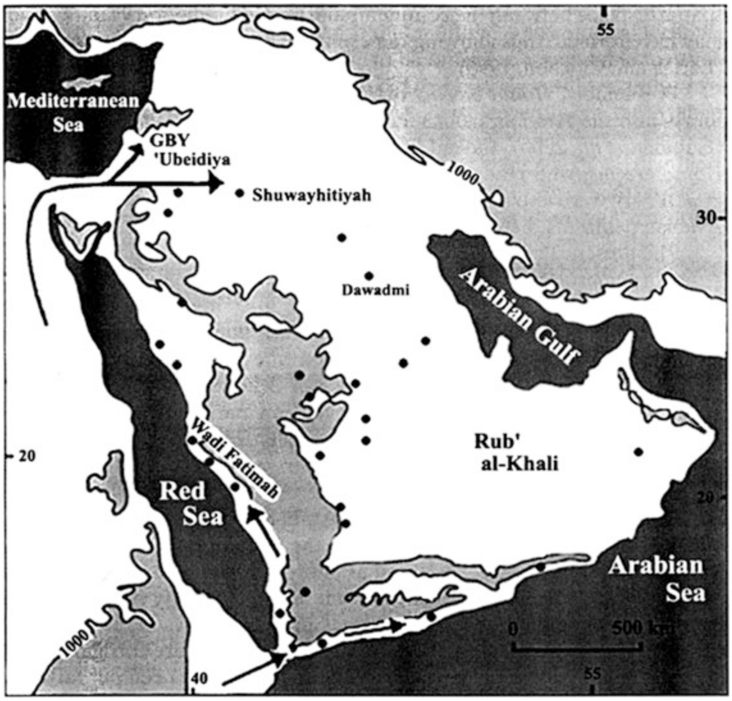

Fig. 1 The Arabian Peninsula with the indication of the most important Early Paleolithic sites (*dots*) and the potential main routes followed by hominids during their "out of Africa" dispersal (s) (*arrows*) (After Petraglia 2003, Fig. 12)

Important radiometric dates for the first human dispersal are available from Dmanisi (Fig. 2) in the Georgian Caucasus (Gabunia et al. 1999; Nioradze and Nioradze 2011). The excavations carried out at this site over a surface of some 300 m^2 led to the discovery of a unique settlement with skeletal remains of early hominids, identified as *Homo ergaster* (Lordkipanidze and Vekua 2006), among which are five skulls, over 10,000 chipped stones obtained from different raw materials (for instance, mostly available close to the site as river pebbles), mainly represented by choppers and flakes, and over 7,000 animal bones, belonging to a faunal assemblage of "Villafranchian type." They undoubtedly show that this dispersal took place not later than 1.8 Myr ago (Gabunia 2000, p. 43; Vekua et al. 2011). Nevertheless, "le mouvement oriental paraît à la fois beaucoup plus complexe et, surtout, beaucoup plus ancien qu'en Europe" (Otte 2000, p. 108). Fortunately, the number of discoveries of Lower Pleistocene sites from this continent is systematically increasing (de Lumley 1976; Agustí et al. 2000; Mussi 2001, p. 20). Although the absolute age of some of these sites is problematic (Santonja and Villa 1990, p. 54), many are undoubtedly much older than supposed only a few years ago (Roebroeks and van Kolfschoten 1994, p. 500). Although the number of radiometric dates currently available from southern Europe is very limited, nevertheless they show that at least some north Mediterranean regions were undoubtedly settled by hominids as early as 1.3 Myr ago (see, e.g., de Lumley et al. 1988; Peretto et al. 1999; Toro-Moyano et al. 2003) as suggested by recent discoveries made at Pirro Nord, in southeastern Italy (Arzarello et al. 2007, 2012).

Fig. 2 Dmanisi (Georgia): A view of the hominid archaeological site with the Medieval pit (*on the right*) from which the first prehistoric bones were discovered (Photograph by P. Biagi)

Chipped Stone Assemblages

Bifaces and Other Tools

As pointed out by Gowlett (2005, p. 51), “East Africa is the key territory for examining the Oldowan and early Acheulean,” in which the first “bifacial tools were created about 1.5 million years ago” (Porr 2005, p. 68) by *Homo ergaster*, as a consequence of a complex series of behavioral, economic, and social factors whose complexity has been pointed out by Porr (2005, p. 77). Until recently, however, they have been considered almost exclusively in the context of “artefacts as a functional form that varies sometimes according to raw material considerations and is manufactured with a recurrent technology within broader parameters” (Ashton and McNabb 1993, p. 190). But the fact that the manufacture of such tools continued for some 1.25 Myr indicates their importance, most probably not only as cutting and/or scavenging weapons (Domínguez-Rodrigo 2002) but also as social indicators independent of their functional meaning(s). According to Draper (1985, p. 7), “we could imagine a situation where an Early Paleolithic hominid might have fabricated a portable cutting tool for scavenging remnant meat from carnivore kills” that “was produced because a Middle Pleistocene knapper . . . was disposed to work stone in a way that produced an object we call a handaxe” (Hopkinson and White 2005, p. 21). The high variability (Sinclair and McNabb 2005, p. 185), the typological and dimensional characteristics (Isaac 1977), their eventual hafting (Ling 2011), and the “wide temporal and geographic distribution” (Wynn 1995, p. 11) of these tools have been noted by many authors, but from different perspectives and with different aims (Bordes 1968, p. 23; Camps 1979; Petraglia 1998, p. 371; McNabb et al. 2004; Hopkinson and White 2005) (Figs. 3 and 4). In Asia, their distribution covers a well-defined region, delimited in the east and the north by the so-called Movius Line (Movius 1944, p. 103), more of a “veil” than a real line according to Otte (2010, p. 274). This “line” is still nowadays often employed to mark the limit between hand axe and other technologies with no evidence of bifacial tools, like the Soanian of northern Pakistan (De Terra and Paterson 1939; Paterson and Drummond 1962), though bifacial tools are recorded from its more recent period of development (Graziosi 1964, p. 12), or the Anyathian of Burma (De Terra and Movius 1943) to make two well-known examples often referred to very different chronological periods of the Paleolithic. In this respect, the discovery of undated bifacial forms in Australia is intriguing and might possibly help clarify some aspects of their manufacture, meaning, and function (Brumm and Rainey 2011).

Although the complexity involved in the production of the lithic artifacts has been openly questioned (Hassan 1988, p. 281), and analysis of manufacturing techniques and debitage dispersal (Andrefsky 2007) across the earliest Paleolithic sites (Gowlett 2005; Petraglia et al. 2005) is still rarely applied by the field archaeologists, a few interesting exceptions should be mentioned. Among these is the MNK chert factory site in the Olduvai Gorge (Tanzania), which is dated to some 1.6 Myr ago. Here chipped stone artifacts, obtained from both local and imported raw materials, show a complex sequence of activities carried out by “early man working a raw material

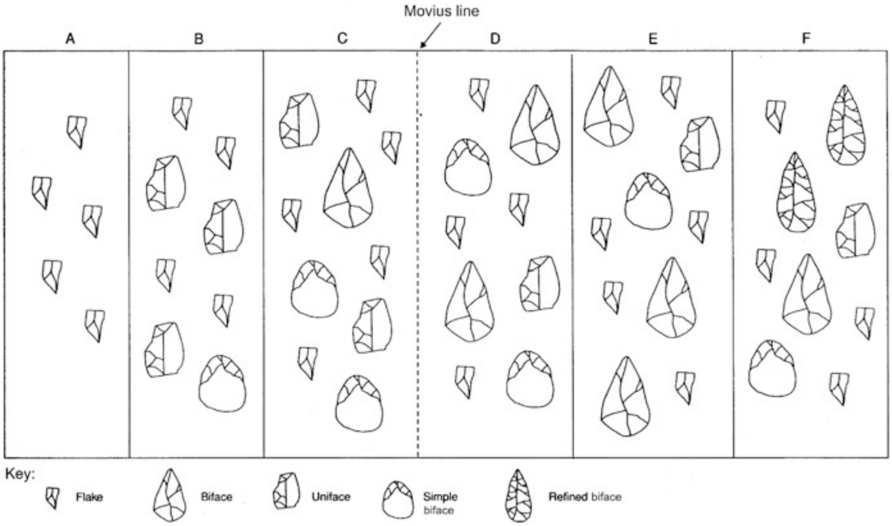

Fig. 3 Variation among lower Paleolithic biface assemblages of Eastern Asia and South Asia. The *dashed line* represents the Movius Line, the traditional demarcation between Mode 1 (Oldowan) and Mode 2 (Acheulean) industries (After Petraglia 1998, Fig. 11.8)

chosen for its technological properties brought to a central locality from diverse sources" (Stiles et al. 1974). FxJi50, in north Kenya, is a site 1.5 Myr old that "consists of a patch of stone artefacts interspersed with broken-up fragments of bone" (Bunn et al. 1980, p. 111), whose precise function is still difficult to define. The chipped stone assemblage, which is composed of flaked cobbles and flakes partly obtained on the spot, "has proved to consist of several dense clusters of material that interconnect with each other" (Bunn et al. 1980, p. 114). This is one of the earliest Paleolithic sites from which "the close association (of bones) with artefacts and the presence of butchering marks suggest that the toolmakers were the first accumulating agency" (Bunn et al. 1980, p. 125). This picture is rather unusual, if we consider that "for most of the sites excavated and reported we do not have certain indications of any specific activities that characterize them, and in very few instances has localization of subsidiary tool kits within a floor even been claimed" (Isaac 1972, p. 185) and that the interpretation of the variability of the spatial distribution pattern of the tools (Whallon 1973, p. 117) within a site surface is often difficult (Keeley 1991, p. 258). Experimental studies have also been made especially regarding hand-axe production employing different techniques and raw materials and using both hard and soft hammerstones (Madsen and Goren-Inbar 2004).

Raw Material, Workshops, and Quarries

When detailed recording methods have been applied, as for instance in the case of some localities excavated in the Indian subcontinent, they have revealed that

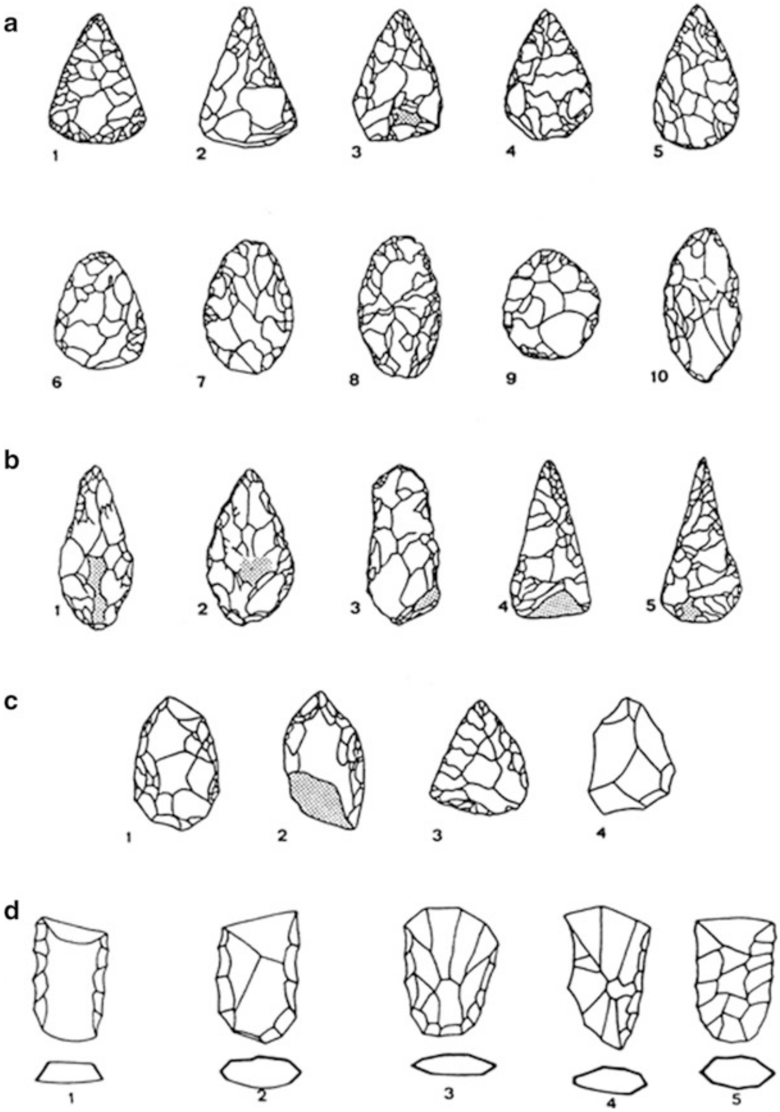

Fig. 4 Different categories of hand axes according to the typological classification proposed by Camps (1979): different types of (**a**) flat bifacials, (**b**) thick bifacials, (**c**) diverse bifacials, and (**d**) *hachereaux* (After Broglio 1998, Fig. 22)

characteristic tools, among them hand axes, cores, hammerstones, and different dimensional classes of debitage flakes, systematically cluster in well-defined spots (see Pappu 2001, pp. 25–54; Paddayya et al. 2002, p. 646). This fact is useful in helping us understand the development of the manufacturing areas within the site and the steps followed by the toolmakers during the production process

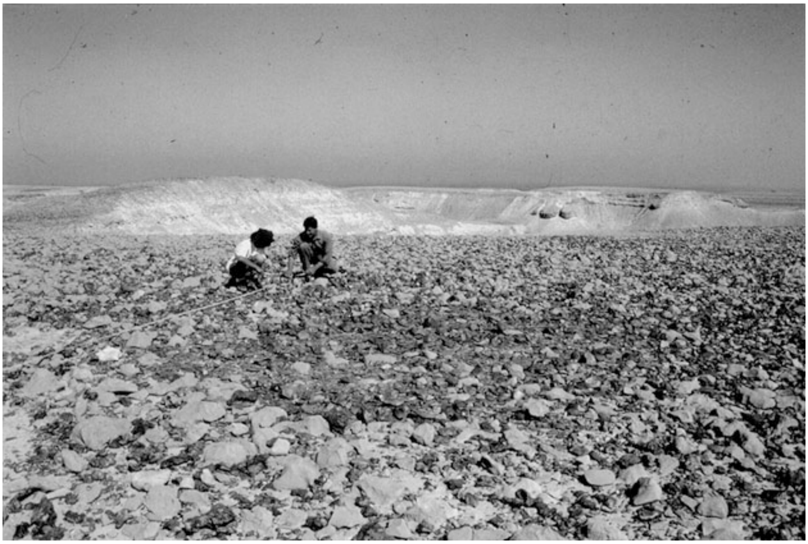

Fig. 5 Ziarāt Pir Shabān on the Rohri Hills (Sindh, Pakistan): The Acheulean hand-axe factory ZPS1 before excavation (Photograph by P. Biagi)

(Hansen and Madsen 1983, p. 51), especially when refitting methods are applied to the entire complex (Bergman et al. 1990, p. 280). This is the case for the some Acheulean sites where different varieties of raw materials for tool production were available, including siliceous limestone (Isampur in India: Petraglia et al. 2005) and good-quality chert from local outcrops (Rohri Hills in Sindh [Pakistan]: Biagi et al. 1996).

The evidence available from the latter shows that the waste products of large hand-axe-manufacturing workshops were scattered along the edges of circular sandy areas representing zones that were comprehensively cleared of limestone and chert boulders in Paleolithic times, before the manufacturing activities took place. For instance, the excavations carried out at Ziarāt Pir Shabān 1 (Fig. 5), one of the many Acheulean workshops discovered on the Rohri Hills that were exclusively devoted to the production of hand axes (Biagi et al. 1996) (Fig. 6), have demonstrated that the perfect, finished bifaces were exclusively transported elsewhere, most probably to camps located in the adjacent Great Indian Desert that are at present buried beneath meters of sand inside thick, stabilized dunes (Misra and Rajaguru 1989). The maximum transfer distance is not known, due to the absence of any detailed research in the Thar Desert to the east of the hills, although the African parallels indicate transport between 15 and 100 km (Petraglia et al. 2005, p. 208). A situation similar to that of the Rohri Hills is known at Ongar, near Hyderabad in lower Sindh (Pakistan), where Acheulean workshops were discovered lying on the top of flat limestone mesas (Figs. 7 and 8). These deposits, very rich in seams of excellent chert, were exploited throughout the entire Paleolithic period, from the Acheulean onward (Biagi 2006, 2008).

Fig. 6 Ziarāt Pir Shabān on the Rohri Hills (Sindh, Pakistan): Acheulean hand-axe rough-outs on the surface of workshop ZPS1 (Photograph by P. Biagi)

Fig. 7 Ongar (Sindh, Pakistan): C-shaped Acheulean chert factory area (Photograph by P. Biagi)

As far as these two latter cases in Sindh are concerned, there is no doubt that the abundance of excellent, workable raw material played a fundamental role in attracting prehistoric populations at least since the Acheulean period (Biagi and Cremaschi 1988, p. 425). The chert used by the earliest Paleolithic people was

Fig. 8 Ongar (Sindh, Pakistan): In situ chert flakes concentration in an Acheulean workshop (Photograph by P. Biagi)

collected from large boulders or extracted from the top of the limestone terraces, as supported by the evidence from accurate surveys carried out along the top of the mesas that did not reveal any trace of Early Paleolithic mining activities.

As far as we know, the first Paleolithic chert quarries were opened by Acheulean populations, both in the Levant (Gopher and Barkai 2011) and Upper Egypt, much earlier than until recently supposed (Smolla 1987, p. 129). According to Vermeersch et al. (1995, p. 22), "a few kilometres south of the Dandara temple …a… hill was clearly subjected to chert extraction by Acheulian people," given the presence of an extractive pit discovered during the excavation of a small trench in an area rich in Late Acheulean tools. In contrast, almost nothing is known of Acheulean raw material procurement systems in this region, which yielded abundant traces of Middle and Upper Paleolithic flint-mining activities (Vermeersch et al 1997, p. 191).

Habitation and Other Structural Remains

Early Paleolithic Mode 1 and 2 sites are often characterized by "concentrations of debris, … which… have usually been interpreted to be the result of various processual phenomena" (Stiles 1998, p. 133). Only a few of them, of varied chronology, have provided us with complex archaeological evidence (see, e.g., Pappu 2001).

In Africa, we know that most of the earliest settlements were located in environments close to lake shores or, more commonly, along (former) river courses

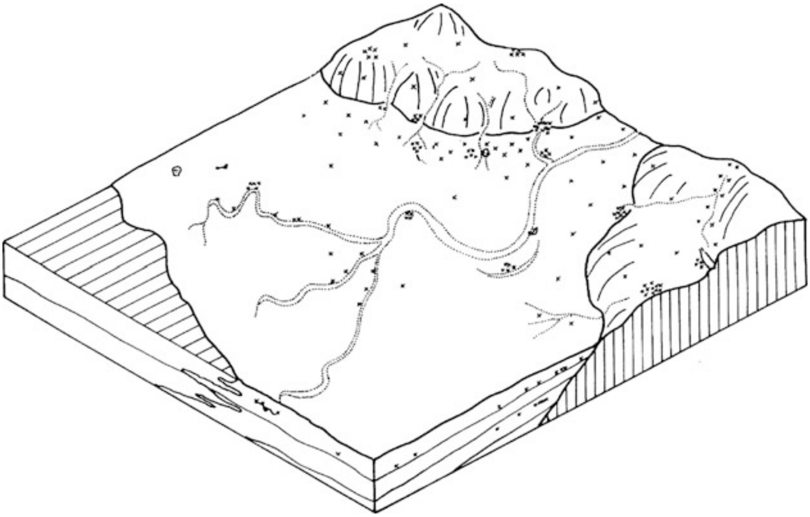

Fig. 9 Schematic representation of a portion of landscape frequented by tool-using hominids, with the locus of discarded artifacts marked X (After Isaac 1976, Fig. 3.3)

(Isaac 1976, Fig. 3.3) (Fig. 9). They have been interpreted as sites that are inhabited during only one season, whose remaining components, mainly lithic artifacts and bones, show they had been planned (Binford 1989a, p. 469). The 1.75-Myr-old Mode 1 site of DK, in Lower Bed I of the Olduvai Gorge (Leakey 1971, p. 24, Fig. 7), yielded evident traces of man-made features, the most important of which consists of a circular structure of lava blocks, some 4.5 m in diameter (Fig.10), that the excavator interpreted as resembling "temporary structures often made by present-day nomadic peoples who build a low stone wall round their dwellings to serve either as windbreak or as a base to support upright branches which are over and covered with either skin or grass" (Leakey 1971, p. 24).

The excavations carried out at Gomboré I, another Mode 1 site located at Melka Konturé in Ethiopia, brought to light a 230 m^2 living floor composed of rounded pebbles and rich in stone tools and faunal remains, with a central empty space of some 10 m^2. The settlement, which has been dated at some 1.6 Myr ago, yielded a "higher platform . . . that . . . could have been roughly adapted for a shelter made of branches and animal skins" (Chavaillon 2004, p. 263). The research carried out at this site revealed the occurrence of "small stone circles aligned north-south in the eastern sector . . . whose . . . external diameter . . . varies from 20 to 40 cm," which were interpreted as possible "wedging stones for pegs set in rather hard soil" (Chavaillon and Chavaillon 2004, p. 448), similar to those recorded from Garba XII in the same region. Recent radiometric dates obtained from a few Early Paleolithic localities in the area revealed a sequence of habitation covering a long period comprised between 1.7 and 0.7 Myr ago (Morgan et al. 2012, p. 108).

Among the Mode 2 sites, extremely interesting and perfectly preserved remains were brought to light at Isernia La Pineta in Molise (Southern Italy). The chronology

Fig. 10 Olduvai Gorge, site DK (Tanzania): Plan of the *stone circle* and the remains of the occupation surface: Stone artifacts shown in *black*, bones in outline (After Leakey 1971, Fig. 7)

of this site is still rather controversial (Mussi 2001, p. 44), although the new radiometric dates indicate that the locality extends over an area of some 30,000 m^2 and is some 0.60 million years old (Coltorti et al. 2005, p. 19), roughly contemporary with Notarchirico in the same region of central Italy (Orain et al. 2013). It yielded traces of four different occupation layers from which more than 10,000 lithic artifacts, chipped from different raw materials, including limestone and chert from diverse sources, were collected (Peretto 1994a). The site was located along the shores of a lake basin that was later buried by fluvial sediments. The most interesting structural remains were discovered during the beginning of the excavations, when an accumulation of animal bones and stone tools was uncovered on an almost semicircular paleosurface that was very rich in remains of *Bison* skulls and horns and *Rhinoceros* cranial bones and was delimited by large, travertine boulders (Giusberti et al. 1983, p. 100) (Figs. 11, 12 and 13). These discoveries might help interpret the spatial variability and activities carried out within this settlement site (Bartram et al. 1991). Remarkable differences have been noted among the lithic assemblages excavated in different areas of the site, both in the raw material employed for producing artifacts and in the typology and dimension of the stone tools (Fig. 14) (Peretto 1983, p. 81). For example, while flint was mainly used to obtain flakes, limestone was employed for the production of pebble tools, often characterized by the removal of just a few flakes from the distal edge (Peretto 1994b). Traceological studies and the experimental reproduction of the

tool types and their chaine operatoire have shown that small flakes were the most important tools of the Isernia inhabitants, while denticulates that represent some 90 % of the total assemblage are in effect only core waste residuals (Crovetto et al. 1993).

In central Italy, an interesting Mode 2 site dated to slightly later than 0.5 Myr ago, and with an assemblage consisting of both elephant long bones and stone bifacial hand axes, has been excavated at Fontana Ranuccio (Biddittu et al. 1979). The presence of bone hand axes is unique to the area (Biddittu 1982), where they become increasingly more common at the slightly later Mode 2 sites, like Castel di Guido in Latium (Radmilli and Boschian 1996), where the use of elephant carcass bones for making tools has been analyzed in detail (Saccà 2012).

Moving westward, the importance of the remains of structures brought to light by H. de Lumley (1966) at Terra Amata, near Nice, in Provence, is represented by a shallow, oval-shaped hut floor attributed to a Mode 2 group of people who inhabited the region around 0.4 Myr ago. Apart from the exceptional discovery of an almost "intact" habitation structure, the site is important because it yielded the first evident traces of a hearth indicating the use of fire by Paleolithic humans in Europe (de Lumley and de Lumley 2011, p. 41). Traces of fire that have long been suggested from a few Lower Pleistocene sites in East Africa (Clark and Harris 1985; Perlès 1977) are known since some 0.8 Myr ago in Israel (Goren-Inbar et al. 2004), although the reanalysis of 30 Paleolithic sites made a few years before had suggested that controlled fires are not earlier than 0.3 Myr ago, most probably associated with very late *Homo erectus* (James 1996, p. 66) whether this taxonomy is still acceptable according to the new findings (Wagner et al. 2007).

The site of Steinrinne near Bilzingsleben, in central Germany, is of extreme importance for the study of Mode 2 hominids, although the interpretation of its stratigraphy, some 1 m thick, is still debated (Mania and Mania 2005; Müller and Pasda 2011), as well as its chronology, which is referred, according to the different authors, either to 0.42–0.35 Myr ago or 0.25–0.20 Myr ago. The remains of three circular hut foundations, 3–4 m in diameter, with entrances systematically facing southeast and with workshop areas and fireplaces, have been discovered at this camp, dated to some 0.37 Myr ago (Fig. 15). The importance of this site is indicated by the occurrence of the earliest so far known intentionally decorated bone objects that suggest "non-utilitarian behaviours . . . connected to reflexive thinking" (Mania and Mania 2005, p. 110), as well as the indisputable traces of what is claimed to be a ritual paved area "with human skull fragments smashed in macerated condition" (Mania and Mania 2005, p. 113). According to Mania and Mania (2005, p. 114), these discoveries demonstrate that "*Homo erectus* was therefore a human being that had a fully developed mind and culture, capable in creating his own socio-cultural environment with living structures, the use of fire and special activity areas," although other authors prefer to attribute the finds to *Homo heidelbergensis* (Henke and Hardt 2012). This also finds confirmation in the traces of Acheulean "art" both in Africa (Bednarik 2003) and in the Indian subcontinent (Bednarik 1990).

Gran Dolina at Atapuerca in Spain is an even earlier multilayered site, where some kind of ritual activity has been supposed to have taken place. The site yielded 150 human bone fragments, which have been attributed to four individuals,

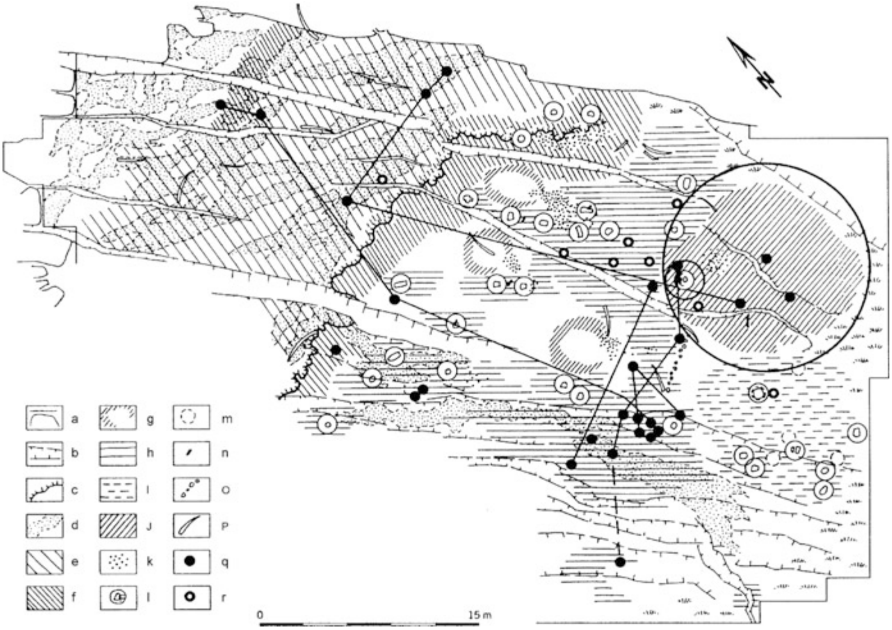

Fig. 15 Bilzingsleben (Germany): Plan of the structuration of the Early Paleolithic camp: (**a**) limits of the excavated area, (**b**) geological fault lines, (**c**) shoreline, (**d**) sandy travertine sediments, (**e**) alluvial fan, (**f**) activity area at the lake shore, (**g**) outlines of living structures, (**h**) workshop areas, (**i**) special workshop area with traces of fire use, (**j**) circular paved area, (**k**) charcoal, (**l**) bone anvils, (**m**) stone with traces of heat, (**n**) bones with intentional markings, (**o**) linear arrangement of stones, (**p**) elephant tusk, (**q**) human skull fragments, (**r**) human tooth (After Mania and Mania 2005, Fig. 7.1)

classified into the new form *Homo antecessor*. Some of the hominid remains from Layer TD6, datable to at least 0.78 Myr ago (Falguères et al. 1999), "show clear cut marks which have been interpreted as evidence of cannibalism" (Mosquera Martínez 1998, p. 17). The chipped stone assemblage from this layer is characterized by relatively small artifacts, among which are utilized flakes, scrapers, denticulates, debitage flakelets, and by-products suggesting the presence of a living floor where different activities had been performed (Carbonell et al. 1999).

Returning to Mediterranean France, this region is very rich in Lower Paleolithic sites, both open air and in caves. Among the latter, the internal deposits of Lazaret Cave (de Lumley 1969), a late Mode 2 Acheulean site attributed to some 0.12 Myr ago, yielded traces of a unique hut structure that has been reconstructed, thanks to the occurrence of stone walls, fireplaces, and "masses of seaweeds possibly used as bedding for site occupants" (Mellars 1995, p. 285). Although this site does not represent the earliest known evidence of cave structural remains in Eurasia, given the traces of much older man-made stonewalls in China (Fang et al. 2004, Fig. 3) and Central Europe (Cyrek 2003, Fig. 6), Lazaret is the only one from which a detailed reconstruction of the events that took place inside the cave in Late Acheulean times has so far been possible (de Lumley and de Lumley 2011, p. 54).

Hunting Weapons

Although, as mentioned earlier, the excavations carried out at Terra Amata in the 1960s had already revealed the presence of one single fireplace, the almost contemporary hunting site of Schöningen, in North Germany, yielded not only the remains of four hearths, one of which is some 1 m in diameter, but even a charred wooden stick, which might “have functioned as a firehook to feed the fire as well as a spit to roast, and also smoke, strips or pieces of meat” (Thieme 2005, p. 127). This site is extremely important because of the occurrence of both the hunting weapons and the other wooden tools brought to light since 1994, which have radically revolutionized our view of the hunting methods and strategies followed by these hominids. The widely accepted view that early *Homo* was unable to conceive and construct throwing weapons is contradicted by the discovery of sophisticated spears, longer than 2 m, which suggest a long tradition in wood shaping and weapon craftsmanship showing that, in contrast to what was previously supposed, this species had already acquired that complex “sequence pattern of behavioural complexes” (Laughlin 1968, p. 305) commonly labeled hunting, which represent “a way of life . . . that . . . has dominated the course of human evolution for hundreds of thousands of years” (Washburn and Lancaster 1968, p. 293). More precisely, “*Homo erectus* in the Middle Pleistocene was fully capable of organising, coordinating and successfully executing the hunting of big game animals in a group using long-distance weapons” (Thieme 2005, p. 127). Although the Schöningen specimens are not the only wooden pointed tools so far recovered from an Early Paleolithic site in Europe (Conard 2007, p. 2008), they undoubtedly represent the best preserved specimens discovered within a horse-hunting camp, a surface of some 3,500 m^2 of which has already been excavated.

Furthermore, it is important to point out that already in the 1980s, Isaac (1984, p. 17) had considered the use of throwing weapons by early hominids when he wrote “if the Lower Pleistocene tool-making hominids were hunting with equipment, they must have been using spears without stone tips (i.e. pointed staves or horns on staves), clubs, and, perhaps most important of all, thrown sticks and stones,” given that “none of the flaked stone artefacts can plausibly be regarded as ‘weapons’” (!). In effect, it has been widely demonstrated that stone hand axes and cleavers (see, for instance, Gilead 1973) are excellent butchering tools, but not hunting weapons, and, in particular, that “the sinuous retouched edge of a hand-axe retains its meat-cutting efficiency longer than a plain flake edge” (Isaac 1984, p. 15).

Conclusion

Apart from the factors mentioned in the introduction, there are many others that make remains of early structures difficult to interpret. Among these are (1) the impossibility of “detailed” radiometric dating of the events that took place at short-term habitation sites, given that hunters periodically moved from site to site following their subsistence strategies (Binford 1978a, 1980), and (2) the difficulty of proving the supposed contemporaneousness of the structural remains within an apparently "homogeneous" area (Binford 1982). This is true even though it is widely assumed that "in inspecting the contents of a single structure, we can be fairly confident that the associated assemblage was all in use at one time, if not made at the same time" (Deetz 1968, p. 283). Besides the two above-mentioned factors, there are three others of major importance regarding (1) the complete excavation of an occupation unit, an enterprise that has been successfully undertaken only on very few occasions (Clark 1968, p. 277), (2) the functional nature of the (seasonal) site itself (Hehmsoth-Le Mouël 1999, p. 81), and (3) the eventual impact of scavengers on the bone remains originated by human activity (Binford et al. 1988).

With the exception of a limited number of cases reported by Clark for East Africa, and a few others which have been described in the preceding chapters, most sites are characterized by more or less dense concentrations of stone artifacts and bones, often closely related to each other (Binford 1989b, p. 459) although differently disposed according to the activities performed (Stevenson 1991, p. 280), reflecting "a complex system of extraction, manufacture, transport, use, resharpening, re-use, renewed transport and eventual discard" (Isaac 1986, Fig. 15.6). Often, these have been subjected to a certain degree of weathering or represent a (complicated) sequence of depositional events that took place over a period of millennia, forming archaeological palimpsests (Hosfield 2005). Isaac (1968, p. 255) classified such concentrations in three main categories according to the vertical and/or horizontal diffusion of the stone tools. The first two of these "represent sporadic, intermittent occupations of great duration," while the third "can probably be interpreted as fairly stable 'home base.'"

Finally, ethnographic analogies are sometimes uncritically accepted by both archaeologists and anthropologists, who often believe "that modern representatives of past stages of cultural development exist" (Freeman 1968, p. 263), sometimes they are simply unaccepted, considered to be unreliable and nonscientific (Hodder 1982, p. 14), even though "any consideration of the implications for archeological interpretation of new ethnographic data . . . requires an examination of the general relationships between ethnographic observations and archeological reasoning" (Binford 1968).

Modeling the Past: Archaeology

Miriam N. Haidle

Contents

Abstract

This chapter looks at the potential explanatory power of archaeology as a paleoanthropological discipline. Through the study of artifacts, archaeology provides insight into human behavior. Five facets of archaeological knowledge can be drawn from the material remains of object-related activities (typological, technological, functional, contextual, and cognitive information), from which other behavioral aspects, like subsistence, settlement, social organization, cultural differences, and the cognitive background, can be derived. Archaeological analyzes face significant constraints, but by integrating results from other disciplines, the limits can be broadened. A brief outline of Paleolithic artifact history shows how this part of the behavior of *Homo* developed and how it is

accessible by archaeological remains. Following the question "What could they do?" the basis of cultural behavior as a crucial aspect in human evolution is traced in its biological, historical-social, and individual dimensions.

Introduction: Archaeology as a Paleoanthropological Discipline

Archaeology is the anthropological field that studies the material remains of the behavior of former human populations. The most ancient of these populations is the subject of Paleolithic archaeology, which deals with the material remains of early hunter-gatherers, from the first documented stone artifacts of 2.6 Ma to artifacts showing the initial steps toward sedentary life and agriculture at the end of the last Ice Age. Paleolithic archaeology studies artifact assemblages made of stone and organic material by hominins. Additionally, faunal, botanical, and sedimentary remains from early human contexts are examined to gain a broad picture of the hominin behavior and the environment. Paleolithic artifacts and associated finds provide clues to subsistence, social, and cultural behaviors and attest to hominins' increasing capabilities and efforts to get beyond the physical limits of their bodies by using tools. Although tool use and manufacture do occur occasionally in the animal kingdom – ranging from the use of unmodified objects in one specific context that some species of invertebrates, insects, birds, and mammals have developed to the tools adaptive to different problem settings that primates, especially great apes, and some bird species, namely, crows, tend to use – tools emerge within a broadening cultural setting as an eminently human product, as will be described below. For modern humans, who have created a culturally dominated world, tools are second nature. How we got from our occasionally tool-using primate ancestors, with limited cultural capacities and relatively narrow ecological boundaries, to a species that is helpless without tools, but that due to increased cultural capacities is able to perform a huge variety of flexible responses to a wide range of environmental requirements, can be traced only by following the development of artifact assemblages. Therefore, this chapter will focus on the potentials and limitations of interpreting artifacts and tools found in archaeological contexts in illuminating this special human character.

From Primary Field Data to Archaeological Interpretation

The main purpose of archaeology as a discipline is to study artifacts (Fig. 1) made and used by prehistoric populations in order to reconstruct human material culture and activity patterns and thereby to elucidate the development of humans as cultural beings. In a broad sense, archaeology can be defined as the search for human activity zones, the recovery and documentation of these zones, and the analyses of remains (artifacts) and their interpretation. To this end the raw data from archaeological excavations (Fig. 2) undergo analysis, and sometimes additional experimental studies (Thomas 2013) are made on the manufacture and use of

Fig. 2 Re-excavation of excavation material at Vogelherd cave, Southwest Germany (Photo: M. Haidle)

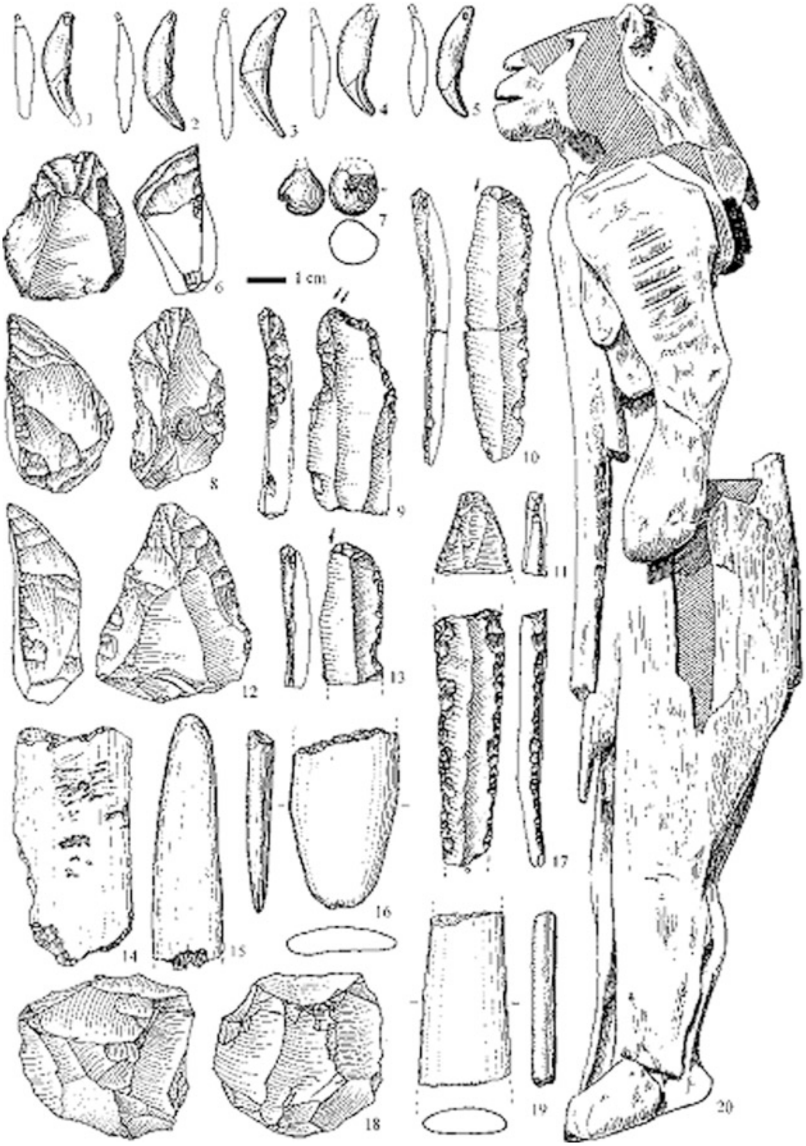

Fig. 3 A selection from the Aurignacian artefact assemblage from Hohlestein-Stadel, Southwest Germany (After Conard and Bolus 2003, p. 344)

artifacts and on the processes through which sites have developed over time. Insights into the origin and formation of artifact assemblages (Fig. 3) may also be gained by examining the object behavior of living human groups via ethnoarchaeology (e.g., Binford 1978; Schiffer 2013) or by comparatively analyzing the material remains of recent and past primate activity (e.g., Mercader et al. 2007).

In sum, artifacts constitute the main material basis of archaeological studies. Additionally, animal bones, plant remains, and sediments from human activity areas are analyzed to provide information on environmental parameters that influenced human behavior (Goldberg and Macphail 2006; VanDerwarker and Peres 2010). Finally, human skeletons can be subject to archaeological research to the extent that they either were directly manipulated – and therefore can be treated as a kind of artifacts – or show physical features induced by certain activities.

What Is an Artifact? What Is a Tool?

"Artifacts" and "tools" are overlapping but not synonymous categories. While tools and their functional use are the main focus of studies of animal behavior, archaeology concentrates on the artificial aspect of manipulating objects in human context. This point of view is summed up by Joachim Hahn (1993), who differentiates among natural objects, items in human context, and things which show signs of human use. Following his definition, the category "artifact" includes all material objects manipulated by humans, from a stone moved by an individual to clearly human-made pits, hearths, and stone structures. More narrowly, Hahn defines artifacts as items of stone, wood, or other materials that show at least some indicative use-wear, whether the objects are separate from or fixed to the environment. The term "tool" bears a technological meaning in archaeology as a subcategory of artifact: They are freely movable objects and were commonly modified in several operational steps, conditions that are not necessary for an object to be accepted as an artifact. Thus, an artifact blank can become a tool intentionally by modification – as in the case of stone flakes reworked into scrapers, denticulates, and burins, for example – or unintentionally by use for some functional purpose, as evidenced by use-wear and retouch on an unmodified blade.

In contrast to the archaeological viewpoint, primatologist Benjamin B. Beck (1980) defines tools not technologically by the object itself, but by the functional use to which an object may be put. Tool use, he writes, is "the external employment of an unattached environmental object to alter more efficiently the form, position, or condition of another object, another organism or the user itself when the user holds or carries the tool during or just prior to use and is responsible for the proper and effective orientation of the tool" (Beck 1980, p. 10). Thus, Beck excludes clearly artificial structures like nests, pits, or other fixed artifacts, which are quite commonly constructed by nonhuman animals and are often highly complex, such as the elaborate nests of bower birds, classifying these instead as the material outcomes of different, non-tool behaviors. Ergonomist Christopher Baber (2003, p. 8) identifies a tool as "a physical object that is manipulated by users in such a manner as to both affect change in some aspect of the environment and also to represent an extension of the users themselves. The manipulation is directed towards a specific goal or purpose, and the associated activity requires a degree of control and coordination." Accordingly, in this functional sense, a simple cookie cutter is a tool, but even the most sophisticated cookies themselves are not: They are mere artifacts of tool use (see chapter "▶ Overview of Paleolithic Archaeology," Vol. 3).

The ethological definition of tool use differs from the archaeological one in two ways: Tool use is not restricted to human behavior, and objects fall into the category of tools by their use, irrespective of the technical aspects of use-wear and modification that characterize archaeologically defined tools. Thus, Beck, dealing mainly with directly observed behavior, is only marginally concerned with the material evidence of use on the artifacts, and for zoologists generally, who focus on behavior and often only in passing document the material inventory of populations or species, the technological details are of minor interest. As a result, a major problem in Lower Paleolithic archaeology, namely, identifying artifacts and used objects made from durable material, is excluded from the domain of ethologists studying modern animal tool behavior. For archaeologists, however, who consider the use and manufacture of objects as a characteristic human means to increase the physically limited abilities of the body in solving problems, the functional separation of tool use sensu stricto from the formation of attached or unattached artificial structures is irrelevant. Both can be subsumed under the category of artifacts to get a more complete picture of the material culture, the subject central to archaeology. Which sort of information artifacts yield through archaeological analyses will be discussed next.

Facets of Archaeological Knowledge

Through the use of diverse methodological approaches, five major facets of knowledge can be drawn from archaeological artifacts. These facets can also be combined to generate pictures of different aspects of prehistoric life, like settlement and subsistence behaviors, social and religious organization, technical progress, and the spread of innovations:

- **Typological facet**: Artifacts tell us the forms and styles of objects used by a group. Features of form or style can be categorized by modern analysts into artifact types, yet may not coincide with the originally intended classifications. Changes in types through time, as seen through stratigraphic analysis, seriation, or both, form the basis of relative chronology (see chapter "▶ Chronometric Methods in Paleoanthropology," Vol. 1). The definition of cultural groups and their geographical distribution is founded on the relative chrono-spatial separation of artifact types (Adams and Adams 2008).
- **Technological facet:** Artifacts tell us the materials, devices, and operational steps used to make tools. By analyzing the different operational steps in tool production, their order, and variations in the production sequences known as *chaînes opératoires* (Pélégrin et al. 1988; Schlanger 1994; Bar-Yosef and Van Peer 2009), and also assisted by experiments and ethnoarchaeological studies (McCall 2012), we can gain insight into the basic crafts of past societies. Further, a survey of the implements necessary to make certain artifacts gives evidence on

the complexity of human object behavior. In addition to technological studies, the management of raw material (Andrefsky 1994) is examined to see, for example, if raw material was taken by chance, if certain raw materials were preferred, or if special raw materials were used for particular artifacts. The effort taken to procure the necessary raw materials and the degree of extensive or intensive exploitation are further relevant to developing hypotheses on how former people differentiated and evaluated technological qualities. A combination of typological and technological aspects of knowledge may refine artifact typology and can give information about group- or period-specific employment of crafts.

- **Functional facet:** Artifacts reveal the technological aspects of not only how they were manufactured and got their form but also how they were used. Through experimentation, use-wear and residue analyzes can indicate the activities and ways in which artifacts were employed (Hardy and Moncel 2011; Rots and Williamson 2004; Stevens et al. 2010). Additionally, functional examination can give evidence about behaviors whose resulting artifacts may be only rarely preserved, such as the manipulation of organic raw material (Soffer 2004; Liu et al. 2013). Further, experiments with reconstructions, as in the cases of the wooden spears from Schöningen/Lower Saxony (Rieder 2003) and of Aurignacian bone flutes from the Swabian Jura/Germany (Münzel et al. 2002), can test hypotheses on the qualities of tools. The examination of specific functions related to special artifact types reveals formal categories already set up at the time of the use of the tools. In all, a combination of functional and technological analyses can disclose the life history of artifacts with sequences of repeated modification and use, as well as provide hypotheses as to which functional necessities of a tool influenced its manufacture.
- **Contextual facet**: Artifacts tell us, from their location in a site, where and when they developed, were made and used, and suggest how sites and life within them were organized. Detailed three-dimensional documentation of where objects manipulated by humans, tools, wastes, and associated finds were found (e.g., Speth et al. 2012), combined with refitting of production sequences (e.g., Machado et al. 2013), allows the classification of loci of activity as dump zones, ateliers, food-processing areas, etc. The spatial and chronological relations between the identified activity zones in contemporaneous sites allow conclusions on the broader organization of prehistoric life. The comparison of elements of the environments used or manipulated by humans, in contrast to purely natural assemblages, yields evidence on the specific functional relationships of different hominin groups with the surrounding natural environment.
- **Cognitive facet**: Via the decisions that either deliberately or unconsciously underlay the conceptualization, manufacture, and use of artifacts, we see in them perception, evaluation, memory, planning, knowledge, reasoning, and sociality (e.g., Stout et al. 2008; Wynn and Coolidge 2010). Thus, comparative analysis of data from the four previous facets can reveal preferences in how tools were designed, produced, and used and where on a site they were made or used, pointing up less favored or rejected alternatives. Information on a population's

artifact array, combined with environmental constraints, gives hints about the range of behavioral choice and aspects of decision-making in typology, technology, use of artifacts, and site organization (e.g., Stout et al. 2005). In this way, the spectrum of the decisions taken by a group reveals its knowledge and comprehension of the world, its cognitive capabilities, and the processes of cultural diffusion underlying artifact types, production, and use. In rare cases, as at the French Magdalenian sites of Etiolles (Pigeot 1990) and Pincevent (Ploux 1989) or the Mousterian site Maastricht-Belvédère site K, Netherlands (Stapert 2007), even individual behavior and apprenticeship can be perceived.

In these five aspects of archaeological knowledge derived from artifacts, it becomes obvious that the archaeological discipline is a combination of the sciences and humanities, not only in its questions and collected data but also in its approach to knowledge. While the technical, functional, and contextual aspects are scientifically oriented, yield somewhat reproducible facts, and are open to experimental falsification (not in the hard scientific sense but in the sense that, e.g., wear patterns on a tool can be repeatedly examined and hypotheses on their origin tested), the typological and, even more so, the cognitive facet involve a humanities-oriented hermeneutic approach which nevertheless has to follow epistemological rules (Garofoli and Haidle 2013). This attitude to knowledge looks not so much for identification of facts and rules, but for understanding of background patterns. Of course, this differentiation between scientific-empirical and humanistic-hermeneutic approaches in archaeology can reveal only tendencies: Almost all archaeological works are a mixture of scientific observations and resulting statements with hermeneutic interpretation. The gradual preference of the one or the other depends very much on the theoretical standpoint of the analyst.

Limits to Archaeological Analyses

Despite the discipline's remarkable insights into otherwise undisclosed aspects of everyday life, archaeology is able to give only an incomplete and fragmented picture of prehistoric activities and behavior. Several preconditions have to be met if archaeological analysis is to gain access to at least some sectors of hominin living (e.g., Audouze and Enloe 1997).

First, to become archaeologically evident today, behavior in the past must have caused a detectable change in the natural environment, producing artifacts or leaving other material traces behind. This prerequisite severely limits archaeological studies to a small, but nonetheless important, portion of the full range of human behavior.

Second, the artifacts must have been embedded in sediment, and the sedimentation should have proceeded quickly but not aggressively, so that the activity context of the artifacts is properly sealed. This is a key point, for large parts of the record can be lost by taphonomic processes in slow or incomplete sedimentation and secondary alterations of the find-bearing strata like erosion and bio- or cryoturbation.

Third, the artifacts must have been preserved over time. A wide range of artifacts made from organic material, for example, is likely to have weathered to unrecognizable shapes or to have decomposed altogether. Physical and chemical destruction of different substances depends very much on climatic and soil conditions, with cave sediments in temperate zones being most favorable for many raw materials and the acidic red soils of tropical regions being among the worst areas for conservation.

Fourth, the artifacts must be discovered. Further, they have to be unearthed along with documentation of their context to reveal the maximum information they still bear. The quantity of archaeological evidence in an area or a period is a direct function of the density of research activities and the exposure of relevant geological strata by natural means or through quarrying or construction work.

Lastly, the traces of behavior kept in the artifacts must be accessible to interpretation. This can depend on actual research paradigms, the possibilities and availability of analytic methods, as well as individual or social limitations affecting the analyst.

In Paleolithic archaeology another problem arises from the difficulties in ascribing artifacts to one of several contemporaneous human species represented by fossil remains in the same region. For example, although the first stone artifacts are widely accepted as the products of early *Homo*, whether *H. habilis* or *H. rudolfensis*, there are also australopithecine/paranthropine candidates for authorship. The hand morphology of *Paranthropus*, in principle, would have enabled them to knap stones (Susman 1991) (see chapter "▶ Analyzing Hominin Phylogeny: Cladistic Approach," Vol. 3), and it is unclear who made the cut marks on bones associated with *Australopithecus garhi* fossils at Bouri/Ethiopia (de Heinzelin et al. 1999). These uncertain attributions hamper the linkage of behavioral data and information derived from physical-biological context and thus obstruct the deciphering of the evolutionary implications of cultural remains.

Extending the Limits: Archaeology as an Integrative Discipline

Beyond the limits of classical artifact analyzes, archaeology develops its full power by applying methods and integrating results from a wide scope of neighboring disciplines. The archaeological prospection of sites, the documentation of finds, and the analyses of artifacts are completed by geophysical methods like remote sensing, supported by geographical information systems, and assisted by microscopy and 3D scanning. Dates and geological, sedimentological, paleofaunal, and paleobotanical data, as well as derived reconstructions of climatological and environmental change (see chapter "▶ The Paleoclimatic Record and Plio-Pleistocene Paleoenvironments," Vol. 1), add supplementary information on associated to archaeological layers. Genetic models based on ancient DNA and the DNA of modern populations help to create and test archaeological hypotheses, classifications, and interpretations (see chapter "▶ Ancient DNA," Vol. 1). Ethnographical and ethological data give hints on possibilities of interpretation and on associated aspects of behavior not preserved in archaeological assemblages.

Archaeology as a Paleoanthropological Subject

While clues to the behavior of vanished species and populations are limited, functional morphology may give insights into general aspects of living by analyzing dentitions adapted to certain diets, or limbs allowing special ways of locomotion, or other features of the genetically based layout of the body. From the physique, behavioral possibilities can be ascertained. A generalized hand, with opposable thumb and the capability of power and precision grip, is able to do what a hoof or fin cannot. Fossil skeletons of *Homo* and other hominins show bipedal primates developing lower limbs specialized for long-distance walking and freed-up hands perfect for object manipulation. But the question of whether robust australopithecines in fact used their theoretically capable hands (see above) to produce Oldowan artifacts must remain open, as must the actual use made of the enlarging brains (see chapters "▶ The Evolution of the Hominid Brain," Vol. 3 and "▶ Evolution of the Primate Brain," Vol. 2) that accompanied the evolution of the genus *Homo* (see chapters "▶ *Homo ergaster* and Its Contemporaries", "▶ Later Middle Pleistocene *Homo*," and "▶ Defining *Homo erectus*," Vol. 3). Only a few features observed on skeletons can be attributed to concrete activities; in most cases, rather unspecific characteristics, like robustness of the bones, are hard to interpret (Bridges 1995), and these limitations are compounded by the sparseness of the skeletal database and lack of systematic examination of the modern reference.

More productive are correlations between basic physical capabilities, including the cumulative markers of effort, stress, and nutrition that can be deduced from skeletons, and archaeological remains, which yield detailed information about actual behavioral episodes. This explanatory power of artifacts may be demonstrated with regard to the issue of subsistence as the prominent behavioral aspect that can be derived from Paleolithic archaeological remains. For years the question has been discussed of whether some of the human ancestral groups were hunting or actually scavenging (e.g., Blumenschine et al. 1994). While traces from carcass-processing give evidence of the range of the prey according to species and age distribution (Ferraro et al. 2013), as well as show the use of the different body parts, finds like the spears from Schöningen (see chapter "▶ Dispersals of Early Humans: Adaptations, Frontiers, and New Territories," Vol. 3) (Thieme 1997) indicate sophisticated hunting activities among *Homo heidelbergensis* (see chapters "▶ Later Middle Pleistocene *Homo*" and "▶ Neanderthals and Their Contemporaries," Vol. 3). Similarly, clues to the composition of the diet can be gathered not only from the faunal and botanical remains from archaeological sites but also from markers detected on artifacts. Thus, digging for termites, well known in chimpanzees (see chapters "▶ Theory of Mind: A Primatological Perspective" and "▶ Great Ape Social Systems," Vol. 2), may also be likely for *Australopithecus robustus*, based on the use-wear analysis on bone tools (Blackwell and d'Errico 2001). Starch grain analyzes of stone tools demonstrate that the selection and processing of barley and wheat was underway in Southwest Asia at least 12,000 years before these grains were domesticated (Piperno et al. 2004), while residues on grinding stones from Shizitan Locality 14, China, indicate the consumption of roots, tubers, and grasses in the last glacial maximum (Liu et al. 2013). A third example is the control of fire, which reaches back at least 1 Ma at Wonderwerk Cave/South Africa, from which burned bone and ashy plant remains show that burning took place in the cave during the early Acheulean occupation (Berna et al. 2012).

Another important issue in Paleolithic archaeology that is accessible through artifact analysis is settlement behavior. Artifacts from a range of settlement sites, from short-term camps with nonspecific structures to long-term dwellings at favorable locations like the Magdalenian sites of Gönnersdorf and Andernach-Martinsberg in the German Rhineland, yield information on the organization of everyday life and on people's mobility, group size, differentiation, and separation of activities (Street et al. 2012).

It is clear from artifact remains that places reserved for special activities developed quite early in human evolution, underscoring that resource management is a key factor in human behavior. There were repeated purposeful visits of early *Homo* to the 1.6-myr-old MNK Chert Factory Site in Olduvai Gorge Bed II, a tool manufacturing site with more than 30,000 documented artifacts made from raw material brought in from about a kilometer away and distributed over an area at least a kilometer from the site (Stiles 1991; Kimura 1997). At the Middle Pleistocene "horse butchery site" Q2 GTP 17 from Boxgrove, *Homo heidelbergensis* brought six to seven flint nodules from the cliff some hundreds of meters away and flaked them into hand axes for the immediate purpose of cutting up the carcass of a horse (Roberts and Parfitt 1999). In analyzing the raw material and artifact transport to and from such sites, the development of larger and more complex settlement systems and territorial organization in human evolution can be brought to light (e.g., Féblot-Augustins 1999).

As a paleoanthropological subject, archaeology can complement the results of other anthropological disciplines in several ways. In analyzing artifacts, archaeology gathers information from short-term behavioral episodes which originate from singular or repeated events and can be fused to a more general picture of the behavioral aspects of chronologically, spatially, or biologically distinctive groups. Furthermore, comparing these results diachronically opens a cultural-historical dimension, thus making the evolutionary perspective on human behavior, and its underlying cognitive development, accessible in its full range. This will be described in more detail below.

What They Did: A Brief Outline of Paleolithic Artifact History

As an overview on historical knowledge derived from artifacts, this section covers the major behavioral developments in the Paleolithic period which can be extracted from archaeological remains; short sketches only, they are organized in roughly chronological order.

Nearly 3.4-million-year-old cut-marked animal bones from Dikika/Ethiopia give the first evidence of possible tool use by hominins; the tools, however, are lacking so far (McPherron et al. 2010). The earliest artifacts to which hominin authorship is assigned are stone tools reported from Gona, Ethiopia (see chapter "▶ Dispersals of Early Humans: Adaptations, Frontiers, and New Territories," Vol. 3) (Semaw et al. 2003), dated to 2.6 Ma BP (Ma). They give evidence of spontaneous secondary tool use, the use of one tool to manufacture another to reach an aim (Kitahara-Frisch 1993), which has thus far been observed only in a hominin context. The use of a hammerstone to produce a flake tool to dissect a carcass represents an extension of the problem-solution distance. This allows the development and use of a set of independent cultural units which can be used as behavioral modules, combined in different ways and put in an effective sequence by acting on and modifying each other (Haidle 2012). Contrary to earlier assumptions that the initial phases of the Early Stone Age (Lower Paleolithic: the Oldowan and the succeeding Developed Oldowan A technocomplexes) could be characterized by a core tool technology with distinctive tool types as intentional end products, experiments have shown that the Oldowan core tools vary with the raw material used and that the main target were cutting tools on flakes (Toth 1985) (see chapter "▶ Over view of Paleolithic Archaeology," Vol. 3). However, besides simple technologies with coarse raw material from which few flakes were detached, there are examples of higher-quality raw material processed in longer operational sequences with up to 70 flakes removed, both unidirectionally and multidirectionally, from both natural and prepared platforms (Kimura 1999; Delagnes and Roche 2005). Flakes, few of which show intentional retouch, served mainly as cutting devices, while cores typologically classified in categories, such as choppers and chopping tools, were used as heavy-duty tools. In the first million years of human stone artifact production, raw material transport rarely exceeded some 5–10 km (Goldman-Neuman and Hovers 2009). No early manufacture of bone tools has been proven so far, yet in rare cases the use of bone has been documented (Brain and Shipman 1993). The earliest sites with Lower Paleolithic artifacts are located in East and South Africa; but by around 1.85–1.78 Ma, the first migrants to West Asia (e.g., Dmanisi: Ferring et al. 2011), and presumably to East Asia, were also equipped with similar technology (see chapters "▶ *Homo ergaster* and Its Contemporaries" and "▶ Dispersals of Early Humans: Adaptations, Frontiers, and New Territories," Vol. 3). Sparse archaeological evidence complements fossil finds that point to an early occupation of Europe around 1.3 Ma (Arribas and Palmqvist 2002; Arzarello et al. 2007). Throughout the Oldowan period observed site organization is widely unspecific, with a focus on processing carcasses and/or stone tool production (Stiles 1991). Simple settlement structures have been postulated at Olduvai Gorge, Tanzania, and Melka Kunture, Ethiopia, for example; but these claims are largely rejected today due to possible natural explanations.

With the Acheulean, a new technological concept of large tools on mainly large flakes and bifacially knapped into specific forms like hand axes, cleavers, and picks was introduced in addition to the Oldowan technology around 1.76 Ma (e.g., Kokiselei, Kenya: Lepre et al. 2011). In East Africa, a temporal refinement between 1.75 and 1 Ma has been documented, from crude tools to hand axes with an increased number of flake scars (Beyene et al. 2013). The bifacial technology eventually spread from the early Acheulean sites in Africa to later sites in Asia and Europe (Lycett and von Cramon Taubadel 2008). Although the Acheulean bifacial concept dominates the perception of that period, these artifacts are in fact copresent with flake tools, though these are often – possibly falsely – classified as spatially and/or chronologically distinct industries like the Clactonian and Tayacian in Europe or the Developed Oldowan B in Africa (White 2000). Movius (1949) has observed that East and Southeast Asia seem to have been completely excluded from the spread of the bifacial technology concept, but recent finds from China (e.g., Bose valley: Hou et al. 2000) and Korea (Norton et al. 2006) that date to the Middle Pleistocene cast doubt on this hypothesis. Probable evidence of the control of fire as a typical human artifact is increasing, with finds from Wonderwerk Cave at around 1 Ma (Berna et al. 2012) and at Gesher Benot Ya'akov, Israel, at about 0.79 Ma (Goren-Inbar et al. 2004), although some instances of fire use, such as at Zhoukoudian/China from the end of the Lower Paleolithic period, have been questioned (Weiner et al. 1998).

From the very end of the Lower Pleistocene on, human occupation has also been proven not only for Southern Europe, e.g., at Atapuerca TD6, Spain (Carbonell et al. 1995; Parés et al. 2013), but also for its boreal zone as documented by the artifact assemblages from the English sites of Happisburgh 3 and Pakefield (Parfitt et al. 2005, 2010). Although the material remains of *Homo* behavior become more numerous in the subcontinent from 0.5 Ma on, it is not likely that the whole of Europe was populated continuously. The observed artifact spectrum widens in the Middle Pleistocene with wooden spears and other tools, e.g., from Clacton (Oakley et al. 1977), Schöningen (Thieme 1997), possibly Bilzingsleben (Mania and Mania 1998), and Gesher Benot Ya'aqov (Belitzky et al. 1991). A few flaked bone tools have been documented in that period, but no bone or ivory projectile points (Villa and d'Errico 2001). Possible evidence of nonfunctional artifacts such as at Berekhat Ram (d'Errico and Nowell 2000), Hunsgi (Paddayya 1977), and Bilzingsleben (Mania and Mania 1988) is very scarce. Postulated settlement structures at Bilzingsleben (Mania 1983) and the Grotte du Lazaret (de Lumley 1969) are questioned.

In the final phase of the Lower Paleolithic, and continuing into the African Middle Stone Age and the European Middle Paleolithic, flakes were increasingly retouched to improve or create the working edges of tools like scrapers, denticulates, notched pieces, and special forms of knives. The rising focus on flake tools can also be traced in Levallois technology, a new concept of core preparation in stone knapping that first appeared between 0.3 and 0.2 Ma. The idea of characteristically prepared Levallois cores that allow predetermined flake forms did not replace the older concepts, but was used in addition to them. In the European Middle Paleolithic, distances of raw material or tool transport increase up to 100 km or, in some cases, more (Féblot-Augustins 1999). Artifact assemblages of the Upper Middle Pleistocene also reveal increasing complexity and diversification. Microwear patterns at Sai Island, Sudan (Rots and Van Peer 2006), and Biache-Saint-Vaast, France (Rots 2013), and the use of hafting materials evident, e.g., in birch tar residues on stone flakes at Bucine, Italy (Mazza et al. 2006), and Inden-Altdorf, Germany (Pawlik and Thissen 2011), indicate the manufacture of composite tools in both Africa and Europe by at least 300 Ka, or possibly even earlier (Wilkins et al. 2012). By fusing several independent elements with specific attributes, composites with new qualities were formed. Hafting of stone tools, for example, combines the cutting qualities of a stone tool with qualities of the "handle" and different fixing qualities of binding materials and adhesives. The resulting product possesses new qualities that go beyond those of the parts. This technological augmentation is seen as a critical cognitive development (Ambrose 2010).

Stone tool assemblages in both Africa and Europe show increasing regional, chronological, and perhaps functional variation. Also on both continents, in late Middle Paleolithic/MSA context, there appear bone tools such as intensively used awls (d'Errico et al. 2003) and bone points (Henshilwood et al. 2001). From around 0.1 Ma, there is possible evidence of intentional interment of human bodies; whether these qualify as burials and indicate symbolic behavior is still under discussion (e.g., Sandgathe et al. 2012; Balter 2012; Hovers and Belfer-Cohen 2013). First instances of marine shells probably used as personal ornaments have been known for some 100 ka from the Levant, North Africa, and South Africa from contexts of anatomically modern humans (Bar-Yosef Mayer et al. 2009; d'Errico et al. 2009; Vanhaeren et al. 2006, 2013); rare evidence, however, has also been documented for Neanderthal contexts around 50 Ka (Zilhão et al. 2010; Peresani et al. 2013). Geometric engravings on pigment nodules (Henshilwood et al. 2009; Mackay and Welz 2008) or on ostrich egg shell (Texier et al. 2013) are known from southern African Middle Stone Age sites. Finally, evidence of hearth structures, for example, at Kebara (Meignen et al. 2000), marks a more habitual use of fire (Sandgathe et al. 2011). Heat treatment of stone to improve knapping qualities appears in South Africa around 164 Ka (Brown et al. 2009), and around 73 Ka, fire was presumably used for site maintenance by burning layers of plant bedding (Wadley et al. 2011). Evidence of stone-tipped arrows by around 65 Ka is increasing (Lombard 2011), thus providing the earliest example of the use of complementary tool sets with expendable elements like arrows and thread, which function in combination with enhancing/controlling elements like bows (for arrows) and needles (for thread) (Lombard and Haidle 2012) (see chapters "▶ Overview of Paleolithic Archaeology" and "▶ Cultural Evolution During the Middle and Late Pleistocene in Africa and Eurasia," Vol. 3).

The Early Upper Paleolithic, starting at around 40,000 years, is characterized by intensified use of bone, antler, and ivory as raw material. In some regions of the world, a burst of personal ornaments and artistic representations is documented, e.g., rock art as in Western Europe (Valladas et al. 2001; González-Sainz et al. 2013) and probably Australia (David et al. 2013), or mobile art (Conard 2003) and musical instruments (Conard et al. 2009) (see chapter "▶ Cultural Evolution During the Middle and Late Pleistocene in Africa and Eurasia," Vol. 3) in caves of the Swabian Alb. Although blades had been elements of the artifact inventories since the Lower Paleolithic, a new technological concept of blade production widely introduced in that period allowed an extended exploitation of the stone cores by optimizing the number of rather uniform blanks. In addition, Upper Paleolithic assemblages show increasing diversification in specific tool types for distinct purposes. Settlement of the European Arctic (Pavlov et al. 2004; Slimak et al. 2011) and of Japan (Takashi 2012) took place in this time period; Australia had become inhabited slightly earlier (O'Connell and Allen 2004; Davidson 2013).

From about 30,000 to roughly 20,000 years ago, the first unquestioned evidence of true burials with symbolic meaning, e.g., at Sungir (Pettitt and Bader 2000), Dolní Věstonice (Klíma 1988; Jelinek 1992), and Krems-Wachtberg (Einwögerer et al. 2006) are documented. Tool types became more and more standardized and regionally diversified. The period is known for an important extension of the find spectrum: evidence of fiber processing (Adovasio et al. 1998), systematic gathering of grass seeds (Piperno et al. 2004), production of unfired and fired clay sculptures (Klíma 1991; Einwögerer 2000), and, for the first time, construction of large and complex settlement structures mainly in the mammoth steppe, for example, at Dolní Věstonice and Pavlov (Klíma 1991). While depictions of animal-human hybrids and of elements of the human body, like vulva signs and hand negatives, are known from the Early Upper Paleolithic, the Middle Upper Paleolithic introduced representations of entire human beings that were extremely rare before (Conard 2009; Neugebauer-Maresch 1989) and that now became part of the parietal and mobile art spectrum in the form of frequent Venus figurines, a few male images, and some portraits. In this period, human occupation was extended to Arctic Siberia (Pitulko et al. 2004; Plumet 2006). Since ca. 20 Ka ceramic containers have been used in East Asia (Wu et al. 2012; Craig et al. 2013). After the last glacial maximum, a new category of artifacts, domesticated animals and plants, started to develop in human cultural contexts. Humans accompanied by the first domesticated animal, the dog (Galibert et al. 2011), migrated from Siberia to the Americas (Leonard et al. 2002), crossing the Beringian land bridge.

In conclusion this brief outline, though only superficial, demonstrates a gradual developmental process of progress, diversification, and intensification in archaeological sites from 2.5 Ma until the end of the Pleistocene. It is important to note, however, that all observations of this period are biased by the decreasing chance over time of artifact conservation. Furthermore, summary views of large time periods and spaces may appear clear-cut but, if examined in detail, become blurred.

What Could They Do? Recovering the Basis

Advanced tool behavior, as observed in great apes (see chapters "▶ Great Ape Social Systems," "▶ Theory of Mind: A Primatological Perspective," and "▶ Cooperation, Coalition, Alliances," Vol. 2) and in the artifact record of *Homo*, is founded to only a minor extent on instincts – genetically based processes automatically released by key stimuli – and is instead derived from cognition. Thus, like all cognitively controlled behaviors, it can be stopped arbitrarily, altered by learning, and improved by experience. However, advanced tool behavior is also founded on social transmission of information, so that not every individual has to find answers to perceived problems on his or her own, but can learn from other group members who apply fitting solutions. The social transmission of information opens up a historical-social dimension of behavioral development, the crucial parameter of cultural behavior. Although basics of cultural behavior have been documented in chimpanzees (McGrew 1992; Whiten et al. 1999), orangutans (van Schaik et al. 2003), bonobos (Hohmann and Fruth 2003), and whales and dolphins (Rendell and Whitehead 2001), cultural evolution is a driving factor in human evolution, revealing unknown spaces for variability and flexible adaptation, for progress as well as regress. The variability is expressed on the group level in different cultural performances, the actual sets of attributes of a group with historical-social developmental aspects in activities and manners and their material or notional manifestations.

The Tubingen model for the evolution of cultural capacities (Haidle and Conard 2011) sees the basis of cultural performances as threefold, with biological, historical-social, and individual dimensions (Fig. 4). The **biological dimension** comprises the biological potential and constraints for cultural behavior – in genes, gene expression, anatomy, and physiology. It is expressed, for example, in the structure of the nervous system and the brain, in sensory perception, in motor and articulation skills, in the form of sociality, and in the abilities to communicate. The biological dimension affects the basic course of life history and the physiological-cognitive potential to perceive, create, learn, and remember cultural traits and the ways in which they can be expressed. For example, the genus *Homo* is characterized by generalized hands facilitating material cultural expressions; by the development of a sound production and perception apparatus enabling language, a specific form of very detailed communication; by an increase of the relative brain size (McHenry and Coffing 2000; Lee and Wolpoff 2003); by changes in brain anatomy (see chapters "▶ Evolution of the Primate Brain," Vol. 2 and "▶ The Evolution of the Hominid Brain," Vol. 3) (Bruner 2010); and by shifts in life history (Schwartz 2012) giving more time for learning. Genetic studies suggest increased gene activity in the brain (Enard et al. 2002) and the mutation of single genes like FOXP2, a gene involved in linguistic articulation (Maricic et al. 2013); their specific roles, however, remain unclear. A modern human possesses markedly different biological equipment for cultural behavior than does a chimpanzee or a dolphin; musicality – which will be referred to below – is one of these biological parameters (Peretz 2006). The species-specific characteristic of the biological dimension of behavioral performances enables the finding of species-specific solutions to species-specific problems. Continuity or change in this dimension in general underlies evolutionary mechanisms like gene replication, mutation, and selection, but it may be partly modified through long-term interaction with the environment and, as part of it, material culture (Fisher and Ridley 2013) (see chapter "▶ Genetics and Paleoanthropology," Vol. 1).

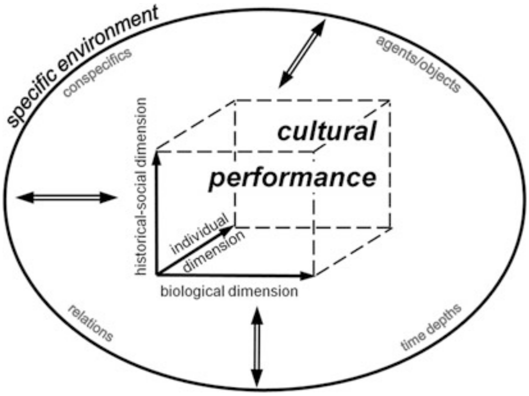

Fig. 4 Tubingen model of cultural evolution showing cultural performance with three dimensions of development (biological, historical-social, and individual). The cultural performance of a group is interdependent with the group-specific environment. This includes conspecifics, agents, and objects as affecting or affected elements with specific relations to the group and in a certain time depth of perception, conception, and action (After Haidle and Conard 2011)

The **historical-social dimension** represents historical and social potentials and constraints. The set of historically acquired knowledge and skills, customs, views, and opinions makes up a part of the individual's environment that can be acted on and used as a basis for further innovation. Social access to the knowledge and skills, customs, views, and opinions can be affected by population density, active communication systems, child-raising habits, teaching systems, systems of religious and political participation, and general group-specific attitudes about learning, innovation, and progress (Rogers 1995). The forms and extent of storage, transmission, permutation, and transformation of the knowledge and skills, customs, views, and opinions support or hamper the unfolding of cultural performances. The historical-social dimension in general affects the ways in which the biological basics are used for cultural behavior, but can also affect the properties of some biological bases (Malafouris 2010; Woollett and Maguire 2011). This dimension unfolds via social transmission from stimulus enhancement to the capacity of teaching, via group-wide adoption of innovations and via transgenerational traditions. The historical-social dimension is self-enhancing; cultural behavior influences factors that foster cultural transmission and creativity (Enquist et al. 2008). An example of the importance of the historical-social dimension is offered by different forms and preferences of musical expression in humans. While there are biological foundations of human musicality and the competence of musical expression and perception (Peretz 2006), historical-social factors determine the different ways in which music is perceived and applied (Cross 2001).

In addition to the biological and historical-social dimensions, cultural performance is defined by a third, **individual dimension**. This dimension reflects individuals' preferences, aversions, skills, and disabilities. The individual dimension incorporates the potential and constraints of an individual, or of a group of individuals, set by the personal social setting and by individual life histories of physical, mental, and emotional experiences. Already in the womb, monozygotic twins with the same genetic complement have different experiences with different epigenetic effects (Petanjek and Kostović 2012). Siblings can be raised in the same family within the same historical-social setting, but nonetheless experience different influences by parents, relatives, friends, teachers, etc., by support or deprivation, by diseases, fortuitous timing, or traumatic accidents. All these factors affect the additional mechanisms of change, which are operative on this dimension: individual learning, personal inventions, and epigenetics, "factors that influence gene expression without modifying the DNA sequence" (Ledón-Rettig et al. 2013, p. 311) (see chapter "▶ Genetics and Paleoanthropology," Vol. 1). Coming back to the music example: while the general musicality of humans is determined by biological factors, the preference for baroque music with cembalo instrumentation, for rock music with electric bass, or for classical Indian sitar music is influenced by historical-social factors, and individual performance in playing one of the instruments depends on individual attraction and training. Wolfgang Amadeus Mozart was a genius with special support by a musician father. He had human, not dolphin, biological capacities and – for his specific work – lived in the favorable historical-social context of eighteenth-century Austria, with orchestras and a broad, fascinated audience, rather than in a small, mobile group as on the Ice Age mammoth steppes.

All of these three major dimensions are multifactorial, and they are not independent. Rather, they influence one another directly or indirectly via reciprocal effects in the context of a specific environment. The latter is the sum of the cultural and social aspects of the environment of an organism or a group, plus the section of the natural environment that affects, or is affected by, the organism or the group. The functional relationships of a group of organisms with elements of the specific environment vary according to the resources they perceive in that environment, given the state of their biological, historical-social, and individual dimensions. Although the natural landscape of a lion and *Homo ergaster* may have been the same, their specific environments differed markedly. These differences include their conspecifics and biotic and abiotic agents, plus objects that they affect or are affected by the form of their relationships with conspecifics/agents/objects and time depth (in perception, conception, and action) in both past and future directions influencing these relationships or behaviors. Cultural performances are thus neither a mere biological product nor solely a historical issue, and they are embedded into the specific environment in which the lives of individuals play out.

While cultural performances represent the actual sets of cultural attributes expressed by an organism or a group, cultural capacities represent the potential range of cultural performances in different subgroups at a given time (Haidle and Conard 2011). The cultural capacity, e.g., of *Homo heidelbergensis* cannot be directly observed, but must be deduced from the sum of quasi-contemporaneous performances seen in the record of material culture preserved at different archaeological sites associated with *H. heidelbergensis* (see chapters "▶ *Homo ergaster* and Its Contemporaries," "▶ Origin of Modern Humans," "▶ Neanderthals and Their Contemporaries," "▶ Later Middle Pleistocene *Homo*," "▶ Defining *Homo erectus*," Vol. 3). The potential cultural capacity of a group, a population, or a species is never completely exhausted by the particular individuals, groups, or populations; rather, different aspects of the capacity are used and expressed.

The range of cultural performances of different groups – and thus the corresponding cultural capacities – has expanded over the course of human evolution. Nonetheless, a single cultural performance in an advanced grade of cultural capacity may be simpler than another performance in an earlier grade (Jones 1995), since different aspects of the full cultural potential can be applied selectively (Hovers and Belfer-Cohen 2006; Lombard and Parsons 2011). The mechanisms of cultural development can be compared with a ratchet (see chapter "▶ Theory of Mind: A Primatological Perspective," Vol. 2) (Tomasello 1999) or better with the act of mountaineering (Lombard 2012); it is always possible to proceed further from any point reached so far, but returning to an earlier or simpler point can also proceed by retracing or following other routes. Using the mountaineering metaphor, cumulative cultural capacity does not only include those cultural efforts that are built upon the highest level achieved but also recursions following on seemingly more advanced solutions. Advanced cultural capacities are not necessarily accompanied by a progressive line of ever more sophisticated and complex solutions built on earlier ones, but allow increasing technological, cognitive, and behavioral flexibility from very simple to highly complex solutions depending on environmental and biological constraints, historical-social paths, and individual decisions. Thus, although the range of cultural performances expands with increasing cultural capacity, cultural evolution is not always linear progressive. The development of cultural capacity is a systemic process involving the coevolution of the three dimensions outlined above and their interactions with the specific environment.

Cognition and culture are the main basis of what prehistoric groups did, and this is partially expressed in the artifacts that have been preserved to our times. Thus, artifacts are a means for detecting the cognitive and cultural background behind their creation. This is not easy. Indications of prehistoric people's cognitive and cultural potential – what they could think and do – have to be separated out from behavior compelled by the restrictions of the specific environment. Archaeology can help to delineate the cognitive space and cultural capacities of prehistoric groups and to trace the development of the biological, historical-social, and individual dimensions. Yet loss of evidence within the archaeological record must also be factored in; it must be kept in mind that absence of evidence cannot be equated with evidence of absence and in not only material but also cognitive and cultural terms (Gott 2002; Speth 2004). What we can detect in the archaeological record is only a group's minimum cognitive potential and cultural performance, as manifested in artifacts. Cognitive faculties and cultural capacities that are apparently unexpressed in material remains because a group did not represent these faculties and capacities, or because an archaeological analyst failed to recognize them, might have been present; yet researchers can only note the lack of such indications.

Conclusions

Through the study of artifacts, archaeology provides insight into tool use as a major part of human behavior. Five facets of archaeological knowledge can be drawn from the material remains of object-bound activities: typological, technological, functional, contextual, and cognitive. From these, other behavioral aspects, such as subsistence, settlement, social organization, and their cognitive backgrounds, can be derived. The only available evidence, though fragmented, on the development of human behavior comes through diachronic comparison of artifact assemblages. So questions of how prehistoric populations used their cognitive potential and cultural capacities, as determined by biological, historical-social, and individual dimensions and limited by environmental constraints, can be approached only through archaeology.

Abstract

Human speech, language, and cognition derive from anatomy and neural mechanisms that have been shaped by the Darwinian process of natural selection acting on variation but that have roots present in other living species. Language did not suddenly arise 50,000–100,000 years ago through a mutation that yielded an innate "faculty of language" nor does the human brain include an organ devoted to language and language alone. Broca's area is not the center of language. Neural circuits linking local activity in different neural structures regulate complex behaviors. Neural circuits that were present in early mammal-like reptiles play a part in regulating laryngeal phonation, conveying both referential information and emotion. Speech plays a central role, enabling transmission of information at a rate that exceeds the auditory fusion frequency. The unique human tongue enhances the robustness of speech, but Neanderthals and other archaic hominins whose neck and skull proportions preclude their having an adult-like human tongue nevertheless could talk. Comparative studies of present-day apes suggest that hominin "protolanguage" lacking syntax never existed. The neural bases of human language are not domain-specific – in other words, they are not devoted to language alone. Mutations on the FOXP2 transcriptional gene shared by humans, Neanderthals, and at least one other archaic species enhanced synaptic plasticity in cortical–basal ganglia circuits that are implicated in motor behavior, cognitive flexibility, language, and associative learning. A selective sweep occurred about 200,000 years ago on a unique human version of this gene. Other transcriptional genes appear to be implicated in enhancing cortical–basal ganglia and other neural circuits.

Introduction

The findings of studies of the communicative capacities of living species, the biological bases of human language including recent advances in neuroscience and genetics, and the archaeological record suggest that human language has a long evolutionary history. Human language makes use of anatomical structures and brain mechanisms that have deep evolutionary roots. The evolutionary framework proposed by Charles Darwin appears to account for human language, which is linked to the biological bases of other aspects of human behavior including cognition and motor control. Aspects of human anatomy and brain mechanisms that were initially adapted to serve other ends were modified to confer human linguistic capacities. Natural selection acted on mutations that were useful in the Darwinian "struggle for existence," entailing the survival of progeny in particular ecosystems. For hominins, this includes their culture. Thus, culture, defined in a broad sense, must be taken into account.

A wide range of independent studies will be taken into account. These include comparative studies of the behavior, morphology, and neuroanatomy of other species. Traditional "experiments in nature" of the behavioral deficits of human subjects arising from trauma, strokes, and neurodegenerative diseases have yielded insights on the neural bases of motor control, language, cognition, and emotional regulation. The findings and implications of these studies will be reviewed. The findings of neuroimaging techniques such as functional magnetic resonance imaging (fMRI)) and diffusion tensor analysis (DTI) have yielded further insights on both the nature and evolution of the brain bases of language and cognition. Recent genetic studies such as ones comparing the DNA of apes, humans, and extinct hominins provide a fresh starting point for understanding how the human brain was shaped. They point to mutations on transcriptional factors and selective sweeps in the last 500 Ka acting on humans, Neanderthals, and other hominin species. A unique human mutation and selective sweep about 250 Ka may have yielded current human cognitive and linguistic capacities. The archaeological record cannot, in itself, serve as an index of cognitive or linguistic ability, but it has yielded valuable insights that will be taken into account.

Although it is probable that earlier forms of hominin language lacked many of the characteristics of present-day languages, many proposals concerning the precise form of language at any period can neither be verified nor refuted owing to the inherent impossibility of observing behavior in prehistory. However, it is possible to rule out some proposals, such as a "protolanguage" that had words but no syntax (Bickerton 1990). The fact that present-day apes raised in a language-using environment can master simple syntax using sign language or manual phonetic systems rules out this possibility. The evolution of the human tongue, which will be discussed here, likewise rules out Neanderthal language being limited to humming (Mithen 2005). Chomsky's (2012) claim that hominins lacked any form of language until 50 Ka is ruled out by the findings of the studies reviewed here. Chomsky's (1972, 2012) dismissal of natural selection having a significant role in biological evolution also is ruled out by this evidence. Selective sweeps on mutilations on transcriptional genes enhanced cortical–basal ganglia circuits implicated in language cognition and motor control (Enard et al. 2002; Reimers-Kipping et al. 2011; Lieberman 2013; Maricic et al 2013).

The Evolutionary Framework

Charles Darwin in 1859 could not have imagined the progress achieved in our understanding of the biological bases of human language and their evolution. Although imperfect – no one can state with certainty how biological brains work – current findings affirm that the agents for the evolution of language are those proposed by Darwin, natural selection, whereby

> . . .any variation, however slight and from whatever cause proceeding, if it be in any degree profitable for an individual of any species, in its infinitely complex relations to other organic beings and to external nature, will tend to the preservation of that individual, and will generally be inherited by its offspring. The offspring, also, will thus have a better chance of surviving. . .. (1859, p. 61)
>
> And the
>
> . . .fact that an organ originally constructed for one purpose. . .may be converted into one for a wholly different purpose. . .. (1859, p. 190)

Only humans possess language, but its evolution does not appear to involve any singular, uniquely human, evolutionary process. Despite what I view as claims to the contrary by Noam Chomsky and his colleagues, the evolution of the specialized anatomy and neural substrates that confer language derives from these Darwinian mechanisms, as is the case for the specialized capabilities of other species, for example, butterflies or anteaters. Moreover, comparative studies and insights from genetics and neurophysiology show that language has roots that can be traced back in time to extinct species, as is the case for other aspects of human behavior. Some aspects of human language can be observed in other living species. It is also becoming apparent that elements of the neural substrate that confer language are involved in other aspects of cognitive and motor behavior. Current research shows that genes that play critical roles in the development of the muscles, lungs, and brains of other species have been modified through the process of natural selection to enhance human cognitive and linguistic capacities.

The seemingly intractable problem in tracing the evolution of human language is the extinction of the hominin species that represent key intermediate stages in the evolution of language. However, the fossil and archaeological records and current knowledge of the biological bases of human language allow us to rule out implausible scenarios and permit reasonable inferences about the evolution of language.

Communication and Cognition

Human language serves as a medium both of thought and communication, and specialized anatomy has evolved to enhance the robustness of human speech, the default modality by which humans communicate using language. Studies of the functional architecture of the brains of primates and other living species show that activity in different parts of the brain linked in *neural circuits* generally is necessary to carry out a "complex" behavior, whether that is picking up an object, comprehending the meaning and emotional content of a sentence, or changing the direction of a thought process (e.g., Alexander et al. 1986; Kotz et al. 2003; Monchi et al. 2001, 2006a; Simard et al. 2011; Wang et al. 2005; Postle 2006; Lieberman 2000, 2002, 2006, 2013). The operations performed by the linked neural structures' circuits do not, in general, appear to be domain-specific. Neural circuits that are active during cognitive tasks – including arithmetic, sorting objects according to shape or color, shifting cognitive sets, etc. – are also involved in linguistic tasks such as keeping words in short-term "working memory" and comprehending the meaning of a sentence. Debates as to whether language evolved to serve communication or cognition are thus inherently irresolvable. Since language plays a role in virtually all aspects of human culture, it also is difficult to identify any single aspect of behavior (e.g., social interaction) that was "the" factor that led to the evolution of human language. Moreover, the specific form of a language appears to both reflect the needs of a culture and to a degree affect the thoughts and manner in which the speakers of a language view the world (Everett 2012). However, it is clear that language is the primary medium by which people communicate, transmitting the information that constitutes a culture from generation to generation and sharing thoughts from individual to individual in every time and place. It is thus improbable that natural selection facilitating communication had no role in the evolution of language (e.g., Chomsky 2012; Fitch 2010).

Comparative Studies

Comparative studies of species other than present-day humans show that they possess some aspects of human language to a lesser degree. Humans and chimpanzees share a common ancestor that lived about six million years ago (The Chimpanzee Sequencing and Analysis Consortium 2005). Thus, although living apes have also evolved since that epoch, studies of the communicative capabilities of apes can yield some inferences on the linguistic abilities of extinct hominin species. Any aspect of language that can be mastered by present-day apes most likely was present in the early stages of hominin evolution. It is apparent that culture plays a role in the acquisition of linguistic capabilities. Chimpanzees, if exposed to a language-using environment early in life, can acquire active vocabularies of about 150 words, communicating their needs and observations to humans and to each other (e.g., Gardner and Gardner 1969; Savage-Rumbaugh et al. 1985). The linguistic environment can even be one in which chimpanzees use a version of American Sign Language (ASL) to communicate with each other. Chimpanzee Loulis in infancy acquired some ASL proficiency when he could only observe and participate in ASL communication with other ASL-using chimpanzees. Biological capacities that may not be apparent in one cultural setting can be observed in other environments. No one, for example, in 1800 could have thought that cars could routinely pass each other at closing speeds that exceed 150 km/h without massive loss of life. Comparative studies of ape communication show that apes can actively use simple syntax and comprehend spoken words and simple spoken sentences. It thus is improbable that any "protolanguage" lacking words ever existed. Other living species can also comprehend spoken words. Some dogs can learn in one trial to reference the meaning of hundreds of spoken words with specific objects (Kaminski et al. 2004). However, no nonhuman species can talk. Apes instead use manual sign language and other manual system to signify words, lending plausibility to the idea that manual gestures played a significant role in the early stages of language evolution (Hewes 1973).

Human Speech

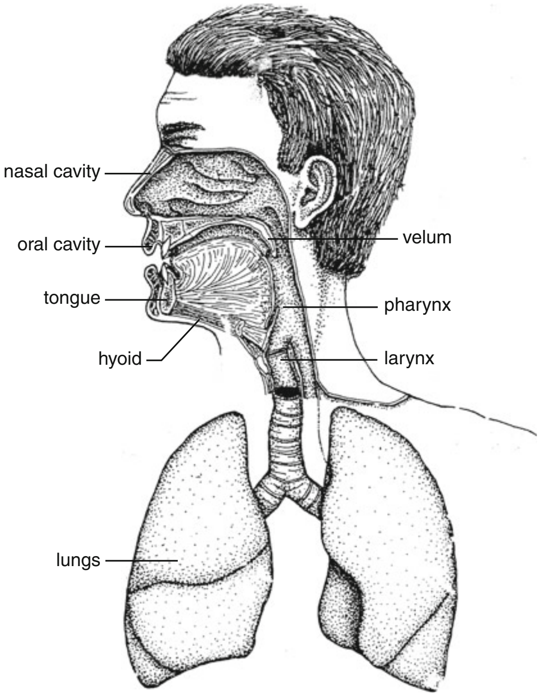
Manual gestures, facial expressions, and body language all continue to play a role in human communication, but speech is the default, primary, phonetic modality of language. Sign languages are a comparatively recent invention, dating to the eighteenth century. Speech confers numerous advantages over communication by means of manual gestures, facial expressions, and posture, such as not having to direct one's attention to individuals who are communicating and freeing one's hands when communicating. However, perhaps more importantly, speech allows humans to rapidly transmit information. The rate at which the sounds that convey words are transmitted exceeds the fusion frequency of the auditory system – the rate at which other sounds merge into a meaningless buzz. The process by which this high transmission rate is achieved has been enhanced through the evolution of the species-specific human tongue and the airway above the larynx. The fossil record thus provides a time line for this process as well as for the evolution of the brain bases for speech motor control, language, and some critical elements of human cognitive ability (Lieberman and McCarthy 2007; Lieberman 2007, 2013). Understanding this process requires some prefatory information on the physiology of speech production.

The invention of pipe organs in mediaeval Europe shows that some knowledge of the physiology of speech production was present. In a pipe organ, a source of acoustic energy with a wide frequency spectrum is filtered by pipes that allow energy to pass through them in narrow ranges of frequency, producing particular musical notes. Johannes Muller systematically described the physiology of speech production in 1848. In Fig. 1 a sketch view of the anatomy involved in speech production is presented.

The lungs provide the source of energy for speech production. Speech is almost always produced during expiration, reflecting the evolutionary history of the lungs. As Darwin pointed out, the lungs of mammals and other terrestrial species evolved from the swim bladders of fish. Swim bladders enabled fish to hover at a particular depth, thereby conserving energy that would otherwise be necessary to move flippers or tails. This is accomplished by storing air extracted from water by gills in elastic sacks, which adjust their body size in order to displace water at a given depth to match their weight. Human lungs retain this elastic property, reflecting the opportunistic, proximate, logic of evolution.

During quiet inspiration, the diaphragm and intercostal and abdominal muscles expand the lungs. The elastic recoil of the lungs then provides the force that expels air during expiration. The duration of inspiration and expiration is almost equal. Since the elastic lungs act in a manner analogous to a rubber balloon, the alveolar air pressure is at a maximum at the start of each expiration and linearly falls as the lungs deflate. The alveolar (lung) air pressure during expiration thus starts at a high level and falls as the volume of the elastic lung sacks falls. The alveolar pressure of the outgoing flow of air impinges on the vocal cords of the larynx. The pattern of activity during speech and singing is quite different. The diaphragm is immobilized. The duration of expiration is keyed to the length of the sentence that a speaker produces, and alveolar air pressure is maintained at an almost uniform level until

Fig. 1 The lungs, larynx, and supralaryngeal vocal tract



the end of expiration. This entails a speaker enabling a set of instructions to the intercostal and abdominal muscles to "hold back" against the force generated by the elastic recoil force, which is high at the start of the expiration and gradually falls. The intercostal and abdominal muscles contain muscle "spindles" that monitor the force that they produce (Bouhuys 1974). The diaphragm contains few spindles, which accounts for its taking no part during speech and singing.

A speaker must anticipate the length of the sentence that he or she intends to produce, generally taking in more air before the start of a long sentence. Since lung volume is higher before the start of a long sentence, the holdback maneuvers of the intercostal and abdominal muscles must take the higher elastic recoil force into account to achieve a relatively level alveolar air pressure during the sentence (Bouhuys 1974).

In his experiments, Johannes Muller found that the rate at which the vocal cords open and close depends on (1) the tension of the muscles that make up the vocal cords, which are complex structures made up of muscles, cartilage, and other tissue, and (2) alveolar air pressure. The fundamental frequency of phonation (Fo) is determined by the rate at which the vocal cords open and close. It is necessary that alveolar air pressure be regulated during speech, as the initial high alveolar air pressure would blow apart the vocal cords, or the fundamental frequency of phonation would start at a very high Fo and rapidly decrease throughout the sentence. This Fo pattern generally does not occur during speech. For most declarative sentences in languages such as English, Fo is more or less level except for momentary controlled peaks that signal emphasis and a sharp decline at the sentence's end (Armstrong and Ward 1926; Lieberman 1967).

Aerostatic and aerodynamic forces and muscle tension acting on the vocal cords of the larynx in all mammals and anurans generate and modulate phonation in much the same manner. However, as Victor Negus (1949) pointed out, the larynges of species that rely on vocal communication, including humans, have been adapted to facilitate phonation at the expense of protecting the lungs from the intrusion of water and reducing the rate at which air can be transferred into the lungs during inspiration. The meaningful calls of many species are differentiated by Fo contours and Fo variations that convey emotional information in all known human cultures and languages. But the fundamental frequency of phonation also conveys linguistic distinctions beyond signaling the end of sentence-like segments and yes–no questions which in English and other languages have rising or level sentence-end Fo contours (Armstrong and Ward 1926; Pike 1945). Local modulation of Fo contours differentiates words in tone languages such as the Chinese languages (Tseng 1981). Many independent studies show that primates signal referential information by means of calls that have different F0 contours (e.g., Cheyney and Seyfarth 1990). This again points out the implausibility of any stage in early hominin communication that relied exclusively on manual gestures.

The Supralaryngeal Vocal Tract and Encoding

The larynx, however, is not the key anatomical structure involved in speech production. Its primary role is that of a *transducer*; the larynx converts the relatively slow flow of air out of the lungs into *phonation.* As the vocal cords open and close an almost periodic series of "puffs" of air enters the airway above the vocal cords, the *supralaryngeal vocal tract* (SVT), that contain acoustic energy at frequencies that are audible. The acoustic energy generated by the larynx is the "source" or energy for phonated vowels such as the vowels and initial consonants of the words *bit* and *map*. Acoustic energy occurs at the fundamental frequency of phonation and at its harmonics, which are integral multiples of Fo.

Movable type is often used as a metaphor to describe the speech signal; speakers ostensibly strung together *phonemes*, segmental sounds approximated by the letters of the alphabet, to form words. The phonemes /t/, /a/, and /b/, for example, can be rearranged to form the words *tab* or *bat*. This, however, is not the case. In the 1960s attempts were made to build devices that would string together phonemes to produce comprehensible speech. The first step appeared to isolate phonemes. It was thought that it would be possible to isolate phonemes, equivalent to the letters of the alphabet, from tape recordings. When a person spoke the word *too*, there hypothetically should be a segment of tape that contained the phoneme /t/ before a segment of tape that contained the phoneme or sound [u] (the phonetic symbol for the actual sound of the vowel of the word *too*). However, much to everyone's surprise, it proved to be impossible to isolate sounds that corresponded to the hypothetical phonemes that formed words. When the segment of recording tape

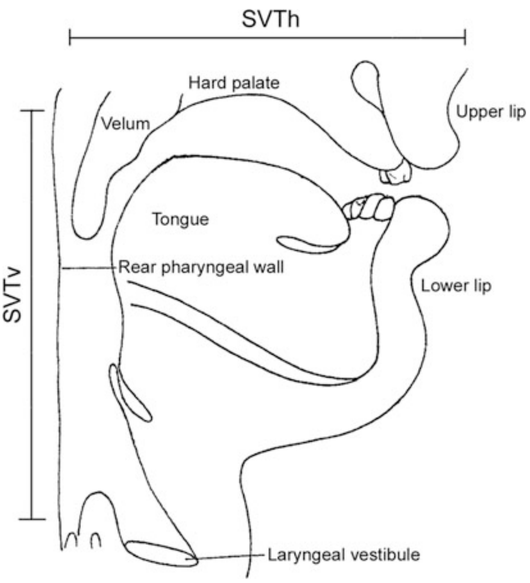


Fig. 2 The adult human tongue and supralaryngeal vocal tract. Half of the tongue, the "SVTh segment," rests in the oral cavity, half the "SVTv segment" rests in the pharynx

that was supposed to correspond to the phoneme /t/ in the word *too* was isolated and linked to the vowel [i] segmented from the word *tea*, the result was incomprehensible. The reason for this phenomenon soon became evident – the position assumed by the lips, tongue, jaw, and larynx for the phoneme /t/ is affected by those necessary to produce the vowel [u] in a different manner than the vowel [i] yielding different overall "encoded" formant frequency patterns for the words *too* and *tea*. It was impossible to segment a "pure" [t] or for that matter any consonant or vowel. Encoding is a general effect. For example, when producing a word such as bit, the position of the tongue, jaw, lips, and larynx which determine the formant frequencies of [b] must move to the different positions necessary to produce [I] (the vowel of this word) and then to produce the [t]. As they move, albeit rapidly, there must be transitions between the SVT shapes of each of the phonemes (see Fig. 2).

Speech allows humans to transmit information at a rate that exceeds that of any other acoustic signal by means of a complex perceptual process. Research at Haskins Laboratories in the 1960s first showed that speech perception involves listeners paying attention to the *encoded*, melded formant frequency pattern that conveys the entire word. The Haskins research program attempted to devise a machine for blind persons that would transform printed texts into speech. They found that it was impossible to find any acoustic signals that would correspond to isolated phonemes. Moreover, when any other nonspeech acoustic signals or mixed tactile/acoustic signals were used to transmit the segmental roughly phonemic representation of words, it was necessary to transmit about 20 phonemes per second to approximate a normal speaking rate. However, the fusion frequency of the human auditory system is about 15 Hz and the hypothetical phonemes would merge into a meaningless buzz. In short, the perceptual unit to which listeners pay attention is the encoded word with the consonant–vowel (CV) syllable being the minimal unit. Listeners perceptually *decode* each word at some internal level, taking account of the constraints of speech production according to the "motor theory of speech perception" (Liberman et al. 1967).

The formant frequency patterns of the hypothetical independent phonemes posited by linguists are always melded together into syllables and words. This seeming deficiency explains why speech is the default medium conveying information through the medium of language. The minimal unit in the speech signal is inherently an encoded CV or longer word sequence. It then can be perceptually decoded into sequences of phoneme. At the neural level, phonemes may be motor-control instruction sets – gestures that a person learns that are instantiated in the motor cortex as *matrisomes*, instructions that guide a set of muscles to perform an act (Sanes et al. 1999). The encoded instruction sets yield the motor acts necessary to produce an entire syllable or word. Segmental un-encoded motor gestures and acoustic cues do not characterize fluent speech. If, for example, a person's lips are viewed when she or he utters the words *too* and *tea* (the syllables [tu] and [ti]), it is apparent that the lips are already pursed and projecting to produce the vowel [u] of *too* at the very start of the syllable. Chinese orthography, which codes words, is a better approximation of the speech signal than alphabetic systems. Successful speech-recognition systems that have been developed since 1967 use algorithms that involve matching the incoming acoustic signal to probable word templates.

The Supralaryngeal Vocal Tract and Normalization

Johannes Muller (1848) realized that the airway above the larynx, *the supralaryngeal vocal tract* (SVT), played a critical role in speech production in a manner similar to a pipe organ. The note that is heard is the product of the organ pipe acoustically filtering the source of sound energy produced by the air flowing through a constriction at the end of the pipe. The airflow through the constriction produces acoustic energy across a wide range of audible frequencies. The organ pipe reduces the amount of sound energy that passes through it at most frequencies. The frequency at which maximum acoustic energy passes through the organ pipe is perceived as the musical note. The length and shape of the organ pipe determines the musical note.

The length and shape of the SVT, which can be thought of as a malleable organ pipe, results in maximum acoustic energy passing through it at *formant frequencies* that are the determinants of individual phonemes along with durational cues. The average formant frequencies of the vowel [i], for example, are 270, 2,300, and 3,000 Hz for the adult males studied by Peterson and Barney (1952), whereas the formant frequencies of the vowel /u/ were 300, 870, and 2,240 Hz. The absolute values of the formant frequencies for any phoneme depend on the length of a speaker's SVT. The average formant frequencies of /i/ and /u/ of the women in Peterson and Barney's study, who had shorter SVTs, were higher. One of the problems encountered in devising automatic speech-recognition systems is how to take into account the effect of speakers' differing SVT lengths. Since the length of the SVT varies from person to person and during the years of childhood and adolescence for the same individual, the absolute values of the formant frequency pattern vary. For example, the formant frequencies of an [i] would be 1.5 times higher for a child whose SVT length was 11.3 cm long than for an adult whose SVT was 17 cm long. Both formant frequency patterns would be perceived as examples of an [i] owing to a speech-specific process of perceptual *normalization* in which listeners internally estimate the length of a speaker's SVT (Nearey 1978). Listeners can estimate SVT length after hearing a short stretch of speech or "reverse engineering" a known phrase such as person saying *hello*. Nearey (1978) showed that the vowel [i] (of the word *see*) was an optimal signal for immediate SVT normalization.

The problem of SVT normalization was evident in one of the earliest studies aimed at achieving speech recognition by machine. Since different speaker's SVTs differ in length, any successful automatic procedure would have to take this into account. Data from Peterson and Barney's (1952) study pointed at [i] (the vowel of see) and to a lesser extent [u] being optimal acoustic cues for SVT normalization. Words having the form [hVd], such as *heed* and *had*, produced by ten different speakers were presented in quasi-random order to a panel of listeners; the listeners had to immediately adjust for different speakers' voices and identify each word. Out of 10,000 trials, listeners misidentified [i] two times, [u] six times, and other vowels hundreds of times. The speakers in Peterson and Barney's (1952) study spoke different dialects of American English, and some had foreign accents, which led to the supposition that dialect differences were responsible for some of the errors. However, Hillenbrand et al. (1995) reported virtually identical results in a study which eliminated dialect variation and made use of computer-implemented technology that was unavailable in 1952 to analyze the speech signals.

The Unique Human Tongue

Charles Darwin raised the question of why the human tongue is so peculiar. Darwin noted:

> The strange fact that every particle of food and drink which we swallow has to pass over the orifice of the trachea, with some risk of falling into the lungs. . .. (1859, p. 191)

In the twentieth century, Victor Negus's studies of comparative anatomy demonstrated both the species-specific nature of the human tongue and the fact that it increased the risk of choking to death on food. Negus concluded that the adult human larynx was carried down into the pharynx because it "is closely apposed to the tongue" (Negus 1949, pp. 25–26). Choking on food remains the fourth leading cause of accidental death in the United States (http://www.nsc.org/library/report_injury_usa.htm). Negus speculated that the unique shape of the human tongue in some manner facilitated speech communication, compensating for increasing the risk of choking. That supposition has been validated by computer-modeling studies that calculate the range of formant frequencies that could be produced by adult human and nonhuman SVTs (Lieberman et al. 1969, 1972; Lieberman and Crelin 1971; Carre et al. 1995; De Boer 2010).

The initial Lieberman et al. (1969) study calculated the formant frequency patterns of the vowels that a rhesus macaque's tongue and SVT could produce. The range of tongue shapes was estimated by taking into account constraints on tongue deformation, which were subsequently confirmed by Takemoto (2001, 2008). The monkey's tongue was positioned as far as possible to produce the SVT configurations used by adult human speakers to yield the "point" vowels [i], [u], and [a]. These vowels delimit the range of vowels used in human languages (Greenberg 1963). The computer-modeling technique showed that the monkey's vowel space did not include these point vowels. Newborn infants have SVTs that are similar to those of nonhuman primates (Negus 1949; Crelin 1969). The SVT computer modeling of Lieberman et al. (1972) used similar techniques to model the SVTs of chimpanzees and human newborn infants.

Crelin had published the first comprehensive anatomy of the human newborn (1969). Crelin concluded that the Neanderthal SVT was similar to that of a large human newborn on the basis of the total pattern of morphological similarities between the basicrania of newborns and the adult male Neanderthal specimen from La Chapelle-aux-Saints. Lieberman and Crelin (1971) produced a computer model of the reconstructed La Chapelle 1 specimen using cineradiographic data on newborn infant cry (Truby et al. 1965) and cineradiographic data on adult human speech (Perkell 1969) to guide the jaw, tongue, lip, and laryngeal maneuvers to derive the range of possible vowels. As Lieberman and Crelin (1971, p. 211) noted, "When we were in doubt as, for example, with respect to the range of variation in the area of the larynx, we used data derived from adult Man that would enhance the phonetic ability of the Neanderthal vocal tract . . ."

At birth in humans, most of the tongue is positioned in the mouth and its shape is flat as is the case for other mammals. The proportion of the tongue in the oral "horizontal" (SVT_H) part of the infant oral cavity relative to the part of the tongue in the "vertical" pharynx (SVT_V) – SVT_H/SVT_V – was 1.5 when the larynx was positioned at its lowest point in the "forceful" cries pictured in Truby et al. (1965, pp. 75–78). The human tongue does not attain its adult 1:1 SVT_H/SVT_V proportions and almost circular posterior midsagittal shape until around 6–8 years of age. The descent and reshaping of the human tongue was determined using cephalometric radiographs of 28 subjects between the ages of 1 month and 14 years. The developmental process by which the species-specific human vocal tract is formed is complex and takes 6–8 years and sometimes as long as 10 years (Lieberman and McCarthy 1999; Lieberman et al. 2001). The length of the oral cavity is first shortened in humans by developmental processes that move the hard palate back on the base of the skull, shortening the nasopharynx (D. Lieberman 2011). The shape and position of the tongue then gradually changes from the newborn tongue, which is flat and is positioned almost entirely in the oral cavity. The human tongue descends down into the pharynx and achieves its posterior rounded contour, carrying the larynx down with it. By 6–8 years of age, SVT_H (the horizontal segment) and SVT_V (the vertical segment) reach the 1:1 proportion. Data from a longitudinal study of 605 subjects imaged using magnetic resonance imaging (MRI) and computed tomography (CT) are consistent with these developmental studies (Vorparian et al. 2009). In contrast, the nonhuman primate tongue is long, rectangular, and positioned primarily in the oral cavity. In fetal development and shortly after birth, the chimpanzee larynx drops slightly owing to an increase in the distance between the larynx and hyoid (Nishimura 2003; Nishimura et al. 2003, 2006, 2008), whereas the human growth pattern involves the descent and shaping of the tongue. Tongue shape and SVT_H/SVT_V proportions in nonhuman primates remain almost constant from birth onward.

The human tongue's oral and pharyngeal proportions and shape explain why only adult humans can produce the vowels [i], [u], and [a] and why these vowels contribute to the robustness of human vocal communication. Half the tongue (SVT_H) is positioned in the oral cavity, and half SVT_V is positioned in the pharynx. SVT_H and SVT_V meet at an approximate right angle, owing to the tongue's posterior circular shape. The extrinsic muscles of the tongue, muscles anchored in bone, can move the almost undeformed tongue to create abrupt midpoint ten-to-one discontinuities in the SVT's cross-sectional area. Stevens's (1972) parallel research explained why the unique human tongue contributed to the robustness of human vocal communication. Stevens showed that only the species-specific human SVT can produce the ten-to-one midpoint area function discontinuities that are necessary to produce the vowels [i], [u], and [a], which he termed "quantal." Stevens employed both computer modeling using Henke's (1966) algorithm and physical models (wooden tubes that could be shifted to change the position of the 10:1 changes in SVT cross-sectional area). Quantal vowels are perceptually salient owing to the convergence of two formant frequencies which yield spectral peaks. Their formant frequency patterns do not shift when tongue position varies about one centimeter about the midpoint. Speakers thus can be sloppy and produce the "same" vowel. Nearey (1978) subsequently showed that the vowel [i] is an optimal signal for determining the length of a speaker's vocal tract – a necessary step in the complex process of recovering the linguistic content from the acoustic signals that convey speech. Whereas the identical formant frequency pattern can represent two different vowels for speakers who have different SVT lengths, no such overlap occurs for tokens of [i].

Independent computer-modeling studies carried out by Lieberman and Crelin (1971), Lieberman et al. (1972); Stevens (1972); Carre et al. (1995), and De Boer (2010) have reached similar conclusions. Carre and his colleagues used a technique that directed the computer model to produce a vocal tract that could produce the full range of formant frequencies of human speech by modifying a nonhuman SVT. The system "grew" a pharynx equal in length to its oral segment. Carre et al. (1995) concluded that in order to produce the full phonetic range of human speech, "a vocal tract must have independently controllable oral and pharyngeal cavities nearly equal in length." The computer-modeling studies of Boë and colleagues (e.g., 2002) have disputed these findings. They claim that Neanderthals and newborn human SVTs have the same phonetic potential as ones having the oral and pharyngeal proportions of human adults. However, their computer model inherently produces irrelevant results because it distorts any SVT into the proportions of a human adult SVT (De Boer and Fitch 2010; Lieberman 2012). A straight plastic mailing tube would also assume the shape and proportions of an adult human tongue during speech using the computer-modeling procedure employed by the Boë studies.

The Linguistic Capacities of Living Nonhuman Species

Syntax and Semantics

The linguistic capacities of other species are seemingly so limited compared to those of humans that they can be ignored. Nonetheless, they can provide insights into the evolution of the different aspects of human language and the role of culture. As noted above, apes raised in environments in which sign language and other manual phonetic means are used can acquire vocabularies of about 150 words. They can also expand the semantic referents of words. The chimpanzee Washoe, for example, used the word *dirty* on her own as an epithet. She had only heard the word before used by the Gardner team to refer to her soiling herself. The limits on the passive vocabulary of chimpanzees have not been determined, but some dogs can learn at least the primary meanings of 200 words (Kaminski et al. 2004). When exposed to a rich human linguistic environment, it is evident that the capacity to learn some aspects of human language exists in other living species. Conversely, humans raised in an extremely deprived linguistic/social environment do not appear to develop either linguistic or cognitive proficiency. Genie, a child locked in a room and virtually deprived of human contact until puberty, failed to develop either normal language or cognitive ability despite intensive therapy (Curtiss 1977). Other less well-documented cases of feral children suggest a similar interaction between the environment and "inherent" biological capacities.

Vocal Tract Normalization and the Range of Speech

The neural basis for vocal tract normalization appears to be genetically transmitted in humans since other species make use of this ability for another purpose – estimating the size of conspecifics and other species from their vocalizations (Fitch 2000).

However, other living species cannot talk. One phonetic limit derives from their tongues. In contrast to the human SVT, the tongues of animals always remain anchored in their mouths during vocalization. Deer, for example, can transiently descend by increasing the distance between the hyoid bone and larynx. The lowered formant frequencies serve to signal to conspecifics that the animal is larger than it actually is. However, the deer cannot change the shape of their SVT to produce quantal speech sounds. This is apparent in the McElligott et al. (2006) study that synchronized audio and video recordings of mature groaning fallow bucks. Their acoustic analyses (e.g., Fig. 1, p. 342) show no change in vowel quality. The deer instead produces the same schwa-like vowel with gradually falling formant frequencies.

Cineradiographs of other mammals vocalizing in Fitch (2000) again show that though transient larynx lowering occurs, the animals cannot produce the shapes necessary to produce quantal vowels because the tongue is still positioned in the animals' mouths. Thus, the dynamic articulatory maneuvers executed by animals discussed in some detail in Fitch (2010, pp. 315–320) do not increase the phonetic range of their vocalizations. Fitch is correct when he notes that the key to the evolution of the human SVT involves the descent of the tongue, not the larynx, which is carried down into the throat as the tongue moves down into the pharynx and is reshaped. However, Fitch overlooks the fact that the SVT shapes that are necessary to produce quantal vowels involve movements of the reshaped human tongue as a whole in the right-angle space formed at the junction of the oral cavity and pharynx. Thus, the undocumented "extinct hominid" discussed by Fitch (2010, p. 318), which has a "flat" nonhuman primate-like tongue anchored in the oral cavity instead of a rounded, human tongue with equal SVT_H and SVT_V segments, could not have produced quantal vowels. Surprisingly, DeBoer and Fitch (2010, p. 41), in their discussion of the vocal tracts of humans and other species, note that the unique attributes of the human tongue and SVT are adaptations for enhancing the robustness of speech communication.

Speech Would Be Possible, Absent the Human Tongue

It is imperative to point out that speech and language are possible without the ability to produce quantal vowels. Lieberman and Crelin concluded in 1971 that the archaeological record demonstrates that Neanderthals must have possessed spoken language in order to transmit their stone-working technology, and in light of the selective advantage of speech's information transfer rate, it is possible to argue that Neanderthals undoubtedly talked. The overall error rate for all vowels in the Peterson and Barney (1952) study was low, only 4.6 %. However, the incremental difference in speech intelligibility that derives from being able to produce quantal vowels is only one example of the fact that small differences drive natural selection. Evolution for adult lactose tolerance, for example, has occurred independently on different genes. It is possible to survive, absent this capacity. The selective advantage was an incremental increase in the food supply (Tishkoff et al. 2007).

As Darwin (1859, p. 61) put it:

> any variation, however slight and from whatever cause proceeding, if it be in any degree profitable to an individual of any species, in its infinitely complex relation to other organic beings and to external nature, will tend to the preservation of that individual, and will generally be inherited by its offspring. The offspring, also, will thus have a better chance of surviving ... I have called this principle, by which each small variation if useful is preserved by the term of Natural selection.

The Fossil Record of Evolution of the Human Tongue and SVT

Given the advantages of the species-specific vocal tract for speech production, it is of great interest to determine the sizes and shapes of hominin vocal tracts. However, this presents challenges since the hyoid bone is the only component of the SVT that fossilizes, so that indirect approaches are necessary to infer the size and shape of the tongue, larynx, and other soft tissues. Researchers have focused on the bones that directly border the vocal tract – the hyoid, basicranium, mandible, cervical vertebrae, clavicles, and sternum – since these bones constrain the size and shape of the SVT. In addition, researchers have used the comparative method to reconstruct characteristics of the vocal tract in hominins.

Hyoid Bone and Larynx

Eight hyoid bones form the hominin fossil record (see Table 1). Capasso et al. (2008:1007) argued that the lack of muscular impressions on a ~400-ky-old hyoid body from Italy indicates a "reduced capability for elevating this hyoid bone and modulating the length of the vocal tract," whereas Martínez et al. (2008) and Rosas et al. (2006) argued that the archaic hyoid bodies from Sima de los Huesos and El Sidrón, Spain, look nearly identical to those for fully modern humans. Arensburg and colleagues (1989; 1990) argued that the Neanderthal hyoid bone from Kebara, Israel, looks essentially modern, although several of its dimensions fall outside the range of variation of modern humans (Lieberman 1993, 1994; Arensburg 1994). However, it is unclear that there is any relationship between hyoid morphology and SVT length and shape.

The hyoid bone can, however, provide concrete evidence about the presence or absence of air sacs. A hyoid body for a juvenile *Australopithecus afarensis* specimen from Dikika, Ethiopia, exhibits a scalloped dorsal surface identical in morphology to the hyoid bodies of great apes that have laryngeal air sacs (Alemseged et al. 2006). This indicates that loss of air sacs occurred sometime between 3.3 Ma and 600 ky (De Boer 2012). In nonhuman primates, laryngeal air sacs are thought to recycle air from the lungs during long vocalizations (Hewitt et al. 2000) and enhance the impression of the vocalizer's size (De Boer 2009), but their presence limits the ability to produce distinctive speech by reducing the perceptual effects of vowels (De Boer 2009, 2012).

The larynx does not fossilize. However, it is possible to say something about its spatial relationships in hominins using comparative data from nonhuman primates. In humans, great apes, and lar gibbons, the thyroid cartilage is separated from the hyoid bone with the lateral thyrohyoid ligament and triteceum cartilage intervening between the two, which allows the thyroid cartilage to move independently of the hyoid (Bibby and Preston 1981; Nishimura 2003). This is different from the hyolaryngeal configuration in monkeys and agile gibbons, where the hyoid bone and thyroid cartilage overlap. Nishimura et al. (2003, 2006, 2008) showed that the thyroid cartilage descends relative to the hyoid prior to 1 year of age in

Table 1 Hyoid bones in the fossil record

Element	Species	Age (m.y.)	Site	References
Body	*Australopithecus afarensis*	3.3	Dikika, Ethiopia	Alemseged et al. (2006)
Bodies	*Homo heidelbergensis*	0.60[b]	Simo de los Huesos, Spain	Martínez et al. (2008)
Body	*Homo heidelbergensis*[a]	0.40	Castel di Guido, Italy	Capasso et al. (2008)
Bodies	*Homo neanderthalensis*	0.043	El Sidrón, Spain	Rosas et al. (2006)
Hyoid	*Homo neanderthalensis*	0.60	Kebara, Israel	Arensburg et al. (1989)
Hyoid	*Homo sapiens*	0.019	Ohalo II, Israel	Hershkovitz et al. (1995)

[a] Capasso et al. (2008) attributed this hyoid to *Homo erectus*
[b] Date from Bischoff et al. (2007)

chimpanzees, much the same as it does in modern humans. It is therefore likely that descent of the thyroid cartilage relative to the hyoid bone is the first step in a multistage process of laryngeal descent that did not necessarily have anything to do with vocalization (Nishimura et al. 2006). Parsimony would suggest that a thyroid cartilage descended relative to the hyoid and the presence of a lateral thyrohyoid ligament and triteceum cartilage were characteristics exhibited by the last common ancestor of chimpanzees and hominins.

Basicranium

The bones of the palate, vomer, sphenoid, and basioccipital (for the purposes of this paper, the "basicranium") form the roof of the SVT. Several lines of research used the basicranium to reconstruct SVT size and shape in hominin specimens. As noted previously, the first such attempt was by Lieberman and Crelin (1971) and Lieberman et al. (1972), who noted that the "unflexed" basicranium of the adult Neanderthal specimen La Chapelle 1 resembled the basicranium of a human infant or a nonhuman primate. These researchers reconstructed La Chapelle 1 as having a superiorly positioned hyoid and larynx, long SVT_H, and unequal SVT_H: SVT_V ratio. Laitman and Crelin (1976) provided additional justification for this approach, noting that the basioccipital rotates ventrally during early postnatal development, bringing the suprahyoid muscles into a more inferior position and contributing to hyoid and larynx descent. By analogy, fossil hominins with "flexed" basicrania were thought to have low hyoids and larynges in a modern-humanlike configuration, whereas hominins with "unflexed" basicrania were thought to have high hyoids and larynges and an infant human- or nonhuman primate-like tongue and SVT. Laitman and colleagues characterized flexion using a "cranial baseline" spanning the palate, nasopharynx, sphenoid, and basioccipital and reconstructed nonhuman primate-like vocal tracts for paranthropiths, australopiths, and some archaic *Homo* and modern humanlike vocal tracts for OH 12 (*Homo habilis*), Kabwe and Steinheim (archaic *Homo*), Skhūl 5, and late Pleistocene *H. sapiens* (Crelin 1973; Laitman et al. 1978, 1979; Laitman and Heimbuch 1982). The statistical procedure used to characterize the cranial baseline took into account the length of the oral cavity and nasopharynx and the angles formed by the basioccipital, vomer, and palate relative to one another. Other researchers have used on the basicranium to make inferences about SVT size and shape. Budil (1994) used the relationship between flexion and orientation of the styloid process in Petralona (archaic *Homo*) to infer a low hyoid and larynx position for this specimen. Duchin (1990) noted that *H. sapiens*, Neanderthals, and *H. erectus* have similarly shaped oral cavities, suggesting that fibers of three muscles (genioglossus, palatoglossus, mylohyoid) important for movements of the tongue had muscle fiber orientations similar to those of modern humans.

The use of the basicranial angle for reconstructing SVT size and shape has been criticized for a number of reasons. First, it has been noted that many normal human populations have unflexed basicrania, like those exhibited by Neanderthals, but normal vocal tracts (Kean and Houghton 1982; Houghton 1993; Frayer and Nicolay 2000). Carlisle and Siegel (1974, 1978) and Falk (1975) noted that the hyoid in Lieberman and Crelin’s (1971) reconstruction was positioned higher relative to the mandible’s inferior border than is normal in chimpanzees. Lieberman and McCarthy (1999) showed that basicranial flexion and laryngeal descent occur at two entirely different times during ontogeny, suggesting that any effect flexion has on laryngeal descent must be indirect. Although there may be no direct relationship between basicranial flexion, craniofacial shortening, and laryngeal descent, other studies note that the modern human naso- and oropharynx do not leave much room for the hyoid and larynx near the skull base, and space limitations are such that normal increases in size of the adenoids, tonsils, and other lymphatic tissues during childhood often threaten the airway (Tourné 1991).

As noted above, Laitman and colleagues characterized various skulls as either “flexed” or “unflexed” using a cranial baseline. However, these terms do not just refer to flexion of the cranial base in a narrow sense, but to the position of the palate relative to the nasopharynx and basioccipital on the underside of the cranium. The use of terminology most often employed for referring to the orientation of the basioccipital, sphenoid, frontal, and ethmoid bones relative to one another on the inner surface (brain side) of the cranium (see Lieberman and McCarthy 1999) was unfortunate, as it has been a perpetual source of misunderstanding. The statistical procedure employed by Laitman et al. (1979) and Laitman and Heimbuch (1982) clustered together hominin specimens with palates angled relative to the nasopharynx and basioccipital. In retrospect, the real characteristic that determines speech ability is not basicranial flexion, but length of the SVT_H, since this dimension cannot be overly long for there to be a 1:1 proportion. There is not necessarily a link between SVT dimensions and flexion of the basicranium as measured by the cranial baseline. Modern humans are characterized by a large, globular brain and cranial vault; short, retracted palate; short nasopharynx; and flexed basioccipital (Lieberman et al. 2002; Lieberman 2008;

Gunz et al. 2010, 2012). In fully modern humans, these traits are related to a SVT with equal-length horizontal and vertical segments, since the palate, nasopharynx, and basioccipital directly border SVT_H. In chimpanzees and other nonhuman primates, a long palate, long nasopharynx, and unflexed basioccipital form the superior border for a long SVT_H and short SVT_V. However, there is a wider range of variation in these parameters in fossil hominins. Olduvai Hominid (OH) 12, Kabwe, and Steinheim have been reconstructed with "flexed" basicrania, but each of these specimens has a long nasopharynx and long, projecting face. In other words, previous reconstructions based on basicranial flexion and/or palate length (Crelin 1973; Laitman and Crelin 1976; Laitman et al. 1978, 1979; Duchin 1990; Budil 1994) agree with reconstructions based on SVT_H length only insofar as a long nasopharynx and long, projecting face are attributes normally associated with an unflexed basicranium. There is one specimen, Skhūl 5, that has an intriguing combination of features in this regard. This specimen has a relatively long palate but a short, fully modern humanlike nasopharynx and flexed basioccipital. However, in this one case, a moderate SVT_H that does not fall outside the modern human range is incompatible with a 1:1 SVT (see below).

One implication of the above discussion is that one way to rule out certain SVT sizes and shapes is to measure or estimate SVT_H. Since modern humans have a 1:1 SVT, this measurement can then be doubled to estimate hominin SVT length. Using this approach, Lieberman and McCarthy (2007) showed that Neanderthal crania are characterized by a long palate and nasopharynx that forms the roof of a SVT_H that is outside the range of modern humans, and Lieberman and McCarthy (2007) and Granat et al. (2007) reconstructed a SVT_H for Skhūl 5 that falls within the high end of the fully modern human range. SVT_H can be approximated by taking a measurement from prosthion (landmark on the alveolar bone between the central incisors) to the pharyngeal tubercle, which is the point where the pharyngeal constrictors that form the posterior pharyngeal wall attach to the basioccipital, and adding ten centimeters to approximate the anteroposterior length of the lips. Several studies (Boe et al. 2002; Granat et al. 2007) have used basion (landmark on the anterior edge of the foramen magnum) instead of the pharyngeal tubercle to model SVT length. These studies claimed that a modern human-shaped tongue would fit into a Neanderthal head and neck, but did not account for the fact that the posterior pharyngeal wall does not extend all the way back to basion. It is clear that Neanderthals and other archaic hominins have long, projecting faces (Arsuaga et al. 1997; Trinkaus 2003) and that they also would have had long SVT_H dimensions.

Mandible

At one time, it was thought that the genial tubercle, which marks the attachment for the genioglossus and geniohyoid muscles of the tongue to the inner border of the mandibular symphysis, provided the "surest anatomical evidence of speech that the skeleton affords" (Hooton 1946, p. 169; see DuBrul and Reed 1960), although its presence and distribution in modern humans is highly variable. In nonhuman primates, the hyoid body is positioned at the mandible's inferior border at or near the gonial angle. As noted above, Lieberman and Crelin (1971) positioned the hyoid body just superior to the mandible's inferior border in their La Chapelle 1 reconstruction, a move which was criticized at the time. However, it is not the inferior border of the mandible that the hyoid must fall below, but instead the mylohyoid line (which marks the attachment area for the mylohyoid muscle to the deep surface of the mandible) and the attachment sites of the other suprahyoid muscles. The hyoid cannot be positioned much higher than this, since the suprahyoid muscles that attach to the hyoid need to act as elevators, not depressors, of the tongue, in order for the tongue to function in swallowing. There is therefore a constraint on the superior position of the hyoid bone relative to the mandible. Finally, there is some evidence that the resting position of the hyoid may be more superior than previously appreciated in nonhuman primates with normal head and neck postures. The inferior position of the hyoid may be partially an artifact of the manner in which nonhuman primates are positioned for MRI (Nishimura et al. 2008), so that the slightly higher hyoid position reconstructed by Lieberman and Crelin (1971) may fall within a normal range of variation. All hominins, therefore, would have possessed hyoids positioned no higher than the inferior attachment points of the suprahyoid muscles to the mandible's inner border, in close approximation to the mandible's inferior border.

Cervical Vertebrae

In modern humans the hyoid descends below the basicranium, palate, and mandible during ontogeny (Lieberman and McCarthy 1999; Lieberman et al. 2001), but maintains a steady position relative to the cervical vertebrae after 2 years of age. At that age, the superior margin of the hyoid body lies opposite the intervertebral disk between C3 and C4 (Carlsöö and Leijon 1960; Roche and Barkla 1965; Westhorpe 1987). In adults, the hyoid body is positioned as far inferiorly as C4 (King 1952; Bench 1963; Ardran and Kemp 1972), the vocal folds of the larynx lie opposite C5, and the cricoid cartilage lies opposite C6–C7 (Roche and Barkla 1965; Koppel et al. 1968; Wind 1976). It is therefore feasible to infer hyoid and larynx position (and, by extension, SVT_V) by reconstructing neck length in Neanderthals and other hominins that have preserved cervical vertebrae. Table 2 shows the ventral heights of cervical vertebrae C3–C7 for two Neanderthals (La Chapelle 1, La Ferrassie 1) and Skhūl 5. Ventral heights for each of the Neanderthal specimens fall within the low end of the range of modern human data (Arensburg et al. 1990). However, it is clear that, when fit together, Neanderthals would have relatively short necks. McCarthy et al. (n.d.) used an algorithm constructed for humans to estimate intervertebral disk heights and reconstructed neck lengths of about 12 cm for the two Neanderthals and 11 cm for Skhūl 5. For comparison, Trinkaus (1983) estimated Shanidar 2's neck length at 11.5 cm. As noted above, in modern human adults, the vocal folds of the larynx lie opposite C5. Placing the vocal folds of the larynx in the same position produces a ~8 cm long SVT_V for

Table 2 Ventral heights of cervical vertebrae. Data are from Arensburg et al. (1990) and McCown and Keith (1939). Parentheses indicate original authors' estimates based on damaged fossils

Vertebra #	La Chapelle 1	La Ferrassie 1	Skhūl 5	Modern human mean (range)
C3	11.25	12.5	(10.0)	14.1 (11.0–17.0)
C4	(10.6)	12.0	8.5	13.5 (10.3–16.2)
C5	11.5	11.5	9.5	12.7 (10.5–15.2)
C6	12.1	12.5	10.0	12.7 (10.2–15.9)
C7	13.4	13.0	12.5	14.4 (11.2–16.3)

Neanderthals and a 7.5 cm SVT_V for Skhūl 5, which are close to the averages for modern humans. However, SVT_H is so long in these specimens that SVT proportions range between 1.54:1 and 1.60:1.

SVT Reconstructions and Constraints on Hyoid and Larynx Position

A more conservative way to reconstruct SVT shape would be to consider constraints on the position of the hyoid and larynx in the throat. The hyoid bone must be positioned at or below the mandible's inferior border; otherwise, the suprahyoid muscles would not function as elevators of the hyoid during swallowing. Similarly, the hyoid bone cannot lie below the pectoral girdle or else the infrahyoid muscles would not act as depressors of the hyoid, and protraction of the hyoid during swallowing would be impeded by the sternum and clavicles. Taking these constraints into account, the lowest possible position for the hyolaryngeal complex in the three specimens above is for the vocal folds to be at C6, which would put the cricoid cartilage at C7/T1. In this case, La Chapelle 1, La Ferrassie 1, and Skhūl 5 would have SVT ratios between 1.31:1 and 1.33:1, still outside the quantal region (see Fig. 3). The anatomical features that result in unequal SVT ratios are different for the Neanderthal specimens and Skhūl 5. The two Neanderthal specimens have a long palate, long nasopharynx, and short neck, whereas Skhūl 5 has a moderately long palate, short nasopharynx, and short neck.

Schedule of Evolutionary Events

The hyoid, basicranium, mandible, and cervical vertebrae all provide different insights into the evolution of the vocal tract and the timing of the appearance of hominin speech abilities. Comparative data on the spatial relationships between the hyoid and larynx (Nishimura 2003), in combination with ontogenetic data for chimpanzees (Nishimura et al. 2003), indicates that descent of the thyroid cartilage relative to the hyoid body in early infancy arose in an ancestor of extant hominoids, probably for reasons unrelated to vocalization. The origin of a straight bar-like hyoid body sometime between 3.3 My and 600 ky ago indicates the loss of laryngeal air sacs in *Homo erectus* or one of its predecessors or descendants

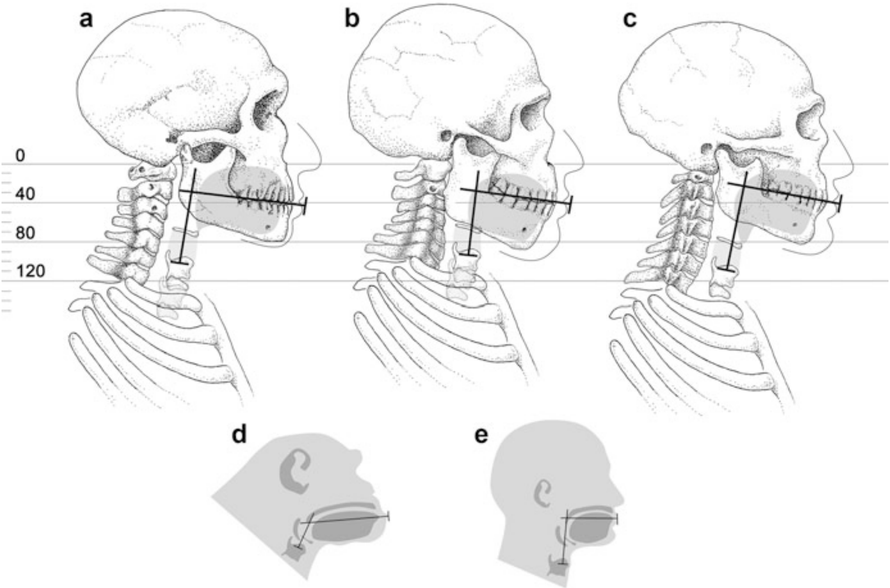

Fig. 3 Position of the hyoid and larynx reconstructed for (**a**) La Ferrassie 1, a Neanderthal, (**b**) Skhūl 5, and (**c**) Predmosti 3, a fully modern human associated with Upper Paleolithic tools. The shaded hyoid and larynx in (**a**) and (**b**) indicate the position of these structures in a hypothetical 1:1 SVT. A (**d**) chimpanzee and (**e**) modern human SVT configuration are provided for comparison

(De Boer 2009, 2012). In great apes, laryngeal air sacs are thought to recycle air from the lungs during prolonged vocalizations. It is known that the nasal cavity, which is parallel to the SVT along the pathway to a speaker's lips, absorbs acoustic energy. This effect degrades the recovery of formant frequencies, reducing speech intelligibility (Bond 1976). Laryngeal air sacs would have had a similar effect, reducing speech intelligibility if hominin speech communication made use of segmental phonemes differentiated in part by their formant frequency patterns. This perhaps accounts for the disappearance of laryngeal air sacs. As noted above, in modern humans, intercostal and abdominal muscles innervated by thoracic nerves are recruited during sustained speech to regulate air pressure. Evidence for an expanded thoracic vertebral canal in Neanderthals and modern humans – and perhaps in *Homo erectus* – may be important in this regard (MacLarnon and Hewitt 2004), although such evidence must remain circumstantial because it is difficult to predict a nerve's cross section from the width of a bony canal, as shown for the hypoglossal canal by DeGusta et al. (1999).

A fully modern humanlike SVT, with equally long horizontal and vertical segments, did not arise until sometime after the appearance of *H. sapiens* 200 ky ago, as the culmination of three distinct processes: (1) shortening of the nasopharynx, (2) shortening of the face, and (perhaps) (3) slight elongation of the neck. Neanderthals and other archaic hominins had a long palate and nasopharynx, a configuration which is associated with a long SVT_H. A long SVT_H cannot be paired with a long SVT_V, unless Neanderthals had necks that were much longer than those of fully modern *H. sapiens*. All available evidence suggests that their necks were short, even if they do fall within the range of variation of modern *H. sapiens*. If one considers the fossil hominins from Mugharet es-Skhūl to be anatomically modern *H. sapiens*, the final two steps in the above schedule occurred after the origin of *H. sapiens*. However, in light of the biological cost of the modern human tongue – an increased propensity for choking to death – it is apparent that speech was the default medium for hominin language before the evolution of a fully modern human tongue. There otherwise would have not been any selective advantage for the retention of mutations and the selective sweep that resulted in the human tongue's proportions. We can thus conclude that the neural substrate for speech production was present in earlier, extinct hominins.

The Neural Substrate for Speech

Neural Circuits

The neural bases of human speech and language have for almost 200 years been linked to discrete localized structures, *organs* of the brain. Locationist theories for the brain bases of language derive from early nineteenth century phrenology. Phrenologists proposed that areas of the neocortex – the outermost layer of the human brain – were the *seats* of complex aspects of human behavior such as piety, language, mathematical ability, and so on (Spurzheim 1815). Each area was devoted to a specific, observable, aspect of behavior. Since direct inspection of the cortex in living subjects was not possible, the area of the skull above the location of the hypothetical seat was the metric that supposedly correlated with the degree to which that behavior was manifested by a particular subject. These claims were tested and were found wanting. When the skulls of clerics were studied, some had exceedingly small areas of their skull at the hypothetical seat for piety. Homicidal individuals instead could be found who had large bumps on their skulls supposedly related to piety and trust.

Phrenology fell into disfavor, but it never died. Paul Broca had decided that the seat of language was not between a person's eyes as Spurzheim had suggested, but Broca operated within the same paradigm. In 1861 Broca published his study of a stroke victim, patient Tan, whose speech was limited to a syllable that sounded like *tan*. Broca limited his postmortem observations to the cortical surface of the patient's brain and linked a cortical area that was damaged to the patient's deficits. Thus, Broca's area was born – a cortical area devoted to language and, according to most accounts, language alone. Broca examined a second patient who had similar speech deficits, in this case also noting damage extending into the basal ganglia, but ignored the subcortical damages. A few neurologists demurred, pointing out the fact that postmortem examinations showed the language and speech were disrupted only when subcortical brain damage was present.

It became evident that Broca's area is not the brain's center of language when the brains of both of the patients examined by Broca were imaged more than a country later. The patients' brains had been preserved in alcohol; a high-resolution MRI of Broca's patient Tan shows that he also had massive damage to the basal ganglia, other subcortical structures, and pathways connecting cortical and subcortical neural structures (Dronkers et al. 2007). Moreover, the left inferior gyrus of the brain – the traditional site of Broca's area in textbook illustrations and published studies – was not the cortical area actually damaged in Tan. Damage occurred anterior to it, close to the ventrolateral prefrontal cortex. After the 1970s, brain imaging techniques such as computerized tomography (CT) and magnetic resonance imaging (MRI) allowed the brains of thousands of patients who suffered aphasia to be examined. Patients who had suffered brain damage limited to cortex that spared subcortical brain structures recovered. Conversely, aphasia only resulted when subcortical structures were damaged. Alexander et al. (1987), for example, documented the speech production deficits of patients who had suffered strokes that damaged the basal ganglia and other subcortical structures, but spared the cortex altogether. The current view, expressed by Stuss and Benson in their comprehensive 1986 study, is that aphasia never occurs without subcortical damage.

Researchers with very divergent positions with linguistic theory share this view in light of the fact that the ventrolateral prefrontal cortex and Broca's area form parts of basal ganglia circuits implicated in regulating speech and language (Lieberman 2000, 2002; Ullman 2004). The brain bases for complex motor acts, such as walking or talking, are neural circuits that link *local* operations performed in different neural structures. While some neural structures, such as those involved in the initial stages of visual perception, are domain-specific, other neural structures perform local operations that constitute elements of different circuits that regulate seemingly unrelated aspects of behavior.

Your car makes use of similar functional architecture. If your car won't start, the repair manual will not instruct you to locate the center of starting. The manual instead will point out a set of linked structures that each performs a local operation. The battery, for example, provides electrical power to the starter motor but it also powers the car's lights, radio, computer, etc., through circuits linking it to these devices. The battery is not in itself the sole device dedicated to electrical power. The generator and voltage regulator form part of the electrical system, and in a hybrid gasoline–electric car, the braking system also charges the battery.

The basal ganglia, subcortical structures that date back in time to anurans similar to present-day frogs, support circuits that link different areas of motor and prefrontal cortex. The basal ganglia operate as a sequencing engine (Marsden and Obeso 1994), regulating motor control and cognition – including aspects of language. Damage to the subcortical basal ganglia or the circuits linking them to cortex explains why the signs and symptoms of aphasia can include speech production deficits, difficulties comprehending the meaning of a sentence, and cognitive deficits. Indeed, although aphasia is usually characterized as a language deficit, Kurt Goldstein (1948), one of the leading aphasia specialists of the twentieth century, pointed out its primary cognitive deficit – loss of the "abstract capacity."

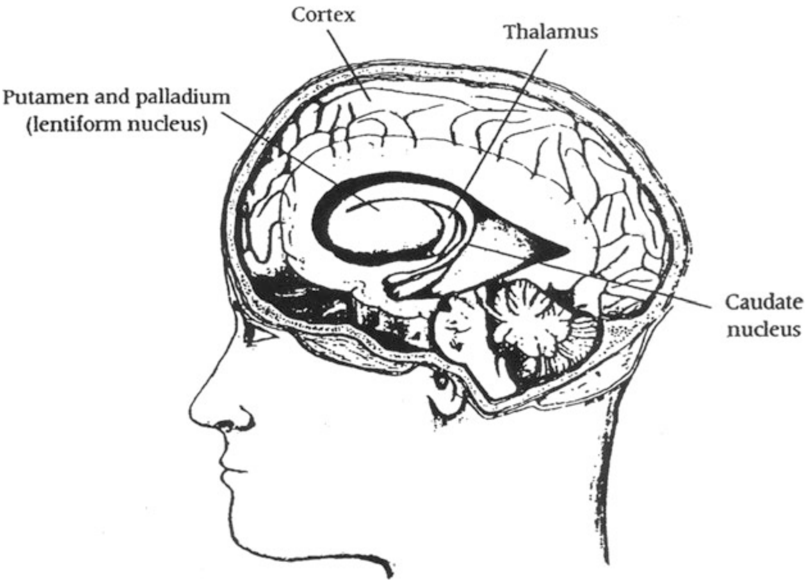

Fig. 4 The basal ganglia and thalamus are positioned deep within the skull. The putamen and globus pallidus (palladium) are contiguous and form the lentiform nucleus

Circuits Linking Cortex and the Basal Ganglia

Invasive tracer studies of the brains of monkeys and other mammals first mapped out a class of circuits that linked areas of motor cortex with the basal ganglia. Retrograde tracer studies entail injecting a chemical or virus that will propagate back down the neural pathway that transmits the electrochemical signals controlling the muscle. The animal must live for a while for the tracer to move down the circuit before being sacrificed. The animal's brain is then sliced into thin sections. Color couplers, similar in principle to those that were used in conventional color film, attach themselves to the tracer and mark out the circuit when the sectioned, color-stained brain tissue is viewed under a microscope. Other tracers can be injected into neural structures that mark the "ascending" neural pathways. Cortical–basal ganglia circuits were discovered that connected areas of prefrontal cortex through the basal ganglia and other subcortical structures to temporal and parietal cortical regions of the brain (e.g., Alexander et al. (1986)). These invasive techniques could not be used to map out human neural circuits, but noninvasive diffusion tensor imaging (DTI) confirmed that these cortical–basal ganglia circuits appear to be similar in humans and nonhuman primates (Lehéricy et al. 2004).

Evidence from studies of neurodegenerative diseases such as Parkinson disease that degrade basal ganglia operations suggested that nonhuman primates and humans had similar cortical–basal ganglia circuits. In Parkinson disease (PD), depletion of the neurotransmitter dopamine degrades the local operations of the basal ganglia (Jellinger 1990). Patients have difficulty in sequencing the submovements that are

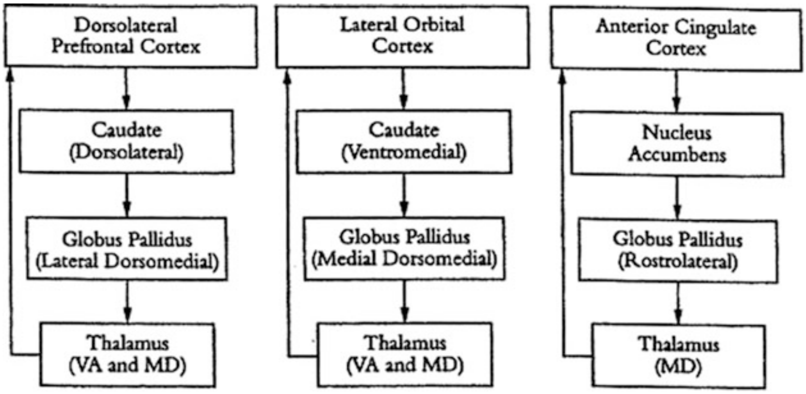

Fig. 5 Studies of the deficits of Parkinson disease and tracer studies of other species formed the basis for three cortical–basal ganglia circuits noted in Cummings (1993). The dorsolateral circuit is involved in cognition, the lateral orbital circuit in emotional regulation, and the anterior cingulate in attention and laryngeal control

necessary to carry out internally directed motor acts such as walking. A common clinical observation is that PD patients who have difficulty walking will do better when they are asked to copy someone walking. An external model allows them to function better. Similar problems occur when PD patients execute manual acts (Harrington and Halland 1991) and speech motor control deteriorates (Lieberman et al. 1992; Lieberman 2006).

Cognitive inflexibility and difficulties performing cognitive acts that require planning or selecting criteria also occur in PD (e.g., Lange et al. 1992). As Alexander et al. (1986), Cummings (1993), and other studies note, prefrontal cortical areas associated with “higher” human cognitive capacities project to the basal ganglia, thus, accounting for cognitive deficits associated with insult to the basal ganglia component of cortical–basal ganglia circuits. A “subcortical dementia” involving profound diminution of cognitive flexibility can occur in Parkinson disease (PD). Patients so afflicted perseverate – in other words, they are unable to change the direction of a thought process or action (Flowers and Robertson 1985; Fig. 5).

Marsden and Obeso (1994) exhaustively reviewed the effects of surgical lesions and dopamine replacement therapy aimed at mitigating the problems associated with PD and concluded that the basal ganglia were a sequencing engine that could link submovements – motor acts stored in motor cortex to carry out an internally guided motor act such as walking. This fit into the traditional view that PD affected motor acts. Marsden and Obeso also noted that when circumstances dictated, the basal ganglia could change a course of action. Focal brain damage limited to the basal ganglia results in similar speech production and cognitive deficits. Bilateral lesions to the caudate nucleus and putamen of the basal ganglia in the subject studied by Pickett et al. (1998) resulted in severe deficits in sequencing the laryngeal, lingual, and lung motor activity necessary to produce articulate speech. The subject had profound difficulty comprehending distinctions in meaning conveyed by syntax that are

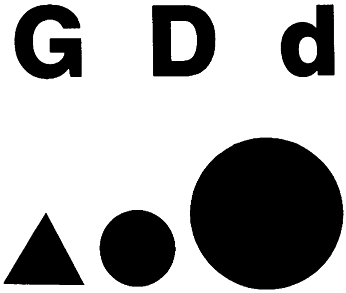

Fig. 6 Two pages of the Odd-Man-Out test. The odd shape or letter of the alphabet can be selected on the basis of either shape or size (uppercase or lowercase for the alphabet). The test subject starts by selecting one sorting criterion but has to shift the criterion after sorting ten cards. This process is repeated four to six times

comprehended by 6-year-old children and was almost incapable of planning her daily activities. When the subject sorted cards in the “Odd-Man-Out” test, which Flowers and Robertson (1985) devised to test PD patients’ cognitive flexibility, she was incapable of changing the sorting criterion. The Odd-Man-Out test uses a pack of cards that each shows three images. For example, the first card might show a large triangle, a small triangle, and a large circle. Subjects are asked to identify the “odd” image on each of ten cards. If the subject had selected shape as the sorting criterion, the circle could be selected. If size was selected as the sorting criterion, the small triangle could be selected. The subjects taking the test are not explicitly given the sorting criteria; they must infer the criteria. The subject can start with either criterion, but after sorting ten cards, the subject is asked to pick a different sorting criterion for the next ten cards and again for at least 14-card sorts. PD patients typically have few errors on the first ten-card sort but have difficulty and high error rates each time that they have to change the sorting criterion. The subject tested by Pickett and her colleagues was unable to even think of a different sorting criterion after successfully completing the first ten-card sort (Fig. 6).

Neuroimaging studies of subjects performing the Wisconsin Card Sorting Test (WCST) confirm the role of the basal ganglia in tasks involving cognitive flexibility and explain why cognitive inflexibility occurs in Parkinson disease. The WCST is an instrument that measures cognitive flexibility – a person’s ability to form cognitive criteria and shift from one criterion to another. The usual form of the WCST entails subjects sorting cards that each have images that differ with respect to shape, color, and number. Subjects have to match test cards to four “reference” cards – a card with one red triangle, a card with two green stars, a card with three yellow + signs, and a card with four green circles. A typical test card might have four yellow stars printed on it. The criterion according to which a test card is matched to one of the reference cards varies and can be the number of images, color, or shape. The subject starts out by making a sort and then is informed whether the sort was “correct” or not. For example, starting with number, matching the test card to the reference card that has four green circles on it would be incorrect if the person running the session wanted to start with color. The subjects then would continue to match by color, receiving a "correct" response until they are being told that the sort was "incorrect" and then having to establish a new sorting criterion without any explicit instruction. After achieving a "correct" response to the new criterion – for example, number – the subject would continue with number, receiving positive feedback until the sorting criterion changed.

The Monchi et al. (2001) fMRI study monitored oxygen levels in the prefrontal cortex, the basal ganglia, and other subcortical structures. Depleted oxygen levels in the ventrolateral prefrontal cortex, the caudate nucleus, and the thalamus confirmed that this cortical–striatal circuit was activated when planning criterion-sorting shifts. Another cortical–striatal circuit that included posterior prefrontal cortex and the putamen was observed during the execution of a sorting criterion set shift. Dorsolateral prefrontal cortex was involved whenever subjects made any decision as they performed card sorts, apparently monitoring whether their responses were consistent with the chosen criterion. Other fMRI studies have replicated these findings and show that the caudate nucleus uses this information when a novel action needs to be planned (Monchi et al. 2006a, 2007).

Similar activation patterns were apparent when subjects were sorting words instead of images and had to match words on the basis of semantic similarity, phonetic similarity of the start of the syllable, or rhyme (Simard et al. 2011). The neural circuits involved thus are not domain-specific, operating solely on visual criteria. Studies ranging from electrophysiological recordings of neuronal activity in the basal ganglia of mice and other animals as they learn tasks (Graybiel 1995; Mirenowicz and Schultz 1996; Jin and Costa 2010) to studies of PD patients (Lang et al. 1992; Monchi et al. 2007) and birds (Brainard and Doupe 2000) also show that the basal ganglia play a critical role in associative learning and in planning and executing motor acts including speech in humans and songs in songbirds. Basal ganglia activity in these cortical–basal ganglia circuits clearly is not domain-specific, i.e., limited to language. Motor activity, associative learning, and cognitive flexibility manifested in both linguistic and visual tasks involve local basal ganglia operations, reflecting the mark of evolution as cortical–basal ganglia circuits were adapted to "new" tasks.

Cortex

Comparative studies of the architecture of the frontal regions of the brains of monkeys and humans have been conducted over the course of more than a century (Brodmann 1908, 1909, 1912). One explanation for why we, but no other primates, can talk and command complex syntax might seem to rest on structural cortical differences. However, this does not seem to be the case. Petrides (2005), in his review of both classical and current studies and his own research, concludes that "the basic architectonic organization" (the distribution of neurons in the frontal layers of the cortex) is the same in humans and monkeys. What characteristics of the human cortical–basal ganglia circuits noted above might allow them to regulate speech motor control and aspects of cognition in humans?

Domain specificity, particularly specificity for language, is inherent in Noam Chomsky's proposal that humans possess a faculty of language devoted to language and language alone. The central premises of Chomsky (2012) and earlier publications and Pinker's (1998) modular view of the brain are that language and other aspects of behavior are each regulated by domain-specific neural circuits and structures. However, noninvasive neuroimaging techniques show that this is not the case. The transmission of information from neuron to neuron in the brain is fueled by burning glucose. Therefore, increased activity in a neural structure uses up more oxygen. Thus, studies using functional magnetic resonance imaging (fMRI), which tracks the level of neural activity in a particular region of the brain by monitoring oxygen depletion, can infer whether a particular cortical area or subcortical structure is active during a task. It is not possible to specify where cortical brain activity is occurring in terms of Brodmann areas on a "standard brain," as is often the practice in neuroimaging studies. Brodmann (1908–1912) microscopically examined brains and found differences in the distribution of neurons in the cortex, which he thought reflected functional differences. The maps that he produced have since been used to refer to delimit areas of the cortex. However, differences in brain morphology make it particularly difficult to identify the particular Brodmann areas in prefrontal cortex (Devlin and Poldark 2007), but some of the local operations performed by different regions of the frontal cortex and in the subcortical components of neural circuits in humans and monkeys are becoming apparent.

The dorsal posterior motor cortex areas control fine motor control during speech and other motor tasks (Petrides 2005). Ventrolateral prefrontal cortex connected to posterior regions by circuits involving the subcortical basal ganglia is active during virtually all tasks that involve selecting and retrieving information according to specific criteria (Duncan and Owen 2000). Dorsolateral prefrontal cortex is active while monitoring motor or cognitive events during a task while taking into account earlier events stored in working memory (Badre and Wagner 2006; Monchi et al. 2001, 2006a, b, 2007; Postle 2006; Wang et al. 2005). These cognitive tasks range from retrieving information and holding it in short-term "working memory" to changing the direction of a thought process.

The Antiquity of Laryngeal Control

The melody of speech which reflects the output of the larynx, or *intonation*, has a deep evolutionary history. Intonation reflects laryngeal activity, and the fundamental frequency of phonation (Fo) and amplitude of speech play a central role in vocal communication, signaling sentence boundaries and other aspects of syntax (c.f., Armstrong and Ward 1926; Lieberman 1967). Controlled Fo contours differentiate words in "tone" languages such as Mandarin Chinese. The neural circuits and anatomy involved in controlling Fo can be traced back to therapsids, mammal-like reptiles who lived during the Triassic, Jurassic, and early Cretaceous lived alongside dinosaurs. The initial role of these structures appears to be mother–infant communication. Studies of human mother–infant communication reveal a special vocal mode or *register*, motherese, by which parents address infants in speech that has a high fundamental frequency of phonation and extreme Fo variation (Fernald et al. 1989). Mammalian infants, (including human infants) also signal for attention by means of a forceful *isolation cry* that has a high Fo and amplitude (Truby et al. 1965) – the cries that can keep parents awake for months. Comparative studies suggest that therapsids employed similar anatomical specializations and neural structures to produce isolation cries. All mammals possess a paleocortex, which includes the anterior cingulate cortex (ACC). The findings of studies of the behavioral effects of damage to the ACC and the neural circuits that connect it to other parts of the human brain show that the anterior cingulate cortex plays a role in controlling Fo and directing attention to virtually anything that one wishes to do. While the soft tissue of the brains of therapsids has not survived, the inference that these mammal-like reptiles had an ACC rests on the fact that they possess three middle ear bones found in all present-day mammals. The initial function of the hinge bones of the reptilian jaw was to open the jaw wide. In the course of evolution, the hinge bones took on a dual role, functioning as "organs" of hearing. This transition from mammal-like reptiles to mammals involved the former jaw bones migrating into the middle ear, where they serve as a mechanical amplifier that enhances auditory acuity. All mammals have both an ACC and these middle ear bones, so that middle ear bones are regarded as an index for the presence of the ACC in mammal-like therapsids.

The Darwinian *struggle for existence* transcends aggressive acts, instead referring to any aspect of behavior that confers a selective advantage and increases reproductive success. Vocal communication that enhances mother–infant contact increases an individual's *biological fitness* and thereby contributes to its reproductive success. Anterior cingular cortex–basal ganglia neural circuits are involved in both attention and laryngeal control and therefore appear to function in that role. For example, lesion studies on mice show that mouse mothers do not pay attention to their infants when neural circuits to the ACC are disrupted (MacLean and Newman 1988; Newman 1985). In adult humans with Parkinson disease, degradation of ACC-to-basal ganglia circuits results in patient apathy (Cummings 1993). *Hypophonation*, an anomalous low-amplitude phonation, is often disrupted in patients with PD (Tsanas et al. 2009), and in extreme cases, PD patients can become mute (Cummings 1993). Virtually every PET or fMRI neuroimaging study ever published shows ACC activity when subjects are asked to perform any task. Our reptilian heritage is evident when an ear ache occurs as result of grinding one's teeth. We retain the "old" nerve pathways between the jaw and bones that have migrated into the middle ear.

An alternate proposal stressing human uniqueness is that laryngeal control in humans derives from a circuit that directly links cortex to the larynx, bypassing the basal ganglia. According to Fitch (2010), this hypothetical circuit is the key to humans being able to learn to talk and the "faculty of language," conferring the ability to form and comprehend sentences that have embedded clauses (Hauser et al. 2002). Fitch also claims that vocal imitation in birds derives from a similar direct cortical-to-laryngeal neural circuit. However, Fitch overlooks evidence that shows that this human-specific hypothetical circuit does not exist.

The basis for Fitch's claim derives from one of the first attempts to study human neural circuits, decades before cortical–basal ganglia circuits were mapped out by tracer studies in other species. Kuypers (1958) attempted to adapt an invasive tracer technique used in early studies on animals to study human brains. The Nauta–Gygax (1954) technique which Kuypers attempted to adapt involves first destroying a discrete part of a living animal's brain. After a few weeks, the animal is sacrificed, its brain is impregnated with a silver solution that highlights neuronal structure, and it is dissected and microscopically examined. The infused silver solution can show damages to *downstream* neurons of the neural circuit that connected them to the structure of the brain that had been destroyed, thereby tracing out a neural circuit. Instead of surgically lesioning any part of a human subject's cortex, Kuypers examined the brains of patients who had died after massive damage to one hemisphere of their brain. Since no one dies because of laryngeal dysfunction (other than from respiratory obstruction), it is difficult to see how this technique could be used to isolate a cortical-to-laryngeal neural circuit. Nonetheless, Iwatsubo et al. (1990) again used the Nauta–Gygax technique to study the brain of an 84-year-old woman who died after two massive strokes. They reported degeneration in spinal cord neurons that they believed revealed a direct cortical-to-laryngeal neural circuit. Jurgens's (2002) review article of 301 studies is cited by Fitch and others to support the claim that this neural circuit is present in humans. However, Jurgens (2002) overlooked damage to basal ganglia and pathways between the cortex and basal ganglia which clearly indicate that the degeneration of brainstem neurons do not constitute evidence for a direct cortical-to-laryngeal circuit. Terao et al. (1997) compared the brainstem neurons of four patients who died from brain damage after strokes with those of four age-matched patients who died from non-neurological diseases. No differences were apparent when the brainstem neurons of the two groups were examined. The neuronal degeneration observed in the Kuypers and Iwatsubo studies therefore may reflect degeneration after death, not downstream damage in circuits linked to cortex.

CT scans and an autopsy of the patient studied by Iwatsubo et al. (1990) showed "massive infarctions of the entire territories of the middle cerebral artery on the right and anterior and middle cerebral arteries on the left." The patient's basal ganglia, pathways to the basal ganglia, and other midbrain and brainstem structures would have been damaged or destroyed by these lesions, resulting in death. Subsequent studies have used noninvasive techniques to study the neural circuits regulating vocalization in living humans. Schulz et al. (2005) used positron emission tomography (PET), which tracks the metabolism of glucose in the brain, to map neural circuits that are active when subjects talked. They concluded that the circuits were a "phylogenetically older system present in all mammals (p. 1845)" involving the basal ganglia and thalamus. As noted above, diffusion tensor imaging (DTI) which directly maps out neural circuits confirms that the human circuits are those present in monkeys and apes (Lehéricy et al. 2004). Fitch apparently overlooked the conclusion of Jurgens's review article. Jurgens (2002, p. 251) concluded that "motor coordination of learned vocal patterns comes from the motor cortex and basal ganglia."

Fitch also takes note of the evolution of vocal imitation in birds to support his claim that direct human cortical control of laryngeal activity is the basis for the evolution of human speech and language. Fitch (2010, p. 352) identifies "X" of the bird brain as the cortical homolog of a circuit similar to the hypothetical Kuypers–Iwatsubo neural circuit. However, area "X" is homologous to the mammalian basal ganglia (Brainard and Doupe 2000).

The Sudden Appearance of Language According to Noam Chomsky

Fitch's hypothetical unique human circuit reflects the position of Noam Chomsky concerning the biological basis of human language. The details of Chomsky's theories have changed over time, but they all posit an innate "faculty of language" that genetically transmits "knowledge of language." In his many publications, Chomsky posits an innate *universal grammar* (UG) that conveys the details of syntax of all human languages. In 1976 Chomsky stated that

> . . .language is as much an organ of the body as the eye or heart or the liver. It's strictly characteristic of the species, has a highly intricate structure, developed more or less independently of experience in very specific ways, and so on. (Chomsky 1976, p. 57)

Chomsky's 2012 model focuses on the proposal made in Hauser et al. (2002) that the faculty of language includes a "narrow" faculty of language, specific to humans, that confers the ability to form and comprehend sentences that contain embedded clause, such as "The boy who fell down was thin." According to linguists following Chomsky's train of thought, sentences having embedded clauses sentence are formed in the human mind by a process of "recursion" that melds simple sentences such as the "The boy is fat" and "The boy fell down" together. It is not clear how Fitch's unique neural circuit to the larynx could account for the evolution of this mental capacity, but that problem is irrelevant because Chomsky's (2012) proposal for the biological bases of human language is outside the framework of evolutionary biology.

Chomsky now claims that human language suddenly appeared between 100,000 and 50,000 years ago by means of a mutation that yielded a mental capacity that he terms *merge*. Following linguistic practice, Chomsky uses the term "rule" *merge* to refer to the mental capacity, the "narrow faculty of language," that yields recursion and complex sentences. Language, in Chomsky's account, was absent before this mutation occurred in one person. The mutation somehow became a characteristic of all human brains, without natural selection playing a role in this process.

Chomsky's theories have been outside of the framework of evolutionary biology for decades. In a 1972 publication, he stated that

> It is perfectly safe to attribute this development [of innate language structures] to 'natural selection', so long as we realize that there is no substance to this assertion, that it amounts to no more than a belief that there is some naturalistic explanation for these phenomena. (Chomsky 1972, p. 97)

The pages of the *Science of Language* (Chomsky 2012) include a sustained argument that natural selection has virtually no role in evolution. Selective sweeps in which a mutation that enhances survival in a particular ecosystem has spread through a human population have been well documented. For example, natural selection acted on different genes to confer the ability to use milk as an additional food source in different parts of the world at different times (Tishkoff et al. 2007). In human settings where domesticated milk-producing animals were absent, adult lactase did not evolve. The interplay between the ecosystem and genetic evolution was stressed by Darwin (1859) throughout *On the Origin of Species*. According to Chomsky and those who share his view, children would not be able to acquire any language because insufficient information supposedly is not present in the utterances that children hear in the early years of life. The syntactic rules, speech sounds, and syllable structures of the language a child hears are acquired because "parameters and principles" that activate them are innate, i.e., genetically transmitted. It's as though all human brains are computers that have identical preloaded software that automatically selects the appropriate instruction set for whatever language a child encounters in the first years of life. In substance, Chomsky's claim is that children do not really learn language in the way that they learn to use forks or chopsticks or the modes of behavior or technology of any human culture. In other words, Chomsky's claim is equivalent to the assertion that no child would "acquire" a language unless this preloaded language software was in his or her brain.

However, natural selection on humans never ended, and this biological certainty demonstrates the implausibility of UG. If anyone's native language was acquired because UG existed, children of Chinese ancestry born and raised in the United States would be unable to fluently speak English. In adult humans, the ability to digest cows' milk is an innate, genetically transmitted biological attribute. In cultures that possessed herds of animals that could be milked, natural selection acted on genetic variations to yield individuals who could digest milk as adults, thereby enhancing their survival and their children's survival. While human cultures exist in which animal husbandry and sources of milk were absent, leading to reduced adult lactose tolerance, language typifies all human cultures.

Virtually all aspects of human life are culturally transmitted, and the primary medium of transmission is language. Thus, if anyone's ancestors had been using any particular language for an extended period – let's say the last 3,000 years (the period when adult lactose tolerance or other attested aspects of human biology evolved) – then if any innate UG were *necessary* to "acquire" that language, natural selection would have acted to enhance survival, optimizing the UG to favor acquiring the particular linguistic characteristics of the indigenous language. The United States is an optimal "experiment in nature" since the ancestors of most Americans did not speak English before their arrival. Since languages differ dramatically, you might have never been able to acquire English if your ancestors were speaking Chinese, Hungarian, or some other language whose structure and sound pattern differs dramatically from English. Natural selection acting over generations would have optimized your innate UG for your ancestral language rendering it deficient for acquiring English. The time depth of the Chinese languages whose syllable structure differs profoundly from that of English would thus prevent Americans of Chinese ancestry from "acquiring" fluent English. Since that is not the case, we can conclude that the innate Chomskian UG does not exist.

Fully Human Linguistic and Cognitive Capability

Brain Size

One aspect of cognitive capability that is apparent in the fossil record is brain size. The first anatomical study of an ape, Tyson's 1699 dissection of an orangutan, revealed many of the anatomical affinities between great apes and humans, but it showed that the ape brain was much smaller than that of any normal adult human. A great deal of attention has since been focused on the human brain being about three times larger than a chimpanzee brain because brains require lots of biological support. Hence, scholars have reasoned that a large brain signifies that it must be useful. Texts on hominin evolution generally include a chart showing an increase in brain size over time. Current assessments show that humans have a scaled-up primate brain with about three times as many neurons (the basic computing elements of all brains) as a chimpanzee brain (Herculano-Houzel 2009).

The size of most parts of the mammalian brain scales up in proportion to overall brain size, but the human brain differs in that the posterior temporal cortex is disproportionately larger than would be expected (Semendeferi et al. 1997, 2002). Temporal cortex is part of the human long-term information storage system. Working memory, the ability to keep information in short-term memory during a cognitive process, appears to access information from permanent memory through neural circuits linking prefrontal cortex to temporal cortex and other structures (Badre and Wagner 2006; Postle 2006). The human prefrontal cortex has long been associated with "higher" cognition and, as noted previously, when linked with the basal ganglia and other neural structures, it is involved in the range of cognitive acts involving "executive control." Dorsolateral and ventrolateral prefrontal cortex work through the basal ganglia as well as through direct neural circuits with information-storing regions of the brain, pulling memory traces of images, words, and probably other stored information into short-term working memory (e.g., Postle 2006; Badre and Wagner 2006; Miller and Wallis 2009).

Although some studies that compared chimpanzee and human brains using magnetic resonance imaging studies have claimed that humans have a disproportionately larger prefrontal cortex, thereby enhancing human cognitive capabilities, that may not be the case. As Semendeferi et al. (2002) noted, MRI scans inherently cannot show that humans have a disproportionately larger prefrontal cortex. The human frontal cortex includes prefrontal as well as posterior areas involved in motor control and, together, these areas are not disproportionately larger than an ape's. It is impossible to differentiate prefrontal cortical areas from the motor regions of the frontal cortex on an MRI. Many proposals have been made for why hominin brains became larger over time. One recurring theory hinges on abrupt climate changes taking place in Africa where early hominins evolved. Alternating periods of frigid glacial cold and heat may have resulted in natural selection for individuals able to think of creative solutions to survival. However, there is no evidence for glacial cold in Africa. Another proposal in the same vein suggests alternating periods of drought and heavy rainfall that resulted in desertlike or lush rain forests in the Rift Valley of Africa as the causal element driving hominin brain size enlargement. However, if archaic hominins responded in a manner similar to other species, the most likely scenario would have involved hominins moving away when the climate became inhospitable. Another theory stressed the ability to communicate with members of one’s group, noting the correlation between group size and size of the neocortex. However, the missing data point is that of solitary orangutans’ brains.

Nonetheless, it is clear that brain size is linked to cognitive ability if only in memory storage capacity. Lartet (1868) noted a gradual increase in brain size in wolves and their prey, and Jerison (1973) and subsequent researchers (e.g., Kondoh 2010) have documented this trend across multiple groups of animals. Acquiring a meal and avoiding being a meal apparently drove the evolution of larger brains. As Darwin (1859, p. 61) pointed out, natural selection will act on any attribute that enhances the survival of progeny in “the infinitely complex relations to other organic beings and to external nature” that all beings face. Given the interlocked neural structures implicated in motor control, cognition, and language, it is improbable that any “one” factor was responsible for driving an increase in hominin brain size.

Transcriptional Genes

Advances in genetics and neurophysiology have unlocked a new means of inquiry into the evolution of human language and cognition. Transcriptional factors are essentially “master” genes that affect the way that other genes are activated to form brains and bodies. Transcription factors are genes that govern the transcription of information stored in DNA into a different form, single-stranded mRNA, which is later translated into functional proteins that make up the building blocks of the body. These proteins bind to DNA sequences near a gene that they regulate so as to control the degree to which they release information to the mRNA. Many members of the extended KE family in London who had severe deficits in speech production, sentence comprehension, and cognitive ability possessed only one copy of the human FOXP2 transcriptional factor, instead of the normal two (Fisher et al. 1998).

The Foxp2 gene is one of many transcription factors that exist in all mammals, birds, and other creatures. The mouse form of Foxp2 (the lowercase spelling indicates that it is not the human version, which is capitalized) controls embryonic development of the lungs, intestinal system, heart, and other muscles as well as the spinal column in mice (Shu et al. 2001). Humans are separated from mice by 75 million years of evolution (Mouse Genome Sequencing Consortium 2002).

The Foxp2 and FOXP2 genes encode a protein that regulates the expression of other genes during processes that mark embryonic development, such as signal transduction, cellular differentiation, and pattern formation. Mutations to other Forkhead transcription factor genes have been implicated in a number of developmental disorders. The areas of expression of FOXP2 and Foxp2 in both the human and mouse brain are similar and include neural structures that form the human cortical–striatal–cortical circuits involved in motor control and cognition – the thalamus, caudate nucleus, putamen, and other subcortical structures (Lai et al. 2003). These neural structures are all intricately interconnected. The cerebellum, which receives input from the inferior olives, is involved in motor coordination. The cortical plate (layer 6), the input level of the cortex, is also affected by the FOXP2 mutation.

The subsequent focus on the role of FOXP2 in human evolution follows from its being one of the few genes that has been shown to differ from its chimpanzee version (The Chimpanzee Sequencing and Analysis Consortium 2005). A "human" version evolved that differs from the version found in chimpanzees during the six- or seven-million-year period that separates humans and chimpanzees. In that period FOXP2$^{\text{human}}$ underwent two substitutions in its DNA sequences, causing two amino acid changes in the FOXP2 protein compared to one amino acid substitution between chimpanzees and mice over the previous 70 million years. The form of FOXP2 that has two amino acid substitutions also occurs in Neanderthals and Denisovans – a group related to Neanderthals. A third change unique to humans occurred in intron 8 of the FOXP2 gene and resulted in a selective sweep during the period in which anatomically modern humans appeared some 260,000 years ago (Maricic et al. 2013).

The date of this "selective sweep" for the unique human form of FOXP2, approximately 260 ky ago, was first established by Enard and colleagues (2002). Selective sweeps occur when a gene confers a significant advantage in the Darwinian "struggle for existence" – an individual's having more surviving children, such as adult lactose tolerance. In most instances it is unclear what the function of a gene is that differs between chimpanzees and humans. However, in this instance, the effects of a FOXP2 anomaly in the KE family showed that it is playing a key role in the attributes of speech, language, and cognition that distinguish humans from chimpanzees and other living species. Members of this extended family who had the anomalous version of FOXP2 had difficulty executing simple orofacial maneuvers – such as simultaneously protruding their tongue while pursing their lips, repeating spoken words, and talking. In addition, these subjects had difficulty comprehending distinction conveyed by syntax, forming sentences, and had as a group, lower scores on intelligence tests (Vargha-Khadem et al. 1995, 1998; Watkins et al. 2002). Anomalies in basal ganglia also were noted (Watkins et al. 2002).

Mouse "knock-in" studies have demonstrated that the human version of FOXP2 enhances information transfer and associative learning in the basal ganglia. In light of basal ganglia activity in both associative learning and motor control, this would account for cognitive deficits in afflicted members of the KE family as well as their inability to learn and execute the complex motor acts that enable us to talk and which also control internally guided motor acts. The human form of FOXP2 was knocked into mice (Enard et al. 2009; Lieberman 2009; Reimers-Kipping et al. 2011). When the human version of FOXP2 was knocked into mouse pups, their vocal calls were somewhat different than the calls of mouse pups that had the normal "wild" version of Foxp2. When the wild form of Foxp2 was knocked out in mouse pups, they died soon after, reflecting its role in lung and cardiovascular development. The critical finding was that the knocked-in human form of FOXP2 conferred increased synaptic plasticity in basal ganglia neurons as well as increased lengths of dendrites in the basal ganglia, thalamus, and layer VI of the cortex. In particular, the human version of FOXP2 increased synaptic plasticity in medium spiny neurons in the basal ganglia and in the substantia nigra, another structure of cortical–basal circuits (Alexander et al. 1986; Cummings 1993).

Increasing synaptic plasticity has been shown to enhance associative motor learning in mice (Jin and Costa 2010), a result consistent with one of the first findings of modern neuroscience. Hebb (1949) formulated the theory that synapses transfer information from one neuron to another, a paradigm that has since guided research on the basic operations of the brain. Synaptic modification is the neural mechanism by which the relations that hold between seemingly unrelated phenomena are learned. The process by which we learn anything – motor acts, words, concepts, etc. – involves modifying synaptic "weights," the degree to which synapses transmit information to a neuron. This is the case for creatures as far removed on the evolutionary scale as humans and mollusks (Carew et al. 1981).

Increased synaptic plasticity and connectivity in the medium spiny neurons of the basal ganglia that resulted from FOXP2 is especially significant in light of their role in associative learning. In combination with dopamine-activated neurons in the basal ganglia and prefrontal cortex, these neurons in essence guide associative learning, coding the expectation of achieving a desired goal or avoiding aversive outcomes (Bar-Gad and Bergman 2001; Joshua et al. 2008; Assad and Eskander 2011). In short, information stored in the synaptic weights of these neurons directs the process of associative learning, allowing animals to learn to perform complex linked sequences. In humans, similar processes account for our learning complex grammatical "rules," as well as the complex "rules" that guide our interactions with other people, other species, and the ever-changing conditions of life.

Other "highly accelerated regions" (HARs) of the human genome may be implicated in neural development (Konopka et al. 2009). These advances in genetics suggest that neural circuits that humans share with other primates were, in effect, "supercharged" by the action of transcriptional genes. Circuits linking prefrontal cortex and the basal ganglia enhance the cognitive and motor capabilities involved in human language and speech. The role of circuits linking cortex and the basal ganglia is well established, but DTI studies reveal a bewildering array of neural circuits in the human brain. We are at the starting point of an understanding of language, cognition, and motor control.

The Archaeological Record

The artifacts preserved in the archaeological record inherently cannot provide direct evidence of their maker's cognitive or linguistic abilities. Computers and software used to write novels represent a technology that is far more complex than Jane Austin's quill pen, yet they do not constitute evidence for a leap in human cognitive ability over the last two centuries. However, there are periods extending over millions of years in which Oldowan tools are virtually identical. Oldowan tools continued to be made by *Homo erectus* as well as hand axes that are more complex, and it is difficult to see how the technique necessary to make them could have been transmitted without some form of language, but they conform to the same pattern over a hundred thousand years. Neanderthal Levallois stone tools are more complex still, and Neanderthals survived in a cold difficult environment. Their brains were as large as humans and they undoubtedly talked. But one signal element that characterizes all human cultures was missing – there is almost no trace of the creative impulse that leads humans to produce art (artifacts that are useless in the struggle for existence that humans produce and value). Nor is there evidence of the pattern of innovation and imitation that mark human behavior in some cultures.

However, the intersection of culture and the biological bases of human cognitive and linguistic ability preclude the archaeological record providing any detailed conclusions on any stage of the evolution of language. In his notebooks, Charles Darwin expressed no doubt that the Yaghan, the indigenous inhabitants of Tierra del Fuego, had the same general cognitive and linguistic capabilities as Europeans (Browne 1995), but he noted the primitive aspects of Yaghan culture. They were naked except for animal skins thrown over their shoulders; later studies found that their tools were similar to those fabricated at Oldowan sites. Yet the three Yaghans who had been brought to England 3 years before on the Beagle had acquired English and conducted themselves in an acceptable early Victorian manner before reverting to Yaghan behavior when they returned to Tierra del Fuego.

Conclusion

The evolution of the biological bases of human language involved natural selection acting on anatomy and neural mechanisms that have a long evolutionary history. Human language did not suddenly arise from a single mutation that occurred 50,000–100,000 years ago, creating an "organ" of the brain – a hypothetical faculty of language – devoted to language and language alone.

The traditional localization of language to Broca's area of the neocortex is also incorrect. Computed tomography (CT) and magnetic resonance (MR) imaging of patients exhibiting aphasia show that damage to subcortical parts of the brain like the basal ganglia, putamen, or olives is necessary to induce permanent loss of language. Neural circuits linking local activity in different neural structures regulate complex behaviors, including speech and language. Circuits linking motor cortex and prefrontal cortex with the basal ganglia play critical roles in motor control including speech, cognitive flexibility, working memory, and other aspects of cognition. Studies of Parkinson, a disease which disrupts basal ganglia operations, have established a relationship between deficits in motor control of internally guided acts and deficits in cognition including language. The basal ganglia constitute a sequencing engine that links internally guided motor acts that control walking, talking, and manual tasks. The basal ganglia also act to interrupt a sequence when changing circumstances suggest a different response. Similar basal ganglia operations involving the basal ganglia linked to prefrontal cortex contribute to cognitive flexibility, the comprehension of distinctions in meaning conveyed by syntax, and tasks such as mental arithmetic. These neural circuits linking cortex and the basal ganglia are not domain-specific, i.e., they are not committed to language and language alone.

Speech plays a critical role in language, permitting information transfer at a rate that exceeds the fusion frequency of the human auditory system. The high data transmission rate of speech involves the process of "encoding," where the individual "phonemes" – roughly equivalent to the letters of the alphabet – are melded together into words. The acoustic signals that convey words are generated by the supralaryngeal vocal tract (SVT), which acts as a variable acoustic filter that produces local energy maxima occurring at *formant frequencies* that are the major determinants of vowel and consonant quality. However, the overall length of a speaker's SVT determines the absolute value of the formant frequencies that conveys a given vowel or consonant. Listeners must form an estimate of the length of the SVT that generated a particular formant frequency pattern to recover the vowel or consonant.

The vowel [i] (the vowel of the word *see*) and to a lesser extent [u] (the vowel of *too*) are optimal signals for recovering the length of a speaker's SVT. Computer-modeling studies and acoustic analyses of the vocalizations of human newborn infants and monkeys and apes show that their SVTs cannot generate these vowels and other "quantal" speech sounds that enhance the robustness of speech communication. Their tongues prevent them from producing the quantal speech sounds that are among the few attested "universals" of human language. Human infants have a tongue situated almost entirely in the oral cavity, more closely resembling the proportions of the tongue in a nonhuman primate or other mammal than that of an adult human. The shape of the adult human tongue is attained through a developmental process involving restructuring of the skull to shorten the length of the oral cavity and descent of the tongue, hyoid, and larynx below the mandible into the neck. This process takes 6–8 years in modern humans. In humans, half the adult tongue is situated in the pharynx in the neck and half is in the oral cavity. Computer-modeling studies show that configuration enables humans to form the SVT shapes necessary to produce quantal sounds.

The evolution of the human tongue can be traced by taking into account the relative length of the oral cavity, which can be determined by examining bony landmarks on the basicrania of fossil hominins and neck length which can be estimated from the dimensions of their cervical vertebrae. Since the tongue carries the larynx down into the neck with it to attain the 1:1 oral to pharyngeal proportions necessary to produce quantal speech sounds, there must be sufficient room for the laryngeal maneuvers involved in swallowing. Taking into account these constraints, Neanderthals and other archaic hominins with a long face and nasopharynx would not have had the 1:1 SVT proportions necessary to produce quantal speech. Speech is, however, possible without the ability to produce quantal sounds. Since the human tongue has a biological liability – increasing the risk of choking on food lodged in a descended larynx – the neural capacity for speech must have been present before the adaptations that yielded the adult humanlike tongue.

The neural circuits that appear to regulate laryngeal phonation appear to have a long evolutionary past, deriving from circuits whose initial purpose was mother–infant communication in transitional mammal-like reptiles. The neural capacity to regulate alveolar (lung) air pressure during speech may also be present in other species. Humans do not appear to have a unique, direct cortical-to-laryngeal neural circuit that confers the ability to learn and execute the motor commands that underlie speech. That seems to be the province of cortical–basal ganglia circuits which in humans are similar to circuits mapped out in nonhuman primates, except that, in the human circuits, synaptic plasticity and dendritic connectivity are enhanced by mutations on the FOXP2 transcriptional gene. Studies of the pattern of deficits of an extended family in which many individuals had only one copy of the FOXP2 gene established the role of the gene in speech motor control, cognition, and language. Comparisons of DNA from chimpanzees, contemporary humans, and fossil DNA recovered from Neanderthals and Denisovans revealed distinctions between the forms of FOXP2 in chimpanzees, Neanderthals, and humans. A series of selective sweeps, the most recent at about 260 ky ago, occurred on the uniquely human form of FOXP2. Other transcriptional genes are most likely implicated in evolution of the neural capacities that confer human cognitive and linguistic ability.

Darwin pointed out that biological evolution and the ecosystem, which for humans includes their culture, are not separable. Selective sweeps for adult lactose tolerance, for example, occurred in cultural settings in which milk-producing animals were domesticated. This argues against the universal grammar (UG), proposed by Chomsky, which specifies the details of syntax and the sound pattern of every language. The UG is necessary for a child to acquire any language. If such were the case, natural selection and selective sweeps would have occurred to optimize UG for the language spoken in a particular culture, rendering it deficient for acquiring languages that differed. However, a child from any cultural background can learn any language with native proficiency if he or she is immersed in a given culture at an early age. Likewise, chimpanzees raised in a human setting where sign language is used can, to a degree, learn to use words and understand simple syntax – demonstrating the continuity of the evolution of human language and the antiquity of some of the elements that constitute language.

General Principles of Evolutionary Morphology

Gabriele A. Macho

Contents

Abstract

Anthropologists analyzing morphology for phylogenetic, functional, or behavioral purposes are confronted by a plethora of obstacles. Morphology is not free to vary but is subject to a number of constraints, which may be historical, developmental, and/or functional, while equivalency in function can be achieved by different means. This, together with the fact that the fossil record is scant, confounds meaningful interpretation of phylogenetic pathways and the reconstruction of function and behavior from fossilized remains. To overcome these difficulties, paleoanthropology is becoming increasingly inter- and multidisciplinary, whereby researchers draw on, and incorporate, approaches and findings obtained in other, sometimes very diverse, disciplines. This contribution briefly reviews the constraints acting on morphology, the limitations faced when interpreting form/function and behavior from morphology, and the different approaches currently explored in paleoanthropology to obtain a better

understanding of hominin paleobiology. While offering exciting new possibilities, researchers should however be mindful of the limitations inherent in new technologies.

Introduction

With rare exceptions (e.g., endocasts, footprints, permafrost remains, peat bodies), only the hard tissues of the body become fossilized. Phylogenetic, functional, and behavioral interpretations of extinct taxa are thus almost exclusively based on analyses of bones and teeth. Yet, fossil remains are mostly incomplete and distorted, while taphonomic biases prevent a good representation of all parts of the body and/or functional units for detailed analyses (chapter "▶ *Homo ergaster* and Its Contemporaries," Vol. 3). It is therefore unsurprising that the search for more fossil material is a priority in paleoanthropology. These shortcomings aside, there exist other more fundamental problems in analyzing and interpreting morphology. Resolving these issues is the aim of diverse research areas, whose integration has only just begun.

Morphology is highly constrained and determined by a cascade of interactions between genetic, epigenetic, and environmental factors modulated through past and present selective pressures. Consequently, morphology and function must not only be interpreted with respect to present-day function and the fitness it confers to the species but should also be viewed against the backdrop of past form, function, and selective pressures. Phenotypic correlations due to pleiotropy, epigenetics or correlated selection, genetic drift, and co-option of characters for functions that were not initially selected for compound appraisals of morphology within a phylogenetic and functional framework. The fact that developmental pathways for various structures are only poorly (if at all) understood complicates this endeavor even further. Questions as to whether form followed function or whether it was the reverse largely remain unanswered. This is problematic though, as speciation is commonly associated with the acquisition of novel morphological characters and/or the exploitation of new ecological niches. Resolving form/function relationships is thus pivotal for evolutionary inquiry.

To overcome problems associated with the interpretation of morphological structures and variation in both extant and extinct populations, evolutionary studies have become increasingly multi- and interdisciplinary. Traditional comparative approaches prevail, but two main strands of distinct research lines have started to emerge. First, evolutionary developmental biology, despite its long (and sometimes misguided) history (Haeckel 1866), is now a well-established discipline (Hall 1992). Such studies combine an experimental, developmental research protocol with comparative analyses of the fossil record in order to determine the developmental and phylogenetic pathways of morphological structures and the constraints acting on their formation. Despite their high power of resolution, experimental developmental studies are not part of mainstream paleoanthropological inquiry: they require specialized knowledge, are time consuming, and are financially costly.

Second, new comparative, functional, and biomechanical tools are increasingly incorporated in paleoanthropological research protocols and have made, and continue to make, a valuable contribution to our understanding of the functional adaptations of extinct species.

A comprehensive review of the various strands of inquiry is beyond the scope of this contribution. Instead, this chapter aims to highlight some of the general problems and limitations associated with interpreting the morphology of fossil remains and when employing new technology.

Comparative Morphology and Constraints

Morphology is not free to vary but is subject to a number of developmental, physical, and historical constraints (Maynard Smith et al. 1985), while, except for more recent hominins like Neanderthals, for example (Green et al. 2010), genetic information is not available and identification of constraints relies exclusively on comparative analyses of hard tissue remains. This limits what can be learned about the paleobiology of our ancestors.

Comparative Morphology and Evolutionary Constraints

Phylogenetic systematics or cladistics is the main tool for reconstructing the phylogenetic relationships of taxa (Hennig 1966) and should precede paleobiological inquiry and functional analyses (Felsenstein 1985; Harvey and Pagel 1991). While the strengths and weaknesses of this method, as well as its assumptions, are reviewed elsewhere in this handbook (chapters "▶ Zoogeography: Primate and Early Hominin Distribution and Migration Patterns," Vol. 1, "▶ The Biotic Environments of the Late Miocene Hominoids," Vol. 2 and "▶ Origins of Homininae and Putative Selection Pressures Acting on the Early Hominins," Vol. 3), some limitations pertaining to the analysis and interpretation of morphology need to be briefly reiterated. Relevant for the discussion of constraints are issues regarding homology and the independence of characters. Analyses of homologous traits are at the heart of cladistic methodology, but experimental studies have provided unequivocal evidence for the hierarchical nature of homology, whereby homologies at one level of organization need not lead to homologies at another (Hall 1994); in fact, Hall (2007) argued for homology and homoplasy to be viewed as opposite extremes of a continuum only. This seems justified as anatomical traits are not independent, but result from pleiotropy, correlated selection, modular networks, and genetic linkage. Although this arguably obscures the elucidation of the phylogenetic history of taxa and hampers inferences about the relationships between form, function, and behavior, such correlations are themselves useful and provide meaningful insights into the evolvability of complex systems (e.g., Marroig et al. 2009), i.e., the tempo and mode of evolution. Unsurprisingly thus, the study of covariances has experienced a renaissance in recent years (Olson 2012).

On the basis of methodologies originally developed in population genetics, various quantitative tests have been employed to appraise the covariations and correlations of traits with the aim of inferring developmental and phylogenetic constraints (Cheverud et al. 1989). In the last few years, paleoanthropology has seen a boom in the application of this approach, aided by the affordability of powerful computers and mathematical advances, such as geometric morphometrics (Bookstein 1991). Investigations tend to focus on serially homologous structures, like hominoid limbs (Rolian et al. 2010; Young et al. 2010) and teeth (Hlusko et al. 2004), and on developmentally and/or functionally integrated (and complex) systems, such as the skull and mandible (Ackermann 2009; Lieberman et al. 2000, 2004; Zelditch et al. 2009) and the pelvis (Grabowski et al. 2011). An understanding of the integration and modularity of various structures is starting to emerge, including their potential for evolutionary change, i.e., evolvability, and the rate at which these changes can occur during evolution. For example, Hlusko et al. (2004) estimated that enamel thickness in baboons could theoretically double in only 50,000 generations. If correct, this character would be prone to homoplasy, and enamel thickness as a defining trait in hominins should be interpreted with caution. Also, the low levels of integration found in the pelvis (Grabowski et al. 2011; Lewton 2012) are likely to underlie both the rapid evolution of bipedality and the diversity of locomotor patterns among hominins (e.g., DeSilva et al. 2013).

Comparative Morphology and Functional Constraints

Comparative studies are at the heart of paleoanthropology, even though hominins do not have a modern analog and have adapted to their environment in unique ways, both behaviorally and morphologically. Unfortunately, natural experiments which directly inform hominin evolution are rare. The only exception is perhaps chapter "▶ *Homo floresiensis*," Vol. 3 (Brown et al. 2004), whose diminutive size and small brain continues to be subject of study (Kubo et al. 2013). While the species' taxonomic affiliation remains unresolved, most researchers view the unique morphology of *H. floresiensis* as a typical response to the environmental conditions encountered on islands, i.e., resource limitations and lack of natural predators (chapter "▶ The Species and Diversity of Australopiths," Vol. 3). For other hominins the link between environment and morphology is far less obvious and inferences are derived predominantly from analyses of hard tissue remains.

Teeth

Teeth are among the most abundant remains within the fossil record and contain a wealth of information for the taxonomists and functional morphologist (chapter "▶ Modeling the Past: The Paleoethnological Approach," Vol. 1). Owing to their pivotal role in the breakdown of food (Strait 1997), overall size, shape, and enamel thickness are considered good indicators of the dietary niches exploited by extinct species (Janis and Fortelius 1988); when analyzed across lineages and clades with specialized diets, they even provide information about global climatic fluctuations

(Fortelius et al. 2002). The importance of tooth morphology for functional inferences is thus undisputed, but the high level of homoplasy compromises the usefulness of teeth for taxonomic purposes. For example, the hypocone probably evolved independently more than 20 times (Hunter and Jernvall 1995), while thick enamel among primates could be the result of convergent evolution also (Janis and Fortelius 1988; Hlusko et al. 2004). For a functional assessment the most useful, yet underexploited, feature is the way in which dental material, particularly the hard and brittle enamel, is strengthened to prevent the propagation of cracks (Rensberger 2000). Structural strengthening is achieved through enamel decussation, which has evolved in large-bodied taxa and those that employ high bite forces (von Koenigswald et al. 1987). Although attempts have been made to deduce prism decussation from their optical manifestations, i.e., the Hunter-Schreger, these optical phenomena do not adequately capture the levels of decussation in primates.

Prismatic enamel is a characteristic trait of Eutheria: it is brought about by the movement of ameloblasts from the dentinoenamel junction to the outer enamel surface during ontogeny and the differential orientation of hydroxyapatite crystals within the prism heads and its surrounding matrix (Boyde 1989; Osborn 1981). As the undulating prisms of one layer are (usually) offset with regard to layers of prisms above and below them (Fig. 1), bundles of prisms (crystals) will not be aligned in parallel, but will be angled in relation to each other. This apparent "crossing-over" provides a powerful crack-stopping mechanism (Rensberger 2000; von Koenigswald et al. 1987). This is because cracks tend to travel along the prism boundaries, i.e., the protein-rich prism sheaths (Fig. 1). Prism boundaries constitute the path of least resistance, whereas considerably more energy is required for a crack to traverse the strong hydroxyapatite crystals (Boyde 1989). By aligning prisms/crystals at angles relative to each other, cracks initiated while biting or through external forces, e.g., a blow to the head, will be stopped and crack propagation and catastrophic tooth failure will be prevented (except in rare circumstances). Differences in enamel prism organization thus hold information about the loading conditions habitually encountered by a species but also about wear resistance. As a case in point, the angles at which prisms intersect the wear surfaces will affect the rate at which the tissue is worn (Shimizu et al. 2005), an information that can be used to appraise whether the thick enamel of hominins is indeed an adaptation to wear resistance, as often conjectured (Macho and Shimizu 2009). Evidently thus, enamel microanatomy provides a wealth of information for an understanding of the ecological niches of hominins, but quantification of these differences remains difficult. Enamel is dense and chemically homogenous such that structural differences are achieved solely by the different orientations of hydroxyapatite crystals/prisms. The means to retrieve microanatomical details are therefore limited and include serial sectioning of the tissue (Hanaizumi et al. 1998; Osborn 1968), using high-resolution specialized imaging techniques such as the synchrotron (Tafforeau et al. 2012), or reconstructing the prism undulations from naturally broken surfaces (Macho et al. 2003; Macho 2004; Jiang et al. 2003). Despite the relative paucity of data resulting from these difficulties, however, it is clear that prism decussation is the combined outcome of prism undulation in

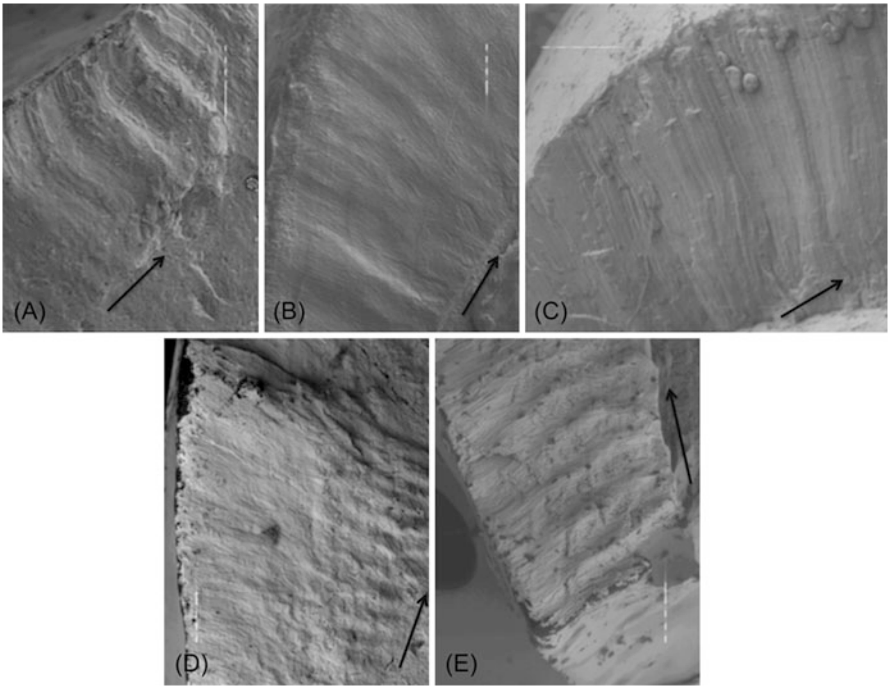

Fig. 1 Scanning electron microscope images (SEM) of naturally broken enamel structures of hominin teeth. (**a**) *Australopithecus afarensis* (LH6, I), (**b**) *Kenyanthropus platyops* (WT38356, RM1/2), (**c**) *Paranthropus boisei* (OH30, RM1), (**d**) *Australopithecus africanus* (Stw208, RM1), and (**e**) early *Homo* from Swartkrans, South Africa (SKX269, RC). *Arrows* are placed at the dentinoenamel junction and point toward the cusp tip; note that the *arrow* for *P. boisei* is directed slightly into the enamel to indicate that the break for this specimen, as for most *P. boisei* specimens, is somewhat oblique. For *A. afarensis* (**a**) and early *Homo* (**e**), images are from more cervical regions, thus explaining the thinner enamel; all other images are from mid-crown levels. Prism undulations are species-specific and levels of decussation vary substantially from high (**e**) to low (**c**)

3D space and the rate at which prism paths are offset in relation to each other apico-cervically. This appears a simple mechanism, yet it suffices to yield remarkably different patterns among closely related hominins (Fig. 1). The biomechanical consequences of these differences are significant too and are not anticipated from analyses of external morphology alone (Macho and Shimizu 2010; Shimizu and Macho 2008). Functional interpretations and dietary inferences based on overall tooth morphology, including enamel thickness, should therefore be viewed cautiously.

Bone

Unlike enamel, bone is a plastic material and continues to remodel throughout life in response to loads placed on it (Wolff 1892; for review see Pearson and Lieberman 2004; Ruff et al. 2006). Not all aspects of bone are equally informative as to their function in vivo (Currey 2002). Joints have evolved to confer both optimal orientation with regard to the direction of load and mobility, although the relative contribution of each of these aspects, as well as the magnitude of loads, remains uncertain. Until recently, the study of joint surfaces has been relatively neglected in paleoanthropology. With the affordability of more powerful computers and with advances in capturing and analyzing complex 3D shapes, this has begun to change (Parr et al. 2011; Tocheri et al. 2007). Analyses of joint surfaces is likely to become an important aspect of functional studies, especially when combined with an assessment of the subchondral bone densities underlying these surfaces (Carlson and Patel 2006; Nowak et al. 2010). Weight-bearing bones (e.g., vertebrae, calcaneus) or weight-bearing aspects of long bones (i.e., proximal ends) gain their structural stability through a meshwork of interconnected trabeculae. Such an arrangement ensures maximum strength while, at the same time, minimizing weight; unsurprisingly 70 % of all the bone is thus trabecular bone (Huiskes 2000). In order to optimize the functional adaptations of bone, trabeculae tend to align along the principal stress trajectories (Abel and Macho 2011; Biewener et al. 1996).

In an innovative comparative study, Ruff et al. (1994) investigated the response of bone remodeling during different stages of ontogeny. They found that increased mechanical loading prior to (or during) adolescence leads to an increase of cortical bone thickness due to periosteal expansion. Conversely, increased loading during later stages of development results in endosteal contraction with external diameters remaining relatively unaltered (Ruff et al. 1994). In addition, cortical bone responds systemically to increased activity levels during ontogeny, even in the absence of direct loading (Lieberman 1996). Increase in bone length, in contrast, is largely stimulated through the effects of growth hormone at the growth plates and indirectly through muscle action (Vogl et al. 1993). Taken together thus, physical activity during development, i.e., during adolescence in particular, will have the greatest effect on bone remodeling through direct and indirect stimulation, whereas activity levels during adulthood will result in comparatively minor changes. With these provisos in mind, activity levels, particular behaviors, and the timing of their onset can be deduced from cortical bone thickness and cross-sectional shapes in archaeological samples and fossil hominins (e.g., Stock 2006). What has thus far been underappreciated in paleoanthropological studies is the potential importance of collagen fiber orientation within the bone matrix, its response to loading and its significance for functional interpretations (McFarlin et al. 2008; Skedros et al. 2011). Like enamel, bone is a structured hierarchical material, whose consequences for mechanical behavior and abilities to absorb and/or distribute loads may be more significant than anticipated from gross anatomy alone (Bechtle et al. 2010) (Fig. 2).

Trabecular alignment within bones similarly responds to loading. Although the main trajectories are developed relatively early during development (Biewener et al. 1996; Tanck et al. 2001), trabeculae continue to grow differentially in areas where strengthening is needed and are resorbed where it is not (Abel and Macho 2011; Biewener et al. 1996; Tanck et al. 2001; Frost 1990; Kobayashi et al. 2003).

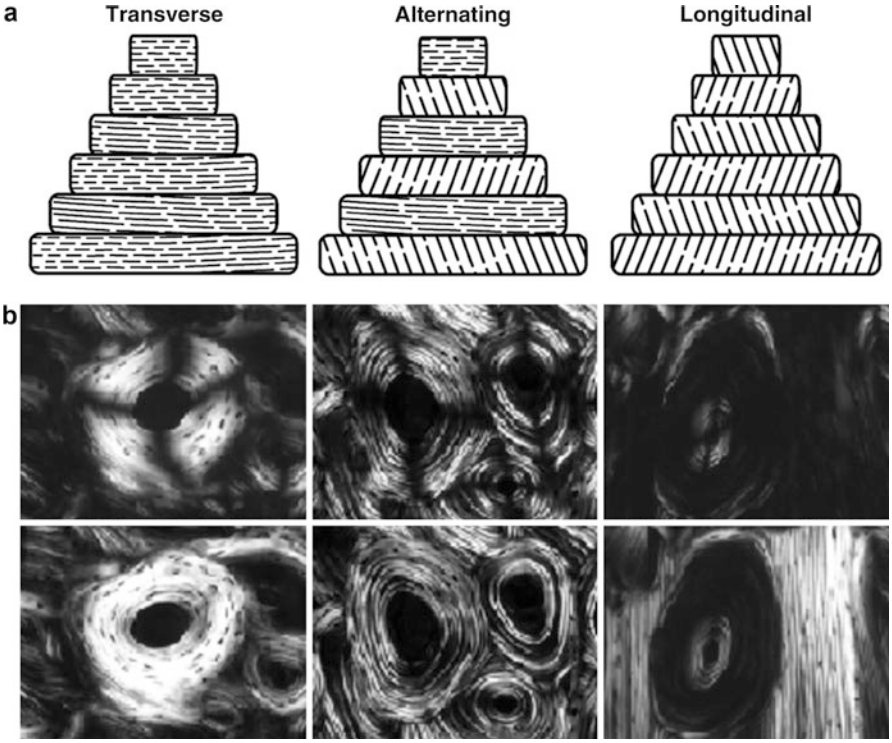

Fig. 2 (**a**) Illustration of the predominant collagen fiber orientation patterns of osteons and (**b**) their appearance in histological sections, i.e., linearly polarized light (*top*) and circularly polarized light (*bottom*) (Adapted from Skedros et al. (2011) and Bromage et al. (2003) with permission)

The potential of trabeculae for (re)modeling later in life offers exciting possibilities for anthropological inquiry. That is, when viewed against overall bone shape, which tends to be phylogenetically and ontogenetically more constrained, trabecular architecture is a better indicator of an animal's behavior in vivo than gross morphology. Combined analyses of external and internal morphology therefore shed light on fundamental questions in paleoanthropology, e.g., whether a primitive morphology constitutes a plesiomorphic character (phylogenetic constraint), whether it has been retained by stabilizing selection (behavior), or whether it has simply not been selected against (phylogenetic inertia) (Ward et al. 2001). These possibilities were recently explored for the capitate of *Australopithecus anamensis* and *A. cf. afarensis* (Macho et al. 2011). Carpals and tarsals are particularly useful when addressing such questions: they lack epiphyseal plates and, with some rare exceptions, muscles attachments (Bryant and Simpson 1984; Dainton and Macho 1999a, b). Consequently, their development is influenced less by hormones and muscle pull, while the internal bony architecture will directly reflect the loading conditions encountered (Fig. 3).

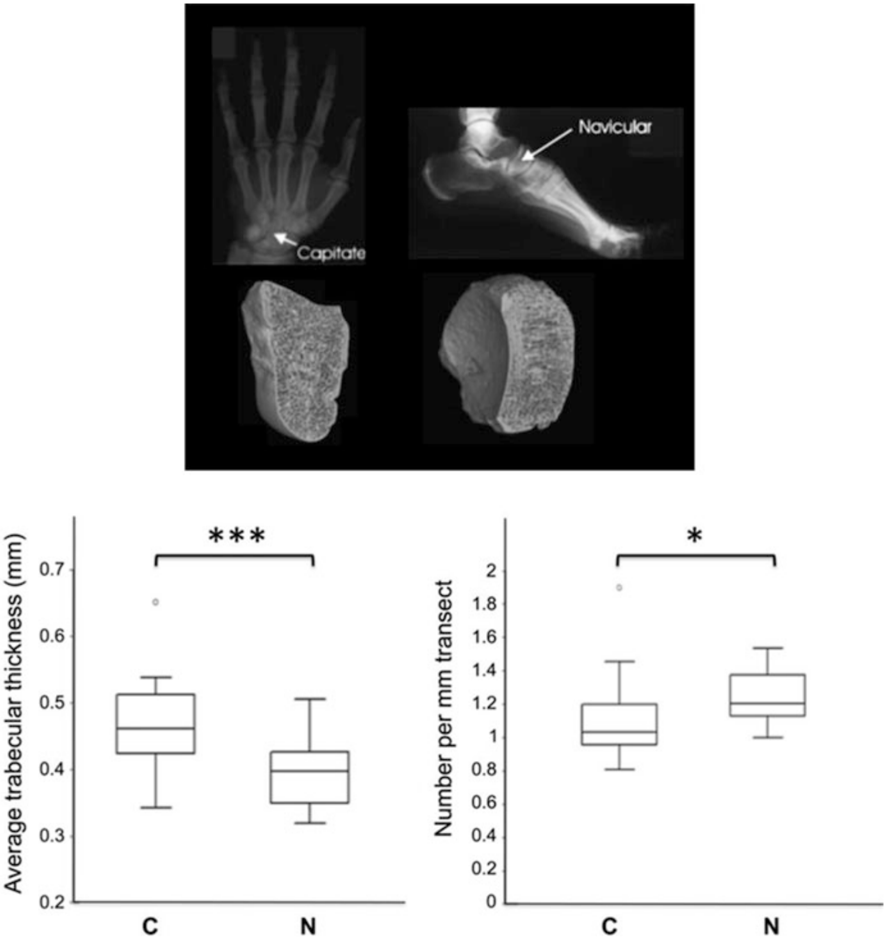

Fig. 3 Systematic differences in isotropy, trabecular thickness, and density between weight-bearing (navicular) and nonweight-bearing (capitate) bones in modern humans (Adapted from Macho et al. 2005). *C* capitate, *N* navicular; asterisks indicate significance levels using paired *t*-tests

Determination of Functional Adaptations

Adaptations are traits which enhance the fitness of the species and have arisen over evolutionary time as a result of natural selection for present biological roles (Rose and Lauder 1996). Inferring the functional adaptations is not trivial even when the traits under investigation do not constitute evolutionary novelties. Comparative analyses based on analogy with extant taxa assume that structure and function are intricately linked, but this is seldom the case (Lauder 1997). Importantly, most biological structures have evolved to fulfill more than one function and many complex systems are mechanically redundant: similar outcomes can be achieved through different means, as shown for the masticatory apparatus, for example (Koolstra 2002). From an evolutionary perspective, redundancy is advantageous, because it increases a structure's evolvability (Wainwright et al. 2005), but for the paleoanthropologist it is troublesome, because it reduces the confidence with which function can be inferred from morphology.

Traits which are advantageous and enhance the fitness of the species may in fact have evolved for a different purpose or they could initially have been the result of random genetic drift, pleiotropy, or correlation with other structures (Gould and Lewontin 1979; Gould and Vrba 1982). Until recently, exaptations have been assumed to be rare, especially in hominins. Two possible exaptations have now been identified: the crack-stopping morphology of the dentine-enamel interface (Shimizu and Macho 2007) and hominin finger proportions which then facilitated the emergence of stone tool technology (Rolian et al. 2010). In order to affirm that evolution has selected for a certain trait, it is imperative that extant analogs exist and that the function is similar in all living species. Inferences about functional adaptations thus formulated should then be supported by biomechanical analyses. Additionally, the first appearance of the feature must be found to coincide with (and be supported by) ecological and environmental evidence, for which the feature and its functional adaptation had apparently been selected (Lauder 1982; Anthony and Kay 1993). Hominin morphology should therefore always be interpreted within the ecological and environmental settings of that species (Vrba et al. 1995; Bromage and Schrenk 1999). On theoretical grounds the procedure for identifying functional adaptations is straightforward but, in reality, it is challenging: the hominin lineage contains only one extant taxon, *Homo sapiens*; the fossil record is incomplete; experimental data on extant species are scarce; and there is much to learn about the environment in which early hominins evolved (chapters "▶ Primate Origins and Supraordinal Relationships: Morphological Evidence," Vol. 2 and "▶ The Miocene Hominoids and the Earliest Putative Hominids," Vol. 3). To overcome some of these limitations, sophisticated experimental tools are now routinely used in paleoanthropology, particularly finite element stress analysis (FESA). This method is well suited to determine the functional constraints of morphologies, provided the limitations and assumptions underlying model creation are borne in mind.

The usefulness of FESA for (paleo)anthropological inquiry was first explored over a decade ago (Macho and Spears 1999; Spears and Macho 1998), and this method has now become part of the mainstream paleoanthropological tool kit (e.g., Ross 2005). FESA is a numerical modeling technique that examines the deformation of a virtual model composed of a meshwork of elements with given material properties, such as elasticity (Young's modulus), Poisson's ratio (the change in width after a given change in length), shear properties (shear modulus), density, bone mineral fraction, etc. (see Rayfield 2007 for a simplified review of the principles of FESA and applications in paleontology). This technique is particularly useful where an assessment of the internal mechanical behavior of structures is sought and/or where noninvasive approaches are required, as is the case for hominin fossils. However, FESA is not without pitfalls. Perhaps most crucial for an assessment of the functional adaptations (apart from overall geometry) is the input of material properties. Both teeth and bone are highly complex hierarchical structures (Figs. 1 and 2). Unfortunately, computer capacities are limited and only a finite number of details can be inputted. Put simply, the larger the structure under investigation, the cruder the model. Although efforts are being made to improve the input parameters and diversity of material properties used, many more improvements are necessary when dealing with large complex objects, like the primate skull. As a case in point, to create the complexity of the entire skull, Strait et al. (2010) used some 311,000 (macaque) and 778,000 (*Australopithecus africanus*) elements. In contrast, the average number of elements used to represent a small block of enamel was 440,000 (Macho et al. 2005; Macho and Shimizu 2010). Despite the apparently high level of detail, these enamel models are still simplifications though: the protein-rich prism sheaths separating enamel prisms were not modeled, although their biomechanical significance is undisputed (Ge et al. 2005). Inputting these data would have surpassed the computational capabilities. Deciding on the boundary conditions, i.e., the loads and constraints placed on the models, is another problematic area and a potential source for misleading results, particularly when investigating complex systems. For example, the masticatory system is redundant (Koolstra 2002) and the mandibular stroke varies within and between individuals depending on the size and properties of food, age, individual preference, pathology, muscle physiology, motor control, etc. (Woda et al. 2006). Deciding on the bite direction is therefore difficult, even more so when dealing with extinct taxa that are represented by incomplete skulls only. This is important, as the orientation of the applied load, and the locations of restraints, i.e., where the model was fixed, will significantly affect the stress flow within that structure. This highlights that while engineering techniques provide powerful and useful tools for functional analyses, models are only as good as the data inputted and the assumptions made.

Determination of Behavior

Determination of behavior is probably the most difficult and contentious aspect of anthropological inquiry. The correspondence between morphology, performance, and behavior is generally inadequate (Lauder 1997). Behavioral inferences largely rest on comparative approaches aiming to deduce the biological role of morphology (bone and tooth size and shape, muscle markings, etc.) from modern analogs. But fossil species are unique: they do not have modern analogs. What is more, the farther back in time, the more fragmented the hominin fossil record becomes with associated partial skeletons being extremely rare (Berger et al. 2010; Johanson et al. 1982, 1987; Toussaint et al. 2003; Walker and Leakey 1993; White et al. 2009). Reconstruction of the bony elements therefore relies on the expertise of the morphologist working with comparative material and/or composite constructs; morphological differences between individuals, as well as temporal changes in morphology, can become obscured.

The fact that a species was capable of performing certain functions and behaviors does not necessarily imply that it habitually did do so. Both modeling and biomechanical analyses can only determine the boundary conditions, i.e., constraints, of morphological structures and infer their *potential* capabilities. A distinction must be made between what a species *could* do and what it *did* do. An animal's behavior is contingent on many factors other than morphology, such as the environment, competition among sympatric species, resource limitations, etc. The evolutionary success of a species will ultimately depend on how it negotiates the challenges and vicissitudes posed by the biotic and abiotic environment within the confines of its own biology. It will be challenging for the paleoanthropologist to separate these aspects. Among hominoids, for example, sympatric *Pan* and *Gorilla* feed on the same fruits during the fruiting season, but food selection changes more dramatically among gorillas than chimpanzees during the dry season (Kuroda et al. 1996). Similar scenarios are possible for sympatric hominins, e.g., *Homo* and *Paranthropus*.

Conclusions

Fossil remains of hard tissue, such as teeth and bones, provide a wealth of information for the evolutionary biologist aiming to reconstruct the phylogenetic history and functional adaptations of extinct species. Unfortunately, disentangling these various aspects is not trivial and requires that paleoanthropologists employ a number of analytical tools, draw on information obtained in other disciplines (i.e., behavioral, developmental, and experimental), and collaborate with researchers in other areas. It has become abundantly clear that no single approach or technique suffices to shed light on the functional adaptations and behaviors of extinct hominins. At the same time each technique has inherent limitations and is built on assumptions that cannot always be overcome. Choosing the appropriate research tools and bearing in mind limitations specific to each approach is essential when interpreting the results. Nonetheless, the increasingly multi- and interdisciplinary nature of paleoanthropological research has much to offer and has begun to generate new and exciting (as well as partially testable) hypotheses at a faster rate than ever before. Given that hominins are large-brained primates that display behavioral flexibility and dietary selectivity, it is perhaps prudent not to ask what they did do but rather what they were incapable of doing. By turning the fundamental question about form, function, and behavior of extinct hominins around, better insights into the evolutionary biology of our lineage can be gained.

Acknowledgments I thank John Skedros and Tim Bromage for permission to reproduce their figures. This chapter is the result of various research projects, funded mainly by the Natural Environment Research Council (UK), The Leverhulme Trust (UK) and the Ministerio de EconomÚa y Competitividad (Spain).

Virtual Anthropology and Biomechanics

Gerhard W. Weber

Contents

Abstract

The scarcity of fossil hominins imposes the obligation to extract as much information as possible from the few existing remains. Virtual anthropology exploits digital technologies in an interdisciplinary framework to study the morphology of specimens in 3D and 4D. It can contribute to this aim because structures are easily accessible, powerful morphometric analyses can inform about intragroup and between-group form and shape variation, data manipulations and reconstructions become more reproducible, and sample sizes can be increased via sharing of electronic data. The six main areas of virtual anthropology – digitize, expose, compare, reconstruct, materialize, and share – are introduced in this chapter. Biomechanics on the other hand allows inferring certain aspects of function via the study of loadings in structures. Though an

efficient formal bridge between those two domains is still missing, there are many overlaps and cross-fertilizations visible, possibly leading into a “virtual functional morphology” to better understand evolutionary adaptations.

Introduction

When the first hominin fossil (later classified as Neanderthal) was found in 1829 by P.C. Schmerling at Engis/Belgium and described by him soon thereafter (1833), there was no such science as paleoanthropology. Not even a proper idea of evolution had been formulated by then, though it was spooking in the head of some enlightened already. This comes as no surprise since the appreciation of human evolution just makes sense if one accepts the changeableness of species and populations – a frightening idea for some against the safe harbor of religious beliefs.

Schmerling recognized that the fossil remains he found were different from what he knew as anatomist and would belong to a “primitive species” (1833, p. 124). Though he was, e.g., impressed by the size of teeth, he had of course no good means to capture size and shape quantitatively to be compared against other populations. T. H. Huxley later used (1863) Engis and the famous calotte from the Neanderthal to argue for Darwin’s ideas. Today, in the second decade of the twenty-first century, we have developed a great many of machines and methods to extract information of all kinds from fossil material so that the approaches of the nineteenth century – describing form mainly qualitatively or adding only a few quantitative measurements – are becoming more rare.

Paleoanthropology tries to settle questions (Henke 2007) like what distinguishes us from our next living relatives, when and where did humans branch off from the other primate tree, which ecological framework enabled the process of becoming human, how many and which hominins were out there, and how did we develop our specific traits like bipedal locomotion or language? The main challenge in our science is that there are only so few sources of evidence available to answer these questions. And even if the number of discovered fossils has increased impressively in the last few decades, we cannot nearly hope to close the gaps in the record or collect representative sample sizes. In the evolutionary sciences, we can only model populations and processes with more or less confidence.

This scarcity of material imposes the obligation to extract as much information as possible from the few existing remains. We have to think hard about experimental designs, methods, and collaborations with other sciences to match this claim. Who would have thought 50 years ago that we would have the complete sequence of the Neanderthal genome (Prüfer et al. 2014) or that the shape of the tiny semicircular canals in the inner ear (Hublin et al. 1996) would suggest a species assignment? If we consider paleoanthropology as a part of the natural sciences (Tattersall and Schwartz 2002), on the other hand we need to follow its rules, i.e., *that explanations must come from observations that can be repeated and confirmed by other researchers*. This requires eliminating subjective opinions and irreproducible results. Otherwise paleoanthropology is indeed nothing else than a narrative science – a story telling in the sense of Landau (1984). Consequently, we have to walk the thin line between exploiting every possible bit of information stored in a fossil, but not exaggerating its interpretation and keeping in mind the uncertainty that comes attached to our data. Darwin himself recognized the poisonous influence of erroneous data (1871, vol. II, p. 385): "False facts are highly injurious to the progress of science, for they often long endure; but false views, if supported by some evidence, do little harm, as every one takes a salutary pleasure in proving their falseness; . . .."

Quantitative data and computer environments offer the advantage that every manipulation becomes obvious, at least it can be made public, if that is the intention. In this sense, virtual anthropology and also biomechanical simulations have the potential to make a step toward reproducibility and, of course, toward sharing ideas and data with the speed of light. This does not guarantee proper investigations. The machines and algorithms will only produce results as intelligent as the researcher has designed the analyses. Critical reflection is important and necessary. T. White put it to the extreme when he said in his Millennium essay (2000, p. 288): "The careerist leaps on each passing technological bandwagon. [. . .] Results can be instant, irreproducible, and irrelevant. When applied without appropriate biological background, they simply muddle fundamental issues in human evolution." We have indeed to take care that methods and machines are used advisedly and that researchers understand the prerequisites and limits of their use. However, there are enough documents in support of useful applications out there and also White and colleagues later used the toolkit of virtual anthropology to describe and analyze their fossils (e.g., Suwa et al. 2009).

Virtual anthropology (VA) exploits digital technologies and pools experts from different domains such as anthropology, paleontology, primatology, medicine, mathematics, statistics, computer science, and engineering. VA, as the author here defines it, deals mainly with the functional morphology of recent and fossil hominoids. Its methods can, of course, be applied in a much broader sense, e.g., for other primates, mammals, vertebrates and invertebrates, and even for plants or tools. The term "virtual anthropology" was coined in the mid-1990s and first published in 1998 (Weber et al. 1998) when computer power and software became available to work reasonably with digital 3D data – though still at enormous expenses. The term is just one of several (e.g., computer-assisted paleoanthropology; Zollikofer et al. 1998) to mark the onset of a new approach in the field of biological anthropology – performing morphological analysis by means of digital data in a computer environment. Many people have contributed to pioneer this field, e.g., Fleagle and Simons (1982) using computed tomography (CT) to study long bones of an Oligocene primate; Wind (1984) investigating the famous Pithecanthropus IV fossil from Java; G. Conroy and M. Vannier with their first attempt to electronically remove matrix from a fossil scan to investigate the cranial cavity (Conroy and Vannier 1984), and a little later (1987) to determine the dental development of the Taung child; Spoor et al. (1994) revealing inner secrets of the bony labyrinth; and Zollikofer and colleagues (1995) virtually reconstructing

Neanderthals and other fossils. The first paleontologist using radiological methods to study hominin fossils, though not digitally, was D. Gorjanovic-Kramberger who published on inner details of the Krapina material (1902) only 7 years after W. Röntgen's discovery of X-rays. For a more comprehensive history of the field, see, e.g., Spoor et al. (2000) or Weber and Bookstein (2011a).

In modern paleoanthropology it is beyond any discussion to use the merits of machine power and simulations. But what did we gain after all? Based on the most striking differences to traditional approaches, namely, that virtual copies are used (which derive from digitization processes such as computed tomography or surface scanning, see below) and that these data can easily be analyzed in 3D or 4D within a computer environment, some crucial advantages resulted:

1. The accessibility of the *entire* structure, including usually *hidden features*, e.g., the braincase, the sinuses, the dentin of teeth, the medullary cavities of long bones, or the heart including its chambers.
2. The *permanent* availability of virtual objects (24/7) on hard drives or servers.
3. The possibility of obtaining a dense mesh of measurements across the whole geometry for *powerful* quantitative analyses of form and function.
4. The great range of options for data handling, statistics, visualization, and data exchange for increasing sample size.
5. The increased reproducibility of procedures and measurements, a fundamental requirement of science, as mentioned above.

It is noteworthy to say that the approach is not restricted to questions in paleoanthropology, though this is the main focus of the current article. Medical applications and comparable studies on living primates have arisen (see below), and tools and artifacts can be analyzed in the same manner (cf. Weber 2013). Talking about fossils, however, needs some extra words on the limitations. Although a fossil appears to be a simple static object, a piece of stone of some specific shape, it may convey a rich variety of data, for instance, with regard to macroanatomy (e.g., the shape of the cranial vault, jaw, or teeth), microanatomy (e.g., the orientation of trabecular structures or the prisms of dental enamel), taphonomy (e.g., the degree of mineralization, the presence of cut marks), individual life history (e.g., traumata and pathologies, incorporated trace elements), or perhaps genetics (ancient DNA from cell mitochondria or nucleus). A virtual fossil currently only contains a small fraction of this information, mostly concerning macroanatomy (and occasionally, depending on the resolution, microanatomy), and probably taphonomy and life history. In the case of volume data, e.g., CT, there is no color or texture information. In the case of surface data, there is information on texture and color together with the digitized surface, but there are no internal structures beneath the surface. Other data channels are missing entirely most often, for instance, a virtual fossil usually does not provide any information on DNA or trace elements. Virtual fossils are thus *not intended as a substitute* for real fossils. They are useful for specific purposes only: to work on all kinds of aspects with regard to shape and form of the whole structure or its parts. And it is advisable in many cases to look at the original or a

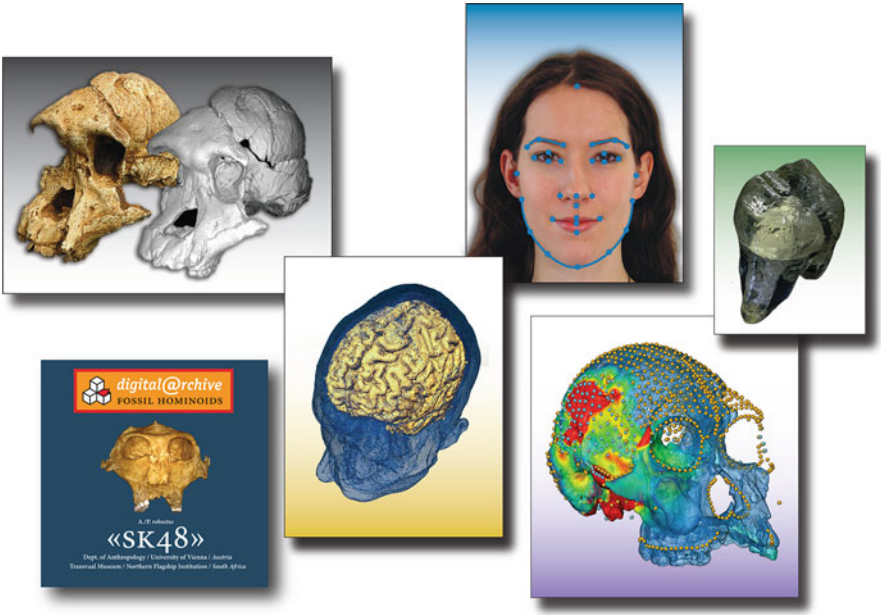

Fig. 1 The six operational areas of virtual anthropology: Digitize (*top left*) – an original specimen and its virtual copy (Stw 505). Compare (*top middle*) – landmarks and curves to capture the shape of a face. Materialize (*top right*) – upscaled transparent stereolithographic model of an australopithecine tooth (Photo by R. Ginner). Share (*bottom left*) – example CD-ROM from the digital@rchive of fossil hominoids. Expose (*bottom middle*) – Magnetic Resonance Tomography, segmented brain, and transparent head. premium cast during work since our senses are not well adapted to rely on screen simulations only.

While virtual anthropology was quite an exclusive endeavor in the 1990s, today the demands fall within the feasible range of a medium-cost lab. The most typical infrastructural and personal requirements for a VA lab are fast PCs with multiple core processors; high-end graphics cards (such as those that gamers use); big storage systems (often underestimated in costs); software for image processing, 3D manipulation and visualization, programming, and statistics; and staff to handle all these components. The team would ideally combine people with training in biology, anatomy, mathematics, statistics, programming, physics, and radiology. Devices for data acquisition do not have to be in the same lab or university, but they should be accessible conveniently, as via collaborations.

Virtual anthropology can be divided, with overlaps of course, into six operational areas (Fig. 1):

1. Digitize – mapping the physical world
2. Expose – looking inside
3. Compare – using numbers

4. Reconstruct – dealing with missing data
5. Materialize – back to the real world
6. Share – collaboration at the speed of the internet

All six are described in detail in a comprehensive textbook of this discipline (Weber and Bookstein 2011a). A summary of each of the six areas will be given below.

Digitize

The conversion of the real objects into virtual ones is obviously the first step in VA. There is a variety of technologies available today, some still sophisticated and costly, others simple in use and cheap. Digital data is a projection of continuous data into the space of integers. The range of numbers used for quantification is therefore limited to a discrete set of values, and the number of elements recorded is limited by the resolution of the sensor. Hence, the first two questions to answer are as follows: (1) Is it enough for the intended purpose (e.g., classification, hypothesis testing, modeling) to capture the surface of the object or is the whole volume of the object needed? (2) Independent of the first question, which resolution is reasonable? In paleoanthropology, many preserved features such as bone and enamel thickness, the cranial sinuses, the enamel-dentin junction of teeth, or the trabecular structures of the pelvis and long bones may carry important information with regard to interpretation of functional morphology and taxonomical assessment. Volume data, i.e., 3D data throughout the whole structure such as CT, is therefore often mandatory. In archaeology or face recognition of living subjects, for instance, surface data would satisfy many applications because the inner composition might be known, as, e.g., with stone tools, or not be part of the investigation. Surface scans can thus be ideal for the sake of saving time and money. Though many, if not most, paleo-questions would involve the inner structures of fossils earlier or later, surface scans can nevertheless be the choice of digitalization because volume data acquisition could simply be not possible for the moment, for instance, in the field or because no permission to transport fossils to the next volume scanner is available.

To scan the whole volume, all kinds of “tomographic” procedures (imaging by sections) are in principle applicable. Computed tomography (CT), a standard medical imaging procedure commonly used for scanning living patients; micro-computed tomography (μ-CT), an industrial imaging routine to examine materials in very high resolution; or magnetic resonance tomography (MRT), another medical routine to image patients avoiding ionizing radiation, are popular examples. The latter can capture soft tissues very well but hardly delivers usable signals from hard tissues such as bones and teeth. It is used to examine the brain, the heart, the cartilage in joints, and the like in living subjects. Its use for paleoanthropology is limited to very specific problems, predominantly to scan extant primates for comparative purposes (e.g., the relative size of frontal lobes (Semendeferi et al. 1997) or cranial base flexion during ontogeny (Jeffery and Spoor 2002)). In contrast, CT and μ-CT can cope easily with dense and very dense objects like bones, teeth, ivory, antler, shells, and stones. Like any of these tomographic methods, it delivers a stack of 2D images (called “slices”) that are combined to a 3D volume. Images are based on X-ray technology which means that radiation is emitted by a tube, the rays are partly absorbed by the object which is penetrated, and the remaining X-rays are recorded at a detector behind the object. In medical scanners, the object rests at a moving table and the tube-detector system rotates around it. In μ-CT, the object rotates instead which implies the necessity of a rigid fixation at the rotation table to avoid motion artifacts. Since paleoanthropology deals with dead material, the radiation dose is of low interest in both modalities (there might, however, be effects on color and preserved DNA; Paredes et al. 2012; Richards et al. 2012).

Each slice of the volume data consists of small picture elements, like those of any electronic image. While these elements in a 2D photo are called “pixels,” we call elements of 3D volume data “voxels” because they offer a third dimension, a thickness. Voxels carry information about their individual position in the x, y, and z grid of the volume – plus a specific value for their grey value. The inner composition of a scanned object is detected based on the different densities of materials which lead to different grey values of the voxels (a function of the attenuation of the X-rays). If that inner composition is to be expected homogenous, then there is no argument of using a tomographic technology. If, in contrast, different materials or change of material over space can be expected, then it is the appropriate procedure. CT can deliver a resolution of roughly a millimeter down to ~200 μm. Features being smaller cannot be acquired. μ-CT starts somewhere around 100 μm and can go down to 1 μm, depending on the capabilities of the system (e.g., the diameter of the micro-focused X-ray beam, the size of the detector elements) and the applied magnification which again depends on the size of the object and the scanner geometry. Many recording chambers of μ-CTs are limited to relatively small objects (usually only some centimeters in diameter). Only a few machines can handle large objects of the size of a human skull or femur (e.g., VISCOM X8060 II, see www.micro-ct.at). A further increase in contrast quality and resolution is possible with synchrotron tomography which may go down as far as 0.7 μm (Sanchez et al. 2012). However, research times at those facilities are quite in demand and therefore hard to obtain.

The resolution of the data should be generally “good enough for the purpose” (Weber and Bookstein 2011a). While it rarely makes sense for the investigation of the gross geometry of a skull to go down with resolution lower than 200 μm, another scan at 50 μm could still be too coarse for the analysis of tooth wear facets. A good question to start is thus: What is the smallest structure that needs to be detected? And why not digitize everything using μ-CT? Firstly, the accessibility to these machines is still very restricted. They are immobile or, at best, can be transported only with great difficulty. Secondly, mammoth data volumes emerge (e.g., a cranium with 50 μm voxels is roughly 70 GB data), which require high-end computers for their processing. This is where the technical development of computers and storage media still lags, in an affordable price range, behind the possibilities of the technical scan. Thirdly, only small objects can be examined, while crania, jaws, or long bone fragments in many cases do not fit into the recording chamber, with exceptions as mentioned above. For precious objects such as fossils which can undergo an examination perhaps only once, μ-CT is definitely the preferred choice because it delivers data good enough for virtually all purposes and for the middle-term future (even if we have to await technical development to fully use it).

Surface scanning on the other hand does not allow looking even a nanometer below the exterior interface, but, depending on the system used, can digitize the surface in very high resolution too (also in the μm range). Scanners are often based on laser beams or structured light (dark and bright stripes) that are projected over the object. A sensor is measuring the reflected light, respectively the pattern of stripe distortion. Since the geometry of the light/pattern emitting and receiving system is known, the object geometry can be computed by means of triangulation. The acquisition of one such "shot" can be very fast (within seconds). But comparable to photography, it represents only one view. Hence, the object has to be rotated and captured again and again, with overlapping areas. Smart routines in the software will stitch together the different views until the whole object surface is recorded in all dimensions. Data sets are rather small compared to volume data (because the objects are "hollow"), and in some cases also texture/color information can be recorded. This can be an important additional aspect in paleoanthropology – to keep this kind of information in the analysis (which is not possible with any of the tomographic procedures). Surface scanners are easier to transport than CT or μ-CT scanners and a magnitude cheaper. Applications in the field are thus feasible (if there is electric power available). Stereoscopic photography is also an alternative to obtain 3D data from multiple images taken from different views. Recent software packages (e.g., PhotoModeler® http://www.photomodeler.com) assist in calibrating the camera system and identifying overlapping points on images to create a 3D model of the object (Paul et al. 2013).

For scanning bones and fossils, there shaped up a list of do's and don'ts in practice. For instance, all metal parts (e.g., fixing pins, clips) should be removed from the object to avoid artifacts, the gantry tilt in medical devices should be kept at zero, an appropriate *field of view* to maximize resolution and the smallest possible slice thickness to minimize the *partial volume effect* should be chosen, the contrast should be maximized and CT scale overflow artifacts avoided, and the kernel (the convolution filter used for back projection) should be neutral to slightly hard. In any case, the raw data should be kept. New reconstructions can be computed afterward from this source. And after scanning, it is a matter of courtesy to share the data and leave a copy with the institution that hosts the collection of fossils. The brevity of this article does not allow for a discussion in length, but for more technical advice, see, e.g., Spoor et al. (2000); Zollikofer and Ponce de León (2005), or Weber and Bookstein (2011a).

Expose

There is nothing to expose with surface data, as mentioned above, because only the visible surface was recorded. Working with tomographic data, the outer *and* the inner structure can be examined. In contrast to invasive techniques such as histological thin sections or grinding, the advantage is that the object does not have to be destroyed and only has to be touched for transport to a scanner and back. Its interior can be inspected by browsing through the stack of images (like most radiologists still do with their light box examining CT or MRT scans of patients) or by *segmenting* structures of interest as 3D objects. Segmentation means to separate particular areas of the image from their neighborhood and address them as different logical entities. For instance, the brain in a MRT scan is often segmented from the surrounding liquor, meninges, bones, and muscles to work on its morphology. Paleoanthropologists do the same with the interior of the braincase, the only remainder in fossils to infer speculations about our ancestor's cognitive capacities. In a dried skull, and often in fossils, the braincase is filled with air which has a different grey value (black) than the bone (white). There are semiautomated algorithms (mostly thresholded region growing) available in many programs (e.g., Amira™, Analyze™) that help labeling the borders between the regions without much manual intervention. The latter is important to approximate the goal of reproducibility, thus avoiding subjective influences. Once this is done for each slice of the volume, there is a new object that is called "virtual endocast" (Weber et al. 1998). It can be rendered on a computer screen (Fig. 2), where it appears as a "positive" of the formerly hollow cavity. Surface details like imprints of brain convolutions or vessels can be described, and it can be measured, e.g., the cranial capacity (volume). Likewise, other hollow structures can be created as virtual endocasts, for instance, the frontal and the maxillary sinuses or the pulp of a tooth.

Since the brain development is one of the critical issues in human evolution, endocranial endocasts are important sources to compute indices such as the encephalization quotient, which is based on the estimated brain to body size ratio (Martin 1983). Cranial capacity, i.e., the volume of the endocranial cavity, is, however, not equal to the size of the brain but about 10 % less (Holloway et al. 2004). Virtual endocasts were used in many fossil studies to infer an approximate brain volume or other descriptions (Conroy et al. 1998, 2000; Recheis et al. 1999; Falk et al. 2000; Tobias 2001; Prossinger et al. 2003; Bräuer et al. 2004; Carlson et al. 2011; Curnoe et al. 2012) and were also used for modern humans, primates, and vertebrates (Colbert et al. 2005; Rowe et al. 2005; Macrini et al. 2007). Unfortunately, they provide no direct information with regard to the internal structures of the brain, e.g., the number of neurons and their density and histological structure, or about the connectivity between areas of the brain. But beside the mere volume, the full range of the morphometric tool kit (including landmarks, curves, and surfaces, see below) can be used for the quantitative comparison of the internal morphology just as for the outside of skulls. Beside size change, it is mainly changes in the overall proportions of the brain or the

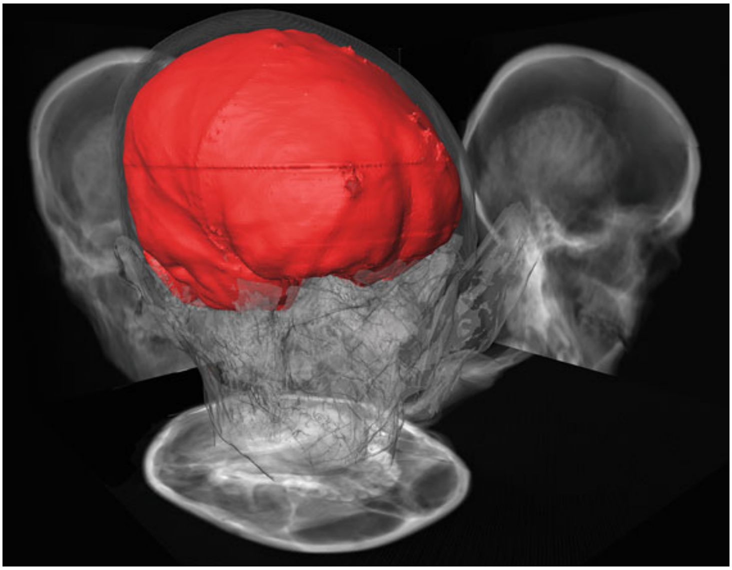

Fig. 2 Virtual endocast of the Tyrolean Iceman "Ötzi" which represents the size and shape of the endocranial cavity. The projected X-rays in the background show the actual shrunken brain

proportions of its components such as the size of the frontal cortex and cerebellum (Seidler et al. 1997), or the parietal lobes (Bruner et al. 2003), or the pattern of vascular supply (Neubauer et al. 2004) that inform about hominin evolution. Also the ontogenetic patterns of brain development changed in the course of evolution, which can be studied in fossils and in comparison to extant apes (Neubauer and Hublin 2012).

Staying with the brain for a moment longer, there are of course applications of the VA action "expose" to extant humans as well, reaching far into medicine. The fetal alcohol syndrome, for instance, leaves its traces in the connecting structure between the hemispheres, the corpus callosum. With the use of MRT scans and semilandmarks along its midline, researchers (Bookstein et al. 2006) could clearly show a specific geometric signal indicating brain damage in this class of birth defect that is triggered by alcohol abuse during pregnancy. The method is even used in American courtrooms to detect this damage in the brains of certain convicted murders at risk of a death sentence. Virtual endocasts of recent humans have also been used to illustrate the effects of a new surgical intervention to relief intracranial pressure in cases of severe brain edema. "Posterior-hinged circular craniotomy" (Traxler et al. 2002) is applied when conventional therapy and trepanation fails. The whole calotte is cut, with the only exception of a small region at the occiput to protect the vital blood drainage via the sagittal sinus. But the gain in volume at a certain degree of frontal elevation of the calotte is almost impossible to measure on a patient while it is quite simple by means of virtual endocasts where this elevation can be simulated on the computer and volume increase be measured and correlated with skull shape and other factors such as sex.

Coming back to paleoanthropology, “electronic preparation” of specimens is another important domain of VA. A form of interest in many fossils is not or only partly accessible because it is covered by some foreign material, sometimes called “matrix” or “encrustation.” The foreign material must be removed without jeopardizing the surface of the object any more than necessary. Physical preparation is a manual procedure that requires highly trained and experienced staff with good eyesight and steady hands. Miniature chisels, air hammers, sandblasters, and the like are used to remove the matrix bit by bit. Nevertheless, there is a considerable element of risk because the matrix could be excised too deeply, destroying actual fossil bone. Good preparators avoid such errors by working very slowly. Still, internal features like sinuses or cranial cavities are impossible to uncover.

Electronic preparation, in contrast, is based on volume data (surface data do not inform about internal characteristics) which allows access at any point of the object. For fossils, these are typically CT or μ-CT scans. If the fossilized bone displays a distinctly different range of grey values (density) than the matrix does, the removal of the foreign material is a fairly straightforward job. The material properties of matrix vary, however, widely, as do the difficulties associated with their virtual removal. But one overwhelming advantage of computer-based methods is immediately evident: the original specimen is not impaired. There is no “undo” command for operations on physical objects.

In difficult cases, there is overlap in grey values (density) between fossilized bone and matrix or the matrix is heterogeneous, as when gravels and grains of rock are embedded in calcareous sand. Sophisticated filtering might be necessary during segmentation to find a clear boundary between bone and matrix. Such filters to enhance the boundaries may involve a single application of a Sobel, Laplace, Low Pass or other filter (Weber and Bookstein 2011a), or even a fine-tuned sequence of many filters (e.g., Prossinger et al. 2003). Morphological filtering is another routine to support the separation of logically different units by breaking up tiny bridges that may be left over after region-growing procedures or to smooth the results. There is a huge literature out there about digital image processing, which is not related to VA specific tasks, but very helpful to consult (e.g., Gonzalez and Woods 2008; O’Gorman et al. 2008; Yoo 2004).

Compare

Morphological studies involve the need to capture the shape and form of objects and to compare individuals or samples to each other. Typical questions that arise are the following: How does the average form look like? How does form vary in a population around this average? How are two groups differing from each other? What might be the functional meaning of such form differences? In VA, the aim is to treat the shape and form of specimens or groups by means of numbers, which ideally consider the whole form under investigation rather than “atomizing” it by describing countless separate traits (e.g., occipital bun, high parietal boss, low cranium, projecting midface) by words or by characterizing form by a restricted and unrelated set of measurements. This brings along some advantages. The numbers help limiting subjectivity as far as possible. Considering the whole form at once avoids treating the skull as a set of features that could not actually be independent. And using computing power and memory facilitates the comparison of hundreds of "traits" (actually then the whole form at once) from hundreds of individuals simultaneously (see, e.g., Gunz et al. 2009a). The human mind is not able to keep an overview over such large data sets and tends to overlook facts and introduce its opinions. Paleoanthropology is probably not a bad example for this inherent imperfection of the human analogous computing mode (which has admittedly great advantages otherwise, see below).

VA uses machines to do the computing of powerful statistics, not to interpret them meaningfully. This is still the domain of the researcher in front of the machine (with his/her integrative brain, a feature that machines are still very bad in simulating). Nevertheless, this way offers a step toward more reproducible results, a fundamental claim of any natural science. There are several different techniques to quantify shape and form, for instance, outline approaches such as elliptic Fourier analysis (EFA, Kuhl and Giardina 1982) capturing closed contours quite well and not being dependent of evenly spaced points or equal number of points across specimens, or Euclidean distance matrix analysis (EDMA, Lele and Richtsmeier 1991) based on distances between landmarks and thus well suitable for sufficiently large sets of caliper measurements. Another approach is called "geometric morphometrics (GM)" which uses multivariate statistics based on 3D coordinate data. Avoiding distances and angles (which have some specific disadvantageous statistical properties such as introducing artifactual covariance structures (Rohlf 1999) and biased mean estimates (Rohlf 2003; Slice 2005)) and orientation problems, GM retains all geometric information contained within the data. A combination of outline and landmark-based approaches would be desirable in some cases (Baylac and Friess 2005). There are of course many pros and cons for the individual approaches. The space of this review article does by far not allow for a detailed discussion; however, some references are suggested to form an opinion (e.g., Bookstein 1991; Rohlf and Marcus 1993; Bookstein 1996; Dryden and Mardia 1998; Lele and Richtsmeier 2001; Slice 2005; Weber and Bookstein 2011a).

Comparisons of biological forms have to be kept under the control of biological theory: the rule of homology (comparing like to like). GM utilizes a particular formal technique, that of landmark/semilandmark points, which enforces this rule. Landmarks are specific points on a form or image of a form located according to some rule. There are several types of landmarks corresponding to the method how they are identified. For instance, they can be located at the crossing of bony sutures or at extreme points of curvature or along ridges (see landmark types I–VI in Weber and Bookstein 2011a). Central to the GM approach are some key elements such as generalized procrustes analysis (GPA; Gower 1975; Marcus et al. 1996), principal component analysis (PCA), and thin plate spline warping (TPS; Bookstein 1978, 1991) that lead to representations of form by size along with shape coordinates and

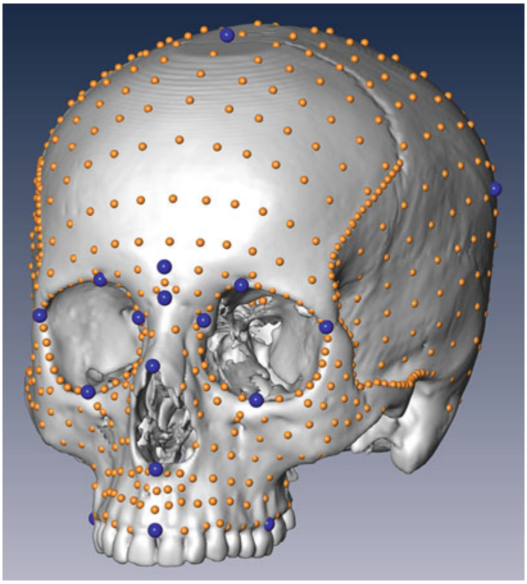

Fig. 3 Rendered 3D model of human cranium with 25 classical landmarks (biologically homologous measuring points) as dark spheres and 824 semilandmarks (geometrically homologous measuring points) as bright spheres. Almost the complete geometry of the cranium can be captured with this method

visualization not only of single forms but also of comparisons via the deformation grids that illustrate and formalize shape differences between geometrical objects. Moreover, the way data are represented allows the scientist to compute means and variances of groups at the same time that differences between two specimens or mean configurations are visualized as deformation grids. Importantly, size can be kept in or otherwise be eliminated from the analysis (the message to remember is *form is shape and size*).

Classic landmarks have a long tradition in anthropology (for a comprehensive list see, e.g., Martin 1914), but they are rare on many structures, for instance, on the braincase, where obviously whole regions on the frontal, parietal, occipital, and temporal bone offer no landmarks. The same problem applies to many other structures, also in the viscerocranium, on most of the postcranial skeleton, on the teeth, and of course on the face and body of living humans. The GM machinery allows identifying the so-called semilandmarks on curves and surfaces. These points are geometrically homologous (Bookstein 1989; Gunz et al. 2005) and can capture previously unattended regions. The 3D model of the human cranium provided here (Fig. 3) shows 25 classic landmarks like those that are usually applied to “caliper” studies and 824 semilandmarks on curves (temporal line, zygomatic arch, orbita, alveolar rim of the maxilla) and surfaces that capture previously unattended regions. The semilandmark approach obviously considers more information and thus can support more sophisticated statements about shape and form differences between groups or individuals. However, these semilandmarks cannot be identified in the physical world, rather they have to be constructed following certain principals that can only be followed in the virtual world. In practice, semilandmarks (sLM) are identified on one template specimen (any from the sample to start with) and then projected to the other specimens in the sample. After this step, they need to be "slid" (curve sLM have 1° of freedom, surface sLM have 2° of freedom, free points have 3° of freedom). Semilandmarks are matched between specimens under control of some global energy term, such as the bending energy of the thin plate spline. After this first round, the template specimen is replaced by the new Procrustes average configuration, and the process repeated until no changes appear. The number of semilandmarks needs to be sufficient to capture the spatial nature of variation or covariation that will emerge from multivariate analysis of these shape coordinates (Weber and Bookstein 2011a).

What works well with skulls and bones also works with stones and artifacts, soft tissues, or even cars. Particularly, the last years have seen the applications of geometric morphometrics in the context of quantitative analysis of lithic assemblages, for instance, using landmark/semilandmark approaches (Lycett et al. 2010; Archer and Braun 2010; Buchanan and Collard 2010) or surface areas (Lin et al. 2010). GM is widely used to characterize facial shape and its asymmetries and relations to other tissues (e.g., Fink et al. 2005; Bugaighis et al. 2010; Pflüger et al. 2012; Meindl et al. 2012; Kustár et al. 2013), and even the shape of "car faces" was associated with trait attribution (Windhager et al. 2012).

The common problem of all these applications of GM is that they need a fairly rich theoretical background before they can be used properly and that programming knowledge is often necessary to translate theory into results. In the early 2000s, mathematical packages such as Mathematica™ (Wolfram Research) or Matlab™ (MathWorks) had to be used to write routines that perform generalized procrustes analysis or thin plate spline warping. Not every good biologist is necessarily a good programmer, thus the application of GM often stranded for practical reasons. While the *development* of new algorithms inevitably needs the interdisciplinary action (a core domain of VA) between biologists, mathematicians/statisticians, and software engineers, the *application* of established procedures became meanwhile easier with some software solutions that did not reach the standard of commercial products but are "usable for the accustomed user." Morphologika (https://sites.google.com/site/hymsfme/downloadmorphologica) was one of the first such solutions that could process 2D and 3D data and handle GPA, PCA, regression, and warping. Morpheus (http://www.morphometrics.org/) by Dennis Slice, Viewbox (http://www.dhal.com/viewboxindex.htm) by Demetrios Halazonetis, the suite of tps programs (http://life.bio.sunysb.edu/ee/rohlf/software.html) by James Rohlf, and edgewarp (http://brainmap.stat.washington.edu/edgewarp/, restricted to Linux) by Bill Green offer access to some or almost all GM routines to a varying degree. In an attempt to spread knowledge among young European scientists and to establish VA-related infrastructure, the EU-funded project EVAN (European Virtual Anthropology Network) has developed and released the EVAN Toolbox (ET; http://www.evan-society.org/node/23, Fig. 4). Beside for research purposes, ET has turned out to be a fairly good teaching tool so that the issues of GPA, PCA, TPS, group mean comparisons, regression, reflected relabeling, or the analysis of asymmetry (Mardia et al. 2000) lose some of their frightening flavor during practical application with real data. Programming is not necessary because all operations can

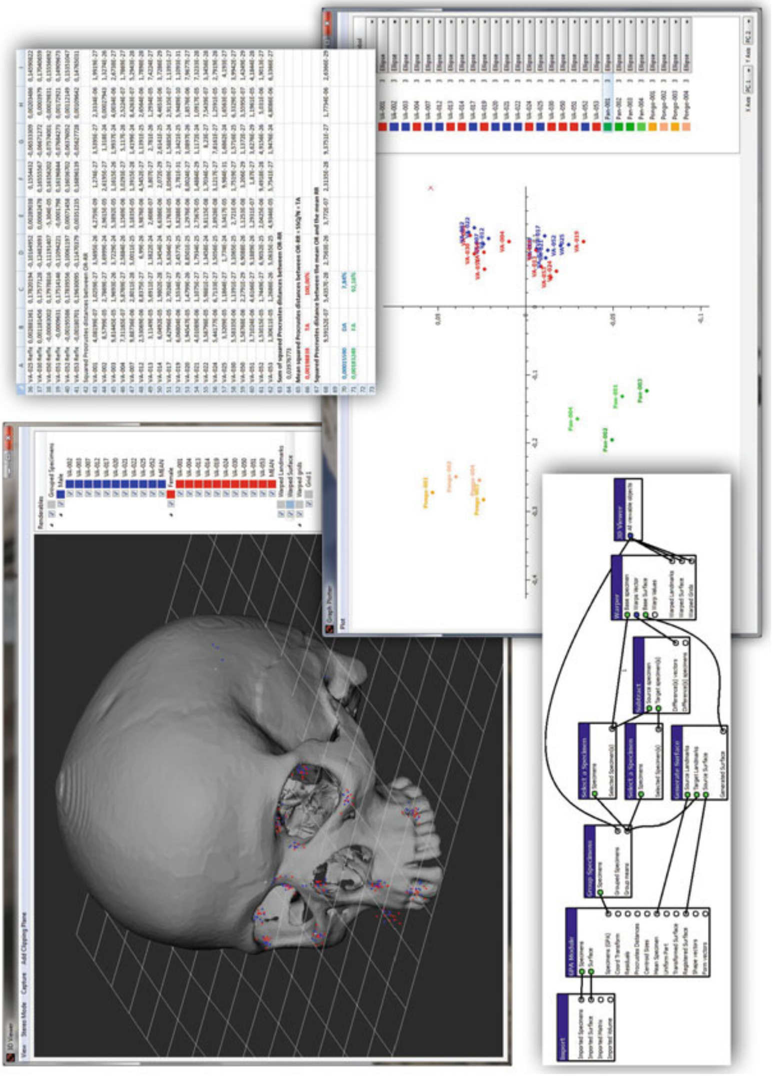

Fig. 4 Screenshots of the EVAN Toolbox. Mean shapes can be warped between sexes (*top left*); Procrustes distances are exported into a spreadsheet for further computation (*top right*); principal component analysis of shape for modern humans, chimps, and orangutans is shown for the first two relative warps (*bottom right*); a typical visual programming network to operate analyses (*bottom left*)

be put together in visual programming networks, just as modules that are connected by lines.

Independent of which software and methodological approach is used, it seems most important for advances in quantitative morphology to train young people on a broad scale to use these techniques of the twenty-first century.

Reconstruct

Reconstruction in virtual anthropology refers to the form and shape of biological objects, while in archaeology it refers to the form and shape of artifacts or buildings. Whenever the present form of an object fails to correspond with its supposed original form, reconstruction might be needed. Taphonomic processes, but also damage during excavation or manipulation, can lead to four principal kinds of disturbances of a form (Weber and Bookstein 2011a). All of these apply similarly to archaeological objects:

1. An object can be broken, but (almost) all pieces are preserved. This is called a *type 1* disturbance, e.g., a broken cranium, even if it consists of many pieces, which can be fully restored using glue.
2. Whenever parts of an objects are missing, it is called a *type 2* disturbance, e.g., a humerus that is basically intact but missing its head.
3. An object can be deformed. That is a *type 3* disturbance, e.g., a fossilized pelvis that shows plastic deformations due to million-year-long pressure of the overlaying rocks.
4. An object can be intact but not be directly accessible because it is covered by a foreign material. This *type 4* disturbance was mentioned above in the context of electronic preparation, e.g., a finger bone that is embedded in calcareous sands.

Of course, all kinds of combinations of these disturbances may exist, and in fact, we rarely find one alone (e.g., there is often broken & missing, broken & covered, missing & deformed & covered, etc.). We speak of reconstruction when a disturbance has been recognized and corrected (Weber and Bookstein 2011a). The types of disturbances introduced above help thinking about the varieties of reconstruction problems that one will face during the process. Single types 1 and 4 problems can have unique solutions, at least in principle (there are only very limited degrees of freedom to put together a complete 3D puzzle, and e-preparation can eliminate matrix in many cases entirely). For most type 2 problems, there is no unique solution, and the same is true for type 3 problems (except for those where the deformation forces are known or one half of a symmetric structure is unaffected and can be mirrored). This is because the form of missing or deformed parts has to be estimated which involves data about undisturbed forms of the same group of objects and assumptions.

A reconstruction can therefore never duplicate the original. It can approximate it. The role of VA in reconstruction is to make the various manipulations reproducible, ergo to involve numbers in the process as far as possible. Biological forms follow constraints, for instance, laws of physics such as gravity, material strength, and load; they respond to the mechanisms of evolution such as the selection of environmentally favorable traits, and anatomical modules develop in concert (integration). The numerous genetic, developmental, and functional factors applying to the form of biological objects enable us to reduce the "degrees of freedom," the uncertainties, for a reconstruction. However, there is also a lot of interindividual variation in a group, another principle of evolution. For instance, the form of an upper jaw (maxilla) is of course known in principle for modern humans, but each human has a slightly different form which is determined by genetic and environmental factors. Bone remodeling happens during the whole life. A maxilla's form is depending on the inherited skull form, the individual loadings (related to muscles and diet), the preservation and position of teeth (e.g., some might be lost, some inclined forward or backward), or other behavioral aspects (e.g., teeth might be used as tool or clenched during the night). In biology, we can thus reconstruct most parts only based on a reference data set (a sample of similar organisms) and with a particular likelihood. In contrast, if a portion of a ceramic vase is missing, it could be relatively easy to recreate its initial form because it would follow a pretty strict rule of a smooth surface (especially if done with a potter's wheel). With fossils, it becomes actually more difficult because the reference sample might be small or even absent. In those cases, reconstruction resorts to the closest sample available – a compromise.

The advantage of using VA in reconstruction is that reference data and assumptions have to be made explicit. There is no mumbo jumbo of the expert who pulls out a reconstruction of the hat like a rabbit. Everything is based on measurements and explicit statements can be made, e.g., which kind of reference data was used or which geometric constraint (e.g., bilateral symmetry) was applied. In lucky cases, the task may boil down to limit the 6° of freedom (three to translate, three to rotate) to possibly zero when putting pieces together or to apply a priori knowledge about the form (e.g., smoothness of curvature, radial or bilateral symmetry) during estimation of missing parts.

In opposite to a physical reconstruction, a virtual one is not depending on sources of irritation such as gravity, glue, or having only one trial. This is one of the reasons why they appeared already very early in the history of VA (Kalvin et al. 1995; Zollikofer et al. 1995; Thompson and Illerhaus 1998). Absolute control over fragment translations and rotations can be achieved with many software packages, particularly in the CAD (computer aided design) domain, that also support the process with aiding constructions such as B-splines or NURBS (non-uniform rational B-splines). Aside from a highly controlled merging of pieces on the screen (already an important improvement) and including occasionally mirroring of pieces, as we see it frequently in *anatomical* reconstructions (Zollikofer et al. 2005; Ryan et al. 2008), some other technology introduced under "compare" can be used for estimating missing or deformed parts (i.e., types 2 and 3 problems).

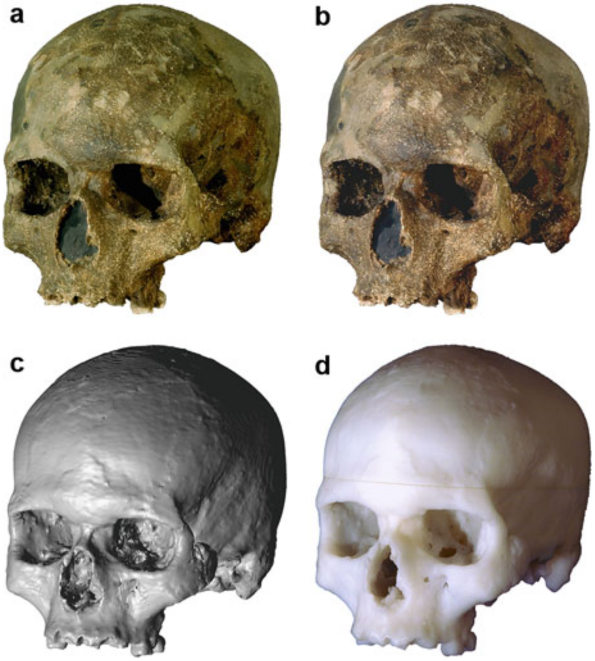
Thin plate spline interpolation (Neubauer et al. 2004; Gunz et al. 2009b; Grine et al. 2010; Weber and Bookstein 2011a; Senck et al. 2013) can be applied for *geometric* reconstruction. It uses a map of landmarks and semilandmarks from a complete specimen (the “reference”) and whatever is left on the specimen to be reconstructed (the “target”). It is a deformation of the reference that is computed to match the location of the corresponding points on the target while filling in the rest of the information. Noteworthy, this is not a simple “copy and paste” action, rather it takes the preserved morphology of the target into account and adapts the missing parts, which are filled in from the template. Applications range from fossil reconstructions (Gunz et al. 2009b; Benazzi et al. 2011a, 2013a) to the preoperative implant planning for large skull defects (Heuzé et al. 2008). There is, however, a caveat of TPS-based reconstruction: it should not be used when it is an extrapolation – when the region being reconstructed extends substantially beyond the limits of the region present in the target (i.e., do not reconstruct the face if just the braincase is preserved). Nevertheless, it works particularly well to reconstruct smooth surfaces, such as the neurocranium, when coordinate-based landmarks and semilandmarks are sampled densely. Alternatively, a reference database can be used to drive reconstructions via multivariate regressions, which rely on the covariation among the observable coordinates (Gunz et al. 2009b; cf. Neeser et al. 2009). However, the sample has to be sufficiently large to increase the certainty of estimates – a demand that is rarely met in paleoanthropology. TPS in contrast just needs one reference specimen but the result is entirely depending on it. Whenever more than one reference specimen is available, multiple reconstructions can be computed to assess their range of possible variation (Gunz et al. 2009b; Benazzi et al. 2011a; Weber and Bookstein 2011a) or the sample average can be computed and used for the TPS warping (Senck et al. 2013).

In a science that is highly depending on reconstructed forms on the one hand (be it for morphological comparison or just for museum display) but which has only a few intact templates to offer on the other, we naturally have to make compromises. In some cases, even a composite fossil (Kalvin et al. 1995) might be a solution to make a further step in a heuristic process. Strait et al. (2009), for instance, have used a fairly complete but edentulous cranium of *Australopithecus africanus* (Sts 5) and a fairly complete dentition of another member of this taxon (Sts 52) to be able to simulate loadings on the cranium during different modes of bite. Though both specimens were in a similar dental stage and the preserved tooth roots of Sts 5 were matched with the teeth of Sts 52, the reconstruction would certainly deviate within limits from the original appearance of Sts 5 in its lifetime. However, these deviations could be regarded small enough to be accepted in a situation where a more persuasive solution is impossible (at least until a complete and undeformed cranium with dentition is unearthed and accessible).

Materialize

There are *two* sources for appraising morphology in classical anthropology, original specimens and their casts, and there are *two* in virtual anthropology, digital copies on the screen and rapid prototyping models deriving from these copies (Fig. 5).

Fig. 5 The Upper Paleolithic cranium of Mladeč 1 as (**a**) original, (**b**) traditional cast, (**c**) virtual specimen on the computer screen, and (**d**) rapid prototyping model (With permission of the Natural History Museum Vienna)



For teaching and training purposes, as well as for permanent museum display, real models can be more desirable media to create knowledge than virtual ones. In any case they are essential when there is no computer available. But also for the researcher, real models provide a substantial aid to understand three-dimensional relationships of spatially complex structures. Architects are certainly among the best trained people with regard to spatial imagination, but in practice many of them still build real models of constructions to appraise complex interactions of structures. There is a German word called "begreifen" which not by accident means both "to touch" and "to understand."

Rapid prototyping (RP) technology was realized in the 1980s to facilitate quick and relatively cheap manufacturing of industrial prototypes. The idea is to have something real in hand that was initially created in a computer environment, a newly designed telephone before mass production, an implant to train with before surgery, a downscaled model of an airplane to be tested in the wind tunnel, and the like. The principle behind all kinds of different RP techniques out there is to build an object layer by layer with small elements. This is actually a very ancient idea looking at the Great Pyramids of Giza that are constructed the same way, layers of stones over layers of stones. The great advantage of the relatively slow layer-wise approach is that even hollow spaces and undercuts can be built which is not possible with other techniques, e.g., with CNC (computer numerical control) machinery.

Stereolithography (STL) was one of the first and still is one of the most advanced procedures which allow producing accurate models down to a resolution of ~0.1 mm.

The STL data generated during preparation derive from 3D volume or surface data, e.g., CT or surface scans, or constructed surfaces like CAD objects, or a reconstructed fossil. They serve to control a mobile mirror that directs an ultraviolet (UV) laser beam in accordance with the layer geometry. Where the UV laser beam comes into contact with a photosensitive liquid acrylate or epoxide resin, it hardens. Then the part is lowered deeper – by the thickness of one layer – into the liquid polymer bath. The surface must be leveled initially by a recoating system and then the next layer is hardened. This process continues automatically until the production of the 3D part has been completed. Supporting constructions permit the fabrication of "overhanging" parts that would otherwise float away before they are connected to the structures above.

Other methods use powders rather than liquids (e.g., Z-printing, laser sintering) or meltable plastics (e.g., fused deposition modeling) applied through heating nozzles, comparable to what a printer does with ink. There can be huge differences in the price, the speed, and in the quality of models (see Weber and Bookstein 2011a for an overview). A decision with regard to the planned application is thus needed – cheap, accurate, enduring, fast, transparent, and multicolor are some of the options to be considered.

Whatever the choice of method is, any type of RP model has some advantages over casts in the following respects:

1. There is no mold that is aging (of course the model itself will age, but it can be reproduced to 100 %), only the digital data has to be kept save.
2. There is no contact to the original object, only contactless scanning is required, a big issue in many cases of fragile and brittle specimens with porous surfaces.
3. Most biological objects feature hollow structures and undercuts which are no problem to be realized with RP. To access them, models can be built as separate parts, e.g., a skull with removable calotte to enable inspection of the cranial cavity.
4. Models can be up- or downscaled (e.g., 25 %-sized "pocket replicas" of skulls or a 400 %-sized model of trabeculi in a cut of the femoral neck).

Of course, there are drawbacks of RP procedures as well: Some of them are rather expensive (a stereolithography of a skull can cost more than € 1,000). However, there is a growing market of desktop 3D printers that permit production of models in a very low price range (some machines are cheaper than a STL model). The other important drawback is the limited resolution of RP models, somewhere in the 100 μm range. It depends on the incoming data, which in the case of medical CT is even lower (typically 200–500 μm), and the characteristics of the RP procedure itself. On account of their layered structure, the aliasing effect (jagged surface) of all RP models can be recognized – a smooth surface can be achieved only by intensive reworking. Recent developments can improve resolution considerably by a combination of micro-computed tomography and micro-stereolithography. The size of objects is limited, but a layer thickness of less than 25 μm is possible. A first application to a fossil object (lower molar of an *Australopithecus afarensis*) is described in Weber and Bookstein (2011a, p. 321).

The usefulness of rapid prototyping models has been amply argued over the years. The first stereolithographic model in anthropology was by the way done on the Tyrolean Iceman "Ötzi" to get access to the skull of the precious mummy (Seidler et al. 1992; zur Nedden et al. 1994). The full potential for anthropological application turned out soon thereafter (e.g., Hjalgrim et al. 1995; Zollikofer et al. 1995; Seidler et al. 1997; Recheis et al. 1999; Ponce de León and Zollikofer 1999; Weber et al. 2001; Kimbel et al. 2004). In the medical field, RP models are used as well since the early 1990s, particularly for implant planning (e.g., Klein et al. 1992; Anderl et al. 1994; Yau et al. 1995). There is thus a considerable overlap in techniques used in paleoanthropology and surgery planning, which opens possibilities for collaborations and jobs for (paleo)anthropologists.

Share

Speaking of collaboration, most contemporaries have recognized that scientific progress can be advanced by sharing methods and data resources. Studying biological and evolutionary questions, it is of the essence to talk about intragroup and between-group variation. There is one very simple guideline coming from statistics: The larger the samples are the sharper is our picture with regard to variation and differences. With the introduction of the Internet, some sciences saw a progressively increasing behavior of sharing information. Open access journals are meanwhile widespread, and data archives were and are created in any field of research. Probably the most consequent application is found in genetics, where the human sequences and meta-information are published as a matter of course (e.g., http://www.ncbi.nlm.nih.gov/gene, http://www.genecards.org/). Paleoanthropology, however, is a field where the idea of sharing data for the sake of creating knowledge is still not pervasively accepted. The first electronic archive of hominin fossils was created in 1999 (http://www.virtual-anthropology.com/3d_data/3d-archive), and the idea of an opening – "glasnost in paleoanthropology" – was expressed soon after the Millennium (Weber 2001). The paleo community saw reviews and conferences on the topic (Gibbons 2002; Soares 2003; Delson et al. 2007; Kullmer 2008; Mafart 2008), and some further archives were established (e.g., NESPOS, EVAN-Society, ORSA, DigiMorph, Paleoanthportal, RHOI, AHOB, Visible Human Server). However, researchers and curators remained reluctant (Weber and Bookstein 2011b). The digital@rchive of fossil hominoids is still the largest database providing access to a significant number of very important hominin fossils without restrictions.

Beyond doubt, there are a lot of difficult questions involved in this problem, for instance, how to protect the legitimate interests of the discoverers who often invested considerable amounts of time and money, in some cases even risking their life in the field, to make their findings. How should large funding agencies and journals act to enforce publication of data, rules that are somewhere hidden in the fine print? It seems reasonable to allocate sufficient time for the discoverers to work on their specimens. Yet, there are large numbers of fossils that are not accessible, even decades after their discovery. As mentioned at the beginning, it is a quite essential claim in science that results can be checked by others, particularly if a new taxon is described and established. As a consequence, there is thus a reasonable demand that at least electronic data from specimens should be accessible after a publication, or, if nothing is published, after a certain number of years.

Gene sequences of humans are accessible because they represent our common evolutionary heritage and an important resource to gain further knowledge for the benefit of all. When a fossil is discovered, it is usually owned by the country from which it originates. The fossil is then carefully stored in a national institution such as a natural history museum and administered by the local curator who acts as the representative of the owner (which is the country but not the curator). Although it is alright that the country has this exclusive control over its property, there is another obligation associated with the curation – to grant access to all researchers who have a reasonable research question and the capacity to answer it. A hominin fossil contains data about our common evolutionary heritage, as well as genes do. Restriction of access to data cannot be found on the list of privileges associated with ownership. In other words, fossils may be owned, but they may not be copyrighted.

Data itself can have diverse characteristics which are associated to the mode of measurement and to the user's context. It is necessary to reflect these qualities of data because they are relevant for access policies and structuring data archives. For instance, when a data archive is to be established for paleoanthropological purposes, a number of researchers will probably be interested in data from hominids, e.g., a CT scan of an *Australopithecus* skull or a chimpanzee thigh bone. These data can be called "source data" because they were mainly acquired by a machine (e.g., CT, μ-CT, surface scanner) and are thus much less biased by any intellectual treatment of colleagues than another kind of data that can be called "derived data." The latter would be, for instance, coordinate measurements of landmarks or a virtual reconstruction because these tasks involve an observer's perception and include individual interpretation. It is a fundamental issue for access rights on the one hand and for further application of data on the other to be aware of this history. An anthropologist will ultimately also want to make use of the geochronologists', paleontologists', or pathologists' data archives in order to acquire another sort of data, "contextual data" pertaining to the specimen under examination. Electronic archives have to be structured according to these needs.

In the first place, clear access policies are necessary; it is secondary what they actually are. A minimum standard could be that museums and other organizations accommodating valuable material in their collections make accessible list of specimens and statements as regards curation and access policies. A recently upcoming attitude of a "data embargo" continuing over many years after fossils have been scanned by some researchers should also be condemned because it does not lead to an opening and the protection of specimens but just to other data syndicates preventing access and to the desire for re-scanning.

Biomechanical Analysis of Biological Objects

The mechanics of organismal structures can be studied in various ways, including physical and mathematical models (Demes and Creel 1988; Spencer and Demes 1993), in vivo and in vitro experimentation (Hylander 1979; Ravosa et al. 2000; Daegling and Hotzman 2003; Wang and Dechow 2006), and, since the availability of adequate computer technology, computer-based simulations (Sellers and Crompton 2004; Koolstra and Van Eijden 2005; Rayfield 2005; Ross 2005; Dumont et al. 2009; Strait et al. 2009, 2010, 2013; Kupczik et al. 2009; Wroe et al. 2010; Benazzi et al. 2011b; Gröning et al. 2011; O'Higgins et al. 2012). One approach to study how mechanical systems such as the musculoskeletal apparatus move under the influence of forces is Multibody Dynamics Analysis (Curtis et al. 2008, 2013; Fitton et al. 2012; O'Higgins et al. 2012). Finite element analysis (FEA), another engineering technique, has been particularly widely applied in clinical and evolutionary biomechanics because it allows exploring how objects of complex geometries respond to external loads. It has thus the potential to test biomechanical hypotheses in functional morphology. Models are created by capturing the geometry (obviously one of the major inputs and an important link to VA), assigning material properties, specifying simulated forces, and imposing constraints. Models have to be validated, comparing results with in vivo or in vitro experimental data, and can be altered to examine the consequences of changes to input parameters. The output of FEA is quantitative too and mostly relates to stress, which is a measure of the amount of force per unit area; to strain, which is a measure of deformation representing the relative displacement between units in the material body; and to strain energy, which is the net potential energy stored in a solid that has been deformed by forces.

FEA is a deterministic process, i.e., the outputs of two simulations using different parameters (varying geometry, material properties, force, constraints) will always lead to different results. The problem with FEA is that there is no method to compare them in a statistical sense, e.g., how different are the results between two group average models compared to within group variation? As discussed above, geometric morphometrics can deliver a group mean configuration or a warped intermediate geometry. It can also inform about shape and form variation within groups or between groups and it can provide reconstructed input forms for biomechanics in a more reproducible way than traditional procedures can do. Nevertheless, whatever the inputs of FEA are, the outputs are most often colored images (Fig. 6) that can just be compared visually. While one observer might interpret the differences in stress and strain between models as being "almost similar," another might exclaim how different they are. The discrepancy between the mathematical physics of elastic theory, essential for mechanics, and the quite different mathematics used in shape analysis – respectively a missing mathematical bridge between them – is a major problem in biomechanical analysis of biological forms (Weber et al. 2011). A theoretical solution was published recently (Bookstein 2012), but has not yet been tested with real data. Other attempts were undertaken to make FEA results comparable between specimens and groups. However, strain

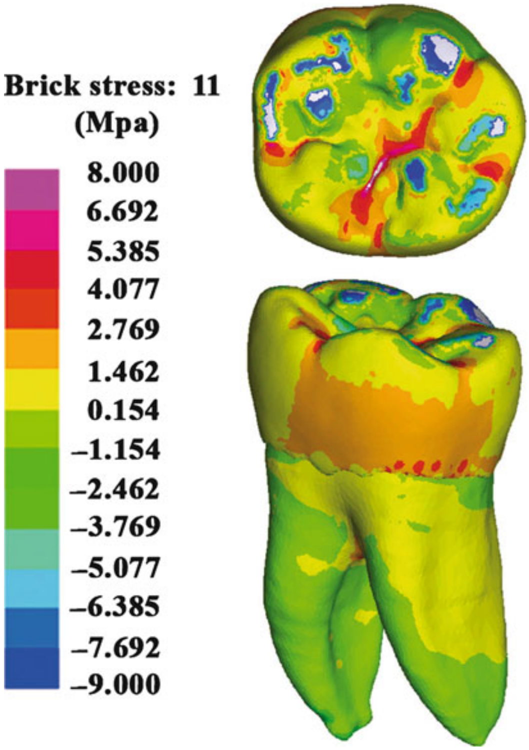


Fig. 6 Maximum principal stress distribution observed in FEA when a human molar is loaded onto occlusal contact areas (maximum intercuspation) detected by the occlusal fingerprint analysis. First row, occlusal view; second row, distolingual view. Note the high tensile stresses along the fissures (*dark areas*) (From Benazzi et al. 2011b)

frequency plots, e.g., used in a recent publication (Parr et al. 2012), cannot relate strains to the actual location (instead they just provide a summed picture of appearing strains), and landmark point strains cannot be based on semilandmarks for the mentioned mathematically incompatible differential equations. Others (Strait et al. 2009; O'Higgins et al. 2010; Wroe et al. 2010; Cox et al. 2011; Gröning et al. 2011) relied on visual comparisons between strain plots, or have tried to infer the mean of, e.g., appearing maximum and minimum principal strains, or invoked profiles along a structure of such. However, these measures only provide very scant pictures of the whole structure or sometimes involve subjective judgments. Displacement plots (O'Higgins et al. 2010; Gröning et al. 2011) again only carry information on the direction of displacements but cannot inform about the quantity of work to impose particular simulated strains.

Despite the still absent formalism to join geometry and biomechanics effectively, it can still be a step forward to simulate stresses and strains in a form. The loadings appearing on human teeth during chewing are, for instance, not well known. Recent studies (Benazzi et al. 2011b, 2013b) combining FEA and occlusal fingerprint analysis (a technique to determine actual movements from wear signals of the teeth, Kullmer et al. 2009) could show that high tensile stresses appear particularly along the fissures of the occlusal surface when realistic loading scenarios were applied (Fig. 6). Even if no big samples can be statistically compared so far, the simulations reveal important aspects that have not been considered yet, e.g., the mechanical consequences of filling fissures for protection against caries, a common dental practice. Other studies showed that the pattern of strain distribution during biting could be relatively conservative within species, regardless the actual magnitudes (Smith et al. 2014), or that certain facial geometries are not well adapted to produce high bite forces due to occurring distractive joint reaction forces (Ledogar et al. 2014). In many of those biomechanical studies, VA methods are a vital component, e.g., to virtually reconstruct a fossil form prior to FE model creation or to determine a limited set of extreme group forms to be modeled then in the FE process. Biomechanics is not part of VA but the cross-fertilizations are manifold, and innovations resulting from this combination are considerable.

Conclusion: Virtual Functional Morphology

Morphology deals with the study of shape and form of organisms and their parts. Functional morphology is the study of the relationship between the structure and the function of an organism's parts. Functional morphology is concerned with explaining how body structures such as bones, teeth, muscles, or tendons relate to different behaviors, including locomotion, feeding, defense, and reproduction. It integrates concepts from anatomy, mechanics, evolution, and development. The idea of "form follows function" in biology is an old one, for instance, expressed by Georges Cuvier (1769–1832) in his "conditions d'existence" (roughly speaking, Cuvier argued that all organismal parts that we see are already optimized toward their functional demands, otherwise the animal would not subsist). Although we have learned in the meantime that shape and form may deviate from this strong canon (genetics and theory of evolution had not been discovered at Cuvier's time), we recognize the importance of the relationship between form and function. Functional morphology is thus a fundamental approach to studying biology on a macro-level with the goal of understanding how shape and size might affect function or what the function of a structure might be at all (Rohen 2007; Lucas 2004). Such knowledge is important for developing an integrated view on biological form in the light of its function and, last but not least, it is essential to relate the phenotype with the genotype.

If we just look at the masticatory apparatus, which is certainly a key to studies in hominin evolution, the kind of unresolved fundamental questions in biology and medicine that touch closely paleoanthropology are, for instance:

- How does *variation* of skull shape relate to *variation* of mechanical loadings? At this point, we have no good data whether there is a tight relationship or not. We also do not know how the entity of a skull might compensate in one part for deficiencies in another.
- How far can geometry deviate from the mean shape to meet a given functional demand? The surviving members of a taxon were all successful despite their individual shape variation. How would a chimp, or australopithecine, or

Neanderthal, or modern human with a shape outside the 99 % sample confidence interval cope with default mechanical stresses?

- Which particular feeding behavior (which is strongly related to ecology) would make the skull shape unsuccessful? Can we predict a skull shape that would fail – given a certain behavior?
- How do the shape and mechanics of the teeth (e.g., relative cusp size, cusp relief) relate to the biomechanics of the entire skull? Can we describe patterns that make particular configurations (e.g., larger/smaller teeth, flat/high relief, protruding/retracted faces) more favorable combinations?
- What were the biomechanical consequences of the evolutionary form changes of the human skull, e.g., when jaws became smaller, the braincase grew bigger, and cranial base flexion increased?
- Depending on the result of the former question, what then could have been the feeding strategies that favored those changes, and how do they fit to what we know about related paleoecology?

We have still great difficulties to understand our evolutionary adaptations, and we do not base the treatment of patients on thorough knowledge of function in dependence of form in the field of dentistry, orthodontics, or craniofacial surgery. However, a growing number of publications are documenting a substantial progress in the development of methods, software packages, computer power, and awareness of the technologies for each field separately. Many pieces of the puzzle are already there since Schmerling discovered Engis and Darwin put evolutionary theory in place. A "virtual functional morphology" that integrates shape and form analysis with biomechanics and also considers developmental pathways controlled by genes is the next step forward for systems biology and evolutionary sciences.

Paleopathology: Vestiges of Pathological Conditions in Fossil Human Bone

Michael Schultz and Tyede H. Schmidt-Schultz

Contents

Abstract

The methods and techniques of paleopathology are briefly described. Up to now, paleopathology has not really played a role in the field of paleoanthropology, although this relatively new science can contribute valuable facts to the reconstruction of the life of fossil humans and their antecessors. Examining the vestiges of pathological processes, the paleopathologist can reconstruct, within certain limits, the diseases early man suffered from (e.g., inflammatory and tumorous diseases) and even the hard living conditions, particularly the physical strain of everyday life. We might be able to gain substantial information about the musculoskeletal system, involved, for instance, in locomotion and work as well as some clues about possible social behavior and care (e.g., of an injured or disabled member of the social group). Not only the vestiges of pathological

processes provide indications of how early man endured his hostile environment but also how the outcome of physical strain of everyday life can partially be reconstructed from the results of the study of the functional morphology. Therefore, selected results of a paleopathological analysis illustrating future prospects are discussed.

Introduction

Paleopathology is a research field closely related to bioarchaeology and is interdisciplinary between medicine, physical anthropology, and archaeology. This innovative scientific discipline deals with the investigation of past diseases. The wide scope of bioarchaeology which is also an interdisciplinary research field and has recently been outlined for the Anglo-Saxon World by Jane Buikstra and Lane Beck (Buikstra and Beck 2006) also suggests certain procedural methods for the future of paleoanthropology. Archaeological human skeletal remains, mummies, bog bodies, and fossil human bones are examined both with scientific and with medical methods. Human fossil remains can also be regarded as bio-historical documents because they report on the everyday life, afflictions, and illness occurring at the dawning of mankind when no written records were available. Similar to written records, fossils "can be read" in the same way that archaeological skeletal and mummified remains of peoples of the past can be. In certain cases, the biography of an individual who lived thousands of years ago can be written, of course with some limitations. In this regard, the research of a paleopathologist resembles the efforts made by forensic medical people. Frequently, according to the results of a paleopathological investigation, it is possible to reconstruct not only the health status of a past population and the nature of diseases from which they suffered but also nutrition, housing and working conditions, and geographic and climatic as well as hygienic and sanitary factors. Thus, to a certain extent, it is possible to reconstruct living conditions of human antecessors.

To date, paleopathological investigations have rarely been carried out on fossilized specimens, although this kind of research is very promising because such examinations of prehistoric and early historical skeletal remains provide highly interesting results. Therefore, this short article suggests routine inclusion of paleopathology in paleoanthropological research.

Methods and Techniques Applied in Paleopathological Investigations of Fossils

Ideally, a paleopathological investigation on fossilized remains requires distinct macroscopic and microscopic methods to establish a reliable diagnosis. All surfaces of a find have to be inspected macroscopically. The examination with the naked eye should be supported by a magnifying glass or by a low-power light microscope. To date, most human fossils investigated have been studied macroscopically (e.g., Trinkaus 1983).

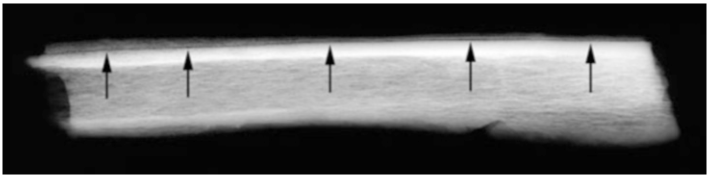

Fig. 1 Paleolithic male from Brno (Brno II). X-ray image of right ulna (anterior-posterior path of rays). Small gap (*arrows*) between the apposition and the original compact bone substance of the shaft (periostitis)

The use of a technical endoscope provides an informative basis for additional research and leads to a better understanding of morphological formations which cannot be observed by the macroscopic inspection alone. If no endoscope is available, vestiges of an inflammatory process inside the maxillary sinus can only be evaluated if a wall of the sinus is extensively broken or missing. Furthermore, an endoscopic view frequently allows a more detailed interpretation of a morphological feature because this instrument provides not only a better accessibility to a narrow space but also magnifies the feature up to 50 fold.

Conventional X-ray investigations, computerized tomography (CT), and micro-CT can add substantial information for a reliable diagnosis in paleopathology (e.g., Chhem and Brothwell 2008). Although several researchers believe that micro-CT is a noninvasive investigation, it is, indeed, only a less-invasive technique (e.g., Kuhn et al. 2007; Rühli et al. 2007). Of course, the sample investigated will not be damaged at the virtual cutting plane; however, for this analysis, it is necessary to previously remove a sample of the bone because the chambers of modern micro-CT machines are too small to hold a bone longer than a few centimeters. Therefore, micro-CT cannot be used in every fossil bone, although a true-to-life cast or a plaster complement would compensate for the loss of such a small piece of bone (cf. Schultz and Schmidt-Schultz 2014). Interpreting conventional X-ray images of fossil bones, researchers should not expect too much from such images. Postmortem loss of bone substance and secondary washing in of soil particles by water (diagenesis) might change the original bone substance such that in an X-ray image, there seem to be intra vitam changes due to disease. Furthermore, an X-ray image presenting a porotic appearance of a compact or cortical bone fragment does not allow us to diagnose, for instance, whether the bone had been affected by an inflammatory or a diagenetic process. Also osteoclastic destruction at the microlevel might not be visible in a conventional X-ray image which might lead to a false diagnosis. As an example, the Paleolithic case of the "Fossil Man from Brno II" can be mentioned. In this relatively well-preserved skeleton, among other findings, a slightly porotic bone apposition is visible on the shaft fragment of the right ulna (Schultz and Nováček 2005). There is a very small gap between the apposition and the original compact bone substance of the shaft which appears not to be affected by an osteoclastic process (Fig. 1). However, the subsequently conducted microscopic investigation of this ulna showed that the compact bone had already been destroyed intra vitam by osteoclastic resorption. This example demonstrates the shortcomings of a disease diagnosis in fossil bones using only macroscopic and radiological techniques. Another case deals with the macroscopically and radiologically (CT) established diagnosis of probable chronic anemia in the archaic *Homo sapiens* cranium KNM-ES 11693 from Eliye Springs at Lake Turkana, Kenya (Bräuer et al. 2003). Here, the nature and the location of the enormous thickening of the skull vault and the porotic structure of its external surface are typical morphological features probably characteristic of healed chronic anemia (e.g., Aufderheide and Rodríguez-Martín 1998; Ortner 2003; Steinbock 1976). Without microscopic examination, a more detailed diagnosis is not possible.

Scanning-electron microscopy and, particularly, light microscopy are useful tools for the examination of fossil bone at the microlevel (cf. Schultz 1999; Schultz and Schmidt-Schultz 2014).

Additionally, physical, molecular, and biochemical methods and techniques can successfully be carried out in paleoanthropology to diagnose diseases (cf. Schmidt-Schultz and Schultz 2014). However, to date, this research field is just getting started.

Elements of Paleopathology in Paleoanthropology

As mentioned above, in the study of human skeletal remains, various processes and activities which influenced this individual in the course of his life and provoked characteristic vestiges on bone surfaces can be detected and investigated. These activities can include everyday accomplishments, such as household chores, occupation, sports and combat, however, in particular, also diseases which lower the quality of life and diminish any positive feeling toward life. The goal of a paleopathological investigation is to explore the nature (casuistics), the causes (etiology), the frequencies, and the spread of diseases (epidemiology) in the past. These aims can also be pursued in paleoanthropology, although, as a rule, the number of cases we can observe is limited. Innovative aspects are conclusions on basic social affiliation in human antecessors. When establishing a diagnosis, researchers might act with caution because, occasionally, pseudopathology might cause mistakes (e.g., Wells 1967). Due to advanced age, particularly in fossil bones, vestiges of postmortem destruction (e.g., diagenesis) might mimic products of pathological conditions.

First Descriptions of Vestiges of Disease in Human Fossils

One of the first researchers to study human fossils was the German anatomist Hermann Schaaffhausen. He recognized, in the skull of the Neanderthal from the Kleine Feldhofer Grotte, vestiges of traumatic origin (Schaaffhausen 1859, 1888), whereas Rudolf Virchow, the famous German pathologist who, unfortunately, misinterpreted the nature of this Neanderthal noted the fracture of the left arm (Virchow 1872).

Pioneering work in this field was also carried out, for instance, by Eugène Dubois (Dubois 1896) who, for the first time in a human fossil, described an eye-catching huge bone exostosis on the left femur of the *Homo erectus* ("*Pithecanthropus erectus*") from Trinil (Java). This exostosis originated after a severe traumatic distraction of the muscles and tendons (*Myositis ossificans*) in the medial region of the left thigh (e.g., adductor muscles). Roy L. Moodie, the leading pioneer in paleopathology before World War II, reported, in several articles (e.g., Moodie 1918) and in his very innovative book dealing with animal and human paleopathology (Moodie 1923), on cases, causes, and conditions of various diseases in subfossil and fossil bones.

Selected Examples of Pathological Cases Illustrating the Potential of Paleopathology in Paleoanthropology

Since the beginning of time, the biotope has played a major role in human life, not only for human antecessors but also for the modern humans of the Early Modern Times and, in some parts of the world, right up to today. Particularly, the provision of food has stood in the foreground of all activities, and therefore, hunting was once the most widespread occupation, particularly in the times of the Neanderthals. As large animals, such as mammoths and large ungulates were predominantly hunted, there was a high risk of injury (Berger and Trinkaus 1995). This might explain the nature and the frequency of fractures (Fig. 2) observed in the skeletons of Neanderthals (e.g., Schaaffhausen 1858; Schultz 2006; Berger and Trinkaus 1995). This risk led to the comparison drawn between the fracture pattern of Neanderthals and that of rodeo riders (Trinkaus 2012). However, we cannot neglect the possibility that also, probably additionally, interhuman violence took place and might have been responsible for such traumata (Churchill et al. 2009; Zollikofer et al. 2002). Typical examples for the latter assumption are the Neanderthal cases of Shanidar 3 (Churchill et al. 2009) and St. Césaire 1 (Zollikofer et al. 2002). The adult male from Shanidar 3 shows a puncture wound in the left ninth rib (Churchill et al. 2009). Here, a lithic point had perforated the bone. Probably, the weapon would have been an arrowpoint; however, also the lithic blade of a knife or a spear point cannot be excluded (Churchill et al. 2009). The second example, the young adult individual from St. Césaire dating back to 36,000 years ago, suffered from a skull injury caused by a sharp implement which healed leaving a bony scar (Zollikofer et al. 2002). These two cases demonstrate that the highly developed Mousterian weaponry was not only used for hunting but also for combat which is, probably, a characteristic human trait.

Indeed, in paleopathology, the nature, the location, and the pattern of injuries tell us much about the locomotion as well as about occupational stress. If an individual was badly injured or hurt in some other life-threatening way, the expectation would be that there was no chance to survive. However, some Neanderthals exhibit vestiges of very severe traumata which had healed and the individuals survived for many years, however, with marked disability (Fig. 2). Such cases were, for

Fig. 2 Left ulna of the male Neanderthal from the Kleine Feldhofer Grotte. Due to fracture, wrong position of olecranon, significantly reduced radial notch, and rotation of the distal part of the ulna shaft: (**a**) lateral view, (**b**) X-ray images, *1* medial-lateral path of rays, *2* anterior-posterior path of rays

instance, the Neanderthals from the Shanidar Cave in the Zagros Mountains, Iraq (Shanidar 1; Trinkaus and Timmerman 1982; Trinkaus 1983), and from the Kleine Feldhofer Grotte, Germany (Czarnetzki and Pusch 2002; Schultz 2006). In both groups, the individuals only survived because their social group took care for them, in the case of Shanidar 1 even extensively.

The occurrence and the frequency of degenerative joint disease are closely associated with physical strain and occupational stress. This explains the appearance of osteoarthritis in Paleolithic individuals. Astonishingly, the intensity and the severity of such lesions in Paleolithic people are, as a rule, less pronounced (e.g., in the elderly male from the Kleine Feldhofer Grotte; Schultz 2006) than, for instance, in late medieval individuals. Corresponding findings are also existent in early historical hunter-gatherer populations and sedentary populations. The cause of this phenomenon is probably to be found in a frequent muscle training which allowed a more efficient muscular action leading to a more effective muscle guidance of the joints. Due to the better muscle guidance, the joint cartilage was less stressed which prevented early joint wear. Sometimes, however, degenerative joints have to be regarded as posttraumatic alterations (e.g., Berger and Trinkaus 1995).

Enthesopathies which are musculoskeletal stressmarkers (Capasso et al. 1999; Hawkey and Merbs 1995) are related to muscle function and joint strain. As a rule, they represent primarily painful disorders of muscle or tendon attachments at the bone surfaces (e.g., myotendinitis) which might heal after a while if the muscles are not strained any longer, which is not very probable in Paleolithic people who had to struggle for their lives. The kind and the location of enthesopathies in the human

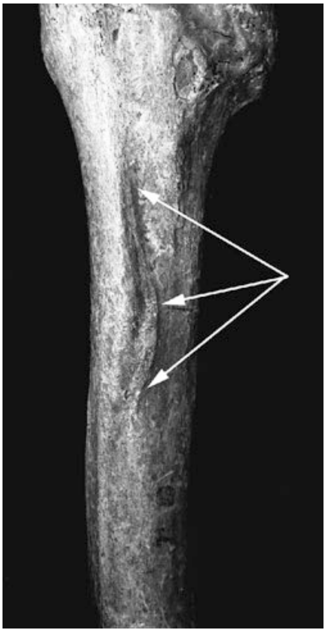

Fig. 3 Ventral view of the shaft of the right humerus of the male Neanderthal from the Kleine Feldhofer Grotte. Enlarged lateral lip of the bicipital groove (*arrows*)

skeleton tell us which muscle groups had been stressed (Fig. 3) and give clues to the nature of the physical strain which had affected the individual. Enthesopathies are relatively frequently found in Neanderthals. Principally, there are two kinds of strained tendons: (1) "osteoblastic enthesopathies," in which constant physical load enlarges the bone muscle attachments. Thus, a relatively regular surface protuberance of various sizes might originate (Fig. 3). If severe strain intensively affects the bone surface, additionally, the periosteum is stressed and micro-bleeding might occur in the region of the attachment of the tendon. After healing, the hemorrhage can be organized as connective tissue which might later ossify. In this way, the enlargement of muscle attachments can be explained. (2) "Osteoclastic enthesopathies" is a condition wherein very sudden, intermittent tractions of a muscle at the bony attachment might cause an interruption of the blood vessel supply of the bone at the microlevel which leads to a decay of the neighboring bone tissue. Thus, this tissue becomes necrotic and is eaten away by osteoclasts. A fosse will develop approximately of the size and the shape of the attaching part of the tendon which will be filled in the cause of healing by connective tissue producing a fibrous scar. After maceration (decomposition), a fosse-like cavity is left indicating physical strain. As a rule, in Neanderthals and other Paleolithic individuals, only the first group of "osteoblastic enthesopathies" described is found.

During the course of paleopathological research on human fossil remains, frequently changes on the internal skull lamina are neglected. This is probably due to the fact that researchers might not be quite aware of this kind of morphological alteration, due to intra vitam reactions of the meninges (cf. Schultz 2006), such as hemorrhages and inflammations (e.g., small epidural hematomas due to

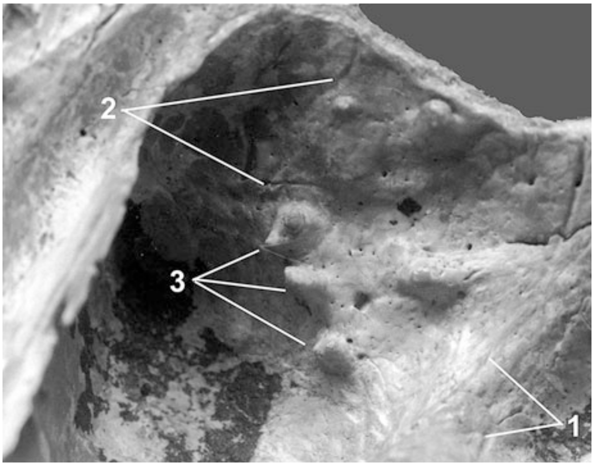

Fig. 4 Left zygomatic bone (NN 34, excavated 2000) of the male Neanderthal from the Kleine Feldhofer Grotte. View into recess of the left maxillary sinus. *1* well organized bone apposition, *2* blood vessel impressions, *3* tumor-like formations

trauma or bacterial meningitis). A reliable differentiation of the nature of such meningeal afflictions can only be established by microscopy (e.g., Schultz 2001, 2003, 2012). The elderly male from the Kleine Feldhofer Grotte exhibits changes on the internal lamina of both parietal bones which are probably the vestiges of a healed pathological meningeal process (Schultz 2006). The same individual also shows vestiges of a healed hemorrhagic or inflammatory meningeal process in the sulcus of the superior sagittal sinus of the brain.

The endoscopic inspection of the nasal cavity and the paranasal sinuses, as well as the middle ear region, provides, as a rule, interesting results also in fossil human remains. The walls of the zygomatic recess of the left maxillary sinus of the elderly Neanderthal from the Kleine Feldhofer Grotte (Fig. 4) reveal residuals of a chronic inflammatory process (Schultz 2006). Additional to the well-known features of a chronic inflammation which is expressed by coarse and sclerotic bone surfaces and some residues of abnormal, fine blood vessel impressions, there are several relatively small, pluglike, or polypoid formations (Fig. 4) which partly represent the healing stage of a small ulcer or a “pre-tumor stage” (Fig. 5a) or partly new tumorous formations (Fig. 5b). This case is particularly interesting because it is uncommon that at the bottom of such a chronic inflammatory process, tumorous growth developed. It is known from prehistoric and early historical populations that inflammatory processes of the middle ear region and the paranasal sinuses are found four or five times as frequently in individuals of the lower class as in members of the upper class (e.g., Schultz 1996). Thus, this group of diseases is called “poor people’s disease.” Probably, the most important primary cause of this kind of infection is to be found in inadequate housing conditions. Here, the smoke of the fire in the hearth probably played the major role for the occurrence of this disease. To date, for Neanderthals, we do not have sufficient information on the frequency and the intensity of chronic inflammations of the paranasal sinuses and the middle ear region which might be related to the living conditions in caves. For the male from the Kleine Feldhofer Grotte, we can assume that he ran a high risk of being

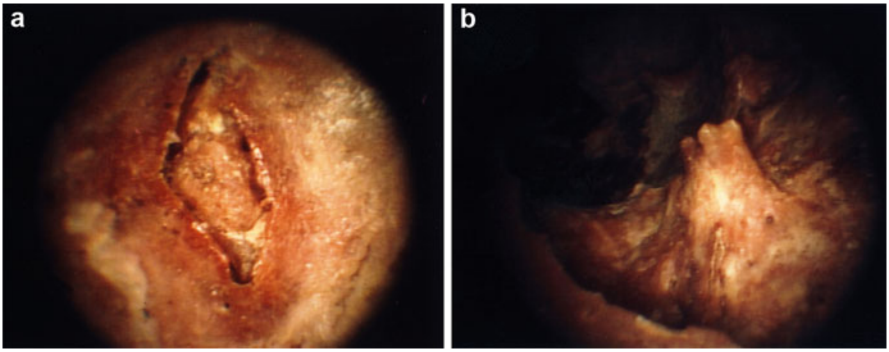

Fig. 5 Endoscopic views. Left maxillary sinus of the male Neanderthal from the Kleine Feldhofer Grotte: (**a**) bone formation which represents the healing stage of a small ulcer or a "pre-tumor stage," (**b**) small polypoid bone tumor

killed by this relapsing purulent disease (e.g., sepsis). Probably this was not the case, for the first few years after he had started to suffer from sinusitis. During this time, probably his immune system became weakened which might have contributed to his death.

Finally, in Paleolithic human remains, in a few cases, vestiges of deficiency and infectious diseases have been observed. However, as a rule, without microscopic investigations, reliable diagnoses cannot be established. Thus, only tentative diagnoses are possible. Still, some examples can be briefly mentioned. Of the group of the nonspecific stressmarkers, transverse linear enamel hypoplasias (LEH) were observed. These less-mineralized lines in the dental enamel which, in paleopathology, provide an estimation of the relative morbidity of prehistoric and early historical populations can be caused by malnutrition and infectious diseases. Such lines were found in the young adult *Homo erectus* from Dmanisi (Bräuer et al. 1995; Bräuer and Schultz 1996) and in several Neanderthals (Ogilvie et al. 1989). In Neanderthals, these lines are relatively frequently seen with 75 % (Ogilvie et al. 1989). As already mentioned above, the skull of the archaic *Homo sapiens* cranium KNM-ES 11693 from Eliye Springs exhibits morphological features which suggest chronic anemia of unknown origin to be responsible for the enormous thickening of the vault (Bräuer et al. 2003). Although CT images were available, without the results of a microscopic examination, no convincing diagnosis was possible to reliably diagnose this disease case. As an example of a rare infectious disease, we cite the *Homo erectus* cranium from Kocabaş in the western Turkish province of Denizli (Kappelman et al. 2008). The fragment of the right frontal bone shows lesions in the endocranial surface of the anterior cranial cavity which resemble the small granular impressions which are characteristic for *Leptomeningitis tuberculosa* (Kappelman et al. 2008). However, without further microscopic investigations, no reliable diagnosis can be established. A rather unconvincing case of diffuse idiopathic skeletal hyperostosis (DISH) was published dealing again with the Shanidar 1 individual (Crubézy and Trinkaus 1992). In the skeleton of this elderly male, enthesopathic osteophytes were observed in the lumbar vertebrae, in the left olecranon, both patellae and both calcanei (upper calcaneus spur). Only relatively slight osteophytic formations were found in both coracoid processes and the greater trochanter (Crubézy and Trinkaus 1992). Probably, these changes caused pain and a certain disability.

Conclusion

Paleopathology, which combines physical anthropology, medicine, and forensics, contributes substantially to the wide field of paleoanthropology as practiced today and also suggests certain methodological procedures for the future of this scientific discipline. Thus, the results of a paleopathological investigation provide information on the everyday life, afflictions, and illness occurring at the dawning of mankind. In particular, we learn about the nature of diseases of human antecessors and their health status. Furthermore, all these facts allow, of course within limits, the reconstruction of the past environment, with respect to factors such as nutrition, housing and working conditions, and geographic and climatic as well as hygienic and sanitary factors.

To reach this goal, standardized methods and techniques are suggested. For example, accurate scoring of nonphysiological changes in fossil human bones using predefined morphological features including vestiges of pathological processes should be employed to establish standards for further comparative analyses (e.g., Hawkey and Merbs 1995; Schultz 1988; Tilhaud 1994). Particularly, in diagnostics, the nature, the causes, as well as, the spread and the frequency of diseases in human antecessors should be studied comparatively as for prehistoric and early historical people. There is only the one difficulty, i.e., the low numbers of individuals available for such studies. However, it is absolutely worthwhile to start comparative work in this innovative field which will allow us to recognize certain tentative aspects which will, in turn, help to significantly enlarge our knowledge on the living conditions of human antecessors.

The practice of forensic anthropology also belongs to innovative aspects of paleoanthropological research. The cases of Shanidar 1 and 3, Kleine Feldhofer Grotte, and St. Césaire 1 demonstrate that many fossil remains might be of paleoforensic interest. Particularly the cases of Shanidar 3 and St. Césaire 1 raise the assumption that the Middle Paleolithic Neanderthal implements (or those of early modern humans) might be used as weaponry in an interpersonal behavioral context. Thus, the injury pattern observed in Neanderthals should be interpreted as resulting from a variety of causes, not just hunting. Activity-induced changes in the postcranial skeleton of human antecessors, for instance, the occurrence of enthesopathies, tell us about the nature and the intensity of locomotion and occupational strain.

Aspects of social care in Neanderthals can frequently be seen in connection with traumatic events. Examples are the cases of Shanidar 1 (Trinkaus 1983), St. Césaire 1 (Zollikofer et al. 2002), and Kleine Feldhofer Grotte (Czarnetzki and Pusch 2002;

Schultz 2006). Potentially, as for prehistoric and early historical individuals, effects of sociobiology of diseases might be studied. As particular diseases, so-called poor people's diseases (e.g., inflammatory processes in the middle ear region and the paranasal sinuses) or even gender-specific diseases can be explored. As we know from the Neolithic and younger periods (e.g., the early Middle Ages), there are apparently gender-related differences in the location and the frequency of osteoarthritis of the large extremity joints (e.g., Schultz 1996; Schulting and Fibiger 2012a, b). Seemingly, in early historic populations, sometimes an interdependence between the frequency of degenerative joint lesions and the social status of the diseased individuals as well as between female and male individuals can be observed (cf. Schultz 1996). Very probably, this will be not the case in Neanderthals. However, the distribution of osteoarthritis with regard to the sex and the age of individuals might, also in Neanderthals, provide interesting results.

Finally, we might obtain clues for the origin of diseases and the housing conditions of Neanderthals who lived, as a rule, in caves. A possible high frequency of inflammatory processes in the nasal and the paranasal sinuses, perhaps also of pathological processes in the middle ear region and even of the meninges, might be associated with life in a cave.

Microscopic Research on Fossil Human Bone

Michael Schultz and Tyede H. Schmidt-Schultz

Contents

Abstract

The methods and techniques of light microscopy and scanning electron microscopy are briefly described, and the advantages of polarization microscopy are discussed. Particularly, light microscopy is a useful tool to diagnose fossil bone at the micro-level. Selected samples of fossilized human bones (e.g., *Australopithecus*, *Homo erectus*, *Homo neanderthalensis*, and Paleolithic *Homo sapiens*) were examined using plain and polarized light. The histomorphological findings show that microscopic research adds much to what can be found by macroscopic

examination or by X-ray techniques. In particular, emphasis is placed on morphological structures that give clues to the taxonomy and the functional anatomy of early hominids. Furthermore, morphological structures which originated during the lifetime of the individual (e.g., individual age at death, physical strain, diseases) are explicable. Future perspectives of microscopic analyses are discussed.

Introduction

Up to now, microscopic studies of bone histology have not played a major role in paleoanthropology (see chapter "▶ The Earliest Putative *Homo* Fossils," Vol. 3). Seemingly, the scientific problem does not primarily require the information although the basic approach has the potential to open up and facilitate the informative value of an anthropological investigation on human fossil remains. Initial microscopic research studies have shown that it is possible to collect data which contribute substantial information on individual living conditions, diseases, and locomotion of early human beings. Thus, the microscopic investigation and light microscopy, including confocal laser microscopy (CLM) and scanning electron microscopy (SEM), open up a unique chance to obtain new and interesting information using innovative techniques. As a rule, such investigations are laborious and sometimes even expensive. Probably, this is the main reason why microscopic examination of fossil bones has only rarely been carried out. Furthermore, a microscopic examination often necessitates taking a sample of the fossil (e.g., for thin-ground section microscopy, scanning electron microscopy) which is an invasive technique. This leads to the loss of a certain amount of original substance which is usually, however, only small. At first sight, sampling constitutes irreversible damage. However, the missing part can be replaced by a true-to-life cast or by a plaster complement which can be stained in the same way as the original bone. Nevertheless, in the case of sampling, the necessity for such an intervention has to be carefully considered.

This contribution briefly outlines the principal methods and techniques as well as the possible benefits of a microscopic investigation on fossilized materials in paleoanthropology.

What Does Fossil Bone Represent at the Microscopic Level?

Fossils are preserved remains of past organisms (see chapters "▶ Taphonomic and Diagenetic Processes," Vol. 1 and "▶ Paleoecology: An Adequate Window on the Past?," Vol. 1). Several mechanisms are known to lie behind fossilization processes. Bony tissues might mainly be fossilized by various kinds of mineralization, such as peri-mineralization, replacement, and recrystallization. If the original tissue is completely degraded and lost, the external shape of a bone might be preserved as a cast. Interestingly, sometimes bones of respectable age, such as from Neanderthals, do not show any characteristics of a fossilization process. Thus, such a bone has only been preserved by protective conditions, for instance, by the protective climate and the shelter of a cave and still might have kept its original morphological and physical character just like fresh bone.

Using microscopic techniques, particularly with plain and polarized transmission light, the nature of a well-preserved fossil and the kind and the degree of the fossilization process can be determined. Thus, the individual micro-morphological features of lamellar bone, such as circumferential and tangential lamellae, osteons, and fragmented osteons, as well as various formations of woven bone can be clearly studied. Furthermore, structures at the cellular level of the bone tissue can be analyzed, such as the size and the shape of the lacunae of the osteocytes and their canaliculi and Howship's lacunae built by the osteoclasts. Although cells and soft tissues are degraded and lost, the morphological structures which were produced by these cells can be investigated. Also in the case of poorly preserved fossils, frequently these structures are still observable and might provide substantial information adding to our knowledge about the physical strain and diseases of man's ancestors.

Techniques Suitable for the Microscopic Analysis of Fossil Bone

Generally, any fossil sample is suitable for microscopic analysis. As a rule, pieces of compact bone provide better results than samples of spongy bone. However, the consistency of the bone and the state of preservation dictate which technique has to be applied to produce a satisfying microscopic specimen (Schultz 2001).

Principally, light microscopy will be the first choice, the "gold standard" of all microscopic methods to explore the micro-morphology of fossil bone. Scanning electron microscopy (SEM) (see chapter "▶ Virtual Anthropology and Biomechanics," Vol. 1) including the examination with the backscattered mode of the scanning electron microscope (BSEM) gives us information on the external or superficial morphology of a sample taken (Bell 1990). Using this technique, also accurately prepared high-quality casts can be used.

The light microscopic investigation of a thin-ground section with its various techniques allows us to look into and through the deeper levels of the interior structure of the same sample. Thus, in the bright-field, in plain transmission light the general micro-morphology of a thin-ground section can be seen. Using polarized transmission light, particular bone structures, such as collagen fiber bundles, and also diagenetically caused formations, as products of postmortem bone destruction (e.g., brushite, which is a product of degradation and transformation processes of the hydroxylapatite) and secondarily originated (e.g., calcite) or secondarily submerged soil-dependent crystals (e.g., calcite, silicates, granular quartz), can be detected and analyzed. These secondary admixtures inform us about the microenvironments with which this bone was confronted during its long period of storage in the soil (Schultz 2001, 2003, 2012).

The results of fluorescence microscopy applied to fossil bone are, admittedly, relatively meager although this technique provides very interesting results in

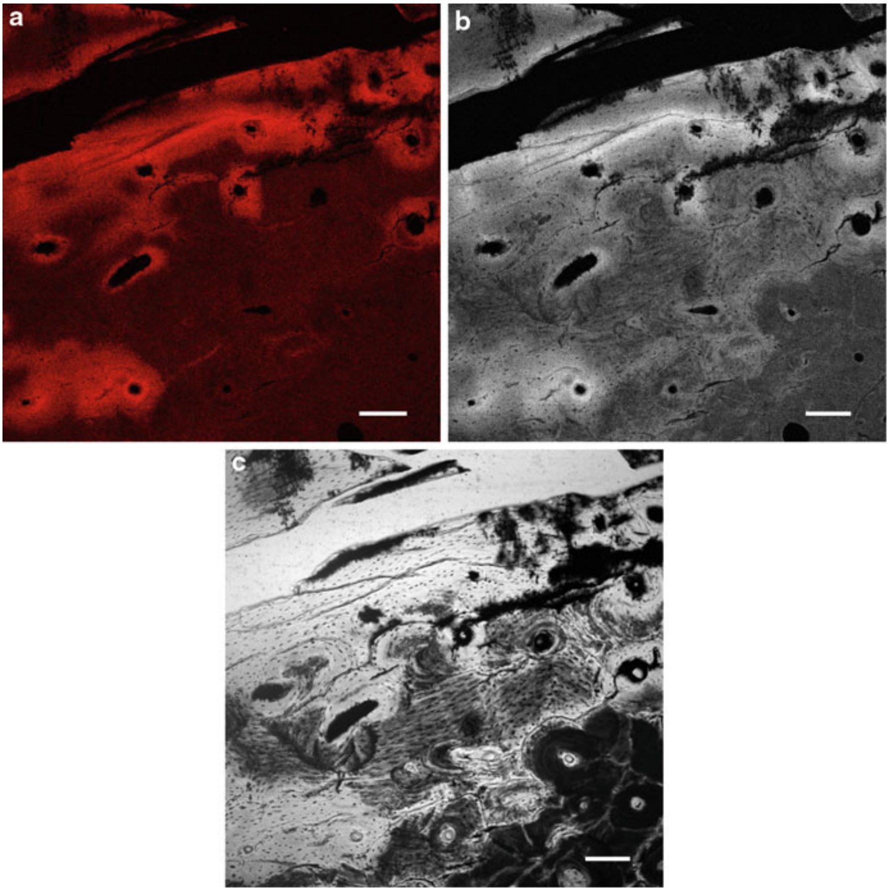

Fig. 1 *Australopithecus* from Swartkrans. Femur shaft fragment. Transverse section viewed in transmission light. Confocal laser scanning microscopic images. Bar = 0.15 mm. Compare different representation of morphological features and preservation state (Photos: Bernd Püschel, Department of Anatomy, University Medical School Göttingen (Germany))

archaeological bone specimens. This can also be said of the use of confocal laser microscopy (CLM) which, however, allows analysis of only one very thin level (Fig. 1) in the relatively thick thin-ground sections of 50 or 70 μm (Maggiano et al. 2006). Dark-field microscopy yields some useful results because various features might be visible (e.g., contours and cement lines as well as osteocyte lacunae of postmortem degraded osteons), which cannot be seen so clearly in bright-field microscopy.

Apart from transmission light, fossil bone samples can also be examined by reflected light. In this case, polished bone surfaces are analyzed in plain or in polarized light. However, in reflected light microscopy, only the superficial structures can be analyzed, whereas in transmission light microscopy, the deeper levels of the interior structure of the same sample can be studied. Furthermore, the morphological features examined using reflected light are usually not as clearly visible in detail.

As mentioned above, many skeletal remains of human antecessors are not really fossilized in the geological or paleontological sense (e.g., most Neanderthals; Fig. 2). Thus, their dry bony structure might be very fragile and brittle, and, as a rule, they have been pre-damaged by microfracture lines and postmortem resorption holes. Therefore, fossil bone samples should be embedded before being cut or ground (Schultz 1988, 2001).

Several techniques are available for the efficient embedment of bone samples and preparation of high-quality, large-scale thin-ground sections (Cho 2012; Frost 1958; Maat et al. 2006; Schultz 1988, 2001; Schultz and Drommer 1983). To guarantee a high-quality thin-ground section, the bone sample must be embedded properly which means that it should not be coated with but rather permeated by the embedding resin. In our experience, epoxy resins are the best suited embedding substances, for instance, Biodur® (type E12 and catalyst E1) which has a very high permeation due to its viscosity and is used in the plastination procedure developed by Gunther von Hagens (1979). For the embedding of archaeological specimens, this technique was modified (Schultz 1988, 2001) and is also suitable for the embedding of brittle fossils.

As a rule, fossilized bone samples are not stained with special substances to differentiate between various tissues because, frequently, diagenetic alterations do not allow a true stain (cf. Schultz 1988). Consequently, the same stain might produce a varying coloration of the same morphological structure (e.g., a collagen fiber bundle). Using polarized light, specific bone structures, such as collagen fiber bundles, can be viewed and analyzed, also without staining the bone sample. However, the thin-ground section should have a thickness of 50 or 70 μm since, otherwise, relevant structures are not determinable (e.g., in the case of a thickness of 10 μm, collagen fiber bundles are not observable).

What Can Light Microscopy Contribute to Paleoanthropology?

In general, most morphological features of fossil bone can be examined and studied at the micro-level in a similar way to recent fresh bone samples using thin-section microscopy. Among other features, the nature and the degree of the fossilization process can be determined, and we might learn something about the conditions of the microenvironment the bone was confronted with during its long period of storage in the soil which tells us, additionally, something about soil sedimentation (Fig. 3) and past climatic changes.

Occasionally, also fossil bone shows changes in its micro-texture due to diagenetic processes (Behrensmeyer et al. 1989; Bell 2012; Schultz 2001, 2012). This circumstance sometimes complicates the microscopic analysis but does not make it impossible. Vestiges of diagenetic processes sometimes resemble vestiges of

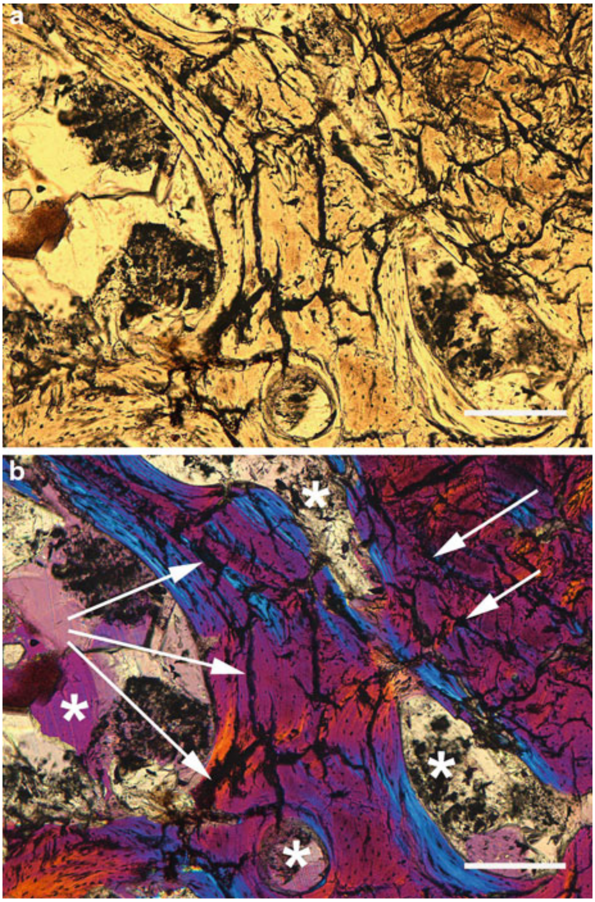
diseases (pseudopathology). However, in the majority of cases, alterations caused by disease during the lifetime can be reliably differentiated from changes caused by postmortem reactions (Schultz 1997, 2001).

Thus, processes of aging (e.g., Nováček 2012), decrease or increase of functional activity (e.g., Maggiano et al. 2008), evidence of malnutrition (e.g., Mays 2008; Ortner 2003; Schultz 2001, 2003, 2012), as well as the different structures occurring through specific and nonspecific bone inflammations (e.g., Schultz 2001, 2003, 2012; Schultz and Roberts 2002; Schultz and Teschler-Nicola 1987) can be detected. Also changes caused by metabolic diseases or circulatory disturbances (e.g., Mays 2008; Schultz 2001), the nature of bone tumors and tumorous lesions (e.g., Schultz 1986), and genetic disorders are identifiable with the aid of microscopic methods. Up to now, these methods have never been used in an extended and comparative study using the remains of fossil hominids and other Hominoidea. In the following, several examples are given to illustrate the benefit of light microscopy in paleoanthropology.

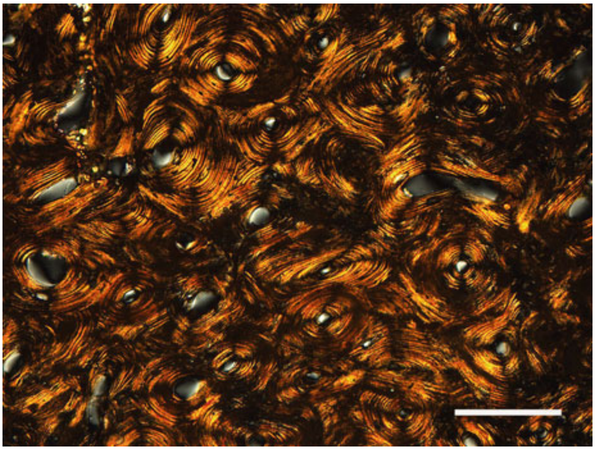
Fig. 4 *Australopithecus* from Swartkrans (SK-82). Femur shaft fragment. Transverse section viewed in transmission light. Diagenetic changes: *arrows* = postmortem microfractures due to soil pressure; *asterisk* = postmortem fill (crystals). Bar = 0.2 mm. (**a**) Plain light image, (**b**) linearly polarized light image with λ-plate red I order



Diagenetic Changes

Even fossils can show vestiges of diagenetic changes which tell us something about the microenvironment during their long period of storage in the soil (Fig. 4). Frequently, we can observe vestiges of destruction caused by soil and water, such as very fine cracks resulting from microfracture lines originated by soil pressure and products of a postmortem crystallization process (e.g., calcite crystals). Thus, newly crystallized structures can sometimes aggregate and partly break up internal structures of a bone (Schultz 1997, 2001). As a general rule, in contrast to the situation in archaeological, i.e., prehistoric or early historical, skeletal remains, we rarely see vestiges due to destruction by microorganisms, such as plant roots, fungi, algae, bacteria, or arthropods. The reason for this phenomenon is, probably, that a bone severely affected by microorganisms will completely degrade during the very long time of storage in the soil. Thus, only skeletal remains preserved in a protected environment (e.g., cave; muddy soil, ashes) have a chance to survive as a fossil.

Fig. 5 *Homo sapiens* from Preclassic Tlatelcomila, Tetelpan (Mexico, DF). Mid-shaft of femur shaft fragment. Transverse thin-ground section viewed in linearly polarized transmission light. Compact bone structure of an adult individual shows evidence of low heat influence (collagen fiber bundles show *yellowy-orange* coloration) and perimortem cut marks. Bar = 0.2 mm



Low Heat-Induced Changes

Effects of heat and fire cause typical changes in the microstructure of bony tissues (Grimm and Strauch 1959; Nováček 2012; Piepenbrink and Herrmann 1988; Schultz 2001; Wolf 1999) which are also observable in the bone collagen (Schultz 1997, 2001; Teschler-Nicola and Schultz 1984).

As investigations on prehistoric and early historical skeletal remains have shown, relatively low temperatures (below 300 °C), maintained over a longer time period, can apparently cause characteristic changes in the morphological behavior of the collagen fiber bundles seen in polarized transmission light (Schultz 1997; Teschler-Nicola and Schultz 1984). The collagen structures are colored, yellowy orange, not white as usual (Fig. 5). The cause of this phenomenon probably lies in a minimal shrinkage of the fibers.

Prehistoric bones which show this change of coloration using polarizing light microscopy are sometimes associated with the practice of cannibalism, particularly if perimortem cut marks are observable (cf. Turner and Turner 1999).

To date, no such cases are known in paleoanthropology. However, there is a femur found by Adolf Kleinschmidt at Salzgitter-Lebenstedt (cf. Hublin 1984; Kleinschmidt 1965) which shows Neanderthaloid morphology and from which a thin-ground section was prepared. In polarized light this section exhibits the feature of low heat influence (Fig. 6).

Estimation of Individual Age

The estimation of the biological age of archaeological specimens using microscopic techniques is a well-known method; however, it is not really frequently used in physical anthropology (Streeter 2012). Up to the present, this method of age estimation has not been carried out on paleoanthropological materials. The reason

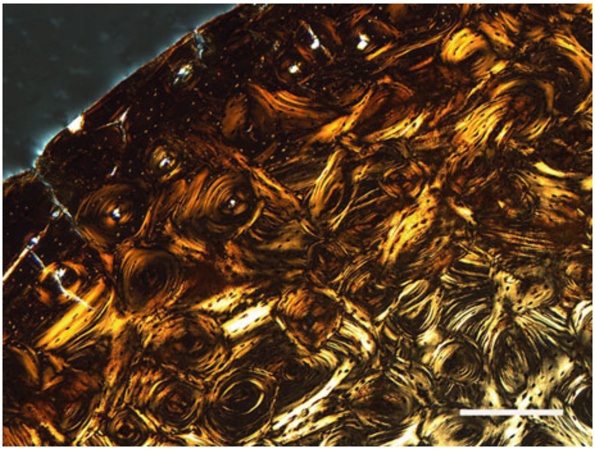


Fig. 6 *Homo neanderthalensis* from Salzgitter-Lebenstedt. Distal third of shaft of the right femur. Transverse thin-ground section viewed in linearly polarized transmission light. Compact bone structure of an adult individual shows evidence of low heat influence (collagen fiber bundles show *yellowy-orange* coloration). Bar = 0.2 mm

probably lies in the fact that, to date, we do not have age-determined specimens available for comparison purposes. Two different methods are used to estimate microscopically biological age in the postcranial skeleton: (1) the histomorphometrical method (HMM) and (2) the histomorphological method (HML). The HMM method which was introduced by the forensic anthropologist Ellis R. Kerley is applied to long tubular bones (Ahlquist and Damsten 1969; Drusini 1987; Kerley 1965; Kerley and Ubelaker 1978; Robling 1998; Uytterschaut 1985, 1993). However, also other parts of the human skeleton can be used, such as clavicle sections (e.g., Stout 1989; Stout and Gehlert 1980; Stout and Stanley 1991; Stout et al. 1996; Stout and Paine 1992). The application of this method is based upon the frequencies of osteons (Haversian systems), fragmented osteons (interstitial lamellae), non-Haversian canals, and the percentage of the external circumferential lamellae (Kerley 1965). The HML method is based upon the morphological nature (presence, size, shape, development) of the following features: external and internal circumferential lamellae, osteons, fragmented osteons, and non-Haversian canals (Nováček 2012; Schultz 1986, 1997; Wolf 1999).

Possible Taxonomic Changes in Bone Morphology at the Micro-level?

Microscopic analyses of thin-ground sections taken from long tubular bones of *Homo sapiens* and *Homo neanderthalensis* show no differences in the morphology of the compact bone substance. Indeed, there are slight morphological differences between *Home erectus* and *Homo sapiens* and *Homo neanderthalensis*. In *Homo erectus*, the relatively small, regularly rounded and densely packed osteons have a relatively narrow canal. In *Australopithecus*, the difference to *Homo sapiens* and *Homo neanderthalensis* is evident (Fig. 7). The external circumferential lamellae are very thick. The small osteons are regularly rounded, are densely packed, and

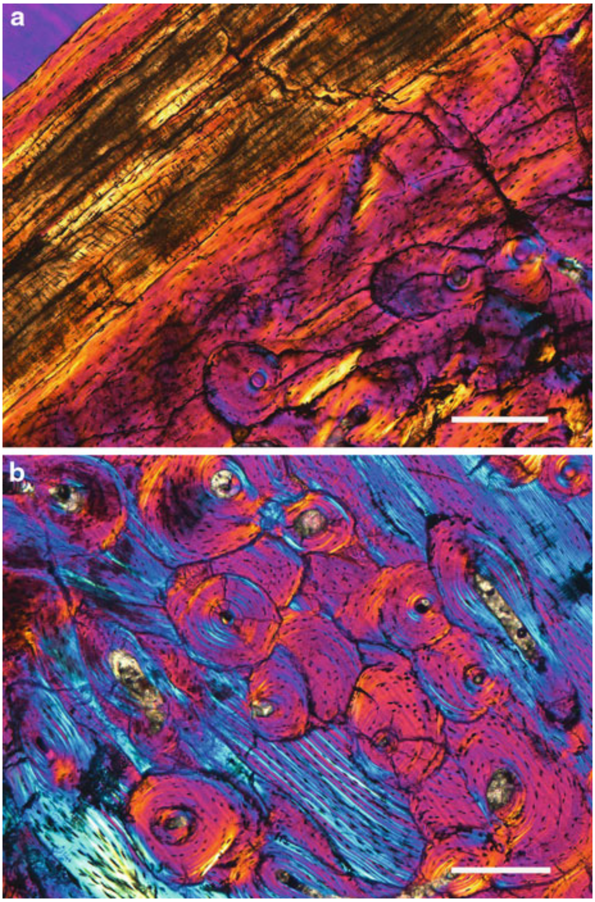

Fig. 7 *Australopithecus* from Swartkrans (SK-82). Femur shaft fragment. Transverse section viewed in linearly polarized transmission light with λ-plate red I order. Bar = 0.2 mm. (**a**) External circumferential lamellae, (**b**) osteons

have a narrow canal (Schultz 1999). The structure of the compact bone substance slightly resembles that which can be observed in *Pan paniscus* (Schultz 1999). Thus, micro-morphological features of bone are of value for additional information in taxonomic analyses.

Functional Activity and Locomotion

It is well known that locomotion and special functional activity influence the musculoskeletal system as well as functional inactivity (cf. Maggiano et al. 2011). Therefore, in bones, activity hypertrophy and inactivity atrophy can be studied at the micro-level to yield information on locomotion (see chapter "▶ Origin of Bipedal Locomotion," Vol. 3) and the use of particular parts of the skeleton. Although microscopic studies have rarely been carried out, the results of such an investigation might sometimes shed some light on the life of our ancestors. For instance,

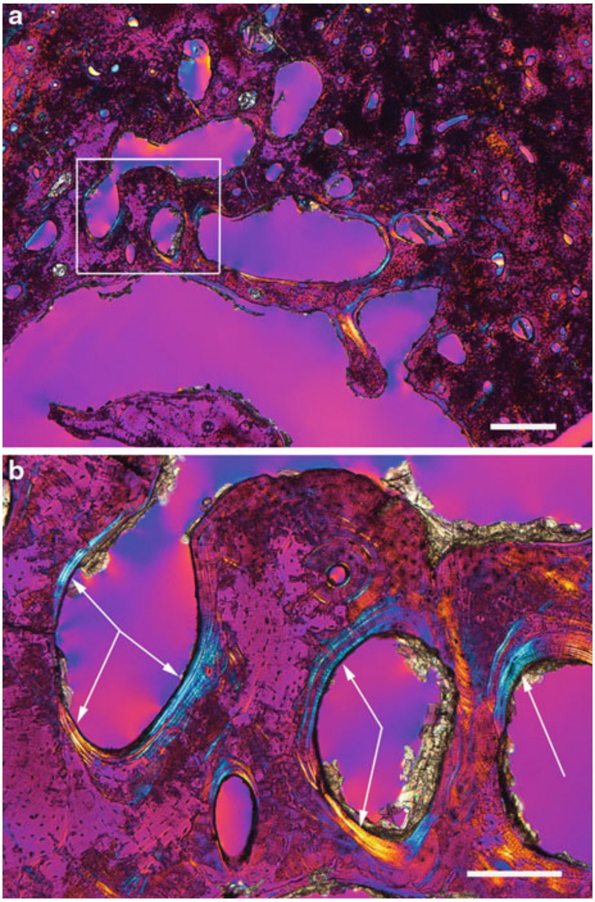

Fig. 8 *Homo neanderthalensis* from the Kleine Feldhofer Grotte. Proximal third of the shaft of left ulna. Transverse thin-ground section viewed in linearly polarized transmission light with λ-plate red I order. (**a**) Osteoporosis caused by inactivity atrophy. Bar = 0.5 mm. (**b**) Detail of (**a**) (frame); resorption holes with their own lamellar walls (*arrows*) indicating no active osteoclastic process. Bar = 0.2 mm

the Neanderthal from the Kleine Feldhofer Grotte, whose left ulna was broken many years before his death, exhibits large resorption holes at the micro-level in the primarily fractured bone (Schultz 2006). These holes are situated in the compact bone substance closely to the medullary cavity and have their own lamellar walls (Fig. 8). Additionally, the left humerus which is more gracile than the right bone shows porotic structures as vestiges of inactivity atrophy, at the micro-level, which are, however, not as pronounced as in the left ulna. These holes were responsible for the already macroscopically visible bone porosity at the transverse section level. They represent resorption holes due to the inactivity atrophy induced by the disability of the left arm after the fracture. As the margins of the holes are smooth and covered by a special regular lamellar wall, it was, indeed, an old process which the individual survived for many years.

Additionally, there are also other morphological features visible at the micro-level (e.g., tangential lamellae) which are due to inactivity atrophy (Schultz 2001, 2003, 2012).

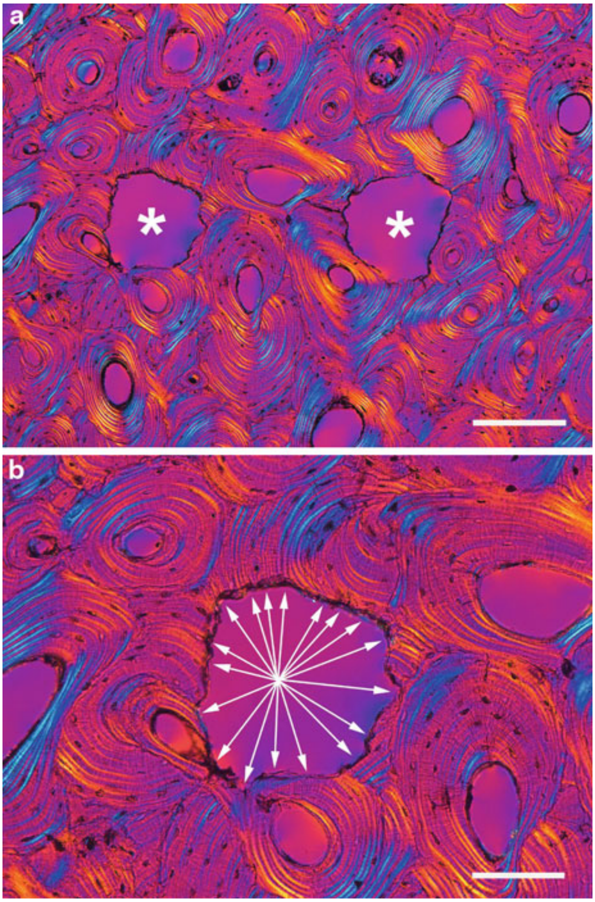

Fig. 9 *Homo neanderthalensis* from the Kleine Feldhofer Grotte. Mid-shaft of the right humerus. Transverse thin-ground section viewed in linearly polarized transmission light with λ-plate red I order. (**a**) Two large resorption holes (*asterisk*); bar = 0.2 mm. (**b**) Detail of (**a**); resorption hole with numerous Howship's lacunae (*arrows*) indicating an active osteoclastic process. Bar = 0.1 mm

Diseases and Disorders

Finally, vestiges of various diseases and pathological conditions and disorders can be diagnosed in fossil remains using microscopy. Unfortunately, paleopathology has not yet really been discovered in the wide field of paleoanthropology. Some case studies are already available, usually dealing with macroscopic findings (e.g., Trinkaus and Zimmerman 1982). An etiological or epidemiological investigation of population groups using microscopic techniques to obtain reliable diagnoses is still missing.

In summary, it would be worthwhile analyzing the following groups of diseases: evidence of malnutrition (e.g., scurvy, rickets), inflammatory bone diseases, bone tumors and tumorous lesions, and genetic disorders. However, also vestiges of the onset of disease can be detected using thin-section microscopy. As an example, the Neanderthal from the Kleine Feldhofer Grotte should be mentioned again (Schultz 2006). This mature male exhibits a frequent occurrence of irregular resorption holes (Fig. 9) in the compact bone substance of the humeri, ulnae, and femora.

The margins of these holes show many Howship's lacunae which are proof of an increased activity of osteoclasts. Probably, these changes are not normal. They might indicate the onset of a malignant process of unknown origin.

Conclusion

Microscopy, particularly the light microscopic investigation of the bones of man and his antecessors, can contribute not only ample information on the fossilization process and diagenetic circumstances, but also on heat-induced changes, functional activity and locomotion, disabilities, diseases and physical disorders, and, within limits, the individual age and even taxonomy.

For the future, microscopy could become a powerful tool which should be handled with the necessary responsibility because each sampling is an invasive intervention. The fact that a sample taken can be replaced by a true-to-life cast or a plaster complement should make this sampling more acceptable.

Investigation on Extracellular Matrix Proteins in Fossil Bone: Facts and Perspectives

Tyede H. Schmidt-Schultz and Michael Schultz

Contents

Abstract

For several years, it has been possible to detect typical extracellular matrix proteins (ECMs), such as osteopontin, osteonectin, and osteocalcin, in archaeological bone. Additionally, it has proven possible to detect growth factors and hormones (e.g., TGF-β, BMP-2, gonatropine), bone matrix proteins of the immune system (e.g., IgG, IgA, interleukine), and biomarker for diseases, such as tumor markers (e.g., PSA, PSA/ACT) or typical molecules characteristic for nonspecific infectious disease (e.g., TNF-α, IFN-γ) and specific infectious diseases (e.g., from *Mycobacterium tuberculosis*, Ag 85), in dry (macerated) bone. Now, we are able to detect these ECMs in fossil bone as well. Thus, evolutionarily old molecules, such as BMP-2, albumin, and matrix-gla-proteins (MPG), can be detected in fossil bone of various specimens (e.g., *Anancus arvernensis*) and compared to each other and to recent specimens. Furthermore, the bone matrix

protein patterns of childhood and adulthood (at the date of death) in the same individual can be compared, providing us with information on changes of living conditions during the individual's lifetime. Finally, the future possibilities of the study of ECMs in fossil human species are briefly outlined.

This contribution hopes to attract interest in newly available methods of biochemical and, in particular proteomic, research in paleoanthropology. These have potential to provide insights toward a better understanding of the evolution of mankind.

Introduction

Among the vertebrate organ systems, bone is unique in both structure and function. Bone is a biphasic system, consisting of an organic matrix in intimate contact with a microcrystalline mineral phase. Bone is a highly dynamic tissue that has evolved over millions of years under gravitational stress to provide mechanical support for both locomotion and protection, to serve as a calcium reservoir for mineral homeostasis, and to support hematopoiesis (Einhorn 1996). Proteomics evaluation involves the detection and characterization of the protein components of cells and tissues by partial sequence analysis and database matching.

Living bone consists of about 2 % cells and more than 90 % calcified tissue, the extracellular matrix (ECM). In contrast to other organic materials, bone tissue has a better chance of being preserved over a long time span after death due to its durability and resistance to decomposition and diagenesis. Conditions within the compact bone structure, which might be also characterized by the relatively low water content (ECM of bone 5–10 % water, in contrast a living cell contains 70 % water) and degradation enzymes, are favorable for the preservation of bone proteins (Clarke 2008). ECM proteins of the living bone bind very tightly to hydroxyapatite and/or to collagens. The apatite in which the proteins are embedded provides considerable protection against the destructive effects of temperature and chemical agents after death (Schweitzer et al. 1994).

In well-preserved bones, for many thousands of years after death, the ECM proteins are sometimes conserved as in fresh bone tissue (Fig. 1). The most serious problem to overcome is to extract and solubilize these proteins, for only if the proteins are solubilized it is possible to conduct the separation by electrophoresis, and only then it is possible to identify the proteins by so-called Western blot or mass spectroscopy.

Which ECM Proteins Can Be Detected in Ancient and Fossil Bones?

The ECM of bone consists of 65 % inorganic molecules such as calcium phosphates and about 35 % organic molecules, most of them proteins. Of these organic molecules, 90 % are collagen type 1 and only 10 % are non-collagenous proteins. These 10 % of non-collagenous proteins of the bone ECM have a tremendous

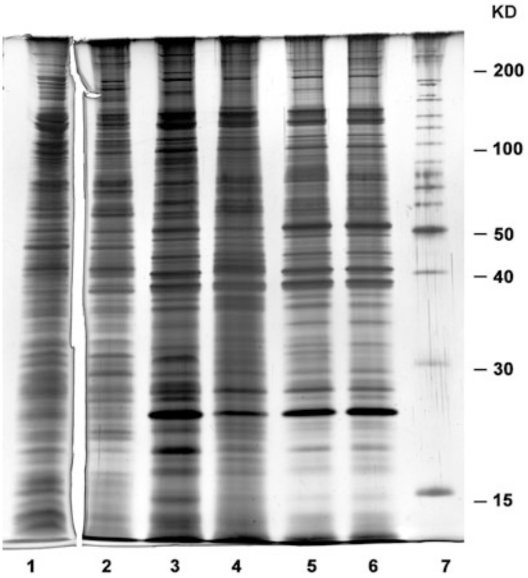

Fig. 1 1-D electrophoresis of human ECM proteins from compact bone and tooth dentin stained with silver. diversity, and many of them belong to several groups of the extracellular signaling molecules known as cytokines. Growth factors are responsible for differentiation and proliferation of cells, for example, transforming growth factor-ß (TGF-β) or bone morphogenetic protein (BMP) or erythropoietin (EPO) (Centrella et al. 1994). Another group is the interleukines (interleukine-1 [IL-1], interleukine-6 [IL-6], or tumor necrosis factor-a [TNF-α]), which have a special function in immune defense and inflammatory processes (Waage et al. 1989). A further group are the interferons (IFN), involved in defense against viruses, inhibition of proliferation, and in the apoptosis process (Sen 2001). The last group of cytokines is represented by proteins that are more involved in migration and chemotaxis of cells (Baggiolini et al. 1997). Some of these cytokines (TGF-β, BMP-2, TNF-α, IGF-II, IL-1β, IL-6, IFN-γ) can also be detected in bones from archaeological sites (Schmidt-Schultz and Schultz 2005, 2010). Also other typical bone proteins, such as osteopontin, osteonectin, osteocalcin, alkaline phosphates, and bone sialoprotein, have been identified in recent bone and bones from archaeological sites (Schmidt-Schultz and Schultz 2004, 2007). Thus, paleoproteomic research can provide results which cannot be

(**a**) ECM proteins from compact bone, (left femur), male, 30–39 (45) years old, Basta (Jordan), Late PPNB (7500–6000 BC); (**b**) ECM proteins from dentin (tooth 27), male, 30–39 (45) years old, Basta (Jordan), Late PPNB (7500–6000 BC)

achieved by the examination of ancient DNA. Osteopontin, osteonectin, and BMP-2 were extracted and identified in Western blots using special antibodies in a 3.4 million-year-old pre-mastodon, *Anancus avernensis* (Schmidt-Schultz et al., manuscript in preparation). Recent investigations have shown that the number of different bone matrix proteins in recent native bone is much higher than thought before: 3,038 unique proteins were identified in bone samples of four individuals (Alves et al. 2011). In three out of four bone samples, a total of 1,213 proteins were present (Alves et al. 2011). Out of these, 1,051 non-collagenous proteins could be quantified (Alves et al. 2011). Also, for only the non-collagenous proteins, this is an extremely high number of ECMs. Therefore, chances are that also in ancient and fossil well-preserved bone samples, an adequate number of proteins might also be detected. Paleoproteomic analyses thus appear to have a high potential.

Different ECM-Protein Pattern in Childhood and Adulthood

It is interesting that there is an apparent difference between the protein patterns of bone and of teeth stemming from the same individual (Fig. 2). Additionally, by creating a MatchSet with PDQuest 7.2, in which the protein spots from the different gels are matched to each other, a comparison was done that shows clearly the differences of the nature of the ECM proteins in two age sets from the same individual. Only 16 % of protein spots in the tooth were also found in the bone of this individual (Schmidt-Schultz and Schultz 2007); but the total number of spots in the 2-D gel of bone or teeth were almost the same, adding up to about 330 (Fig. 2). This can be explained by the fact that dentin normally does not undergo remodeling in the way that bone does (Borggreven et al. 1994; Cloos and Jensen 2000; Silva et al. 2004). However, also in the various kinds of bone substances, the turnover in cortical bone (i.e., compact bone substance, e.g., from the femur shaft) per year is between 2 % and 3 % (Clarke 2008) and 4 % (Parfitt 1994), while in trabecular bone turnover, it is 28 % per year (Parfitt 1994). For the turnover rate in cortical bone of small (e.g., vertebral bodies, carpal and tarsal bones) and flat bones (shoulder blade, ribs) as well as in permanently existing woven bone structures (e.g., linea aspera, upper ventral iliac spine, deltoid, and gluteal tuberosity), no reliable data are available. But for all that, remodeling rates do not play a major role in maintaining the character of the ECM because all bone ECM proteins are constantly reintegrated into the bone matrix. Thus ancient and, particularly, fossil bones represent a biological archive of ancient life.

Impact of Disease-Connected ECMs

Disease-connected molecules are another interesting field in the investigation of fossil bone. Currently, two different kinds of formation processes are known:

1. During the course of a certain disease, specific molecules are as a rule synthesized in high amounts by the diseased organism. For instance, over the life of an existing malignant tumor of the prostate (prostate carcinoma), prostate-specific antigen (PSA) which is a 30 kDa protein (complexed with a 1-antichymotrypsin 75 kDa), is secreted by the human prostate. Through mechanisms still unknown, PSA is released from the prostate into the blood circulation and ends up in the ECM of bone. The leakage of PSA is promoted by tissue abnormalities provoked by prostate cancer. PSA has been detected in the bone ECM of a 2,700-year-old Scythian king from Arzhan (Siberia, Russia) who suffered from and probably died by a metastasizing carcinoma of the prostate (Schultz et al. 2007; Fig. 3). In this case, the diagnosis “prostate carcinoma” could be established independently and confidently by combining the morphological (gross morphology, histology) and biochemical (proteomic) investigations.
2. Another possibility is to search in macerated bone for molecules that were secreted by pathogens during the lifetime of the diseased organism. For example, *Mycobacterium tuberculosis* secretes in infected individuals the complex antigen 85 (Ag 85), composed of a family of three highly homologous 30–31 kDa proteins: Ag 85A, Ag 85B, and Ag85C. Each of these Ag85 is associated with mycolyltransferases activity in vitro (Belisle et al. 1997) suggesting the essential involvement of the characteristic cell wall of the *Mycobacterium*. Ag 85 could be identified in skeletons from Siberian Arzhan, Russia (700 BC), and from Kirchberg, Germany (tenth–twelfth century AD) (Schmidt-Schultz and Schultz 2014, in press). During the course of this study, a positive control was performed in a recent human bone sample from the pathology collection of the University of Göttingen (Schmidt-Schultz and Schultz 2014, in press).

Very probably, such a diagnostic procedure would also work in fossil human bones. As several authors have shown, ECM-peptides can successfully be detected in nonhuman fossil bones (Schweitzer et al. 2011).

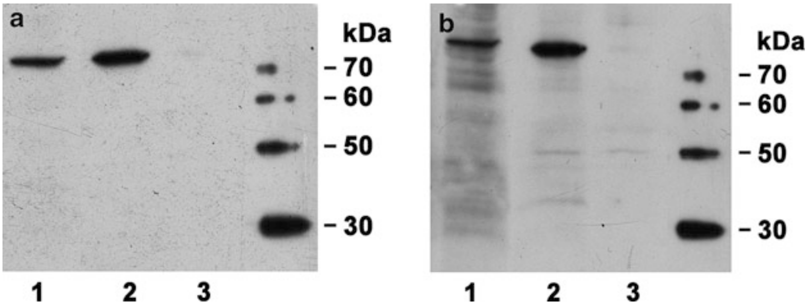

Fig. 3 Western blot. (**a**) Monoclonal antibodies against prostate-specific antigen (PSA). Lane 1, ECM proteins from left tibia of the Scythian ruler from Arzhan, 40–45 years old, early Iron Age (approx. 700 BC); lane 2, ECM proteins from right femur of a recent male body donator, 62 years old, Department of Anatomy, University of Göttingen (Germany), with known diagnosis prostate cancer; lane 3, ECM proteins from right femur of a recent male body donator, 74 years old, Department of Anatomy, University of Göttingen (Germany), not suffering from prostate cancer; right-hand side, molecular weight marker. (**b**) Monoclonal antibodies against PSA complexed with α1-antichymotrypsin (PSA/ACT). Lane 1, ECM proteins from left tibia of the Scythian ruler from Arzhan; lane 2, ECM proteins from the right femur of a recent male body donator, 62 years old, Department of Anatomy, University of Göttingen (Germany), with known diagnosis prostate cancer; lane 3, ECM proteins from the right femur of a recent male body donator, 74 years old, Department of Anatomy, University of Göttingen (Germany), not suffering from prostate cancer; right-hand side, molecular weight marker

Conclusion

Comprehensive knowledge of bone matrix components is a prerequisite for understanding the biochemistry and the physiology of bone. This basic knowledge is also necessary to discuss successfully the nature and the state of particular diseases that may have affected bones in ancient times. This interdisciplinary approach offers a good opportunity to gain more insights into the molecular paleopathology of fossil human bones. Additionally, newly developed techniques allow us to extract, to solubilize, and to detect bone matrix proteins in ancient and even fossil bones. Thus, in the near future, it will be possible to answer questions dealing with many aspects of ancient living conditions, such as aging and maturing, weaning, various diseases and the capacity of the immune system, genetically caused pathological conditions, and nutritional problems, via the examination of macerated bones

Images in Paleoanthropology: Facing Our Ancestors

Stefan Schlager and Ursula Wittwer-Backofen

Contents

Abstract

Images in paleoanthropology are of persuasive power, since they try to illuminate ancient life which is not otherwise visually documented. The scientific community, as well as public media and museums, aim to establish a window into the past in part through visualization of scenarios from prehistoric life and

environments. The role of human ancestors in these settings is captured by body and especially facial reconstructions, which comparatively easily attract attention among nonscientific audiences and therefore raise public understanding of a complex field of research, allowing it to compete successfully with other, at times more tangible scientific subjects. Within the scientific community itself, reconstructions of early hominids play only a limited role, merely supplementing a whole range of field and laboratory research, evolutionary hypotheses, and the analysis of empirical data. Paleoanthropologists and paleontologists are aware of the interpretative character of facial reconstructions that go beyond the limited set of primary facts documented in the fossils themselves.

The visual approach to paleoanthropology has changed strongly over time, varies with the media used, and depends on how we imagine our ancestors in coeval context. On the one hand, evolutionary theories and contemporary social ideas are influencing and shaping how we view and depict our ancestors. On the other hand, hominid reconstructions themselves, in turn, can influence our view and the underlying ideas.

This chapter reflects on the development of facial reconstructions over time, along with influences such as the development of methods and techniques – from drawings to manual modeling to virtual 3D reconstructions. For exemplification, special emphasis will be put on Neanderthal reconstructions, as these are linked both to early attempts at facial reconstruction and to the subsequent methodological development of reconstruction techniques during the twentieth century. Starting with the first hominid fossils found, we trace the “evolution” of facial reconstructions of Neanderthals, in order to highlight contemporary perceptions and limiting factors in the visualization of our ancestors.

Introduction

The human face is among the most popular themes of all time. It delivers uniquely fascinating images. The capability of deriving important information from the human face, such as intentions, emotions, and personality, is one of our prominent evolutionary achievements. Human ethology shows a keen interest in this highly specialized part of the human body, as it significantly enables social interactions between sender and receiver in communication (Landau 1989; Sütterlin 2013; Eibl-Eibesfeldt 2007; Grammer and Oberzaucher 2006).

The central social importance of the human face may have contributed to the wide efforts to create faces based on the fossil hard tissue remains of human ancestors since the beginning of research into fossil bones itself, e.g., the finding of the Neanderthal specimen of 1856. Motivated also by the emergence and reception of Darwin’s evolutionary theory 3 years later, illustrators and sculptors began to create a broad variety of artistic representations (Voss 2009; Larson et al. 2009). In turn, the images they created began to exert influence on evolutionary theory itself, due to their persuasive power (Prodger 2009; literature overview in Sarasin and Sommer 2010). Intensive multidisciplinary research in this field during the last decade has shown the wide range of artistic intentions and imaginations evident in the images presented to the eyes of the beholder. Thus influenced, beholders will then engage their own imagination (Eibl-Eibesfeldt and Sütterlin 2008; Henke 2010; Voss 2007).

Right after the first fossils of human ancestors began to be studied, paleoanthropological research and education generated a huge number of reconstructions, both of entire bodies and of faces. These started to replace the former, generic natural sceneries, as found in Darwin's oeuvre, by focusing on the anatomy of early hominid taxa. The visualization of human ancestors via reconstructions, allowing face-to-face confrontation, came to be a widely accepted device.

Paleoanthropological research has revealed a high degree of specialization in the facial skull, including adaptations of dentition, the vocal tract, midfacial geometry, and the orbital region to specific environmental factors. As facial soft tissues depend on craniofacial shape, the face as well as the underlying craniofacial bone structures can be assumed to be sensitive to environmental conditions, and thus are helpful to consider in paleoecological interpretations. However, it should be noted that only the large mastication-related muscles leave visible markers, whereas the shape and size of muscles responsible for facial expressions cannot be estimated from the remaining bone material.

In sum, in addition to the general, inherent attraction of pictures representing an extinct world, due to our ethological interest in faces, facial reconstructions of our ancestors are of special attractiveness to the public as well as to the scientific community.

But does facial reconstruction really fulfil the scientific criteria to be regarded as a legitimate window into the past? Are facial reconstructions of our ancestors strictly a result of manipulating "facts" and hence nothing more than an objective visualization of those facts?

There are several arguments which cast doubt on this assumption. For one, paleoanthropological reconstructions try to capture the hitherto unknown appearance of extinct human taxa, whether or not their faces resembled ours. However, humans are inherently sensitive to variations in physiognomic appearance in their species and prefer individuals who are similar to themselves. Even given a set of modern methods which try to achieve standardization, and despite deliberate efforts towards objectivity, it is not possible to overcome this bias. Modern reconstructions have an immanent intention to attract and emotionally reach the beholder. This can be achieved to a maximum degree with faces similar to the beholder.

Thus, the well-known, clearly established "cross-race" effect is an unavoidable factor influencing reconstruction results. Psychological research on perception has shown that identification, recognition, and interpretation of human faces is much more successful with faces belonging to the perceiver's own ethnic group, compared to out-group faces (Meissner and Brigham 2001; Sporer 2001).

A typical manifestation of this phenomenon can be seen with reconstructions of Australopithecines or early hominids that have been given white sclera, in contrast to models of non-human modern primates, which are mostly equipped with brownish sclera. According to the cooperative eye hypothesis, humans are especially reliant on gaze-following in social situations; the hypothesis suggests that eyes developed a new social function in the course of human evolution, most likely to support cooperative social interactions (Tomasello et al. 2007). In actuality, white sclera may have evolved much later in the hominization process than suggested by the respective reconstructions but, presumably since they make gaze-following easier, white sclera are more pleasant to look at for the human beholder than brown sclera.

Facial reconstructions of unidentified bodies in forensic anthropology, which can draw on better methodology with respect to the thickness and texture of soft tissue layers compared to paleoanthropological reconstructions, have shown an unavoidable tendency to implement familiar facial features, regardless of the ethnic origin of the dead. This is owed to the fact that these traits are familiar to the person executing the reconstruction. The effect can be expected to be even more pronounced in the case of extinct taxa, where less reliable information is available and a wide range of prejudices interacts with scientific approaches (Schmölders 1995).

Recent reconstructions of hominids tend to personalize, trying to appeal to the beholder by evoking the notion of an individual's fate. Since neither destiny nor fate of the respective hominid specimens are known, this represents an interpretation. While scientists might agree on a reconstruction's general anatomical features, texture details – such as eye, hair, and skin color – or aging traits largely lack scientific foundation. The concept of population variability has replaced obsolete typological definitions of modern human populations, a development that has been discussed intensively by anthropologists over the last decades. Little, however, is known about the facial phenotypes of human ancestors. The more details are modeled, the more "realistic" a reconstruction seems to be. But in the absence of knowledge about anatomical variability at the population level, the opposite is true.

Whether the set of depicted traits ever existed in a real phenotype, or whether they fit into the range of variability, cannot be answered based on the inherent features of the material. Hublin (2007) summarizes this dilemma as follows: "'Scientifically based' reconstructions of fossil hominids filling the museums in Europe and America may say much more about our way of perceiving human diversity than about the actual aspect of these hominids. In this respect, the progress of our reconstructions since the beginning of the twentieth century may be more limited than is often assumed" (Hublin 2007, p. 825).

However, the media in which reconstructions are presented serve different functions, and therefore reconstructions are introduced differently in different settings. Within the scientific community of paleoanthropologists, reconstructions are more cautiously employed than in media of public interest, where they often are the items of central interest. The recently issued second edition of a textbook titled *Our Origins* (Larsen 2011) addresses students and lecturers in physical anthropology; it successfully manages to explain evolutionary processes within around 500 pages, richly illustrated by numerous concrete figures, but includes very few facial reconstructions, demonstrating just general types. Museums, on the other hand, which legitimately aim to interest the broad public in our history and, accordingly, try to offer immediate experiences, surpass each other with individualized reconstructions of early hominids, sometimes using dermoplastic materials that mimic human skin (as is the case, e.g., with reconstructions created by Elisabeth Daynès, John Gurche, and Alfons and Adrie Kennis) or applying forensic methods (Senckenberg Natural History Collection Dresden 2011; see http://www.demografische-chance.de/mitmachen/forschungsmuseen-erklaeren-den-wandel/senckenberg-naturmuseum.html). This individualization, however, hides the diversity of phenotypes that is known to have existed, and thus limits the viewer's appreciation of the complex mechanisms of environmental adaptations and interactions.

Apart from reconstructions of this type, produced mostly by scientists or by institutions claiming to be educational, a large variety of popular representations exist, including science fiction and cartoon artwork. These renditions, however, which claim little if any allegiance to scientific facts, are addressed elsewhere (Sarasin and Sommer 2010). The present chapter aims, first, to define the target audiences of paleoanthropological reconstructions and their specific goals, perceptions, and techniques, and then, by way of a concrete case study, to follow the change of Neanderthal reconstructions from a historical perspective. Finally, the implementation of certain very recent imaging techniques and shape analysis methods in this field will be discussed.

Methods of Facial Reconstruction

Craniofacial reconstruction (CFR) techniques have developed intensively during the last decades and led to a wide field of research and application. In the context of forensic analyses, special quality requirements have to be fulfilled in order for facial reconstructions to serve the aim of identification and allow for reproducibility of results. The variety of techniques used in the reconstruction process, as well as the different forms of presentation, differ from each other in how they address these requirements of the forensic recognition process. The development of computerized methods in recent years has helped to objectify facial reconstructions and to reduce artistic interpretation, rendering these innovations of special importance to forensic work.

In contrast, early hominid reconstructions have a choice between depicting a species type and capturing an individualized appearance. Research has focused on implementing automated procedures and improving our knowledge about the correlation of bone and soft tissue, which helps in generating realistic facial surfaces (Wittwer-Backofen 2012). While this work addresses the requirements of forensic anthropology (Stephan 2009), it is less helpful in paleoanthropology, where there is no reference for soft tissue thickness and shape.

Principal Criteria of Craniofacial Reconstruction

For the reconstruction of a facial surface, including elements like eyes, nose, or mouth, precise knowledge of the interdependence of skull shape and facial elements is essential. This includes, for example, knowledge of the proper localization of the eyeballs, their size and protrusion, or of mouth width as estimated from inter-canine distances in modern humans (Stephan and Murphy 2008). Whereas such correlations and their variability may be studied fairly well in sample populations of living individuals, no direct control mechanism is available for work on human ancestors which are represented by fossilized hard tissue materials alone, except for very few existing brain casts.

A second precondition is knowledge of the thickness of the soft tissue layer to be modeled onto the skull. Based on modern human samples, this derives a surface prediction of the face. However, several errors may occur in this step: as facial soft tissue depth has been studied for a limited number of facial landmarks only, interjacent areas are modeled as mere approximations, depending on the scientist's experience or the artistic skill of the practitioner. Apart from the limitation to specific available landmarks, published soft tissue data often suffer from small reference samples, unsuitable techniques, or insufficient background data for specification of soft tissue thickness according to age or sex (Helmer 1998; 34 landmarks). Even less information is available on ethnicity or nutritional status (De Greef et al. 2006; 31 landmarks). In the future, studies drawing on digital 3D imaging, such as computed tomography, may generate more adequately sized datasets from clinical patients, once the issue of position-dependent soft tissue shift is resolved (Claes et al. 2006a; Starbuck and Ward 2007; Wittwer-Backofen et al. 2007). These requirements are also not satisfied in the case of reconstructions of human ancestors, due to the obvious lack of reference samples.

A third limitation in the reconstruction process of modern humans relates to the textural details of the face, which are not directly linked to facial bone surface traits but instead inferred from additional information, such as ancestry or specific living conditions. Examples of such textural characteristics are pigmentation, wrinkles, and hair style.

Attempts to overcome these limitations when reconstructing premodern hominids draw on comparisons with our closest relatives in order to infer the appearance of our ancestors. In the past, this practice was only weakly supported by scientific facts. Just recently, molecular genetics has started to contribute a new element to the debate by studying, e.g., the evolution of skin color and of body hair (McEvoy et al. 2006; Rogers et al. 2004) based on data from extant populations (the HapMap project) and supported by hypotheses on evolutionary mechanisms of adaptation (Jablonski and Chaplin 2000; Jablonski 2004). For now, however, we have few clues, leaving us with a very incomplete picture.

Skull Bone Reconstruction

A basic factor for the prospects of a craniofacial reconstruction is the state of preservation of the skull. Ideally, the skull should be completely preserved, with its shape intact and not deformed or fragmented by postmortem diagenetic conditions, such as mechanical soil pressure or exposition to the surface.

Paleoanthropological fossils that meet these requirements are rare. Most of them are heavily distorted and fragmented. Repositioning and completion reconstructions represent interpretations which are often controversial. This mainly applies to older finds that were object to mechanical invasion, requiring assembly of fragments with missing joints. Recently, a set of primarily computer-based methods for the reconstruction of skulls has become available (Zollikofer and Ponce de Léon 2005; for an overview see Uhlhaas 2007). Digital representations of bone fragments from computed tomography can be fused in a virtual 3D environment, in the process allowing for the correction of deformations. Where parts of paired bones are only available for one side of a specimen, these can be mirrored and inserted virtually, assuming lateral symmetry. Missing parts, such as mandibles, can be reconstructed with a certain probability through size adaption of mean shapes. This has been shown for reconstructions in modern humans and can also be applied in paleoanthropology, if comparable data of the same taxon are available (Schlager et al. 2011).

Manual Techniques

The first attempts to reconstruct faces from skulls were made at the end of the nineteenth century. The aim was to recreate the faces of famous persons, such as Johann Sebastian Bach (His 1895) or Friedrich Schiller (Welcker 1883). It is worth mentioning that the basic procedures of manual 3D reconstruction techniques that are still in use today were established and discussed in the 1920s already. For example, Von Eickstedt (1925) discusses the advantages and disadvantages of modeling soft-tissue surface in bulk, only restricted by soft-tissue markers, compared to the detailed modeling of facial muscles based on accurate anatomical knowledge.

One of the central characters in the history of scientific facial reconstruction was the Russian anthropologist Mikhail Gerasimov, who in the 1930s successfully applied his profound knowledge concerning individual skull traits and their correlation to soft tissue, thereby starting a new era of CFR based on plastic modeling (Gerasimov 1968). Gerasimov amassed volumes of empirical data that were left almost undocumented. Besides forensic cases and reconstructions of historical personalities such as Schiller, his research interest focused on paleoanthropological reconstructions. His own reconstructions, which became classics, include the *Homo erectus* specimen from Choukoutien, the Steinheim skull (interpolating the missing mandible), the Neanderthal man from La Chapelle-aux-Saints, the Broken Hill (today Kabwe) skull, and the Late Paleolithic Cro-Magnon man.

Gerasimov used skull casts (today replaced by 3D prints) as the basis for his sculptures. In a first layer, facial muscles are modeled in clay, plastiline, or wax according to muscle attachment markers and bone shape. After the eyeballs (formerly clay models, today often glass eyes) have been inserted into the eye sockets, the final skin surface is modeled by connecting the surface markers and giving the face its individual appearance (Gerasimov 1968).

The principles of Gerasimov's method have been widely applied, though precise reproducibility and application of his method was made impossible by shortcomings in his publications (Ullrich and Stephan 2011). The method became known as the “Russian method” and was further developed into the so-called “Manchester method” (Prag and Neave 1997). Another, later modification has been taken up mainly among American forensic anthropologists. This so-called “American method” consists in modeling a single soft tissue layer (Taylor 2001). Reconstruction is performed much faster and with less effort, but the method is less suitable to implementation of variable, individual skull traits.

Artistic refinements such as single hair insertion and detailed texture modeling are technically possible and used for museum presentations. Specialists working on paleoanthropological reconstructions – such as Elisabeth Daynès in France, John Gurche in the United States, or Alfons and Adrie Kennis in the Netherlands – predominantly are referred to, and refer to themselves, as artists rather than scientists. They claim to be supervised by paleoanthropologists, however. During the last decades, elaborate 3D plaster techniques have gained in importance in the visualization of early hominids because these artistic approaches focus on individualized faces with specific texture information (Taylor 2001; Wilkinson 2010). In museum presentations of historical persons or fossil hominids, for example, this type of facial reconstruction has been an impressive success because of the emotions and empathy it evokes (Berge and Daynès 2001; Gurche 2013). However, little information about the underlying rationales regarding soft tissue thickness or placement of facial elements is published by this group of specialists, thus supporting the impression of a predominantly artistic approach.

In short, the clay modeling techniques that were the most commonly applied methods in the early days of facial reconstructions, still play a significant role and are being further developed now into elaborate sculpture techniques for reconstruction of early hominids. In forensic contexts, however, craniofacial reconstructions are increasingly replaced by virtual methods.

Computer-Based Craniofacial Reconstruction

Most scientific approaches to CFR deal with a very technical aspect of soft tissue reconstructions, namely, the individual variability of soft tissue thickness. They are usually directed towards a standardization of the process. This is indeed an important part of the reconstruction challenge, associated with many unsolved questions and unmet desiderata, which among specialists is leading to a growing interest in 3D form analysis (Claes et al. 2010; Wilkinson 2005; Vignal and Schuliar 2002).

Recent developments in digital imaging techniques, such as surface scanning, CT, and MRT scanning, have made it possible to acquire large databases of 3D representations of human heads. Though a digital image is never an exact copy, it still provides very detailed information about the structures represented. During the last two decades, CFR researchers have been trying to exploit these sources of information. In this section, we will provide a short survey of ways to generate algorithms that estimate the skin surface from information on the underlying bone formation. Only those methods that use semi-automated processes are taken into account here, leaving aside those that employ computer graphics to emulate manual reconstruction (Wilkinson 2010).

The basic workflow in computer-assisted CFR is very similar across the various approaches: after examination of the skeletal remains, a template of the soft tissue has to be adapted to the shape of the skull. The prerequisites needed for most approaches are (i) a database containing both bone and skin information (early studies restricted to a single configuration), and (ii) a mapping algorithm applying the information from the database onto the skull. The computer-driven approaches are to some extent a copy of the manual methods, except that they replace the individual knowledge and skill of specialists with information from a database. In doing so, they gain independence from any particular artist/scientist performing the reconstruction. On the other hand, computer-assisted CFR can only be as good as its database and underlying algorithms.

In general, the prediction is performed by using a soft-tissue representation generated from the database and applying a deformation based on a connection between skin and skull surfaces provided by the database. An extensive survey of computer-based reconstruction approaches can be found in Claes et al. (2010).

Survey of Contemporary Methods

Due to the novelty of the imaging techniques which allow to acquire digital 3D representations of skull and skin tissue, computer-assisted methods do not reach back in time as far as manual CFR methods. Vanezis et al. (1989) were the first to propose a reconstruction method based on digitized skulls. Basically, it mimics the “American method” (see above) using 3D representations of the dry skull, where virtual soft-tissue thickness dowels are being placed and the surface between them interpolated. This basic workflow has been followed by most researchers since. The main differences between protocols fall into two types: first, the way the information about the skull is represented, and second, the way the information from the database is transferred onto the skull of the specimen whose facial appearance is to be reconstructed. The following list notes these differences and cites the corresponding literature:

Differing types of skull representation (Fig. 1)

- Sparse sets of landmarks or virtual tissue dowels (Evenhouse et al. 1992; Vanezis and Trujillo 1996; Vanezis and Vanezis 2000; Claes et al. 2006a, b)
- Dense sets of feature points (Jones 2001; Paysan et al. 2009)
- Crest lines on the skull, consisting of discrete 3D coordinates (Quatrehomme et al. 1997; Subsol 2002; Subsol and Quatrehomme 2005; Turner et al. 2005, 2006)

Differing methods of template selection/generation

- A single reference mapped onto the target skull (Evenhouse et al. 1992; Vanezis and Trujillo 1996; Vanezis and Vanezis 2000; Subsol and Quatrehomme 2005; Pei et al. 2008)
- A reference derived from multiple database entries (Vandermeulen et al. 2005, 2006; Claes et al. 2006a, b; Paysan et al. 2009)

Fig. 1 Different types of skull representation. Methods: *left*: sparse set of landmarks; *center*: dense feature points; *right*: crestlines on a skull representing the surface's curvature

All of these variants share the fact that information about the complete skull as well as skin information is used for mapping a template face onto a dry skull.

Problems Arising in the Reconstruction of Extinct Hominid Species

The problems that occur when trying to apply the above methods to bone material of extinct hominid species are obvious: the central feature of semi-automated methods is an extensive database from which the estimation algorithms are derived – the database that serves to "teach" computer programs the association between bone structure and the covering facial surface shape. For extinct species there is no way to acquire a priori information about this association. When automated methods are used on non-*sapiens* bone material, the result will be a face from *H. sapiens* deformed onto the skull of another species. Even when regularization is applied in order to increase the probability of the estimation, the reconstructed face will basically be a distorted face of a modern human. In his dissertation, Claes (2007) takes this approach to a Neanderthal skull; the result appears to resemble a human face turned into a grimace fitting the Neanderthal skull, rather than the face of another hominid species.

Since computer-based algorithms rely on machine-learned correlations drawn from existing datasets, these approaches are of limited applicability to hominid reconstructions; for obvious reasons, data from the specific taxon are not available. All such approaches, when applying data from *H. sapiens*, will lead to a strong bias in soft tissue reconstruction towards modern humans.

Target Audiences of Paleoanthropological Reconstructions

Ever since the general acceptance – both in science and in public opinion – of Darwin's theory of evolution and the subsequent paradigm shift, which demoted humans from being the crown of creation to being just another species that evolved from previous forms, artists and scientists have been trying to visualize our ancestors. It is fruitful for the interpretation of these reconstructions to analyze the context within which they were produced: interpretations of paleo-/prehistoric findings are often entangled with ethnocentric preconceptions and are used implicitly or explicitly to support these preconceptions. A recent example of this entanglement is the case of the so-called Kennewick Man, involving an approximately 9,400-year-old skeleton found in Kennewick, Washington. In the absence of thorough scientific analyses, public media and various groups – among them a neo-pagan Norse cult – tried to exploit the acclaimed Caucasoid skull features of this skeleton to create bizarre theories about a prehistoric American of European descent.

Before we concern ourselves with the historical and scientific implications associated with paleoanthropological reconstructions, we will briefly discuss their intended target audiences. Generally speaking, there are two main target groups: (i) the scientific community of paleontologists and paleoanthropologists and (ii) the general public. In the process of considering these groups, we will no differentially cover the wide variety of hominid reconstruction techniques in play, from rough drawings to highly detailed dermoplastics. What matters in the present context is that all of these techniques go beyond pure documentation of fossil remains.

The Scientific Community

At first glance, visual reconstructions of extinct hominids might be considered irrelevant in the field of anthropology, because their contribution to scientific insight is marginal. Most details of visualizations, such as facial expression or life environment, are only loosely related to hard facts. As mentioned above, scientific publications tend to concentrate on scientific argumentation and quantitative analyses, only occasionally adding facial or whole body reconstructions to the text.

It would be a mistake, however, to deny any effect of reconstructions on scientific theories. These depictions are "not just visual translations of theories about past humans" (Moser 1992, p. 831) but play an important role in shaping or even creating the sociocultural background for the propagated theories. Reconstructions can be understood as hypotheses rather than illustrations (Drell 2000; Sommer 2006; Stoczkowski 2002), exploiting the power of visual language to make their point. Despite the fact that these visualizations are usually presented in newspapers, magazines, or museums conceived for a wider public, they still are able to influence the scientific community by manipulating public opinion and creating biases towards specific theories. Thus, they are fighting the same war for expert favor on a different battlefield. As will be seen below (see section "The History of Neanderthal Depictions: Between "Us" and "Them""), it can be argued that reconstructions played a crucial role in the basic understanding and definition of Neanderthals at the beginning of the twentieth century, when two diverging theories of human evolution (the multilinear vs. the unilinear view; cf. Moser 1992) both employed powerful images. Science and its results are always, at least to some extent, a product of specific social and cultural circumstances and deeply rooted within this social context. Therefore, effective control and manipulation of this social context may be essential to a theory's success, not only in the public opinion but also within the scientific community and, to a considerable degree, in the business world supporting science. Although they are not the main target audience for hominid reconstructions, scientists and their respective theories are likely to be affected by popular visualizations of human ancestors, through their integration into a common cultural environment.

Nonscientific Audiences

The field of paleoanthropology is of great interest to the general public because it deals with human evolution and hence plays a fundamental role in human self-definition and self-understanding (Trinkaus and Shipman 1993a, b). When, after the general acceptance of Darwin's theory, (Western) human self-definition and self-esteem could no longer be based on the belief that humans were the most valuable product of a divine creator, placed into a world that was centered around their needs, people needed to get accustomed to the idea of being one species among many and subject to the same biological principles as others – such as natural selection and evolution. Scientific results from the field of paleoanthropology, therefore, were deemed to be of high public interest. As an example of this evident hunger for information, one might mention the outrage of socialist media in France about the relatively high price of Marcellin Boule's 1913 monograph on the Old Man of La Chapelle-aux-Saints, which made the book unaffordable for the working class (Sommer 2006). However, scientific research reports are often hard to read for nonscientists, and the meaning and implications of the reported results can be far from intuitive. For this reason, visualizations became an essential tool for introducing theories of human evolution to the public (Sommer 2006). It is important to note here that visualizations never merely serve illustrative purposes but also, always, function as a vehicle for specific theories (Hamilton 2011). Today, just as in the last century, public access to these visualizations occurs mainly through mass media, such as television or magazines, and through public display in museums.

Museums

Museums aim both to educate and to entertain their visitors. Yet unadorned exhibitions of fossilized hard tissue remains of early hominids do not hold much interest for the average visitor: fragmented and fossilized bones bear only little visual resemblance to the specimen during its lifetime, and the non-expert public will likely find it hard to grasp the meaning and implications associated with a specific find. Also, time spent on a museum visit is limited, as is visitors' attention span. Dioramas or a body and facial reconstruction are helpful, therefore, insofar as they can convey a lot of information without demanding extensive text reading. Additionally, spectacular visualizations can generate a lot of welcome publicity, increasing visitor numbers and generating much-needed museum revenue. The most impressive reconstructions of extinct hominids are therefore commonly part of elaborate museum dioramas with fully physical, life-size elements, supporting the impression of a realism and thus implicitly proclaiming the truth of the theories underlying the design of the depicted scene. These visualizations are more or less dissociated from their causal explanations and their contextualization within a theoretical framework – that is, from much that would be essential for scientific understanding. This may lead to the integration of reconstructions into pre-existing pre- and misconceptions about human evolution, rather than explaining the current scientific models (Scott 2010).

Public Media

Public media – be it television, print media, or internet-based services – are using similar methods as museums: they distill complex theories down into brief (spoken or printed) texts accompanied by visual transcodings. Making the content easier to understand and more attractive to potential audiences demands radically simplified expositions of underlying theories, illustrated with suggestive images that rather serve to support preconceptions than to present actual research results. Another obvious problem is the fact that many media science writers are not scientists themselves, leading to distortions due to wrongly interpreted research results (Sommer 2006). There also seems to be an urgent need to accompany any news about current research on human evolution with images of reconstructions of extinct hominids. A recent example can be found on *Spiegel Online* (http://www.spiegel.de/wissenschaft/mensch/falsche-altersbestimmung-neandertaler-verschwand-frueher-als-gedacht-a-881640.html [Version from: 08/02/1913]), the online presence of a major German magazine, where information about new dating results of Neanderthal fossils is illustrated with a large image of a dermoplastic reconstruction of a Neanderthal – completely irrelevant to the text. The image merely serves as an eye-catcher, giving the reader something tangible to relate to. The original journal article cited by *Spiegel* (Wood et al. 2013) contains, of course, no such visualizations but instead presents raw data in table form and discusses interpretations; the only visual elements are maps and drawings of a specific archaeological site.

The History of Neanderthal Depictions: Between "Us" and "Them"

Soft-tissue reconstructions of extinct hominids intend to associate dry fossilized bones with the appearance the individual might have had during his or her lifetime. Since soft tissue decomposes completely after death, little evidence exists on the relationship between lifetime appearance and remaining material in extinct species (see section "Methods of Facial Reconstruction"). Visualizations therefore are necessarily subject to influences independent of the actual physical remains. Such influences might cover sociocultural bias and/or the artists'/scientists' individual preconceptions and may result in erroneous conclusions concerning the correlation between bones and soft tissue shape and texture. Especially *Homo neanderthalensis*, our most closely related hominid species both temporally and phylogenetically, has undergone multiple shifts in reception paradigms since the first finding (first in being recognized as an extinct hominid species) in 1856 in the Feldhofer Cave. The semantic range of these receptions can be summed up in the dichotomy of "*the same*" versus "*the other*," where the latter stands for a view in which close hominid relatives of man serve as the "outside" that defines the borders of humanity. From conceptions of an apish brute to ones of a relative who is only slightly different from us, all nuances have been covered by Neanderthal reconstructions based on the same physical objects: fossil bones.

Evaluations of scientific research in paleoanthropology as a field of physical anthropology are mainly performed in the social sciences, e.g., in sociology and archaeology. These follow their own scientific traditions and employ their own terminology and modes of argumentation. Besides the reconstructions themselves, the resulting insights constitute an important element in the interpretation of hominid reconstructions. Therefore, this chapter presents concepts from these fields of social science in their original terminology, in keeping with common practice in the paleoanthropological literature.

The intense focus on *H. neanderthalensis* is, of course, owed to the large number of available fossils, as well as to the fact that Neanderthals were the first species to be identified as an extinct hominid species. This makes the Neanderthals a perfect case study for inquiry into reciprocal interactions between sociocultural environments loaded with intrinsic preconceptions, individual points of views regarding the scientific interpretations of fossil remains, and the resulting multitude of divergent reconstructions of extinct hominid species. Indeed, the topic has been discussed intensively for the last 20 years. In this section we offer a survey of the central arguments and the changes in paradigm associated with different eras of reconstruction (see Table 1).

The Nineteenth Century: Early (Pre-)conceptions

When the fossils of the type skeleton of *H. neanderthalensis* were found in the Feldhofer Cave in 1865, the local schoolteacher Johann Carl Fuhlrott postulated that they belonged to a human that had lived during the last Ice Age. The temporal proximity of this finding to Charles Darwin's publication of *On the Origin of Species by Means of Natural Selection* in 1859 made it a perfect example for man's redefinition as "just" another species, subject to natural selection and evolutionary processes (Drell 2000). Auffermann and Weniger (2006) as well as Trinkaus and Shipman (1993a) claim that the Neanderthals gained their initial public and scientific image from the European archetype of the "savage man". This image was applied to the Neanderthal, who served as "crown witness" (Auffermann and Weniger 2006) for the theory of evolution that was to replace the religious view of man as the major achievement of a divine creator. Thus, the first reconstructions were applications of this archetype rather than scientifically sound approximations of the Neanderthals' actual physique.

Table 1 Timetable of Neanderthal reconstructions, listing scientific paradigm and scientific changes, influential in the specific period

Timeframe	Scientist/artist (selection)	(Scientific) paradigm of appearance	Scientific changes
1856–1909	Illustration in *Harper's Weekly*	Neanderthals as incorporation of the "savage man"	Darwin's *On the Origin of Species*
	Mouston, Friedenthal, Schaafhausen		
1909	Boule	Stooped, bent-legged, apish	Complete post-cranial skeletons (La Chapelle-aux-Saints, La Ferrassie)
1911	Keith	Modern, sensitive, wearing body decoration, manufacturing tools	
1913	Boule	The facial reconstruction is restricted to muscle tissue. The neck appears to refer to the vertebral pathologies	
1915–1918	McGregor/ Osborne	Humane appearance	
1920s	von Eickstedt, Blaschke, Weinert, Mollison	Heavily relying on Boule's paradigm. Neanderthals are suggested to be dim-witted sub-humans	
1930s	Gerasimov	Gerasimov's reconstruction is relatively human-like	Findings of more ancient hominid species (*H. erectus*, Australopithecines)
	Coon (based on the reconstruction by McGregor)	Coon indicates that dressed modern, the Neanderthal is indistinguishable from modern humans	
1950s–1980s	Gerhard Wandel, Jay Matternes/Eric Trinkaus	Neanderthals are similar to modern humans, both in appearance and behavior. "Modern spirits trapped in archaic bodies"	Confutation of Boule's analyses by Patté, Arambourg, Straus and Cave (1955–57)
			Findings in the Guattari Cave, leading to the (false) postulation of ritual cannibalism.
			"Flower burial" and social behavior deducted from findings in Shanidar Cave (1971–75)
1990s – now	John Gurche, Elisabeth Daynés, A&A Kennis	Depiction of Neanderthals as humane but distinct species. Capable of cultural achievements and human emotions	Neanderthal genome project

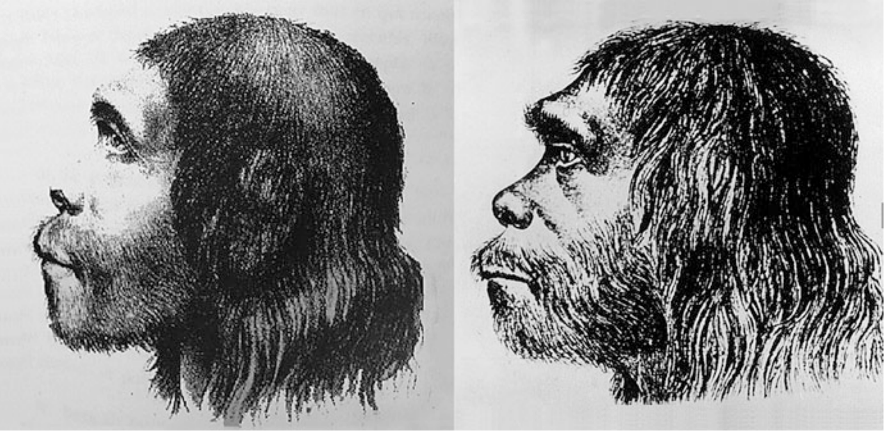

Fig. 2 Reconstruction by Schaaffhausen based on the skeleton from the Feldhofer Grotto. *Left*: Initial version from 1876; *right*: revised version from 1888

The probably first visualization of a Neanderthal was published in the magazine *Harper's Weekly* (Weltersbach 2007). It depicted a ready-to-fight male at the opening of his cave, accompanied by a dog. In the nineteenth century, evolution was often understood as a process of improvement, both physically and morally, from the more primitive to the more complex. The most advanced state was, of course, that of Western civilization, with other human societies placed below. Prehistoric life thus could be approximated by tracing the evolutionary slope "downward." The resulting body visualizations express these preconceptions without being supported by evidence from fossil bones. Other popular visualizations from this period are a romantic lithograph by Mouston (1887) (cf. Henke et al. 1996; Schrenk and Müller 2005), a drawing of a "cave dwelling Neanderthal" (Drell 2000) by Friedenthal, and two reconstructions by Schaaffhausen – the original version from 1877 depicts a mild-looking young man, whereas its revision from 1888 appears more brutish and simian (Fig. 2). Schaaffhausen's reconstructions differ from the visualizations of his contemporaries insofar as he worked closely with the skull bone, which, however, lacked any facial parts.

Boule vs. Keith: A Struggle of Views

When the geologist and paleontologist Marcellin Boule examined the remains of the Old Man from La Chapelle-aux-Saints in 1908, in which (unlike the Neanderthal skeleton from the Feldhofer Cave) facial bones were preserved, he created a stereotype that stuck to the Neanderthal throughout the first half of the twentieth century: that of a species of stooped, apish appearance, too primitive to be a direct ancestor of modern humans. Boule's views were mainly based on a faulty analysis of vertebral deformations, caused by osteoarthritis, which led him to the erroneous conclusion that the entire *species* (and not only this particular individual) lacked a spinal column suitable for completely upright posture. Some authors argue that Boule's neglect of the pathological nature of the vertebral shape was "fully cognizant" (Trinkaus and Shipman 1993a, p. 196), in order to fit the results of his analysis to his theory of human evolution: Boule was convinced that human evolution was to be understood as multilinear, forming a phylogenetic tree with dead ends. A detailed analysis of the motivations that drove Boule to his conclusions can be found in Hammond (1982).

Boule's theory stood in opposition to the common unilinear view, shared by influential contemporary scientists like Gustav Schwalbe and Dragutin Gorjanović-Kramberger (Henke 2006), who postulated a single line leading directly from earlier hominids to modern humans. At the beginning of the twentieth century, there was indeed no physical evidence available to support Boule's theory. A hominid species temporally not very distant from modern humans, yet exhibiting apish traits, would have well proven his point. Boule reported his conclusions concerning Neanderthal appearance to the French Academy of Sciences between December 1908 and June 1909, stating that most parts of the skeleton showed simian-like characteristics, while neglecting to point out a multitude of traits shared with modern humans.

The first reconstruction based on Boule's analyses was the influential drawing by the Czech artist František Kupka depicting the Neanderthal as a brutish ape, lurking ready-to-fight behind a rock with a boulder in one hand and a club in the other. The artist was completely ignorant of the large number of elaborate tools associated with the Mousterian culture that were already known at that point. The Neanderthal's body is covered with hair, and his facial expression is grim and lacks human features. The image was published in February 1909 in the French Magazine *L'Illustration* and 1 week later in the English magazine *London Illustrated News* (Moser 1992). It gained its importance from the claim to be not just hypothetical or based on the imagination but to be "*accurate*" (Reichart 1909). Moser (1992) states that this claim transformed its meaning from being an illustrative figure accompanying text to being a "scientific document" itself. By attesting accuracy, the image purports to incorporate scientific research results directly.

While it is difficult to estimate precisely the extent of Boule's influence on Kupka's rendition of the Neanderthal's body itself, it is known that he instructed the artist about details of the landscape (Reichart 1909; Moser 1992; Sommer 2006). Moser (1992) concludes that the fact that Boule allowed the image to be printed and associated with his name and research makes it safe to assume that he generally agreed with its content. When Boule finalized his analyses, published in the *Annales de Paléontologie* (Boule 1911, 1912, 1913), the stooped posture shown in the image, resulting from the (pathologically deformed) vertebral shape, served as a central argument that Neanderthals were an extinct side branch of human evolution – and therefore not our direct predecessors. To emphasize his point, Boule depicted the proposed Neanderthal posture from the Old-Man of La Chapelle-aux-Saints next to the skeleton of an Australian Aborigine; these native

Australians were, at that time, believed to be the most primitive of modern humans. The gist of the comparison is obvious: if the most primitive of living men are already that distant from Neanderthals, how can modern humanity have evolved from Neanderthals in such a short period of time? One might conjecture that, at the least, Kupka's powerful visualization influenced Boule's subsequent theoretical conclusions (Moser 1992).

Two years after Kupka's image of the brutish Neanderthal was published, Amédée Forestier, in collaboration with the anthropologist Arthur Keith, produced a reconstruction drawing which diametrically opposed Boule's/Kupka's view in the very same British magazine, the *London Illustrated News* (Keith 1911). The image depicts a male individual sitting in a homely cave by a fire, manufacturing tools from flint stone. He wears fur and a necklace. By choosing this set of accessories, Keith assigns fundamental insignias of human civilization to the Neanderthals: control of fire, production of tools, clothing and body decoration. The male figure also wears his hair braided and woven around his head. His gaze is not apish at all but shows sensitivity and diligence. The image clearly indicates that the Neanderthal is rather "the same" as we are, and not too different at all. This assemblage was of course not based on scientific analyses but tried to enforce and emphasize, once again, theoretical constructions and beliefs of its creator (Moser 1992; Weltersbach 2007). At that time, Keith, unlike Boule, was convinced that humanity had evolved in a single line of descent from earlier species, without dead ends. Ultimately, however, Boule's point of view prevailed, not least because Keith changed his opinion radically only 1 year after the publication of the article in the *London Illustrated News*, now taking up Boule's position. As Moser (1992) points out, Keith's new perspective was again expressed in a visualization, where Keith now uses the same features that Kupka/Boule assigned to their Neanderthal: those of "stooped, club-wielding brutes."

The Aftermath: An Image That Sticks

The prevailing image of the Neanderthal, drawn by Kupka/Boule, enforced the scientific conclusions concerning the Old Man of La Chapelle-aux-Saints. As a visualization of mainstream theory, it was widely accepted in the first half of the twentieth century, thus "setting the cornerstone of Neanderthal reception" (Auffermann and Weniger 2006). Most reconstruction attempts of Neanderthals during that period referred to Boule's analyses to justify their approach. Consequently, Neanderthals appear either as stooped, apish brutes or as dim-witted, degenerate humanoids that serve well to make modern humans appear noble and intelligent. One might view this as an attempt to rehabilitate humankind to its pre-Darwinian position as the crown of living organisms – this time not owing to divine creation but to its superior evolutionary status when compared to other, "inferior" hominids. A very extensive display of *H. neanderthalensis* as human's dim-witted cousin can, for example, be found in the reconstructions by Frederick

Blaschke, which accompanied the book *Neanderthal* (*Mousterian*) *Man* (Farrington and Field 1929): all his depictions of Neanderthals suggested the species to be lost in a hostile environment, incapable of surviving on its own. Von Eickstedt (1925) published an elaborate article describing minutely the steps taken to reconstruct the facial surface of the Old Man of La Chapelle-aux-Saints, in which he justified soft-tissue depth and appearance by citing Boule's monograph and emphasizing the apish and primitive nature of the species (e.g., by referring to the "chimpanzoid vertebrae"). As a result, exactly this preconception is reproduced in a modeled bust exhibiting simian traits such as massive supra-orbital rims; the latter seem to be over-exaggerated in light of the supraorbital bone structures.

A few exceptions to this mainstream paradigm for reconstructions do exist: a bust created in 1915 by the artist Howard McGregor, guided by the American paleontologist Henry Fairfield Osborne, depicts a Neanderthal that appears intelligent and sensitive, and not that different in appearance from modern humans (Auffermann and Weniger 2006). Interestingly, one of the least suggestive reconstructions is by Boule himself (Fig. 3). It only shows facial muscles, without added skin layer, texture, or further accessories. This bust actually limits itself to details of anatomical features which can be scientifically justified, without supplying additional information inspired by preconceptions and the imagination.

Fig. 3 Bust of the Old Man of La Chapelle-aux-Saints under guidance of Marcellin Boule

Coming Closer

A shift in the Neanderthal's image was slowly introduced in the 1930s, triggered by a variety of scientific and cultural changes. During the 1920s and 1930s new fossils of previously unknown, extinct hominid species, the Australopithecines, were discovered in Africa. At this point the emerging variety of *pre-sapiens* hominid species made it increasingly difficult to maintain a simplistic view of human evolution. Meanwhile, *H. neanderthalensis* appeared more and more similar to modern humans, especially when compared the older hominids (Trinkaus and Shipman 1993a). Boule's conclusions regarding stature were first questioned by the German Kleinschmidt in 1938. However, the final dismissal had to wait until the mid-1950s, when different scientists (Patté, Arambourg, Straus and Cave) concluded almost independently that the vertebral shape of the Old Man of La Chapelle-aux-Saints was actually owed to osteoarthritis rather than indicating a species-wide trait that would have led to a forward-bent stature (Trinkaus and Shipman 1993a). The most powerful visualization indicating this change in paradigm is the famous drawing presented by Carlton Coon (1939), depicting the Neanderthal reconstruction by McGregor (see above) now shaved, dressed in contemporary clothing, and wearing a hat. The image's caption states: "Although we do not know that the reconstruction of the soft parts is accurate, nevertheless the facial features were probably essentially human" (Coon 1939, p. 24). This exemplifies the radical shift from the Neanderthals being perceived as "the other" to being "similar." The simian-like appearance, closer to a beast, has turned into a species that would not be recognized as different from humans when put into our modern sociocultural context and equipped with suitable requisites.

Another reconstruction from this period that also makes the Neanderthal appear more human is a bust from 1938 created by the famous Russian anthropologist Michail Gerasimov. It is again based on the skull of the Old Man of La Chapelle-aux-Saints and has an apparently human facial expression, although it is covered with a wild mop of hair (Gerasimov 1949). Aside from becoming more human, this Neanderthal has lost his "brute benightedness" (Trinkaus and Shipman 1993a), not least due to Alberto Blanc's erroneous postulation of *ritual* cannibalism among Neanderthals. While there had already been conjectures about habitual cannibalism among Neanderthals, based on the findings from Krapina, Croatia, this time the relevant clues were associated with sophisticated burial rites. Blanc based his claims on findings from the Guattari Cave in Italy, which he failed to identify as a hyena den, instead interpreting the traces of animal teeth on the surface of hominid bones in it as the results of burial rites involving defleshing and consumption of the deceased's remains (White et al. 1991; Trinkaus and Shipman 1993a).

Despite progressive achievements in science and the resulting change in Neanderthal reception, Boule's primitive image still prevailed in popular Neanderthal depictions until the 1960s. For example, artists like Zdeněk Burian or Charles Robert Knight influenced the public image by producing reconstructions to illustrate books or accompany museum exhibitions where Neanderthals were visualized according to Boule's analyses and/or the associated drawing by Kupka (Auffermann and Weniger 2006).

Flower People

Another potential connection between scientific theory and scientists' sociocultural environment can be seen in the interpretation of the fossils from the Shanidar Cave in Iraq. Between 1957 and 1960, nine adult Neanderthal individuals and one child were found, four of them apparently killed by rockfall, the other five seemingly buried intentionally. Soil samples from the immediate vicinity of Shanidar IV contained a large amount of wildflower pollen. Solecki (1971) interpreted this as evidence for a sophisticated burial ceremony, involving large amounts of flowers. The subsequent monograph about his research was titled *Shanidar*: *The first flower people*; it fit neatly into the general sociocultural context of the late 1960s and early 1970s. Burial rites which seemed to be similar to our own made it easier to accept Neanderthals as close relatives. Thus Solecki (1975, p. 880) writes: "The discovery of pollen clusters of different kinds of flowers [. . .] furthers our acceptance of the Neanderthals in our line of evolution." He further states that this indicates that the Neanderthal "had 'soul'". More recent evaluations doubt these interpretations and suggest alternative causes for the accumulation of flower pollen, for example, that they had been carried in by rodents (Sommer 1999). Another important – and undisputed – finding from Shanidar, however, is the fact that Neanderthals seem to have cared for their handicapped. Shanidar I shows signs of severe skull trauma, leaving him probably half-blind, combined with a multitude of healed postcranial bone fractures, and with an unusable right arm. As the fractures were not fatal but had healed instead, his group members must have taken care of him, providing food and assistance so that he could master his everyday life. These inferred acts of mercy and *humanity*[*!*] made the Neanderthals more presentable as close relatives with whom we share similar moral standards. Solecki subsumed this impression under the extremely simplifying formula of the Neanderthals having a modern spirit trapped in an archaic body (Solecki 1975). He prompted a shift in the argumentation from mere interpretation of skeletal remains to conclusions concerning the Neanderthals' *behavior* (Trinkaus and Shipman 1993b).

Many reconstructions from this period depict the Neanderthals as human, with an appearance almost indistinguishable from that of modern humans; examples are the "squatting Neanderthal" by Gerhard Wandel from 1962 and the reconstructions by Jay Matternes, depicted in Henke et al. (1996).

Readjusting the View

Recent studies have led to a more refined picture of Neanderthals as hominids very similar to modern humans yet distinct in their morphology. Their differing morphological features were most likely adaptations to the environment of Upper

Paleolithic western Europe. While some of these features are very distinct from those of modern humans, many others are not. Additionally, advances in scientific methods, such as genetic sequencing of ancient DNA, have contributed greatly to our understanding of the phylogenetic relation between modern humans and Neanderthals. Studies have proved genetic differences to be relatively small. Indeed, there likely was some interbreeding with early European *H. sapiens* (Green et al. 2010). At this point it is fair to conclude "that the humanity of Neanderthals cannot be denied anymore" (Auffermann and Weniger 2006, p. 188).

As a result, most recent reconstructions tend to visualize Neanderthals as very similar to modern humans (Henke et al. 1996; Koepfer and Gurche 2003). Many artists make use of latex-based dermoplastic that allows the creation of astonishingly lifelike appearances, giving the reconstructed specimens personality by sculpturing gestures and emotional facial expressions (cf. the reconstructions of laughing Neanderthals by Alfons and Adrie Kennis or of an Ante-Neanderthal male called "The Thinker" by Elisabeth Daynès). The resulting implications of similarity to modern humans with respect to emotions and their expression are not indisputable: recent comparative genetic analyses (Green et al. 2010) suggest genetic differences on DNA sequences associated with nerve growth and brain functions (one of them implicated in autism). The reconstructed details mentioned above are in no way supported by the available material but are subject to the artists' imagination and creativity. Here again, reconstructions of extinct hominids serve as transport vehicles for a prevailing scientific view – in this case the modern view that Neanderthals are a human species, capable of the same range of emotions as we are, distinct in morphological detail but with an overall appearance not that different from our own. Since the time of Coon's Neanderthal reconstruction it has also become common to dress reconstructions as modern humans, to emphasize the fact that they would be indistinguishable from us if we were to meet them in our own, modern world (e.g., Auffermann and Orschiedt 2006).

Conclusion and Outlook

Although various virtual techniques have arisen during the last decades, reconstruction methods today still rely more on craft skills and observer experience than on exact calculations. However, computational methods are beginning to play an important supporting role. For example, recent studies explore the combination of Geometric Morphometrics and Finite Element Analyses (O'Higgins et al. 2011; O'Higgins and Milne 2013; Bookstein 2013). Geometric Morphometrics (GMM) is an approach that quantifies the shape of complex geometrical structures based on the extrapolation of well-defined coordinates (landmarks) relevant for the structure's shape. Finite Element Analysis (FEA) is an appropriate method to analyze the mechanical properties of complex structures (Richmond et al. 2005), by partitioning their geometry into a finite number of elements. Technically, FEA is a numeric procedure to solve partial differential equation systems occurring in specific physical problems. The method relies on experimental data, e.g., from compression or tensile testing, to estimate the parameters associated with the material in question.

Since the beginning of the twenty-first century, Finite Element (FE) modeling has been applied to address biomechanical issues in anthropology by assessing functional shape characteristics of anatomical structures (e.g., Witzel and Preuschoft 2006). This approach has become a common tool in paleoanthropology for mapping morphological traits onto biomechanical properties, which, in turn, can help to formulate valid hypotheses regarding specific adaptations. To create accurate FE models from fragmented fossils, GMM can provide solutions to establish biologically valid correspondences (represented by dense sets of homologous landmarks) between the shapes of recent species and their extinct relatives. These correspondences allow the deformation of a FE model generated from recent species onto the fossil remains. The generated model can be assumed to be close to the non-existent original. As a result, it is possible to create FE models of extinct species. Additionally, the method allows correction for intra-species variation, as an initial GMM analysis of a sufficiently large sample of the extant species can help identify those specimens close enough to the sample's average to serve as suitable representatives of the species.

The following examples present a selection of paleoanthropological studies which have derived interesting results from application of FEA to fossil material.

Strait et al. (2005, 2007) investigated the biomechanical benefits of increased palatal thickness – one of the most significant synapomorphies in *Paranthropus*, assumed to be related to mastication. They used CT data to generate a model of the skull of *Macaca fascicularis* in order to conduct bone-strain experiments for validation purposes. Based on this model, muscle forces relevant to mastication were simulated by FEA. To verify their hypothesis, the authors designed a second model with increased palatal thickness. The simulated output suggested that increased palatal thickness leads to a decrease of stress in the palate. These results indicate that palatal thickness has functional consequences related to mastication, and that increased thickness might be considered an adaptation to hard food.

A more recent study applies FEA methods to estimate bite forces and the muscular forces involved, comparing the results from extant primates and extinct hominid species, such as *Australopithecus africanus* and *Paranthropus boisei* (Wroe et. al. 2010). Along these lines, analyses concerning the structural rigidity of the facial skeleton may provide insight about diet and dietary adaptations of extinct species (Strait et al. 2009, 2010, 2012).

While there are presently no approaches that directly involve FEA in hominid reconstructions, it appears that results obtained by application of these methods may provide additional details regarding specific biomechanical adaptations that are probably reflected in their muscle mass, which in turn shapes physical appearance.

Based on the above examples it can be expected that technical advances will lead to a higher degree of documentation, objectivity, and reproducibility in future reconstructions. The more scientific aspects will be incorporated into the reconstruction process, the more likely it is that reconstructions will be accepted within the scientific community.

Abstract

Paleoanthropology is primarily rooted in the study of fossils and the analysis of sites. Dependence on these resources leads to challenges resulting from difficulty in gaining access to scarce, precious, and sometimes overprotected materials and from issues of control over field sites. The development of virtual paleoanthropology can sometimes be a way to partially solve the first problem. However, on some occasions, the access to and utilization of numerical data has also become an issue of dispute. In parallel, recent advances in studies focusing on microstructures, isotopic composition, and paleogenetics require direct sampling of the fossils. The trend in paleoanthropology is to integrate approaches from different scientific fields, and this is especially visible in developmental sciences, genetics, and environmental studies. In the meantime, dealing with

human evolution remains a sensitive topic, subject to clear ideological and religious biases. The interest of the media and of the public in this science does not always contribute to an objective approach to the questions. Finally, among other issues, the expansion of paleoanthropological studies in developing countries must depend on a decline in its colonial image.

Introduction

In many respects, paleoanthropology is a paradoxical science. Although it addresses the oldest origins of humans, the discipline itself developed quite recently in the history of science. The first fossil hominid specimen on record, an immature Neanderthal skull, was discovered in 1830 in Engis (Belgium). However, it was not until the end of the nineteenth century that certain fossil specimens were truly accepted by the majority of the scientific community as evidence for the evolutionary process that gave birth to the human species. Although very significant discoveries occurred during the first half of the twentieth century and provided the basic framework for paleoanthropological studies, the last three decades of that century witnessed a spectacular increase in the available fossil record as well as in major advances in the knowledge of past environments and the chronological background of human evolution. Moreover, the birth of paleogenetics added a new dimension to the analysis of relationships among fossil hominid species. The current state of the discipline results not only from methodological progress but also from a major effort of field research. For the public, the media, and students, it is always a matter of amazement, and sometimes of criticism, to realize that the field of paleoanthropology is such a changing terrain. If prediction is always a difficult exercise, in science as in many other domains, it is even more challenging in this particular science, which is relatively newly born and still rapidly evolving.

Another distinctive aspect of paleoanthropology lies in the fact that the study of fossil specimens remains the core of the discipline. These are rare and precious objects. It is often emphasized that for the study of some extinct groups, the specimens are fewer than the specialists who analyze them, and sometimes the competition is harsh. After an undefined period during which they remain under the relatively rigid control of individuals or groups responsible for publishing descriptions of them, they are usually curated in museums or other institutions. While the specimens are in their possession, the curating institutions may also restrict access to the fossil specimens, emphasizing their conservation rather than their scientific study. On the one hand, there is therefore strong pressure to consult the fossil material, and on the other, growing restrictions that result from a multitude of reasons that range from the desire to maintain scientific monopoly to the legitimate policy of protecting fragile and valuable objects. In parallel, new techniques for the study of the specimens have been developed. However, while these new methods sometimes resolve issues, sometimes they generate new difficulties.

Virtual Paleoanthropology

Since the 1980s, new techniques in medical and industrial imaging have revolutionized the fields of human paleontology and physical anthropology (Wind 1984; Wind and Zonneveld 1985; Zonneveld and Wind 1985) allowing the development of what has become commonly called as "virtual paleoanthropology." The growing use of computed tomography as well as industrial imaging techniques (microtomography and laser scanners) has allowed the production of 3D images of fossil specimens. Combined with stereolithography and other techniques of 3D printing, these virtual representations have opened a number of new possibilities for the analysis of the specimens. Most notable among these are:

- Virtual extraction and reconstruction (including correction of plastic distortions) (Kalvin et al. 1992; Zollikofer et al. 1995; Ponce de León and Zollikofer 1999)
- Precise quantitative analysis of inaccessible internal structure (including tiny structures, such as middle and inner ears, bony tables, and vascular foramina) and their comparison with living references (Zonneveld et al. 1989; Hublin et al. 1996; Spoor et al. 1996)
- 3D morphometric analysis with the development of new mathematical tools (Harvati 2002)
- Modeling of ontogenetic processes, biomechanical properties, and of evolutionary changes themselves (Ponce de León and Zollikofer 2001; Mitteroecker et al. 2004; Gunz et al. 2010; Freidline et al. 2012)

Growing evidence suggests that, with increasing frequency, the anatomy of fossil hominins will be systematically studied not from the specimens themselves but from virtual representations. Principal among all the new possibilities opened by virtual paleoanthropology is the reduced need to manipulate real objects. Consequently, these techniques should be welcomed by many curators. However, they also raise new questions. One is related to the quality of the data. Until recently, the CT scanners that have been used to acquire the data were primarily those available in the medical environment. Although they evolve rapidly, machines of this type have their own limitations and are not specifically designed to explore fossilized specimens filled with dense sediments. The resolution of the 3D pictures produced in this way does not allow for the assessment of fine structures at an appropriate resolution. In recent years, large museums curating fossils, as well as research institutions, have been increasingly equipped with microCT scanners, initially designed for industrial uses, which provide high-resolution data in the order of magnitude of a micron or even under. Imagery techniques based on the use of synchrotrons such as the face contrast allow the study of microstructures otherwise inaccessible to the analysis in a nondestructive way (Tafforeau and Smith 2008).

Among the pitfalls related to the development of virtual paleoanthropology is a shift from a situation where access to the fossil specimens was difficult to a situation where access to the numerical data is even more challenging. Curators are sometimes reluctant to allow repeated acquisitions of these numerical data, while the techniques and equipment evolve rapidly. Often, the data are monopolized by those who acquired them initially, and they are hard to upgrade. In the long term, databases may develop in some institutions and on the Internet (Hublin 2013). To date, however, the development of such databases has faced insuperable difficulties. The commercialization of some of these data by the institutions concerned, or the simple trading of data between teams, will remain, for some time, the only alternative.

Another concern relates to the possibility that repeated irradiation of fossil material may alter biomolecules such as ancient DNA. Although this problem has been to date little investigated, it may in the future lead to necessary choices in priorities regarding the analysis of recent fossil material.

Into the Matter of Bone

In a somewhat opposite direction to virtual paleoanthropology, there are a number of other new approaches that have been developed in the fields of human paleontology, physical anthropology, and archaeology. Such techniques were initially based on rather invasive analyses of the specimens, inherited primarily from histology and geochemistry. However, with the rise of non- (or less) destructive methods, this field is rapidly expanding. In the future, study of the actual fossil remains will likely be reserved for the kinds of analyses that cannot be performed on virtual representations. At present, such analyses include, on the one hand, histological approaches mainly addressing bone and tooth microstructures and, on the other hand, chemical analyses addressing either geochronological or paleobiological questions.

Microstructural studies have developed mostly in the field of dental anthropology. The recognition of different types of incremental mineralized structures in the dentine and the enamel since the middle of the twentieth century has led to systematic analyses of their variation in extant and fossil primates (Dean 1987; Stringer et al. 1990; Lieberman 1993; Zhao et al. 2000; Dean et al. 2001; Martin et al. 2003; Schwartz et al. 2003; Smith et al. 2003). This development has been made possible by the improvement of technical equipment such as the scanning electron microscope, the confocal microscope, and computer-assisted microscopy for 3D visualization. The interest in these studies comes from the knowledge that microstructures could be the main, if not the only way, to assess life history in extinct species (Fitz Gerald 1998). This issue has been given increasing attention in an evolutionary perspective since the genetic bases of development have become better understood and their importance for evolutionary changes better appreciated. Future research in this direction will certainly include extensive work on modern variability and more experiments to assess the biological significance of accretional microstructures and their relevance for calibrating the growth patterns of extinct species. Although it is possible to work on externally visible features, such as perikymata (Ramirez Rozzi and Bermudez de Castro 2004), a drawback of these methods is the necessity of slicing precious fossil specimens to analyze fine internal microstructures. However, the technique of thin slicing has greatly improved, and it is possible today to “rebuild” a specimen after analysis following minimal destruction of tissue. In the future, new techniques of imaging may also partly resolve this problem. Although, to date, it remains a very expensive technique, the use of synchrotrons allows access to bone and tooth microstructures without destruction (Tafforeau et al. 2006).

Chemical analyses of fossil specimens have been aimed at reconstructing paleobiological features and are mostly concerned with the extraction of organic molecules. Nonorganic chemical properties of the fossil remains are primarily relevant to the determination of their geological age and are marginally useful in addressing paleobiological issues. To date, DNA and collagen have been the main targets of the research on ancient biomolecules. Techniques based on the use of restriction enzymes have allowed the duplication and subsequent sequencing of tiny and rare fragments of DNA chains. So far, this work has been based primarily on the analysis of mitochondrial DNA, which is smaller and much more abundant than nuclear DNA. The sequencing of a fragment of mitochondrial DNA of the Feldhofer 1 (Neanderthal) specimen in 1997 opened a new era of paleoanthropological studies (Krings et al. 1997). Future development of this research will involve the reconstruction of the entire sequence of the mitochondrial DNA in specimens such as Neanderthals. With the development of new techniques, future work will also address the issue of nuclear DNA in fossil hominids. However, the natural degradation of DNA under given physical conditions imposes a chronological barrier that today seems oddly unsurpassable. Another serious problem in paleogenetic studies comes from the potential for contamination. Paradoxically, the DNA of modern and relatively recent humans remains very difficult to identify as genuine fossil DNA and to distinguish from subsequent contamination (Serre et al. 2004). Studies on the taphonomic processes affecting the deterioration of DNA chains in archaeological or geological deposits may provide an answer to this problem.

Isotopic compositions of the mineral portions of hominid fossils have been used to assess biological issues. These studies face the difficult questions of the taphonomic transformation of the chemical composition of fossils in geological layers (Radosevich 1993; Fabig and Herrmann 2002). Most researchers have thus focused on the more stable component of bone, the protein collagen (Schoeninger 1985; Ambrose 1986; Bocherens et al. 1991, 1997; Richards et al. 2000, 2001). Collagen has been the primary source for the analysis of stable isotopes such as oxygen, nitrogen, and carbon. These isotopes are fixed in the living tissues antemortem, either at an early stage of individual development (e.g., in the teeth) or at some time before death. They are an essential source of information about the environment and the diet of individuals during their lifetimes. One constraint of these studies is that they are limited by the long-term preservation of collagen. For older hominins, carbon fixed in the mineral part of the dental tissues has also been used to investigate what type of plants (C3 or C4) herbivores and their predators extracted their food. One can expect that, as with the study of recent archaeological series, such analyses in the future will bring unexpected knowledge of issues such as migration, seasonality, or even mating strategies among relatively ancient hominids. New research into extracting other longer-surviving proteins, such as osteocalcin, has the potential to provide material for isotopic studies for much older material. An interesting development comes from the combination of microstructural studies and isotopic analyses to assess fine timescale changes in the diet or the environments of fossil individuals (Humphrey et al. 2004). The extension of isotopic analyses to new elements may also lead to interesting developments in this field. For example, sulfur isotopes in collagen, along with strontium and oxygen in minerals, can tell a lot about migration and movement patterns (Nehlich et al. 2010). Isotopic studies (especially of oxygen) will also likely contribute to a much greater knowledge of past environmental conditions and their rapid variation in continental environments, a topic that so far remains much less explored than in oceanic environments and the ice caps.

Understanding Evolutionary Processes

The reconstruction of the evolutionary history of hominoids, and more specifically of fossil humans, has for a long time focused primarily on taxonomic and phylogenetic questions. Important methodological progress has been made in this field during recent decades. In particular, the use of cladistic approaches has provided a better theoretical background. Although these approaches also have their own limitations (Trinkaus 1990), they have become indispensable for assessing the significance and the polarity of features. However, it should be underlined that the development of mathematical techniques to analyze size and shape, including 3D morphometrics, has at times led to the regression of some studies to a precladistic stage. The emphasis placed on the shape distances should not lead researchers to forget that morphological similarity is not a reliable way to analyze phylogenetic relationships when the polarity of the features is not taken into account.

A major problem, discussed extensively in recent years, resides in the features used by paleoanthropologists for cladistic analyses. These discussions have focused on features' significance and relationships either to genetic determinism or to environmental conditions and behavior or to an interaction between the two. Beyond these discussions lie issues such as the independence of such features in their development and their homology when one passes from one species to another (Lieberman 1999; Wood 1999). These are critical questions for the analysis of the fossil evidence and the reconstruction of phylogenetic relationships from a parsimony perspective. However, one may be reasonably optimistic in this matter, as experimental data and a better understanding of the precise genetic and epigenetic mechanisms underlying the development of features will resolve these questions. These may also bring answers to related problems such as the discrepancy sometimes underlined between biomolecular evidence and phylogenetic reconstructions based on the analysis of morphological features of the phenotype (Collard and

Wood 2000; Strait and Grine 2004). They may also bring new light to the debate surrounding modular versus integrative models in the biological development of extinct organisms (Wagner 1996; Wagner and Altenberg 1996; Williams and Nagy 2001; Winther 2001).

As far as the recent stages of human evolution are concerned, it is reasonable to expect that taxonomic and phylogenetic issues will become of minor interest in the future as the main taxa are identified and their phylogenetic relationships understood. However, better understanding of variability, not only in extinct taxa but also in living forms, remains a crucial issue. Although some have predicted the decline of such anatomical studies, it is still striking to contemplate the lack of knowledge of the variability in living humans with respect to many features commonly used in paleoanthropological research. After several centuries of anatomical studies, longitudinal data on the growth and development of many anatomical features is still desperately needed. This lack of data is even more dramatic when one considers the populations of living apes, the closest relatives of humans in the animal world; most of them will likely become extinct in the wild before they have been properly studied.

Research may focus more on paleobiological issues. Changes in growth and development processes during life history, in terms of timing and pattern, are increasingly seen as powerful mechanisms to explain evolutionary changes. Studies of extinct species consider this dimension with increasing frequency, and developmental trajectories will hopefully be identified for different taxa as will the effects of epigenetic phenomena. This is, of course, dependent on an increase in the available paleontological material and also on a greater interaction between paleoanthropology and developmental genetics. 3D morphometrics and other mathematical tools have been identified recently as powerful tools for the reconstruction of those developmental trajectories that can sometimes be modeled (Ponce de León and Zollikofer 2001). Establishing reliable tools to assess the calendar ages of immature individuals in the fossil record is of crucial importance in this matter (Coqueugniot et al. 2004), and developing studies of skeletal microstructure seems an inevitable way to address this problem.

Other aspects of the biology of extinct species might also become accessible through progress in the extraction of biomolecules such as proteins. Osteocalcin has recently been extracted from Neanderthal remains and sequenced (Nielsen-Marsh et al. 2005). In the future, extraction of proteins or lipids from ancient material may even shed new light on the physiology of our ancestors and cousin species. It should also be noted that the extraction of ancient proteins and their sequencing may be extended much further back in time as some of these molecules seem to resist taphonomic degradation much better than DNA.

In recent years, paleodemographic questions have become more and more interesting to paleoanthropologists. Topics such as life history and longevity are critically important to understanding the biological and social adaptations of ancient groups, as well as to addressing questions of learning time during individual life and the transmission of knowledge from one individual to another. Other paleodemographic parameters that appear to be important are the questions of population densities in given areas in a geological time frame and their possible catastrophic variation in relation to environmental changes. Although paleodemographic parameters have long appeared unreachable (Bocquet-Appel and Masset 1982, 1996), different methods of evaluating size fluctuation in ancient populations have emerged from genetic or paleogenetic studies. In addition to providing new understanding of phylogenetic relationships, gene flow between groups, and differences in gene coding for some characters in ancient hominids, paleogenetics has also introduced a new way to assess group size through time in ancient humans (Meyer et al. 2012). Although paleogenetic studies on the Neanderthals did not revolutionize views of their phylogenetic relationships, they did bring a new way to assess genetic variability in ancient populations and, consequently, population size changes (Currat and Excoffier 2004; Serre et al. 2004). The animal models appear to be a tempting alternative for testing demographic fluctuations and their effects on genetic variability during the recent periods of the Pleistocene (Orlando et al. 2002). Such knowledge will allow a better understanding of the possible effects of demographic crashes and genetic bottlenecking on evolutionary processes themselves, as well as the relative roles of genetic drift and natural selection. Combining isotopic analysis and microstructural studies will also allow the garnering of information such as the weaning age of fossil individuals. A fine knowledge of climatic environmental changes, sometimes perceptible on the scale of one human life, also brings new light to the way human populations have adapted biologically and culturally. In this perspective, a better integration of biological and cultural evidence seems necessary for a more thorough understanding of human evolution.

Chronology

The determination of the geological age of fossil hominids is central to paleoanthropological work. Until recently, such determination has centered on the application of radiometric methods to the archaeological context of the discoveries. Although available methods require improvement in their precision and in their calibration, their direct application to hominid specimens also represents major progress, especially for specimens anciently discovered and/or for which the context is unknown or inaccessible. Once more, the development of such approaches has been limited initially by the destructive aspects of these investigations. However, the emergence of new techniques, such as laser ablation, makes the analysis of light or heavy isotopes on precious specimens almost completely nondestructive. In the future, these studies may be applied routinely and become the best way to establish a precise chronology.

As far as the radiometric methods based on C^{14} disintegration are concerned, the development of mass spectrometry has allowed the direct dating of fossil specimens by requiring only small amounts of matter for analysis. Since 2009 the calibration curve for C^{14} dates has been extended back to 50,000 BP, which makes the method more reliable in this time range that is of such crucial importance to the history of modern human dispersal (Reimer et al. 2009). In addition to calibration, contamination remains a major problem and the origin of the sampled carbon must be securely established; methods such as the ultrafiltration of the collagen may allow for the control of this factor. Another future development will be to work with organic carbon from biomolecules such as amino acids that can be identified as genuine fossil molecules belonging to the extinct organisms from which they were extracted. In practice, all this means that many C^{14} dates acquired during the last decades may become meaningless because of the limitations of the techniques used to establish them. Large databases that have been built to process these dates by the thousands and that provide a picture of biological and cultural evolution of humans, especially at the time of the replacement of Neanderthals by modern humans in Europe, can be improved by a critical assessment of the compiled dates. However, the screening process has provided very contrasting pictures and has not satisfactorily solved all questions. This probably results from some bias in the selection process of the data retained, partly depending on the views that different authors have on the evolutionary and peopling processes involved. Eventually, such databases may become obsolete and will need to be rebuilt with more reliable geochronological information.

Picture of an Ancestor

Every human society has built up physicotheological explanations to deal with the question of its origins. In the historical record, such explanations have been furnished by religions and mythologies, but from the middle of the nineteenth century, western societies substituted a scientifically based explicatory model for biblically based explanations. The question of human origins became the concern of scientists rather than priests. However, in 1863, T. H. Huxley, a major supporter of Darwin's views, wrote: "The question of questions for mankind, the problem which underlies all others, and is more deeply interesting than any other, is the ascertainment of the place which man occupies in nature, and of his relationship to the universe of things. Whence our race has come; what are the limits of our power over nature; to what goal are we tending are the problems which present themselves anew, and with undiminished interest, to every man born into the world" (see Huxley 1863, p. 71). Almost 150 years later, this issue is still not free of ideological, if not metaphysical, constraints. This may partly explain why the public has developed such an interest in this field of science. Aside from the inherent attraction of pictures of extinct worlds, any piece of evidence in paleoanthropological studies also becomes a matter of opinion and feeling, even for non-knowledgeable audiences. Prehistory is also consistently the topic of novels, films, and documentaries in which science always has to defend itself against fantasy (Sommer 2006, 2007; Stoczkowski 1994). Museums and educational centers have become incredibly successful with this subject, showing increasing sophistication in their ways of responding to the demands of the public for pictures or 3D reconstructions. Although some of these reconstructions are produced today (Fig. 1) using advanced techniques, they have their own limitations. It is certainly possible to provide reasonable

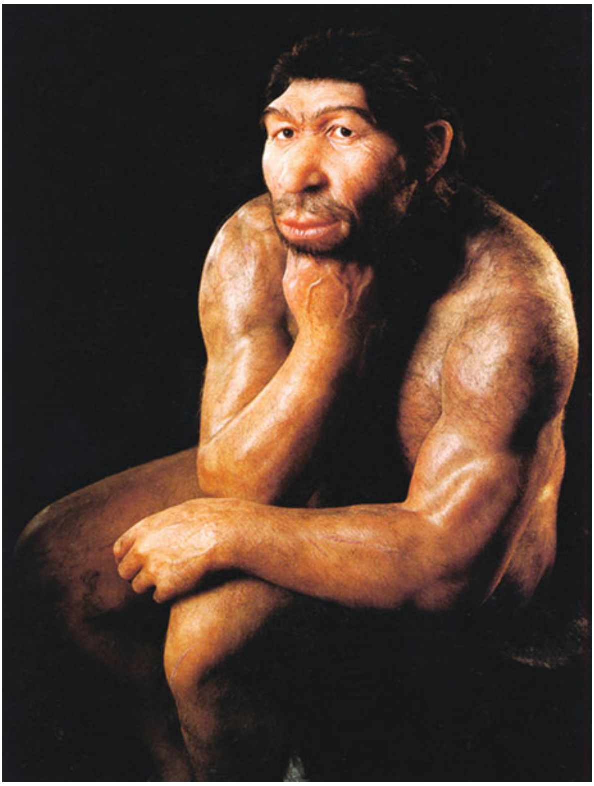

Fig. 1 A reconstruction of a pre-Neanderthal at the Landesmuseum für Vorgeschichte (Halle, Germany). Accurate methods have been developed to reconstruct soft tissues in fossil hominids. However today, like in the past, the picture of ancient humans primarily remains a projection of human fantasies

reconstructions of the general anatomy of well-known fossil species. However, to date, many fine anatomical details, such as skin, hair, and eyes, remain beyond the range of scientific assessment. Unfortunately, they are also of crucial importance to the way other species of humans appear from a modern perspective. The "scientifically based" reconstructions of fossil hominids filling the museums in Europe and America may say much more about the way human diversity is perceived than about the actual aspects of these hominins. In this respect, the progress of the reconstructions since the beginning of the twentieth century may be more limited than is often assumed. Underlying notions of humans as belonging to different species, and possibly contemporaneous in the past, are difficult to integrate, not only for the public but also for scientists from sister disciplines. The humanist framework within which the human and social sciences developed in universities may explain the difficulty that cultural anthropologists and archaeologists, attached to the notion of "uniqueness" of the human being, face in dealing with notions such as ape cultures or the multispecific nature of hominins. More generally, in the post-Second World War era, new conceptions understandably developed around human diversity that provided an ideological framework to which paleoanthropological evolutionary models had to adapt. The questions of Neanderthal nature and abilities and their relationship to extant humans, in other words the last well-documented divergence in the human phylogenetic tree, is one arena in which science and ideological preconceptions have clashed in a complex way.

In this interaction between scientists and the public, the media play an important role. There are many reasons why scientists need to communicate with the public. One is that the interest of the public partly justifies society's investment in this field of pure research. Another may result from more personal reasons. For a department, for a team, for an individual, the visibility of the scientific results obtained becomes increasingly important as it impacts on possible personal promotion and political decisions to support this field of research in general, or a project in particular. Thus, the scientist and the reporter face each other in a dialogue where each needs the other. The reporter needs material for exciting articles; the scientist needs a reporter for publicity (Henke 2010). In the past few decades, this interaction has become increasingly important and has sometimes led to undesirable effects. One obvious pitfall is that the public and reporters are more interested in some issues than in others. Those problems most debated in the media may be of limited interest to the scientific community, and vice versa. Sex between Neanderthals and modern humans is an example of a question universally addressed to paleoanthropologists, and one danger is that, in the need to be well represented in the media, scientists might be led to pander to such questions or even to develop research interests geared to public attention. It is amazing to see how well-developed press services have become, not just in institutions dedicated to public education and communication but also within research structures as well.

Recently these interactions between scientists and the media have entered a new dimension, as personal issues or rivalries between individuals have become of themselves a matter of interest for the press. High-profile international scientific journals have developed "people sections" that deal almost exclusively with these subjects. Reporters have therefore become part of the scientific debate and actors in rivalries, by promoting opinions and sometimes by fueling controversies and conflicts in a way designed to make their articles more exciting.

The Unbalanced Ecology of Paleoanthropology

Paleoanthropology is based on the study of specimens to which access may be difficult. It is also based on sites and fieldwork. The result is that it can be a highly territorial activity, to an extent unequaled in other fields of science. Indeed, aside from scientific problems, the paleoanthropologist must also face a series of political and ethical issues. Although specimens discovered and published a long time ago should be fully accessible to the scientific community, this is not always the case. The situation is even more complex regarding specimens soon after their discovery and/or after a partial description. So far, the scientific community has not established a consensus on resolving such questions. The discoverer of a new specimen has a scientific and moral right to it and is granted priority in providing a scientific analysis of this material, alone or in collaboration with other specialists. However, this well-accepted notion is often blurred by complications. One such complication can result from the multiplicity of the discoverers involved and from lack of agreement at the time of the discovery, or later. And many discoveries occur during the course of archaeological excavations conducted by teams that were not anticipating the possibility of hominin discoveries. Another problem can result from an abusive extension of the time spent between a discovery and the publication of a reasonably comprehensive description of it. The competition that is natural in science is sometimes displayed in a negative form, such as preventing challengers from accessing material, which may be used as a more efficient way to surpass them than producing better scientific results.

Similar situations have developed with respect to site and field access. Most commonly, research teams obtain the monopoly of the study of one site or a geographical area for a certain length of time in order to conduct a defined scientific program. However, apart from this formal arrangement, there are a number of situations where informally and based on political influence, tradition, or nationalistic issues, institutions manage to secure a geographical domain of influence. This is often the case when excavations or field operations are conducted by scientists from western countries in less developed areas. Often, this is facilitated by the fact that the studied areas are located in countries lacking indigenous research in the field of paleoanthropology and/or scientists trained in this discipline. In such cases the work is conducted under the authorization of local administrations that are primarily preoccupied by the conservation of their national patrimony. Here again, different institutions or scientific communities may develop some level of competition in guaranteeing their access to the field. Different countries have developed different regulations restricting the exploitation of archaeological and paleontological material. Situations in which fossil specimens can simply be transferred from the country of their discovery to scientific institutions or museums in Europe or America have almost completely disappeared today.

Many scientists have felt compelled to develop balanced collaborations with the host countries in which they conduct their research, in particular, by helping with the conservation of the material and with the training of local scientists. Furthermore, many countries outside of the western world have managed to develop their own programs and scholars, and the trend is more and more to develop joint projects, although a very unequal equilibrium in terms of financial contribution and/or scientific expertise can lead to bitter conflicts. Although the time of scientific colonialism is over, and in an ideal world, fossils and sites should be accessible to “everyone,” this ideal situation is still far from being reality. Archaeological and paleontological materials are considered as part of the national patrimony in most counties, yet the future of the field lies in fair and fruitful international collaborations.

Conclusion

In summary, although the development of virtual paleoanthropology has opened new venues to access the fossil evidence and to study it, paleoanthropology remains a science primarily centered on objects and sites to which access for researchers is far from being guaranteed. In the last two decades, the field has witnessed spectacular methodological progress providing new insights into the processes of human evolution. However, the question of the origin and nature of humankind remains a sensitive issue. In addressing these questions, science is challenged by many preconceptions.

Primate Evolution and Human Origins

Primate Origins and Supraordinal Relationships: Morphological Evidence

Mary T. Silcox, Eric J. Sargis, Jonathan I. Bloch, and Doug M. Boyer

Contents

Abstract

There are five major scenarios that have been advanced to account for the early events in the origination of the order Primates: a transition from terrestriality to arboreality, the adoption of a grasp-leaping mode of locomotion, the evolution of features for visual predation, an adaptation to terminal branch feeding occurring

during angiosperm diversification, or a combination involving terminal branch feeding followed by visual predation. These hypotheses are assessed using both neontological and fossil data. Of the five scenarios, the angiosperm diversification hypothesis is not contradicted by modern data and is found to be the most consistent with the fossil record. In particular, the evolution of features for manual grasping and dental processing of fruit in the earliest primates (primitive plesiadapiforms), and the subsequent development of features for better grasping and more intense frugivory in the common ancestor of Euprimates and Plesiadapoidea, is consistent with a close relationship between early primate and angiosperm evolution. All the other scenarios are less consistent with the pattern of trait acquisition through time observed in the fossil record. Consideration of non-euprimates (e.g., scandentians and plesiadapiforms) is found to be essential to viewing primate origins as a series of incremental steps rather than as an event.

Introduction: What Is a Primate?

Perhaps the most fundamental issue facing students of primate origins can be summarized by a simple question: what *is* a primate? A clear concept of the diagnosis and taxonomic composition of Primates is essential to providing a coherent understanding of when and why the order separated from the rest of Mammalia. Attempts to define the order Primates have typically started by considering which features of modern primates are present in multiple primate species and are distinctive relative to other mammals. Four major adaptive complexes of traits have been recognized as characteristic of primates of modern aspect (=Euprimates Hoffstetter 1977; see Mivart 1873; Le Gros Clark 1959; Napier and Napier 1967; Martin 1968, 1986, 1990; Szalay 1968; Cartmill 1972, 1992; Szalay et al. 1987):

1. Traits associated with grasping. These include relatively longer hand and foot phalanges, a divergent thumb and big toe, and digits tipped with nails rather than claws.
2. Traits associated with leaping. Although such features have been lost in some extant primates (e.g., *Homo sapiens*), the most primitive euprimates have leaping characteristics that include hind limbs that are long relative to the forelimbs and modified ankle bones.
3. Traits associated with improvements to the visual system. These features include large eyes, convergent orbits, and a postorbital bar or septum. The larger and more complex brain in modern primates compared to other euarchontans may also be associated, in part, with this complex (Barton 1998; Kirk 2006; Silcox et al. 2009b, 2010a). A smaller apparatus for the sense of smell is presumably associated with an increasing reliance on vision as well, leading to a short snout and proportionally reduced related areas of the brain (Silcox et al. 2011).

4. Dental traits associated with herbivory. Relative to specialized insectivores, primates possess teeth that are low crowned, with blunt and bulbous (bunodont) cusps and broad talonid basins, which are features related to eating non-leafy plant materials (e.g., fruit) rather than insects or meat.

Presence of a petrosal bulla has also often been cited as an ordinally diagnostic primate trait (e.g., Cartmill 1972). However, the ubiquity of this feature is questionable since developmental data are required to definitively document it (MacPhee et al. 1983), and its adaptive significance (if any) is unclear.

Defining the order Primates using observations on living taxa as a starting point is problematic because any traits chosen are unlikely to have evolved simultaneously. Instead, a definition that recognizes the process of primate evolution and that encompasses the earliest, possibly stem, members of the order will have greater explanatory power. This problem is discussed further below.

Ecological Scenarios for Primate and Euprimate Origins

Researchers investigating primate origins have typically focused on building an ecological scenario that could explain the evolution of one or more of these adaptive complexes. The earliest such scenario is the arboreal hypothesis of primate origins, which traces its roots back to the work of G. Elliot Smith and F. Wood Jones in the early part of the twentieth century. The arboreal hypothesis was extended and broadly popularized by W.E. Le Gros Clark (1959). In this hypothesis, grasping extremities were seen as having value for more secure climbing, and the distinctive primate orbital features were explained as being useful for judging distances in the trees during leaping.

All the other ecological scenarios that have been developed assume a life in the trees for ancestral primates but seek to go beyond simple arboreality to consider more specific types of behavior. Szalay and colleagues (e.g., Szalay and Delson 1979; Szalay and Dagosto 1980, 1988; Szalay et al. 1987; Dagosto 1988) considered a derived locomotor mode, grasp-leaping, to have driven the evolution of most of the features that characterize euprimates, including those of the visual apparatus. They linked the ability to rapidly jump from branch to branch with the need to be "…subsequently securely anchored" (Szalay and Delson 1979, p. 561) to the landing point. Visual changes were relevant to judging distances in rapid, leaping locomotion (Szalay and Dagosto 1980, 1988: Dagosto 2007). Crompton (Crompton et al. 1993; Crompton 1995; Crompton and Sellars 2007) subsequently argued that acrobatic leaping in euprimates requires visual specializations and that leaping may have evolved as a predator evasion strategy, based on studies of leaping mode and proclivity in modern strepsirhines. In Szalay's hypothesis, anatomical changes for grasp-leaping were preceded by a shift to a more herbivorous diet in primitive primates (i.e., plesiadapiforms) thought to be ancestral to Euprimates (Szalay 1968, 1972; Szalay and Dagosto 1980; Szalay et al. 1987).

Cartmill (1972, 1974, 1992, 2012) focused on visual predation as key to the origin of Euprimates. The visual predation hypothesis as originally conceptualized (see below) linked visual features beneficial to accurately gauging the distance to prey items with grasping hands and feet that could provide both a secure hold on narrow supports and a prehensile apparatus for snatching prey (Cartmill 1974). Because he thought they lacked orbital specializations and grasping features, Cartmill advocated excluding plesiadapiforms from Primates.

Sussman (1991; Sussman and Raven 1978; Sussman et al. 2013) suggested a link between the origin of Primates and the Cenozoic diversification of angiosperms (i.e., trees that produce fruit and flowers). He agreed with Szalay that a key event in early primate evolution was the invasion of the "arboreal mixed feeding adaptive zones" (Sussman and Raven 1978, p. 734) in the Paleocene. This involved increased use of non-leafy plant resources by early primates as angiosperms developed features that made them more tempting to non-insect seed and pollen dispersers, such as specialized flowers and larger fruit. With the appearance of still larger propagative plant organs (e.g., fruit, seeds) near the Paleocene-Eocene boundary, the ancestral euprimates developed features for entering terminal branches to better exploit these resources.

Two major classes of data have been used to assess the relative validity of these various ecological scenarios. The first "tests" various ecological functions assigned to character complexes in the different models using the comparative method (e.g., Kay and Cartmill 1977; but see Bock and von Wahlert 1965; Bock 1977). The second employs the fossil record to document the sequence of anatomical changes that occurred in primate evolution and seeks to tie these changes to adaptive shifts (e.g., Bloch and Boyer 2002; Bloch et al. 2007).

Comparative Method

Cartmill (1970, 1972, 1974) assessed the then prevalent arboreal hypothesis from the point of view of the diversity of modern arboreal animals. He argued that if living in an arboreal habitat could explain the distinctive features of primates, then these traits should also be found in other arboreal forms, and particularly in the arboreal members of groups that also include terrestrial species. Cartmill found that arboreal animals in general do not have features similar to those seen in modern primates. For example, arboreal squirrels are not more primate-like than terrestrial squirrels in certain specialized grasping traits, such as a reduction of the claws, or in vision-related features like the degree of orbital convergence. Nonetheless, arboreal squirrels are successful at many of the same behaviors practiced by primates, including making reasonably long jumps and foraging among slender branches. He argued that forward-facing orbits, while enhancing stereoscopy, decrease parallax and with it the ability to judge distance at longer ranges. For this reason, orbital convergence is not a very useful trait for gauging distances in a jump, but is very effective for visualizing objects close to the face. Based on these comparisons, it seems unlikely that the distinctive adaptive complex of euprimates can be simply linked to a shift to an arboreal mode of life.

Cartmill's hypothesis of primate origins, visual predation, has also been challenged from the standpoint of modern analogy. Sussman (1991; Sussman et al. 2013; see also Crompton 1995) pointed out that most living primates are omnivores, not specialized insectivores. This includes, for example, cheirogaleids (Atsalis 2008), which are often viewed as good living models for the ancestral euprimate (Sussman et al. 2013). What's more, for many primates their methods of prey capture emphasize scent and hearing over vision (Sussman et al. 2013). For example, tarsiers have been observed to capture their prey with their eyes closed (Niemitz 1979), and the most orbitally convergent primates, the lorises, use scent to detect their slow-moving and often smelly prey (Sussman et al. 2013). If living primates are not typically specialized visual predators, it is not clear why one would expect morphologically similar extinct species to be.

Alternatively, some authors (e.g., Sussman and Raven 1978; Sussman 1991; Crompton 1995) have sought analogues for early primates among frugivores, such as Old World fruit bats. The absence of primate-like visual features in some modern visual predators (e.g., mongooses, tupaiid treeshrews, many species of birds; Cartmill 1992; Sussman et al. 2013) and the presence of convergent orbits in some exclusively herbivorous taxa (koalas, sloths, fruit bats, kinkajous; Rasmussen and Sussman 2007; Sussman et al. 2013) suggest that there is no simple relationship between forward-facing orbits and visual predation. A possible "solution" to this criticism that the euprimate-like mechanism of orbital convergence for prey capture is only needed in nocturnal animals (Allman 1977; Cartmill 1992) could be refuted if the earliest euprimates were not nocturnal (see below).

Sussman's (1991; Sussman and Raven 1978; Sussman et al. 2013) angiosperm diversification hypothesis has been criticized based on the lack of an association between the diversification of angiosperms and the evolution of adaptations in arboreal marsupials that converge on those seen in primates (Cartmill 1992). Nonetheless, in a study of the somewhat primate-like South American didelphid marsupial *Caluromys derbianus*, Rasmussen (1990) did find some support for Sussman's model, in that a substantial part of its diet comes from terminal branch fruit feeding in a manner similar to modern primates. Rasmussen and Sussman (2007) found similarly analogous species among the Australian marsupial radiation, including, for example, the pygmy-possum *Cercartetus nanus*. These species do eat insects, which they capture by grasping them with their hands, perhaps providing some support for Cartmill's model; *Cercartetus* in particular has quite convergent orbits (Cartmill 1974). However, *Caluromys* does not have orbits that compare with primates in their degree of convergence (Rasmussen 1990), and a more detailed understanding of the behavior of *C. nanus* has led to its characterization as a flower specialist that only eats insects opportunistically, rather than as a visual predator (Rasmussen and Sussman 2007). These observations substantially weaken the link between convergent orbits and visual predation.

Rasmussen's (1990) study can be seen as providing a fifth, composite scenario for primate origins that has ancestral primates initially venturing out onto terminal branches to find fruit and other plant parts, with the secondary evolution of features for prey capture to capitalize on the insect resources they found in this milieu (Rasmussen 1990; Cartmill 1992).

The grasp-leaping scenario of primate origins (Szalay and Delson 1979; Szalay and Dagosto 1980, 1988; Szalay et al. 1987; Dagosto 1988) is less susceptible to criticisms based on modern analogy than the other ecological scenarios because it does not depend on a general evolutionary relationship for its validity. Rather, it stems from a "fossil-first" approach to considering adaptive change, beginning with the evolutionary transitions documented in the fossil record, and then attempting to determine their adaptive meaning in a form-functional context. This highlights a major contrast in approaches to the question of primate origins among the major participants in the debate. Under Szalay's approach, the unique origins, constraints, and evolutionary histories of different mammalian lineages mean that adaptive explanations applied to one group need not apply to any other. Cartmill, however, argues that "[t]he only evolutionary changes we can hope to explain are. . .*parallelisms*: recurrent modifications that show up over and over again in different lineages for the same structural or adaptive reasons. . ." (Cartmill 1993, p. 226).

One limitation of Cartmill's approach is that it assumes that all adaptive shifts of interest must be parallelisms, because otherwise there would be no possibility of explaining them. This reflects a more general issue with the use of modern analogy to test hypotheses about evolution. Any historical event is by definition a unique occurrence, even if it is more or less similar to other such unique occurrences that have taken place in other lineages. There is no reason to believe that everything that has happened once has happened twice. The evolutionary process that produced primates began at a unique starting point (i.e., the divergence of this clade from the rest of Mammalia), at a particular point in time, with a unique environmental and geographical context, and finished at a unique endpoint (i.e., the diversity of extant species). The starting point was heavily constrained by the evolutionary history of what went before, and the adaptive significance of the features evident at the current endpoint is dependent not only on the current usage of a given trait but also on the biological needs of all the animals that existed along the evolutionary lineage leading to a particular modern species. Modern non-primates that appear similar to primates might have passed through series of adaptive stages quite different from those experienced by primates' distant ancestors and thus may have arrived at their current form by a very different path. For this reason, arguments that ancient marsupials did not acquire their primate-like traits as a result of angiosperm diversification are not directly relevant to the question of whether or not primates did. The study of modern primates, or modern non-primate analogues, in isolation cannot provide a demonstrably accurate picture of the process of primate origins – it can only yield hypotheses that are more or less plausible for subsequent testing by the fossil record.

A somewhat analogous situation occurred in the early history of human paleontology. In the early part of the twentieth century, quite plausible scenarios were proposed that suggested either a large brain or bipedal locomotion as being the first-occurring distinct human trait (Lewin 1987). With the discovery and then acceptance of australopiths (primitive human ancestors with adaptations for bipedal locomotion but relatively small brains; McHenry and Coffing 2000) as hominins any "brains first" scenario was decisively falsified, no matter how plausible it may have seemed on the surface. And so too must any ecological scenario of primate origins be considered falsified, if the predicted pattern of trait acquisition is not matched by the fossil record.

Fossil Record

Primate Supraordinal Relationships

While in a strict sense the origin of Primates was no more dramatic than a single speciation event (Henke and Tattersall 2007; Cartmill 2012), the fossil record suggests that many of the characteristics thought to distinguish Euprimates were acquired incrementally through the first ten million years of primate evolution in the Paleocene (Bloch et al. 2007). It is to this process that the ecological hypotheses for Primate origins apply. Elucidation of this adaptive process relies centrally on knowing the relationships of taxa at the base of the primate tree, to understand the evolutionary steps taken to build the first euprimate.

There is a growing consensus on the broader relationships of Primates within Mammalia. Molecular analyses have fairly consistently recovered a group including Primates, treeshrews (Scandentia), and colugos (Dermoptera; Adkins and Honeycutt 1991; Waddell et al. 1999; Liu et al. 2001; Murphy et al. 2001a, b; Springer et al. 2003, 2004). Waddell et al. (1999) suggested the name Euarchonta for this clade. This name makes allusion to an earlier hypothesis of primate supraordinal relationships: the group Archonta, which included bats with these three orders (Gregory 1910; Novacek 1992; McKenna and Bell 1997). Molecular studies have consistently failed to find a close relationship between bats and the other archontans – rather, chiropterans have generally grouped with carnivorans and ungulates (e.g., Pumo et al. 1998; Miyamoto et al. 2000; Liu et al. 2001; Murphy et al. 2001a, b; Springer et al. 2003, 2004). As a result, the concept of Archonta sensu lato has fallen out of favor. Rodents and rabbits (Glires) are supported as the closest relatives to Euarchonta (Murphy et al. 2001a, b; Madsen et al. 2001). The resulting clade has come to be known as Euarchontoglires (Murphy et al. 2001b). Euarchontoglires is linked to a clade including ungulates, whales, lipotyphlan "insectivores," carnivorans, and bats (Laurasiatheria) in Boreoeutheria (Springer and de Jong 2001).

Within Euarchonta, there is less of a consensus about the branching pattern among the three ordinal groups. In terms of the sister taxon of Primates, all three possibilities have been recovered in various analyses: Scandentia (e.g., Novacek 1992; Liu et al. 2009), Dermoptera (e.g., Janečka et al. 2007), and Sundatheria (Scandentia + Dermoptera; e.g., Liu et al. 2001; Murphy et al. 2001a, b; Springer et al. 2003, 2004; Bloch et al. 2007; Nie et al. 2008; Ni et al. 2010). In an analysis that combined molecular data with the largest morphological dataset yet compiled for the study of mammalian interrelationships, O'Leary et al. (2013) found strong support for Sundatheria as the sister taxon of Primates. If this hypothesis is correct, it implies that the best model for the ancestor of primates based on extant forms is represented by the reconstructed common ancestor of Euarchonta, not by treeshrews in isolation. In particular tupaiids, the diurnal family of treeshrews often used for comparison to primates (e.g., Beard 1993a), become less relevant as ancestral primate models. The sole living member of the family Ptilocercidae, *Ptilocercus lowii*, is the extant treeshrew closest to the base of Scandentia (Olson et al. 2004, 2005; Roberts et al. 2011) and shares many more features than tupaiids do with dermopterans (Sargis 2001a, 2002a, b, c, d, 2004, 2007). These shared features are present in *Ptilocercus* and dermopterans in spite of some fundamental differences between their locomotor modes (gliding in dermopterans, arboreal quadrupedalism in *Ptilocercus*; Sargis 2001a, 2002a, b, c, d, 2004, 2007), implying that they may be ancestral for the common ancestor of Dermoptera and Scandentia, or even of Euarchonta. As such, *Ptilocercus lowii* might provide the best living model for the common ancestor of Primates (Fig. 1). Even if this hypothesis of relationships is not correct, and either Scandentia or Dermoptera is the true sister taxon to primates, the fact that *Ptilocercus* is consistently recovered as the most basally divergent treeshrew (Olson et al. 2004, 2005; Roberts et al. 2011), coupled with the extremely

Fig. 1 Illustration of *P. lowii*, the pen-tailed treeshrew. This arboreal species may be the best living model for the ancestor of Euarchonta and of Primates (Photo by Annette Zitzmann © 1995)

specialized morphology of all living dermopterans, implies that *Ptilocercus* is probably still the best living model for the common ancestor of Primates.

In terms of extinct taxa, the group most critical to evaluating the supraordinal relationships of primates are the plesiadapiforms. "Plesiadapiformes" is a paraphyletic grouping of extinct fossil mammals known from the Paleocene and Eocene of North America, Europe, and Asia (Russell 1964; Beard and Wang 1995; Fu et al. 2002; Smith et al. 2004; Silcox and Gunnell 2008). Although Tabuce et al. (2004) argued that there was also an African family of plesiadapiforms (Azibiidae), they later revised their interpretation and classified the relevant species into Euprimates as primitive strepsirhines (Tabuce et al. 2009). Represented by over 140 named species classified into 11 families, plesiadapiforms represent a very diverse radiation and form a significant component of the fauna recovered from many Paleocene localities (Rose 1981; Gunnell et al. 1995).

The systematic position of plesiadapiforms has been a matter of long-standing debate. Based largely on dental similarities, most early workers classified plesiadapiforms in Primates, often specifically in Tarsiidae (e.g., Matthew and Granger 1921; Gidley 1923). More recently plesiadapiforms have been thought of as the first radiation of the order Primates, more primitive than any modern group (e.g., Szalay and Delson 1979; MacPhee et al. 1983; Szalay et al. 1987). This idea has been challenged on a variety of fronts. Martin (1968) and Cartmill (1972) advocated removing plesiadapiforms from Primates to allow for a clearer definition of the order. However, in failing to provide a clear alternative classification for plesiadapiforms (beyond dumping them in a wastebasket "Insectivora"), this approach did little to clarify primate supraordinal relationships. Wible and Covert (1987) also suggested removing plesiadapiforms from the order Primates, on the grounds that cranial evidence was more supportive of a scandentian-euprimate tie than a plesiadapiform-euprimate one. They argued that the dental evidence linking plesiadapiforms to euprimates (excluding scandentians) consisted only of ill-defined "trends" (Wible and Covert 1987, p. 9). This conclusion was not based on any *detailed* consideration of teeth, however, which is particularly problematic since the euprimate-plesiadapiform relationship had always been supported largely by dental evidence. And, like earlier objections to classifying plesiadapiforms in Primates, this argument dealt only with the issue of euprimate relationships, without providing any clear resolution to the question of where plesiadapiforms would be classified. Finally, in the early 1990s, an alternative systematic position for plesiadapiforms was suggested by Beard (1989, 1990, 1993a, b) and Kay et al. (1990, 1992), who argued that at least some members of this group (Paromomyidae and Micromomyidae) shared closer ties to Dermoptera than Euprimates. Although these authors agreed on this point, their hypotheses of relationships were in disagreement in virtually every other way, including which taxon was the sister group to Euprimates (Scandentia in the case of Kay et al. 1992; Dermoptera + plesiadapiforms according to Beard 1993a). And, as in Wible and Covert (1987), very little consideration was given to the dentition.

Beard's (1989, 1990, 1993a, b) and Kay and colleagues' (1990, 1992) conclusions have been challenged by numerous studies on both phylogenetic and functional grounds (e.g., Krause 1991; Szalay and Lucas 1993, 1996; Wible 1993; Wible and Martin 1993; Van Valen 1994; Runestad and Ruff 1995; Stafford and Thorington 1998; Hamrick et al. 1999; Bloch and Silcox 2001; Sargis 2002d, 2007; Bloch and Boyer 2002, 2003; Silcox 2001, 2003, 2008; Bloch et al. 2007; Boyer and Bloch 2008). As one example, a key character proffered (Beard 1990, 1993b) in support of a relationship between some plesiadapiforms (paromomyids and micromomyids) and dermopterans to the exclusion of euprimates was unusual hand proportions, with elongate intermediate phalanges (Beard 1990, 1993b). Subsequent discoveries of better-associated plesiadapiform postcranial fossils have demonstrated that this inference was incorrect – the calculated hand proportions were the product of mixing hand and foot bones (Bloch et al. 2007; Boyer and Bloch 2008; see also Krause 1991; Hamrick et al. 1999).

Discovery of numerous new specimens of plesiadapiforms, documenting previously poorly known or totally unknown anatomical regions (Bloch and Boyer 2002, 2003; Bloch and Silcox 2001, 2006; Bloch et al. 2007; Boyer and Bloch 2008; Boyer 2009; Fig. 2), has prompted a reconsideration of plesiadapiform relationships. These data were included in an analysis that sampled the cranium, dentition, and postcranium (Bloch et al. 2007; Fig. 3a) and incorporated observations on *Ptilocercus*. The results of this analysis failed to support the plesiadapiform-dermopteran relationship. Rather, plesiadapiforms formed a paraphyletic stem group at the base of the order Primates. One subset of plesiadapiforms, the plesiadapoids (Plesiadapidae + Carpolestidae + Saxonellidae), was the sister taxon of Euprimates, making them crucial for establishing primitive states for that clade. Results from a subsequent analysis that included a broader sampling of mammals outside Euarchonta and a wider range of cranial and postcranial characters (Silcox et al. 2010b; Fig. 3b) were largely congruent with those of Bloch et al. (2007), apart from some details of the branching order among primitive plesiadapiforms (micromomyids and microsyopids).

One implication of these results is that plesiadapiforms might be best included in the order Primates (Bloch et al. 2007; Silcox 2007), in a return to earlier conceptions of how to define the group (e.g., Szalay 1975; Szalay and Delson 1979; Szalay et al. 1987). This notion has received some support from a previous proponent of the plesiadapiform-dermopteran clade (Kay 2003) and was recently incorporated into papers by workers on opposite sides of the debate over the ecological context of primate origins (Cartmill 2012; Sussman et al. 2013; but see Ni et al. 2010, 2013 for an opposing view).

The ecological scenarios discussed above take as their starting point the common features of modern primates. Plesiadapiforms do not possess all of these traits. If plesiadapiforms constitute the primate stem lineage, discussing “primate origins” then involves dealing with at least two sets of evolutionary transitions – first, the branching off of the primate stem and evolution of the earliest primate (*Purgatorius*; Van Valen and Sloan 1965; Johnston and Fox 1984; Fox and Scott 2011) and, second, the origin of Euprimates. Earlier discussions of “primate origins” that explicitly endeavored to explain only the latter transition (e.g., Cartmill 1972; Rasmussen 1990; Sussman 1991) are inherently flawed in trying to account for the concerted

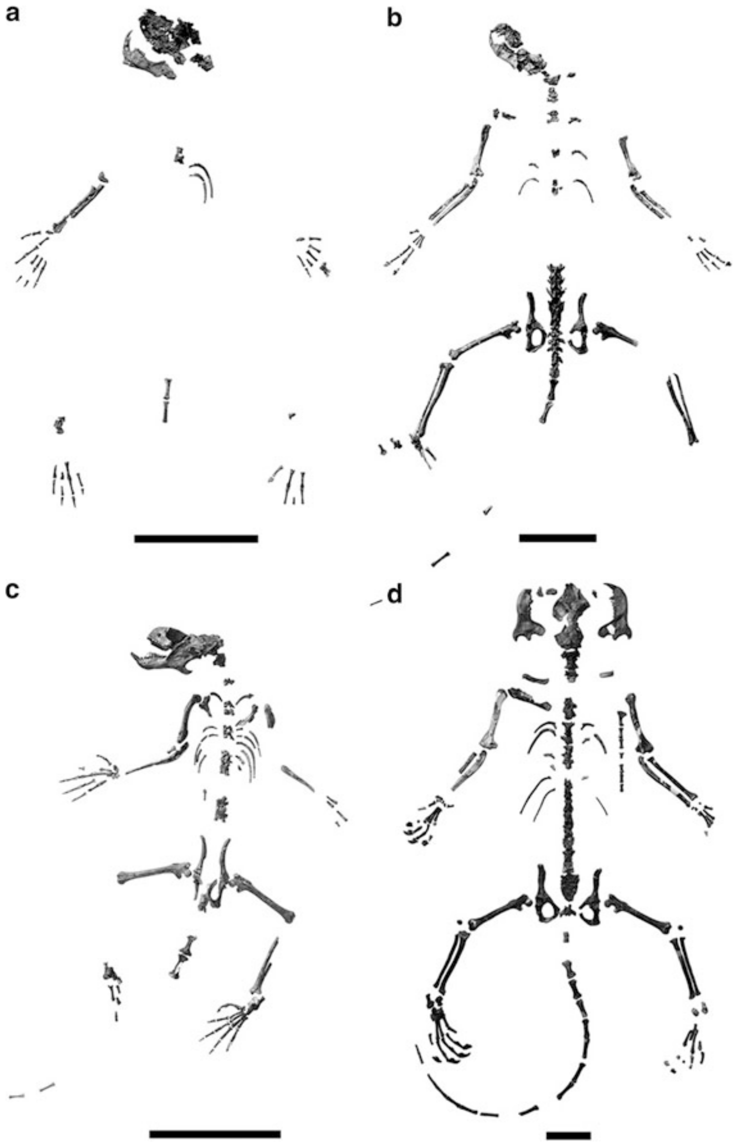

Fig. 2 Skeletons representing three plesiadapiform families were recovered from Late Paleocene limestones (Bloch and Boyer 2007, Fig. 3). Paromomyidae is represented by (**a**) *Acidomomys hebeticus* (UM 108207) and (**b**) *Ignacius* cf. *I. graybullianus* (UM 108210). Carpolestidae is represented by (**c**) *Carpolestes simpsoni* (UM 101963; Bloch and Boyer 2002, Fig. 2a). Plesiadapidae is represented by (**d**) *Plesiadapis cookei* (UM 87990). Scales = 5 cm

evolution of character complexes that did not arise at the same time, mixing the effect of multiple evolutionary transitions. This is true even if one chooses to classify plesiadapiforms as a non-primate sister group to the order.

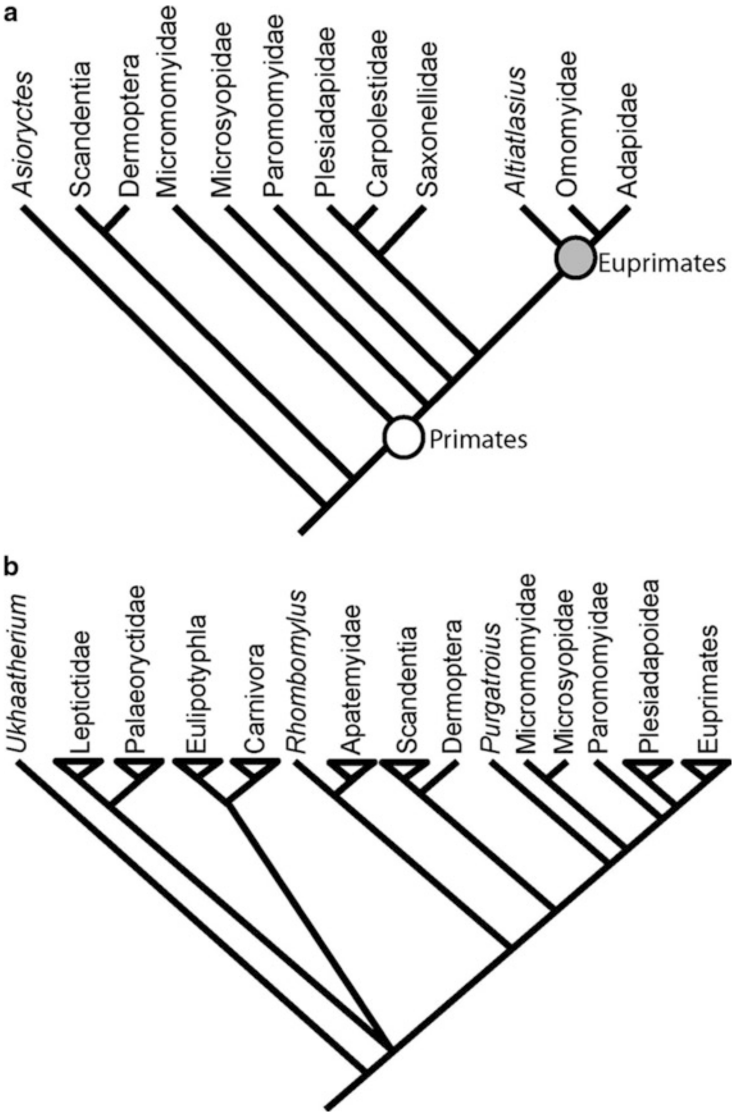

Fig. 3 (**a**) Single most parsimonious tree from a maximum parsimony analysis of 173 dental, cranial, and postcranial characters by Bloch et al. (2007). (**b**) Strict consensus tree of three most parsimonious trees from a maximum parsimony analysis of 240 dental, cranial, and postcranial characters by Silcox et al. (2010b). Note that in both analyses plesiadapiforms form a series of paraphyletic stem taxa at the base of Primates, and Plesiadapoidea is the sister taxon of Euprimates

Using the hypothesis of primate supraordinal relationships given in Fig. 3a, Bloch et al. (2007) tested predictions about the sequence in which anatomical transformations occurred pursuant to the various ecological scenarios (e.g., Cartmill 1992). In the same way that “brains first” scenarios of human origins relied on the evolution of large brains before features for bipedalism, so the ecological scenarios of primate origins require a certain order for the addition of traits through time for them to be considered valid.

Predictions for Ecological Scenarios of Primate and Euprimate Origins

Under the arboreal hypothesis, the prediction is inherent that the evolution of characteristically primate traits coincided with a move into an arboreal habitus. If, on the other hand, the ancestors of primates were already arboreal while lacking such traits, then the arboreal hypothesis would be effectively falsified. It would also be falsified if the evolution of characteristic primate features pre-dated a move to the trees, for example, if forward-facing orbits were found in an animal otherwise adapted for a terrestrial habitus.

The grasp-leaping hypothesis posits a relationship between the evolution of features for grasping and those for leaping. As such, if grasp-leaping is to function as an explanatory hypothesis for euprimate origins, then the evolution of these features should coincide in time. Visual features for improved stereoscopy should also coincide with the adoption of a more rapid, leaping, locomotor mode. Although it may still be true that early euprimates were functionally grasp-leapers, if such a coincident evolution of the relevant traits is not found, then this hypothesis would lose its explanatory power as a central motivating force in euprimate origins.

It is more difficult to generate a set of predictions for the visual predation hypothesis because Cartmill's views appear to have changed through time with respect to how the various distinctive primate traits are supposed to have evolved in the context of this scenario. Cartmill (1974) made an explicit link between the utility of specialized grasping with hindfeet and visual predation: "…these visually guided predators [*Cercartetus* and *Caluromys*] also have grasping hindfeet. The utility of this trait to their way of life is evident" (p. 69). "…it is reasonable to conclude that these novelties ["grasping extremities and large, convergent orbits"] were functionally related…" (p. 70). At the time he apparently did not consider clawlessness per se to be part of this complex: "Reduction of the claws and development of grasping specializations of the hand have occurred independently, in different ways and for different reasons in various primate lineages" (p. 76).

On the other hand, in 1992 Cartmill suggested that grasping extremities and claw loss, he suggested, had also originated as predatory adaptations (Cartmill 1992, p. 107; emphasis ours) based on the habits of small prosimian primates like *Microcebus*, *Loris*, and *Tarsius*, which track insect prey by sight and seize them in their hands. This implies that these features should be tied together temporally, since they were acquired as part of the same adaptive shift to more predatory behaviors.

However, Kirk et al. (2003, p. 741b) claimed that Bloch and Boyer (2002) mis-characterized visual predation suggesting that "[a]s originally formulated (Cartmill 1972), Cartmill's thesis interprets the prehensile, clawless extremities of primates as adaptations for locomotion on slender arboreal supports," and Cartmill (2012, p. 216) stated that "[c]omparative anatomy reveals no necessary connection between grasping hind feet and visual predation." This suggests that

Cartmill now considers visual predation not to be the explanation for the evolution of grasping characteristics in primate evolution in spite of his earlier assertions.

What is impossible to deny, however, is that visual predation is a dietary hypothesis. Since visual predation involves an increasing reliance on insect prey, this should also be reflected in the teeth of the earliest euprimates. This is true even if these forms were grasping prey with their hands rather than with their teeth (contra Cartmill 1972, 1974), because dental features for insectivory reflect not only prey capture but also processing of food items with the unique physical properties of insects. If early primates or euprimates were found to be equally or less insectivorous than their forbears, visual predation would be refuted as a central motivating force in early primate evolution. Since visual predation also relies to some degree on nocturnality (Allman 1977; Cartmill 1992), a finding that the earliest primates or euprimates were diurnal would substantially weaken this hypothesis.

The angiosperm diversification hypothesis predicts two stages in the evolution of primates. First, with the initial exploitation of the arboreal mixed feeding adaptive zone, a dental shift reflecting more use of plant resources should be seen. Second, as the terminal branches were invaded and the use of the food resources from this milieu was intensified, grasping and dental features reflecting these changes should appear. Disassociation between traits for eating fruit or flowers, and those indicating the ability to access terminal branches, would weaken the explanatory power of this hypothesis.

Similarly, the combined hypothesis suggested by Rasmussen (1990), involving first terminal branch feeding on fruit, and then visual predation, requires that “the earliest euprimates had grasping feet and blunt teeth adapted for eating fruit, but retained small, divergent orbits like those of *Plesiadapis*” (Cartmill 1992, p. 111). Subsequent evolution should add features for visual predation, such as forward-facing orbits and teeth with improved capabilities for processing insects, to this basic model. If, however, convergent orbits evolved at the same time as grasping feet or blunt teeth or their appearance was not coincident with the evolution of teeth better designed for eating insects, then this model would be effectively falsified.

Assessment of Ecological Scenarios

With the well-supported pattern of relationships found by the current authors (Bloch et al. 2007; Fig. 3a), it becomes possible to consider the predictions outlined above in light of what is known about the fossil record (Fig. 4). In terms of the arboreal hypothesis, the inferred arboreal habits of all plesiadapiforms known from postcranials (Szalay and Decker 1974; Szalay et al. 1975; Szalay and Drawhorn 1980; Szalay and Dagosto 1980; Szalay 1981; Gingerich and Gunnell 1992; Beard 1989; Bloch and Boyer 2002, 2003, 2007; Bloch et al. 2007; Boyer and Bloch 2008) make it clear that the ancestors of Euprimates were already arboreal. Identification of arboreal features in ankle elements of the most primitive known primate, *Purgatorius*, underlines the antiquity of this feature in the context of the primate radiation (Chester et al. 2012). This is further reinforced by the inclusion of Primates in Euarchonta, because this supraordinal group likely had an arboreal

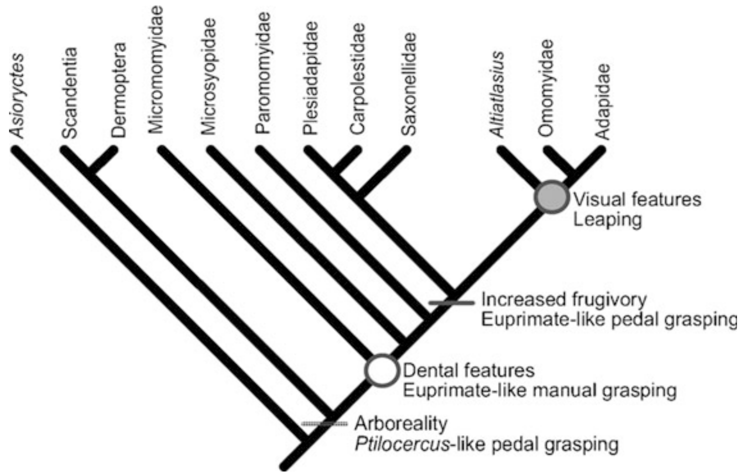

Fig. 4 Results from a maximum parsimony analysis of 173 dental, cranial, and postcranial characters by Bloch et al. (2007), with the most significant evolutionary transitions for primates mapped on. "Dental features" include molars that are low crowned, with bunodont cusps and broad talonid basins (all three of which are related to increased herbivory; Szalay 1968), an enlarged M_3 hypoconulid, and a postprotocingulum (nannopithex or postprotocone fold) on P^4. Evidence for euprimate-like manual grasping includes an increase in the relative length of the digits. Pedal grasping involves the evolution of a divergent big toe with a nail. Visual features include increased orbital convergence and the postorbital bar. Note that these transitions occur in a steplike fashion, with only visual features and leaping being added at the euprimate node

ancestor (Szalay and Drawhorn 1980; Sargis 2001a, 2002e). As such, distinctively euprimate traits cannot be linked to a simple move from a terrestrial to an arboreal habitus. The fact that *Ptilocercus lowii*, an arboreal mammal, may be the best living model for the ancestor of Euarchonta, and thus possibly for Primates (Sargis 2001a, 2002e; Bloch et al. 2003; see above), strongly suggests that arboreality is a feature that evolved prior to the base of the primate radiation (Szalay and Drawhorn 1980). Many of the features that have been cited as possible euarchontan synapomorphies (Szalay and Drawhorn 1980; Szalay and Lucas 1996; Sargis 2002d; Silcox et al. 2005) can also be linked to arboreal locomotion. It is likely that arboreality evolved in the ancestor of Euarchonta (Szalay and Drawhorn 1980; Sargis 2001a, 2002e) and that this trait was retained (but did not originate) in the ancestor of Primates.

The evolution of grasping is central both to the assessment of the grasp-leaping hypothesis and to the visual predation hypothesis as outlined by Cartmill in 1992. With a better fossil record for plesiadapiforms, it is now clear that grasping is not a single character state or set of coordinated transformations. The ancestral euarchontan was likely capable of *Ptilocercus*-like grasping (Szalay and Dagosto 1988; Sargis 2001b, 2002b, e, 2004; Sargis et al. 2007). As Bloch and Boyer (2002, 2003; see also Sargis et al. 2007) demonstrated, the evolution of fully euprimate-like grasping was at least a two-stage process. Features for manual grasping, including relatively long digits of the hand, are present in all plesiadapiforms known from relevant material, with the exception of plesiadapids who are inferred to have secondarily lost this trait (Bloch and Boyer 2002, 2003; Boyer et al. 2004; Kirk et al. 2008; Boyer 2009). Euprimate-like pedal grasping, including an opposable big toe with a nail, is present in *Carpolestes simpsoni* and can be reconstructed as having evolved in the common ancestor of Plesiadapoidea and Euprimates (Bloch and Boyer 2003; Sargis et al. 2007). Although Gebo (2009) took issue with the characterization of the morphology of *Carpolestes simpsoni* as euprimate-like, the shared possession of critical features such as the saddle-shaped distal facet on the entocuneiform for articulation with the first metatarsal, proximal expansion of the medial surface of this facet, and torsion of the first metatarsal (Bloch and Boyer 2002, 2003; Sargis et al. 2007) demonstrates that these groups both possess key elements of the grasping functional complex. As such, Cartmill's (2012, p. 216) assertion that grasping feet "probably evolved independently in *C. simpsoni* and euprimates" is a matter of opinion that has not been demonstrated in a phylogenetic framework.

Plesiadapiforms lack features associated with specialized leaping (Szalay et al. 1975; Szalay and Dagosto 1980; Gingerich and Gunnell 1992; Beard 1989; Bloch and Boyer 2002, 2007; Bloch et al. 2007). *Carpolestes simpsoni*, for example, lacks the relatively long legs typically seen in a leaping mammal, indicating that it was a more generalized arboreal quadruped (Fig. 2c; Bloch and Boyer 2002). The semicircular canal evidence also supports the inference that plesiadapiforms known from cranial material did not use "jerky patterns" of locomotion characteristic of leaping primates (Silcox et al. 2009a). The first primate taxa with some leaping characteristics are early euprimates such as *Cantius*, *Teilhardina*, and *Omomys* (Rose and Walker 1985; Anemone and Covert 2000; Gebo et al. 2012). Although current evidence suggests leaping and visual traits did evolve at the same time, there is a distinct offset between the evolution of features related to grasping and those for leaping. In light of this, although early euprimates were likely grasp-leapers and leaping may have evolved in the ancestral euprimate (Szalay and Dagosto 1980, 1988; Dagosto 1988), the evolution of grasp-leaping was not the event that shaped the origin of Primates or Euprimates.

Similarly, no known plesiadapiforms show any of the specialized features of the orbital system that are associated with euprimate-like vision, including a complete postorbital bar, convergent orbits, reduced snout, or an enlarged and reorganized brain (McKenna 1966; Szalay 1969, 1972; Russell 1964; Kay and Cartmill 1977; Kay et al. 1992; Bloch and Silcox 2006). Therefore, there is an offset between the evolution of grasping and visual features. As such, their coordinated acquisition as part of a shift to a new mode of feeding, visual predation, was not the decisive event in shaping primate or euprimate origins.

It is still possible that adding visual predation to the behavioral repertoire of Euprimates was an important event in the evolution of this group, in which grasping features effectively acted as an exaptation ("preadaptation," Gould and Vrba 1982). There are multiple lines of evidence that lead one to doubt this scenario, however. First, as discussed above, visual predation becomes mechanistically implausible if the earliest euprimates were diurnal (Allman 1977; Cartmill 1992). The primitive activity pattern of Primates is very much in debate. For example, Ni et al. (2004) interpreted a primitive euprimate skull from Asia as having been diurnal. Although there are some problems with this conclusion (Martin 2004; Heesy and Ross 2004; Bloch and Silcox 2006), it draws attention to the fact that the ancestral activity period for euprimates cannot be assumed to have been nocturnal. Indeed, Ankel-Simons and Rasmussen (2008) suggest that early euprimate communities likely included a mix of nocturnal and diurnal species. This would make it difficult to argue that nocturnal visual predation would have been universally important to early euprimates.

Second, if euprimates did undergo a transition to becoming more focused on visual predation, then they should have teeth that are indicative of a more insectivorous diet than their precursors. This is not demonstrably true. The earliest known euprimate, *Altiatlasius koulchii*, has extremely low-crowned teeth with very bunodont cusps (Sigé et al. 1990), which is not consistent with a predominantly insectivorous diet. Of the two best-documented groups of early euprimates, adapoids are usually viewed as being frugivorous and omomyoids as omnivorous (Rose 1995; Bloch and Boyer 2003). The only gut contents known for a primitive fossil primate (the adapoid *Darwinius* from Messel) include fruit remains and no insects. This is likely a real reflection of diet, rather than a taphonomic artifact because in other Messel specimens insect remains preserve well (Franzen and Wilde 2003). Cartmill (2012, p. 216) responded to this objection by suggesting that "[w]e cannot determine which dietary preference is oldest by counting noses." It is certainly true that commonness of a feature does not imply primitiveness (Maddison et al. 1984). However, it is possible to use optimization techniques to infer, from the distribution of traits across a set of relationships, what is most parsimoniously considered to be primitive. Boyer (2007) performed precisely such a test and found no evidence for a shift in dietary behavior toward insectivory at the basal Euprimate node.

What's more, if early euprimates were succeeding and diversifying primarily because they were improving their insect-harvesting abilities, then they should show dental features that indicate that they were at least as well adapted for processing insects as insectivorous mammals living at the same time. This is not the case – most specialized insectivores from the Paleocene and Eocene have much higher crowned teeth and sharper cusps than early primates. It is precisely the absence of such features and the presence of characteristics for processing non-leafy plant material, such as low-crowned molars with broad talonid basins, that makes it possible to separate primitive primate and insectivore teeth in the fossil record. The insectivores most similar to primates in dental form can be reconstructed as having a more omnivorous diet than their specialized insectivorous kin. For example, the erinaceomorph *Macrocranion tupaiodon* from Eocene deposits at Messel, which has superficially primate-like teeth, is known from stomach contents to have eaten not only insects but also plant material and substantial quantities of fish (Storch and Richter 1994).

Cartmill (2012, p. 216) suggested that the fossil record is too incomplete to be used to understand adaptive events around the euprimate node, so that "the main evidence for the ecological correlates of the euprimate peculiarities has to come from functional and comparative anatomy," presumably of extant species. As discussed above, there are numerous incidences of a lack of fit between visual predation and orbital convergence from such studies. Furthermore, there are competing adaptive hypotheses for having convergent orbits. For example, Changizi and Shimojo (2008) argued for a distinct adaptive context for this feature, related to picking out items from a cluttered environment, such as a tree with leaves. These items include any object of greater interest than the clutter, whether it be the location of a branch, a flower, an insect, or a predator. Not only are forward-facing eyes more useful in a cluttered environment, but laterally placed eyes (as in squirrels) are less critical for predator detection since inhabiting a "cluttered" environment also bestows cover from the eyes of hunting predators.

The features suggesting a more herbivorous diet in early primates and euprimates are supportive of the angiosperm diversification hypothesis (Sussman et al. 2013). Within various plesiadapiform lineages and early euprimate groups, improved features for exploiting plant propagative organs continue to appear through the Paleocene and Eocene (Gingerich 1976; Biknevicius 1986; Rose 1995; Bloch and Boyer 2002).

It has been argued (Cartmill 1992) that the angiosperm diversification hypothesis fails to explain the rest of the distinctive traits seen in modern primates (i.e., visual features and leaping). However, Changizi and Shimojo (2008) consider this hypothesis to be consistent with their ideas about the evolution of convergent orbits for differentiating objects in a cluttered environment. Crompton (1995, p. 18) also made this point, suggesting that convergent orbits might have been beneficial in allowing detection of the "small, *and often very inconspicuous"* food items taken by small primates. Cartmill's (2012, p. 217) response to this proposal was to suggest that special visual features are not needed to perceive fruits or flowers because angiosperms advertise their presence with "shiny bright colors and sweet smells." However, it seems important to remember that angiosperms are not advertising their fruit to any possible frugivore. It does an angiosperm no good to have its seeds destroyed or deposited too close to the parent tree, so fruiting trees do not necessarily produce fruit that will be conspicuous to all. Not all fruit in a tropical environment is as easy to see as a domesticated banana.

In terms of leaping, Rasmussen's (1990, p. 273) observations of *Caluromys* also offer a potential explanation for the value of this locomotor mode to a terminal branch feeder: "[t]he grasping and leaping acrobatics exhibited by *C. derbianus* in Costa Rica enabled them to gain access to fruit that was apparently off limits to most of the other nocturnal frugivores of the study area." Perhaps it was refinements to terminal branch feeding technique, offering new access to previously inaccessible food sources and greater abilities for discriminating food choice, that marked the transition to Euprimates.

Rasmussen's combination hypothesis might be seen as offering an alternative to the angiosperm origins scenario that explains, first, the grasping and fruit-eating dental features of basal primates and then the visual characteristics of euprimates. However, this combination hypothesis suffers from the same problems as visual predation in linking the evolution of orbital traits to increased insectivory in the absence of evidence for such a dietary shift. Based on the current evidence, the angiosperm diversification hypothesis applies best to the evolution of early primates. Furthermore, Szalay's (1968) view of the key event in primate origins being a dietary transition to a more plant-dominated repertoire is also supported by the current evidence.

Timing and Place of Origin of Primates and Euprimates

The earliest occurring primate known is *Purgatorius*. Although one possible specimen of this genus is described as coming from the latest Cretaceous (Van Valen and Sloan 1965; Van Valen 1994), it is not a particularly diagnostic tooth (Clemens 2004; Silcox 2008) and comes from a deposit that is time averaged (Lofgren 1995). The earliest, well-dated, diagnostic primate material that has been published in detail pertains to *Purgatorius coracis* from the earliest Paleocene (Pu2) of Saskatchewan (Johnston and Fox 1984; Fox and Scott 2011; see Clemens and Wilson 2012 for a possible even earlier occurrence). Most of the rest of the early primate fossil record is North American, including all definitive micromomyids and palaechthonids, most microsyopids, and all the most primitive paromomyids, carpolestids, plesiadapids, and possibly saxonellid (Fox 1991). Plesiadapiforms have only been known from Asia since 1995 (Beard and Wang 1995), which suggests that this geographic bias may be a sampling phenomenon. The only Asian species that shows relatively primitive plesiadapiform morphology is *Asioplesiadapis youngi* Fu, Wang and Tong 2002 which is similar in some ways to the most primitive families of plesiadapiforms, the Purgatoriidae and "Palaechthonidae," and differs in other ways including having a relatively reduced dental formula (Silcox 2008). As a relatively late-occurring species (early Eocene), *A. youngi* hints at the presence of more primitive lineages of primates in Asia. There remain, however, no Asian taxa as primitive in morphology as North American *Purgatorius*, implying that the fossil record is still most supportive of a North American origin for Primates.

Springer et al. (2012) supported an Asian origin for Euprimates. However, their analysis was based on a molecular phylogeny, without the inclusion of any fossils. Since it is clear that the biogeographic patterns of many mammalian groups have changed over the last 65+ million years, it is critical to consider fossil evidence when assessing the place of origin for any group. Using evidence from the fossil record, Beard (1998) also argued that the origin of Euprimates could be reconstructed as unequivocally Asian. Silcox (2001, 2008) and Bloch et al. (2007) are more conservative in their interpretation of the fossil record, with origins in Asia, Africa, North America, or even Europe being possible in the context of current knowledge. Causes for this equivocation include the African location of the earliest known euprimate, *Altiatlasius koulchii*; the Asian location of the primitive euprimate *Altanius orlovi*; the North American location of much of the primitive plesiadapoid and euprimate record; and the European location of both some early euprimates (e.g., *Donrussellia*) and the poorly sampled plesiadapiform family Toliapinidae, which may be related to early euprimates (Silcox 2001).

The time of origin of Primates and Euprimates can only be minimally constrained using fossil data. As noted above, the earliest known primate, *Purgatorius*, is from the earliest Paleocene (Fox and Scott 2011). In light of the primitive nature of this taxon, the fossil record is not consistent with a date much earlier than this, putting the origin of the group in the earliest Paleocene or latest Cretaceous. The fossil record for mammals more generally suggests a period of very rapid diversification shortly after the Cretaceous-Paleogene boundary (O'Leary et al. 2013).

The earliest occurring euprimate, *Altiatlasius koulchii*, is late Paleocene in age (Sigé et al. 1990; Gheerbrant et al. 1998), implying a divergence for Euprimates before the early Eocene. Furthermore, since the sister group to Euprimates (i.e., Plesiadapoidea) had diverged from their common stem by the latest early Paleocene, Euprimates must be at least that old. Recent molecular dating estimates, which take into account some of the more problematic assumptions inherent in molecular clock models, are starting to approach this timeframe. For example, Springer et al. (2012) estimated that living Primates shared a last common ancestor 71–63 million years ago, which suggests that molecular and fossil datasets are not as divergent as they once seemed (contra Cartmill 2012).

Conclusions: What Is a Primate? (Coda)

When Cartmill developed the visual predation hypothesis, he suggested the removal from Primates of any taxa that lacked modern primate-like orbital and grasping features and thus presumably had not used this mode of feeding (Cartmill 1972, 1974). This was the primary basis for his suggested removal of plesiadapiforms from Primates. Such an approach to defining primates was perhaps an over-optimistic view of the support for visual predation – if, as suggested here, an evolutionary transition to this pattern of behavior is not clearly indicated by the fossil record, then this is surely not an appropriate criterion by which to determine inclusion or exclusion of taxa in the order Primates. This view is underscored by the fact that, of the three "ordinally diagnostic" traits that Cartmill (1972, p. 121) named to diagnose a plesiadapiform-free order Primates – "…the petrosal bulla, complete postorbital bar, and divergent hallux or pollex bearing a flattened nail…" – two are now known in plesiadapoid plesiadapiforms (Bloch and Boyer 2002, 2003; Bloch and Silcox 2006; Boyer 2009). The fossil record demonstrates that the characteristic primate traits listed in the introduction arose in a steplike fashion (Fig. 4). Thus, the criterion that all of these features must be present in a particular taxon for it to be considered a primate is biologically unnatural. Doing so would exclude taxa on the primate stem, which have some, but not all, of these traits, but postdate the divergence of the primate lineage from the rest of Mammalia. As demonstrated above, such stem taxa are critical for understanding the origin and early evolution of Primates, as well as the accumulation and modification of crucial features within this lineage.

As advocates of phylogenetic taxonomy have made clear, there are some distinct advantages to formal taxonomic definitions that are based on specifying a particular ancestor, rather than on a list of mutable characters (Rowe 1987; De Queiroz and Gauthier 1990; Silcox 2007). For this reason, although compiling lists of distinctive primate traits is useful to the process of understanding primate origins, it is inappropriate to consider them formal definitions. Using the precepts of phylogenetic taxonomy, Silcox (2007) suggested the following definition for Primates: “the clade stemming from the most recent common ancestor of *Purgatorius* and Euprimates.”

New discoveries will almost certainly change the prevailing views on the early parts of primate evolution. There is a number of substantial holes in the fossil record for primate origins which, when filled, may fundamentally shift perceptions of primate evolutionary history. First, there is a sizeable spatial discontinuity in the fossils currently available. Plesiadapiforms have only been discovered in Asia in the last 18 years (Beard and Wang 1995). For early euprimates, the few specimens of primitive forms known from Asia and Africa are suggestive of a much larger radiation that is almost completely unknown (Silcox 2001, 2008). Even in North America, the geotemporal patterning of the plesiadapiform and euprimate fossil records means that there are still substantial areas at crucial times that remain unsampled.

Second, some taxonomic groups are also undersampled. Two families of plesiadapiforms, “Palaechthonidae” and Toliapinidae, have the potential to be crucial to an understanding of early primate and euprimate evolution, but both are very poorly known (but see Chester et al. 2011). The best-known plesiadapoids are all relatively derived members of their respective families. In light of the important position of Plesiadapoidea as the sister taxon to Euprimates, finding more, and more complete, primitive plesiadapoid specimens is vital (e.g., Boyer et al. 2004, 2012; Boyer 2009). Perhaps most importantly, a gap still exists between the known plesiadapiforms and the earliest euprimates. No known plesiadapoid has the morphology that would be expected in a euprimate ancestor – they are all too derived in features such as dental reduction, enlargement of the anterior-most incisors, and/or the shape of P_4. Because the earliest plesiadapoids are late early Paleocene in age, Euprimates must have a ghost lineage, stretching through the middle and late Paleocene, which is entirely unsampled. Filling this particular gap will be central to clarifying the evolutionary and adaptive significance of traits for euprimate-like vision and leaping. In light of the complete absence of taxa to fill this gap from the comparatively well-sampled North American record, it seems most plausible that they were living in the Old World.

Finally, since understanding the supraordinal relationships of primates is central to reconstructing events at the base of the order, a better fossil record for other euarchontan groups is also central to the problem of primate origins. As it stands, the Paleogene fossil record for scandentians and dermopterans is virtually nonexistent, with the exception of dentognathic remains that already exhibit peculiarities of extant dermopterans (Ducrocq et al. 1992; Marivaux et al. 2006), fragments of scandentian teeth from the Eocene of China (Tong 1988), and plagiomenids, which may be fossil dermopterans (Bloch et al. 2007; but see Yapuncich et al. 2011). Furthermore, a better understanding of various other fossil groups for whom a tie to Euarchonta, or specifically to Primates, has been suggested (e.g., apatemyids, nyctitheriid insectivores, mixodectids; Szalay and Lucas 1996; Hooker 2001; Silcox 2001; Silcox et al. 2005) has the potential to further clarify the evolutionary events downstream from Primates in the euarchontan evolutionary tree (Silcox et al. 2010b).

Although this discussion of missing data in the fossil record may seem disheartening, the enormous progress that has been made in the last 15 years in understanding primate origins suggests some of these holes may soon be filled. Researchers interested in this topic have moved from a position analogous to that of early anthropologists arguing about whether brains or bipedalism arose first in human evolution, without having any relevant data to choose between the two, to being able to actually test hypotheses about the order of acquisition of traits in early primate evolution. It can only be hoped that continuing diligence on the part of researchers interested in primate origins will serve to fill some of these gaps and allow knowledge of the earliest chapters in human evolution to continue to expand.

Acknowledgments Our thanks to JG Fleagle, SGB Chester, PD Gingerich, KD Rose, FS Szalay, and AC Walker for conversations relevant to this chapter. We thank Annette Zitzmann for providing the photo of *Ptilocercus* in Fig. 11. Research was funded by grants from Wenner Gren, the Paleobiological Fund, Sigma Xi, NSF (SBR-9815884), the University of Winnipeg, and NSERC to MTS; NSF (BCS-0129601) to G.F. Gunnell, P.D. Gingerich, and JIB; NSF (SBR-9616194), Field Museum of Natural History, Sigma Xi, and the Yale University Social Science Faculty Research Fund to EJS; 2002 NSFGRF, NSF DDIG (BCS-0622544), a Leakey Foundation Grant, and NSF (BCS-1317525) to DMB. A portion of this updated manuscript was written when JIB was supported as an Edward P. Bass Distinguished Visiting Environmental Scholar in the Yale Institute for Biospheric Studies (YIBS).

Abstract

Molecular data have become an important source of evidence on primate evolutionary history, particularly when the fossil evidence is limited or lacking. The most recent molecular phylogenetic studies of primate evolutionary relationships and divergence times are reviewed here, primarily at the family level and above. Paleontological data are not entirely omitted, but the focus here is on the molecular results. The current molecular evidence for the branching pattern among the primates, colugos, and treeshrews is presented, and current studies provide weak support for a sister group relationship between primates and colugos. The haplorhine affinities of the tarsier are documented out of a sense of duty; hopefully, it will be possible to stop pretending this is an open question sometime soon. The relationships among the platyrrhine families are quite convincingly resolved in favor of an atelid and cebid clade, but the relationships among *Aotus*, the cebines, and the callitrichines in the Cebidae are poorly resolved. It seems that the molecular evidence will eventually support reciprocal monophyly of the living galagos and lorises, but the molecular data are not presently very helpful. Excluding the early diverging *Daubentonia* lineage, the relationship of the remaining four lemur families almost certainly includes a cheirogaleid-lepilemurid clade but is otherwise poorly resolved by molecular data. Advances in divergence date estimation methodology have begun to rectify some of the absurdly early estimates for the time of origin of the crown primate radiation, but there is still a lot of work to do. Fossil calibration remains problematically applied, and some highly cited studies have poorly justified or unjustifiable calibrations. New methods are being developed for mostly or completely fossil calibration-free divergence date estimation and are very promising.

Introduction

Studies of molecular data have contributed significantly to our understanding of primate origins and evolution, from the seminal immunological studies in the 1960s (Goodman 1961, 1963; Sarich and Wilson 1966, 1967) that contributed to a revision of the hominoid relationships and dramatically shortened the time frame of human evolution to the early years of the DNA era when substantial morphological homoplasy in the Papionini was confirmed from analysis of mitochondrial DNA (mtDNA) sequences (Disotell et al. 1992; Disotell 1994). But what have molecular data done for you lately? In this chapter, the most recent molecular evidence on the higher level relationships of primates is reviewed, from their nearest interordinal relatives to relationships among families and some subfamilies, and presents the most recently published estimates of divergence times.

The ideal molecular phylogenetic study of the primates would include unbiased, genome-wide sequence data from all primate species. These data would be analyzed using the best available phylogenetic reconstruction method; if, as is the case today, there were several well-regarded methods, they would be analyzed using all leading approaches. Any significant discrepancy among the results from the different methods would be investigated and explained. To the extent that primate evolution can be represented by a strictly bifurcating history, a single best estimate of the phylogeny would be presented. Lineage divergence dates (with confidence intervals) would be calculated from evolutionary rate estimates along lineages derived from either well-dated, justifiable calibration points or some other independent rate estimate. No such study has been published. Nothing even comes particularly close. It is an impossible ideal at the moment. Aside from the expense and practical problems associated with collecting sequence data from all primate species, or even all genera, it is not clear that current computational abilities could efficiently analyze the data. Given that current efforts must fall short of the ideal, it is necessary to choose the best estimates among studies with various shortcomings.

For most primate groups, there are now dozens of published phylogenies and divergence date estimates. Given all these choices, it is possible to support quite different evolutionary scenarios by cherry-picking convenient results. One source of this proliferation is that most research groups with a focus on molecular systematics publish series of papers with expanding datasets and new methods. From these series, only the most recently published are presented, unless there are important differences in dataset, question, or analytic method between successive papers from a single author or research group. In addition, no phylogeny or divergence date study published more than a decade ago is given a great deal of weight; these older papers are usually based on very limited datasets and outmoded methods of analysis. The history of the discipline is, of course, important, but the main goal of this review is to update the reader on the most current molecular evidence on primate origins and evolution.

Broader taxon sampling is known to improve phylogenetic reconstruction (Hendy and Penny 1989; Baurain et al. 2007), so the results from studies with broader taxon sampling are prioritized here. However, in the pursuit of the broadest possible taxon sampling, it has become common to create data matrices with large amounts of missing data (e.g., 70 % missing data in Fabre et al. (2009). Whether missing data negatively counteract the benefits of being able to include more taxa is contentious (Misawa and Nei 2003; Lemmon et al. 2009; Simmons 2012; Wiens and Tiu 2012; Roure et al. 2013), and little work has been done on the effect of missing data on divergence date estimation.

Studies that report clearly erroneous topologies are excluded. For instance, not only were Arnason et al. (2008) unable to resolve the phylogenetic position of the tarsier, they placed the colugo (flying lemur) as the sister taxon to the anthropoids within the primates. Of course, some relationships are unknown, and it would be unfair to fault a study that reports a relationship that is now rejected if, at the time the study was published, the relationship in question was truly poorly understood. However, in 2008, even if one only read the molecular systematic literature, it was readily apparent that the tarsier is a haplorhine and colugos are not primates (Goodman et al. 1998; Ziętkiewicz et al. 1999; Murphy et al. 2001b; Schmitz et al. 2001, 2002; Waddell et al. 2001; Janečka et al. 2007).

Admittedly, these criteria are subjective. Therefore, apart from filtering out older studies that have been superseded by more recent publications from the same research groups, studies that are simply outmoded, and publications with dramatically incorrect topologies, data are presented from most broadly sampling primate molecular systematic publications from the last decade. In the figures, those studies that have the best estimates are italicized. In case the reader's preferences differ, information about all of the included divergence date studies (Table 1) and their calibration points (Table 2) are tabulated so that you may make your own informed choices.

Calibration

Most current divergence date estimation methods rely on fossil calibration points, but good calibration is hard to achieve (Raaum et al. 2005; Benton et al. 2009). At the very minimum, a fossil securely within the clade must support any calibrated node. For instance, a fossil used to calibrate the minimum age of the ancestor of the living catarrhines must be attributed by a reasonable consensus of primate paleontologists to the crown catarrhines. This seems obvious, but look through recently used calibrations (Table 2). It should be clear by now that any molecular systematist who attempts to estimate divergence dates using fossil calibration points should be conversant enough with the paleontological literature to be able to cite specific fossil taxa or really must seek out some paleontologist colleagues.

Fossils can only constrain the most recent age of a clade (Hedges and Kumar 2004; Raaum et al. 2005; Benton et al. 2009). If a fossil is properly identified as the earliest member of a clade, then it is not possible for the common ancestor of that clade to have lived more recently. However, there is nothing that can conclusively and usefully constrain the earliest age of a clade. It is possible to absolutely constrain the ancestor of the living catarrhines to sometime after the earliest evidence for land animals, but this is not useful. Despite this, upper bounds on calibration points are common. This ubiquity exists because most divergence dating algorithms require an upper boundary to provide reasonable estimates. For instance, the popular MCMCTree software requires either at least one lower and one upper bound or a calibration distribution that can act as both upper and lower bound (e.g., a normally distributed calibration prior) (Yang and Rannala 2006).

The most commonly used divergence dating algorithms allow the use of probability distributions for calibrations. These probability distributions are an estimate of the likelihood that the true divergence falls within a particular range of dates. For instance, most paleontological data suggests that the most recent common ancestor of humans and chimpanzees lived prior to 5 Ma with no fossils suggestive of common ancestors prior to about 7 Ma. Given these data, it is possible to construct a prior belief (probability distribution) on the likely date of the human-chimpanzee divergence. It is the responsibility of the investigator to ensure that the calibration distribution that is chosen reflects paleontological understanding. For commonly chosen calibration nodes, it might be reasonable to believe that investigators would

Table 1 Summary of divergence dating studies discussed in the text

Study	Focus	Number of primates	mtDNA	nDNA	Dating method	Notes
Bininda-Emonds et al. 2007	Mammals	233	~14,000 bp	~37,000	Local molecular clock (Bailey et al. 1991, Purvis 1995)	Dating method is simplistic and obsolete but given the size of their tree (all mammals) may have been the only practical choice. Only one calibration point within primates
Chatterjee et al. 2009	Primates	219	6,138 bp >40 % missing		Bayesian relaxed clock uncorrelated rates model (BEAST)	
dos Reis et al. 2012	Placentals	32	10,980 bp	20,600,000 bp	Bayesian relaxed clock autocorrelated rates model (MCMCTree)	A tree with divergence dates was estimated from 36 species with nDNA data. The divergence dates estimated on this tree were used as the calibration priors for 274 species with mtDNA data
Fabre et al. 2009	Primates	199–271	8,796 bp 59 % missing	32,493 bp 85 % missing	Bayesian relaxed clock autocorrelated rates model (MULTIDIVTIME)	
Finstermeier et al. 2013	Primates	83	13,281 bp		Bayesian relaxed clock uncorrelated rates model (BEAST)	Used Perelman et al.'s calibrations, many of which are questionable (Table 2)
Hallström and Janke 2010	Placentals	9		2,863,797 bp 21 % missing	Nonparametric relaxed clock autocorrelated rates model (TREEFINDER)	TREEFINDER implements Sanderson's (1997) nonparametric rate smoothing algorithm. The narrow confidence intervals on these estimates reflect only sequence sampling variance and do not include uncertainty in rate estimates. Only two calibration points within primates

(*continued*)

Table 1 (continued)

Study	Focus	Number of primates	mtDNA	nDNA	Dating method	Notes
Hodgson et al. 2009	Platyrrhines	16	10,906 bp		Bayesian relaxed clock autocorrelated rates model (MULTIDIVTIME)	
Horvath et al. 2008	Lemuriforms	32		14,539 bp	Bayesian relaxed clock uncorrelated rates model (BEAST)	Limited calibration (Table 2)
Jameson et al. 2011	Primates	16		505,357 bp <10 % missing	Bayesian relaxed clock autocorrelated rates model (MCMCTree)	
Kitazoe et al. 2007	Placentals	11	3,660 aa		Nonparametric relaxed clock autocorrelated rates model	Branch lengths are estimated by a new method that is designed to correct for convergent evolution. Divergence dates are estimated similarly to Sanderson's (1997) NPRS, but with a cost function that is more tolerant of abrupt rate changes. No calibration points within the primates. Confidence intervals not calculated for most nodes
Masters et al. 2013	Strepsirhines	22	3,529 bp		Bayesian relaxed clock uncorrelated rates model (BEAST)	Calibrated the crown primate node with molecular estimates from Chatterjee et al. (2009) and Perelman et al. (2011), which is not a recommended calibration practice. Dates presented here are from the younger Chatterjee et al. sourced calibration at 77.5 Ma

Matsui et al. 2009	Strepsirhines	26	3,753 aa		Bayesian relaxed clock autocorrelated rates model (MULTIDIVTIME)	Only one calibration point within the primates (Table 2)
Meredith et al. 2011	Placentals	13		35,603 bp 9 % missing 11,010 aa	Bayesian relaxed clock autocorrelated and independent rates models (MCMCTree)	Date estimates are average of estimates from both nucleotide and protein sequence analyses from both autocorrelated and uncorrelated rates models with both hard- and soft-bounded calibrations
Perelman et al. 2011	Primates	186		34,921 bp	Bayesian relaxed clock uncorrelated rates model (BEAST)	Many calibrations are questionable or unjustifiable (Table 2)
Perez et al. 2013	Platyrrhines	28	12,996 bp	34,941 bp	Bayesian relaxed clock uncorrelated rates model (BEAST)	Divergence dates presented here are using the Wildman et al. (2009) topology and the “second hypothesis” calibrations, which does not assume that *Dolichocebus* and *Tremacebus* are crown platyrrhines
Schrago and Voloch 2013	Hominoids	7		560,880 bp	Bayesian relaxed clock uncorrelated rates model (BEAST)	
Schrago et al. 2012	Primates	43	11,672 bp		Bayesian relaxed clock uncorrelated rates model (MCMCTree)	
Schrago et al. 2013	Platyrrhines		~4,200 bp	~156,500 bp 10–15 % missing	Bayesian relaxed clock uncorrelated rates model (MCMCTree)	Dates reported here are from their analysis of molecular data only

(*continued*)

Table 1 (continued)

Study	Focus	Number of primates	mtDNA	nDNA	Dating method	Notes
Springer et al. 2012	Primates	367	9,398 bp >50 % missing	51,801 bp >50 % missing	Bayesian relaxed clock autocorrelated and independent rates models (MCMCTree)	Date estimates are average of estimates from both autocorrelated and uncorrelated rates models with both hard- and soft-bounded calibrations
Steiper and Seiffert 2012	Primates	8		422,687 bp	Bayesian relaxed clock autocorrelated rates model (MCMCTree)	The rate estimates from the Bayesian relaxed clock analysis were regressed against body size and endocranial volume. These regressions were then used to estimate divergence dates from maximum likelihood estimated branch lengths. Dates presented here are the averages from the body size-based estimates.
		61		27,536 bp		
		14		12,478 bp		
		16		5,573,099 bp		
Wilkinson et al. 2010	Primates	15		82,670 bp 13 % missing	Bayesian relaxed clock autocorrelated rates model (MCMCTree)	Calibration prior distributions derive from an explicit model of lineage diversification, fossilization, and fossil recovery

Table 2 (continued)

Study	Calibrated node	Constraint	Fossils cited	References cited	Notes
Steiper and Seiffert 2012	MRCA Lorisiformes	>20.0, truncated Cauchy distribution[b]		Seiffert 2007	Used only to generate "weakly calibrated" rate estimates
	MRCA Papionini	6.0–8.0, with hard lower and soft upper bounds[c]	Earliest macaques	Moyà-Solà et al. 2004	Used only to generate "weakly calibrated" rate estimates
	MRCA *Homo-Pan*	6.0–8.0, with hard lower and soft upper bounds[c]	Earliest hominins	Vignaud et al. 2002; Lebatard et al. 2008	Used only to generate "weakly calibrated" rate estimates

[a] See Chatterjee et al. calibration distribution in Fig. 1 as an example

[b] See Jameson et al. calibration distribution in Fig. 1 as an example (Jameson et al. have a hard lower boundary)

[c] In Fig. 1, compare hard bounds of Hallström and Janke calibration distribution to soft bounds of dos Reis et al. distribution

[d] See Perelman et al. calibration distribution in Fig. 1 as an example

[e] See Perez et al. calibration distribution in Fig. 1 as an example

[f] Springer et al. use all of the previously listed calibration points of Meredith et al. (2011) as well

choose similar calibration distributions, but this reasonable expectation is often false. As an example, six different calibration distributions used for the crown catarrhine node within the last 5 years are presented in Fig. 1. This diversity of calibration distributions is not a result of any meaningful disagreement on the paleontological information: most cite fossils dated to about the same time (i.e., *Morotopithecus*, *Proconsul*, *Victoriapithecus*) as the calibration point (Table 2).

In general, somewhat more lenient distributions are preferable, since it seems problematic to exclude a divergence date that would be a good model fit (Yang and Rannala 2006). In the molecular divergence dating literature, this is reflected in the development and preference for "soft"-bounded calibrations (as opposed to "hard"-bounded minimums and maximums that strictly contain calibration dates). The long tails of the Chatterjee et al. (2009), Jameson et al. (2011) and Perez et al. (2013) catarrhine calibrations in Fig. 1 are all examples of soft boundaries where the probability of an older value from the calibration distribution is limited, but nonzero. In addition to these long tails, many divergence dating algorithms allow for some probability density more recent than the calibrating fossil date to accommodate the possibility that the calibration fossil is misdated or mistakenly attributed to the crown group. As an example, in Fig. 1, the Hallström and Janke (2010) catarrhine

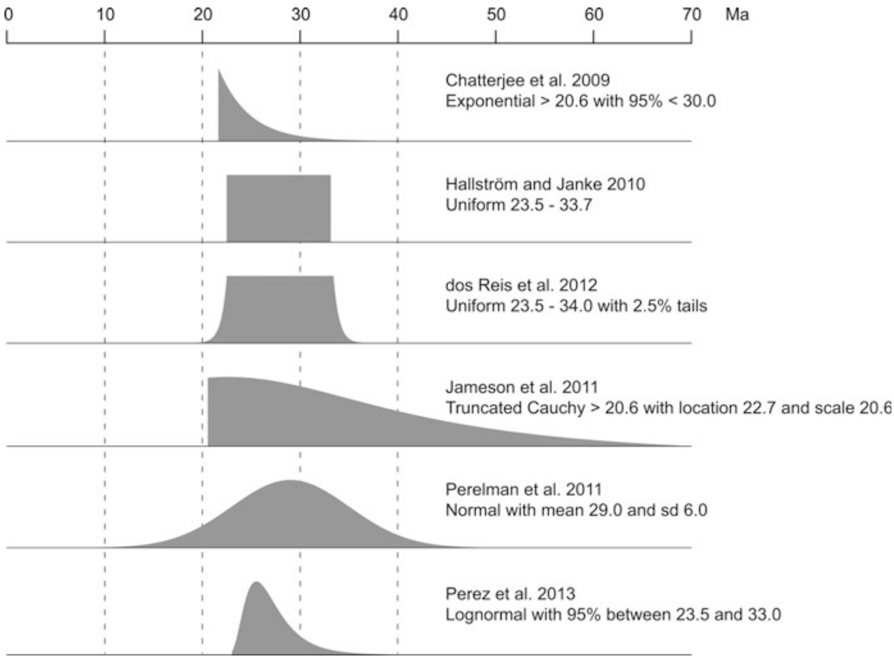

Fig. 1 Examples of various calibration prior distributions. Some examples of calibration density distributions beyond simple minimum or maximum bounds. Distributions may have "hard" boundaries that preclude divergence date estimates at the calibrated node beyond a specified boundary or "soft" boundaries that allow but place low probability on divergence date values outside specified minima or maxima

calibration has hard boundaries, indicating that the model should not be able to choose a divergence date for the calibration node outside the specified minimum and maximum, while the dos Reis et al. (2012) catarrhine calibration extends 2.5 % of the calibration density distribution above and below the specified minimum and maximum.

Given that fossil calibrations are the minimum age of the most recent common ancestor of a clade, a consensus has emerged for the most justifiable calibration distribution shape (Hedges and Kumar 2004; Benton et al. 2009) and the most commonly used software packages for divergence date estimation implement at least one appropriate calibration distribution (Drummond et al. 2006, 2012; Yang and Rannala 2006; Inoue et al. 2010). This preferred calibration density distribution has the most weight nearest the age of the calibrating fossil and a long tail which prioritizes dates nearest the calibration date but accommodates lineages with gaps in the fossil record (i.e., the earliest hominid and hylobatid fossils are found millions of years after most paleontologists believe the hylobatid-hominid divergence occurred). Of the calibration densities shown in Fig. 1 for the crown catarrhine node, those of Chatterjee et al. (2009), Jameson et al. (2011) and Perez et al. (2013) fit this general shape.

Finally, it is important to remember that divergence dates based on fossil calibrations are not estimates of the lineage divergence times but estimates of the minimum age of lineage divergences (Hedges and Kumar 2004; Benton et al. 2009). It is tempting to interpret them as estimates of the time at which the descendant lineages actually diverged, but this would only be true if all of the fossil used for calibrations were among the very first members of the daughter lineages, dated to shortly after the speciation. Because this is almost certainly not true for primate divergence dates, it is important to interpret divergence date estimates as "must have diverged before" rather than "most likely diverged at."

Most of the recently published divergence date estimates are presented, but those studies that best meet good analytic criteria are indicated in the figures. In addition to preferences for recent publications with broad taxon sampling, the following are preferred: studies with dates resulting from clearly justifiable calibration points; studies that use more calibration points within the primates, especially if they are placed at all time depths of the primate radiation (Smith and Peterson 2002; Raaum et al. 2005), and calibration probability density distributions with long tails (see Jameson et al. calibration in Fig. 1); and studies that properly discuss divergence dates as estimates of the minimum age of divergence.

The Place of Primates Within Mammals

Primates' Sister Taxon

Following Gregory (1910), primates were usually classified in the superorder Archonta, along with treeshrews (Scandentia), colugos (Dermoptera), and bats (Chiroptera), and a close relationship of these orders was favored through most of the last century (Simpson 1945; Szalay 1977; Novacek et al. 1988; Novacek 1992; McKenna et al. 1997; Shoshani and McKenna 1998). The demise of Archonta grew out of the proposal that fruit-eating bats (Megachiroptera) might be more closely related to primates than to other bats (Smith and Madkour 1980; Pettigrew et al. 1989). Molecular data collected to test this hypothesis supported bat monophyly but also revealed that bats are not closely related to the other archontans (Bailey et al. 1992; Adkins and Honeycutt 1993; Simmons 1994; Pumo et al. 1998).

The molecular genetic hypothesis of mammalian ordinal relationships was first presented close to its current form in 2001 (Murphy et al. 2001a, b; Waddell et al. 2001). These studies analyzed concatenated data from the mitochondrial genome and 14–19 gene fragments from the nuclear genome to identify four superordinal groups of placental mammals: (1) Euarchontoglires (primates, treeshrews, colugos, rodents, lagomorphs), (2) Afrotheria (aardvarks, elephants, golden moles, hyraxes, sea cows, sengis (elephant shrews), and tenrecs), (3) Xenarthra (anteaters, armadillos, and tree sloths), and (4) Laurasiatheria (artiodactyls, bats, carnivores, cetaceans, gymnures (moonrats), hedgehogs, moles, pangolins, perissodactyls, shrews, and solenodons). All of these groups have received broad support in studies of ever-growing molecular phylogenetic datasets ranging from a handful of short mitochondrial and nuclear sequences to complete mitochondrial sequences to thousands of unlinked nuclear loci (Waddell and Shelley 2003; Nishihara et al. 2006, 2009; Kriegs et al. 2006; Bininda-Emonds et al. 2007; Nikolaev et al. 2007; Waters et al. 2007; Wildman et al. 2007; Hallström et al. 2007; Murphy et al. 2007; Arnason et al. 2008; Prasad et al. 2008; Hallström and Janke 2008, 2010; Meredith et al. 2011; Song et al. 2012b; McCormack et al. 2012; Morgan et al. 2013). Despite large phylogenomic datasets and methodological advances, there is no current molecular genetic consensus on the branching order among Afrotheria, Boreotheria (Euarchontoglires plus Laurasiatheria), and Xenarthra (Nikolaev et al. 2007; Wildman et al. 2007; Churakov et al. 2009; McCormack et al. 2012; Song et al. 2012a; Morgan et al. 2013; Romiguier et al. 2013; Teeling and Hedges 2013).

Within Euarchontoglires, most studies support the clade Euarchonta for primates, treeshrews, and colugos, but the branching order within this clade is not well resolved (Liu et al. 2001; Murphy et al. 2001a, b; Waddell et al. 2001; Janečka et al. 2007; Nie et al. 2008; Perelman et al. 2011). One major impediment to a fully convincing resolution of these relationships is the relative paucity of molecular genetic data for colugos, probably because there are none in captivity. Since it is impossible to meaningfully resolve euarchontan relationships without colugos, only those studies that were able to include colugo data are discussed here. There are two main hypotheses of relationships. In the Primatomorpha hypothesis, primates and colugos are sister taxa (Waddell et al. 2001; Waddell and Shelley 2003; Bininda-Emonds et al. 2007; Janečka et al. 2007; Meredith et al. 2011; Perelman et al. 2011), and in the Sundatheria hypothesis, treeshrews and colugos are sister taxa (Liu et al. 2001; Murphy et al. 2001b, 2007; Nie et al. 2008).

The Primatomorpha hypothesis currently has better support. The strongest evidence comes from Janečka et al. (2007), who find seven amino acid insertion/deletions (indels) that support Primatomorpha and none that support Sundatheria (amino acid indels should be less homoplasious than single nucleotide variants [Simmons et al. 2001]). In addition, in their analysis of ~14 kb of concatenated sequences from 19 nDNA loci, they find consistent support for Primatomorpha when data are included from both families of colugos. That is, broader taxon sampling is required for these groups in order to break up long branches and mitigate the consequences of long branch attraction (Hendy and Penny 1989; Hillis 1996; Pollock et al. 2002).

Long branch attraction can occur in any phylogenetic analysis where two or more of the taxa included are very distant from all other study taxa (i.e., have "long branches") (Felsenstein 1978; Hendy and Penny 1989). In these circumstances, there will usually be relatively few shared, derived characters present in the data matrix to link the long branch taxa to their closest relatives. Even more troublesome, homoplasious resemblances to other taxa may overwhelm homologous ones for these long branch taxa. This misleading homoplasy is more likely in DNA sequence data, because there are only four possible character states for DNA sequence data. Multiple mutations can occur at the same site, resulting in back mutation to the ancestral state or independent mutation to the derived state in another group, and unlike morphological data where convergently acquired characteristics might not be identical on closer inspection, convergently acquired nucleotide characters are identical. Because transposable element insertions and other indels are less likely to converge, these data have been prioritized in resolving the relationships of long branch taxa (Kriegs et al. 2006; Janečka et al. 2007). If there are two or more long branch taxa, they have a good chance of sharing many homoplasious character states and being grouped together. Since outgroup taxa almost invariably have long branches, any ingroup long branch taxa will often be pulled towards the outgroup. Two or more ingroup long branch taxa can also be pulled together. In Euarchontoglires, two of the five orders have long branches in most phylogenetic analyses: the colugos and the treeshrews.

Further support for Primatomorpha is found in Perelman et al.'s (2011) analysis of a mostly independent sequence dataset. Other studies reporting some support of Primatomorpha do not have substantially independent data (Meredith et al. 2011), report varying relationships across different methods of phylogenetic reconstruction (Waddell et al. 2001), or are based on very limited colugo or treeshrew data (Waddell et al. 2001; Bininda-Emonds et al. 2007). While Murphy et al. (2001b, 2007) did initially report support for Sundatheria, these results are superseded by later publications from this research group supporting Primatomorpha (Janečka et al. 2007; Meredith et al. 2011). The sole non-contraindicated molecular support for Sundatheria is found in a chromosome rearrangement reported to be shared by treeshrews and colugos (Nie et al. 2008), but the limited chromosome map generated in this report is more intriguing than convincing.

Dating Primate Origins

Paleontological data suggest that both inter- and intraordinal diversification of placental mammals occurred after the Cretaceous-Paleogene (K-Pg) event (Archibald and Deutschman 2001; O'Leary et al. 2013). In contrast, most molecular studies have reported dates before the K-Pg event for both interordinal splits and at least some intraordinal diversification (Janke et al. 1994; Hedges et al. 1996; Easteal and Herbert 1997; Kumar and Hedges 1998; Arnason et al. 2000, 2001; Springer et al. 2003).

Estimates of the minimum time of the strepsirhine-haplorhine split fall into two groups (Fig. 2). The majority present minimum divergence dates falling between 58 and 72 Ma (Kitazoe et al. 2007; Chatterjee et al. 2009; Hallström and Janke 2010; Jameson et al. 2011; Meredith et al. 2011; dos Reis et al. 2012; Springer

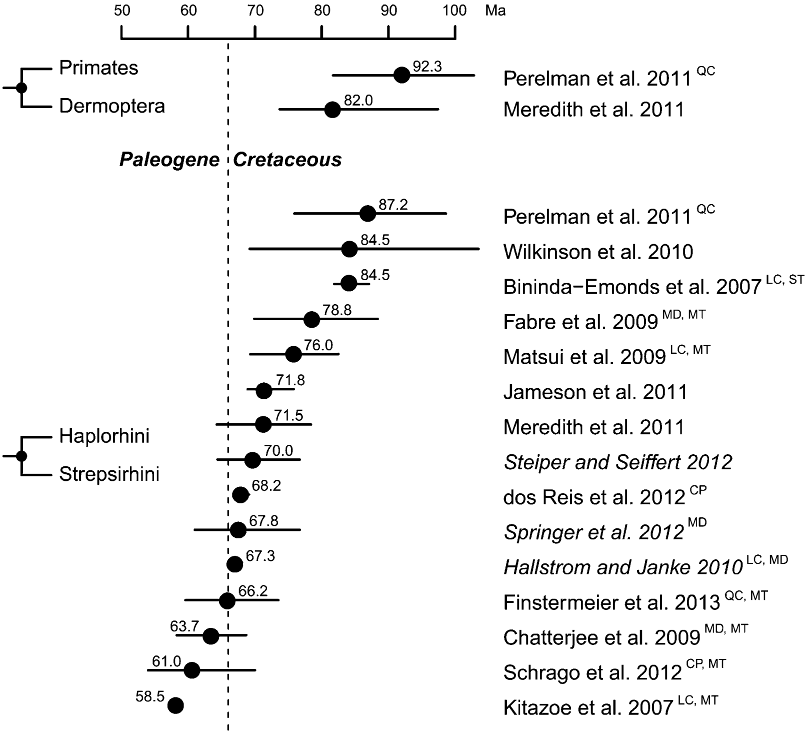

Fig. 2 Divergence date estimates at the base of the Primatomorpha and the Primates. Point divergence date estimates and 95 % confidence/credibility intervals from recent studies. Article citations in italics best meet the quality criteria discussed in the Introduction. Abbreviations following citations are as follows: *CP* calibration point, *LC* limited calibration within primates (see Table 2); *MD* >20 % missing data, *MT* based largely or solely on mtDNA sequences, *ST* supertree-based analysis, *QC* questionable calibration (see Table 2)

et al. 2012; Steiper and Seiffert 2012; Finstermeier et al. 2013), most of which have confidence intervals wide enough that they cannot definitively be said to pre- or postdate the K-Pg event. The second set of divergence dates fall well into the Upper Cretaceous between 78 and 92 Ma and definitively predate the K-Pg event (Bininda-Emonds et al. 2007; Arnason et al. 2008; Fabre et al. 2009; Wilkinson et al. 2010; Perelman et al. 2011).

One of the most innovative studies among those cited above is Steiper and Seiffert (2012). Recognizing the problems with fossil-calibrated divergence date estimation, particularly for earlier divergences where the fossil record can be sparse, Steiper and Seiffert sought to estimate divergence dates with minimal dependence on fossil dates for calibration. Their method takes advantage of the observation that the neutral rate of molecular evolution is correlated with generation time (Wu and Li 1985; Li et al. 1996; Yi et al. 2002; Tsantes and Steiper 2009). And because generation time is correlated with brain and body size (Calder 1984; Harvey and Clutton-Brock 1985; Deaner et al. 2002), the fossil record can be used to inform a model of molecular evolutionary rate change over time.

Steiper and Seiffert first modeled the evolutionary history of body and brain size in primates using data from extant and extinct primates. Second, they verified that brain and body size can explain a substantial proportion of the variance in evolutionary rate across the living primates. Finally, they combined their evolutionary models of brain and body size evolution with their models predicting the rate of molecular evolution from brain and body size to predict evolutionary rates through primate evolutionary history, which provides estimates of divergence dates. While they do use some fossil calibrations (Tables 1 and 2) to generate their initial estimates of molecular evolutionary rates in primate evolution, they deliberately use very few calibration points in order that rate variation across lineages is minimally accounted for by the usual fossil-calibrated divergence dating methods. To the extent that Steiper and Seiffert (2012) accurately model evolutionary rate variation through primate evolutionary history, the divergence date estimates from their method are estimates of the actual date of genetic divergence, rather than estimates of the minimum date of genetic divergence. As such, they can be more directly and correctly interpreted.

Because the identification of the closest living relative of primates has been contentious and colugo data is so limited, there are only two estimates for the primate-colugo divergence that are the most recent estimates from independent molecular systematic research groups and derive from analyses that include data from all euarchontans (Fig. 2). Both of these estimates are well before the K-Pg event, but there is reason to believe that they are overestimates. Meredith et al. (2011) present an estimate of 82.0 Ma (95 % CI: 73.7–97.4), and Perelman et al. (2011) place the primate-colugo divergence at 92.3 Ma (95 % CI: 81.7–102.8). However, both Meredith et al. and Perelman et al. estimate strepsirhine-haplorhine divergence dates that are considerably earlier than almost all other estimates for this node as well (Fig. 2). Nonetheless, the primate-colugo divergence must predate the haplorhine-strepsirhine divergence, and since all estimates of the minimum age of strepsirhine-haplorhine divergence lie near the K-Pg event, it seems most likely that the primate-colugo divergence predates the Paleogene.

Future Directions

The limited evidence for colugos is the major impediment to resolving euarchontan relationships and refining the timing of primate origins. Since there are no captive colugos, it is certainly more difficult to collect DNA from this order. However, while they are geographically restricted to Southeast Asia, they are neither endangered nor particularly rare (there is a free-ranging population of Sunda colugos on the grounds of the Singapore Zoo). Acquiring data from both genera of colugo, the Sunda colugo (*Galeopterus*) and the Philippine colugo (*Cynocephalus*) should be prioritized in order to break up the long colugo branch (these species are estimated to have diverged about 20 Ma [Janečka et al. 2008]). More data are available for treeshrews, including draft genomes for two northern treeshrews (Fan et al. 2013). However, most of the available genetic data available for treeshrews is from *Tupaia* (Tupaiidae), and it should be a priority to obtain more data from smooth-tailed treeshrews (*Dendrogale*, Tupaiidae) and pen-tailed treeshrews (*Ptilocercus*, Ptilocercidae). These genera diverged from *Tupaia* approximately 30–50 and 50–70 Ma, respectively (Roberts et al. 2011). Collecting more sequence data from *Dendrogale* and *Ptilocercus* species will help to break up the long treeshrew branch. Of course, new fossils of early crown primates, especially from the Paleocene, would be very desirable and useful as well.

Haplorhine Relationships and Diversification

Tarsiers Are Haplorhine Primates

The molecular data clearly show that anthropoids are the sister group to tarsiers (Goodman et al. 1998; Ziętkiewicz et al. 1999; Schmitz et al. 2001, 2002; Matsui et al. 2009; Jameson et al. 2011; Lindblad-Toh et al. 2011; Hartig et al. 2013). Much of the early molecular phylogenetic research in primates was based on the analysis of mitochondrial DNA sequences and often showed tarsiers as the sister taxon to the strepsirhines. However, tarsiers have retained some ancestral features in their mitochondrial DNA. In both DNA nucleotide composition and amino acid usage, the tarsier shows a pattern that is more like that seen in non-primate placental mammals and strepsirhines (Waddell et al. 2001; Schmitz et al. 2002; Matsui et al. 2009). In addition, tarsiers have a long independent evolutionary history, which leads to long branch attraction problems in phylogenetic reconstruction. The haplorhine affinity of tarsiers has been recently reaffirmed by analyses of a 1.25 Mb nDNA sequence alignment (Jameson et al. 2011), a genome-wide study of transposable elements (Hartig et al. 2013), and whole genome sequences (Lindblad-Toh et al. 2011).

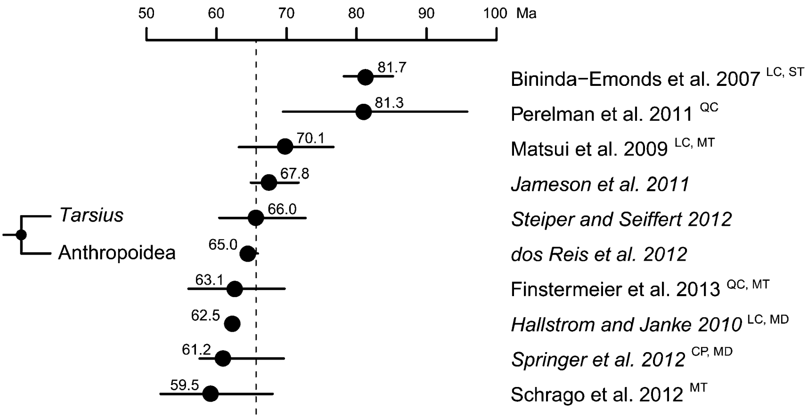

Fig. 3 Crown haplorhine divergence date estimates. Abbreviations and italics as described in the caption to Fig. 2

Dating the Tarsier-Anthropoid Divergence

There are two clear clusters of tarsier-anthropoid divergence times (Fig. 3). A majority of recent studies report that the most recent date of the tarsier-anthropoid divergence lies between 61 and 70 Ma (Matsui et al. 2009; Hallström and Janke 2010; Jameson et al. 2011; Meredith et al. 2011; dos Reis et al. 2012; Springer et al. 2012; Steiper and Seiffert 2012; Finstermeier et al. 2013). Most of these estimates have 95 % confidence intervals compatible with a post-K-Pg diversification of the primates. There are two clear outlier estimates for this divergence date at 82 Ma: one from the placental evolution-oriented supertree study of Bininda-Emonds et al. (2007) and the other from the questionably calibrated study of Perelmen et al. (2011).

Anthropoid Diversification

There are two major branches of the anthropoids, the Catarrhini (Old World monkeys and apes) and the Platyrrhini (New World monkeys or neotropical primates). It is universally agreed across recent molecular dating studies that the catarrhine and platyrrhine lineages must have diverged before the end of the Eocene (Fig. 4). Of course, since the Eocene is the longest epoch of the Cenozoic, this is not altogether satisfying. The best estimates indicate that anthropoid diversification began before 35–45 Ma (Kitazoe et al. 2007; Jameson et al. 2011; dos Reis et al. 2012; Springer et al. 2012; Steiper and Seiffert 2012; Perez et al. 2013; Schrago et al. 2013). The major molecular phylogenetic questions within the anthropoids are the relationships among the platyrrhine families and the time of their diversification and the timing of catarrhine diversification.

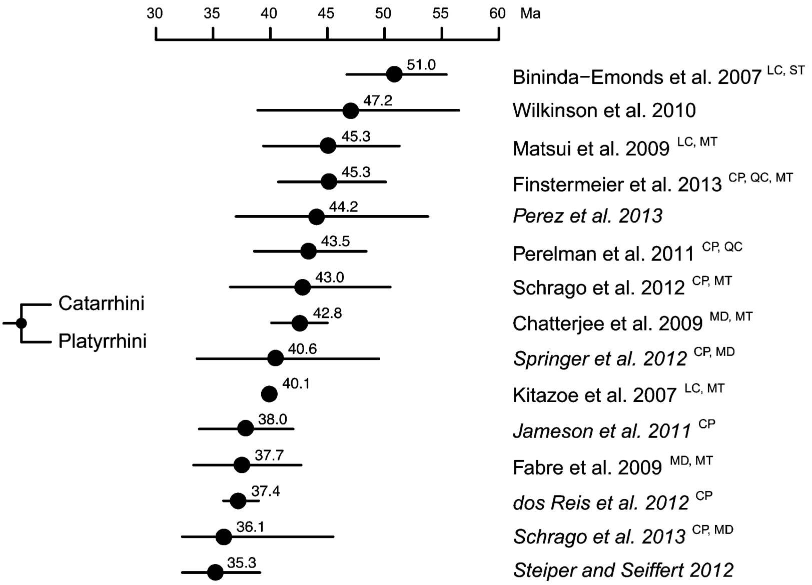

Fig. 4 Crown anthropoid divergence date estimates. Abbreviations and italics as described in the caption to Fig. 2

Relationships of the Major Platyrrhine Lineages

There is broad agreement that there are three major clades of platyrrhines: the Atelidae (spider monkeys, howler monkeys, woolly monkeys, and muriquis), the Cebidae (capuchins, squirrel monkeys, owl monkeys, marmosets, and tamarins), and the Pitheciidae (titi monkeys, sakis, and uakaris) (Goodman et al. 1998; Opazo et al. 2006; Wildman et al. 2009; Perez et al. 2012; Schrago et al. 2012). Early molecular studies reported conflicting relationships among these three families, with some support for all three options: a close relationship of the Atelidae and Pitheciidae (Schneider et al. 1993, 1996, 2001; Harada et al. 1995; Porter et al. 1997, 1999; Goodman et al. 1998; Horovitz et al. 1998; Canavez et al. 1999; Opazo et al. 2006), a close relationship of the Cebidae and Pitheciidae (Schneider et al. 1996; Barroso et al. 1997), and a close relationship of the Atelidae and Cebidae (Chaves et al. 1999; von Dornum and Ruvolo 1999; Steiper and Ruvolo 2003; Ray et al. 2005; Opazo et al. 2006).

There is now a clear consensus that Atelidae and Cebidae are sister taxa (Fabre et al. 2009; Hodgson et al. 2009; Osterholz et al. 2009; Perelman et al. 2011; Perez et al. 2012; Schrago et al. 2012, 2013; Springer et al. 2012; Finstermeier et al. 2013). This conflicts with the earlier molecular publications, the majority of which supported Atelidae and Pitheciidae as sister taxa. The reason for this conflict is that much of the early platyrrhine molecular phylogenetics was based on a handful of nDNA sequences (IRBP, vWF, G6PD, B2M, HBE1), analyzed individually in the earlier papers, then in combination in the later papers. Unfortunately, three of those loci (IRBP, B2M, HBE1) have gene trees that conflict with parts of the platyrrhine species tree. Analyzing any of these three separately or in combination leads to misleading topologies. Even worse, combinations of sequences from other loci with these three often resulted in mistaken phylogenetic inference (e.g., Schneider et al. 2001). Only with the collection of complete mtDNA sequences (Hodgson et al. 2009; Schrago et al. 2012; Finstermeier et al. 2013), rare insertion events (e.g., SINEs) (Ray et al. 2005; Osterholz et al. 2009), and data from dozens of additional nDNA loci (Wildman et al. 2009; Perelman et al. 2011; Springer et al. 2012; Schrago et al. 2013) were the misleading gene trees of these early sequencing targets revealed.

Relationships Within the Cebidae

The owl monkeys, *Aotus*, are difficult to place. All recent molecular phylogenetic studies have found them to be related to the other members of the Cebidae but have reported *Aotus* variably as the sister taxon to the cebines (capuchins and squirrel monkeys) (Wildman et al. 2009; Finstermeier et al. 2013; Schrago et al. 2013), as the sister taxon to the callitrichines (marmosets and tamarins) (Chatterjee et al. 2009; Fabre et al. 2009; Hodgson et al. 2009; Perelman et al. 2011; Schrago et al. 2012; Springer et al. 2012; Finstermeier et al. 2013), or as the sister taxon to a clade containing both the cebines and the callitrichines (Wildman et al. 2009; Perez et al. 2012).

By citation count alone, it would seem that recent molecular work comes down in support of a sister taxon relationship between *Aotus* and the callitrichines. However, many of these studies are based entirely or largely on mtDNA sequences. Wildman et al. (2009) have the best data of all of the cited studies; they collected 11 new independently evolving, putatively neutral, single copy nDNA sequences. (Most of the nDNA loci analyzed in other studies are sequences of functional, adaptive, or biomedical interest.) In their analysis of the newly collected data alone, they recovered *Aotus* as the sister taxon to a cebine-callitrichine clade, but when they combined these new data with previously published genic nDNA sequences, they recovered *Aotus* as the sister taxon to the cebines. Both groupings had low support.

Wildman et al. analyzed concatenated data, which has been the usual approach to multi-locus data (de Queiroz and Gatesy 2007). With concatenated data, different data partitions (sets of sites, codons, loci, etc.) are modeled with different evolutionary parameters (substitution rates, base composition, etc.), but all are evaluated on the same tree topology. This is not ideal. As noted above in the discussion of the relationships among the platyrrhine families, individual loci have histories that can and do differ from each other and the species tree (Pamilo and Nei 1988; Maddison 1997). Until recently, inference of the species tree from a combined analysis of multiple, independent gene trees has been impractical, but computational advances and new methodological developments have now made this approach feasible in what is called the "multispecies coalescent" (Degnan and Rosenberg 2009; Edwards 2009; Ting and Sterner 2013). Perez et al. (2012) reanalyzed the

Wildman et al. data in the multispecies coalescent framework (as implemented in *BEAST [Heled and Drummond 2010]) and recovered the same result as Wildman et al. (*Aotus* as the sister taxon to a clade containing the cebines and callitrichines). Of course, in and of itself, this is not particularly interesting. But Perez et al. also reanalyzed a subset of the Perelman et al. (2011) data matrix (trimmed to minimize missing data while retaining at least one member of each platyrrhine genus) and recovered the same topology as Wildman et al. (which is not what Perelman et al. found in their original *concatenated* analysis). The sole remaining non-mtDNA-based support for grouping *Aotus* and the callitrichines comes from Springer et al. (2012), but this paper is not substantially independent from Perelman et al. (Springer et al. collected sequences from an additional 15 loci and concatenated them with the 54 loci in the Perelman et al. dataset). It seems likely that if Perez et al. repeated their multispecies coalescent analysis with data from the Springer et al. collection, they might still recover *Aotus* as sister to a cebine-callitrichid clade.

Divergence Dates Within the Platyrrhines

The most heated question in the timing of the platyrrhine radiation is the antiquity of the crown lineages (Delson and Rosenberger 1984; Rosenberger 2002, 2010; Kay et al. 2008; Hodgson et al. 2009; Rosenberger et al. 2009; Kay and Fleagle 2010; Perez et al. 2013). The earliest platyrrhine fossils (i.e., *Branisella*) are found in late Oligocene deposits dated to around 26 Ma, but the available material is relatively limited and cannot be convincingly linked to any specific living platyrrhine (Takai et al. 2000). The next earliest fossils are dated at 20 Ma and lie at the heart of the debate about the age of the crown lineages. *Dolichocebus gaimanensis*, from the early Miocene of Argentina (Kay et al. 2008), has been linked to the living cebines (*Saimiri* and *Cebus*) (Rosenberger 1979; Tejedor 2008), perhaps specifically to *Saimiri* (Rosenberger 1979). *Tremacebus harringtoni*, also from the early Miocene of Argentina (Hershkovitz 1974; Kay et al. 2004), has been linked specifically to *Aotus* (Rosenberger 2002; Tejedor 2008). The attribution of these early fossil platyrrhines to crown groups has been termed the “Long Lineages Hypothesis.” My colleagues and I dubbed the alternative – that these early platyrrhines are not closely related to any specific living platyrrhine – the “Successive Radiations Hypothesis” (Hodgson et al. 2009).

For any variant of the Long Lineages Hypothesis to be possible, the specifically linked living lineage must have diverged from its nearest relative by at least 20 Ma. In the most specific linkage, if *Dolichocebus* is most closely related to *Saimiri* among the living forms (Rosenberger 2002), then the *Saimiri* lineage must have split from the *Cebus* lineage by 20 Ma. If *Dolichocebus* is not linked specifically to *Saimiri* but to the larger cebine clade, then the cebines must have diverged from their nearest relative by 20 Ma. Finally, if the hypothesis is simply that *Dolichocebus* could fall *somewhere* within the crown platyrrhines, then the deepest diversification of the living lineages must have occurred by 20 Ma. The same line of reasoning follows for *Tremacebus* with appropriate substitutions for the putative relatives.

It seems reasonable to believe that molecular divergence date estimates could provide some insight into the question of whether or not these early platyrrhines might belong to the crown radiation, and several studies have commented on that hypothesis (Hodgson et al. 2009; Schrago et al. 2012, 2013; Perez et al. 2013). Unfortunately, as discussed towards the beginning of this review, divergence date estimates should usually be read as "are estimated to have diverged before" and cannot provide very strong evidence to exclude an earlier fossil taxon from a crown group, except when there is a large discrepancy (i.e., if the crown group is estimated to have diverged prior to 5 Ma and the questionable fossil is dated at 25 Ma, it seems very likely that it is not part of the crown group). What are required are divergence dates that estimate the actual date of lineage bifurcation rather than minimum dates of bifurcation. Of all the divergence date estimates presented here, those of Steiper and Seiffert (2012) come closest to estimating actual divergence dates (as discussed earlier in the "Dating Primate Origins" section). While their method of date estimation does start with a time-calibrated tree, they did not use any fossil calibrations within the platyrrhines. A second calibration-free set of divergence dates are provided by Perez et al. (2013), who apply a variation of the Steiper and Seiffert method to platyrrhine divergence date estimation.

Focusing on the calibration-free and nearly calibration-free methods, there is an immediate discrepancy. Steiper and Seiffert (2012) estimate that the crown platyrrhines diverged between 17.9 and 20.2 Ma, and Perez et al. (2013) report 20.3–28.5 Ma (Fig. 5). There are too many differences in the details of the procedures that these two studies followed to be able to pinpoint the source of their differences and select a preferred estimate. The Perez et al. estimate of the time to the most recent common ancestor of the living platyrrhines would not directly

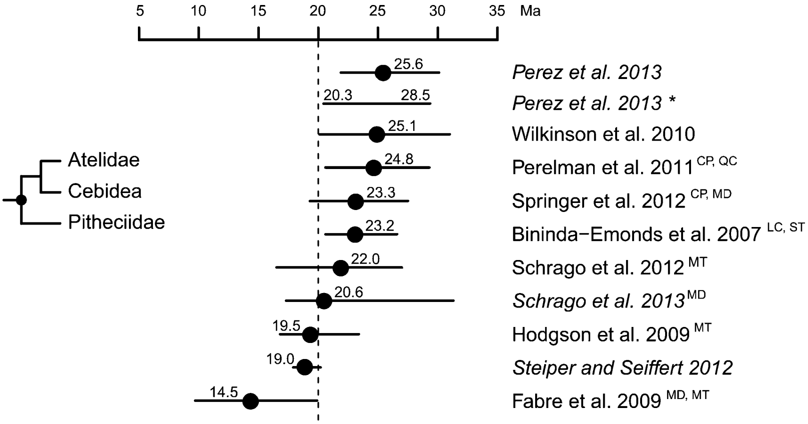

Fig. 5 Crown platyrrhine divergence date estimates. The *dashed line* at 20 Ma indicates the age of the disputed fossil platyrrhine taxa *Dolichocebus* and *Tremacebus*. *Asterisk* indicates the fossil calibration-free divergence date estimates of Perez et al. (2013) as discussed in the text. Abbreviations and italics otherwise as described in the caption to Fig. 2

exclude any of the fossil forms from the crown radiation, while the Steiper and Seiffert estimates would clearly exclude *Branisella* from the crown group but could include *Dolichocebus* and *Tremacebus*.

For the crown Cebidae, Steiper and Seiffert (2012) estimate a divergence between 15.9 and 17.8 Ma, and Perez et al. (2013) estimate 15.6–21.8 Ma (Fig. 6). Again, there is a discrepancy in these date estimates that has consequences

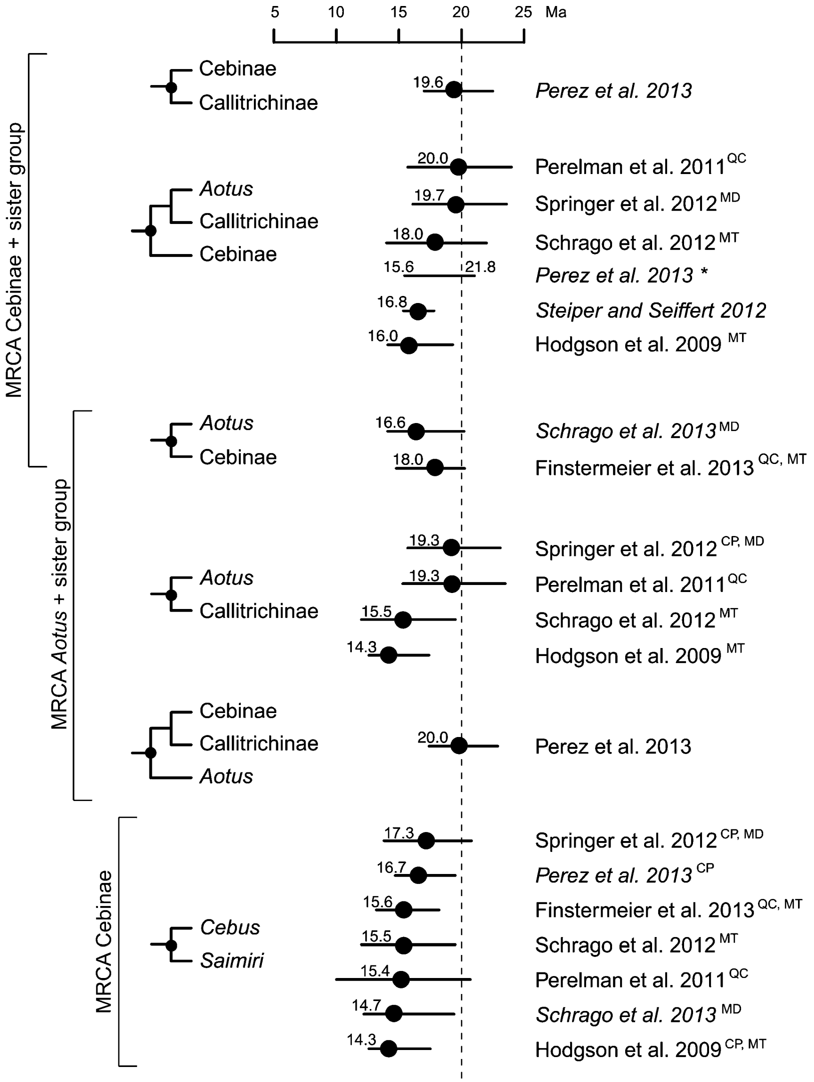

Fig. 6 Divergence date estimates of and within the crown Cebidae. The *dashed line* at 20 Ma indicates the age of the disputed fossil platyrrhine taxa *Dolichocebus* and *Tremacebus*. *Asterisk* indicates the fossil calibration-free divergence date estimates of Perez et al. (2013) as discussed in the text. Abbreviations and italics otherwise as described in the caption to Fig. 2

for our possible interpretation of the early Miocene fossils. Steiper and Seiffert's date clearly excludes *Dolichocebus* and *Tremacebus* from the crown cebids, while Perez et al.'s date range could include them. However, the Perez et al. range only *just* extends deep enough in time to potentially include *Dolichocebus* and *Tremacebus*. If any earlier fossils of these forms were to be found, they would become excluded. Furthermore, while Perez et al. did not present divergence dates within Cebidae (i.e., the *Cebus*-*Saimiri* and the *Aotus*-sister taxon divergences), it seems possible that those date estimates could exclude *Dolichocebus* from the *Saimiri* lineage and *Tremacebus* from the *Aotus* lineage.

Divergence Dates Within the Catarrhines

There is no disagreement on higher level relationships within the catarrhines. There are two superfamilies, the Cercopithecoidea (Old World monkeys) and the Hominoidea (apes and humans), each of which has two subdivisions. The Old World monkeys are split between two subfamilies, the Colobinae (colobines and langurs) and the Cercopithecinae (baboons, guenons, and macaques), while the hominoids are split between the Hylobatidae (small apes: gibbons and siamang) and the Hominidae (great apes: orangutans, gorillas, chimpanzee, bonobo, and human).

The best estimates of the divergence of the cercopithecoids and hominoids range from 23 to 28 Ma (Fig. 7) (Hallström and Janke 2010; Jameson et al. 2011; dos Reis et al. 2012; Springer et al. 2012; Steiper and Seiffert 2012; Schrago and Voloch 2013), consistent with the hypothesis that catarrhine diversification began during the late Oligocene. *Kamoyapithecus*, from deposits dated at 24–28 Ma, is often mentioned as a possible early hominoid (Boschetto et al. 1992; Leakey et al. 1995) and, if so, could be one of the earliest members of the group. However, *Kamoyapithecus* is very fragmentary and may well be a stem catarrhine (Harrison 2002). More recently, both an early stem ape, *Nsungwepithecus gunnelli*, and an early stem Old World monkey, *Rukwapithecus fleaglei*, have been reported from deposits dated at just before 25 Ma (Stevens et al. 2013). While the fossil material from both is very limited, their date is consistent with the 23–28 Ma range from the best recent molecular estimates and could represent some of the very earliest members of each superfamily. Within the hominoids, the best estimates place the split between the smaller and larger apes at 17–21 Ma (Fig. 8) (Springer et al. 2012; Schrago and Voloch 2013). The earliest possible hylobatids are not found until the late Miocene (Jablonski and Chaplin 2009) and the earliest putative stem hominids only begin to appear after 13 Ma (Moyà-Solà et al. 2009; Casanovas-Vilar et al. 2011). Thus, molecular divergence estimates suggest at least 4 Ma of currently undocumented hominid evolution.

There is a broad range in the estimated dates for the divergence between the colobines and cercopithecines from 11 to 24 Ma (Fig. 8). All of the estimates greater than 20 Ma are based on the analysis of mtDNA data alone, so it seems that there is a problem estimating the date of this node from mtDNA, possibly related to the changing substitution rate within the sister hominoid clade (Goodman 1961, 1963, 1996;

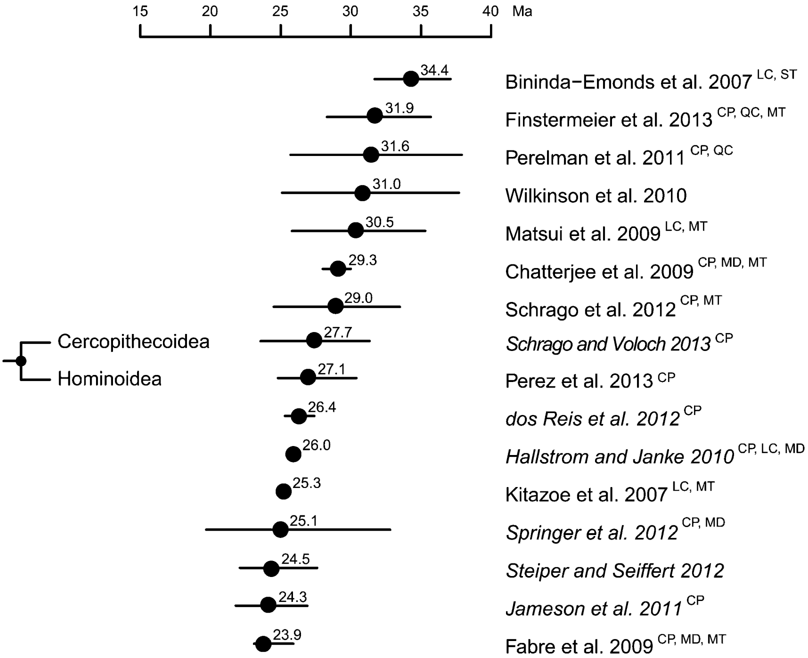

Fig. 7 Crown catarrhine divergence date estimates. Abbreviations and italics as described in the caption to Fig. 2

Steiper et al. 2004). All estimates based on datasets including or entirely comprised of nDNA sequences are less than 18 Ma, and the best of those are between 11 and 14 Ma (Jameson et al. 2011; Springer et al. 2012; Steiper and Seiffert 2012). Recently, Rossie et al. (2013) reported on two isolated cercopithecoid molars from Kenya dated at 12.5 Ma and tentatively assigned them to an unknown colobine genus. These teeth are contemporaneous with the best current molecular divergence date estimates and could either represent some of the earliest colobines or indicate that the molecular estimates should be recalibrated for a slightly older cercopithecine-colobine divergence.

Future Directions

Of the platyrrhine phylogenetic questions presented here, the one least resolved is the branching order among *Aotus*, the cebines, and the callitrichines. While the topology with *Aotus* as the sister taxon to a cebine plus callitrichine clade has been presented as best supported by molecular data, this topology does not have particularly strong support. Since there are fairly substantial mtDNA and nDNA data available for these taxa, there may have been a rapid diversification at the origins of the Cebidae or reticulation and hybridization following the initial diversification. The second least resolved platyrrhine systematic question is whether or not the late

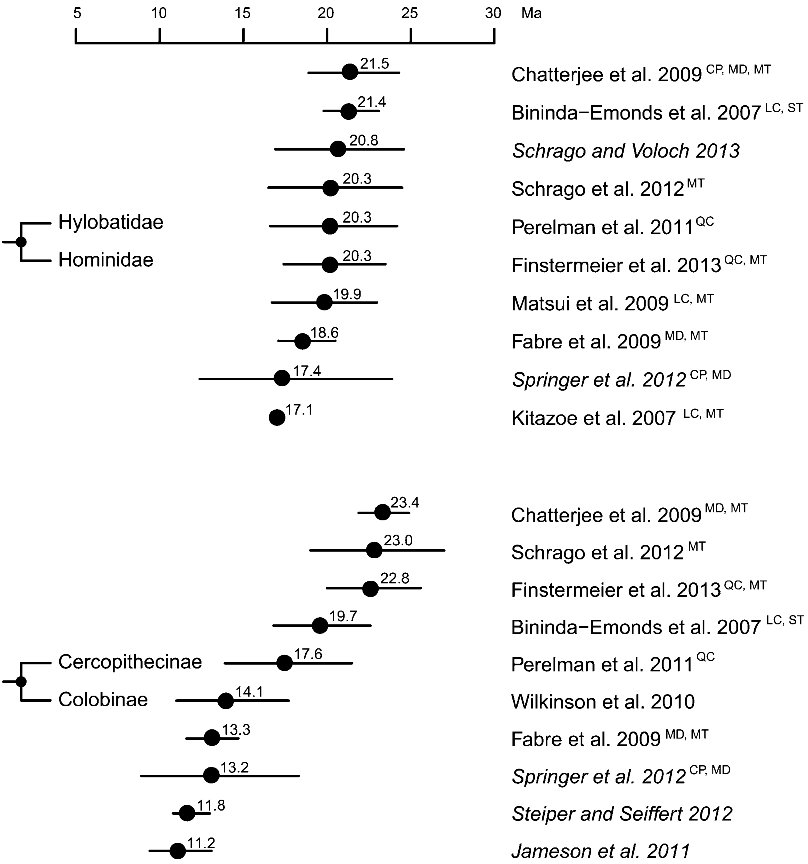

Fig. 8 Crown cercopithecoid and hominoid divergence date estimates. Abbreviations and italics as described in the caption to Fig. 2

Oligocene and early Miocene fossil platyrrhines belong to the crown radiation, they cannot easily be resolved with molecular data, primarily because most current divergence date estimates require fossil calibrations and as a result are minimum divergence dates only. Divergence dates that are mostly or entirely independent of fossil calibration data suggest that the early Miocene forms could be crown platyrrhines, but are less supportive of relating these forms to specific extant genera. Ultimately, this is a problem that will primarily be resolved in the paleontological literature (Kay et al. 2008; Kay and Fleagle 2010; Rosenberger 2010).

Within the catarrhines, there are no higher level phylogenetic questions that are unresolved, and divergence date estimates are beginning to converge on similar values. The major unresolved questions for catarrhine primates lie in the relationships among genera within (sub)families and the relationships of species within genera. Is the kipunji (*Rungwecebus*) more closely related to *Lophocebus* mangabeys or baboons (Burrell et al. 2009; Zinner et al. 2009; Roberts et al. 2010)? What are the relationships among the hylobatid genera (Chan et al. 2010, 2012, 2013; Israfil et al. 2011; Meyer et al. 2012; Wall et al. 2013)? What are the relationships among the colobine genera and are the African colobines paraphyletic (Sterner et al. 2006; Karanth et al. 2008; Osterholz et al. 2008; Roos et al. 2011; Liedigk et al. 2012; Wang et al. 2012)?

Strepsirhine Relationships and Diversification

Divergence of the Lemuriform and Lorisiform Strepsirhines

Estimates for the divergence of the lemuriform and lorisiform lineages range from 49 to 73 Ma (Fig. 9). Four estimates from studies with questionable calibration, based mostly or solely on mtDNA sequence data, or with limited calibration within the primates can probably be dismissed out of hand (Bininda-Emonds et al. 2007; Fabre et al. 2009; Matsui et al. 2009; Perelman et al. 2011). The remaining studies provide estimates between 49 and 57 Ma, with the best ranging from 51 to 56 Ma (Hallström and Janke 2010; Jameson et al. 2011; dos Reis et al. 2012; Springer et al. 2012; Steiper and Seiffert 2012). These early Eocene dates for the lemuriform-lorisiform divergence seem to be generally compatible with current paleontological interpretations of strepsirhine origins (Switek 2010; Maiolino et al. 2012; Seiffert 2012).

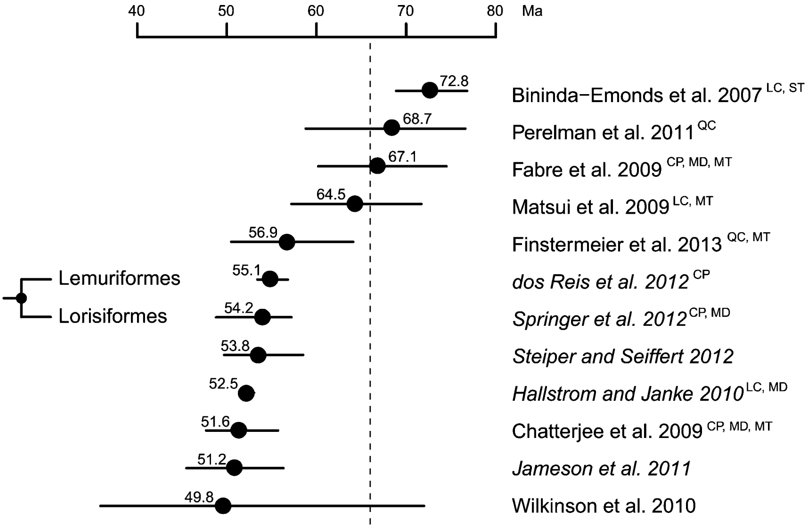

Fig. 9 Crown strepsirhine divergence date estimates. Abbreviations and italics as described in the caption to Fig. 2

Relationships of the Lemuriform Families

There are five families of lemurs: Cheirogaleidae (dwarf lemurs, mouse lemurs, and fork-crowned lemurs), Daubentoniidae (the aye-aye), Indriidae (indri, sifakas, and woolly lemurs), Lemuridae (true lemurs, ring-tailed lemur, ruffed lemurs, and bamboo lemurs), and Lepilemuridae (sportive lemurs). The sole point of agreement in higher level lemur systematics is that *Daubentonia* is the sister group to the others (Horvath et al. 2008; Chatterjee et al. 2009; Fabre et al. 2009; Perelman et al. 2011; McLain et al. 2012; Springer et al. 2012; Finstermeier et al. 2013; Masters et al. 2013; Yoder 2013). For the remaining four lemur families, there are four different topologies across the most recent lemur-focused or primate-wide phylogenetic studies (Fig. 10).

A sister group relationship of Cheirogaleidae and Lepilemuridae receives support across most studies (Fig. 10a–c) (Horvath et al. 2008; Chatterjee et al. 2009; Fabre et al. 2009; Perelman et al. 2011; McLain et al. 2012; Springer et al. 2012; Masters et al. 2013). The sole study that did not recover a Cheirogaleidae-Lepilemuridae clade has quite limited taxon sampling among the lemurs, is based only on the analysis of mtDNA sequences, shows a unique Indriidae-Lepilemuridae clade (with very low bootstrap support), and estimates divergence dates on a tree different from their best fit tree (dated tree has a Indriidae-Lemuridae clade) (Finstermeier et al. 2013).

Of the studies that do report a cheirogaleid-lepilemurid clade, two alternate topologies for the relations of the Indriidae and Lemuridae receive notable support. First, three studies report that the indriids are the sister taxon to the

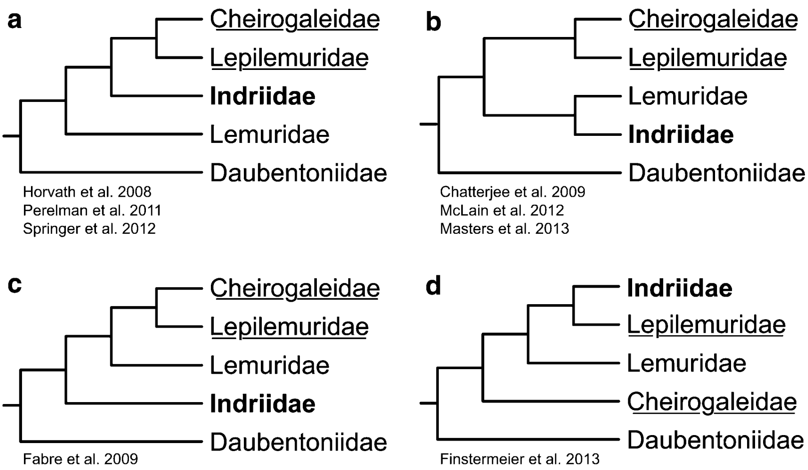

Fig. 10 Alternate hypotheses of relationships within the lemuriforms. Four different topologies for the branching relationships among the Cheirogaleidae, Indriidae, Lemuridae, and Lepilemuridae have been proposed in recent molecular systematic studies. The major difference among these cladograms is the position of the Indriidae (in *bold*). Most hypotheses of relationship have the Cheirogaleidae and Lepilemuridae as sister taxa (these families are *underlined*)

cheirogaleid-lepilemurid clade (Fig. 10a) (Horvath et al. 2008; Perelman et al. 2011; Springer et al. 2012). However, these studies do not constitute independent confirmation of this relationship. Perelman et al. (2011) include the 11 loci developed by Horvath et al. (2008) in their 54-locus data matrix, and Springer et al. (2012) add an additional 15 sequences to the Perelman et al. data matrix. In addition, all report poor bootstrap support for the node grouping the indriids with the cheirogaleid-lepilemurid clade. Second, three other studies report an Indriidae-Lemuridae clade as the sister group to the cheirogaleid-lepilemurid clade (Fig. 8b) (Chatterjee et al. 2009; McLain et al. 2012; Masters et al. 2013), but without strong support. Masters et al. (2013) and Chatterjee et al. (2009) both analyzed mtDNA sequences and report bootstrap support of 50 % or less for the indriid-lemurid clade. McLain et al. (2012) identified 111 new transposable elements informative for lemur phylogeny but did not find any additional support for a indriid-lemurid clade beyond the single transposable element insertion previously reported by Roos et al. (2004). While homoplasy by convergence (independent, identical insertion or perfect excision) is unlikely for transposable elements (Ray et al. 2006), they are no more immune from homoplasy by incomplete lineage sorting or secondary admixture than any other genetic marker (Churakov et al. 2009).

Divergence Dates Within the Lemuriforms

Because there are no fossil lemurs, fossil-calibrated divergence date estimates for the lemur radiation are probably less reliable than estimates of other primate divergence dates. The lineage leading to *Daubentonia* is estimated to have diverged from the other lemurs between 45 and 60 Ma, with most falling between 45 and 50 Ma (Fig. 11a) (Bininda-Emonds et al. 2007; Chatterjee et al. 2009; Fabre et al. 2009; Matsui et al. 2009; Perelman et al. 2011; Springer et al. 2012; Finstermeier et al. 2013; Masters et al. 2013). The split of the cheirogaleids and the lepilemurids is estimated to have occurred between 27 and 33 Ma (Fig. 11c) (Horvath et al. 2008; Chatterjee et al. 2009; Perelman et al. 2011; Springer et al. 2012; Masters et al. 2013).

Divergence dates among the other lemur families will be difficult to pin down while the phylogeny remains in flux. For instance, for those studies that reported a cheirogaleid-lepilemurid clade, their estimates of the time of divergence of this clade from their closest relative are shown in Fig. 11b. For this node, a trichotomous divergence of the cheirogaleids, the indriids, and the lepilemurids is estimated at 31 Ma (Springer et al. 2012), the divergence of the cheirogaleid-lepilemurid clade from a indriid-lemurid clade is found to be between 32 and 34 Ma (Chatterjee et al. 2009; Masters et al. 2013), and the divergence of the cheirogaleid-lepilemurid clade from the indriids is estimated at 35–38 Ma (Horvath et al. 2008; Perelman et al. 2011). While it is tempting to read the differences in divergence dates for this node across the different phylogenetic reconstructions as informative, this impulse should probably be resisted. The Perelman et al. dates are generally on the higher end of the range of estimated dates, particularly for the deeper nodes, and the

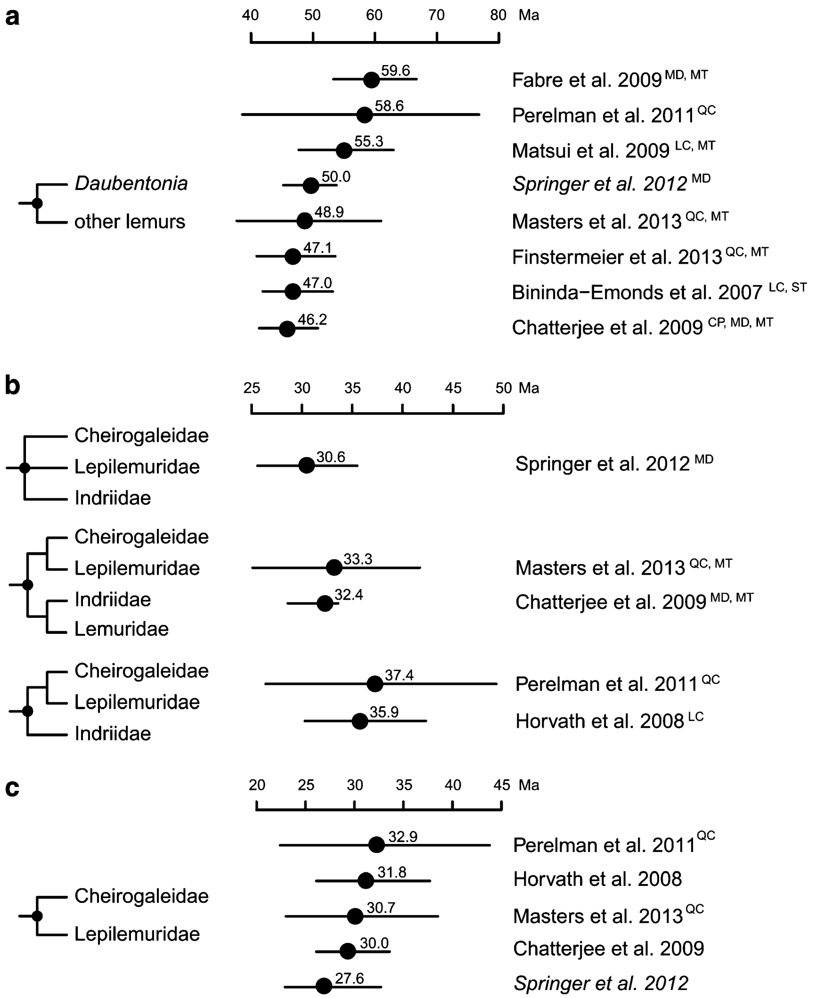

Fig. 11 Divergence date estimates among lemuriform families. Abbreviations and italics as described in the caption to Fig. 2

Springer et al. dates are usually more recent (see Figs. 2, 3, 4 and 9). The best that can be said at the moment is that the diversification of the non-*Daubentonia* lemur lineages probably began in the early Oligocene or late Eocene.

Relationships Among the Galagos and Lorises

Traditionally, Lorisiformes are split into two families, the African Galagidae (galagos or bush babies) and the African and Asian Lorisidae (lorises, slow lorises, and pottos). Each of these families has a host of apparently shared, derived behavioral, physiological, and osteological features confirming their monophyly (Rasmussen and Nekaris 1998). However, almost all early molecular studies suggested that the lorises are paraphyletic, with one or more genera more closely related to galagos than to the other lorises (Porter et al. 1997; Goodman et al. 1998; Yoder et al. 2001).

More recent studies based mostly or entirely on mtDNA sequence analysis continue to recover loris paraphyly (Chatterjee et al. 2009; Fabre et al. 2009; Matsui et al. 2009; Finstermeier et al. 2013; Masters et al. 2013), while those based on sequences from multiple nDNA loci recover loris monophyly, with the Asian Lorisinae (*Loris* and *Nycticebus*) sister to the African Perodicticinae (*Arctocebus* and *Perodicticus*) (Perelman et al. 2011; Springer et al. 2012). Transposable element insertions support the division of the lorises into these African and Asian clades but do not resolve a trichotomy among the galagos, African lorises, and Asian lorises (Roos et al. 2004). The combination of the extensive phenotypic data linking the lorises with the molecular confirmation of this group in studies based on nDNA is good evidence for loris monophyly. However, the molecular data alone are not convincing. The three nDNA sequence-based studies reporting loris monophyly are based on intersecting data matrices and report poor bootstrap support for the node linking the lorises (Horvath et al. 2008; Perelman et al. 2011; Springer et al. 2012).

Divergence Dates Within the Lorisiforms

Estimates for the minimum time of divergence between the Lorisidae and Galagidae range from 34 to 41 Ma (Bininda-Emonds et al. 2007; Perelman et al. 2011; Springer et al. 2012). The subsequence divergence of the Asian and African lorisids may have taken place within 3 Ma or less of this basal diversification. If this short internode time between the basal lorisiform and the basal lorisid split is correct, it would explain the difficulty that has been encountered resolving this node with molecular data. With short times between divergences, not only do fewer shared, derived mutations develop, but incomplete lineage sorting is more likely (Degnan and Rosenberg 2009).

A Galagidae-Lorisidae divergence at 35 Ma (Springer et al. 2012) would appear to conflict with evidence from the fossil record, where the earliest crown lorisiforms are dated at 37 Ma (Seiffert 2007), but it must be remembered that fossil-calibrated divergence dates estimate the most recent possible date of divergence. The Galagidae-Lorisidae divergence is very commonly used as a calibration point (Table 1), based on the identification of the late Eocene *Karanisia* as a lorisid and the similarly late Eocene *Saharagalago* as a galagid (Seiffert et al. 2003; Seiffert 2007). While Springer et al. (2012) did set a lower bound for the Galagidae-Lorisidae divergence at 37.1 Ma, they also used soft-bounded calibration points as part of their estimate, which allow date estimates outside of the calibration bounds. Assuming the dating of the deposits is correct, later studies should consider setting a harder lower boundary for this calibration point.

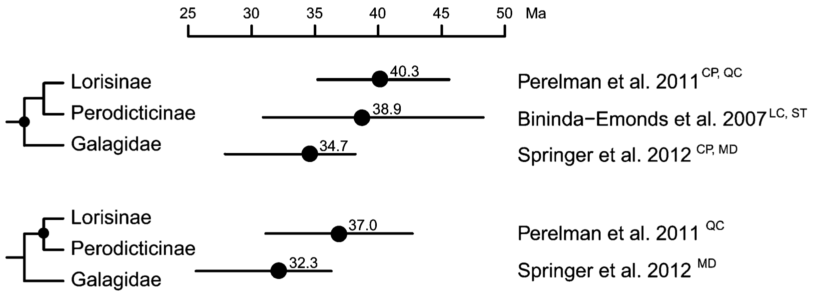

Fig. 12 Divergence date estimates among lorisiform families. Abbreviations and italics as described in the caption to Fig. 2

Future Directions

Beyond the division between the lorisiforms and the lemuriforms and the division of the lemuriforms between *Daubentonia* and all other lemurs, none of the interfamilial relations of the strepsirhines are completely resolved. There is some intriguing evidence that both the lorisiform families and most of the lemuriform families diversified rather rapidly in the latest Oligocene and earliest Miocene (Figs. 11 and 12) that deserves further study and better resolution of the divergence date estimates. Better resolution of these divergence dates is complicated, especially in the lemuriforms, by the absence of a fossil record for calibration. Even the mostly calibration-free method of Steiper and Seiffert (2012) requires phenotypic information from fossils to best model changes in evolutionary rate through time.

Conclusion

Many questions in higher level primate systematics now have good answers. Unless overwhelming evidence and convincing analysis can be presented that the tarsier is actually more closely related to the strepsirhines, anyone who mentions the haplorhine affinities of the tarsier as an important result of their study reveals only that they have nothing interesting to say. The relationships among the platyrrhine families are now well resolved in favor of a sister group relationship between the Cebidae and the Atelidae. Molecular evidence is beginning to converge on the monophyly of the lorises long found in morphological analyses. On the other hand, there are still many questions without completely convincing answers, including the branching pattern among the primates, colugos, and treeshrews; the relationships among the (non-Daubentoniidae) lemur families; and the placement of *Aotus* within the Cebidae. Most of these should be resolvable with more extensive genome-wide data from the relevant taxa.

Divergence date estimates are still in flux, especially in the depths of the primate radiation. For these questions, more genome-wide data from the relevant taxa is certainly going to be helpful, but methodological developments are going to be more important. Beyond the discrepancy between how we would like to interpret these dates (as the time of lineage divergence) and what they actually are (the most recent possible date of lineage divergence), there is also the problem of poor precision. Confidence intervals on divergence date estimates are broad, often encompassing millions of years, even for relatively recent nodes, and it may be that current methods cannot achieve greater precision (Schrago and Voloch 2013). New methods that attempt to directly estimate molecular evolution rates with little to no reliance on fossil calibrations offer some hope that it might be possible to produce divergence date estimates that can be interpreted as actual lineage divergences (Langergraber et al. 2012; Steiper and Seiffert 2012). For these methods to be successful, it will be necessary to carefully quantify the relationship between characteristics measurable in the fossil record (i.e., body size) and life history characteristics related to variation in the rate of molecular evolution (i.e., generation time). In this, we will need help from our colleagues in primatology, especially since many compilations of primate life history data appear to be undependable (Borries et al. 2013).

Many questions also remain in genus- and species-level primate systematics. First, there is the question of identifying all extant primate species. New species are still being described (Hart et al. 2012), and ongoing, and perhaps ultimately fruitless, debates on delineation of identified populations into distinct species continue (Jolly 1993; Weisrock et al. 2010). In addition, relationships among the genera within many families and relationships among species within genera remain unresolved in many cases. Some of the difficulties that are encountered in addressing these lower level phylogenetic questions are consequences of limited data and will be easily resolved by whoever is able to obtain sequences from multiple independent nDNA loci for the group in question. However, many of these problems seem to be the result of mismatches among gene trees and between many gene trees and the species tree as a result of incomplete lineage sorting and secondary hybridization and introgression (Tosi et al. 2003; Detwiler 2004; Burrell et al. 2009; Roos et al. 2011; Wall et al. 2013). Resolving those relationships will be complicated and could shed light on some of the difficulties encountered in resolving higher level relationships of primates.

Abstract

The Paleogene primate fossil record is reviewed following higher systematic categories. Among Strepsirhini, Adapiformes underwent Eocene radiations in North America (Notharctinae) and Europe (Cercamoniinae, Adapinae). Several occasional occurrences due to dispersals are found in North America, Europe, and Africa. Asia reveals a limited diversification (Sivaladapidae) and isolated occurrences indicating a central yet poorly understood role. In Africa the origin of living Lemuriformes is documented in the Late Eocene; odd stem lemuriforms occur earlier. The Eocene florescence of Omomyiformes is documented in North America (Anaptomorphinae, Omomyinae) and in Europe (Microchoeridae). Isolated occurrences, including the stem genus *Teilhardina*, are known in Asia. Two genera of Tarsiidae, known in the Middle Eocene of Asia, lead to a possible character-based definition of Haplorhini. The Asiatic Eosimiidae may belong in this group, and *Archicebus* may possibly lie on its stem. The Eocene South Asiatic Amphipithecidae are specialized hard-object feeders whose affinities remain enigmatic. Character-based Anthropoidea, or Simiiformes, are documented in the Late Eocene and Oligocene of Africa (Parapithecidae, Proteopithecidae, Oligopithecidae, Propliopithecidae). Toward the end of the Oligocene, the first African proconsuloids and the first South American platyrrhines appear. Anthropoidean origins are still a field of debate and discovery, with unconvincing Asiatic stem simians and a possible role for African Afrotarsiidae. The fossil record is extremely uneven, going from richly documented lineages in the Eocene of North America, to well-delineated radiations in the Eocene of North America and Europe and the Eocene–Oligocene of Africa, to more dispersed occurrences and enormous gaps during the early periods in Africa and Asia. The latters explain persisting controversies. Many aspects of primate evolution are documented over almost 20 million years, including locomotion, diet, vision and other sensory capacities, brain evolution, and one aspect of social structure via sexual dimorphism. The best records allow researchers to approach specific lineages, evolutionary modes, and analysis of faunistic changes.

Introduction

When Ludwig Rütimeyer (1862) referred some dental remains from the Swiss locality Egerkingen to an Eocene primate, his contemporaries did not believe that this was possible. Othniel Marsh later recognized primates through some lemur-like limb bones from the Eocene of Wyoming. When skulls with complete postorbital bars were found in the Quercy phosphate quarries in 1873, the scientific community had to admit that lemur-like primates had inhabited North America and Europe in Eocene times, and that *Adapis*, named much earlier by Georges Cuvier from a partial and crushed skull, was indeed a primate. Since then the discoveries have continued; indeed, so many have been added in the last decades that there are now more than 250 species of fossil primates known between the Late Paleocene and the end of the Oligocene. The record also includes families of Plesiadapiformes that are excluded here (see below).

The Paleogene is the first period of the Tertiary sub-era. It comprises three successive Epochs: the Paleocene, Eocene, and Oligocene. It starts at the famous Cretaceous-Tertiary (K-T) boundary, a geological limit around 65 million years ago ("Ma" will be used in the text for million years ago, and "My" for million-year durations). This limit coincides with an extinction event which affected many groups in the ocean and on land, including the then-dominant dinosaurs. These extinctions allowed the explosive diversification of mammals, among them the primates. However, not all groups of mammals are recognizable in the Early Paleocene. Several modern orders of mammals are well known only 10 Ma later, in the Eocene. Such is the case for primates, despite one exception in the Late Paleocene. Geological epochs, the main stages, some geological formations, stratigraphic scales, and some of the most important localities are shown in Fig. 1.

The Order Primates can be defined by a series of derived characters shared by all living members of the order: presence of a postorbital bar (or complete postorbital septum) surrounding large eyes that are directed forward and allow some degree of stereoscopic vision; presence of a maximum of two incisors, indicating loss of one incisor relative to primitive eutherians; a tympanic bulla formed by the petrosal; presence of an opposable hallux (prehensile foot) and typically presence of nails instead of claws (the two living primate groups bearing claws – Callitrichinae among South American monkeys and *Daubentonia* among Malagasy lemuriforms – are considered to have secondarily evolved claws from a nailed ancestor). These synapomorphies allow a clear delineation of living primates from all other mammals, including tree shrews, which between the 1920s and 1980s were usually considered to be primitive primates. This same definition excludes the Paleocene-Eocene Plesiadapiformes, which lack a postorbital bar and large forward-directed eyes, and also bear claws. If another more inclusive definition of primates is used, subsuming the plesiadapiforms, the above criteria apply at a lower systematic level, defining Euprimates as opposed to Plesiadapiformes (see chapter "▶ Primate Origins and Supraordinal Relationships: Morphological Evidence," Vol. 2).

The origin of the primates as defined above is still undocumented, because terrestrial faunas from the right time and region are lacking. A dense and continuous fossil record of mammals is known in North America, but primates originated

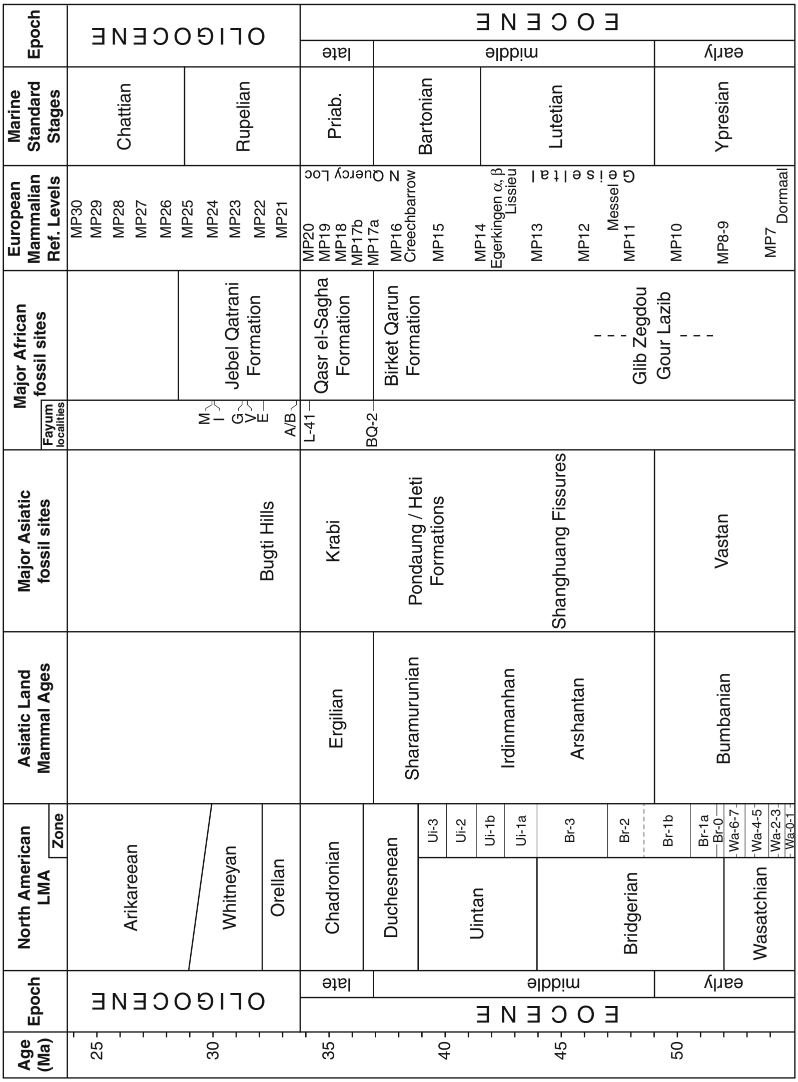

Fig. 1 (continued)

elsewhere. A more discontinuous fossil record of Paleocene mammals is known in South America, in Europe, and in Eastern Asia (Mongolia, China), but again without early primates. Despite recent progress, the Paleocene fossil record of mammals remains very poor in Africa, although one fauna yielded the single Paleocene primate known at the moment, *Altiatlasius* from Morocco, discussed below. This fossil shows that primates had reached Africa by the Late Paleocene; however, there is strong evidence that they did not originate in Africa but rather in Asia, where their two living sister groups, the tree shrews and flying lemurs, are found today (see chapter "▶ Primate Origins and Supraordinal Relationships: Morphological Evidence," Vol. 2). A Paleocene fossil record of Southeast or Western Asia should give some definitive clues to this enigma; it would at the same time test a competing scenario, that of an origin on the northward-rafting Indian plate.

The Paleocene-Eocene boundary, 55 Ma ago, witnessed a series of climatic and paleogeographic events that resulted in the first occurrence of primates in North America, Europe, and Asia (China). This occurrence is part of a much broader dispersal event concerning several orders of mammals as well as other animals and plants. This dispersal followed a dramatic episode of global warming, which is one of the most fascinating climatic events discovered in the last 20 years (e.g., Aubry et al. 1998). Starting in the Early Eocene, a tropical climate and environment at high latitudes allowed the radiation of primate groups on northern continents, including Europe and North America. For geological and historical reasons, these radiations have been the best documented, allowing the study of well-circumscribed primate radiations during almost 20 My. However, these relatively well-known groups became extinct around the Eocene-Oligocene boundary, close to 33 Ma. The latter is marked by a global climatic cooling, rendering northern continents inhospitable for primates. Therefore, these Eocene radiations shed no light on the origin of living primate families, the history of which took place in Asia or on southern continents. This explains why, despite a rich Eocene fossil record, there are still controversies concerning the origin of major groups of living primates, among them the anthropoids: they originated in regions and times with a still insufficient fossil record. The northern Eocene radiations also increase the complexity of primate systematics and phylogeny. The phylogeny inferred from living primates is consensual. It divides them into two suborders: the Strepsirhini, which include the Lemuriformes (Malagasy lemuroids and Afro-Asiatic lorisoids), and the Haplorhini, which unite Anthropoidea or Simiiformes with extant Tarsiidae. The introduction of a variety of fossil families renders these notions problematic, as will be seen below. The term "prosimians" will also be used, to designate all non-anthropoidean primates.

◄

Fig. 1 Summary chart showing ages, epochs, marine standard stages, and mammal ages or reference-levels for terrestrial deposits on different continents. Some of the main localities or formations containing primates are indicated. Ma is for millions of years, LMA is for land mammal ages, and Ref. Levels is for the European mammalian reference-levels (MP). The North American Wasatchian is recalibrated following recent work on the Wasatchian-Bridgerian transition. The richest primate records are found in the best-documented intervals, especially the Early Eocene in North America, the Late Eocene in Europe (N Quercy Loc refers to the new Quercy localities), and the Eocene-Oligocene in North Africa (BQ2 to M refer to the Fayum fossil localities)

Because there are many uncertainties and debates in primate phylogeny, an important conceptual choice is made in this chapter: the adoption of character-based definitions of higher taxa. This choice serves both clarity and stability, as will become apparent on several occasions below. It is usually well recognized that a crown group definition of taxa (all species descended from the common ancestor of living forms) has inconveniences: if many members of a group are extinct, the crown group is too small. Williams and Kay (1995) illustrated this with examples like the genus *Homo*, which cannot be limited to *H. sapiens*. One might add that the well-known *Aegyptopithecus* is usually considered a catarrhine, although it probably does not pertain to the crown group. Concerning the order Primates, a character-based definition is provided above. There might be several clades bearing the five primate synapomorphies listed above which would be branches preceding the strepsirhine/haplorhine dichotomy. It would not be reasonable to exclude such groups from the order Primates because they branch before the dichotomy leading to the living groups. Different but equally unfortunate inconveniences arise from the use of stem-based definitions. Too often, the node separating two higher taxon stem lineages is unknown, so that fossils can be moved from one higher taxon to another and back, depending on cladistic analyses whose results often appear highly unstable. And if the node were known, i.e., the genus in which the initial speciation took place, stem-based definitions would lead to a spread between different higher taxa of species of one and the same stem genus. Any such definition of a higher taxon becomes minuscule in terms of characters, i.e., almost useless. All these inconveniences, bound up with definitions that proceed either from living in-group survivors or from living sister groups, are avoided by the use of character-based definitions. Furthermore, in primate origins and in primate evolution, a number of important anatomical innovations occurred, and instrumental use of these in systematics helps to convey this critical information, instead of ignoring it.

The fossil record is presented here via the well-documented major radiations since the Early Eocene: Adapiformes and Omomyiformes, followed by their close kin Lemuriformes and Tarsiiformes, respectively. Several enigmatic groups are mentioned next, before Simiiformes (=Anthropoidea) and anthropoidean origins are discussed. The following rough size categories will be used: “very small” for primates weighing 100 g or less, “small” for primates between 100 and 500 g, “middle-sized” for primates between 500 g and 2 kg, and “large” above 2 kg. Weight is a very important adaptive and ecological factor; however, the estimation of body weight in fossils is not easy. Body weight estimates will be given only for fossils for which weight indications from dental remains can be supplemented by estimates based on cranial or postcranial remains.

The Adapiformes Radiations

The Adapiformes are an almost cosmopolitan group of fossil primates which diversified during the Eocene and survived in Asia until the Late Miocene. They include around 46 genera and 105 species. They provide some of the best-known fossil primates. In terms of size, dental adaptation, and locomotion, they compare relatively closely with living lemurs. Hence they are usually described as lemur-like, and some cranial and postcranial characters seem to justify their grouping with living Lemuriformes as strepsirhines, a notion analyzed below.

The Adapiformes divide into three families: the Notharctidae, Adapidae and Sivaladapidae.

North American Notharctids

The Notharctidae are the oldest documented adapiforms, being represented in the Earliest Eocene by the genus *Cantius* in North America and Europe, and by the genus *Donrussellia* in Europe only. From these two stem genera, two subfamilies diversify: the Notharctinae mainly in North America (plus *Cantius* surviving several My in Europe), and the Cercamoniinae in Europe. In North America, the history of the subfamily is well known. There are around 10 species of *Cantius* in North America. The oldest, *C. torresi* and *C. ralstoni*, as well as the European *C. eppsi*, show the typical dental characters of the genus (Fig. 2). The dentition is on the whole moderately bunodont, having somewhat rounded molar cusps. Small incisors, a large canine, and four premolars are typical primitive primate characters. P/1 to P/3 are simple, with one main cusp increasing in size and the posterior part broadening from P/1 to P/3. P/4 is still longer, has a well-formed metaconid, and a broad and short talonid with a small median hypoconid cusp. The lower molars increase in length from M/1 to M/3, whereas the trigonid becomes anteroposteriorly shorter. There is a large lingual paraconid well separated from the metaconid on M/1, and the paraconid merges progressively with the metaconid summit on M/2 and M/3. The trigonid is transversely broad and opens posteriorly on M/3, which is typical of *Cantius* and advanced over *Donrussellia*. M/3 has an elongated third lobe, and its triangular outline, narrowing posteriorly, is also typical of the genus. P3/ and P4/ have massive outlines. The protocone lobe is slightly narrower than the labial part on P4/, and much narrower and smaller on P3/. The M2/ is always more transversely elongated than M1/, which is slightly anteroposteriorly longer. Both have small conules, a postmetaconule-crista going toward the base of the metacone, and a distinct protocone fold.

A lineage *Cantius–Notharctus* is documented in the Bighorn Basin of Wyoming by successive assemblages that can be placed in a synthetic stratigraphic sequence. The assemblages are so close in time and in morphology that this provides one of the most convincing cases of gradual evolution in mammals (Gingerich 1976). This lineage includes the successive species *C. ralstoni, C. mckennai, C. trigonodus, C. abditus*, and *C. nunienus*. These species have no precise boundaries, but the distinction between them is necessary to convey the underlying evolutionary information. The lineage is characterized not only by the size increase evident on diagrams, but also by the progressive development of new dental characters, including an entoconid notch on the lower molars, a hypocone on the upper molars, as well as a mesostyle which will progressively lead to W-shaped labial crests as found in several living folivorous primates (Gingerich and Simons 1977). The hypocone

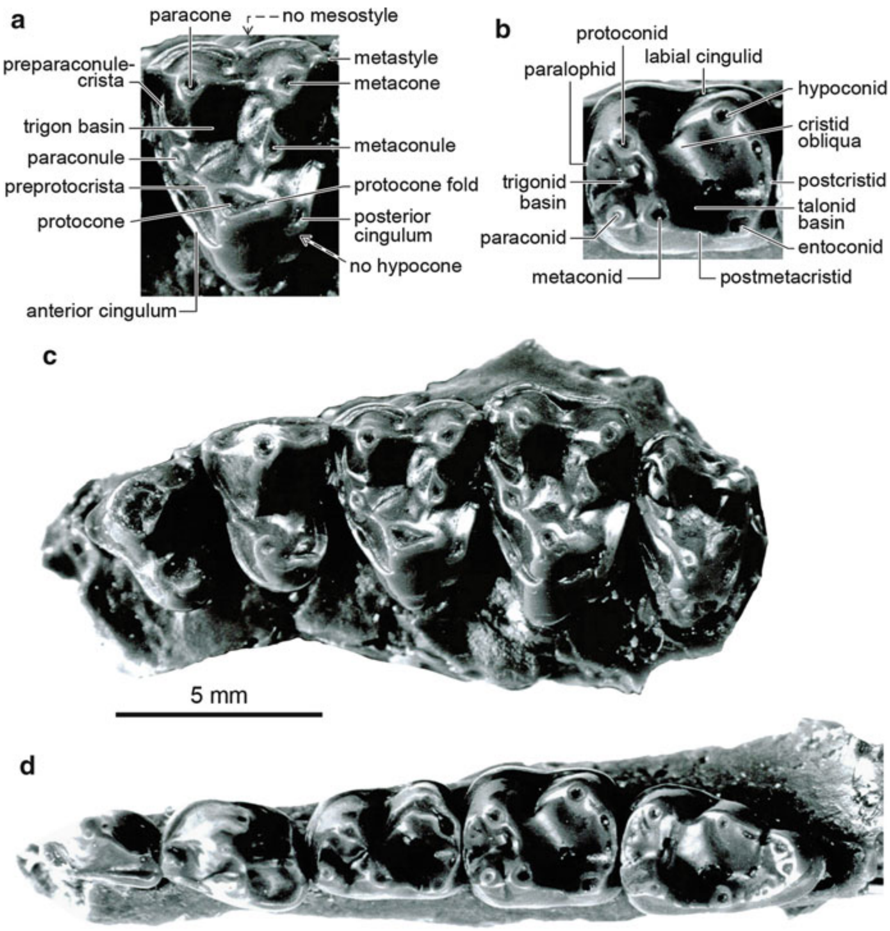

Fig. 2 Upper and lower jugal teeth of *Cantius eppsi* showing the primitive dental morphology of notharctines. (**c**), upper series from P3/ to M3/; (**d**) lower series from P/3 to M/3. The upper M1/ in (**a**) and the lower M/2 in (**b**) illustrate most of the terms of dental morphology used in the text. Upper molars have three main cusps and no hypocone. Lower M/1 and M/2 have large paraconids, and P/4 has a main cusp and is relatively elongated (photographs of epoxy casts)

grows on the protocone fold, not from the cingulum as in most other primates. It is thus often referred to as a pseudohypocone. *Cantius* had unfused lower jaws, anteriorly appressed; some later *Notharctus* have frequently fused lower jaws, with a long horizontal symphysis. Variations in the size and orientation of the anterior lower incisors among *Cantius* and *Notharctus* species are illustrated by Rose et al. (1999). The lineage keeps four premolars all along. Among other species, *C. simonsi* is the largest one, found in Late Wasatchian beds (Wa7) of the Bighorn basin; *C. angulatus* is found in the San Juan Basin of New Mexico; and *C. frugivorus* is found in the latter and in several other basins (Beard 1988; Gunnell 2002).

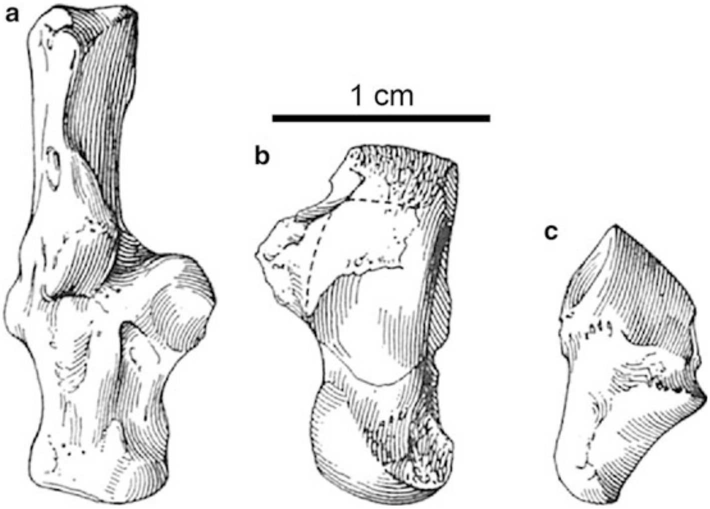

Fig. 3 Foot bones of *Cantius frugivorus*. (**a**) calcaneum; (**b**) astragalus; (**c**) entocuneiform; all in dorsal view. The distal articulation of the entocuneiform for the first metatarsal is sellar in relation to the opposability of the first pedal digit (hallux) typical of primates (From Matthew in Matthew and Granger 1915)

A crushed skull of *Cantius abditus* appears relatively short and broad in its proportions. It displays characters that are interpreted as primitive in notharctids, such as a ventrally keeled basioccipital, a flat basisphenoid, and proximally broadening nasals (Rose et al. 1999). The auditory region is very similar to that of *Notharctus* and living lemurs. It shows a large stapedial artery and a much smaller promontory artery, which seems to have followed an open sulcus along the promontorium. This morphology, shared with lemurs, may be primitive in adapiforms, and the bony tubes present in *Notharctus* and *Smilodectes* may be derived.

A partial skeleton of *Cantius trigonodus* includes a fragment of a distal humerus with a prominent brachialis flange, a proximal ulna with a well-developed olecranon process, and a proximal and distal radius showing a strong shaft (Rose and Walker 1985). A partial pelvis shows a relatively long ischium and short ilium compared with living lemurs, probably primitive. The femoral head is less spherical than in living lemurs, and relatively far separated from the greater trochanter. The distum of the femur is anteroposteriorly high, with a prominent lateral ridge, suggesting leaping abilities. The proximal tibia shows retroflexed condyles and a prominent tibial crest. The relatively distal tibial tuberosity may indicate quadrupedalism and also be primitive, associated with the long ischium. An astragalus, a calcaneum and an entocuneiform of *C. trigonodus* were figured by Matthew in Matthew and Granger (1915) (Fig. 3). Adding characters of the astragalus and the prominent peroneal tubercle of a proximal hallucial metatarsal, Rose and Walker (1985) infer for *Cantius* the locomotor behavior of an active arboreal quadruped with a propensity for leaping. Additional foot bones, cuboid, navicular, medial cuneiform, and a distal nail-bearing phalanx of *C. mckennai* were

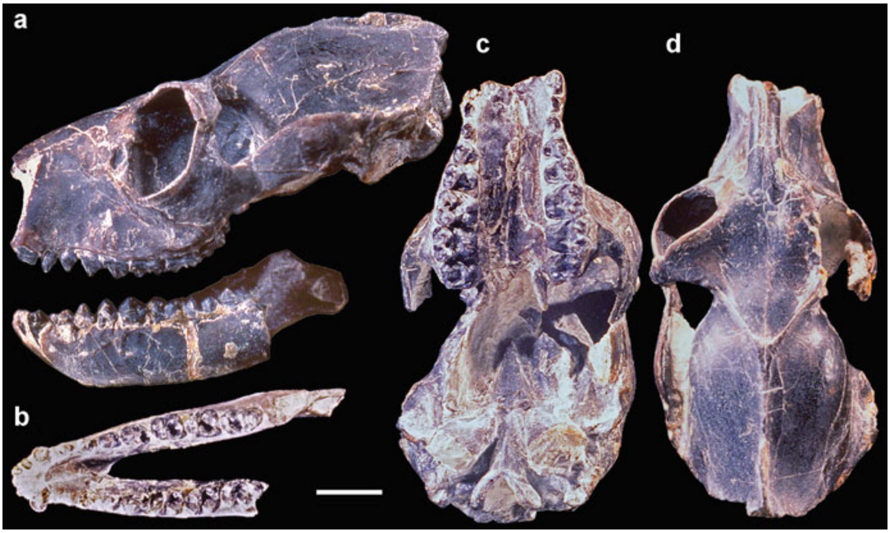

Fig. 4 Skull of *Notharctus tenebrosus* in profile view (**a**), mandibles in occlusal view (**b**), and cranium in ventral (**c**) and dorsal (**d**) views. The dorsal view shows some deformation of the left zygomatic arcade, which may have a slightly exaggerated orbit height on the profile view. The mandibles have a long, inclined, fused symphysis

described by Covert (1988), who inferred high foot mobility and powerful grasping in this species. Because tarsals are frequently found in general and the Early Eocene fossil record is rich, more than 150 tarsals of *Cantius* species, and probably some *Pelycodus* and *Copelemur*, were identified (Gebo et al. 1991). They show no significant change, whereas there are some small differences between them and later *Notharctus* and *Smilodectes* tarsals.

Species of *Notharctus* became particularly well known with the publication of a beautiful monograph by Gregory (1920). The reconstruction of the skull of *N. tenebrosus* by Gregory, based on distorted specimens, was not exact from today's perspective, with too long a muzzle. This has since been corrected due to the discovery of more complete skulls (Alexander 1994; Godinot 1998), which show a higher and shorter muzzle (Fig. 4). Partial skeletons allowed Gregory (1920) to describe long bones, a partial scapula and pelvis, and foot and hand bones. He could conclude the analysis of *Notharctus*'s locomotor behavior by inferring a clear leaping adaptation, albeit one less extreme than in living vertical clingers and leapers (VCL): in *Notharctus* the forearm still played a more important role in locomotion, muscular insertions on the pelvis were less pronounced, and feet were less specialized than in living indriids. More recent studies have generally concurred with Gregory, with nuances emphasizing either *Notharctus*'s leaping propensity or, in contrast, its quadrupedal postures. It can be viewed as a frequent leaper, though probably a pronograde (horizontal) leaper and quadruped rather than a VCL. Gregory had reconstructed an incomplete and very long hand. A more complete specimen allowed the description of all carpals, metacarpals, and phalanges, and a better reconstruction of the hand

(Hamrick and Alexander 1996). This hand has remarkably long digits due to very long proximal phalanges. The thumb is divergent, and the short second metacarpal appears markedly divergent from the third. The second digit is reconstructed unreduced and placed in the middle of the space between digits one and three. This results in a functionally bizarre hand, which furthermore bears a strange and unique distal phalanx on the second digit. The divergence of the metacarpals and length of the digits give rise to the suspicion that this hand might have used schizodactylous grips, with the support between digits two and three as in living *Alouatta*.

There are five species of *Notharctus*. *N. venticolus* is the earliest one, known from the latest Wasatchian and earliest Bridgerian, and in temporal and morphological continuity with *Cantius abditus*. An assemblage of this species has clearly shown a strong sexual dimorphism in upper canine size and shape, as admitted by earlier authors from more scattered specimens (Krishtalka et al. 1990). The species is followed by *N. robinsoni* (BR1B) and *N. tenebrosus* (BR2). Skull shape differences between males and females in *N. tenebrosus* have been described by Alexander (1994), and beautiful skull illustrations have been produced (Alexander and Burger 2001). *N. robustior* is the largest species of the genus, which had a body weight estimated between 6 and 8 kg.

Another well-known Middle Eocene genus is *Smilodectes*. The best-known species is *S. gracilis* (Middle Bridgerian), whose skull and endocranial cast were described by Gazin (1958, 1965). It has a slightly shorter and higher cranium than *Notharctus*. Its skeleton is also well known, but was not studied in as much detail as that of *Notharctus*. The two are in fact broadly similar. *Smilodectes* too had a pronograde and leaping adaptation. It also developed the shearing adaptation of the upper molars (W of labial crests), which produced similar upper molar characters. Such similarities can result in the two genera appearing as sister groups in a cladistic analysis (Covert 1990). However, *Smilodectes* has a long ventrolingually sloping paralophid on the lower molars, which indicates a different lineage, not derivable from *C. trigonodus*, and convergence with *Notharctus* in upper molar characters. The same result is obtained after careful evaluation of the characters sustaining different trees obtained by cladistic analysis, leading researchers to favor the close relationship of *Smilodectes* and *Copelemur* – included in a tribe Copelemurini — and as a consequence postulating convergences between *Smilodectes* and *Notharctus* (Beard 1988; Gunnell 2002). There are two other species of *Smilodectes* besides *S. gracilis*: *S. mcgrewi* is Early Bridgerian, and *S. sororis* is earliest Bridgerian, both of Wyoming.

Species of *Copelemur* are characterized by low and anteroposteriorly elongated P/2–4, lower molars with narrow trigonids, a small ventrally placed paraconid or paralophid, and an anteriorly shifted entoconid linked to the trigonid by a long postmetacristid and followed by an entoconid notch; upper molars have a mesostyle, and a protocone fold but no hypocone (Gingerich and Simons 1977; Beard 1988). There are three species of *Copelemur*, starting with *C. praetutus* from the Middle and Late Wasatchian (Wa4-6) of Wyoming and Colorado. It is followed by *C. australotutus* (Wa5-6) and *C. tutus* (Wa7), the latter of which was the first discovered, by Cope, in the San Juan Basin of New Mexico. *Copelemur* is considered closely related to *Smilodectes*; however, the origin of neither taxon is clear, probably involving southern and less well-sampled regions.

Two other genera are recognized in the North American Eocene, *Pelycodus* and *Hesperolemur*. *Pelycodus* is more bunodont than other notharctines. *P. jarrovii* is found in the late Wasatchian (Wa6) of New Mexico and rarely shows up in Wyoming. *P. danielsae*, known only by two fragmentary specimens, is a very large species with an estimated weight of above 6 kg (Froehlich and Lucas 1991). The origin of *Pelycodus* probably lay in the poorly documented southern regions of the United States. A rooting in the earliest Wasatchian *Cantius torresi* seems possible. The case of *Hesperolemur* is more complex. It was named based on a cranium and two other specimens from the Uintan of California (Gunnell 1995b), but the interpretation of some of its cranial characters was later criticized by Rose et al. (1999), who proposed to refer it to a species of *Cantius*. However, it differs from the most derived species of *Cantius* and appears somewhat reminiscent of *Pelycodus*, albeit distinct from it due to its weak mesostyle. Gunnell (2002) still considers it to be a valid genus. North American notharctines became extinct in Wyoming at the end of the Bridgerian, but *Hesperolemur* found refuge in Southern California in the Early Uintan. Their extinction is related to the shrinking of forested areas, due to the surrection of the Rocky Mountain Range and drying of the areas on its eastern side.

European Notharctids

The European notharctid radiation also starts in the Earliest Eocene, represented by a primitive species of *Cantius*, with survivors during the Early Eocene, and by species of *Donrussellia*, more primitive than *Cantius*, that seem to be at the root of the European Cercamoniinae. *D. provincialis* from Rians, southern France, shows the most primitive adapiform dentition known today (Fig. 5). The anterior part of the dentary is thin and presents a very anteriorly inclined symphyseal region. Alveoli suggest small incisors (probably two), a large canine, a single-rooted P/1, and a double-rooted P/2. P/3 and P/4 are elongated and narrow, P/4 bears an incipient metaconid. A slight crowding of the premolars is shown by some inclination of the roots of P/2 and P/3, the anterior one being more labial than the posterior one. M/1 has a big lingual paraconid well separated from the metaconid; its trigonid is longer than its talonid. The trigonid of the lower molars decreases in size from M/1 to M/3, the paraconid becoming smaller and closer to the metaconid. The talonid basin, in contrast, increases from M/1 to M/3, which has a relatively expanded third lobe. The upper molars are transverse and simple, without any trace of lingual cingulum or hypocone. The postprotocrista starts with a short posterior inclination, being continuous on M2/ and interrupted on some M1/, but there is no real protocone fold. The conules are small and there is no postmetaconule-crista. Other species of *Donrussellia* are known: *D. lusitanica* in Silveirinha, Portugal (Estravis 2000), the small and more insectivore-like *D. gallica* from Avenay, Paris Basin, and the larger *D. magna* from Palette, southern France, which appears

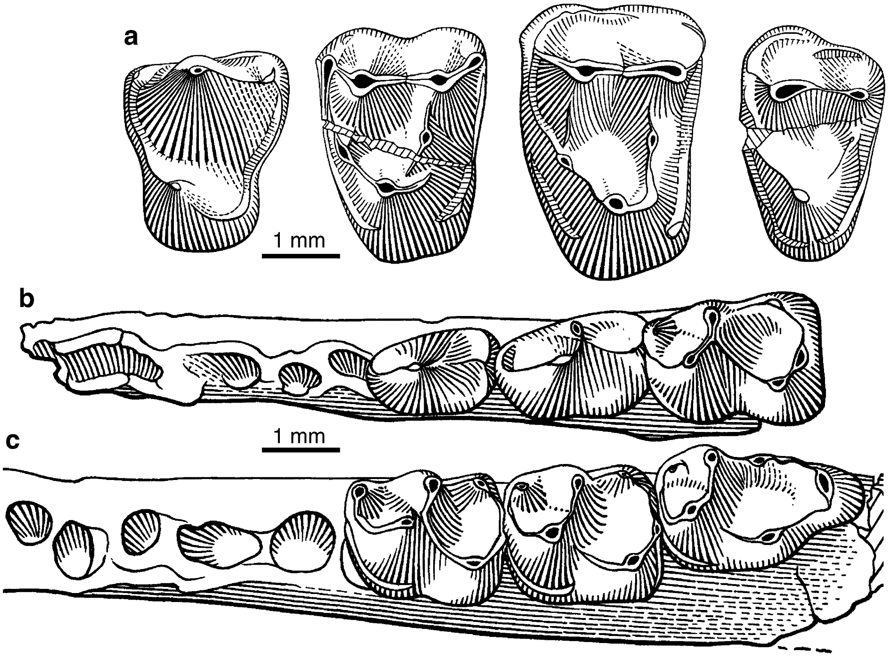

Fig. 5 Dentition of *Donrussellia provincialis*. Upper teeth, P4/ to M3/ (**a**), one mandible showing P/3 to M/1 (**b**), and one with M/1 to M/3 (**c**). The *upper* teeth are among the most primitive known in primates, with three main cusps and no hypocone. Lower molars also show a primitive large trigonid on M/1-2 with a well-formed paraconid. P/3 and P/4 are simple and relatively narrow. Alveoli reveal a relatively large canine followed by a single-rooted P/1 and a double-rooted P/2

intermediate with *Cantius* and thus suggests that at least three species dispersed into Europe in the Earliest Eocene.

In the late Early Eocene, larger and more derived species occur, which can be associated in groups of related genera. The first group includes *Protoadapis, Europolemur*, and *Barnesia*. Species of *Protoadapis* appear less common now than previously thought. The earliest species seems to be *P. curvicuspidens*, named long ago by Lemoine from late Early Eocene sites which are not precisely located. The species is present but rare in Grauves, the MP 10 reference locality. In *Protoadapis*, the paraconid is a residual cuspule on a relatively long and subhorizontal paralophid. The genus is also characterized by a P/3 higher than P/4. Other similar-sized species of *Protoadapis* are *P. angustidens*, from an unknown level in the Quercy, and *P. ignoratus* and *P. muechelnensis*, from the Middle Eocene lignite mines of the Geiseltal, Germany (MP 12, Thalmann 1994). Two larger species of *Protoadapis* are also described from lower jaws alone. *P. (Cercamonius) brachyrhynchus* is also from an unknown level of the Quercy fissure fillings, whereas *P. weigelti* is from the same level in the Geiseltal as the above-mentioned species. These species have more robust teeth and jaws. Robustness of the jaw and possible anterior premolar reduction and more vertical symphysis led Gingerich (1975) to erect the new genus *"Cercamonius"* for the species *brachyrhynchus*, considered to be evolving toward anthropoid characters. However, Thalmann (1994) followed Szalay and Delson (1979) in rejecting the new genus, noting only small differences between *P. brachyrhynchus* and *P. weigelti*. More material is necessary to ascertain the differences between these species, and *Cercamonius* can be retained as a subgenus to mark its distinctness. Species of *Protoadapis* remain poorly known, with only a few upper teeth referred to *P. curvicuspidens*, among which one figured specimen is misidentified (Russell et al. 1967).

Species of *Europolemur* are known through partial skeletons found in the Middle Eocene localities of Messel and the Geiseltal in Germany, and dental material from Eckfeld, Bouxwiller, and probably also the Paris Basin in France. The Messel Oil Shale deposited in a volcanic lake dated close to 47 Ma. The skeleton of *Europolemur koenigswaldi* was found there in two parts: the anterior part, crushed skull, forelimb, and trunk were found first (Franzen 1987); the rear part was found later, allowing the reconstruction of the entire animal (Franzen and Frey 1993). It was relatively small. The first weight estimate from dental regressions was close to 2 kg; however, a more reliable estimate from trunk length suggests a much lower weight, around 300 g, underlining the uncertainties associated with weight estimates from tooth dimensions alone. Crushed skeletal parts are difficult to study, but they show parts that are most often unknown in fossils. The anterior part is that of a young adult, with erupting M/3 and still functional DP/3–4/. The muzzle appears elongated, and the small orbits suggest a diurnal way of life. Incisors are in place, recalling those of *Notharctus*, with I1/ two times broader than I2/. From the breakage not being in midline, Franzen (1987) deduced that the two mandibles were fused. X-ray images show the outline of middle ear ossicles within the right tympanic bulla, as well as parts of a tympanic ring. The vertebral column is preserved from the axis to the os sacrum, the latter consisting only of two fused sacral vertebrae. Ribs 1–13 can be seen. A right forearm is there, from scapula to hand. The scapula, rarely found in fossils, has a shape close to that of *Galago* and *Eulemur macaco*. The broad humerus is broken. The hand shows flexed digits, digit one isolated from the others on the palmar side, as well as a large pisiform. Two distal phalanges appear broad, flat, and scutiform. The rear part of another individual, ascribed to the same species, shows a long tail with 30 vertebrae. Proportions of femur and tibia led to a crural index of 83, and an estimation of the intermembral index of 72.6. Among the tarsals, the astragalus shows a wedge-shaped trochlea, and a neck and a posterior trochlear shelf more extended than in *Notharctus*. The calcaneum is slender, elongated (index of anterior part 45.2 %), and with a short posterior astragalar facet – characters which suggest leaping propensities. The two feet are complete but crushed. Their metatarsals are short, the first one being very robust. The terminal phalanges are quite narrow with a flat plantar side, suggesting the presence of narrow nails (this difference with the anterior part is bizarre, raising a question about their association). There is no special toilet claw. Franzen and Frey (1993) reconstruct *E. koenigswaldi* as an arboreal quadruped, climbing above branches and having leaping capacities.

Another somewhat larger species is *E. kelleri*, named from a crushed skull. Several earlier finds were referred to this species: a pelvis, baculum, and hindlimbs, and a forearm with hand (Franzen 1988, 2000a; von Koenigswald 1979). *E. klatti* from the Geiseltal is the type species of the genus. It was described from a crushed cranium bei Weigelt (1933). Its dentition includes a large laterally compressed upper canine, a small P2/ and a single-cusped P3/, upper molars with complete lingual cingulum and large hypocone, but no metaconule. Details on the variation in dental characters are given by Thalmann (1994), who tentatively ascribed to the species some isolated postcranials, an atlas, an astragalus, and a calcaneum. *E. dunaifi* from Bouxwiller, known only through isolated teeth, appears very close to *E. klatti*. A crushed cranium from the highest level of the Geiseltal (MP 14) shows upper teeth close to those of *Europolemur*, though different enough for Thalmann (1994) to erect a new genus and species, *Barnesia hauboldi*. Its M2/ is enlarged in comparison with M1/ and M3/. It is transversely elongated, and on its lingual cingulum a pericone is added to a moderately large-sized hypocone. The species is possibly present in Bouxwiller.

The genera *Pronycticebus* and *Godinotia* constitute an isolated lineage rooted in primitive forms. It has been known for a long time through the description by Grandidier (1904) of a beautiful cranium and jaw coming from the old phosphate exploitations of the Quercy region, southern France, which he named *P. gaudryi*. Its age is not precisely known; however, one tooth attributed to a close species was found in a new Quercy locality, dated MP 10–11. This suggests that *Pronycticebus* is probably a Lutetian genus. The skull of *P. gaudryi* is important because it is the only cercamoniine skull that is three-dimensionally well preserved. Its tympanic bulla and basicranial foramina are similar to those of lemurs and adapids, and partial preparation of one bulla also shows a free tympanic ring, which is often considered typical of strepsirhines (Le Gros Clark 1934; Simons 1962). A CT-scan analysis revealed the morphology of its bony labyrinth (cochlea and semi-circular canals), which appears closest to that of Adapinae, both having similarities with lemuroids (Lebrun et al. 2012). A relatively complete and somewhat crushed skeleton from an MP 12 level in the Geiseltal lignite series, Germany, was described as “*P.*” *neglectus* (Thalmann et al. 1989). A mandible previously ascribed to *Europolemur klatti* was also referred to this species by Thalmann (1994). The species was made the type of a new genus *Godinotia* by Franzen (2000b); however, this was based on the misallocation to this species of the first slab of *Darwinius* (see below). The species seems to be dentally close to *P. gaudryi*, but it differs from it by the loss of P1 and reduction of P2, which are single-rooted above and below, versus double-rooted in *P. gaudryi*. This may justify a generic (or subgeneric) distinction. Among the best preserved skeletal elements are a left humerus, a right forearm and hand, with some carpals, five metacarpals, and some very elongated proximal phalanges (Thalmann 1994). *Godinotia* appears to have more gracile limb bones than *Europolemur* and *Darwinius* (Franzen et al. 2009).

A third group of cercamoniines consists of *Agerinia*, *Periconodon*, and *Darwinius*. New faunas under study reveal an abundant new species in the Paris Basin that is close to *Agerinia* and *Periconodon*, and also appears closely related to *Darwinius* (Herbomel and Godinot 2011). Species of *Periconodon* are named after the presence of a supplementary cusp on the upper molars called a pericone (Stehlin 1916). The taxonomy is uncertain and provisionally follows Godinot (1988), with *P. helveticus* from Egerkingen as type species of the genus (Stehlin 1916). Its type specimen is a maxilla bearing P3/ and M1–2/. These molars have a transversely short trigon basin, a long lingual slope of the protocone, a well-developed pericone that is lingual or slightly anterolingual to the protocone summit, and a large hypocone. P3/ is high and pointed. Its lingual border is underlined by a moderate bulging, without any cusp or protocone lobe. A very close species is *P. huerzeleri* from Bouxwiller, the type specimen of which is a mandible (Gingerich 1977a). The lower molars of this species show a high intraspecific variability, e.g., M/1 with or without a tiny paraconid; lower molars with a clear separation between the premetacristid and the curved paralophid, or a paralophid continuous until the metaconid on M/3; and M/3 with a more or less extended talonid basin, with or without distinct entoconid. Upper molars vary in their transverse extension, and in the variable presence of a crest linking hypocone and pericone (Godinot 1988). Similar high variations occur on the teeth of *P. jaegeri* from a lower level at Bouxwiller, with hypocone and pericone varying from small to very large and lingually bulging. This species is typified by crenulated enamel and lower molars with a supplementary anterolingual crest issued from the metaconid (entometacristid). *P. helleri* is known through a maxilla from the Geiseltal series (MP 13–14). Its teeth are worn and chemically eroded. It shows a P4/ having a relatively short protocone lobe. A dentary of *Periconodon* sp. is reported from the rich locality Eckfeld Maar (MP 13). It preserves P/4, P/3, an incomplete and apparently two-rooted P/2, and the alveolus for a P/1 (Franzen 2004). The older *P. lemoinei* proposed by Gingerich (1977a) needs further study. Until now, all species of *Periconodon* are known dentally only.

Agerinia is known through its type species *A. roselli* from Les Saleres, Spain (MP 10), and through another species from southern France. Only lower teeth have been described, which include narrow P/3 and P/4 with curved preprotocristid and lingual cingulum. The lower molars have no more paraconid, and a paralophid joining a premetacristid, thus realizing a complete crest anteriorly joining protoconid and metaconid. The included trigonid basin (or fovea) becomes anteroposteriorly shorter and labiolingually longer from M/1 to M/3. The talonid basin is especially broad, with rounded outline, on M/1 and M/2. It is this distinctive morphology of M/2, with very short trigonid and broad talonid, which makes *Darwinius* remarkably similar to *Agerinia* in these rare derived traits. This suggests a close phylogenetic relationship between them, also shared with a new species from the Paris Basin (Herbomel and Godinot 2011).

D. masillae is the name given to the most complete Messel skeleton, which has an unusual history. After it was found by amateurs in the form of two opposite slabs, the first of these, which was incomplete, was supplemented by fake parts and described for the first time as the sixth Messel primate by Franzen (1994). It was at that time referred to "*Caenopithecus neglectus*." The preserved parts were

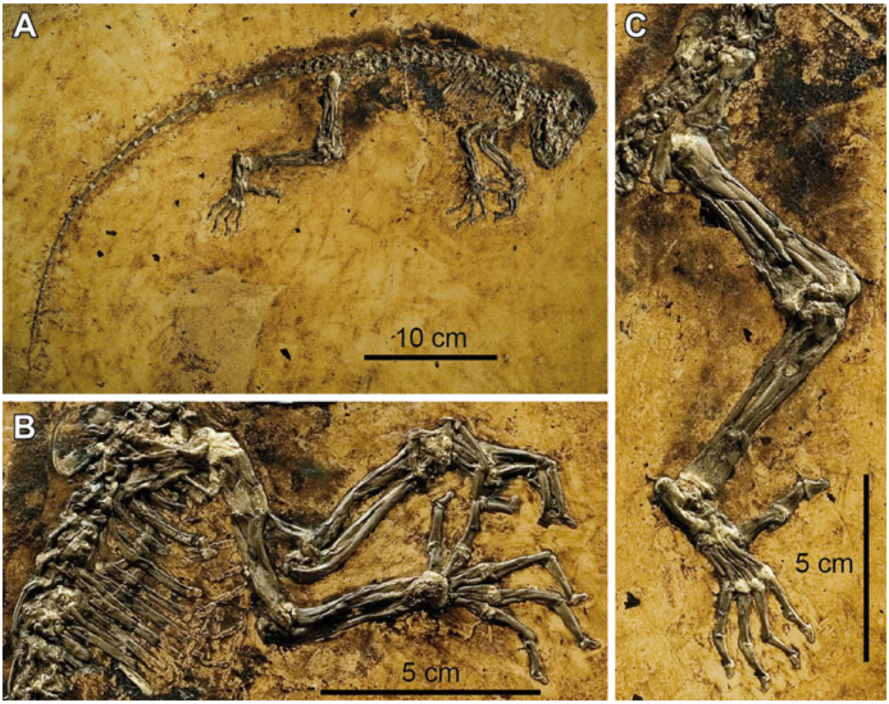

Fig. 6 The skeleton of *Darwinius masillae* from Messel, Germany. (**a**) the best-preserved plate; (**b**) detail of the same showing forelimbs and part of the vertebral column and rib cage; (**c**) detail of right hindlimb with complete foot. Note the presence of fur impressions on the complete skeleton, heavily crushed skull, a callus on the right wrist due to reaction after an accident, probably falling from a tree. The right foot shows a strongly opposable first toe and the dorsal side of the astragalus (Courtesy of J. L. Franzen)

already remarkable, including a crushed skull, the anterior part of the trunk and forelimbs up to the middle of the forearms, the rear part of the trunk, anterior part of the tail, and a hindlimb almost to the extremity of tibia and fibula. Outlines of the soft part of the body were visible. The specimen was described in detail. It is a juvenile individual with milk dentition and just erupted M/1, with a reduced DP/2, a short cranium, large orbits, and proportions of humerus, ulna, and tibia different from those of *Europolemur*. Further dental comparisons led Franzen to refer the species to a new genus as *"Godinotia neglecta"* (Franzen 2000b). Study of the dark remnants corresponding to gut content allowed the identification of a 3–4 mm seed coat and scattered leaf particles. These, together with the absence of insect cuticle, which is normally well preserved in insectivorous Messel mammals, suggest that the species had a frugivorous-folivorous diet (Franzen and Wilde 2003). Several years later, the second slab from the same individual was made available to science, leading to the in-depth analysis of the most complete fossil primate skeleton, now referred to *Darwinius* as *D. masillae* (Franzen et al. 2009) and nicknamed "Ida" (Fig. 6).

The complete skeleton confirms *Darwinius* to have possessed a relatively short rostrum, a steep face, large orbits, and a rather large braincase. Among its noticeable characters are the unusually short forelimb, the proximally curved ulna, mesaxonic hand (third ray the longest, primitive) with relatively small and short pollex, short metacarpals and long proximal phalanges, and scutiform nail-bearing distal phalanges. Analysis of its tarsus appears insufficient. Franzen et al. (2009) write that the fibular facet of the astragalus would be steep as in primitive primates ("haplorhines" for them); however, their best figure (idem Fig. 10) seems to expose the astragalus in dorsal view, showing mainly its tibial trochlea. A short ribbon of fibular facet is insufficient to describe its slope. The other parts of the foot – navicular, cuneiforms, and enormous pollex – are lemur-like, and it would be very surprising to find them associated with a laterally primitive astragalus. The fibular facet is steep but strepsirhine-like in closely related species from the Paris Basin (Godinot et al. 2011). Future micro-CT-scan studies will complete the first analyses, which raise some questions (e.g., the articulations between trapezoid and MC-II, and hamate and MC-V, are said to be saddle-shaped, which is bizarre). A radiographic study added to the CT-scan revals the pattern of dental replacement in Ida. The specimen is a juvenile with fully erupted M1, M2 probably erupted but with incomplete roots, M3 not erupted, DP3 and DP4 functional. Comparison with living primates suggests rapid growth, similar to that of "medium fast" primates with a maximum life span of 12–20 years (Schultz 1960; Franzen et al. 2009). It suggests that Ida was a juvenile, weaned and independently feeding, which during its life suffered an accident causing a severe trauma of its right wrist, probably a fall from a tree (Franzen et al. 2012). Ida has no baculum, whereas this bone is large and conspicuous in some *Europolemur* rear skeletons interpreted as males (von Koenigswald 1979); so Ida probably is a female. Its weight is estimated at 650–900 g, depending on the estimators. Its locomotion is reconstructed from a multivariate analysis as quadrupedal without specialization for climbing or leaping. However, such multivariate approach is likely to be influenced by evolutionary trends (e.g., the long lumbar region is likely primitive). The intermembral index (IMI) is more directly linked to locomotor adaptation. The IMI calculated for *Darwinius* from its measurements is 63–64, relatively low, indicating that its locomotion included frequent leaping. It is thus more likely to have been an arboreal quadruped leaper. A haplorhine status has been advocated for *Darwinius*, but only on weak grounds (Franzen et al. 2009). For example, a fused mandibular symphysis evolved many times in primates; loss of a grooming claw is uncertain in *Darwinius* but such a grooming claw exists in *Europolemur* and, moreover, reveals a complex pattern of evolution (von Koenigswald et al. 2012; Maiolino et al. 2012); see above concerning the fibular facet of the astragalus. *Darwinius* is a cercamoniine showing similarities with *Pronycticebus* (large orbit, large upper canine), as well as with *Agerinia* and *Periconodon* in dental morphology, and the placement of adapiforms with the strepsirhines appears well founded (see below).

A series of smaller species and genera of cercamoniines are known, mainly dentally. They include three genera close to *Anchomomys*, which will be grouped in a restricted tribe Anchomomyini. They lived during a large part of the Middle

Eocene. The smallest of them is the type species of *Anchomomys*, *A. gaillardi*, known by a maxilla and a mandible from Lissieu (MP 14), described by Stehlin (1916). The upper teeth are very simple, lingually narrow with the three main cusps, a continuous crista obliqua without metaconule, a paraconule, a very small incipient hypocone on M1–2/, and a non-reduced M3/. The lower molars are elongated and narrow. Typical of *Anchomomys* species is their almost rectilinear anterior paralophid, which in occlusal and in anterior view is at a roughly right angle with the strongly sloping preprotocristid. There is no trace of a paraconid. This thin paralophid, always well separated from the base of the metaconid, is reminiscent of adapines (and of *Pronycticebus* M/3). The trigonid becomes shorter from M/1 to M/3. Two dentaries from Egerkingen referred to *A.* cf *pygmaeus* (taxonomy uncertain) add some information. One shows a P/4 which is anteroposteriorly elongated, narrow, has no trace of a metaconid, and bears only one posterior median crest descending from the protoconid summit, and a well-formed talonid with hypoconid and lingually inclined basin surrounded by a lingual cingulid. The other dentary shows anterior alveoli, which suggest the presence of two small incisors, a relatively large canine, and a two-rooted P/2 (Stehlin 1916; Szalay and Delson 1979).

Other species of *Anchomomys* include the slightly larger *A. (Huerzeleris) quercyi*, which has a larger but still small hypocone. The type specimen is from old Quercy collections, without precise location; however, very close specimens have been found in new Quercy faunas from reference levels 16 and 17a. *A. frontanyensis* from Sant Jaume de Frontanyà (MP 14/15, Spain) completes our knowledge of the genus. Described are a robust, slightly recurved upper canine, small P1/, P2/, and larger P3/ which are subtriangular in outline, surrounded by an almost continuous cingulum. P4/ is transversely elongated with a well-formed protocone. M1–2/ have very small cingular hypocones (Marigo et al. 2011). Among the lower teeth are a robust canine with cingulids descending from the apex, a surprisingly large P/1 (P/2?), P/2, and P/3 oval in outline and surrounded by a continuous cingulid, and an elongated P/4 close to that of *A.* cf *pygmaeus*. Among the lower molars, several M/3 show an unusually high variability of their talonids, broad and short or elongated, with variable supplementary cuspules on their periphery. Postcranials of this species are known and allow a weight estimate of 120 g. The astragalus is close to those of small notharctids (Moyà-Solà and Köhler 1993). The first metatarsal has a moderate-sized peroneal process (Roig and Moyà-Solà 2011). The calcaneum has remarkable proportions. Its anterior part is more elongated than in any other known adapiform, rather resembling omomyids in this proportion. However, the authors conclude that such proportions are a compensatory effect in grasping foot postures, and not an indication of leaping propensities (Moyà-Solà et al. 2012). Other postcranials are said to confirm a cheirogaleid-like, generalized type of arboreal locomotion for *A. frontanyensis*.

Among the species closely related to *Anchomomys* are two species of *Buxella*, *B. prisca* and *B. magna*, described from the locality of Bouxwiller and known only by isolated teeth (Godinot 1988); *Nievesia sossisensis* from Sossis, Spain, known by a maxilla with M2–3/ and isolated teeth, is distinct due to the presence on the lower molars of a premetacristid joining the paralophid, closing a sloping trigonid

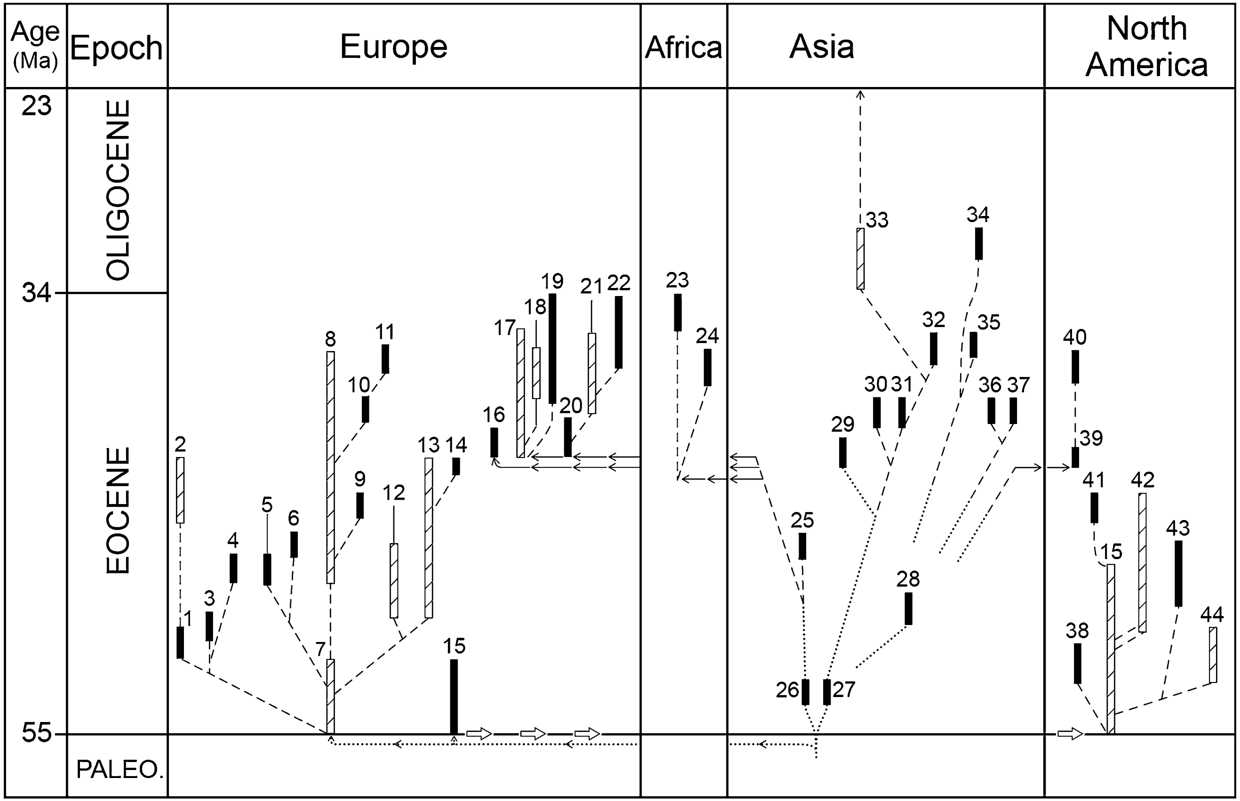

Fig. 7 (continued)

basin (Marigo et al. 2013); and *Mazateronodon endemicus*. The latter is from the Middle Eocene Spanish locality Mazateron (MP 15–16), in the Almazan Basin. This basin is further west in comparion with other Pyrenean/Catalan basins, and its fauna, including *Mazateronodon*, reveals some endemism relative to other European localities (Marigo et al. 2010). Like *Nievesia*, *M. endemicus* has lower molars with a closed trigonid basin. Two upper incisors referred to this species show an elongated cutting edge reminiscent of adapines. In contrast, a referred lower incisor seems not to fit well with the uppers and would suggest a great amount of evolution in comparison with the alveoli of *A.* cf *pygmaeus*. A referred P4/ has a very narrow lingual lobe. One mandible fragment with P/3–4 and the canine shows the latter to be robust and of triangular outline. P/3 and P/4 on this specimen and on another one are noteworthy: elongated, blade-like, slightly crowded with the anterior root more labial than the posterior one. P/3 is longer and higher than P/4, somewhat posterodorsally inclined; P/3 is slightly narrower, more elongated and more inclined on the specimen bearing the canine than on the other. On both, P/3 displays a long anterior blade, suggesting a possible honing mechanism for the robust upper canine (which is also described). This should be explored: it would be remarkable for such a small species. In any case, *M. endemicus* shows an interesting evolution of the lower premolars, possibly convergent with catarrhines. Middle Eocene anchomomyins survived longer than other cercamoniines, probably because their small size induced them to avoid competition with the then-dominating adapines. They must have been partly insectivorous.

Adapids in Europe and Three Other Continents

The family Adapidae is known by a classical group of European forms, the Adapinae, and by a series of more primitive and almost cosmopolitan forms (Fig. 7), provisionally grouped in the Caenopithecinae. The adapines arrive as

Fig. 7 Known stratigraphic ranges and suggested phylogenetic relationships among genera of Adapiformes. *Dashed bars* indicate genera including more than one specific lineage; *black bars* indicate that only one specific lineage is known; simple *vertical lines* indicate uncertainty in the stratigraphic range. The global picture of this record is a good reflection of the whole Eocene primate record: relatively well known in Europe and North America, much less in Africa. In Asia, which played a central role, several groups are documented; however, the record is too scanty to allow even a vague schema of possible relationships. *Dashed lines* indicate reasonable phylogenetic hypotheses; *dotted lines* indicate unknown origins and affinities for Asiatic groups. *Arrows* indicate dispersals between continents (or the continuation of sivaladapines in the Miocene above 33). *1*, new species close to *Periconodon* and *Agerinia*; *2*, *Periconodon*; *3*, *Agerinia*; *4*, *Darwinius*; *5*, *Pronycticebus*; *6*, *Godinotia*; *7*, *Donrussellia*; *8*, *Anchomomys*; *9*, *Buxella*; *10*, *Mazateronodon*; *11*, *Nievesia*; *12*, *Protoadapis*; *13*, *Europolemur*; *14*, *Barnesia*; *15*, *Cantius*; *16*, *Caenopithecus*; *17*, *Leptadapis*; *18*, *Magnadapis*; *19*, *Cryptadapis*; *20*, *Microadapis*; *21*, *Adapis*; *22*, *Paleolemur*; *23*, *Aframonius*; *24*, *Afradapis*; *25*, *Adapoides*; *26*, *Marcgodinotius*; *27*, *Asiadapis*; *28*, *Panobius*; *29*, *Lushius*; *30*, *Rencunius*; *31*, *Hoanghonius*; *32*, *Wailekia*; *33*, *Guangxilemur*; *34*, *Bugtilemur*; *35*, *Muangthanhinius*; *36*, *Paukkaungia*; *37*, *Kyitchaungia*; *38*, *Pelycodus*; *39*, *Mescalerolemur*; *40*, *Mahgarita*; *41*, *Hesperolemur*; *42*, *Notharctus*; *43*, *Smilodectes*; *44*, *Copelemur*

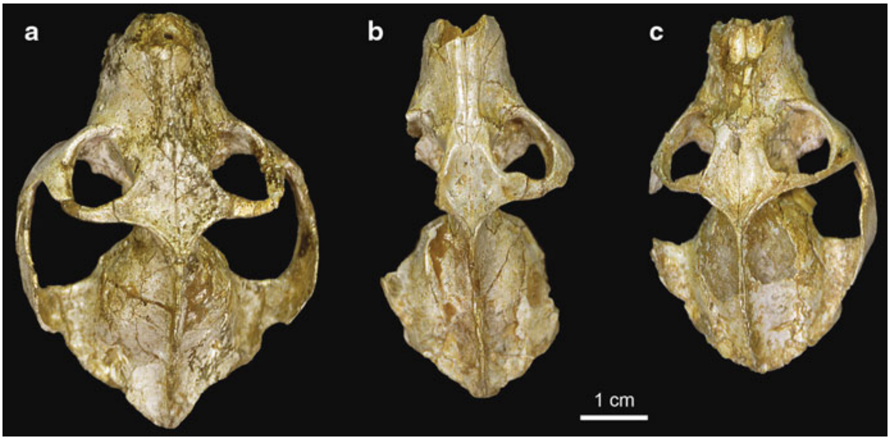

Fig. 8 Three crania of Late Eocene large adapines coming from old Quercy collections. (**a**) is the type specimen of *Magnadapis intermedius*, (**b**) is the type specimen of *Leptadapis magnus*, and (**c**) is the type specimen of *L. filholi*. Note that the interorbital breadth and the muzzle are larger in (**a**) than in (**b**) and (**c**). Cranial superstructures are also more developed in (**a**) in comparison with the two others; however, specimens with very low or no sagittal crest exist in both genera

several lineages, *Microadapis* and *Leptadapis* (including *Paradapis*), between reference levels 13 and 14. Until now, it has not been possible to root them convincingly in European cercamoniines, despite some similarities. Surprisingly, a species with marked similarities with adapids has been found in China, suggesting an origin of the subfamily in some intermediate area and strengthening the notion of a dispersal into Europe. Adapines make a small radiation in the Late Eocene of Europe, documented by the beautiful skulls found in the Quercy fissure fillings in the nineteenth century. A detailed description and analysis of these skulls was provided by Stehlin (1912). Information on one beautifully preserved cranium of *Adapis* and its endocast is given by Gingerich and Martin (1981). A careful revision of the large-sized adapines more recently has led to the distinction of two genera: *Leptadapis*, with a narrow interorbital breadth and muzzle (three species), and *Magnadapis*, with broader interorbital breadth and muzzle (four species) (Fig. 8). In both genera, some species show large or extreme cranial superstructures (sagittal and nuchal crests, thickened zygomatic arcades), while others show small ones or none. Whereas one study had proposed to interpret these differences as a marked sexual dimorphism (Gingerich 1981), restudy of more material, which underlined modest differences in canine sizes and morphological changes in dental morphology, led to the hypothesis of different lineages, some of them characterized now by a marked increase in cranial superstructures (Godinot and Couette 2008). A similar systematic revision is needed for the smaller *Adapis*-sized species, which are also numerous (Lanèque 1992, 1993). The postcranials of adapines are distinctive, showing no hindlimb lengthening and calcanea which have a very short anterior part, shorter than in any living strepsirhine (Dagosto 1983). The sole known complete femur has a relatively broad distal end (Fig. 9). These characters are

Fig. 9 Limb bones of *Adapis*-sized adapines from the old and new Quercy collections. The humerus (**a**), femur (**b**), and tibia (**c**) may come from the same fissure : They have the same type of preservation and were described together by Filhol. The calcaneum (**d**) and the first metatarsal (**g**) also come from old Quercy collections, whereas the two astragali come from two new localities, Rosières 2 (**e**) and Escamps (**f**). Proportions of humerus and femur suggest a not-elongated hind limb. The anterior part of the calcaneum is particularly short, and the peroneal tubercle of the first metatarsal is small. The two astragali are quite different, (**e**) with a much longer trochlea and (**f**) with a shorter, broader, and flatter one reflecting different locomotor adaptations in different *Adapis*-sized species

interpreted as indicative of climbing and a relatively slow locomotion (Dagosto 1983). However, some *Adapis*-sized species appear to have varied in locomotor modes, one being more walking and running than the other (Godinot 1992a; Fig. 9). The variety of femora that can be attributed to *Adapis*-sized species show that they underwent a diversification in their locomotor adaptations, resulting in five different types, some of which were more climbing and others more walking and running forms (Bacon and Godinot 1998).

All of these adapines have highly crested molars and molarized P/4. Their phylogeny is rather complex and not yet understood. Species of *Cryptadapis* had a large hypocone, whereas large adapines show a progressive reduction of this cusp. Several lineages further increase their shearing adaptation in developing a metastylid on their lower molars. They appear adapted to shearing food, which is suggestive of degrees of folivory; however, they varied in their diets. Microwear analysis suggests that *Cryptadapis tertius* was strictly folivorous, whereas one *Adapis* species added more fruits to its diet than two other adapines (Ramdarshan et al. 2011). Adapine remains from well-dated faunas reveal that the large genera, *Leptadapis* and *Magnadapis*, preceded the mid-sized ones, and that the latter became extinct in the Quercy region at the end of the Eocene. The adapines apparently did not survive the Terminal Eocene Event, or "Grande Coupure," in Europe, which involved an invasion of Asiatic mammals better adapted to more open environments, as well as to cooler and more seasonal climates. However, it seems that one species of a relatively large adapine briefly survived the dispersal event in England (Hooker 2010).

The more primitive adapids provisionally grouped in the subfamily Caenopithecinae are found in Europe, North America, Africa, and possibly Asia. The Asiatic *Adapoides troglodytes*, from the Middle Eocene Shanghuang fissure fillings, China, is known by a lower dentary with M/2–3 and isolated upper molars and DP4/ (Beard et al. 1994). Its lower molars are so derived in an adapid direction, with anteroposteriorly compressed trigonid, long ventrolingually sloping paracristid, and deep talonid notch, that they could point toward adapine affinities. However, the upper molars (including the "*Europolemur*-like" molar of Beard et al. 1994) are transversely elongated and show no hypocone or only a tiny incipient one, characters markedly more primitive than in the adapines. Without knowledge of the P4/4 and their degree of molarization, it will be difficult to determine the place of this genus relative to the adapines. A small adapiform astragalus from Shanghuang appears already adapine-like, suggesting climbing propensities (Gebo et al. 2001). The European primitive adapids include *Caenopithecus* and *Microadapis*, which arrive in Europe at the same time (Egerkingen fissure fillings, Middle Eocene, Switzerland). *C. lemuroides* shows a number of similarities with later adapines, but it also has non-molarized P/4/ –a primitive trait – and a metastylid on the lower molars and a mesostyle on the uppers, the latter being a derived character unknown in adapines and otherwise found, among adapids, only in the African *Afradapis*. *Microadapis* is small, has no metastylid, a simple premolariform P/4 and relatively narrow and elongated P/4–2, and a moderate-sized P/1. A referred upper molar bears a very large hypocone, as well as a metaconule – a small cusp usually lost in other genera, including *Adapoides*. The most primitive adapids probably differentiated somewhere on the Eurasiatic landmass between Europe and China. *Marcgodinotius* from India (see below) might have some relevance.

The two African genera *Aframonius* and *Afradapis* from the Late Eocene deposits of the Fayum, Egypt, also appear to show affinities with this group, revealing its dispersal into Africa. *Afradapis longicristatus* is from the Late Eocene BQ-2 locality (Seiffert et al. 2009), whereas *Aframonius dieides* is from the Latest Eocene locality L-41 (Simons et al. 1995; Simons and Miller 1997). The two genera have upper molars with a broad trigon basin, high crests, and a large hypocone linked to the posterior cingulum (Fig. 10). The long and sharp centrocrista is slightly labially deflected on the M2/ and M3/ of *Aframonius*, and even more

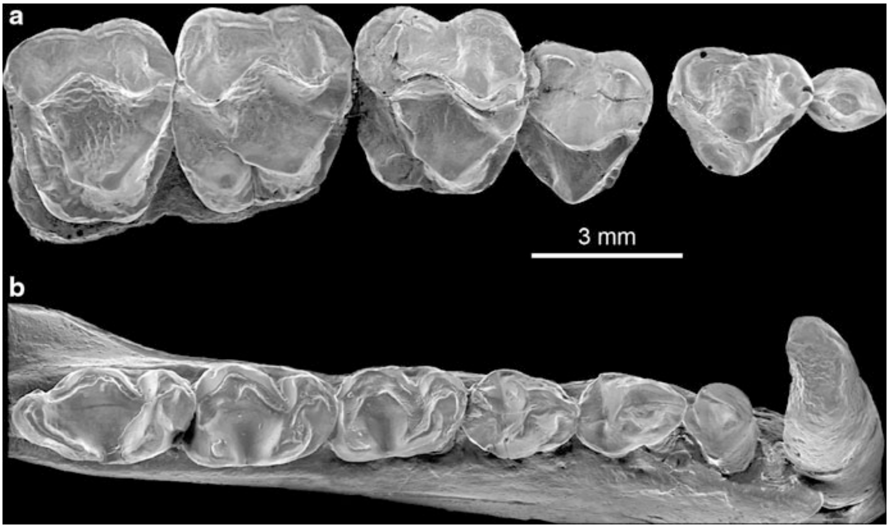

Fig. 10 The dentition of *Aframonius dieides* from the Fayum, Egypt. (**a**) upper dentition from the large M3/to the small P2/in occlusal view; P3/and P4/are in a more labial orientation, with the protocone partly hidden, due to specimen deformation; (**b**) lower dentition from M/3 to the lower canine in occlusal view. Scanning electron micrographs (SEM) of casts

deflected and joining a mesostyle on the M1–2/of *Afradapis*. Their P4/ are simple with a broad protocone lobe, and their P3/ are triangular due to a narrower protocone lobe. Both have lower molars without paraconids. Those of *Aframonius* have shorter paracristids, and metaconids posterior relative to the protoconid. Those of *Afradapis* have a more anterior metaconid, a longer protocristid, and longer paracristids which increasingly curve toward the metaconid summit from M/1 to M/3. The P/3–4 of *Aframonius* are relatively short, posteriorly broad, and only incipiently molarized. The P/3 and P/4 of *Afradapis* are remarkable and unique among adapiforms. P/4 is elongated, molarized through a high metaconid almost as anterior as the protoconid, has a well-formed and narrow talonid basin, and is unusual because of its anteriorly elongated protocristid. P/3 is even larger than P/4, higher and much longer. Its anteriorly elongated protocristid served as a honing device for the large upper canine. Lower dentaries show that there was no P/2 in *Afradapis*, which appears convergent with catarrhines in the possession of only two premolars and an enlarged P/3 honing with the upper canine. The dentaries of *Afradapis* were fused, whereas there was variability in this character in *Aframonius*, which retains a moderate-sized P/2. Both upper and lower isolated incisors have been ascribed to *Afradapis*. The lowers make a transverse cropping mechanism analogous to that of *Adapis*. A large phylogenetic analysis proposed a placement of the two African genera close to the European *Caenopithecus* (Seiffert et al. 2009). Given that *Aframonius* had some more primitive characters, the two groups likely share a close common ancestor, whose descendents were able to disperse to Europe and to North Africa in the Middle Eocene.

Finally, there are two North American genera, *Mahgarita* and *Mescalerolemur*, which are of uncertain affinities. *Mahgarita stevensi*, from the Latest Eocene of Texas, has long been recognized to have no affinity with the North American notharctines (Wilson and Szalay 1976). Similarities with primitive adapines led to its inclusion in that group (Godinot 1998). However, the description of the older and more primitive *Mescalerolemur horneri* and more detailed phylogenetic analyses showed the adapid features of *Mahgarita* to be probably convergent, and both these genera to be probably rooted in more primitive adapiforms (Kirk and Williams 2011). A dispersal from Asia, as for many other Eocene forms, appears likely. Both genera have upper molars with a well-formed crestiform hypocone and complete lingual cingulum on M1–2/. M2/ is transversely broader than M1/. The M1/ of *Mescalerolemur* is more triangular, with a strong prehypocone-crista and an expanded basin posterior to the postprotocrista. Whereas *Mahgarita* has a P4/ with a broad protocone recalling adapines, that of *Mescalerolemur* has a much narrower protocone lobe. P3/ is triangular, dissymmetrical due to its posterior protocone lobe, in *Mahgarita*. It is even more unusual in *Mescalerolemur*, with a pinched posterior protocone lobe underlined by a strong posterior ectoflexus. Both taxa have lost P1 and have reduced P2 above and below. The lower molars of both genera have very reduced paracristids. *Mescalerolemur* has a small anterior paraconid on M/1 only. The posteriorly broad and elongated M/3 of *Mahgarita* could be reminiscent of adapines; however, similar morphologies occur in cercamoniines as well, and *Mescalerolemur* has a shorter and posteriorly narrower M/3. P/3 and P/4 appear particularly simple in both genera, transversely narrow and with no metaconid or paraconid. In *Mahgarita*, where the large canines are known, the lower canine is posteriorly recurved, but the upper canine – straight, with a strong basal cingulum, a sharp posterior crest, and vertical grooves – is somewhat reminiscent of *Leptadapis*. *Mescalerolemur* has an unfused symphysis, whereas *Mahgarita* has a fused one – evidently one more convergence with adapines and with many other primates. These two genera have an overall similarity and very peculiar P3–4/ which demonstrate their close affinity. *Mescalerolemur* is lacking clear derived similarities with adapids, and its origin will be in more primitive Asiatic adapiforms.

The holotype of *Mahgarita stevensi* is a crushed cranium which shows a number of features: a high maxilla, a pronounced posterior palatal spine, a very low occipital height, and a posteriorly directed foramen magnum. The basicranial morphology was earlier considered essentially lemur-like (Wilson and Szalay 1976). Further study of this crushed cranium and two other partial crania led Rasmussen (1990) to add a number of observations. For example, there is noticeable petromastoid pneumatization; one specimen has a much reduced stapedial canal and the other has none at all. Rasmussen also suggested that *Mahgarita* had a lateral transverse septum resembling that of *Aegyptopithecus*, that there was an ectotympanic band fused to the petrosal, and probably not enough space for a free ectotympanic ring. However, restudy of these structures led others to refute these suggestions and reaffirm that *Mahgarita* was adapid-like in tympanic position and morphology (Ross 1994).

Asiatic Sivaladapids and Primitive Adapiforms

The family Sivaladapidae is restricted to Asia, where the sivaladapines survived until the Late Miocene. The subfamily Hoanghoniinae is naturally placed near them. Here will also be placed the recently described Early Eocene Asiadapini, which are probably related to them, and other more divergent Asiatic adapiforms. This radiation is, on the whole, poorly documented: no skull has yet been described. The best-known members of the group were until recently the Miocene sivaladapines, for which upper and lower jaws allow a description of their dental adaptations. Very high-crested molars and highly molarized P4/4 indicate a folivorous adaptation. A similar adaptation seems to be present in the Late Eocene–Early Oligocene genus *Guangxilemur*. First described through *G. tongi*, known by one M2/ and one upper canine from the Gongkang Formation of Guangxi Province, China (Qi and Beard 1998), its analysis was completed by the description of the Early Oligocene *G. singsilai* from Pakistan (Marivaux et al. 2002). The M2/ of *G. tongi* has high crests, a mesostyle linked to the centrocrista contributing to W-shaped labial crests, and pre- and postprotocristae as divergent as in the Miocene sivaladapines. The main difference with the latter is its possession of large hypocone and pericone. *G. singsilai* differs by a smaller hypocone and pericone, and a straight centrocrista on M2/. It also shows a highly molarized P4/, a DP4/, a simple P/3 with very small and narrow talonid, and an M/1–2 with salient crests, broad paracristid not joining the metaconid summit, and big, close, and deeply separated entoconid and hypoconulid. This morphology relates *Guangxilemur* to *Hoanghonius stehlini* and its close relative *Rencunius zhoui*, both from Late Eocene beds of the Heti Formation, Shanxi Province, China (Gingerich et al. 1994). Both species bear the hallmarks of this group: lower molars with twinned entoconid and hypoconulid, and upper molars with a continuous lingual cingulum bearing hypocone and pericone and a wide trigon basin limited by very divergent protocristae. On the mandible of *Hoanghonius*, which bears M/2 and M/3, a continuous paracristid joins the metaconid anteriorly. On the mandible of *Rencunius*, which bears M/1–2 and P/4, the molars are more bunodont, M/1 bears a well-formed paraconid, and P/4 is simple with a small metaconid, very short rounded talonid shelf, and continuous cingulids. The M1/ of *Rencunius* resembles the isolated upper molar of *Hoanghonius* but differs in some details, such as a more lingually bulging pericone, larger conules, and less waisting of the posterior border. The associated P4/ of *Rencunius* is very simple, with a large paracone, smaller protocone, and well-formed preprotocrista. Another sivaladapid very close to the above-mentioned genera is *Wailaikia*, from the Late Eocene Krabi mine of Thailand. *W. orientale* is represented by a mandible bearing M/2 and M/3 (Ducrocq et al. 1995). Alveoli for the anterior teeth show that it possessed a long premolar series with an unreduced two-rooted P/2 and a relatively large canine. The continuous and transversely long paracristid and the twinned entoconid and hypoconulid leave no doubt that this species is a sivaladapid close to *Hoanghonius*. It differs from the latter by its broader lower molars and much shorter M/3 with a barely salient third lobe. The dentary is low and elongated, and it preserves a high coronoid process and the articular condyle.

The bizarre maxilla known under the name of *Lushius quinlinensis*, from the late Middle Eocene of Shanxi, might pertain to the same group. Considered an adapiform *incertae sedis* by Szalay and Delson (1979), its M2/ bears similarities with that of *Hoanghonius*, both in outline – the posterior half being narrower than the anterior one – and in trajectory of postprotocrista. It is more primitive with respect to its incomplete lingual cingulum, and more derived with respect to its extremely high paracone, metacone, and crests joining them. These constitute a high ectoloph recalling some ungulates and a very unusual morphology for primates. However, this specialization goes in a direction analogous to many high-crested sivaladapids, and thus its least unlikely affinities are probably with sivaladapids.

The Early Eocene beds of the Vastan Mine, Cambay Formation, Gujarat, India, are dated around 53 Ma. They have been yielding new adapiforms in the last years. *Marcgodinotius indicus* was named by Bajpai et al. (2005), *Asiadapis cambayensis* by Rose et al. (2007), and a synthesis on these taxa is provided by Rose et al. (2009). Both are small and primitive adapiforms, with global phenetic similarity with early European cercamoniines, but they also have interesting differences. The dentaries of *M. indicus* are elongated and slender and show a large canine, small P/1, two-rooted P/2, and some compression of the premolar series leading to an anterolingual shift of their root pairs. P/3–4 are simple; P/3 is higher than P/4, and the latter bears a small, low, little-differentiated metaconid. The lower molars have simple talonid basins. M/1 has a large paraconid in anterior (not lingual) position. M/2 has a shelf-like paracristid, and M/3 has a short trigonid with narrow and rounded paracristid, and also a very small and narrow third lobe. M1/ is remarkable for its overall triangular outline, with a lingual part much narrower anteroposteriorly than its labial part. It also has a strong parastyle, a posterolabially directed postmetacrista, a well-expressed posterior cingulum making a small hypocone shelf without cusp, and a very marked waisting of its posterior border. These characters differ markedly from those of *Donrussellia*, and several of them might be primitive, which would lead to a reappraisal of the adapiform ancestral morphotype. It would be important to find some M2/. *Asiadapis cambayensis* is larger than *M. indicus*. It differs from it by a single-rooted P/2, several details of the lower teeth (small paraconid present on some M/2–3, larger third lobe on M/3), and the upper teeth showing more massive outlines and proportions as well as a well-formed crista obliqua almost continuous to the tip of the metacone. Some characters of this species are again quite different from those of cercamoniines; for example, some M/2–3 have a deep groove between protoconid and metaconid, and an M1/ has a preprotocrista leading to a paraconule and continuing toward the tip of the paracone. The differences noted between these two genera and European cercamoniines underline a marked systematic separation between the two groups.

Several limb bones of these asiadapines have been described (Rose et al. 2009). A beautiful complete humerus shows a rounded head, a prominent and low greater tubercle, a salient deltopectoral crest slightly overhanging the bicipital groove, and a proximally extended brachialis flange. Its distal extremity shows a spherical capitulum projecting distally beyond the trochlea, a well-formed intercondylar groove, a conical trochlea projecting only very slightly distally (more than in *Cantius* and *Notharctus*, less than in the omomyiforms *Microchoerus* and *Shoshonius*). Its characters are in overall agreement with a generalized arboreal quadruped. Proximal radii show a slightly ovoid head (slightly rounder than in *Cantius*, but less than in living galagos). Two femora have a subspherical head and a long neck making an angle relative to the shaft near 57°, as in adapoids and living lemurs. The greater trochanter does not project as far proximally as the head. The trochanteric fossa is deep, narrow, and bordered by a salient paratrochanteric crest. A small third trochanter is distal, opposite to the distal part of the lesser trochanter. The femoral shaft is elongate and comparable to that of *Cantius*, *Notharctus*, and living lemurs. However, the distal extremity is not as high anteroposteriorly as in these fossils or in leaping prosimians. Again, the femora fit with the notion of an active arboreal quadruped. Tarsals have also been found, 11 calcanea and 5 astragali. These fall into two size classes and probably pertain to more than two species. The three larger partial calcanea, probably belonging to *A. cambayensis*, appear very similar to, but smaller than, those of *Cantius*. Among the smaller ones, four appear again similar (probably *M. indicus*) and four differ slightly in proportions, having a shorter proximal and a longer distal part, indicative of increased leaping propensities. It is difficult to establish whether these differences reflect a different species or merely extensive intraspecific variability (Rose et al. 2009). One large and four smaller astragali are very similar to those of notharctids. Only one of them has a lower neck angle, closer to those of omomyids and eosimiids. However, relative neck length is more discriminant of primate groups, and by that measure these astragali are like those of notharctids. The postcranials as a whole reflect the adaptations of small active arboreal quadrupeds. In conjunction with tooth dimensions, the postcranials permit relatively good weight estimates for these species, which are around 100–120 g for *M. indicus* and 250–300 g for *A. cambayensis* (Rose et al. 2009).

Asiatic adapiforms of late Early and early Middle Eocene age are restricted to small species from Pakistan. The Early Eocene Gandhara Quarry yielded an assemblage of *Panobius russelli*, which shows interesting characters (Gunnell et al. 2008). M/2 in the holotype dentary is remarkably primitive due to its large lingual paraconid, well separated from the metaconid, and a P/4 that is more elongated and posteriorly narrower than in *Donrussellia*. The sole illustrated M1or 2/ is very transversely elongated, due to the extended lingual slope of the protocone. *Panobius* might have some dental characters more primitive than in *Marcgodinotius*, and it probably would add to a reconstruction of the primitive adapiform morphotype. Two other species, *P. afridi* and *P. amplior*, are from the younger locality of Chorlakki, early Middle Eocene, and are more fragmentarily known (Russell and Gingerich 1987; Gunnell et al. 2008). *Sulaimania arifi* from the Gandhera Quarry is known only through an isolated M/2, revealing a small adapiform with a continuous anterior paralophid, reminiscent of some anchomomyini.

Four genera of small Asiatic adapiforms have been described from Late Eocene and Early Oligocene beds of Thailand, Burma, and Pakistan. They are all known by very fragmentary material. The first described, *Bugtilemur mathesoni* from the Early Oligocene of Pakistan, is also the best known, being represented by some upper teeth in addition to lowers (Marivaux et al. 2001). Its upper molars are simple, with a continuous lingual cingulum, no hypocone and conules, a postprotocrista posteriorly directed, and a posteriorly opened trigon basin. A high centrocrista is reported as shared-derived with living *Cheirogaleus*. The lower molars have a short trigonid with metaconid posterior to the protoconid, a broad talonid basin rounded posteriorly, and an anteriorly directed cristid obliqua. The P/4 is elongated, molarized with a narrow trigonid and a broad talonid basin with a small entoconid. Many dental similarities with *Cheirogaleus* led a parsimony analysis to place *Bugtilemur* as a sister group of *Cheirogaleus*, nested within the Malagasy lemuriform radiation, despite its lower canine not having the morphology of a tooth comb canine. The subsequent description of a small mandible from the Late Eocene of Thailand, named *Muangthanhinius siami*, revealed important features: an elongated and low dentary, a two-rooted, high and unreduced P/2, a partial canine root that is large and relatively vertically implanted – all suggestive of adapiform affinities. Some differences notwithstanding, P/3 to M/1 show a remarkable general similarity with those of *Bugtilemur* (Marivaux et al. 2006), which established adapiform status for both genera.

Four isolated teeth from two different localities of the Pondaung Formation, late Middle Eocene of Myanmar, were described as the smallest sivaladapid species, *Paukkaungia parva* (Beard et al. 2007). The M/1 is primitive by its broad trigonid with large paraconid and extended trigonid basin. Its talonid is broad and rounded in outline. It is possible to identify a hypoconulid and an entoconid among the poorly differentiated posterolingual cusps, making this species reminiscent of other sivaladapids. The P/3 and P/4 attributed to this species have a protoconid which is very extended anteroposteriorly and at the same time low. They have a sloping talonid basin restricted lingually by the posterior extension of the postprotocristid. P/3 has a low crestiform hypoconid, P/4 had a better differentiated one (worn) and a small entoconid. The roots of P/3–4 show a partial coalescence, suggesting a trend toward premolar compaction (Beard et al. 2007). Their unusually low relief might have been linked to some anteroposterior overlapping. They are intriguing in any event. The other species, *Kyitchaungia takaii*, is based on one isolated M/2 that is partially eroded. It is larger than *Paukkaungia parva*, and its entoconid and hypoconulid are better differentiated. Some postcranials are referred to this species. A calcaneum is relatively similar to those of the notharctids, although it differs from them by a broader proximal facet and a deep medially offset cuboid pivot. The curvature of its proximal part is marked. An astragalus without head also resembles those of small notharctids. A proximal femur from the same locality, attributed to the same individual as the tarsals, has been described in detail (Marivaux et al. 2008). It reflects good hip mobility. All of these elements in *Kyitchaungia* suggest a broad locomotor repertoire with quadrupedalism, including some leaping, climbing, and possible suspensory activities.

On the whole, the Asiatic adapiforms remain poorly known, with no skull described, many taxa known only by fragmentary dental remains, and a recently expanded but still limited postcranial record. Various recent discoveries have substantially increased our knowledge, confirming that the Asiatic adapiform radiation probably played a central role as the source of dispersals into Europe, North America, and Africa. However, much more remains to be discovered.

Eocene Lemuriformes, Stem Lemuriforms, and the Concept of Strepsirhini

Eocene Lemuriformes

Living lemuriforms can be easily distinguished from fossil adapiforms by the possession of a dental complex, the tooth comb, formed at the anterior extremity of the lower jaws by the closely appressed and proclive lower incisors and canines. Recurrent speculations about the affinity of some adapiform genera, lately anchomomyins, with the Lemuriformes were put to rest by the discovery in Africa of Eocene lemuriforms bearing a tooth comb (Seiffert et al. 2003). Found in the Egyptian Fayum stratigraphic sequence, they come from the two localities seen above for the two adapids. *Saharagalago* and *Karanisia* come from BQ–2, early Late Eocene (around 37 Ma), and *Wadilemur* from L-41, a Latest Eocene locality (Seiffert et al. 2005a; Seiffert 2006). They are all small primates whose upper molars have a well-formed cingular hypocone, protocone crests surrounding an anteroposteriorly broad trigon basin, and a sharply defined postprotocrista joining the metacone on *Karanisia* and *Saharagalago*, but not reaching its summit in *Wadilemur*. The lower molars have an anteroposteriorly compressed trigonid without paraconid and with a long paracristid often joining the metaconid summit. *Karanisia* is peculiar by its continuous lingual cingulum and extensive hypocone shelf, with small crestiform hypocone. Its P4/ and P3/ have a broad protocone lobe and cusp, with P4/ also showing a continuous lingual cingulum. A lower dentary of *W. elegans* shows procumbent incisor and canine alveoli, and P/2–4. P/2 and P/3 have crowns which project anteriorly with some overlap of successive teeth. P/4 has a well-formed talonid basin, with a tall labial hypoconid and a long acute cristid obliqua. This morphology is reminiscent of later galagids. A partial femur ascribed to *Wadilemur* presents characters reminiscent of those of living galagids, e.g., a cylindrical femoral head, suggesting frequent leaping in its repertoire, but less specialized than in the vertical clinging and leaping galagos. *Wadilemur* and *Saharagalago* are interpreted as stem Galagidae, and *Karanisia* as a stem lorisoid (Seiffert et al. 2003, 2005a). This implies that the split between lorisoids and the Malagasy lemuroids would be older than Late Eocene; however, the lemuroid morphotype is unknown. Two genera found in the Early Oligocene of Oman, *Omanodon* and *Shizarodon*, are known only by isolated teeth and have remained relatively enigmatic (Gheerbrant et al. 1993). Dental similarities between *O. minor* and *S. misrensis* suggest that they probably belong to the same group of early lemuriforms (Godinot 2006).

Stem Lemuriformes

Two distinct genera can be placed in a family named the Djebelemuridae, which are now assumed to be stem lemuriforms – which means, closely related to Lemuriformes but not possessing their defining apomorphy, the tooth comb. *Djebelemur martinezi* occurs in the late Early or early Middle Eocene locality of Chambi, Tunisia (Hartenberger and Marandat 1992; Marivaux et al. 2013). The type mandible preserves P/3–M/3, and alveoli for a moderate-sized canine and P/2. P/3 and P/4 are very simple, elongated and narrow, relatively low, bearing a continuous lingual cingulid and a simple talonid cusp. The lower molars have long paracristids joining the metaconid summit. An isolated lower canine and P/2, and a maxilla bearing P3–M3/, were added recently. P/2 is single-rooted, moderate in size, slightly procumbent. The canine is surprisingly small, and also somewhat procumbent. The upper molars have a trigon resembling that of Eocene lemuriforms, but there is no hypocone, whereas there is an almost complete lingual cingulum, interrupted only lingually to the protocone summit. P3/ and P4/ are triangular in outline, P4/ having a small and low protocone, and P3/ only a cingular cuspule. The polarity of these premolar characters is intriguing: primitive or secondarily simplified? An astragalus from Chambi shows the typical characters of small strepsirhines, with a strongly sloping fibular facet and a posterior trochlear shelf with a laterally offset groove for the flexor fibularis tendon. The elongated neck and tightly curved profile of the trochlea suggest that leaping was a part of its locomotor repertoire (Marivaux et al. 2013). Isolated petrosals from Chambi also pertain to *Djebelemur* or to a small azibiid present in the fauna. Their detailed study with micro-CT-scan reveals interesting characters (Benoit et al. 2013). Among them are a stapedial and a promontory artery that are very small and suggest that the internal carotid was supplemented by another vessel.

Another more recent species, awaiting a new generic name, is *“Anchomomys” milleri* from the L-41 locality, Latest Eocene of the Fayum, Egypt (Simons 1997). A mandible bearing all teeth from canine to M/2 shows M/1–2 similar to those of *Djebelemur*, and broader P/3 and P/4, the latter having a second crest descending posteriorly from the protoconid summit (Fig. 11). P/2 is somewhat smaller than P/3, not reduced. The canine is larger than P/4, low with a curved anterior border and a relatively low and rounded summit. Its crown is slightly procumbent, but the root is rather vertical. Its continuous lingual cingulid becomes posteriorly higher above the crown base, all this giving it a premolariform appearance. Both *Djebelemur* and *“A.” milleri* clearly did not possess a tooth comb, yet their canines are no longer the high pointed canines of primitive adapiforms; they are low and slightly procumbent, probably illustrating a step in the transformation of a primitive canine into a procumbent tooth comb canine. Phylogenetic analyses recover the place of djebelemurids as stem lemuriforms, along with *Plesiopithecus* (Seiffert et al. 2005; Marivaux et al. 2013).

Plesiopithecus teras is a very unusual primate found in Quarry L-41 of the Fayum. Its lower mandible bears an enormous, procumbent anterior tooth which is a lower incisor or a canine, followed by a very reduced canine or P/1. The lower premolars are simple; they are broader, lower, and more anteroposteriorly compressed than in djebelemurids. The lower molars likewise have anteroposteriorly

Fig. 11 Lower teeth of the stem lemuriform *“Anchomomys” milleri* from the Fayum in occlusal (**a**) and lingual (**b**) views. The anterior tooth on the *left* is a canine, which is relatively low and premolariform. It is followed by long and narrow P/2 and P/3, a larger P/4, and two molars, which have a short trigonid without a paraconid. SEM of casts

compressed trigonids with long paracristids, and they also are much broader and lower than in djebelemurids. There is sometimes a metastylid, and M/3 is much shorter than in *Djebelemur*, having a very abbreviated third lobe. A distorted cranium shows upper molars decreasing in size from M1/ to M3/ (Simons and Rasmussen 1994). They are relatively simple, with a continuous lingual cingulum but without hypocones. Whereas P4/ is transversely broad, P3/ is single-cusped and the small P2/ is bilaterally compressed. There is a very large vertical canine, inserted in a high muzzle. The roof of the cranium is anteroposteriorly arched. The orbits were large and indicate nocturnal habits. *Plesiopithecus* is highly autapomorphic. Its lower jugal teeth recall djebelemurids and lorisoids, and the very large lower tooth could indicate an enlarged tooth comb canine accompanied by incisor loss (Simons and Rasmussen 1994). This scenario or possible ties with *Daubentonia* (Godinot 2006) would imply a lemuriform status, whereas scenarios from a more primitive djebelemurid state imply a stem lemuriform status as found in the cladistic analyses.

Azibiidae

It took recent recovery of sufficient dental remains for researchers to better realize what these bizarre primates probably are. They occur in late Early or early Middle

Eocene localities of North Africa. After the initial description of *Azibius trerki* from the Gour Lazib, Algeria, by Sudre (1975) as a probable prosimian, the dentary of this genus was later disputed. Its high and roughly blade-like P/4 was so unusual that the primate status of the genus was doubted (Szalay and Delson 1979). Isolated molars of the smaller *Algeripithecus minutus*, found in the close Glib Zegdou, Algeria, are extremely bunodont, and its M2/ is so similar to that of some parapithecids that its anthropoid status received general agreement (Godinot and Mahboubi 1992, 1994). However, more complete material recovered later revealed that the two genera were close to each other and led researchers to synonymize two other genera (Tabuce et al. 2009). A dentary of *Algeripithecus* shows a tooth row increasing in height from a low M/3 to an M/1 with elongated and high trigonid, to long, high and blade-like P/3–4, P/4 with two successive summits, P/3 with a second summit, presumably a metaconid, smaller and lower than the protoconid. P/3 and P/4 have complete labial and lingual cingulids showing an anterior elevation. Anterior alveoli are interpreted as those of a small single-rooted and procumbent P/2 and of a large canine, procumbent and with a long posterior root lingual to the roots of P/3. The upper teeth are all isolated. The upper molars are extremely bunodont. The transversely elongated M2/ has a large hypocone, almost as high as the protocone, a metaconule, and an extended labial slope of the paracone. The anteroposterior crests on the paracone and metacone are salient. M1/ is less transversely broad, and its paracone is higher, with steeper slopes. P4/ has two labial cusps, the larger one being a high peak, in profile view, with a high labial slope suggesting some exodaenodonty (enamel extended beyond the alveolar margin, along the roots). The tooth is transversely short, with the lingual lobe bearing two small cusps, a small pointed protocone and a smaller hypocone. The high P3/ seems to have one large cusp. A smaller transversely compressed P2/ is associated with the others.

The dentition of *Azibius trerki* is roughly similar but also shows some differences. Aside from its larger size, it is even more bunodont, and its P3–4/ are more transversely extended and more molarized: P4/ has a recognizable trigon basin and paraconule, and P3/ a small protocone lobe. A small portion of maxilla bearing P3/ and P4/ revealed a large infraorbital foramen, the trace of a lacrimal canal oblique anteroventrally, and a part of the orbital floor suggesting that the orbits were large, as in nocturnal primates. All these characters are more typical of strepsirhines (or omomyiforms), and the phylogenetic analysis of Tabuce et al. (2009) placed azibiids as primitive sister group of a clade (dejbelemurids + lemuriforms). In the future, such a position as stem lemuriforms might even be shifted within lemuriforms, if the long procumbent lower canine of *Algeripithecus* turns out to be as reminiscent of a tooth comb canine as the authors suggest. Strepsirhine affinity is confirmed by the description of an astragalus ascribed to *Azibius* and a larger to a larger undescribed species of the same group. These astragali show the laterally sloping fibular facet typical of strepsirhines (Marivaux et al. 2011). Researchers have inferred quadrupedal and climbing abilities for this species that are similar to those of living cheirogaleids. One of the most intriguing aspects of these azibiids has received little attention until now, namely the adaptive significance of their dental specialization. Most living and fossil lemuriforms of small size are highly insectivorous. What may have been the diet of *Algeripithecus*, whose body weight is estimated between 65 and 85 g?

The Concept of Strepsirhini

A number of shared derived characters, which will be detailed below, unite tarsiids and simians in a monophyletic clade, the Haplorhini. By contrast, living Lemuriformes and Strepsirhini appear basically primitive. This is not a problem for living lemuriforms, which can easily be diagnosed by their possession of the tooth comb, a derived character. However, it becomes critical when one considers the place of fossil adapiforms, which are most often considered strepsirhines. Such an affinity has long been assumed, based on their possession of middle ear characters extremely similar to those of living lemurs. The bulla, the free tympanic ring inside of it (formed by the ectotympanic), the carotid entry into the bulla, and the arterial circulation inside it are extremely similar in adapid and living lemur crania (Stehlin 1912). However, inasmuch as these characters have long been considered primitive in primates, they do not prove close affinity. Nevertheless, detailed morphological and embryological studies enable us to identify possible synapomorphies. The truly annular ectotympanic is a specialized retention of a fetal character limited to adapiforms and lemuriforms, and rarely found elsewhere among mammals (among which most "ring-like" ectotympanics are in fact slightly expanded; MacPhee 1981, 1987; MacPhee and Cartmill 1986). Another potential synapomorphy is a gap existing in the annular bridge connecting the ectotympanic and the bulla wall ("recessus dehiscence"; Beard and MacPhee 1994). Furthermore, clearly shared-derived between adapiforms and lemuriforms are a suite of characters issued from studies of postcranial anatomy. Several characters of the astragalus – a laterally sloping fibular facet, a position of the groove for the flexor fibularis tendon offset from the posterior trochlear facet, a long posterior trochlear shelf – are derived and found in both adapiforms and lemuriforms. They are complemented by characters of the distal tibia and the navicular (Dagosto 1985; Gebo 1988; Covert 1988). This suite of characters indicates increased hallucial opposability, more habitually inverted foot postures, and foot flexion/extension accompanied by some conjunct rotation at the upper ankle joint. So far, there is no evidence of convergent acquisition of these characters, some of which are found in stem lemuriforms (Marivaux et al. 2011, 2013). These characters are probably strengthened by hand characters: adapiform hands have a structurally divergent thumb, as do those of lemuriforms, probably derived relative to simian hands (Godinot 1992b). However, this depends on the reconstruction of the primitive primate morphotype, which is under debate (see below in anthropoid origins part). Early omomyiform and simiiform hands are almost unknown. In any case, regardless of possible hand characters, strepsirhine monophyly appears well established.

The Omomyiformes Radiations

Besides adapiformes, many smaller fossils have been described in Eocene times; these are either united in one family, the Omomyidae, or spread out over two – the Omomyidae for the North American forms and Microchoeridae for the European ones. For a long time, these small forms were found to be "tarsier-like" and referred to an infra-order Tarsiiformes. They have also been suspected to possibly include anthropoid ancestors. However, the so-called similarities with *Tarsius* were exaggerated. Most omomyids have large eyes due to their small size and nocturnal adaptation; yet these eyes are no larger than in living small nocturnal strepsirhines. Despite new discoveries, recurrent re-analyses of fossils, and increasingly sophisticated phylogenetic analyses, it has proven impossible until now to identify among the Omomyidae a group which would be a consensual sister group of Tarsiidae. Moreover, most of these fossils appear not to possess the characters indicating anatomical haplorhinism (explained below for Tarsiidae). Thus, for the sake of clarity and consistency, these omomyids should not be included in Tarsiiformes. A number of omomyid groups had their own history and became extinct without showing any trace of evolution toward tarsiid or simian characters. The best choice is to place them in the taxon Omomyiformes, proposed by Schmid (1982), which has been adopted by a growing number of specialists (e.g., Ross et al. 1998; Williams et al. 2010). That is probably a paraphyletic grouping, but it is not appropriate to transfer some of them to a useful Tarsiiformes until it can definitively be shown that the group is a sister group to tarsiids. This is an ongoing debate, to which we will return below after discussion of the Tarsiidae. There are more than a hundred species of omomyiforms, found on three continents, which indicates a complex history for this broad group.

The Stem Genus *Teilhardina*

The genus *Teilhardina* is exceptional in many respects. Found on three different continents in the Earliest Eocene, it appears at the base of the later diversification of several subfamilies. As such it is paraphyletic and represents one of the goals of paleontologists: to identify an ancestral genus, a true stem genus at the base of the evolutionary diversification of entire families or subfamilies. This genus was first described from dental remains from the Belgian locality of Dormaal, and was named "*Omomys*" *belgicus* (Teilhard de Chardin 1927). The species was removed from *Omomys* and placed in a new genus *Teilhardina*, as *T. belgica*, by Simpson (1940). The same genus was later identified in an Early Eocene locality from the Willwood Formation, Wyoming, by Bown (1976), who named it *T. americana*. Several other North American species were subsequently named (see below). Eventually, the genus was also discovered in China. A cranium and associated mandibles, named *T. asiatica*, increased our knowledge of the genus substantially (Ni et al. 2004). One species has also been named from

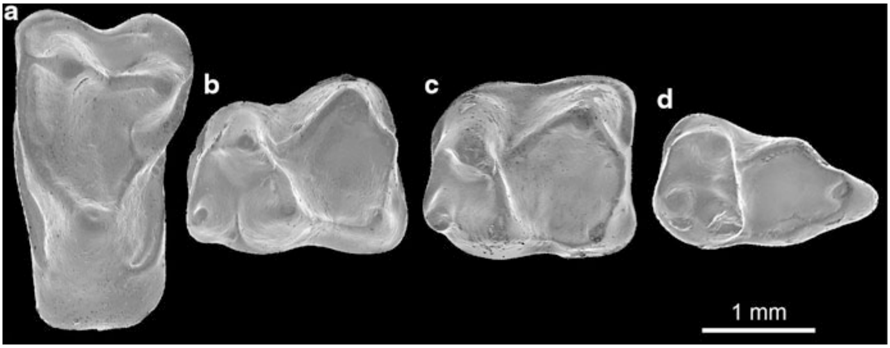

Fig. 12 Isolated teeth of *Teilhardina belgica* from Dormaal, Begium, all in occlusal view. The M2/ (**a**) is very simple and primitive, transversely elongated without hypocone or protocone fold; however, there is a slight lingual thickening of the posterior cingulum. Lower molars are M/1 (**b**), M/2 (**c**), and M/3 (**d**); M/1 and M/3 appear primitive through their large trigonid with a large paraconid. SEM of casts

the Tuscahoma Formation of Mississippi (*T. magnoliana*, Beard 2008). Linked to the rapid warming of Paleocene–Eocene boundary events, *Teilhardina* spread from Asia to the two other continents – probably through Europe to North America (*T. belgica* and Earliest Eocene American *T. brandti*, Smith et al. 2006). Species of *Teilhardina* are very small, with dentally estimated body weights around 30 g, similar to the smallest living primates. They have a very primitive dentition, with four premolars, a tiny metaconid on P/4, lower molars with a large paraconid on M/1, reducing on M/2 and M/3, and upper molars without hypocone (Fig. 12). The cranium is the oldest known for primates. It shows a broad and rounded braincase and probably featured a somewhat shortened snout. Its orbits are smaller than in any other omomyid, probably reflecting diurnal habits. In contrast, most later omomyiforms are considered to have been nocturnal. These orbits are convergent (angle estimated at 51°) and the interorbital breadth is narrow (Ni et al. 2004). The infraorbital foramen is relatively large. In the case of *T. belgica*, postranials are known (Szalay 1976). A moderate elongation of its calcaneum suggests leaping abilities and a locomotor repertoire close to that of living cheirogaleids.

North American Anaptomorphinae

Among the North American Omomyidae two subfamilies are recognized, succeeding each other in abundance through time: species of Anaptomorphinae are the most abundant during the Early Eocene, whereas Omomyinae become dominant during the Middle Eocene. Several clades of anaptomorphines can be recognized in the Early Eocene (Bown and Rose 1987). Some of the Middle Eocene followers can be linked to these clades whereas others are more difficult to root in the earlier forms.

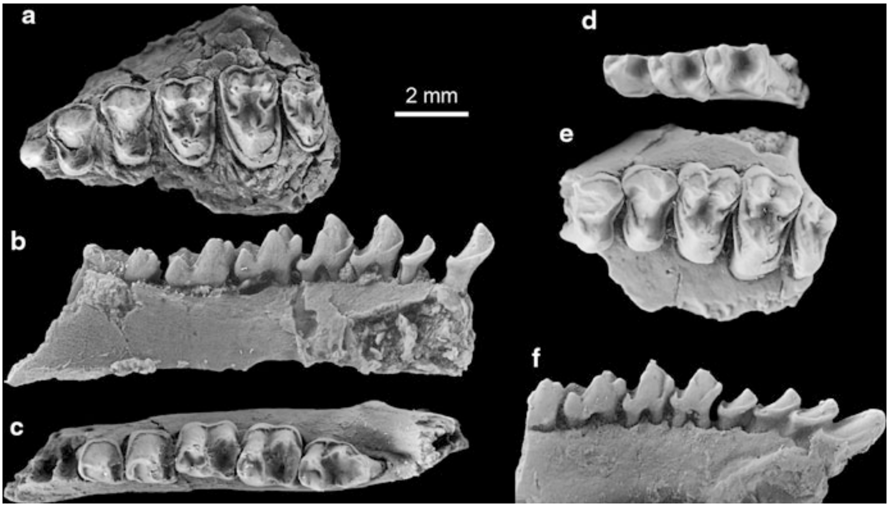

Fig. 13 Dentitions of primitive North American anaptomorphines, *Teilhardina* and *Anemorhysis*. Maxillae of *Teilhardina* intermediate between *T. americana* and *T. crasssidens* in occlusal view (**a**) and of *T. crassidens* (**e**); mandibles of *T. americana* in lingual view (**b**), *T. crassidens* in occlusal view (**c**), and intermediate between the two species in lingual view (**f**). Left mandible of *Anemorhysis sublettensis* in occlusal view (**d**). The anterior incisor is enlarged in the lineage (**f**), and the canine in the intermediate specimens (**f**) is more reduced than in *Teilhardina americana* (**b**: from right to left canine, small P/2, P/3, P/4, M/1-2-3). Photographs of white-coated epoxy casts, all at the same scale

The first clade, that of *Teilhardina-Anemorhysis*, starts from *T. americana*. In the exceptional fossil record of the Bighorn Basin, Wyoming, a series of assemblages links the species *T. americana* and *T. crassidens* through intermediate assemblages (Bown and Rose 1987). The whole lineage has an I/1 relatively enlarged in comparison with *T. belgica* or *T. brandti* (Fig. 13). This anagenetic lineage shows a slight diminution in size, broadening of the cheek teeth, lowering of P/3 and P/4 which become more molarized (P/4 with larger paraconid and metaconid, P/3 with small metaconid), a small mesostyle present on M1/, variable on M2/. A very rare smaller species *T. tenuicula* occurs later. In the Bighorn Basin, species of *Anemorhysis* show up later as punctuated occurrences, showing that the lineage was evolving elsewhere and species were entering from time to time in the Basin. The five species of *Anemorhysis* have a wide geographic distribution in the Early Eocene of Wyoming, Utah, and North Dakota, surviving in the earliest Middle Eocene of Wyoming. They differ from *Teilhardina* and *Tetonius* species by their more molarized P/4, lower molars with sharp cusps less basally inflated than in *Tetonius*, anteriorly broad talonid basin and straight postcristid (Fig. 13). P/4 has a well-developed metaconid, a prominent paraconid, and a well-developed talonid basin with hypoconid and small entoconid. *A. savagei*, from the Washakie and Wind River Basins (Lysite, Wa6), Wyoming, is considered a structural intermediate between *Teilhardina* and later *Anemorhysis* species (Williams and Covert 1994).

It is small, retains a P/2 and has relatively simple P/4. *A. wortmani* and *A. sublettensis* have P/4 with a large paraconid close to the metaconid, and the second is further derived by its long and broad talonid basin. *A. pattersoni* is larger and has a low and weak P/4 paraconid. *A. natronensis*, from the earliest Bridger, is distinct through narrow lower molars, a very large entoconid on P/4, and I/1 only slightly larger than I/2.

It is possible that this clade gave rise to *Arapahovius*. The difficulty of making systematic decisions involving morphologically close species, even ones represented by abundant dental material, is illustrated by *Tetonoides pearcei*. Since its creation by Gazin (1962) this species has many times been placed in *Anemorhysis*, then subsequently removed and placed again in a valid genus *Tetonoides*. Lately, Gunnell and Rose (2002) listed it as an *Anemorhysis* species. Cuozzo (2002) showed that Late Graybullian material assigned to *T. pearcei* differs only in very subtle details from Lysitean specimens referred to *A. savagei*, implying that both be placed in *Anemorhysis*. However, Tornow (2008) determined *T. pearcei* to be in the position of a separate genus related to *Arapahovius*, and listed a second species, *T. coverti*, that was named in a dissertation. The message is that these species are very close to each other. It is possible that artifacts of cladistics and nomenclature are blurring the incipient divergence of lineages.

Contrary to *Tetonoides, Arapahovius* differs by marked characters. Found in the upper part of the Wasatch Formation (Lysite equivalent), Wyoming, *A. gazini* is characterized by crenulated enamel on all molars and upper premolars (Savage and Waters 1978). The upper molars are transversely elongated, bear a well-formed protocone fold, conules with marked pre- and postcristae, and an incomplete lingual cingulum without hypocone. On the dentaries, alveoli show its I/1 to have been moderately enlarged, with I/2 and C being smaller. P/3 and P/4 are moderately molarized, and P/2 is reduced. M/2–3 have broad and anteroposteriorly short trigonids. Tarsals of *Arapahovius* include an astragalus which has an elongated neck, a tibial trochlea with lateral ridge higher than the medial one, a posterior trochlear shelf, and a very rounded head. Partial calcanea present a short anterior part and a distal elongation indicating leaping propensities. A navicular and a cuboid are both moderately elongated, contributing to foot elongation as in *Hemiacodon* (see below). A smaller and more primitive species, A. *advena*, has been found in the Bighorn Basin (Bown and Rose 1991).

A second clade that is well identified in the Early Eocene is represented by the *Tetonius-Pseudotetonius* group. At the beginning, it is still very close to some *Teilhardina*. It contains the remarkable series of assemblages linking *T. matthewi* to *P. ambiguus* through intermediate assemblages that have been difficult to name (Fig. 14). This series illustrates one of the most beautiful anagenetic lineages showing progressive morphological change through time, in the ideal context of regional stratigraphic superposition (Bown and Rose 1987). This lineage displays a progressive increase in size of I/1 and P/4, and reduction of the teeth which are between them. In *T. matthewi*, I/1 is large and P/3–4 have a normal size relative to M/1. At the end of the lineage, I/1 has become enormous, P/4 is strongly enlarged relative to M/1, one tooth has been lost, and the others are crowded and reduced,

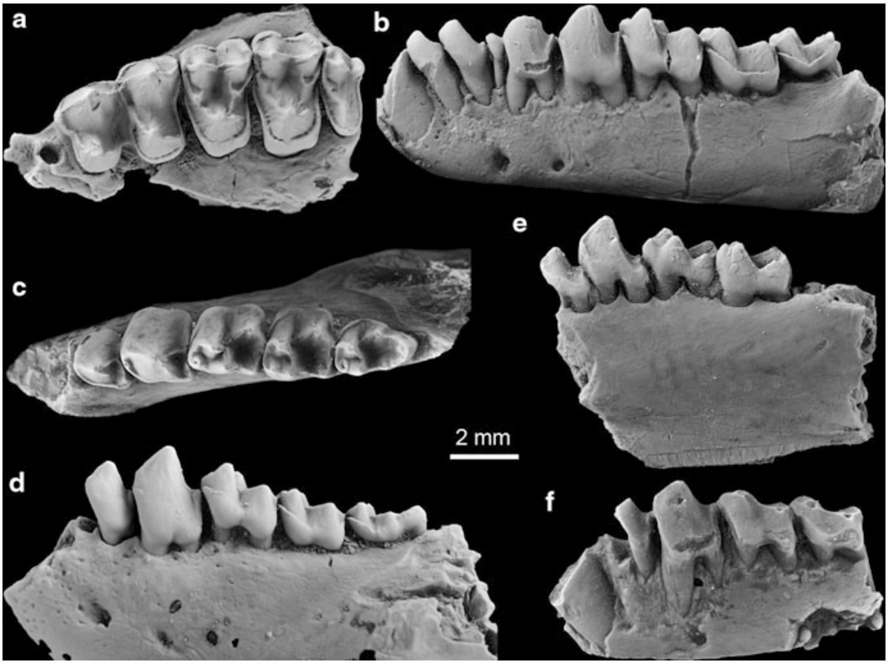

Fig. 14 The lineage *Tetonius-Pseudotetonius*. Maxilla (**a**) and mandible (**b**) of *Tetonius*; mandible of an intermediate, stage 3 of Bown and Rose (1987), in occlusal (**c**) and lingual (**d**) views (**d** inverted for comparison); two mandibles of *Pseudotetonius* in lingual (**e**) and labial (**f**) views. There is a marked difference between the mandible of *Tetonius*, with a large P/3 and three teeth between P/4 and the large incisor (**b**), and that of *Pseudotetonius*, with a very small P/3 and alveoli for two other small teeth between the large anterior incisor and P/4 (**f**). The intermediate stage (**c** and **d**) shows a moderately reduced P/3. Photographs of white-coated epoxy casts, all at the same scale

justifying a different generic name. Intermediate assemblages show some reduction of I/2 and C, the loss of P/2, and a progressive reduction of P/3, which becomes single-rooted and later very small. Changes occur not abruptly but through displacements in variations. The process of anterior incisor increase linked to a reduction of the teeth between it and P/4 or P/3 is a common evolutionary trend, usually explained by selection on anterior incisor function. The small *Tatmanius szalayi*, which has a high pointed P/4 without metaconid, is considered a likely descendant of *Pseudotetonius* (Bown and Rose 1991).

Tetonius is a well-known genus. The skull of *T. homunculus* is known since its description by Cope in 1884, and it has been restudied since (e.g., Szalay 1976). The cranium is broad and short in dorsal view. A large orbit is circumscribed by a complete postorbital bar. The cranium is incomplete and crushed. A remnant of bulla wall shows that the bulla was large. In its accessible details, such as the promontory canal included in a septum, Szalay (1976) found it very similar to *Necrolemur*. The dental formula was discussed by earlier authors. Szalay (1976)

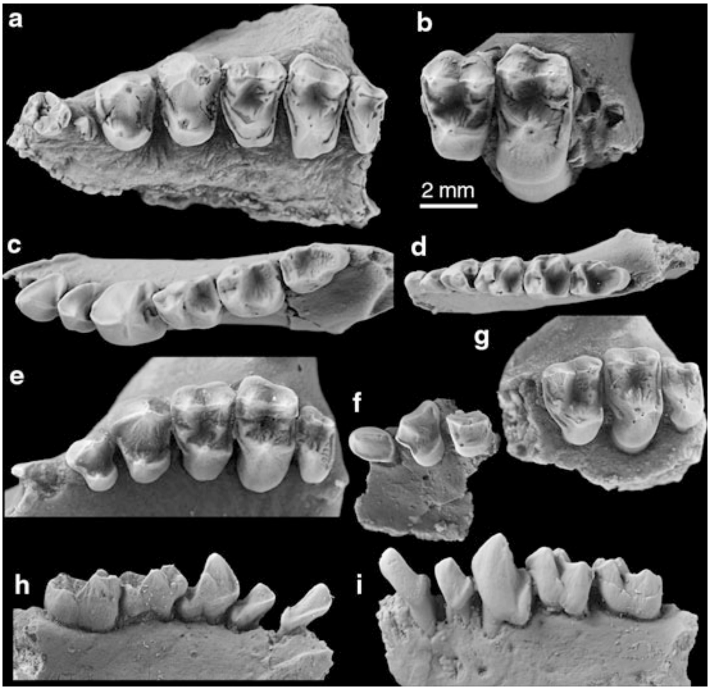

Fig. 15 *Absarokius*, other derived anaptomorphines, and *Trogolemur*. Maxilla of *Absarokius abbotti* (**a**) and mandible of *A. nocerai* (**c**). Maxilla of *Gazinius amplus* (**b**), mandible of *Trogolemur myodes* (**d**), and maxilla of *Strigorhysis bridgerensis* (**e**). Upper dentition (**f** and **g**) and mandible (**h** and **i**) of *Aycrossia lovei*. (**f**) shows P2/, P3/, and the lingual part of P4/. All are occlusal views, except for (**h**), which is lingual, and (**i**), which is labial. Photographs of white-coated epoxy casts, all at the same scale

identified isolated teeth and reconstructed *T. homunculus* as having enlarged anterior incisors, smaller roughly similar-sized I2 and canine, and very reduced P2 above and below. The P4 are slightly enlarged above and below, the lower one being higher than the molars and P/3. P/3 and P/4 are simple, P/4 being broad with reduced or absent metaconid and paraconid. M2/ is transversely elongated. M1/ and M2/ have a protocone fold, small conules, and a complete lingual cingulum (Fig. 14). The lower molars have a lingually placed paraconid that is large on M/1, smaller and closer to the metaconid on M/2–3. The M3s are reduced.

The third clade of anaptomorphines which is differentiated in the Early Eocene is that represented by species of *Absarokius*, its close derivatives *Strigorhysis* and *Artimonius*, and Middle Eocene genera considered to be descendants of this group, namely *Aycrossia* and *Gazinius* (Fig. 15), as well as possibly *Anaptomorphus*. The genus *Absarokius* is characterized by enlarged upper and lower P4, associated with incisors much smaller and M3 more reduced than in *Tetonius*. In the rich and detailed record of the Bighorn Basin, Bown and Rose (1987) distinguish two divergent specific lineages, *A. metoecus* and *A. abbotti*, both showing anagenetic change through time and giving rise to two different genera. The lineage of *A. metoecus* shows trends toward transverse narrowing and trigon basin broadening on M/1–2, some ridulation of upper molar enamel, and labiolingual narrowing of the M/1 trigonid. These characters are found in the Late Wastachian, briefly occurring *A. gazini*, which has narrow lower molars and somewhat enlarged incisors. The *A. metoecus* specific lineage is giving rise directly to species of *Strigorhysis*, which split in the Early Bridgerian into *S. bridgerensis* and *S. huerfanensis*. There are three species of *Strigorhysis*, which differ from those of *Absarokius* by rugose enamel on all molars and upper molars in which the protocone fold has increased and joined the posterior cingulum to realize one strong posterior crest (postprotocingulum). These species are well represented in the Aycross Formation, Wyoming, and also the Willwood Formation of Wyoming and the Huerfano Formation of Colorado. The second lineage of *Absarokius, A. abbotti*, shows a tendency toward size increase, as seen in M/1–2 size, and increased hypertrophy and exodaenodonty of P/4 (ventral expansion of enamel on its labial side). These trends continue in the latest Wasatchian and earliest Bridgerian in three species formerly included in *Absarokius* and now included in the genus *Artimonius* (Muldoon and Gunnell 2002). In addition to the increase in P/4 hypertrophy, these species show different degrees of lower premolar crowding. They all have lost P/2. P/3 becomes single-rooted in *Artimonius nocerai* and *A. australis*, and P/3 is very reduced in *A. australis* and *A. witteri*. Several limb bones of *Absarokius* have been described (Covert and Hamrick 1993). A distal humerus shows the trochlea to be well separated from the capitulum by a groove. A distal tibia exhibits a proximally long facet for the fibula, reflecting close appression between the two bones. The omomyid-like astragalus shows a well-grooved trochlea, and the calaneum has an elongated anterior part (54 % of total length). These characters indicate a small quadrupedal and leaping primate (weight estimated around 200 g).

Aycrossia and *Gazinius* include three rare species, known by fragmentary material (Fig. 15). The first species were discovered in the Aycross Formation of Wyoming, which samples basin margin, upland areas (Bown 1979). *A. lovei* has a tall P/4, small two-rooted P/3, M/1 with large paraconid, transversely elongated M1–2/, M3 not much reduced. *Gazinius amplus* is a large anaptomorphine which has a transversely very elongated M2/ lacking conules, postparacrista, and protocone fold, and with a lingual part so expanded that the protocone is almost centrally placed. *G. bowni*, found in the Green River Basin, is represented only by one M2/, which is smaller than that of *G. amplus* and has a well-formed postprotocrista and protocone fold (Gunnell 1995a).

Chlororhysis and *Anaptomorphus* are also genera known by fragmentary material and difficult to relate closely to the other, better documented anaptomorphine lineages. *C. knightensis*, known by four specimens (Early Eocene), is similar to *Teilhardina* in retaining unreduced canine and P/2, but it has more crowded anterior teeth and P/3–4 with more developed lingual cingulid. Gunnell and Rose (2002) note that it is similar to the omomyine *Loveina*. *C. incomptus* differs by small details. Two or three species of *Anaptomorphus* are known later, during the Middle Eocene, separated from potential ancestral forms by a long gap. They remain very small species, generalized, which have lost P/2 and have small M3. The lower molars are slightly bunodont, with bulbous cusps. M2/ is transversely elongated with expanded lingual slope. M1–2/ have well-developed metaconules and protocone fold. *A. westi* differs in being larger; sometimes a third species, *A. wortmani*, is also distinguished by its smaller size (or it is lumped into *A. aemulus*). These species remain poorly known.

The genus *Trogolemur* is so distinctive that it has often been placed in a special tribe, the Trogolemurini. However, the content of the tribe is in debate. *Trogolemur* represents the extreme in the trend toward I/1 size increase common in anaptomorphines. Its lower incisor is so large that its root is posteriorly extended below the molars. *T. myodes* is known through a number of specimens from the Bridgerian (Br2 and Br3) of the Bridger Formation, southern Green River Basin, Wyoming (Gunnell 1995a), and from Nevada (Emry 1990) (Fig. 15). Slightly older species, *T. amplior* and *T. fragilis*, have been described from the earliest Bridgerian (Br1) of the Wind River Basin; however, these are very fragmentary (Beard et al. 1992). The genus *Sphacorhysis* has been erected for a species which shows a morphology plesiomorph in comparison with *Trogolemur* but is advanced in its direction in comparison with other genera. Several phylogenetic analyses have rooted *Trogolemur* (+*Sphacorhysis*) near *Anemorhysis*, postulating a sister group relationship of this clade with *Tetonoides* and *Arapahovius*. However, the content of such an extended tribe of Trogolemurini is not consensual among specialists (e.g., *Arapahovius* + *Tetonoides* are rooted in *Teilhardina crassidens* according to Tornow 2008).

Omomyinae

The subfamily Omomyinae is a beautiful example of mosaic evolution during a phase of diversification. Starting with the Early Eocene generalized genus *Steinius*, a rapid diversification leads to a large number of genera in the Middle Eocene, well recorded in Wyoming and surrounding basins, which decreases again in the Late Eocene, during which members of this group find refuge in California and Texas. Dental specializations allow the recognition of a number of tribes or subtribes, but a precise resolution of their phylogenetic relationships is difficult to achieve due to the large number of convergences in their dental characters. Rose et al. (1994, p. 20) summarized the problem thus: “Particular derived characters that must have evolved independently in two or more lineages include enlargement of I/1 (usually associated with crowding of anterior teeth), loss of one or more lower premolars, hypertrophy of P/4, molarization of P/4 (involving more distinct metaconid and paraconid or development of a talonid basin), reduction or enlargement of third molars, crenulation of enamel, and presence of a mesostyle”. In spite of these difficulties, added to an incomplete documentation of their early phases of divergence, successive phylogenetic analyses have recovered certain relationships, some of which are becoming consensual and will be mentioned below (Szalay 1976; Honey 1990; Gunnell 1995a; Muldoon and Gunnell 2002; Tornow 2008).

The record is extremely irregular, including taxa represented by one specimen as well as taxa represented by hundreds of them, and covering long time spans and large geographic areas.

Steinius, Omomys, Diablomomys, and *Chumashius*

These taxa constitute a first group. *Steinius verspertinus* is found in the Early Eocene of Wyoming. It is very primitive in retaining four premolars, a canine relatively as large as in *Teilhardina*, tall P/3 and P/4, and an unreduced P/3. Its sole clearly derived feature is a moderately enlarged I/1. If its unreduced M/3 and the more peripheral cusps on its molars were considered primitive relative to *Teilhardina*, it would imply the existence of an unknown lineage in the Earliest Eocene (Rose et al. 1994). The two latter characters make it a good candidate as an ancestral omomyine. In fact, a second species *S. annectens* is closer to *Omomys* and confirms the proximity of the two genera (Bown and Rose 1991).

The genus *Omomys* was described by Leidy in 1869. The species *O. carteri* is very abundant in Middle Eocene beds of the western regions of North America, accounting for 64–90 % of all omomyid specimens through the Early and Middle Bridgerian (Muldoon and Gunnell 2002). Its dentition is remarkably generalized in comparison with all other omomyines (Fig. 16). It has a moderately enlarged I/1, a

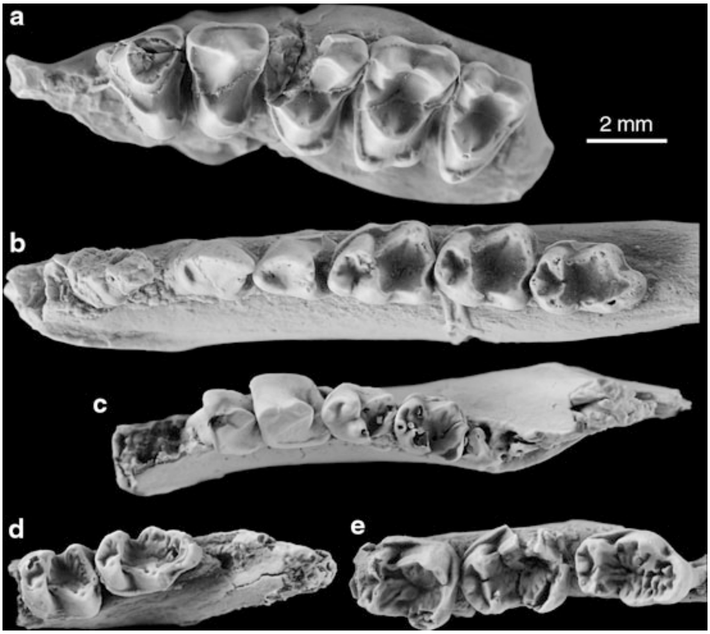

Fig. 16 Dentitions of omomyines, *Omomys, Uintanius*, and two utahiini, *Utahia* and *Stockia*. Maxilla (**a**) and mandible (**b**) of *Omomys carteri* showing a relatively primitive dentition. The right mandible of *Uintanius* shows a very enlarged P/4 (**c**). The molars of *Utahia kayi* (**d**) and *Stockia powayensis* (**e**) are derived through their short trigonid with a reduced paraconid and large crenulated talonid basins. Photographs of white-coated epoxy casts, all at the same scale

relatively small canine (smaller than I/1 and P/3), and a very small single-rooted P/2. P/3 and P/4 are relatively high and elongated; P/3 is simple and its short talonid is somewhat crowded below the anterior part of P/4. P/4 has a small metaconid. The three lower molars are simple with peripheral cusps and sharp crests. M/3 is unreduced. The paraconid is large and lingual on M/1, smaller and more labial on M/2 and M/3. P2/ is also very reduced. P3/ and P4/ have a large paracone, a parastyle, a lower protocone lobe with a preprotocrista, and a postprotocrista continuous with the complete posterior cingulum. The upper molars have a relatively broad (anteroposteriorly) trigon basin and no protocone fold. Both conules have their pre- and postcristae, and there are a hypoparacrista and a hypometacrista. The lingual cingulum is complete; a hypocone is present posteriorly, and a small pericone anteriorly on M2/. Detailed analysis of large assemblages of *O. carteri* from the Bridger Basin revealed aspects of intraspecific variability in dental traits (e.g., P/4 metaconid present in 91 % of individuals, M2/ pericones present in 80 %) and an increase in the frequency of several premolar features, suggesting anagenetic change through time (Cuozzo 2008). Three petrosals of *O. carteri* were analyzed in detail, revealing a series of characters of the otic capsule and middle ear cavity (Ross and Covert 2000). Most characters conform to an omomyiform model as documented in *Necrolemur* and *Shoshonius*, with minor differences between them. Postcranials of *O. carteri*, which are analyzed below, allowed an estimation of its body weight at 230 g (between 170 and 290 g; Anemone and Covert 2000).

A smaller species *O. lloydi* is documented in the early Middle Eocene. *Diablomomys dalquesti* is based on a maxilla from the Middle Eocene (Late Unintan) from Texas. Its M1/ is narrower lingually and has larger conules than in *Omomys*, and it has no lingual cingulum (Williams and Kirk 2008). *Chumashius balchi*, represented by a small number of specimens from California, is very close to *Omomys*. It differs from the latter only by its relatively larger canine, lower P/3 and P/4, and lack of distinct pericones and hypocones on the upper molars.

Uintanius and *Jemezius*

These form a small group of three species, sometimes considered close to *Omomys*, found to be a primitive sister group of the washakiins by Tornow (2008). *Uintanius* is characterized by enlarged P/3 and very enlarged P/4, which are exodaenodont: their enamel is ventrally extended below the alveolar margin on the labial side (Fig. 16). The upper premolars are also enlarged and have a reduced protocone lobe. The molars are relatively simple, the uppers having a small protocone fold. Alveoli of the anterior teeth preserved on a dentary of *U.* cf *rutherfurdi* show that *Uintanius* had two small subequal incisors, and a somewhat larger canine and P/2 (Gunnell 1995a). Szalay (1976) postulated that *Uintanius* specialized in food items which required great force to open but not much mastication. Gunnell found confirmation of this claim in a high proportion of dental specimens that showed heavy wear or had been broken and polished during life. *Jemezius szalayi*, found in the Early Eocene of New Mexico, has a lower and more complex P/4, relatively larger P3/ and P4/ protocones, and a relatively larger M/3 with a less compressed trigonid – characters which put it closer to *Steinius*.

Utahiini

A tribe Utahiini can be used to unite *Utahia, Stockia, Ourayia, Chipetaia, Asiomomys, Wyomomys*, and *Ageitodendron* (equivalent to the Ourayiini of Gunnell 1995a; Gunnell and Rose 2002). With the exception of *Ourayia*, known by two species (three specimens for each), all of these genera are monospecific and known essentially by (sometimes very limited) dental remains. They are all found in Middle Eocene beds, and *Utahia kayi* starts in the late Early Eocene of Wyoming. *Utahia, Stockia*, and *Chipetaia* have lower molars with large talonid basins, as well as compressed trigonids with reduced paraconids on M/2–3 (Fig. 16). The lower molars of *Chipetaia* are low and heavily crenulated (convergent with *Microchoerus*), reminiscent of frugivores with emphasis on seeds (Rasmussen 1996). *Asiomomys changbaicus*, from the Middle Eocene of northeastern China, known by one mandible bearing P/3 and M/2–3, is believed to be close enough to *Stockia* to testify to an utahiin dispersal from North America to China during the Middle Eocene (Beard and Wang 1991). The molars of *Asiomomys* are also partially convergent with those of the European *Nannopithex*, which does not imply close affinity but recalls how pervasive convergent characters can be. Gunnell (1995a) proposed a morphocline from *Wyomomys bridgeri*, which shows rounded simple talonids with robust labially bulging ectocingulid on M/2–3, without a talonid notch as found in *Utahia*, and with paraconid and metaconid isolated by a deep fissure; to *Ageitodendron matthewi*, which has a more reduced paraconid; to *Ourayia uintensis*, which has a more compressed trigonid without paraconid. More complete material from all these taxa is needed to more securely establish their relationships. Fragmentary hindlimb bones of *Ouraya* and *Chipetaia* are relatively similar to those of *Omomys* and *Hemiacodon*, which are detailed below (Dunn et al. 2006). Features such as the cylindrical shape of the femoral head in *Chipetaia* and details of the tibial plateau in *Ourayia* reflect a relatively large amount of leaping in these mid-sized primates. Body weight estimates are 500–700 g for *C. lamporea*, and 1,500–2,000 g for *O. uintensis* (Dunn et al. 2006).

Macrotarsiini

A tribe Macrotarsiini is used sensu Gunnell and Rose (2002) to unite *Macrotarsius, Hemiacodon*, and *Yaquius*, and to also include *Tarka, Tarkadectes*, and *Tarkops*, which have recently been shown to be closely related (Ni et al. 2010). *Hemiacodon* is a well-known genus described by Marsh, known by postcranials (Simpson 1940) and beautifully described by Szalay (1976, including a frontal). Gunnell mentioned 370 specimens of *H. gracilis*, from 50 different localities, in the collections of the University of Michigan. Yet its phylogenetic affinities have been debated (Fig. 17). It shares many dental characters with the washakiins, with which it was classified, with doubt, by

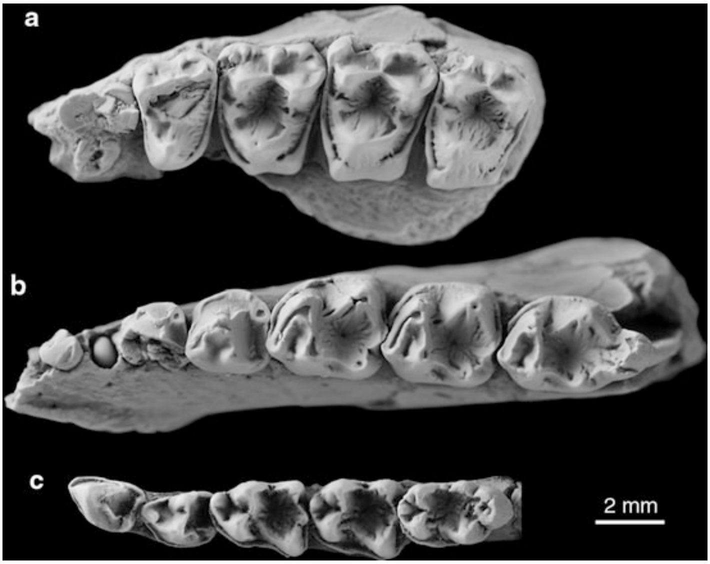

Fig. 17 *Macrotarsius* and *Hemiacodon*. Upper dentition of *Macrotarsius* showing the prominent molar mesostyle (**a**) and right mandible of *M. montanus* (**b**). Left mandible of *Hemiacodon gracilis* showing its P/4 with a well-formed trigonid (**c**). Photographs of white-coated epoxy casts, all at the same scale

Szalay (1976). It was taken out of the washakiins by Honey (1990), who emphasized that *Hemiacodon* has a greatly enlarged I/1 relative to I/2, more elongated and narrow (primitive) P/3–4, and a P/3 higher than P/4, whereas the known I/1–2 in washakiins are subequal in size and small, and their P/3 is slightly molarized, bearing incipient paraconid and metaconid. A different classification implies that *Hemiacodon* evolved enlarged conules, hypocones, and pericones in parallel with some washakiins. Honey hypothesized a sister group relationship with an extended concept of omomyini, including *Macrotarsius*, and Gunnell (1995a) restricted this close relationship to *Macrotarsius* only, a choice preserved by Gunnell and Rose (2002). *Hemiacodon* is found sister to a clade (*Macrotarsius* + Utahiins) by Tornow (2008). The upper molars of *H. gracilis* are more transversely elongated than in *Macrotarsius*; they have a protocone fold, large conules, rugose enamel, and a hypocone more distinct than in *Macrotarsius*. In the lower dentition, the P/4 is molarized, with a lingually arching paracristid and a well-formed and short talonid. The lower molars have peripheral cusps and high crests, and M/1–2 have a very wide talonid basin and distinct hypoconulids. The putative earlier species *H. casamissus*, represented by dentary fragments and worn molars, is considered doubtful. A new late Middle Eocene species, *H. engardae*, is larger and shows more acute crests on its lower molars and P/4, suggesting a probable increase in folivory (Murphey and Dunn 2009). *Hemiacodon gracilis* has long been the postcranially best-known omomyid. Its bones are analyzed below.

Five species of *Marcrotarsius* have been named. This genus has a wide geographic distribution, being found in Middle and Late Eocene beds of the western interior basins, Texas, California, Canada, and possibly also in China. The most primitive species, *M. jepseni*, is known by two dentaries and the palate of one individual. *M. montanus* has reduced lower premolars and especially small canines relative to its molars. Upper molars have an anteroposteriorly wide trigon, no hypocone or protocone fold, big mesostyles linked to the centrocrista, big parastyles, and a thick crenulated labial cingulum (Fig. 17). The lower molars are unusual in possessing a prominent crest posteriorly joining the metaconid to the entoconid. The species *M. macrorhysis* is based on two isolated teeth from the Middle Eocene Shanghuang fissure fillings of Jiangsu Province, China (Beard et al. 1994). These P/4 and M/1 are similar to those of *Macrotarsius* species; however, given the high number of dental convergences among omomyiforms, it would be important to have more complete evidence to confirm this generic attribution and its consequences for dispersals.

Three dentally specialized Middle Eocene genera are united in a subtribe or tribe Tarkadectini. Because they appear firmly rooted in species of *Macrotarsius* in the phylogenetic analysis of Ni et al. (2010), they are included here in the Marcrotarsiini. *Tarka stylifera* (Ui1) and *Tarkadectes montanensis* (Ui) were enigmatic species from the late Middle Eocene of Wyoming and Montana, often referred to the Plagiomenidae (Dermoptera) due to their broad lower molars bearing supplementary cuspules and upper molars with a wide stylar shelf and complex stylar cusps. The discovery of a more complete dentary in a Middle Eocene locality of Inner Mongolia, pertaining to a slightly less derived species named *Tarkops mckennai*, showed the anterior dentition to be typical of omomyids and unlike plagiomenids (Ni et al. 2010). At the same time, it illustrated another example of Middle Eocene dispersal between North America and Asia. The alveoli in front of the dentary of *T. mckennai* show that there was a large anteriorly inclined I/1, a small I/2, a larger vertical canine, a tiny P/2, and a two-rooted P/3. P/4 has a large metaconid, almost as high and anterior as the protoconid, and a smaller and lower paraconid. The lower molars are very bunodont; they have a shallow crenulated talonid basin, a long postmetacristid, and a peculiar cingular cusp at the labial base of the protoconid. *Tarka* and *Tarkadectes* have exaggerated the transversal breadth of their lower molars, which are endowed with supplementary cuspules.

Washakiini

This is one of the most interesting tribes of the omomyines. It includes 10 species, contained in the genera *Loveina, Basius, Shoshonius, Washakius* (4 species) and *Dyseolemur* (Fig. 18). They are known from the late Early and Middle Eocene, and *Dyseolemur* survives in the Late Eocene of California. They have transversely elongated upper molars with conules and a protocone fold. They tend to develop a moderately sized hypocone (*Washakius*) or a big mesostyle (*Shoshonius*). Their P/3–4 are moderate in size and slightly molarized. The P/4 paraconid and metaconid are well developed in *Washakius*. Their lower molars have a relatively transversely narrow trigonid. They develop a metastylid on the lower molars,

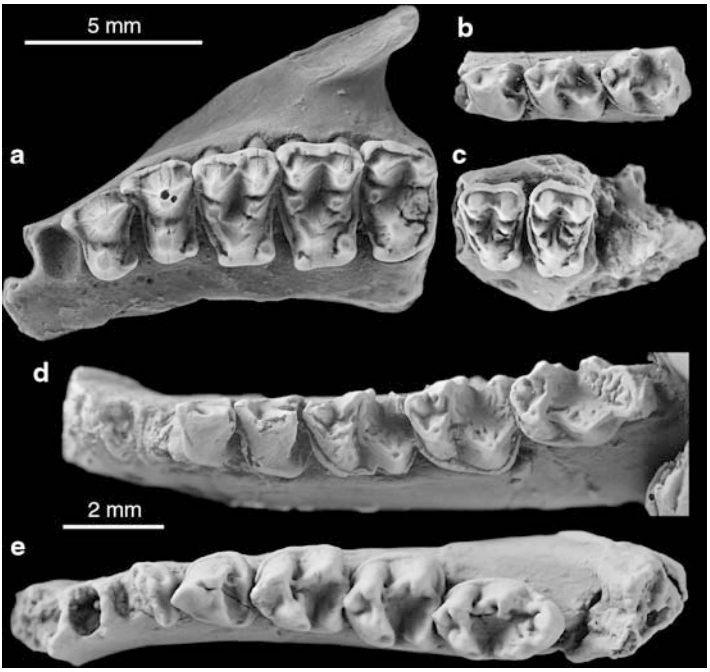

Fig. 18 Dentitions of Washakiini. Maxilla with upper teeth (**a**) and left mandible with P/4-M/2 (**b**) of *Washakius insignis* and fragmentary maxilla with M1-2/of *W. woodringi* (**c**), all at the same scale. Left mandible of *Shoshonius cooperi* (**d**) and right mandible of *Dyseolemur pacificus* (**e**), both at a similar scale, larger than for (**a**–**c**). Increase in cusp number is easily seen on the upper molars (**a** and **c**), and a metastylid behind the metaconid can be seen on the lower molars in (**d**) and (**e**). Photographs of white-coated epoxy casts

considered to be homologous between *Shoshonius, Washakius*, and *Dyseolemur*. They all have an elongated M/3. *Loveina* is the most primitive genus, starting with the rare and small *L. minuta* (Lisyte). Honey (1990) described two primitive species which extended the range of two separate lineages. *Shoshonius bowni*, more primitive than *S. cooperi*, was included in *Shoshonius* because it possesses enlarged mesostyles on its upper molars (convergent with *Ourayia* and *Macrotarsius*). *Washakius izetti* completed a morphocline *W. izetti – woodringi – insignis*, tracking a progressive enlargement of pericone and hypocone, as well as an increase in size of the metastylid. This morphocline in fact includes two lineages, and *W. woodringi* is clearly ancestral to *Dyseolemur*.

The washakiins have received renewed attention since the discovery of several partial crania and postcranials of *Shoshonius cooperi* in the late Early Eocene of the Wind River Basin, Wyoming (Beard et al. 1991; Beard and MacPhee 1994; Dagosto et al. 1999). The crania possess very large orbits, which not only indicate probable nocturnality but also raise the issue of a possible relationship with tarsiids. A detailed analysis of available cranial characters led to the conclusion that *Shoshonius*, *Tetonius, Necrolemur*, and *Tarsius* pertained to a monophyletic taxon, Tarsiiformes (Beard and MacPhee 1994). They share a series of derived characters: posteromedial and anterolateral bony flanges that overlap the bulla, narrow, peaked choanae, a narrow central stem of basicranium, reduced snout, parotic fissure, and suprameatal foramen. The authors add that, among the fossil tarsiiforms known by relatively complete cranial remains, *Shoshonius* appears to share the most recent common ancestry with *Tarsius*. They refrain from referring the washakiins to Tarsiidae because the phylogenetic relationships between washakiins and other omomyine tribes are not clearly resolved. In fact, several of the listed characters might be consequences of small size and large orbits as much as common heritage. Information from more omomyid genera is needed to further evaluate these characters. In the recent description of *Archicebus, Necrolemur* is said to have a non-reduced snout (Ni et al. 2013). Furthermore, *Necrolemur* has also been cited as possessing anatomical strepsirhinism. The monophyly of a broad tarsiiform clade comprising tarsiids, omomyids, and michrochoerids implies the convergent evolution of anatomical haplorhinism in tarsiiforms and simians, which would destroy the basis for the concept of Haplorhini (based on tarsiids + anthropoideans, see below). Such a far-reaching conclusion needs to be carefully evaluated. The postcranials of *Shoshonius* are analyzed below with those of other omomyines. When the postcranial characters were added to the cranial characters used in the phylogenetic analysis described above, tarsiiform monophyly was again recovered, but this time with *Necrolemur* as the sister group of *Tarsius* instead of *Shoshonius* (Dagosto et al. 1999). Adding the dental evidence would not clarify the issue, as *Tarsius* can hardly be rooted in the microchoerids, most of which have a very distinctive dental formula, and it is not any easier to root the dentition of *Tarsius* in the washakiin dentition (or the reverse). If there are phylogenetic relationships, they are not close. The phylogenetic relationships of *Tarsius* are further considered below.

The postcranial anatomy of the omomyines is progressively better documented, and its interpretation in terms of locomotor behavior has been correlatively enhanced. For a long time the limb bones of *Hemiacodon gracilis* were the best documents. Several bones were found together, including a partial pelvis, femoral and tibial extremities, and a partial right foot with astragalus, calcaneum, cuboid, navicular, entocuneiform, and first metatarsal (Simpson 1940; Szalay 1976). Their functional interpretation progressively improved (e.g., Dagosto 1985, 1993; Gebo 1988). Postcranials of two other omomyines were subsequently found and described at almost the same time: those of *Shoshonius cooperi* (Dagosto et al. 1999) and those of *Omomys carteri* (Anemone and Covert 2000). Because the bones in common between these taxa show an overall similarity, they are described and analyzed jointly here. The lower limb is the best documented, and it shows clear signs of leaping adaptation. A complete femur is known only for *Shoshonius*, in which it appears relatively short and robust. The proximal femur has an overall similarity in the three genera, bearing a semicylindrical articular surface on its head and a short neck forming an angle of more than 90° with the shaft. The articulation of the head is more cylindrical and the neck angle close to 90° in living specialized leapers. The morphology of the knee joint particularly well reflects its

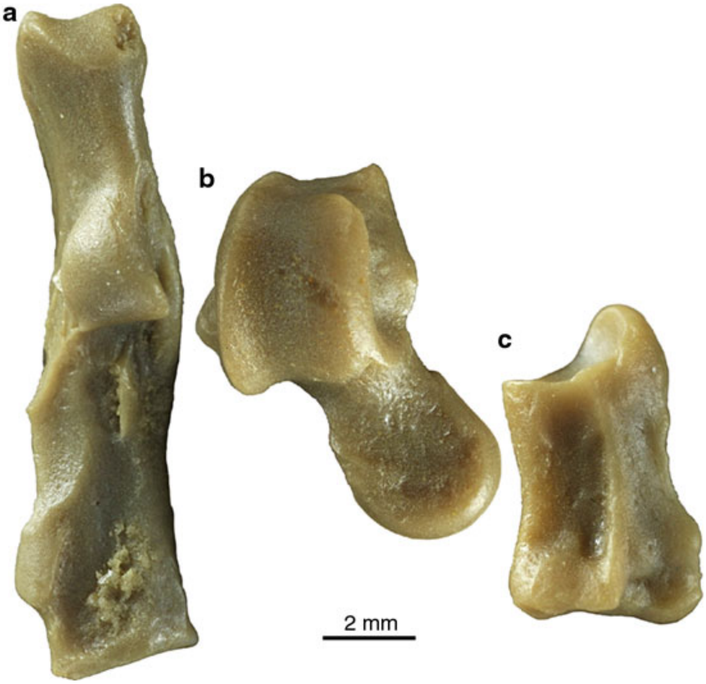

Fig. 19 Three foot bones of *Omomys carteri*. Calcaneum (**a**), astragalus (**b**), and navicular (**c**), all in dorsal view. The calcaneum shows the two articular facets on which the astragalus lies and a marked distal elongation (and small artifacts of casting). The astragalus shows the long and salient lateral rim of the tibial trochlea. The well-grooved trochlea and calcaneal and navicular elongation are interpreted as reflecting a moderate leaping adaptation

function. The three genera have a distal femur with an anteroposteriorly very high distum, a deep patellar groove bordered by a prominent lateral ridge. The femoral condylar index of 111 in *Omomys* and 119 in *Hemiacodon* (111.5 in *Shoshonius* for a close index) is similar to that of specialized leapers. *Omomys* has a retroflexed tibial plateau and a mediolaterally compressed proximal shaft. All of these characters are typical of specialized leapers, implying that powerful leaping was a component of the locomotor repertoire in these genera (Anemone and Covert 2000). The distal tibia shows an extensive distal articulation between tibia and fibula, which prevents rotation and is found in leaping primates. It seems that this articular surface is more extensive in *Shoshonius* (around 25–35 % of tibial length; Dagosto et al. 1999) than in *Omomys*. Concerning foot bones, the three genera have very similar calcanea (also quite similar to those of *Teilhardina*) (Fig. 19). They all show a moderate elongation of their anterior part (anterior length/total length is 51 % in *Shoshonius*, 51.4 % in *Omomys*, 52 % in *Hemiacodon*; also 53 % in *Washakius insignis*, Gebo 1988). Their astragali as well are similar to each other and to those of other omomyines: high and narrow trochlea, long neck, spherical head (not in *Hemiacodon*), no posterior trochlear shelf. The navicular is moderately elongated, as is the calcaneum, which is similarly the case for both in living cheirogaleids. However, in *Hemiacodon* and *Omomys* there are also a cuboid and an entocuneiform which are more elongated than in living primates. Elongation of the foot is another indication of leaping; however, the foot of these omomyines is not as extremely elongated as in the living specialized leapers. There is a screw-like articulation between astragalus and calcaneum, and a pivot joint between calcaneum and cuboid, allowing for some rotation of the foot. Both the entocuneiform and its sellar articular facet, and the first metatarsal with its enormous peroneal tubercle (long, tall, mediolaterally narrow), reflect a foot with powerful hallucial grasping. The pelvis, partially known in *Hemiacodon* and *Omomys*, reveals in the latter a shorter ilium and a longer ischium than in living prosimians. The ischium is also less dorsally expanded than in leaping prosimians. These proportions might be more primitive (they recall tree shrews) and/or indicative of a more generalized form of leaping than in living leapers, using horizontal and oblique supports more than vertical ones (Anemone and Covert 2000).

The forelimb is less well documented. A complete humerus is known only in *Shoshonius*. It has a relatively round head, strongly developed attachment areas for the shoulder muscles, and a prominent brachial flange. The trochlea is long and low. The elbow joint, like the shoulder joint, is that of a quadruped and leaper (Dagosto et al. 1999). The presence of a complete humerus and femur allows an estimation of the humero-femoral index at 64.6 for *Shoshonius* (and of an intermembral index probably between 64 and 68). Most of these anatomical characters suggest that these omomyines were similar in their locomotor repertoire to cheirogaleids or to the more frequently quadrupedal galagos (*Otolemur, Galagoides*). They probably used powerful leaping, although quadrupedalism and climbing were also important parts of their locomotor repertoire. There are certainly more small differences between them than the few mentioned above, and more precise interpretations in terms of frequencies of behavior or support use are difficult to obtain (Dagosto 1993). The deep slope on the fibular side of the astragalus and the moderate medial rotation of the tibial malleolus indicate that dorsiflexion of the foot was accompanied by only a slight degree of abduction of the foot, contrary to what is observed in strepsirhines (Dagosto 1985).

European Microchoeridae

The European Microchoeridae are numerous enough to deserve recognition as a family. They had long been suspected to be rooted in the Earliest Eocene *Teilhardina belgica*; this hypothesis received a recent confirmation through the discovery of two Early Eocene intermediate species, of the genus *Melaneremia*. *M. schrevei* is the older and more primitive (Hooker 2012). Compared to *T. belgica*, it shows a lowering of the protoconid of P/4, more accentuated on P/3, a broadening of P/4, especially of its posterior part, and a more developed paraconid and metaconid on that tooth, more developed cingulids on the lower molars, a marked broadening of the M/3 talonid basin and third lobe, and incipient modifications of the M/2–3 trigonid. The younger *M. bryanti* has a more reduced P/3 (Hooker 2007). These species provide a link with the genus *Nannopithex*, which is known through many species in the late Early and Middle Eocene. Two crushed crania and several almost complete lower jaws are known in species found in the Lutetian lignite mines of the Geiseltal, Germany. They show that these species had a very enlarged lower anterior incisor, followed by a reduced I/2, a canine, and two premolars. Compression of the teeth located between I/1 and P/4 led to the loss of P/2 and the reduction of P/3, which is single-rooted. The resulting dental formula, 2123 for lower teeth, will remain stable in later microchoerids. In the upper dentition, I1/ is enlarged, followed by a smaller I2/ and a larger canine; in some of these *Nannopithex* P2/ is lost, whereas it will still be present in later necrolemurines. The oldest species, the late Early Eocene *N. zuccolae*, shows a number of characters typical of *Nannopithex*: enlarged P/4 with ventrally expanded enamel on its labial side, very small metaconid and curved paracristid without paraconid; lower molars with trigonid becoming narrower on M/2–3, smaller paraconid slightly labial and joined to the metaconid summit by a crest; large M/3 talonid basin posteriorly extended in the broad third lobe, and some enamel wrinkling. On the upper teeth, P4/ appears transversely extensive (as much as M1/), with a protocone lobe slightly narrower than the labial part and a low protocone. The upper molars have small conules, with a postmetaconule-crista joining the metaconid summit, whereas a postparaconule-crista is only variably present; there is no lingual cingulum or hypocone, and a protocone fold is variably present. Among evolutionary tendencies observed in *Nannopithex* species are a progressive broadening of the protocone lobe of P3/, on upper molars an increase in the size of the conules and development of supplementary crests on the walls of the trigon basin, strengthening and isolation of the protocone fold ("*Nannopithex*-fold"), and development of a small cingular hypocone on the posterior cingulum; on M/2, the paraconid continues to shrink into a continuous paralophid. These characters are best expressed in *N. filholi* from Lissieu, an MP 14 locality (Godinot et al. 1992). Three other species, *N. raabi, N. humilidens*, and *N. barnesi*, are known in the Geiseltal sequence (Thalmann 1994). The genus *Nannopithex* is probably a paraphyletic stem genus, in which most later clades of microchoerids originate.

The genus *Vectipithex* has been erected for three species known almost exclusively by isolated teeth (Hooker and Harrison 2008). They show that species phenetically close to *Nannopithex* survived in northern European localities until the Late Eocene, at a time when *Pseudoloris* and microchoerines were abundant in more southern regions. The oldest one, *V. quaylei* from Creechbarrow (Bartonian, MP 16), retains very large anterior incisors, a transversely broad P4/, and a P3/ with a small protocone lobe. It is advanced over *Nannopithex* through its M/1 without paraconid and its upper molars having an almost complete lingual cingulum with crestiform hypocone. M2/ is lingually narrow, whereas M1/ is broader in its lingual part. The Late Eocene *V. smithorum* is larger and has a lingually narrower P4/ and somewhat transversely shorter upper molars with slightly larger hypocones. The Late Eocene *V. ulmensis* from Ehrenstein in Germany is known by a few isolated teeth, which are again larger and have more massive proportions. In their

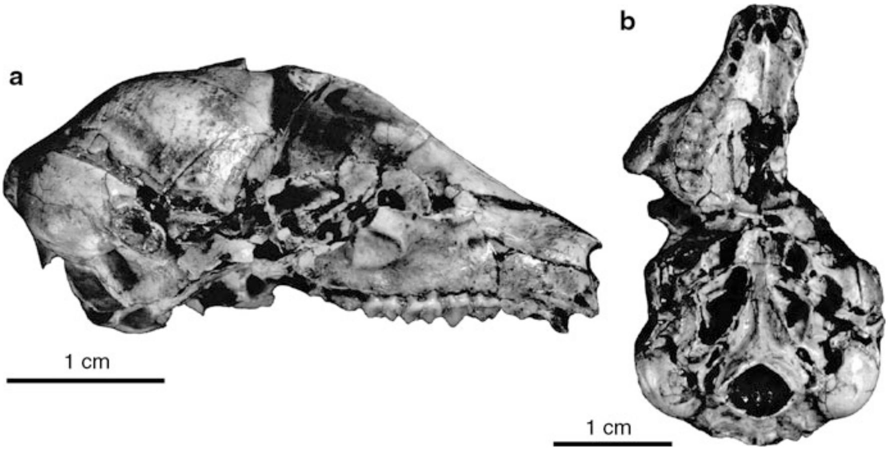

Fig. 20 One of the best-preserved crania of *Necrolemur antiquus* from the old Quercy collections (Montauban) in lateral (**a**) and ventral (**b**) views at two different scales. On the ventral side, the tympanic bullae have been prepared; their posterior extensions, or mastoid bullae, are preserved; anteriorly, alveoli show the presence of two well-separated and large anterior incisors. The lateral view shows that the muzzle of *Necrolemur* is anteriorly elongated

phylogenetic analysis, Hooker and Harrison (2008) find *Vectipithex* species to be rooted close to *N. raabi* and thus transfer the latter species into *Vectipithex*.

Species of *Necrolemur* and *Microchoerus* form a morphologically tight group, abundant in the late Middle and Late Eocene. The species *Necrolemur antiquus* has long been known by beautiful crania found in Quercy fissure fillings (Filhol 1874; Stehlin 1916). Its orbits are relatively large, an observation which was used to support tarsiiform affinities; however, these orbits are like those of living strepsirhines, and are interpreted as reflecting nocturnal habits. A posterior expansion of the auditory chambers is so large that it forms a "mastoid bulla" which is salient on each side on the back of the cranium (Fig. 20). The basicranium of *N. antiquus* was studied in detail by Szalay (1975). It has since served as one of the best-known references for omomyiform basicranial characters (see below on Haplorhini and tarsiid sister groups). *Necrolemur* differs from species of *Nannopithex* by more squared upper molars, especially M1/, linked to a larger cuspidate hypocone. It has crenulated molars and a duplicated metaconule. Lower molars have a trigonid which becomes shorter and transversely broader from M/1 to M/3. Contrary to *Nannopithex*, the M/3 is short with a reduced third lobe, and almost rectangular with trigonid and talonid of similar breadth. M/1 retains a large paraconid. A progressive increase in crenulation and upper molar lingual breadth can be observed from the primitive unnamed species of Egerkingen to intermediate forms from La Bouffie, to Late Eocene forms closer to the *N. antiquus* type specimen, which has stronger crenulation and a larger hypocone on M1/ and M2/ (Godinot 2003). Such a crenulated dentition has no analogue in living prosimians; it presumably suggests an adaptation to some kind of abrasive food. Postcranials of

Quercy *N. antiquus* include an elongated femur with high distal extremity, a fused distal tibia and fibula and an extremely elongated calcaneum, such as occur only in *Tarsius* among living primates, and an astragalus with a deeply grooved trochlea which was tightly maintained between the tibial and peroneal malleolae (Schlosser 1907; Godinot and Dagosto 1983). All of these characters typify an extreme leaping adaptation, unique until now in the Eocene fossil record, as is found in living forms which essentially move by long jumps between vertical supports (VCL). Vertical clinging is confirmed by the position of the foramen magnum below the cranium, visible in a larger *Necrolemur* skull.

Species of *Microchoerus* are essentially large *Necrolemur* with more crenulated enamel, which develop a mesostyle on their upper molars. Two species are known in the Bartonian locality of Creechbarrow, England (MP 16), *M. wardi* and *M. creechbarrowensis*. Hooker (1986) related these two species to the later occurring *M. erinaceus* (Hordle, MP 17a, England) and *M. edwardsi* from an unknown level in the Quercy region, which are also large, heavily crenulated, and display the most strongly molarized p/4 of all, with big and high metaconid and paraconid. However, the study of assemblages from Quercy in biochronological order revealed a continuous lineage, which increases in size and molar crenulation and develops a mesostyle. This lineage links a species of *Necrolemur* cf *antiquus* (stage of La Bouffie) to assemblages extremely close to *M. erinaceus* (Godinot 1985). These hypotheses will have to be restudied with quantitative approaches. There are convergences in the increasing molar crenulation of different lineages. This process culminates with the extraordinary *M. ornatus* described by Stehlin (1916), which has highly tuberculated upper teeth.

Species of *Pseudoloris* are small and developed pointed teeth, adapted to insectivory, which are convergent with those of *Tarsius*. However, the anterior dentition retains the stamp of the family, with moderately enlarged anterior incisors of typical morphology and single-rooted P/3 somewhat crowded under the P/4 (it probably lost the reduced I/2 of others). The muzzle of *Pseudoloris* shows proportionately large orbits, due to its small size, and this makes it even more similar to *Tarsius* (see discussion of tarsiid sister groups below). The best-known species is *P. parvulus* from the Quercy fissure fillings, which appears long-lived. Early assemblages from Le Bretou show lower molars with a relatively open trigonid, whereas later assemblages usually show them with a longer paracristid more or less closing the trigonid anteriorly. M/3 have a narrow third lobe. P/4 remains very simple, with only an incipient metaconid. Upper molars have a small paraconule and a well formed metaconule with well formed pre- and postmetaconule-cristae. There are small variations in the size of the hypocone, which in any case remains small. Larger species known by fragmentary remains are documented: *P. crusafonti* from Grisolles, France, and *P. reguanti* from Sant Cugat de Gavadons, Spain (Louis and Sudre 1975; Minwer-Barakat et al. 2013). New species of *Pseudoloris* have been described from Spain: *P. cuestai* and *P. pyrenaicus* (Minwer-Barakat et al. 2010, 2012). *P. cuestai* is typified by I/1 quite unlike those of other microchoerids, which calls for further analysis. One species, *P. godinoti*, has been demonstrated to have survived the Late Eocene climatic deterioration, being present in the lower Oligocene of Spain (Köhler and Moyà-Solà 1999). The oldest species sometimes referred to *Pseudoloris* deserve to be placed in a different genus, *Pivetonia*, with *P. isabenae* known in Spain and *P. saalae* known in the Geiseltal (Thalmann 1994). These very small species are phenetically closer to *Nannopithex* species, suggesting a rooting of the *Pseudoloris* group as well in the stem genus *Nannopithex*. *Pseudoloris* has been mentioned in the Late Eocene of Nei Mongol (Wang 2008), but the lower molar referred to *"P. erenensis"* is too different from the European genus. It belongs to another taxon.

The species *Paraloris bavaricus* has been found in Late Eocene marine sediments. Its lower jaw with four teeth shows a unique combination of characters: posteriorly narrowing P/4 without metaconid, smooth enamel on lower molars, M/1 with moderate-sized paraconid, relatively short paracristid on M/2–3 (Fahlbusch 1995). It is unlike all other genera, possibly due to branching very early (before *Melaneremia* for Hooker and Harrison 2008). It shows that undocumented lineages existed in unsampled regions of Europe, e.g., towards the east.

Possible Asiatic Omomyiforms

Other omomyiforms have been described in Asia. The existence of *Teilhardina asiatica*, described above with other species of *Teilhardina*, underlines the fact that a diversification of omomyiforms in Asia can be expected. However, several species are known only by very fragmentary remains. These were first compared with European and North American taxa, but they most probably document Asiatic groups. *Baataromomys* is known by one lower molar from the Early Eocene of Inner Mongolia, close to that of a *Teilhardina* (Ni et al. 2007). As mentioned above, "*Pseudoloris*" *erenensis* from younger Eocene strata of the same country is not a microchoerid (Wang 2008). Is it an omomyiform, or an eosimiid? *Vastanomys*, from the Early Eocene Vastan mine in India, has an omomyid-like M/2; but a referred upper molar, transversely elongated, is also reminiscent of eosimiids (Bajpai et al. 2005). More material is eagerly awaited. Among several species from the late Early Eocene of Pakistan, *Kohatius* is known by isolated M/1 and P/4, and *Indusius* by isolated M2/ and M/2 which are somewhat reminiscent of microchoerids (Russell and Gingerich 1987; Gunnell et al. 2008). These fragmentary fossils confirm that a vast proportion of Eocene Asiatic primates, particularly the omomyiforms, are still unknown.

The Early Eocene *Altanius* from Mongolia is better documented. It is an extremely small species, with the primitive dental formula of 2143 below and probably above (Fig. 21). Alveoli show a canine larger than the two small incisors below, and larger than the anterior premolars above and below. P/4 through M/3 are superficially omomyid-like, but their protoconids have extended labial slopes, especially on M/1, which recall plesiadapiforms. Its upper molars are transversely extended and bear well-formed para- and metaconules. Their crown is very high in labial view, and a strong protocone fold is added to the protocristae (i.e., not derived from the postprotocrista as in omomyids), contributing to its plesiadapiform stamp. Despite being described as a primitive

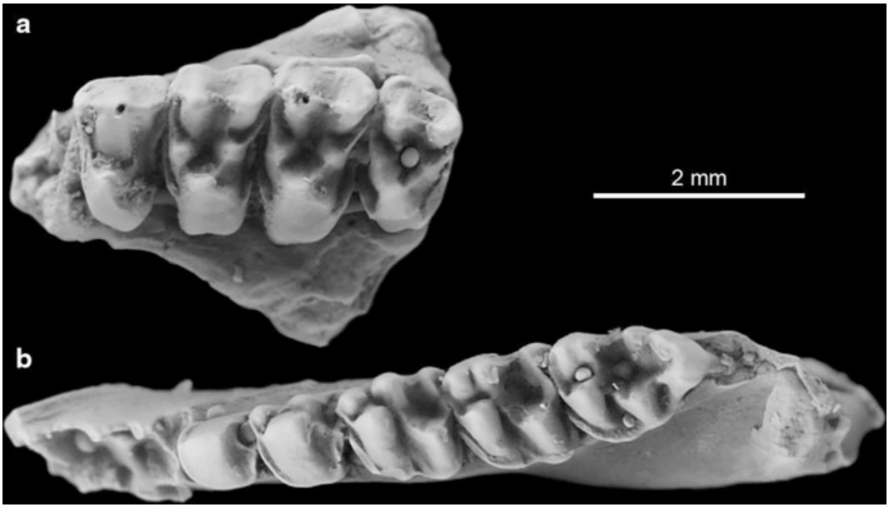

Fig. 21 *Altanius orlovi* from the Early Eocene of Mongolia, upper (**a**) and lower dentition (**b**): it is a very tiny species. Photographs of white-coated epoxy casts, both at the same scale

omomyid (Dashzeveg and McKenna 1977) and considered an anaptomorphine by Szalay and Delson (1979), its affinities are probably closer to plesiadapiforms than to the earliest primates (Rose and Krause 1984). If it were a primate, it would contribute critical information to the reconstruction of their primitive dental morphotype. A better understanding of its dental adaptation and affinities would be welcome.

Tarsiidae, Possible Tarsiiformes, and the Concept of Haplorhini

The Concept of Haplorhini

Among living primates, shared derived characters of soft anatomy, reproductive organs, and genetic markers unite tarsiids and simians in a monophyletic clade Haplorhini. The name comes from characters of the nose and face: tarsiers and simians have lost the moist rhinarium typical of strepsirhines and other mammals, and replaced it with dry and hairy skin. Anatomists have looked for osteological characters, which would allow the recognition of fossil haplorhines. The most attractive of them, the presence of a postorbital septum isolating the eye from the temporal cavity, has turned out to be problematic. The orbital wall of simians consists of the frontal, alisphenoid, and a large zygomatic, whereas that of tarsiers consists of the frontal, alisphenoid, a small zygomatic, and a large amount of maxillary bone. Because the constituents are not the same, some researchers have argued that the two septa must have evolved convergently (e.g., Simons and Russell 1960; Simons and Rasmussen 1989), whereas others have argued that sutures can move through time, and that a zygomatic-alisphenoid contact is so exceptional that it must be at least partly homologous (e.g., Cartmill 1980). Recent embryological work concerning the septum shows that of tarsiers to be formed by a processus different from that of simians: no frontal spur, and ossification of a membrane (Smith et al. 2013). This seems to support the convergence hypothesis, even though some paleontological confirmation would be welcome to eliminate any kind of common precursor morphology. In any case, detailed anatomical work has found other derived anatomical characters supporting a clade (*Tarsius* + simians) in the basicranium, a region which has provided characters linked to higher systematic categories. MacPhee and Cartmill (1986) provided six such characters from the otic region, which subsequently have been elaborated (Ross 1994; Ross and Covert 2000). Agreed upon are the presence of a septum isolating an anterior tympanic accessory cavity, the anteromedial location of the posterior carotid foramen, the perbullar carotid pathway (through the petrosal septum), the extrabullar ventral edge of the tympanic bone (no annular bridge), and a highly reduced or absent stapedial artery.

To the above list can be added characters more or less directly dependent of anatomical haplorhinism. The absence of an interincisor diastema, between the roots of the two I1/, is correlated with the loss of the rhinarium, which requires such a space for its philtrum (Beard 1988). Haplorhinism had been correlated with a smaller infraorbital foramen indicative of a reduction of the sensory organs of the muzzle, the vibrissae (Kay and Cartmill 1977). However, this has recently been refuted in favor of a different adaptive meaning, related to diet (Muchlinski 2010a). Haplorhinism is likely correlated with an abbreviated snout, and some reduction of the nasal cavity and olfactory organs. Linked to this is a reorientation of the nasolacrimal canal, which is anteriorly inclined in strepsirhines, and shorter and vertical in haplorhines. A detailed embryological study showed that the vertical canal and duct in tarsiers and simians is acquired by exactly similar embryological processes, giving a strong argument in favor of their homology, and of a monophyletic Haplorhini (Rossie and Smith 2007).

The whole process of the acquisition of anatomical haplorhinism may have been driven by an emphasis on vision in the lineage leading to haplorhines. Tarsiers and simians possess a fovea in their retina, which considerably increases visual acuity. They also lack the tapetum lucidum, a reflecting membrane behind the retina which enhances vision in low levels of light and is present in living nocturnal strepsirhines. This lack explains why tarsiers possess such enormous eyes, larger than those of other nocturnal prosimians. Some of the peculiar cranial characters of tarsiers are probably related to these enormous eyes, starting with their postorbital septum. The fovea in the eye was probably acquired to enhance vision in diurnal species. Hence the early haplorhines can be reconstructed as diurnal, possessing relatively small orbits (Cartmill 1980). *Tarsius* became secondarily nocturnal and in the process acquired its enormous eyes and other autapomorphies.

The preceding list of characters strongly supports a clade Haplorhini, based on the derived characters shared by tarsiers and anthropoids, even if some of them turn out to be difficult to use (e.g., the quantitative ones) or include partial homoplasy. However, these numerous characters were acquired sequentially, and fossil evidence will be needed to decipher in what order. Some characters used to define haplorhines in the past now appear problematic; for example, the apical passage of the olfactory nerves above an interorbital septum was thought to characterize a more inclusive group (omomyiforms + crown haplorhines) until it was found lacking in the simiiform *Aegyptopithecus* (Simons and Rasmussen 1989). Because known omomyids lack most of the above-listed characters, it is unwise to extend to them a definition of haplorhines, which would thereby lose its content. Alternatively, if the washakiins can be shown to share enough of these characters, they might be included in tarsiiforms and character-based haplorhines. An alternative view is supported by those who propose a sister group relationship between some omomyiforms and *Tarsius*. Such a view implies that anatomical haplorhinism was acquired convergently in tarsiids and anthropoideans – an unparsimonious assumption, which would require grounding in a convincing fossil record, or else refutation of the homologies listed above. This discussion will be picked up again in section "Proposed Sister Groups for Tarsiids" below.

Fossil Tarsiidae

The family Tarsiidae has long been absent from the Paleogene fossil record. However, the discovery of teeth extremely similar to those of the living tarsier led to the description of *Tarsius eocaenus* in the Middle Eocene fissure fillings from Shanghuang, China (Beard et al. 1994). These five isolated cheek teeth were completed by the description of a piece of maxilla with P3/, coming from a different fissure but also very similar to the living *Tarsius* (Rossie et al. 2006). Specifically, this small specimen shows two similarities with *Tarsius*: a relatively reduced infraorbital foramen and a short vertical nasolacrimal duct. As seen above, the former is not as diagnostic as formerly believed; the latter, however, really seems to turn the specimen into an "anatomical haplorhine" (Rossie et al. 2006), i.e., a haplorhine in the sense used here. By contrast, contemporary omomyiforms appear markedly different.

Tarsal bones found in the Shanghuang fissure fillings have also been ascribed to tarsiids (Gebo et al. 2001). The calcaneum is distally incomplete; but it appears elongated in its distal part, and also progressively narrower distally, which makes it more similar to tarsiers than other Shanghuang calcanea (see Fig. 35). An astragalus is similar to that of *Tarsius* in its wide body bearing a wedge-shaped trochlea, a short neck, and a low neck angle. Many of these characters suggest a marked leaping adaptation. However, the astragalus also has a small trochlear shelf, whereas *Tarsius* is lacking such a shelf. Some other differences with *Tarsius* led the authors to conclude that these tarsals belong to a genus other than *Tarsius* (Gebo et al. 2001). Possibly Shanghuang dental tarsiids shared the nocturnal adaptation of *Tarsius* and associated anatomical characters, but not yet the full vertical clinging and leaping (VCL) specialization of living tarsiers.

Another Middle Eocene genus found in the Heti Formation of the Yuanqu Basin (Shanxi Province, China) has been ascribed to the tarsiids. *Xanthorhysis tabrumi* is represented by a tiny lower jaw bearing P/3–M/3 and alveoli for a P/2 and a larger canine (Beard 1998). P/3 and P/4 have a pointed protoconid and a very simple and reduced talonid. P/4 has a small metaconid, a weak and almost complete labial cingulid, and a thicker anterolingual cingulid. The lower molars are primitive in possessing a trigonid with strong paraconid. The trigonid is similar in M/1–M/3, as is typical of *Tarsius*. The talonid basin is broader than the trigonid, and the entoconid is well formed. M/3 has a very short third lobe, much smaller than in *Tarsius*, similar to that of *Eosimias* but more pinched. The dentition shows a striking overall similarity to that of *Eosimias*, a genus studied below.

Proposed Sister Groups for Tarsiids

Comparisons of small Eocene fossil primates with *Tarsius* have been conducted for a long time. At the beginning of the twentieth century several authors held the view that omomyids were not distinct enough to be placed in a different family, and they were thus ascribed to Tarsiidae (e.g. Matthew in Matthew and Granger 1915). However, there were dissenting views as well. Central to these discussions were the crania of *Tetonius* and *Necrolemur*. For example, Stehlin (1916) gives a detailed explanation of why he does not follow Gregory in placing *Necrolemur* in Tarsiidae, and why he prefers to maintain a family of “Necrolemuridae” (=Microchoeridae); he argues that *Necrolemur* and *Microchoerus* are dentally too specialized and thus follow a divergent evolutionary line (also shown by the mastoid inflation) – a point made earlier by Schlosser (1907). A revived defense of the close affinity of *Necrolemur* and *Tarsius* was put forth by Simons (1961), who nevertheless used the family “Necrolemuridae.” As seen above, the matter has become more complex in recent decades, with more omomyid crania discovered, tarsiids identified by the Middle Eocene, Eosimiidae entering these discussions (see below), and renewed anatomical research. Clearly, however, the view that tarsiids could be part of a monophyletic Tarsiiformes that includes a number of omomyiforms (and particularly microchoerids) stands in sharp opposition with the concept of Haplorhini as endorsed here. As seen above, it would imply the convergent acquisition of haplorhinism in tarsiiforms and simians, a far-reaching conclusion.

The two groups which continue to be central to this debate are the microchoerids with *Necrolemur* and *Pseudoloris*, and the washakiins with *Shoshonius*. The large orbits of *Necrolemur* have been emphasized, but they appear to be as in nocturnal strepsirhines of similar size, not tarsier-like. The characters linked to an extreme leaping specialization, reaching the stage of tibio-fibular fusion, also produce a list of shared derived characters that can lead to *Necrolemur* being the sister group of *Tarsius* in some parsimony analyses (Dagosto et al. 1999). However, as discussed long ago by Stehlin (1916), leaping specializations are numerous in primates, so that convergence is easily possible. The most powerful arguments in favor of the *Necrolemur*-tarsier hypothesis were reassessed by Rosenberger (1985), who added the peaked shape of the choanae, the pterygoid fossa encroached by the bulla, and recalled the significance of the extensive laminar contact between pterygoid and bulla, the shape of the guttered temporo-mandibular joint, and some less striking characters. These shared derived characters have been given as evidence in favor of close *Necrolemur*-tarsier phylogenetic relationships. However, as seen above, *Necrolemur* has anatomical strepsirhinism, a relatively long snout, and orbits of "normal" nocturnal size. Also, as emphasized by earlier authors, *Tarsius* is very unlikely to be derived from a species having the typical microchoerid dental formula; it possesses an anterior accessory auditory chamber, whereas the microchoerids developed their posterior mastoid inflation, demonstrating that they belong to two divergent phylogenetic lineages.

Pseudoloris plays a role in the debate because it shows additional similarities with *Tarsius* in dental traits linked to insectivory. Its position as sister group of *Tarsius* sometimes reappears in parsimony analyses of very large data sets (e.g., Ni et al. 2013). However, inasmuch as a position of *Tarsius* nested within microchoerids is impossible, this result shows that parsimony analyses can be driven by overall phenetic similarity, to the detriment of real phylogenetic affinities. Taxon sampling to date has not been complete enough to allow resolution of the debate. *Necrolemur* and *Pseudoloris* appear well inserted in the European microchoerid radiation, which has an almost continuous history going back to *Teilhardina belgica*, and in which the distinctive dental formula was acquired very early. They are unlikely to be sister group of tarsiids, but raise good questions concerning the acquisition of the above-mentioned synapomorphies: were these inherited from *Teilhardina* on, or did they converge under similar adaptive pressures (especially on vision)?

Another candidate for the sister taxon of *Tarsius* is the North American omomyine *Shoshonius* (Beard et al. 1991). After careful reevaluation of many cranial characters, Beard and MacPhee (1994) find a number of similarities shared with *Necrolemur* (presence of a parotic fissure) and other characters more specifically shared with *Tarsius* (e.g., enlarged orbits, abbreviated snout, narrower annular bridge). Furthermore, Rossie et al. (2006) briefly mention that *Shoshonius* possessed a vertical nasolacrimal canal, like *Tarsius*. This might make *Shoshonius* a real tarsiiform and character-based haplorhine, or it might be an argument in favor of convergent acquisition of haplorhinism. Then again, *Shoshonius* does not show the beginning of a postorbital closure similar to that of *Tarsius*, its dentition is not especially similar to that of tarsiids, and its postcranial characters are much less specialized for leaping than in tarsiids: their phylogenetic relationship cannot be very close. Also, such a relationship would call for an analysis of the washakiin tribe, in which all specialists place *Shoshonius*: are the washakiins well nested within the omomyine radiation? The omomyines seem to represent a relatively well-documented North American diversification, rooted in *Steinius*; the *Tarsius*–*Shoshonius* relationship would thus imply a North American origin for the tarsiids, which would have to be descended from a washakiin dispersal into Asia. Other omomyin tribes, when known, appear not to have acquired hypertrophied orbits and other characters linking them so closely to *Tarsius*. Another possible scenario is that the washakiins represent immigrants from Asia, pertaining to a group closely related to tarsiids. These scenarios need to be further explored and tested.

To conclude, if *Tarsius* were shown to be the sister group of more primitive omomyiforms, and not of early anthropoideans, this would imply the convergent acquisition of haplorhinism in the two groups. Haplorhinism would become an adaptive grade, reached by two lineages and more or less approached by others, under the adaptive emphasis on vision in small species (snout and nose reduction). Until now, the evidence does not appear sufficient to adopt this gradistic view, to the detriment of the haplorhine clade.

Archicebidae

For the recently described *Archicebus achilles*, from the Earliest Eocene of China, a new family Archicebidae has been erected, placed by the authors in their extended concept of Tarsiiformes (Ni et al. 2013). Whereas the placement of this fossil in early tarsiiforms or early omomyiforms or something else is debatable, its description adds considerably to our knowledge of the earliest primate radiation. It is represented by a crushed skull, isolated elements of the forelimb, and the entire rear part consisting of lumbar vertebrae, pelvis, tail, and both posterior limbs. Its skull length is approximately 2.5 cm, its long tail more than 13 cm, and its body weight is estimated to be 20–30 g. The crushed skull shows orbits of a relatively small size, indicative of likely diurnal habits. The skull shape is described as close to that of *Teilhardina asiatica*. The snout is said to be very short, as in *Tarsius* and some omomyids. The dentition is close to that of the other primitive primates; however, it shows a derived single-rooted P/2, and P1 and P2 appear reduced in comparison with adapiforms. The skeletal elements show elongated hindlimbs, long tibiae and long metatarsals, and other characters linked to a moderate leaping adaptation. Remarkably, the calcaneum of *A. achilles* is broad in its distal half, and is described as anthropoidean-like. Several of its tarsal characters are admitted as primitive in primates. The importance of this fossil lies, among other aspects, in the documentation of a calcaneum strongly different from that of *Teilhardina*–more primitive and associated with a moderate leaping adaptation – which substantially adds to our knowledge of early primate locomotor adaptations.

Eosimiidae

The Asiatic family Eosimiidae has provided crucial information and challenge concerning the early primate radiation (Beard et al. 1994, 1996). This family now includes three genera from the Middle Eocene of China and Thailand – *Eosimias* (three species), *Phenacopithecus* (two species), and *Bahinia* – and possibly a fourth one from the lower Oligocene of Pakistan – *Phileosimias*. The upper molars of *Eosimias* and *Phenacopithecus* are extremely primitive, transversely elongated with a marked waisting lingual to the labial cusps (Fig. 22); this waisting, very

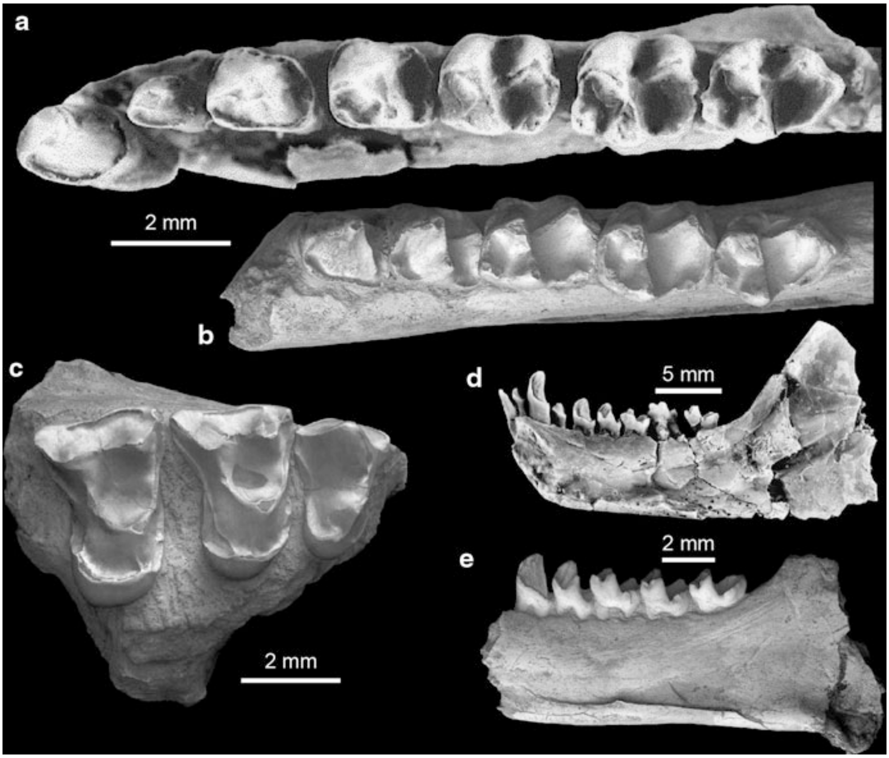

Fig. 22 Dentition of Eosimiidae. Mandibles of *Eosimias centennicus* in occlusal (**a** and **b**) and lingual (**d** and **e**) views. Maxilla of *Phenacopithecus krishtalkai* in occlusal view (**c**). Upper and lower molars are remarkably primitive, the two mandibles illustrate an interesting intraspecific dental variability, and premolars in (**e**) are reminiscent of *Xanthorhysis* (Courtesy of K. C. Beard)

marked on the posterior border of M1/, is also present on M2/, and is slightly marked on the anterior border of both teeth, which is exceptional (Beard and Wang 2004). On the labial side, there is a well-formed parastyle, as well as some labial extension of the crown labially to M2/, showing the remnant of a stylar shelf. These proportions give to these upper molars an extraordinarily primitive stamp. The complete lingual cingulum is derived in comparison with *Teilhardina* and *Donrussellia*; however, the absence of a hypocone by Middle Eocene time is very archaic in comparison with most other fossil primates. The upper P3/and P4/have narrow protocone lobes, presumably also primitive. The lower dentition as well shows many primitive characters. It is best documented on the two lower jaws of *Eosimias centennicus*, which show the complete lower dentition and aspects of the posterior part of the mandible (Beard et al. 1996). The incisors are small; I/2 shows one pointed cusp and I/1 was probably similar. Both incisors have a complete lingual cingulid. The canine is large, robust, and recurved anteriorly. A cingulid starts at the apex, descends posteriorly, and terminates as a posterior basal cingulid. There is a small, single-rooted P/2 bearing a single cusp and a posterior and lingual cingulid. P/3 and P/4, quite similar to each other, are massive, broad, and long premolars. P/3 is simple. Its massive protoconid has a curved preprotocristid in profile view and is surrounded by an almost complete cingulid. In occlusal view, its base shows an anterolabial bulge, associated with a labially shifted anterior root. P/4 is similarly massive and is more molarized, bearing a metaconid, a paraconid linked to the latter, and a more extended talonid. P/3 and P/4 have an almost complete labial cingulid, and on the labial side the enamel is ventrally extensive below the cingulid (exodaenodonty, easy to see on the anterior view of the isolated P/4 of *Phenacopithecus xueshii*; Beard and Wang 2004, Fig 16). Intraspecific variations in dental detail are described by Beard and Wang (2004). One of their specimens illustrates very well a degree of premolar crowding, by which P/3 is canted anterodorsally and its base is crowded below the anterior part of P/4, exactly as in the tarsiid *Xanthorhysis*. The main cusps of P/3 and P/4 are aligned with molar cusps as usual, but the bases of these cusps are anterolabially expanded, linked to a labial shift of their anterior root (Fig. 22). The three lower molars of *Eosimias* display a combination of high cusps recalling insectivorous species and rounded summits giving them a slight bunodont touch. They have a broad and elongated trigonid, bearing a big paraconid well separated from the metaconid. In occlusal view the trigonid is almost exactly the same from M/1 to M/3, a situation typical of tarsiids and exceptional in other Eocene prosimians. On the type specimen the notch on the protocristid is deeper (a deep V) on M/3 than on M/2. There is some waisting on the labial side of M/2 (ectoflexus) between the trigonid and the talonid. The talonid basin is deep, transversely broad, and anteroposteriorly short. A hypoconulid is posteriorly salient on M/2, being slightly closer to the hypoconid than to the entoconid. M/3 is noteworthy for the small size of its talonid, which is narrower than the trigonid, and for the small size of its third lobe, which is reduced to a very moderate hypoconulid (slightly less salient than in *Xanthorhysis*). The dentaries of *Eosimias* are relatively high and robust, with a vertical and anteroposteriorly short symphyseal region. The posterior part of the dentary of *E. centennicus* shows a rounded angular region and a small coronoid process.

Some important facial characters of eosimiids were revealed by a species of *Phenacopithecus*, another genus found in the Middle Eocene beds of the Heti Formation of Shanxi (Beard and Wang 2004). These species are close to *Eosimias*: they are larger and differ by some details of P/4 and other teeth. A maxilla of *P. krishtalkai* shows that this bone is high between the orbital margin and the alveolar rim. The orbits seem to have been small, suggesting diurnal activity. The infraorbital foramen is also relatively small; however, this is no more proof of haplorhinism.

Another eosimiid has been found in the late Middle Eocene Pondaung Formation of Myanmar, *Bahinia pondaungensis* (Jaeger et al. 1999). Two associated maxillae and a partial mandible revealed many dental characters of this species, which is larger than *Eosimias* and *Phenacopithecus*. The upper canine is especially large, with a rounded outline, and roots show that the upper incisors were vertically implanted, I1/being slightly larger than I2/. This morphology is said to resemble *Tarsius* more than the omomyids (Jaeger et al. 1999). The upper premolars have a

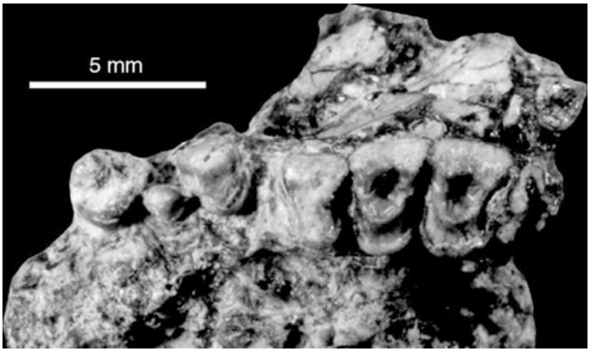

Fig. 23 Left part of the palate of *Bahinia pondaungensis* showing the broken canine, very small P2/, P3/, damaged P4/, M1/, and M2 (Courtesy of R. L. Ciochon)

lingual lobe but no differentiated protocone. The upper molars show well-developed protocristae, one joining the metacone, the crista obliqua, and another quite rare in primates joining almost directly the paracone (Fig. 23). These upper molars also have a thick labial and a continuous, strong lingual cingulum, with M2/ showing a slight thickening of the cingulum that represents an incipient hypocone. The P/2 is larger than in *Eosimias*. P/3 and P/4 are large, having roughly the same size. P/4 has no metaconid or paraconid, in contrast to *Eosimias*. The right maxilla allows the delineation of an orbit of small size, a relatively high distance between the ventral orbital rim (with exposed maxilla) and the alveolar margin, and a small zygomaticofacial foramen (Kay et al. 2004b).

Another eosimiid genus has been described from Early Oligocene beds of Pakistan (Marivaux et al. 2005). *Phileosimias kamali* is represented by eight isolated teeth (and the very close, possibly conspecific, *P. brahuiorum* by two upper molars). The upper molars differ from other eosimiids by well-formed conules, lingually rounded paracone and metacone (no crista obliqua), and a cuspidate hypocone on the M2/ of *P. brahuiorum*. The lower molars seem to have a more bunodont appearance and a somewhat reduced paraconid, slightly shifted lingually in comparison with *Eosimias*. The M/3 has a larger talonid with a broader third lobe than in *Eosimias*. The P/4 has a small crestiform metaconid and is narrow in its posterior part. P/3 and P/4 are slightly exodaenodont. If the affinities with more typical eosimiids are confirmed, this later taxon would illustrate a trend opposite to that seen in *Bahinia*: it increased bunodonty and the development of conules, whereas *Bahinia* increased its crests. Its smaller P/3 and P/4 also appear to represent a trend opposite to what is observed in *Eosimias*. The mention of an Early Eocene eosimiid *"Anthrasimias gujaratensis,"* in the Vastan Mine, India, is a misidentification (Bajpai et al. 2008; Rose et al. 2009).

Among the tarsals found in the Shanghuang fissure fills, one group is attributed to the eosimiids (Gebo et al. 2000, 2001). These tarsals present calcanea with whole proportions intermediate between those of the omomyids and tarsiids, which are narrower, and those of the anthropoideans, which are broader (see Fig. 35). They present a moderately elongated distal part (45–62 %), a long heel (28–36 %) and a relatively long and narrow posterior calcaneal facet. These characters suggest a mixture of quadrupedalism and leaping. Distally, these calcanea present a cuboid facet that is relatively flat, with a wedge removed from the medioplantar region. The astragali ascribed to eosimiids are moderately high, and also have a moderate neck angle. They possess a posterior trochlear shelf. Astragalar characters concur with those of the calcanea to suggest quadrupedalism, and more leaping than in platyrrhines (Gebo et al. 2001).

The phylogenetic affinities of Eosimiidae have been debated since their discovery. Many authors have followed Beard and collaborators, who defended close affinity with anthropoideans (an anthropoidean status with a stem-based definition of that group, or a stem anthropoidean or protoanthropoidean status based on our conventions), e.g., Kay et al. (1997), Marivaux et al. (2005), Williams et al. (2010). However, others have disagreed (Godinot 1994; Gunnell and Miller 2001; Simons 2003). The noteworthy aspects of the eosimiid dentition that need to be evaluated foremost are some of its extraordinarily primitive characters. Most authors agree that the transversely elongated upper molars, with the remnant of a stylar shelf labial to the metacone, marked waisting in the median part, and complete absence of a hypocone, are primitive characters – with the first two of these being more primitive than in *Teilhardina*, and thereby modifying the concept of the primitive primate dental morphotype. Such is also the case for the very large paraconid of the lower molars, especially on M/3. These observations raise further questions: Could the short M/3 talonid also be primitive in primates? Could the lower metaconid relative to the protoconid also be primitive by comparison with a primitive out-group, contrary to Gunnell and Miller (2001), who consider an equal height of these cusps likely to be primitive? These and other important questions will have to be scrutinized in the future. In any case, eosimiid dental features are leading researchers to modify the primitive primate dental morphotype, which plays a critical role in primate phylogenetic analyses.

Other characters that have been considered shared-derived with anthropoideans include P/3 and P/4 that are slightly exodaenodont and show an anterior root more labial than the posterior one. These features are shared with several early African simians; an oblique though not exodaenodont P/4 is considered part of the African simian morphotype by Gunnell and Miller (2001). Furthermore, these characters appear on P/3 and P/4 of very large size relative to the molars, larger than in any early African simian. Whereas the latter have a broad and short P/4 and a relatively large P/2, *Eosimias* has long, anterobasally inflated P/3–4 reflecting a peculiar adaptation emphasizing these big premolars, associated with a reduction of its P/2. This suggests the possibility of a partial functional convergence leading to labial reinforcement and some exodaenodonty of P/3–4 (probably also to a high and robust dentary). The vertically implanted lower incisors and the short vertical symphyseal region are shared with anthropoideans, but they can also be expected in haplorhines having acquired an abbreviated snout. As these incisors are very small and pointed, whereas those of anthropoideans are spatulate and usually larger, there is little evidence of characters exclusively shared with anthropoideans; these observations more probably indicate a haplorhine grade. It is difficult to find convincing phylogenetic signals in the very primitive molars of *Eosimias*. There is some convergence between more crested genera, as e.g., in the eosimiid *Bahinia* and the anthropoidean *Catopithecus*, which acquired a complete crista obliqua and an almost continuous crest linking protocone and paracone. However, known lower teeth of *Bahinia* are very different from those of oligopithecids, making a close link between them unlikely. The bunodont trend in eosimiids possibly led to the Oligocene *Phileosimias*, which is far from any known African simian. In the absence of indisputably derived characters homologous with those of African simians, are there other possible phylogenetic links? A sister group relationship with Amphipithecidae was advocated by Jaeger et al. (1999), and thus is examined below with that group.

A probable close affinity between *Eosimias* and the tarsiid *Xanthorhysis* has been mentioned above. The lower molars are higher and more pointed in *Xanthorhysis*. The P/3 and P/4 share a similar global pattern, including even the peculiar crowding between P/3 and P/4 described above. *Eosimias* appears as a more bunodont version of *Xanthorhysis*, having increased the size of its P/3 and the anterobasal robustness of its P/3–4. Found in omomyids, such differences would not prevent the placement of two genera in the same subfamily, because the overall pattern is so similar. This is significant and should not be ignored. The resemblance is not a proof of direct tarsiid affinities, however, because *Xanthorhysis* might turn out to be the most primitive eosimiid. Not enough is known about *Tarsius eocaenus* and its possible close relatives to decide on this. However, the similarity clearly does point towards close affinities between the two families. In this context, the recently introduced concept of Eosimiiformes appears problematic (Chaimanee et al. 2012).

Certain facial characters mentioned above show that the eosimiids were probably diurnal. Being diurnal is sometimes considered a challenge for possible tarsiiform affinities (Beard and Wang 2004); however, as seen above, early haplorhines are in fact expected to be diurnal (Cartmill 1980; Ross 1996). Thus Tarsiiformes other than tarsiids or tarsiines are expected to be diurnal, as eosimiids are. The simplest scenario, backed up by the strong dental similarities between *Tarsius, Xanthorhysis*, and *Eosimias*, is that eosimiids are tarsiiforms, and are character-based haplorhines. An isolated petrosal from the Shanghuang fissure fillings, attributed to an eosimiid, may add to our knowledge of eosimiid cranial anatomy (MacPhee et al. 1995). This petrosal exhibits a large canal reflecting a fully functional stapedial artery. Large and subequal stapedial and promontorial canals are also found in *Shoshonius* and *Omomys*; they contrast with another omomyid (*Necrolemur*) and *Rooneyia*, in which the stapedial canal is consistently smaller, and even more with the anthropoideans and *Tarsius*, in which it is further reduced or lost (probably convergently). The authors conclude that for this character, eosimiids probably retained a primitive state. They also conclude that eosimiids preceded the reorganization of the anthropoidean ear region (MacPhee et al. 1995), which agrees with a tarsiiform or an omomyiform view. The postcranial evidence for eosimiids has also been used to argue in favor of anthropoidean affinities. However, there are a number of caveats to be noted. Thus, a wedge in the plantar region of the cuboid facet developed in several primate groups. Astragali of eosimiids have a posterior trochlear shelf, which is absent in anthropoideans.

They share with anthropoideans a reduced medial tibial facet, but this character is likely primitive in primates. In other respects they are, in the words of Gebo et al. (2001, p. 96) “unlike anthropoids and resemble omomyids.” Postcranial characters are further discussed below in the anthropoidean origins part. The extreme leaping specialization of the living *Tarsius* leads one to suspect that primitive tarsiids were less specialized, as seen in the Shanghuang tarsiids; *a fortiori*, other early tarsiiforms are expected to be differently adapted, more quadrupedal. In conclusion, eosimiids probably fit in among early tarsiiforms (unless the petrosal, if well attributed, indicates omomyiforms).

North American and Asiatic Enigmas: Rooneyiidae, *Ekgmowechashala*, and Amphipithecidae

Rooneyiidae

The two North American genera *Rooneyia* and *Ekgmowechashala* occurred relatively late, in the Latest Eocene and in the Oligo-Miocene, respectively. They were both included in the systematic revision of the Omomyidae by Szalay (1976) and continue to be considered a possible tribe of omomyines, in the case of *Rooneyia*, and a problematic omomyid, in the case of *Ekgmowechashala* (Gunnell and Rose 2002). However, their status is questioned in several recent analyses. *Rooneyia viejaensis* is known by its type cranium from the Late Eocene of Texas, which is well preserved (Wilson 1966). Its upper dentition is bunodont and anteriorly abbreviated. The upper molars bear large conules (and P4/ a large paraconule) and a hypocone almost as large as the protocone on M1/. There are only two upper premolars and a very small canine. The bunodont molars bear similarities with those of anthropoideans, whereas the two premolars resemble only those of catarrhines. However, the small canine together with other cranial characters exclude a close affinity with the latter. Nevertheless the cranium of *Rooneyia* shows a number of characters which make this genus unique among primates. It shares with omomyids the presence of a tubular ectotympanic. Differences with omomyids include the lack of any inflation of the petromastoid region and relatively small orbits which suggest diurnal habits, contrary to other omomyids (with the exception of *Teilhardina*). Characters unique to *Rooneyia* concern its orbits. The large frontal with fused metopic suture extends above the orbit as a partial roof; the lateral frontal process is high and constitutes an incipient postorbital closure; the orbital fossa is funnel-shaped and pushed slightly below the forebrain (Rosenberger 2006). In addition, the orbits of *Rooneyia* show high degrees of convergence and frontation which position this taxon closer to living anthropoideans than to living prosimians (Ross 1995). These characters led Rosenberger (2006) to propose for *Rooneyia* a formal status of Protoanthropoidea. The unique combination of characters found in *Rooneyia* resulted in various placements. The large cladistic analysis of Kay et al. (2004b) led to a preferred tree in which *Rooneyia* appears nested within the adapiform radiation, as a primitive sister group of a clade (amphipithecids +

Fig. 24 Lower dentition of *Ekgmowechashala philotau*. Supplementary cusps are present on P/4 and molars, and the very low relief can be seen on M/3, which is less worn than the other teeth. Photograph of a white-coated epoxy cast

adapids). However, in the phylogenetic analysis of Ni et al. (2010), *Rooneyia* appears nested within the washakiins, which seems hard to reconcile with the cranial characters of *Shoshonius*. In view of these contradictory results, it seems important to acknowledge the uniqueness of *Rooneyia* by using a family Rooneyiidae, and to keep in mind its important protoanthropoidean-like orbital characters. Because it is known that faunal exchanges between North America and Asia occurred repeatedly, it would be fruitful to pursue comparisons of *Rooneyia* with bunodont Asiatic primates.

Ekgmowechashala

Ekgmowechashala philotau occurs in the Late Oligocene to Early Miocene of South Dakota and Oregon, more than 10 My later than *Rooneyia*. It is known by a dentary with P/3–M/3 and upper P4/–M1/ and half of M2/. The dentary is elongated. Upper and lower P4 and molars have a low relief, heavily crenulated enamel, and supplementary cuspules (Fig. 24). The upper molars have large conules and a large hypocone shifted anteriorly, which is linked to the protocone and sometimes interpreted as arising from a protocone fold. The lower molars have a large cuspidate metastylid and a low posteriorly opened trigonid without paraconid. Both upper and lower P4 have large anterior cusps and a posterior basin. P/2 and P/3 are simple. Alveoli suggest the presence of two small incisors and a larger canine. P/2 is double-rooted, which is otherwise unknown in any omomyid. These dental details have often been compared with those of *Rooneyia*, and *Ekgmowechashala* was at one point thought to be derivable from a form close to *Rooneyia* (Rose and Rensberger 1983). However, the two roots of the P/2 are problematic, suggesting primitively little reduced premolars, contrary to what is seen in the uppers of *Rooneyia*. The two-rooted P/2 is probably among the characters which led to a placement close to *Adapis* in the phylogenetic analysis of Ni et al. (2010). On the whole, the phylogenetic place of *Ekgmowechashala* appears unresolved. Is it possible that there was an unusual, atavistic reversal from one to two roots in P/2? A putative rooting close to the highly bunodont *Chipetaia* might be further explored, as well as possible Asiatic clues.

Amphipithecidae

The Amphipithecidae are a group of Asiatic species found mainly in late Middle Eocene beds of Myanmar; one species comes from the Late Eocene of Thailand, and a small genus possibly survived in the Oligocene of Pakistan. Since the discovery of the fragmentary jaws of *Pondaungia cotteri* (Pilgrim 1927) and *Amphipithecus mogaungensis* (Colbert 1937), the overall similarity of this group with the anthropoideans has been recognized. However, they also show peculiar characters which prevent their placement within the African simian radiation, possibly suggesting affinities with a prosimian group (Szalay and Delson 1979). Associated postcranials have increased the controversy. Despite a growing fossil record, no cranial specimen is complete enough to prove the anthropoidean status of amphipithecids.

The Pondaung Formation of central Myanmar yielded a series of specimens of *Pondaungia* and *Amphipithecus*, the two best documented genera, as well as rare specimens of two other species, *Myanmarpithecus yarshensis* (Takai et al. 2001) and *Ganlea megacanina* (Beard et al. 2009). Species of *Pondaungia* and *Amphipithecus* are close in morphology, showing short, high, and heavy jaws with vertical symphyseal region, parabolic tooth rows in occulsal view, and very bunodont teeth. Importantly, their symphyses are not fused. Many specimens show heavily worn teeth. There are two different sizes in specimens of *Pondaungia* from Pangan and Mogaung, suggesting either a high sexual dimorphism or the presence of two species. Due to the larger-sized specimens being more abundant, Takai and Shigehara (2004) consider the assumption of two species more parsimonious, in which case the large one should be called *P. savagei* (Gunnell et al. 2002). Details of dental morphology seen on *Amphipithecus mogaungensis* include short, wide, posterolingually extended P/3 and P/4 (Fig. 25). These teeth have no well-formed metaconid, only irregularities (cuspules?) on a postero-lingual crest descending from the protoconid summit. A small hypoconid is present on the summit of the posterior cingulid. Its lingual crest joins the preceding crest, or the lingual cingulid on P/3, to surround a talonid basin reduced to a narrow and inclined gully. The lower molars have a long, broad, and shallow talonid basin. Their outlines show a median waisting. The cusps of trigonid and talonid have the same height; they are rounded, robust, low, and highly bunodont. The trigonid is antero-posteriorly short, longer on M/1. There is no hypoconulid. The enamel is smooth on most molars of *Amphipithecus*, which has a small M/3. *Pondaungia* has crenulated enamel and a large M/3. The jaws of the large *Pondaungia* are especially high and longitudinally curved (Jeager et al. 1998), whereas jaws of the smaller *Amphipithecus* are less extreme. Unworn molars of *Pondaungia* show interesting details, among them M/1 having a paraconid, a continuous anterior paracristid joining the metaconid, a

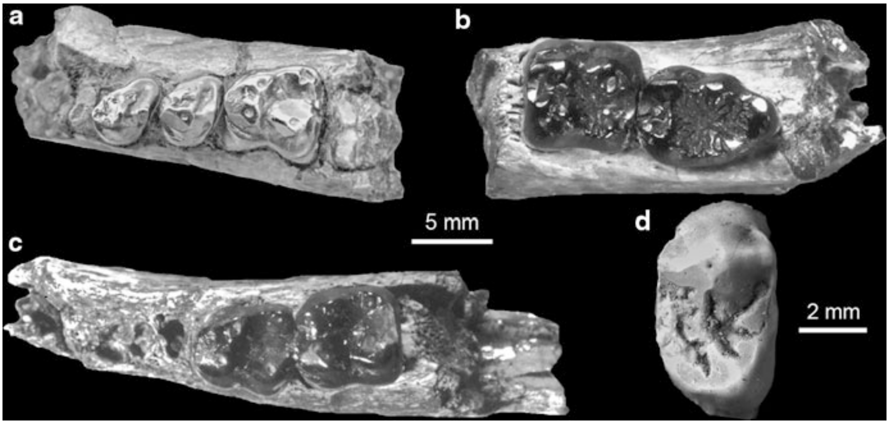

Fig. 25 Dentition of *Amphipithecus* and *Pondaungia*. Left mandibles of *A. mogaungensis* showing P/3, P/4, and M/1 (**a**) and M/1 and M/2 (**c**). Mandible of *P. savagei* showing unworn M/2 and M/3 (**b**) and P4/ of *Pondaungia*, possibly *P. cotteri* (**d**). All are in occlusal views (Courtesy of R. L. Ciochon)

bicuspid metaconid, and a small hypoconulid arising from the postcingulum as in many primitive primate groups.

The upper teeth are correctly documented since the discovery of a maxilla and associated I1/ and canine of *Pondaungia* (Shigehara et al. 2002), and other specimens including a complete unworn P4/ (Gunnell et al. 2002). The I1/ is large, robust, and spatulate. The canine is very large and oval in cross-section. It bears a lingual cingulum and a shallow vertical ridge on its lingual side. P3/ is transversely elongated with rounded extremities and has a protocone only slightly narrower than the paracone. A beautiful P4/ is more transversely elongated than P3/, and shows an anteriorly located protocone issuing three crests (pre-, postprotocrista, postprotocingulum) and a large paraconule. Both protocone and paracone are massive and inflated, yet there is no labial or lingual cingulum as in bunodont simians (Fig. 25). The upper molars are rectangular in outline, with some narrowing of the posterior half of the M2/ in both *Amphipithecus* and *Pondaungia*, and some narrowing of the lingual part of the M1/ in *Amphipithecus* only (Takai and Shigehara 2004). The upper molars are better preserved on specimens of *Pondaungia*, in which they are particularly low-crowned and crenulated. The four major cusps have a rectangular disposition, the hypocone clearly having a strong link to the protocone. Due to this position, isolated from a lingual cingulum on M2/, the hypocone has been interpreted by some authors as a pseudohypocone issued from the posterior flank of the protocone, which would be a rare similarity shared with notharctine adapiforms. However, it is difficult to distinguish those aspects of dental traits which are due to an extreme bunodont adaptation and those which reflect ancestral features of the group. A strong link between hypocone and protocone can develop on a cingular hypocone, e.g., in *Necrolemur*. A pseudohypocone homologous with notharctines is unlikely (Shigehara et al. 2002),

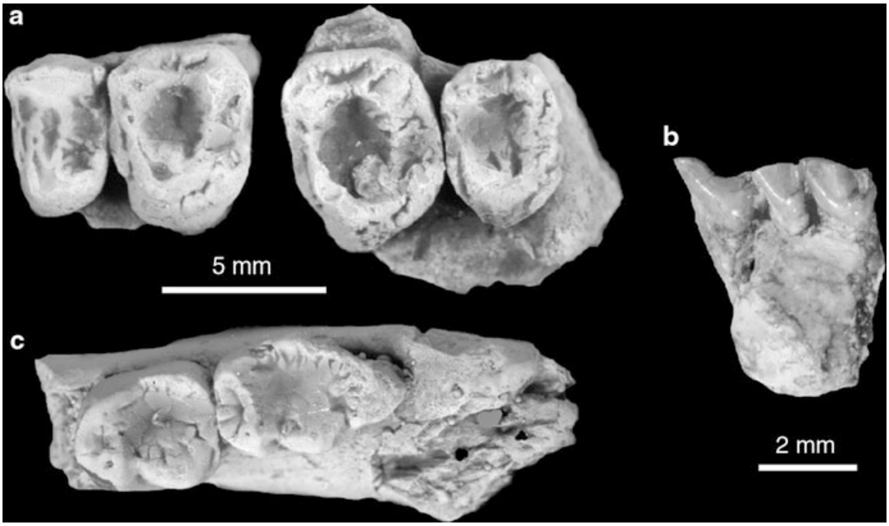

Fig. 26 Dentition of *Myanmarpithecus yarshensis*. Upper teeth P4/ to M3/ (**a**) and lower molars M/2 and M/3 (**c**) at the same scale. The fragment of anterior jaw with canine, P/2, and P/3 in lingual view (**b**) is at a different scale (Courtesy of R. L. Ciochon)

and interpretation of this cusp as a displaced metaconule as in artiodactyls (Coster et al. 2013) is also unlikely. The less derived morphology of *Myanmarpithecus* and *Ganlea* leads to the suspicion that the hypocone of amphipithecids is a cingular one, as in most primates.

Maxillae are known from both *Amphipithecus* and *Pondaungia*. In dorsal view both show an unusual groove on the lateral side of the orbital floor, just medial to the zygomatic wall (Shigehara and Takai 2004). The orbital floor is very flat in *Amphipithecus*. Its posterior border does not show any posterior protrusion as seen in taxa with postorbital closure, indicating that this taxon had an incomplete postorbital closure at the most. However, there is no evidence against or in favor of any development of a posterior part of postorbital closure (Shigehara and Takai 2004). In lateral view, the distance between the base of the orbit and the alveolar rim is moderate: higher than in lemuriforms (nocturnal, with large orbits) but lower than in anthropoideans of comparable size (Shigehara et al. 2002). From the relative size of the upper premolars and the shape of the zygomatic root, Shigehara and Takai (2004) deduce that *Pondaungia* was probably a diurnal primate with a relatively short muzzle. An isolated bone found in close proximity with a maxilla of *Amphipithecus* was initially interpreted as a frontal of this taxon (Gunnell et al. 2002; Takai and Shigehara 2004). It figured in discussions until it was shown to be misidentified, and certainly not to be a primate frontal (Beard et al. 2005).

Myanmarpithecus yarshensis is a small species that also presents highly bunodont teeth and crenulated enamel (Takai et al. 2001). Its upper teeth have more rounded lingual outlines than in the above-mentioned species (Fig. 26).

Despite the fact that the specimen is worn and some details are invisible, the small hypocone on M1/ and M2/ is seen to be peripheral and seems placed on a broad posterolingual cingulum. It would thus seem to be a cingular hypocone. The P4/ is somewhat transversely elongated and has an anteriorly placed protocone without lingual cingulum. A partial left mandible shows C, P/2, and P/3 all with posterolingual expansion and cingulid, bearing resemblance to platyrrhine teeth. This expansion on P/3 is also reminiscent of *Amphipithecus*, even if the tooth is more elongated. M/2 and M/3 have anteroposteriorly compressed trigonids, with an apparently complete paralophid joining the summit of the metaconid. Low relief and reduced labial cingulid are as in other amphipithecids; the M/3 third lobe is elongated. The compressed trigonid and extended M/3 lobe are reminiscent of some fossil prosimians, but no close tie to any one of them has been suggested.

The most recently described amphipithecid *Ganlea megacanina* (Beard et al. 2009) adds interesting information. In size and several aspects of its morphology, it appears intermediate between *Myanmarpithecus* and *Pondaungia*, confirming the place of the former. It also has an enormous canine showing very strong apical wear. P/3 and P/4 are less anteroposteriorly compressed than in *Pondaungia*. P/4 has a relatively large metaconid, P/3 has none. Both premolars have an anteriorly elongated preprotocristid with a paraconid, especially high on P/3, resulting in a very unusual profile for this tooth. An unworn upper molar, interpreted as M1/ or M2/, has a rounded outline as in *Myanmarpithecus*, crenulated enamel, no conules, and only a small cuspule on the posterior cingulum that might be an incipient hypocone. Like other amphipithecids, *Ganlea* was probably a hard-object feeder (Shigehara et al. 2002; Kay et al. 2004a; Beard et al. 2009). The apical wear of its large canine is similar to what is seen in living pitheciines, which are specialized on hard fruits. The same kind of apical wear on canine and premolars is present on *Myanmarpihecus*, which is smaller than living pitheciines.

The large *Siamopithecus* from the Krabi mine in Thailand (Late Eocene) is probably the most extreme in its bunodonty (Chaimanee et al. 1997; Ducrocq 1999). Its upper molars are particularly extended transversely. Their hypocone bears unusual links, being anteriorly directly linked to the protocone, posterolingually directly to the posterior cingulum, and, in the case of M2/, also directly linked to the metacone by a lingual crest. The absence of the crista obliqua linking protocone and metacone, replaced on M2/ by a crest linking hypocone and metacone, as in *Pondaungia*, stands in stark contrast with the morphology of most anthropoideans. The massive, anteroposteriorly long and transversely short P3/ and P4/ are also very distinctive – much more reminiscent of a giant omomyiform than of an anthropoid. To what degree are these premolars autapomorphic, obscuring phylogenetic signals? Maxillary and facial fragments associated with a lower jaw of Krabi have been used to produce a reconstruction of facial elements through synchrotron microtomography, followed by adjustment of digital images (Zollikofer et al. 2009). Despite the fragmentary nature of the remains, the positioning of two parts of the orbital rim suggests that *Siamopithecus* had highly convergent and frontated orbits, as is typical of living anthropoideans. Convergence does not seem so high from the figures, whereas frontation does; it looks higher than in the African simian *Parapithecus*. Estimations of these parameters as well as a morphometric study based on landmarks place *Siamopithecus* phenetically within anthropoideans. However, this fossil is still fragmentary and does not show the key characters of postorbital septum or middle ear morphology that would definitively prove an anthropoidean status.

A small species from the Oligocene of Pakistan, *Bugtipithecus inexpectans*, is represented by six isolated teeth having unusual characters (Marivaux et al. 2005). It is less bunodont than the genera discussed above; it shows a well-formed small cingular hypocone with a prehypocrista linking it to the postprotocrista, a cuspidate metaconule, and labial and lingual cingula on the upper molars. This small survivor may well illustrate primitive character states for amphipithecids. These would point toward a possible connection with eosimiids (posterior waisting, parastyle, salient hypoparacrista on M1/, morphology of P/4), but not with primitive African simians.

The controversies about amphipithecid affinities have been fueled by the discovery of a small set of postcranial specimens, probably of the same individual, in the Pondaung Formation. These bones ("NMMP 20") have the right size to be attributed to species of *Pondaungia*, but have a series of characters that are difficult to reconcile with anthropoidean affinities (Ciochon et al. 2001). An almost complete humerus shows a reduced deltopectoral crest, a shallow bicipital groove, a rounded capitulum with an expanded capitular tail, a groove separating the capitulum and the trochlea and a lateral trochlear rim, an expanded lateral epicondyle, and the absence of a dorsoepitrochlear pit (Fig. 27). On the one hand, these characters and others constitute important differences from anthropoidean humeri, while on the other they present similarities with notharctine adapiforms. However, there are also differences from known notharctines, e.g., a distomedially sloping trochlea, a proximally salient humeral head, and a few other traits. There are also a proximal ulna, a calcaneum lacking its proximal tuber, and other fragments. The calcaneum is quite different from that of simians, showing similarities with notharctines or adapines, as well as a few differences (Fig. 27). The calcaneocuboid facet has similarities with that of *Adapis* in its marked dorsoventral orientation (Ciochon and Gunnell 2004). Functionally, many characters reflect mobile joints and stability, as in slow-mowing arboreal quadrupeds (Kay et al. 2004a). In terms of affinities, most authors agree that these characters are at odds with anthropoidean affinities, leading to two different propositions: (i) they confirm a notharctid origin for amphipithecines (Ciochon et al. 2001; Ciochon and Gunnell 2004); (ii) they must not pertain to *Pondaungia*, considered an anthropoidean, but to a yet unsampled large sivaladapid adapiform, because small adapiforms were found in the Pondaung Formation and large sivaladapids did exist in Asia (Beard et al. 2007). A partial pelvis, found at the same locus and probably pertaining to the same individual, shows strepsirhine rather than anthropoidean affinities, according to Marivaux et al. (2008).

Two isolated astragali from the Pondaung Formation have been successively described, both of which have the right size to be attributed to a large-bodied amphipithecid (Marivaux et al. 2003, 2010). They show no adapiform/strepsirhine character but similarities with omomyids and simians, and have been interpreted in

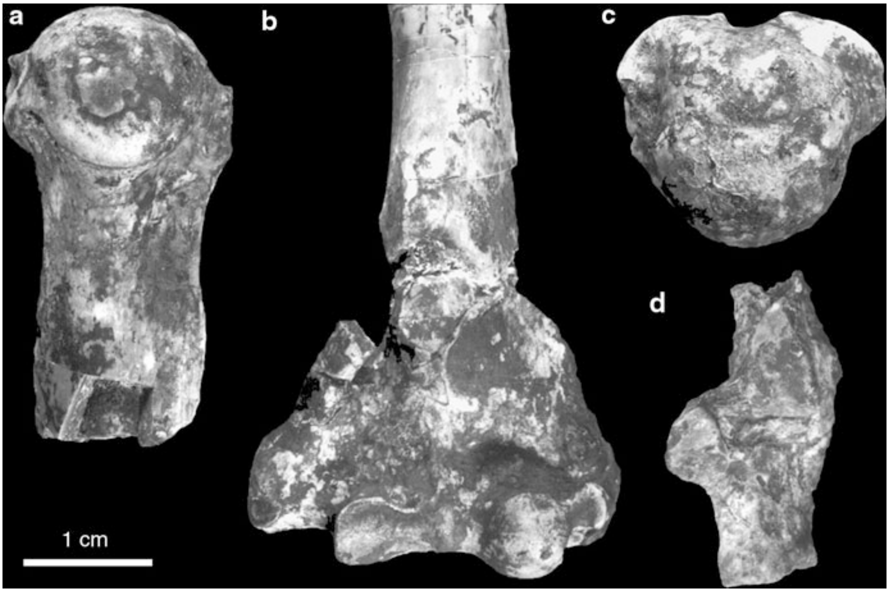

Fig. 27 Some elements pertaining to the controversial NMMP 20 set of postcranials possibly pertaining to *Pondaungia savagei*. Proximal left humerus in posterior (**a**) and proximal (**c**) views; distal left humerus in anterior view (**b**); and distal calcaneum in dorsal view (**d**). All at the same scale (Courtesy of R. L. Ciochon)

favor of simian affinities for amphipithecids (Marivaux et al. 2003, 2010; Dagosto et al. 2010). These bones are clearly lacking the derived strepsirhine/adapiform astragalar characters. However, their similarities with anthropoideans are not definitive proof of simian affinity because, as will be explained below, many of these characters are essentially primitive in primates, allowing only a "haplorhine" (sensu non-strepsirhine) identification (Dagosto et al. 2010).

The postcranial evidence for large-bodied primates from the Pondaung Formation is embarrassing. When the bones are possibly anthropoidean-like, they are attributed to amphipithecids. If they are clearly non-anthropoidean in their characters, proponents of the anthropoidean status of amphipithecids ascribe them to a yet unsampled large sivaladapid. However, it is strange that the growing number of fossil finds in the Pondaung Formation has not to date included discovery of such a large sivaladapid, whereas the number of large amphipithecid specimens has increased considerably. The alternative possibility is that the NMMP 20 bones and the astragali pertain to amphipithecids, and that this group is neither adapiform nor anthropoidean, but instead constitutes some kind of large "haplorhine" primate.

On the whole, craniodental remains of amphipithecids show tantalizing similarities with anthropoideans in the height and robustness of the mandibles, vertical symphysis, and many aspects of the bunodont dentition. But at the same time there are many differences with African simians which prevent researchers from positing a close affinity with propliopithecids or parapithecids (e.g., the latter have big conules and a large hypocone that is never linked to the metacone on the upper molars, short upper premolars with continuous lingual cingulum, lower molars with big hypoconulids, short M/3 lobe, etc.). Some characters of amphipithecids, such as the unfused symphysis in large bunodont species and the waisted lower molars, even more strongly suggest convergent evolution with African simians in other bunodont features. If they were anthropoideans, they would be very distantly related to African families, contrary to the results of numerous recent cladistic analyses. The weakness of parsimony analyses including large dental data sets, applied to very distantly related groups and a fossil record full of gaps, is stunningly apparent in the analysis of Kay et al. (2004b), in which Amphipithecidae are jumping from a place within crown anthropoideans to a place within fossil adapiforms, as a result of a slight change in analytic procedure. The program is evidently trying to ally them with the group presenting the highest number of shared derived characters. However, in an analysis including such primitive taxa as *Teilhardina* and *Donrussellia*, almost all characters of amphipithecids are derived relative to these primitive genera. In the absence of truly diagnostic characters, a high number of similar derived characters of the dentition and the postcranials can show up in two very different groups. What such analyses produce is more a signal of global phenetic similarity than a signal of phylogenetic affinity. The two extremely different results reveal that there is no clear phylogenetic signal in this analysis. Clearly, the data at hand do not allow elucidation of the problem. A similar analysis performed by Beard et al. (2009) nested amphipithecids within African simians; however, we know that this phylogeny is incorrect because *Amphipithecus* and *Pondaungia* lack complete postorbital closure. This demonstrates that a considerable amount of convergence in dental characters occurred, as indicated by the dental characters themselves. In spite of the appealing anthropoidean-like reconstruction of *Siamopithecus* facial parts, *Amphipithecus* and *Pondaungia* lack one of the diagnostic anthropoidean characters; furthermore, their suborbital region is lower than in anthropoideans of similar size (Shigehara et al. 2002), confirming convergence in cranial characters among haplorhine groups. Amphipithecids appear as highly bunodont diurnal primates, convergent with some simians in their craniodental specialization for hard-object feeding.

A sister group relationship between amphipithecids and eosimiids has been suggested by Jaeger et al. (1999). The probability of such a connection has since been increased by the discovery of *Myanmarpithecus*, which partly bridges the gap. It has been strengthened further by the discovery of *Bugtipithecus* and *Phileosimias*. The phylogenetic analysis of Marivaux et al. (2005) showed the two groups to be close, although their analysis continued to ally amphipithecids with African anthropoideans. Such a connection suggests the possibility that amphipithecids are derived from eosimiids and should be placed along with them in Tarsiiformes. As seen above, such a placement fits with the facial and postcranial characters. The two families would considerably broaden the adaptive spectrum of tarsiiforms, and in doing so reset the balance between the two major clades of haplorhines, simiiforms and tarsiiforms.

African Paleogene Anthropoidea or Simiiformes

A whole radiation of anthropoideans, or simians, is documented from the Late Eocene and Oligocene of Egypt. Extensive exposures in the Fayum desert have been yielding fossil primates since the beginning of the twentieth century. Renewed efforts of field crews led by Elwyn Simons and the Egyptian Geological Survey since the 1960s have resulted in the establishment of a succession of faunas, situated in a precise stratigraphic sequence (e.g., Simons 1995). Comparisons with similar faunas from Oman, which are linked with marine deposits, and magnetostratigraphy have led to a new dating of the section (Seiffert 2006). The most productive beds are those of the Jebel Qatrani Formation, which is mostly Oligocene: only one third of the "lower sequence" is Late Eocene in the new temporal framework. The older fauna called BQ-2, found in the Birket Qarun Formation and dated around 37 Ma, has yielded the oldest known undoubted anthropoids (Seiffert et al. 2005b). All families have at least one genus known by its skull. These fossils can thus be included in character-based anthropoideans; they possess their hallmarks, that is, a simian type of postorbital closure and the typical ear region (detailed below for *Parapithecus*).

Parapithecidae

The family Parapithecidae contains a group of four tightly united genera, *Apidium, Parapithecus, Qatrania*, and *Abuqatrania*, which can be considered as Parapithecinae, and the more primitive genus *Biretia*. The oldest and smallest species, *Biretia fayumensis* from BQ-2, shows relatively bunodont upper molars with a large cingular hypocone, a distinct paraconule on M1/, and well developed metaconules on M1–2/, P3/ and P4/ which have small hypocones and a P2/ transversely elongated, with a protocone and three roots (Seiffert et al. 2005b). These characters are shared with some later parapithecines. The lower molars show a moderate bunodonty and a centrally placed hypoconulid. They also retain a complete protocristid and a premetacristid, which will be lost in the later, more extreme bunodont species. P/4 has a cuspidate metaconid linked to the anterolingual cingulid, a hypoconid, and lingual talonid basin; its outline is somewhat anteroposteriorly elongated, whereas it becomes shorter and broader in several later species. It is a small species, with molars between 2 and 3 mm in length and a weight estimate of roughly 200 g. The slightly larger *B. megalopsis*, from the same locality, differs in a few dental details. Its maxilla reveals surprising features: the suborbital region is very shallow, resulting in the exposure of the roots of M1/ and M2/ in the orbital floor, which is formed at their level by the same bony lamina as the palate. The authors infer large orbits and a nocturnal adaptation for *Biretia*, whereas all later African anthropoideans are diurnal (Seiffert et al. 2005b).

Species of *Qatrania* and *Abuqatrania* are also small (length of P/4–M/3 less than 1 cm). Their lower molars are extremely bunodont and somewhat high-crowned (Fig. 28). Their crests are reduced, and their cusps are low and rounded, expanded

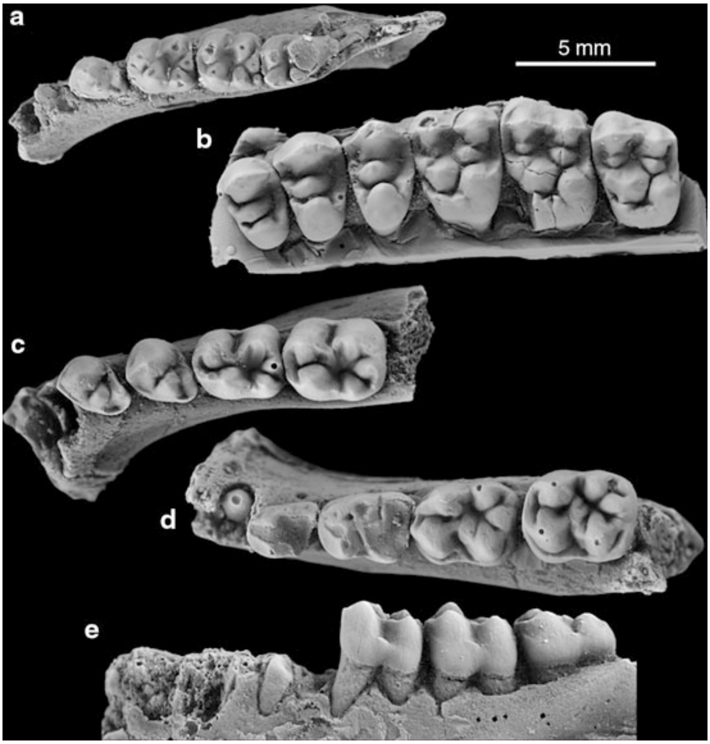

Fig. 28 Dentition of parapithecids. Right lower mandible of *Qatrania wingi* (**a**); maxilla (**b**) and mandibles (**c** and **e**) of *Parapithecus*, probably *P. grangeri*; and left mandible of a juvenile *Apidium phiomense* with worn milk teeth DP/3 and DP/4, and definitive M/1 and M/2 (**d**). The high degree of bunodonty is striking, and the maxilla also shows the supplementary cusp present on the three premolars and the great size of the hypocone, larger than the protocone on M1/ (**b**). All in occlusal views except (**e**), which is a labial view with M/1-M/3. Photographs of white-coated epoxy casts, all at the same scale

into the talonid basins. There is a large centrally placed hypoconulid. M/1 bears a small paraconid. On M/2 and M/3, protoconid and metaconid are separated by an anteroposterior groove; the protocristid is lost. The P/4 is short and simple, with a small metaconid and hypoconid. The mandibular rami of these species have been reported as very shallow (Simons and Kay 1988), and this is beautifully illustrated by the mandible of *Abuqatrania basiodontos*, which has both a very shallow ramus and a high and anteroposteriorly short coronoid process (Simons et al. 2001). One upper molar of *Qatrania* has a very large hypocone. Species of these genera differ by small dental details. The absence of a small posterolingual shelf (fovea) on the M/2 of *A. basiodontos* is emphasized as different from species of *Qatrania*. However, this is a primitive character state, found in the oldest species (from L-41). Placing that species in a different genus may obscure its likely ancestral status relative to the later species, *Q. wingi* and *Q. fleaglei*, from Oligocene levels.

Apidium and *Parapithecus* are clearly larger species found in the Oligocene beds. They are much better known and allow the description of skull and postcranials of parapithecids. There are two species of *Parapithecus*: the type species *P. fraasi*, known through its type mandible described by Schlosser (1911), from an unknown level, and *P. grangeri* (sometimes *"Simonsius" grangeri*), known by more material from Oligocene quarries and now including a cranium (Simons 2001). The lower molars and premolars are larger and accentuate the bunodont characters of *Qatrania*, showing, e.g., a longer and deeper groove between protoconid and metaconid on the lower molars, a larger metaconid isolated from the protoconid by a groove, an anterolingual cingulid and an abbreviated talonid on P/4. P/3 is similar to P/4 on *P. fraasi*, and P/2 is simpler, unicuspid, and bordered by a continuous lingual cingulid. The canine is moderate in size and shows an anterolingually ascending cingulid. The two species differ in size, in some dental details, and in the retention in the type mandible of *P. fraasi* of one incisor on each side, which is of light color and suspected to be a retained deciduous incisor, whereas *P. grangeri* has no more lower incisors at all – a morphology exceptional among simiiforms. The upper teeth are also extremely bunodont. On M1/ and M2/, the rounded cusps are inflated and the conules large, reducing the trigon basin (Fig. 28). The hypocone is almost as large as the protocone on M1/, smaller on M2/ (Kay and Williams 1994). P3/ and P4/ have a paraconule and P2/ appears transversely shorter on the cranium (Simons 2001). The alveoli reveal that there was a moderately large upper canine and two small incisors. Two anterior lower canines appressed against each other with intersticial wear, and wearing flat apically against the upper incisors, constitute a unique dental device – one that is strange in a species reported to be dentally dimorphic. The highly bunodont molars of parapithecids are interpreted as broadly adapted to frugivory, with nuances; e.g., a higher shearing capacity in *Parapithecus* may reflect a slightly more folivorous diet (Kay and Simons 1980).

The cranium of *P. grangeri* is fascinating. It has the complete postorbital closure typical of simians and at the same time an elongated profile recalling more primitive primates (Simons 2001, 2004). Its orbits are posterolaterally inclined in dorsal view, giving a convergence angle of about 105°, and posterodorsally inclined in lateral view, showing a frontation lower than in other simians, similar to some prosimians (Fig. 29). Among its noticeable characters are a large zygomatico-facial (or malar) foramen, as found in some platyrrhines; a glenoid fossa shaped as a transverse trough; a transversely extended postglenoid process; a lateral pterygoid wing extending posteriorly to overlap the lateral bullar wall; a relatively anteriorly located foramen magnum; and a relatively small braincase revealing an encephalization much lower than in living anthropoideans, comparable to that of Eocene prosimians (Simons 2001). This latter assessment depends on body size estimates; those based on dental regressions had initially given body weights ranging from 1.6 to 3 kg. More reliable estimates based on postcranials showed that 1.6 kg is the more likely value (Simons 2004). Even with this low estimate, a better calculation using a CT-scan reconstruction of the brain cavity confirms an encephalization comparable to that of living strepsirhines (Bush et al. 2004).

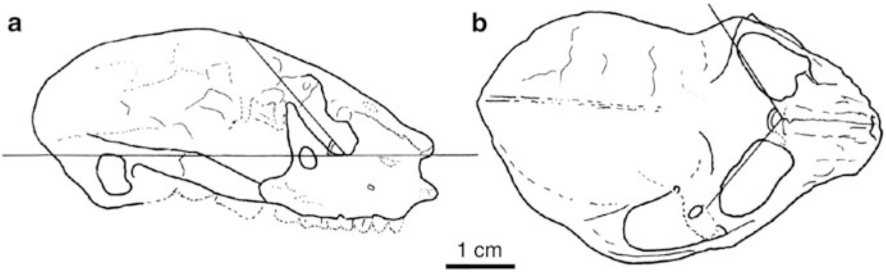

Fig. 29 Schematic drawings of the cranium of *Parapithecus grangeri* in lateral (**a**) and dorsal (**b**) views. It shows the overall elongation of the cranium in lateral view. *Straight lines* indicate the approximate value of the convergence angle (**b**) and the frontation angle (**a**) of the orbits

The complete bullae preserved on the cranium appear relatively distant from each other. They confirm two characters which had been established earlier through the study of isolated parapithecid petrosals: the anular ectotympanic co-ossified with the petrosal around the auditory meatus, and the posteromedial location of the large carotid foramen (Cartmill et al. 1981). The latter study had revealed that there are septa between the promontorium and the ectotympanic. One such septum separates the tympanic cavity from an anterior accessory cavity; the carotid canal travels through this septum, moving for a short distance along the anterior part of the promontorium as a large promontory canal, without a stapedial branch (the perbullar pathway of Cartmill et al. 1981). There is a relatively high degree of petrosal pneumatization, especially of the anterior accessory cavity; a large postglenoid foramen indicates a primitive petrosquamous venous drainage. On the whole, the ectotympanic, pneumatization, and characters of the carotid canal show that parapithecids possessed the distinctive and highly specialized otic complex of living anthropoideans. This morphology bears no resemblance to that of adapiforms. It is in large part shared with *Tarsius* but not with known omomyiforms (Cartmill et al. 1981), and it is a key element at the base of the restricted character-based notion of haplorhines, as endorsed above.

Apidium is a closely related genus, with three species (*A. moustafai, A. phiomense, A. bowni*). It differs from *Parapithecus* by some characters of the dentition. For example, in *A. phiomense*, lower molars increase in size from M/1 to M/3, which is uncommon in anthropoideans; the extremity of their cristid obliqua may be inflated, isolated from the hypoconid by a groove, and forming a centroconid. On the upper molars of *A. moustafai*, the large hypocone is lingually shifted and linked to a thick anterolingual cingulum, which gives the impression that it is larger than the protocone on M1/ and M2/. The anterolingual cingulum can even be cuspidated, resulting in a thick pericone (in *A. phiomense*; Kay and Williams 1994). P2/ is transversely extensive and bears a well-formed paraconule. The upper canines of *Apidium* present an anterior groove which extends into the root (a convergence with cercopithecoids). The highly bunodont teeth of *A. phiomense* would suggest frugivory; however, the species possesses a relatively much thicker enamel than other Fayum primates, and its enamel is of the primitive radial type (not decussating).

A microwear study did not find evidence of hard-object processing (Teaford et al. 1996). Was the diet of this species highly abrasive, and in that case, what was it?

A large sample of postcranials attributed to *A. phiomense* has been studied in detail, which makes it the postcranially best-known Paleogene simian (Fleagle and Simons 1995). The scapula of *Apidium* has a glenoid fossa similar in shape to that of *Saimiri*. It was described by Anapol (1983), who conducted an analysis of scapular angles and the surface of the glenoid fossa, and found the bone to be most similar to those of quadrupedal primates. No humerus shows a complete proximal head. There is a prominent deltopectoral crest, which extends roughly one third of its length. The proximal part is deep anteroposteriorly and narrow mediolaterally. On the distal shaft, the brachialis flange is relatively narrow. There is a large entepicondylar foramen. The articular part shows a relatively small, mediolaterally elongated capitulum, the medial part of which is continuous with the broad trochlea (there is no pronounced groove or lip between them). The trochlea is conical and its medial lip extends further distally than the capitulum. The deep coronoid fossa, the proximal extent of the capitular surface, and the proximal extent of the medial part of the trochlea all suggest that extreme flexion was common in this species. The medial epicondyle is prominent, directed posteriorly at an angle of about 20°, as in arboreal quadrupeds. On the posterior side the trochlear surface is limited by prominent lips, and there is a dorsoepitrochlear pit, a common feature in omomyids and platyrrhines. The ulna has a relatively long olecranon process. The sigmoid cavity, described in detail by Conroy (1976), shows greatest similarity with the platyrrhines *Cebus* and *Saimiri*. The radius presents a head that is oval in shape. Its shaft is very broad and robust in comparison with living primates. Its distal part becomes relatively broad and flattened for a large pronator quadratus muscle, as in arboreal quadrupeds. Its distal articulation shows a sharp styloid process.

Several partial hip bones were recovered (Fleagle and Simons 1979). The ilium shows a broad gluteal plane, rectangular in its preserved part, which is characteristic of anthropoideans, and an expanded iliac plane that narrows proximally, as in *Saguinus*. The ischium is long and proximally broad, and the ischial tuberosity extends slightly above the level of the acetabulum. The dorsal rim of the acetabulum is thicker than the ventral rim. Most characters indicate a quadrupedal primate, although it seems that relative iliac length was lower than in other primates. The femoral head has a rounded articular surface which is restricted anteromedially and expanded posteromedially, as in *Cantius*. Several characters of the femur are typical of leaping primates: a thick and short neck, perpendicular to the shaft; a relatively distal fovea capitis; a prominent intertrochanteric line; a proximal surface of the greater trochanter that is relatively flat and broad in anterior view, anteriorly overhanging the shaft. There is no third trochanter. The lesser trochanter is very large, more rectangular than in living primates, and it joins the greater trochanter to wall off the posterior femoral fossa. The femoral shaft is relatively robust. The distal articulation is higher anteroposteriorly than in all other anthropoideans, and the patellar groove is deep and narrow, bordered by a prominent lateral lip – all characters reflecting a leaping adaptation. The tibia also presents a series of characters associated with leaping:

an extensive, convex lateral condyle and a smaller, concave medial condyle; a proximal shaft that is very narrow mediolaterally; a cnemial crest extending 20–22 % along the shaft, indicating the proximal insertion of the hamstring muscles; tibia and fibula distally appressed for roughly 40 % of their length; a deep medial malleolus and prominent beak on the anterior side, which match the midline groove of the astragalar trochlea, indicating that movements at the ankle joint were restricted to flexion-extension in the parasagittal plane (Fleagle and Simons 1995). The astragalus has a broad dorsal articular surface with pronounced lips and steep sides. The medial trochlear articulation is very shallow, and the fibular facet is steep and relatively shallow. The articular head is ovoid in shape, and its main axis is rotated dorsolaterally. The calcaneum is relatively robust, with a thick tuber and no plantar process. The posterior calcaneal facet is relatively small and very convex, with a steep distal part; the similar size and shape of the matching facet on the astragalus show that there was very little rotation between them at this level. The sustentacular facet is small and circular. There is a prominent peroneal tubercle opposite the sustentaculum. The anterior articular facet faces medially and has little connection with the sustentacular facet, which is unusual and resembles many cercopithecids. The cuboid facet, slightly concave and lunate-shaped, surrounds a deep pit for the calcaneo-cuboid ligament. Below this pit, the tuberosity for the short plantar ligament is more strongly developed than in most platyrrhines. The cuboid is wedge-shaped, broader proximally than distally, and relatively narrow and deep. Its distal face has a single T-shaped facet for one metatarsal, the fourth (MT IV), and the lateral face shows an anterior broad facet for the fifth (MT V). Such a lateral articulation of the fifth metatarsal is unusual among primates; today it is found only in *Tarsius* (Fleagle and Simons 1995). On the navicular, the distal face has three distinct facets for the three cuneiforms, aligned in an L-shaped arrangement as in omomyids, *Tarsius*, and anthropoids (Dagosto 1988).

The bones ascribed to *A. phiomense* show an unusually high variability in size. Few long bones are intact, but the best preserved, completed by others, allow estimations of their median length (e.g., humerus 5.5 cm, femur 8.9 cm). An estimation of the intermembral index gives a score of 62, less than in any other simian and similar to leaping prosimians (Fleagle and Simons 1995). On the whole, *Apidium* shares most characters with small leaping platyrrhines like *Saimiri* or *Saguinus*; however, it was more specialized for pronograde leaping (not VCL), and it also shows a series of other traits – some shared with cercopithecids and others unique among living primates.

The systematic status of Parapithecidae has changed. They have been considered sometimes primitive catarrhines, sometimes platyrrhines, sometimes related to cercopithecoids. Following the detailed analysis of Fleagle and Kay (1987) they have often been considered a primitive sister of all other anthropoideans. However, more recent analyses including Proteopithecidae conclude to an unresolved polytomy between catarrhines, platyrrhines, proteopithecids, and parapithecids (Seiffert et al. 2005b, 2010a). The phylogenetic relationships between these early families and platyrrhines are not yet resolved.

Proteopithecidae and *Arsinoea*

The species *Proteopithecus sylviae* has been found in the locality L-41 of the Fayum. Incomplete dental remains first led researchers to rank it among the oligopithecines; however, the discovery of more complete dental specimens, crania, and some postcranials resulted in revised placement, together with *Serapia eocaena*, in a family Proteopithecidae (Simons 1997a, b; Simons and Seiffert 1999). Members of this family have three premolars above and below. One cranium shows that *Proteopithecus* has spatulate central upper incisors, a relatively large upper canine somewhat transversely compressed, bearing an anterior vertical groove and a lingual cingulum, and upper cheek teeth of large size in relation to palatal breadth. A P2/ smaller than P3/ has only a small lingual lobe with a small protocone and a continuous cingulum. P3/ and P4/ are transversely extended. They both have a strong posterior cingulum which broadens lingually in a shelf reminiscent of the hypocone of the molars. M1/ and M2/ are transversely elongated, have no conule (or only a small paraconule on M1/), a protocone reported to be smaller than the labial cusps, and a relatively large crestiform hypocone. M3/ is reduced. In the lower dentition, P/2 is larger than P/3; both are conical. P/4 is much larger than P/3 and has a large metaconid and a strong lingually recurved preprotocristid, which in occlusal view gives the impression that P/4 has a trigonid similar to that of M/1. It has a short talonid (Fig. 30). The lower molars are generalized, with a trigonid higher than the talonid, which is broad. M/1 has a small paraconid; M/2 and M/3 have a paralophid without cusp. A hypoconulid is frequent on M/1–2, twinned with the entoconid. M/3 is small and shows high variability in its talonid morphology.

The species *P. sylviae* is relatively small; one cranium is 4.4 cm in length. It presents all the simian characters of orbits and auditory region which have been given above for *Parapithecus*, plus a fused metopic suture and lacrimal bone within the orbit (also simian features). Among the distinctive characters of the genus are small premaxillae, large posterior palatine foramina, lack of a posterior palatine torus, and a jugal foramen smaller than in *Parapithecus*. The rostrum is proportionately shorter than in *Catopithecus*, and the anterior margin of the orbit is more forward located, being above a line between P2/ and P3/. The temporal lines converge far posteriorly and join to form a slightly elevated sagittal crest. The latter joins two less distinct nuchal crests and a salient vertical occipital crest. The posterior cresting, more developed than in similar-sized platyrrhines, is probably correlated with the relatively smaller brain size. The glenoid fossa is anteroposteriorly and mediolaterally broad and flat; there is a well-developed postglenoid process and just posteromedially a distinct postglenoid foramen. Both this region and the facing articular process of the mandible are reported as similar to those in *Catopithecus* (Simons 1997a).

Postcranials of *Proteopithecus* include two humeri, a partial femur and hip bone, one femur and two tibiae found in association with a mandible, and an astragalus and a calcaneum (Gebo et al. 1994; Simons and Seiffert 1999; Seiffert et al. 2000; Seiffert and Simons 2001; Gladman et al. 2013). The humerus is very similar to

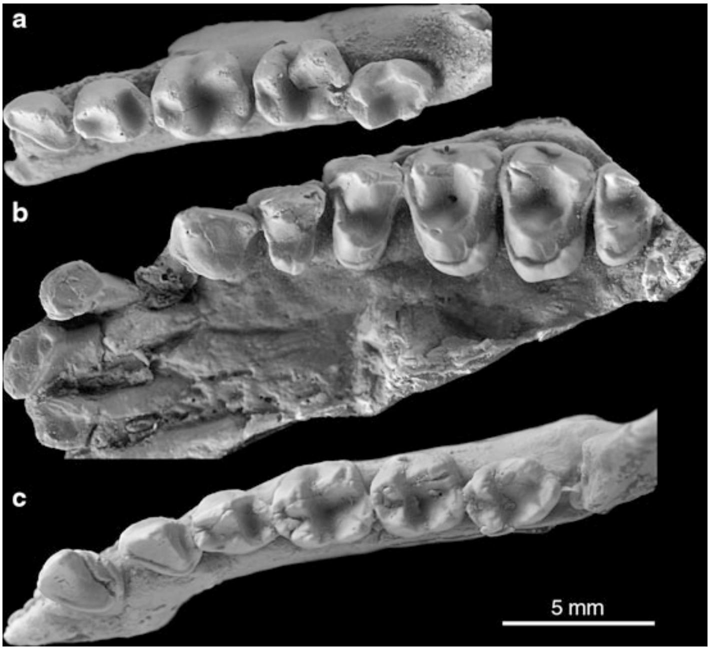

Fig. 30 Dentitions of proteopithecids and oligopithecids. Right mandible of *Proteopithecus sylviae* showing P/3, P/4, and the lower molars (**a**). Partial palate with upper teeth (**b**) and mandible with lower teeth (**c**) of *Catopithecus browni*. The maxilla in (**b**) shows from *left* to *right* the elongated I1/, the shorter I2/ displaced from its broken root, the large and high canine, subtriangular in occlusal view, and the two upper premolars and three molars. On the lower jaw are also preserved the large canine, two premolars, and three molars. Photographs of white-coated epoxy casts, all at the same scale

those of parapithecids. In profile view, its shaft has a distinct sigmoidal curvature. Differences with parapithecids include a less extended supinator crest and less developed brachial flange, narrow and deep bicipital groove (as in *Qatrania fleaglei*), relatively narrow distal articular surface, and broad capitulum confluent with a narrow trochlear surface; on its posterior side the latter shows a well-developed lateral lip within the olecranon fossa. The partial hip bone is similar in many respects to the hip bone of *Apidium*, but has an even larger crest separating the gluteal and iliac planes, and both gluteal and iliac planes are broader in their caudal parts than in *Apidium*. Quantitative ratios used to describe the acetabulum match best with those of extant catarrhines, rather than with platyrrhines or prosimians (Gebo et al. 1994). The femoral neck angle is 108°, and head and neck length are less than in *Apidium*. There is a crista paratrochanterica on the posterior side, between head and greater trochanter. There is a third trochanter at the distal end of the latter, which is more prominent than in any living anthropoidean. The lesser trochanter is large and flange-like. Its lateral crest meets the posterior crest of the greater trochanter, closing the trochanteric fossa as in *Apidium*. However, these crests are less prominent, and the lesser trochanter is less expanded and rectangular, resulting in a trochanteric fossa less extended than in *Apidium*. The trochanteric fossa is interpreted as a more primitive version of that of *Apidium* (Gebo et al. 1994). Distally, the patellar groove is broad and has a prominent lateral lip. The ratio of anteroposterior depth to mediolateral width is 78, lower than in *Apidium* (103). The tibiae are longer and more gracile than those of *Apidium*. Other characters of the proximal part are as in *Apidium* and reflect a leaping adaptation. On the distal part, the fibular articular facet is short (10 % of total length), as in some platyrrhines, contrasting with the long syndesmosis of *Apidium*. The humero-femoral index is 73, higher than in *Apidium* (62). The crural index is 106 (vs. 106–111 in *Apidium*), most similar to those of callitrichines (100–101). The astragalus is very similar to those of parapithecids and small-bodied platyrrhines, but with a lower body and a long axis of the head mediolaterally oriented in distal view (more dorsoplantar in *Apidium*). The calcaneum shows a distal placement of the peroneal tubercle, a distal plantar tubercle, and separated sustentacular and distal astragalar facets – characters which may be shared-derived with parapithecids (Gladman et al. 2013). It also differs from parapithecids in being more slender and in having a greater distal elongation (43 %). Characters of the knee, tibia, and ankle clearly indicate a quadrupedal arboreal locomotion, including frequent rapid running and pronograde leaping.

Proteopithecidae appear to be the most generalized of the African Eocene-Oligocene anthropoideans. They have a large number of similarities with small living platyrrhines, though many of these are considered primitive for simians. It has been suggested repeatedly that proteopithecids are the only serious candidates for a stock from which to derive platyrrhines (Simons 1997a; Simons and Seiffert 1999), because parapithecids and propliopithecids have derived specializations which preclude their playing such a role. However, living platyrrhines also have their own autapomorphies, and until now it has not been possible to identify clear shared derived characters that would ally platyrrhines with proteopithecids. On the contrary, recently found postcranials suggest that proteopithecids may well be more closely related to parapithecids.

The systematic placement of *Arsinoea kallimos*, known only by its lower dentition, has fluctuated. It is a small primate: the complete tooth row of the type mandible, from I/1 to M/3, is less than 2 cm long. Among its distinctive characters are a low-crowned canine, a relatively large, anteroposteriorly elongated I/2, and three simple premolars slightly increasing in size from P/2 to P/4 (Simons 1992). M/2 is reported as low-crowned. There is a large paraconid well separated from the metaconid on M/1, a smaller paraconid close to the metaconid summit on M/2, and no paraconid on M/3. This type of posterior paraconid reduction is unlike what is found in other simians, recalling very different primate groups. *Arsinoea* has been described as “family uncertain,” or found to form a trichotomy with other higher taxa and proposed as member of a new family Arsinoeidae (Simons et al. 2001). More recently, phylogenetic analyses have proposed a place of primitive sister group to other parapithecids (Seiffert et al. 2005a). A closer comparison with *Biretia* would be interesting, and upper teeth would help specify its place.

Catarrhini: Oligopithecidae and Propliopithecidae

For many years, *Oligopithecus savagei* was known only by its type mandible, found in Quarry E of the Fayum. The anterior part of this mandible slightly increases in height anteriorly, and bears a moderate-sized canine with an anteriorly ascending lingual cingulid. There are only two premolars and a P/4 that is relatively short and molarized, with a large metaconid as anterior as the protoconid, and an anteriorly elongated preprotocristid turning lingually into a brief and thick paralophid (almost a paraconid). The P/3 is larger, simpler, and much higher. Its main cusp has a long anterior preprotocristid with wear indicating its honing function for the upper canine. The lower molars are transversely broad, crested with a low relief, with a cristid obliqua reaching the posterior base of the protoconid. M/1 has a small paraconid, and M/2 clearly shows a lingually placed hypoconulid, twinned with the entoconid. The presence of only two premolars, morphologically derived and close to those of *Aegyptopithecus*, makes it a tantalizing catarrhine. However, its molars are quite different from those of the latter, being crested with twinned entoconid and hypoconulid, instead of bunodont with a centrally placed hypoconulid. On the other hand, these molars resemble those of the adapiform *Hoanghonius*, leading to the idea of a status possibly transitional between adapiforms and simians (Gingerich 1977b). This notion was further strengthened by the discovery of an upper molar of *O. savagei* with high crests recalling cercamoniines, interpreted in terms of phylogenetic affinity (Rasmussen and Simons 1988). However, subsequent discoveries, and especially analysis of more complete material of the closely related *Catopithecus*, definitively proved the anthropoidean status of *O. savagei*. A second species of *Oligopithecus, O. rogeri*, was found in the Oligocene locality of Taqah, Oman (Gheerbrant et al. 1995). It completes the knowledge of the genus and shows specific differences. Interesting is the P4/ with a large protocone and well-developed crests forming the lingual part of a trigon (with one labial cusp), and a complete lingual cingulum. The upper molars have an anteroposteriorly more elongated labial part, marked medial waisting, and a thicker and more continuous lingual cingulum, with posterolingual extension on M2/. The trigonid of the lower molars seems less anteroposteriorly compressed.

Catopithecus browni is found in the Latest Eocene locality L-41. Many specimens are known, allowing the description of the dentition, cranium, and parts of the limb skeleton (Fig. 30). The mandibles are anteriorly unfused, a unique case in anthropoideans which suppresses one of their synapomorphies, and also a unique case for catarrhines (Simons and Rasmussen 1996). The lateral incisor is spatulate. The canine is large, projecting, and sexually dimorphic in size. It has a marked cingulid descending anteriorly from the tip and curving posteroventrally on the lingual face. P/3 is also dimorphic. It has a high main cusp and a small talonid. Its preprotocristid serves as honing blade for the upper canine; it is longer in males, which have a broader P/3. P/4 is more complex, with small paraconid and metaconid. The molars are transversely broad. Their crests are not high and their cusps are moderately bunodont. M/1 has a small median paraconid, whereas M/2 and M/3 have a paralophid which seems to enclose the narrow trigonid basin.

The talonid basin is relatively wide, and entoconid and hypoconulid are tightly twinned on all molars. M/3 has roughly the same length but is much narrower than M/1 and M/2; its third lobe is only slightly salient posteriorly. The upper incisors are described and figured by Simons and Rasmussen (1996). They are spatulate and resemble those of small patyrrhines. I1/ is larger and elongated in the mesiodistal plane, and relatively flat on its lingual face, which has a straight margin (Fig. 30). I2/ is smaller and less elongated, with a rounded lingual margin. The upper canine is a simple tooth, transversely compressed, bearing an anterolingual cingulum and an anterior vertical groove, and is dimorphic. P3/ and P4/ are relatively simple, with a large paracone, small styles, the lingual lobe narrower than the labial part, and a continuous thin lingual cingulum at least on P4/. The protocone is smaller on P3/ than on P4/. M1/ and M2/ are relatively simple. Their broad trigon basin is limited lingually by a raised and curved crest, which is formed by a preprotocrista running to the parastyle and a postprotocrista running toward the metacone. A continuous lingual cingulum bears a crestiform hypocone, larger on M2/ than on M1/, and a small pericone on M2/ alone. The labial cingulum is faint and shows a slight mesostyle thickening. M3/ is small, and is reduced in its posterior part.

Six crania of *Catopithecus* are known that are crushed in different ways, allowing many anatomical traits to be recognized (Simons and Rasmussen 1996). In many respects they resemble *Parapithecus* and small extant platyrrhines like *Callithrix*. Thus only some peculiarities are described below. In the facial region, the nasals are broad and long, and the premaxillae have a very broad ascending process. There is a broad interorbital distance, and a broad intercanine distance on the palate. The orbital fissure is made of two parts, an anterior one, which is lenticular, and an inferior one of moderate size. The zygomaticofacial foramen is smaller than in parapithecids and platyrrhines, but larger than in most catarrhines. The relative orbit size indicates diurnality, and convergence is estimated at 120–130°. The anterior margin of the orbit is above the contact between P3/ and P4/, more posterior than in most small platyrrhines. On the ventral side, the palatine bone shows robust pyramidal processes running posterolaterally from the palate, as in *Aegyptopithecus* and some catarrhines; these processes are commonly more gracile in other anthropoideans. On the dorsal side of the cranium, there is no metopic (interfrontal) suture. Strongly developed orbital crests link the posterolateral part of the supraorbital ridges to the temporal lines, which are arcuate and join far posteriorly, bordering a long frontal trigon. The sagittal crest and prominent occipital protuberance suggest a relatively flat and vertical nuchal plane, contrasting with the ballooned shape of small extant platyrrhines. Rough estimates of brain size indicate a low encephalization, even lower than in living prosimians. The relatively large olfactory bulbs project in front of the frontal lobe, as they do in prosimians, whereas they project more downward in extant anthropoideans and *Aegyptopithecus* (Simons and Rasmussen 1996).

Several limb bones have been ascribed to *Catopithecus*. A complete but proximally crushed humerus and two partial distal humeri show that the humerus must have been relatively long; the deltopectoral crest is reduced in comparison with *Proteopithecus*, and the brachial flange is moderately developed. The entepicondylar foramen is smaller and more medially placed than in *Apidium*; it is lost on one of the three specimens; its lateral wall is confluent anteriorly with the medial edge of the trochlea. A large medial epicondyle projects more medially than in other Fayum taxa. On the articular part, the capitulum is very round and sharply demarcated from a long and prominent capitular tail. Compared with *Apidium*, the capitulum and zona conoidea are relatively shorter, whereas the trochlea is broader. The angle of translation of the ulna is small, as in other Fayum primates, whereas it is larger in platyrrhines (Gebo et al. 1994; Rose 1988). A morphometric study of the distal articular surface shows that this surface is phenetically closer to those of propliopithecines than to those of other Fayum anthropoideans (Seiffert et al. 2000). The femur has a relatively short head and neck length, a head more rounded than in *Proteopithecus*, and a notch between the greater trochanter and the head that is shorter and deeper than in *Apidium*. A third trochanter extends farther distally than in *Proteopithecus* and appears variable, ranging from prominent to poorly developed (Seiffert and Simons 2001). The large lesser trochanter does not contact the long trochanteric crest, which runs distally. The astragalus of *Catopithecus* is very different from those of parapithecids and proteopithecids. It has an increased curvature of the distomedial margin of the trochlea, a relatively deep and medially projecting cotylar fossa, and an elevated lateral trochlear rim and increased trochlear wedging (anterior broadening). It also exhibits a laterally projecting fibular facet, a mediolaterally broad head, a low medial body, and a relatively wide distal half of the ectal facet. These limb bones suggest that *Catopithecus* moved more deliberately and climbed more frequently than the smaller parapithecids and proteopithecids. The astragalus reflects an emphasis on inverted and abducted foot postures, as well as powerful hallucial grasps. As with *Aegyptopithecus*, which it resembles, this astralagus may indicate regular hindlimb suspensory behavior.

The recent description of *Talahpithecus parvus*, from the late Middle or Late Eocene of Dur At-Talah in Libya, proves the existence of very small and highly crested oligopithecines (Jaeger et al. 2010). As mentioned above, the dental characters of *O. savagei* first led researchers to hesitate between catarrhine and adapiform affinities. After its anthropoidean status was clearly established, the task remained to assess whether the highly crested oligopithecines had been a primitive sister group of the bunodont (parapithecids + propliopithecids), with convergence in the anterior part of the dentition, or whether they were more closely related to the propliopithecids. Postcranials found subsequently have added a considerable amount of evidence in favor of the second view. The differences in molar morphology, which had previously impressed many scholars, can now be explained by a process of upper molar crest increase associated with a reduction of hypocone and lingual part, as seen in sivaladapids (Seiffert et al. 2004). Thus the loss of P/2 and the similarity in premolar morphology, instead of being convergences, probably reflect the close affinity of oligopithecids and propliopithecids. The presence of solely two premolars remains a hallmark of the catarrhines (and sometimes the oligopithecines are considered a subfamily of the propliopithecids, a possible choice).

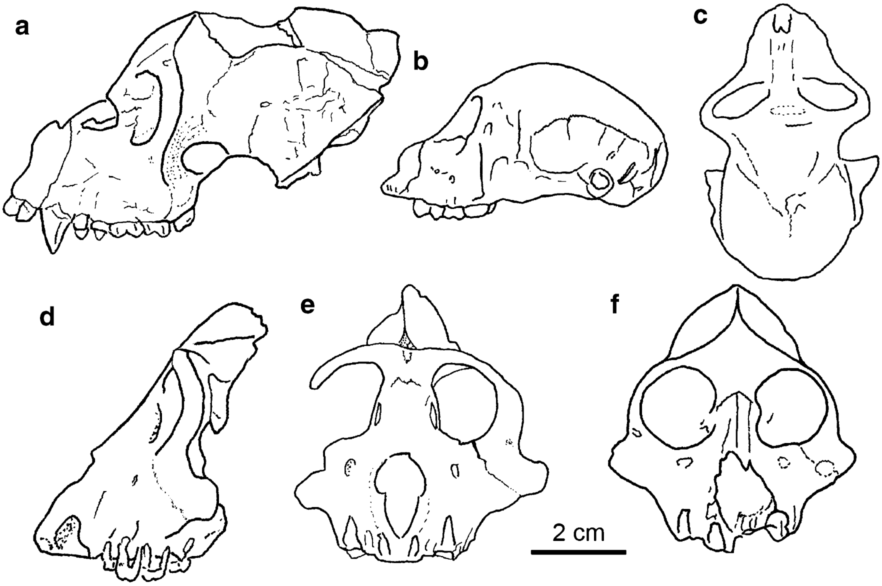

Fig. 31 Schematic drawings of several crania of *Aegyptopithecus zeuxis*. (**a**) is the male cranium reconstructed with some possible deformation of the muzzle, (**b**) is the undistorted cranium of a female, and (**c**) is the dorsal view of the same; (**d**–**f**) are two other faces of males, one in profile (**d**) and anterior (**e**) views, the second only in anterior view (**f**). The extreme sexual dimorphism present in this species can be seen through the size difference between the female (**b** and **c**) and the males and also through the absence of sagittal and nuchal crests in the female. All these crests are present in (**a**), and a strong variability in the development of the sagittal crest can be seen among the males

The family Propliopithecidae, known only in the Oligocene until now, includes the genera *Aegyptopithecus, Propliopithecus*, and *Moeripithecus*. The best-known species by far is *A. zeuxis*, known by many skulls and several postcranial elements from quarries I and M of the Fayum. A cranium of a young male, found in 1966, has been described and depicted many times (e.g., Simons 1967, 1972; Szalay and Delson 1979). It has a relatively long muzzle (Fig. 31), orbits with a slight dorsal orientation in lateral view, tooth rows with a slight posterior divergence, etc. However, this cranium had been reconstructed from a fossil that had been shattered in its facial region. The later discovery of several nondistorted partial male crania brought to light some distortion in this first reconstruction, as well as very high morphological variability (Simons 1987). Comparison of four male crania revealed enormous differences between them: development of the sagittal crest from very low and starting somewhat posteriorly, to very high and shifted anteriorly just behind the orbits (Fig. 31); orbit orientation, in profile view, from slightly turned dorsally to vertical; zygomatic root and suborbital height, from moderate to stronger and much higher. These differences accompany differences in age as visible from tooth eruption and wear. They are themselves attributed to aging, with enlargement of the temporal ridges due to growth of the temporalis muscle and

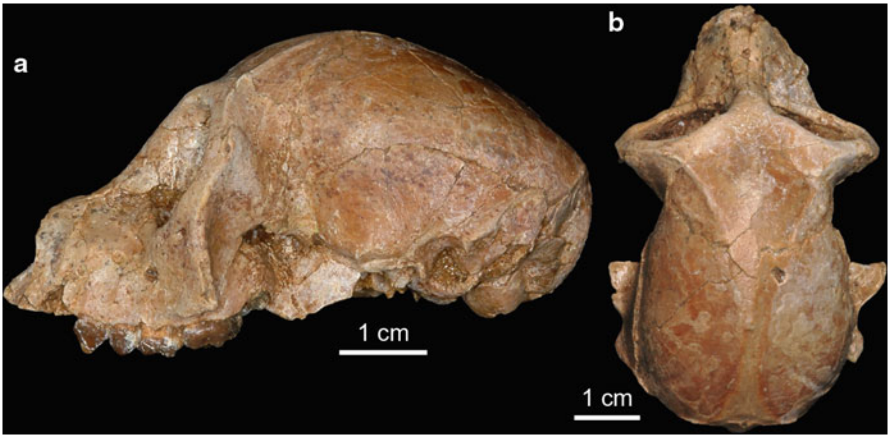

Fig. 32 The undistorted cranium of a female *Aegyptopithecus zeuxis* from the Fayum, Egypt, in lateral (**a**) and dorsal (**b**) views at slightly different scales. This is the only specimen showing the exact relationships between face and braincase in this species (Courtesy of, and copyright by, P. D. Gingerich)

even deepening of the face. Aging also produces differences in ventral view: zygomatic arches mainly above M2/ in young individuals, and above M3/ in older ones; posterior concavities of the palate between M2/ and M3/ in a young male, and well posterior to M3/ in an old one (all indicating an anterior shift of the cheek teeth with age). These differences are further accentuated when males are compared with females, a small individual of which was subsequently described (Simons et al. 2007). The female specimen is minimally damaged and is the only cranium showing the exact placement of the braincase relative to the face in *Aegyptopithecus* (Fig. 32). An angle of 150–160° is measured between the plane of the palate and that of the basioccipital. Several quantitative analyses of tooth dimensions have been done to see if two species could be distinguished in the assemblage from the two quarries; however, until now they all conclude to one species with high cranial variability (Kay et al. 1981; Simons et al. 2007). In fact, *A. zeuxis* reveals for the first time in the Paleogene a sexual dimorphism affecting not only canines and cranial superstructures, but also the size of the postcanine dentition – something found to be the case in only the most dimorphic extant species.

Among other noticeable features of *Aegyptopithecus* are its moderate rostrum length, anteriorly concave nasofrontal region in profile view, and broad interorbital region with a convexity in the medial orbital wall, resembling African great apes; the orbital convergence is 130–135°. The angle of divergence between the tooth rows is 12–13°. The characters of the otic region are those of anthropoideans as seen in parapithecids. However, the lateral pterygoid wing does not contact the auditory bulla. On three specimens, the dorsal part of the ectotympanic extends out in a process, suggesting the incipient development of a tubular ectotympanic (Simons et al. 2007). The use of micro-CT-scan has produced images of the endocast, as well as much better estimates of endocranial volumes than the previous ones: 14.6 cm^3 for the female, instead of the earlier 27 cm^3 for a comparable female cranium (Simons 1993); a new estimate of the young male endocranial volume, 20.5–21.8 cm^3, is again lower than the earlier estimation of 27 cm^3 by Radinsky (1977). The authors conclude that encephalization in *Aegyptopithecus* was very low, "at best strepsirhine-like, and perhaps even non-primate-like" (Simons et al. 2007), although the range of body size estimates is broad. Further scrutiny of body weight should allow more precise estimates of the brain-to-body mass relationship.

The dentition of *Aegyptopithecus* is well known. The two upper incisors are spatulate and have a complete lingual cingulum. I1/ is much larger than I2/ and has a lingual cingular bulging. The robust canines, much larger in males than in females, have an anterior vertical groove and a lingual basal cingulum. The cheek teeth are quite bunodont. The two premolars are subequal in size, bicuspid, and have an almost complete lingual cingulum. The anterolabial part of P3/ can be salient in males. The molars have moderately low and rounded cusps. M2/ is much larger and much more transversely elongated than M1/. The trigon is well formed, with preprotocrista going toward the anterolabial corner and postprotocrista going toward the metacone summit, forming a complete crista obliqua. On M1/ and M2/ the large hypocone is almost as high as the protocone, and linked to a complete lingual cingulum. The M3/ are highly variable. The two mandibles of *A. zeuxis* are high, robust, solidly fused anteriorly, and anteriorly increase in height in males. The incisors are relatively small and narrow, and moderately proclive. They have an elongated crown and a mesial cingulid (seen on DPC 1112). I/2 is slightly larger than I/1. The lower canine is high and pointed, more gracile than the uppers. Its lingual cingulid runs from the posterior base of the crown, curving and ascending toward its tip. The two lower premolars are different. P/4 is short and molarized, with a metaconid almost as high and as anterior as the protoconid; it has an arcuate paralophid, and a small talonid basin limited by a low hypoconid and a subhorizontal postcristid. P/3 is higher and more pointed. Its height in lingual view is underlined by a deep ventral expansion of the posterior cingulid, followed by a continuous anterodorsal ascending course of the cingulid. This difference is accentuated on the P/3 of males, which are larger, higher, and more pointed, and which have a longer preprotocristid for honing with the upper canine. The lower molars differ from those of oligopithecids by some features: absence of a paraconid on M/1, increased bunodonty, transversely broader M/2, M/2 larger than M/1, well-developed posterior cingulid, and a more centrally located hypoconulid, leaving space for a small valley or fovea between entoconid and postcingulid. M/3 is larger than M/2; it is essentially made longer through its much larger, and quite variable, hypoconulid.

Among the Fayum primate limb bones studied by Conroy (1976), one ulna was referred to *Aegyptopithecus*. It was found similar to that of *Alouatta*, the extant howler monkey. Several other bones were subsequently described; a summary of those attributed both to that genus and to *Propliopithecus* was given by Gebo (1993). The humerus of *Aegyptopithecus* is robust and shows strong muscle crests, especially the deltopectoral, and the brachial flange is more laterally extended than in any other anthropoidean. Among the characters which indicate arboreal quadrupedalism are the prominent and laterally placed tubercles bordering the posteriorly facing head, a slight flattening on the top of the head, and the very distal crest for the teres major muscle. There is a wide medial epicondyle (strong flexors), a dorsoepitrochlear fossa, and an entepicondylar foramen. On the distal articular surface, the capitulum is round and has a small capitular tail, the trochlea is relatively wide, the zona conoidea wide and shallow. The olecranon fossa, which is shallow, is one more primitive/quadrupedal feature, whereas the articular surface is of the nontranslatory type as in other catarrhines (Rose 1988; Gebo 1993). Most characters of the ulnae also indicate arboreal quadrupedalism: robust bone, proximal convexity, a relatively long olecranon and low coronoid processes, and a broad and shallow sigmoid notch with oblique orientation of the flexion-extension axis. The prominent pronator crest indicates climbing capabilities. The femur of *Aegyptopithecus* is a very robust bone, which retains a third trochanter (or gluteal tuberosity) – a character independently lost in the parapithecids and later catarrhines (Ankel-Simons et al. 1998). The tibia of *Propliopithecus chirobates* is short and robust, exhibits asymmetrical condyles, and shows a distal articular surface similar to those of Early Miocene proconsulids (Fleagle and Simons 1982). The astragalus of *Aegyptopithecus* shows a relatively long and moderately high body, and a short neck angled medially. The trochlea is asymmetrical, with a higher lateral rim, as well as a medial rim anteromedially curved above a deep medial malleolar cup (cotylar fossa), which produces abduction associated with dorsiflexion of the foot. The fibular facet projects quite far laterally, as in *Catopithecus*. The calcaneum is very broad mediolaterally in both *Aegyptopithecus* and *Propliopithecus*. Its plantar surface is slightly concave anteroposteriorly, and its proximal part slightly bent medially. Its distal part is moderate in length (38 % of total length). It exhibits an elongated posterior facet and an anterior extension of the sustentacular facet, both indicating extensive rotation and sliding of the astragalus on the calcaneum. Distally, a deep pivot indicates high rotational capacities. The first metatarsal is relatively long, curved, and possesses a relatively short peroneal tubercle, as in other anthropoideans. It presents a facet for a prehallux, a primitive character; two other metatarsals also present primitive characters on their narrow proximal part (Gebo and Simons 1987). A long, slender, and moderately curved proximal phalanx is typical of climbers. On the whole, most characters suggest arboreal quadrupedalism and climbing similar to *Alouatta*; increased foot mobility and strong hallucial grasping possibly reflect frequent suspensory feeding postures, as in the latter.

Other species and genera of propliopithecids include three species of *Propliopithecus*, *Moeripithecus markgrafi*, and an unnamed propliopithecid from Taqah, Oman. The three species of *Propliopithecus* are smaller than *A. zeuxis*, and they differ from it by a series of dental characters: lower crowned lower incisors, lower molars with a well-developed labial cingulid, more peripheral cusps and straight-sided crowns, and a transversely broader M1/. *P. haeckeli*, coming from an unknown level and described long ago (Fig. 33), is considered more primitive than

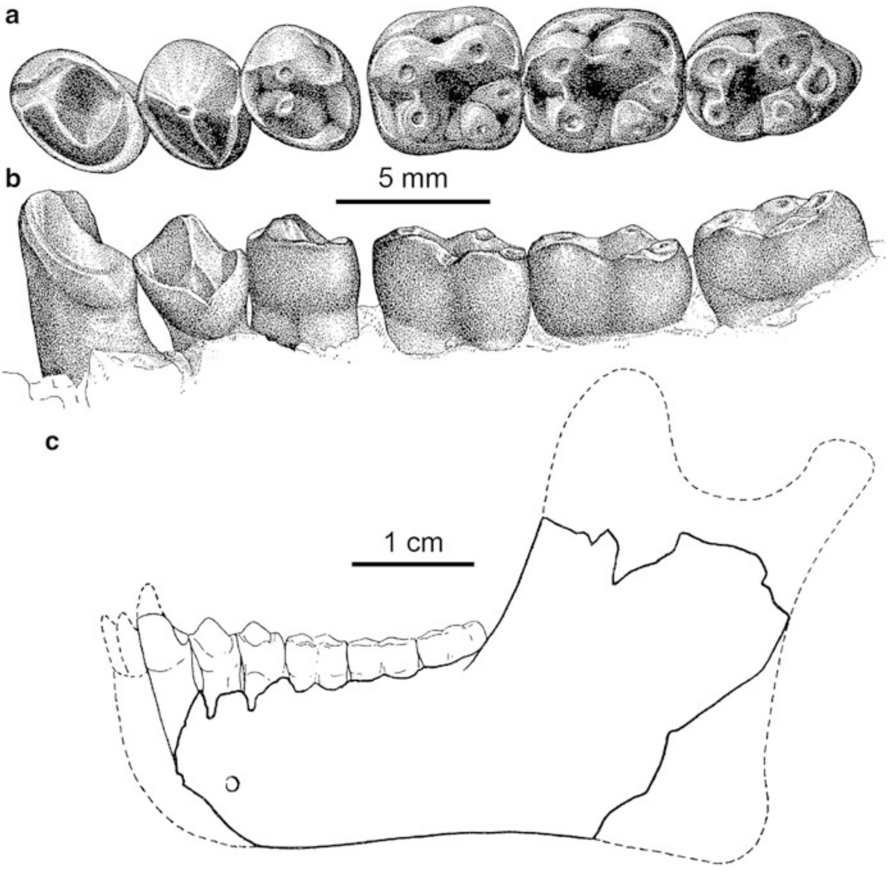

Fig. 33 Right lower dentition in occlusal (**a**) and lingual (**b**) views and reconstruction of the lateral view of the mandible of *Propliopithecus haeckeli* at two different scales (From Kälin 1961)

the larger *P. chirobates*, known by samples from Quarries I and M of the Fayum (Schlosser 1911; Kay et al. 1981). *P. ankeli* from Quarry V is even larger and has transversely very broad lower molars. The type and only known specimen of *Moeripithecus markgrafi* is also an early find without precise stratigraphic provenance. It is a partial mandible with M/1 and M/2, showing a unique combination of characters. The molars have a strong basal crown inflation and a transversely short talonid basin; they are more crested than in other propliopithecids, and their twinned entoconid and hypoconulid recall oligopithecids. Treated for many years as a species of *Propliopithecus*, *M. markgrafi* is now recognized as a valid genus with probable transitional significance. In a similar vein, a better documented Oligocene species from Taqah, Oman, was first described as pertaining to *M. markgrafi*, but in recent years specialists have tended to consider it a distinct taxon – one also presenting characters that are primitive for propliopithecids (Thomas et al. 1991; Seiffert et al. 2010a). Whereas the lower dentition is close to those of other propliopithecids (a male has an enormous P/3), the upper molars are more transversely elongated and show much smaller hypocones, which are clearly primitive characters. The Taqah species, large and Oligocene, underlines the diversity of propliopithecids, which likely deserve the distinction of a fourth genus.

Systematic interpretations of the propliopithecids, mainly *Aegyptopithecus*, have changed dramatically through time, due to the discovery of more complete fossils and the increasing role of locomotor characters for primate phylogenetic reconstruction. The partial dentitions that were found first could reasonably be compared with those of living great apes. Discovery of the skull revealed the primitive, platyrrhine-like state of the ectotympanic. An entepicondylar foramen found on the humerus was also a primitive feature. These two characters prevented placement of *Aegyptopithecus* among crown catarrhines; however, a frequent move was to include *Aegyptopithecus* as a primitive catarrhine because it had only two premolars, and to modify the defining characters of the group accordingly. However, within the catarrhines, classifying *Aegyptopithecus* as a hominoid implied that the two characters at issue had evolved convergently in hominoids and cercopithecoids. For example, Simons (1987) insisted that the similarities shared by *Aegyptopithecus* and the great apes (deep face, temporal cresting, broad lacrimals and interorbital region) were shared-derived and implied a hominoid status for the propliopithecids. However, a more detailed study of the interorbital region and the distribution of its characters concluded that it would be more parsimonious if an African ape-like system of the ethmofrontal sinuses were the primitive condition for crown catarrhines (Rossie et al. 2002). *Aegyptopithecus* and probably *Proconsul* also were considered primitive sister groups of a clade (cercopithecoids + hominoids). The latter view has gained general support based on consideration of locomotor adaptation and associated characters: pronograde arboreal quadrupeds such as *Aegyptopithecus* preceded the more lightly built and tailless proconsulids, which themselves preceded the adaptive divergence of semi-terrestrial cercopithecoids and orthograde arboreal hominoids. Propliopithecids are primitive catarrhines, and likely a primitive sister group of crown catarrhines. They include the ancestors, or good approximates of the actual ancestors, of Miocene–Recent catarrhines. As such they are one of those indispensable paraphyletic taxa that are needed if evolutionary history is to be reconstructed.

The First Proconsuloid

At the end of the Oligocene, a large catarrhine of more modern aspect is found in Kenya. *Kamoyapithecus hamiltoni* is known by dental and gnathic remains only. It is a large animal; the length of its upper tooth row is roughly 1.5 times that of *Aegyptopithecus zeuxis*. The species is documented by a maxilla bearing P4/–M3/, the tip of an upper canine, an anterior mandibular fragment, and an I/2 (Leakey et al. 1995). Its cheek teeth are bunodont, low-crowned, with moderate labial and lingual flaring. P4/ is oval in outline. M2/ is only slightly larger than M1/ and has roughly the same size as M3/. The molars are transversely broad in comparison with

Later Miocene proconsulids, but quite short and square in comparison with propliopithecids. A large hypocone is close to the protocone, present and slightly smaller on M3/ than on M1/ and M2/. The cingulum is not crenulated. The large robust upper canine may be a derived character shared with later forms, as is the position of the hypocone. The very well-developed superior mandibular torus is also found in large-size *Proconsul* species. As seen with the upper molar proportions, *K. hamiltoni* in many ways appears intermediate between earlier propliopithecids and Later Miocene–Recent catarrhines. It can be considered a primitive member of the informal proconsuloids.

Anthropoidean and Platyrrhine Origins, Afrotarsiidae, and Further Phylogenetic Questions

Platyrrhine Origins

Before discussing anthropoidean origins, it is necessary to envisage the origin of the Platyrrhini, the South American monkeys. They are documented in Bolivia in the "Salla Beds," Salla-Luribay Basin, which were long believed to be Early Oligocene (Hoffstetter 1969). However, the Deseadan land mammal age was subsequently redated, and the Salla Beds are now considered Late Oligocene, or Oligo-Miocene (an age of 25–26 Ma is often mentioned). The genus *Branisella* with its only species *B. boliviana* is documented by dental material (Fig. 34). The upper cheek teeth are moderately bunodont; the lower ones are also clearly high-crowned. The roots indicate that P2/ was small. P3/ and P4/ have a well developed lingual part, with large protocone. On P4/, the protocone has a postprotocrista continuous toward the posterolabial part; there is a transversal groove between protocone and paracone, and a continuous and thick lingual and posterior cingulum. The upper molars have the three usual main cusps. It seems that the crista obliqua is sometimes interrupted by a transverse groove. There are important variations in the extension of the lingual cingulum and hypocone, leading to a triangular or more rectangular lingual outline. This led to the initial distinction of some specimens as another taxon *"Szalatavus multicuspis,"* but further specimens showed that these differences reflected high intraspecific variations (Rosenberger et al. 1991; Takai and Anaya 1996; Takai et al. 2000). M3/ is smaller than the other molars and can have a very reduced metacone (variable). The mandibles are fused and the dental arcades are close to a V. I/2 is larger and set more posteriorly than I/1. It has a complete lingual cingulid. The canine is oval in outline, with its longitudinal axis bent anterolaterally; it bears a continuous lingual cingulid. P/2 is not reduced. It has roughly the same size as P/3, is unicuspid, and bears a strong lingual cingulid, curving into a posterior one labially ascending toward the main summit. P/3 has a well-formed metaconid, lower and posterior to the protoconid, whereas P/4 has a metaconid roughly as high and as anterior as the protoconid. P/4 also has a small talonid. The three lower molars are transversely broad, with long labial slopes resulting in transversely short trigonid and talonid basins (Fig. 34). Their anterior

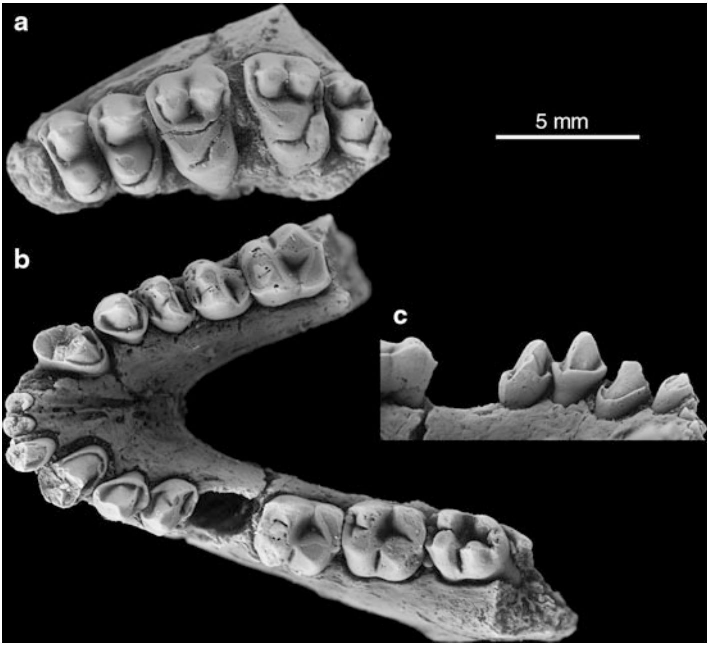

Fig. 34 Dentition of *Branisella boliviana*. Maxilla with two upper premolars and three molars in occlusal view (**a**). A lower jaw with fused symphysis, preserving the anterior teeth, three premolars on the *right* side and the three molars on the *left* side, in occlusal view (**b**) and lingual view of its left anterior teeth P/3, P/2, and partial canine and I/2 (**c**). Photographs of white-coated epoxy casts, all at the same scale

paralophid is transverse and continuous; there is almost no labial cingulid, only a basal closing of the labial trough between protoconid and hypoconid. M/3 is especially short posteriorly; a hypoconulid may be identified on its rounded postcristid, but there is no third lobe.

Branisella is evidently the oldest known platyrrhine. It is sometimes considered as a good ancestral morphotype for them; or as more closely related to one living lineage, implying an earlier diversification (e.g., relatedness to callitrichines for Takai et al. 2000); or, more commonly, as an early primitive sister group of all other platyrrhines. All specimens found in the Salla Beds show strong dental wear, and it has been suggested that their high-crowned lower molars were an adaptation to an abrasive diet, probably related to the semi-arid environment revealed by the fossils and geology of these beds. Therefore, the likely existence of other taxa living in contemporaneous humid and forested areas has been postulated. Whatever its relationships with later platyrrhines, *Branisella* testifies that the group was present in South America by the Late Oligocene. Concerning its origins, all specialists agree that South American platyrrhines must have a common origin with African catarrhines – but when and where? Close affinity between the two groups suggested to Hoffstetter (1972) and others an African origin and subsequent dispersal to South

America. However, a scenario of primates rafting over the Atlantic Ocean, which was already wide at the time, has often met with considerable skepticism (e.g., Conroy 1976). Alternatively, a common source on northern continents and subsequent dispersal to Africa and through North America to South America has been advocated – a proposal sometimes revived in conjunction with putative Asiatic anthropoideans (eosimiids and amphipithecids). However, as seen above and discussed further below, this Asiatic origin is not only far from established, it appears unlikely. With respect to the platyrrhines, it would imply a dispersal through North America – a continent with a rich and continuous fossil record, and yet one in which no suitable ancestor has ever been found. Furthermore, exchanges between the two Americas were interrupted between the Paleocene and the Plio-Pleistocene. This dispersal route for primates thus appears extremely unlikely. On the contrary, new finds in Africa have revealed that the proteopithecids were relatively close to the platyrrhines. *Branisella* and *Proteopithecus* both share the unusual combination of a reduced P2/ and unreduced P/2 (Takai et al. 2000). As seen above, *Proteopithecus* cannot yet be ranked among the platyrrhines. There is still a morphological gap between known African Eocene fossils and platyrrhines, although a common origin is the most consensual view. It is paralleled by the stronger case of an African origin for the South American caviomorphs. A chance dispersal from Africa to South America is thus postulated (Holroyd and Maas 1994). It probably implied the conjunction of several factors: intermediate land on the Mid-Atlantic ridge, a sea-level drop, the rafting of small animals able to survive seasonal food shortage, etc. If this is what occurred, African platyrrhines or stem platyrrhines should be found. It is a real possibility, given that all African anthropoideans named to date come from North Africa and Arabia, leaving the possibility that other groups lived in more southern regions (see below on intriguing fossils found in Namibia).

Anthropoidean Origins and Postcranial Characters

Anthropoidean, or simian, origins have been a field of lively debate during the last two decades. This field has become progressively polarized between three hypotheses: first, a hypothesis rooting the anthropoids in Eocene adapiforms; second, a more commonly adopted hypothesis linking them to the two Asiatic families Eosimiidae and Amphipithecidae; and third, a hypothesis of ancient origin in Afro-Arabia. On the whole, the Fayum anthropoid evidence of three distinct clades differentiated by the early Late Eocene and the implications of platyrrhine origins for a fourth clade jointly provide sufficient evidence to allow researchers to infer a long undocumented history of early simians in Africa, unless the Asiatic connection turns out to be true. As the Paleocene *Altiatlasius* (see below) is found to have possible simian characters, it reinforces the possibility of an ancient African differentiation for the group.

Can an adapiform ancestry be defended? This old hypothesis was revived by the discovery of similarities existing between teeth and dentaries of cercamoniine and hoanghoniine adapiforms, on the one hand, and those of oligopithecids, on the other (Gingerich 1975, 1977b). It was further advocated in studies of both adapiforms (Rasmussen 1990) and Fayum anthropoideans (Simons 1987; Simons and Rasmussen 1996). It was adopted in a study of Messel adapiforms (Franzen 1994) and further argued for in the recent study of *Darwinius*, supposed to be a haplorhine (Franzen et al. 2009). However, the discovery of oligopithecid crania showed that the dental similarities invoked earlier were in fact convergences. As mentioned above, key characters of the auditory region emphatically rule out the adapiform hypothesis (Cartmill et al. 1981). The key haplorhine cranial characters cannot be checked on *Darwinius* because its cranium is crushed; however, *Darwinius* is certainly a cercamoniine adapiform, and in this group the well-preserved skull of *Pronycticebus* shows that they are strepsirhines and certainly not haplorhines. Difficulties linked to the haplorhine concept (*Tarsius* + simians) have been mentioned above. If they were to lead to a view of convergence instead of homology for haplorhine characters, this would not be in favor of the adapiform view, but rather in favor of a third group yet to be identified.

The Asiatic connection could imply multiple dispersals between Asia and Africa. For example, the schema arrived at by Beard et al. (2009) allies eosimiids with African simians and suggests a closer phylogenetic link between amphipithecids, propliopithecids, and platyrrhines. This implies two dispersals, one for eosimiids, and a second one for amphipithecids in either direction, return to Asia in their schema or second dispersal to Africa with a less parsimonious tree. As seen above, amphipithecids cannot be close to propliopithecids, and a more consensual schema would imply one dispersal of an eosimiid giving rise to the African simian radiation (Williams et al. 2010). This is a real possibility (Fig. 36). However, it implies that the Shanghuang petrosal attributed to an eosimiid by MacPhee et al. (1995) be ascribed to an omomyid instead (Kay et al. 1997), which may appear unlikely. That hypothesis is partly sustained by postcranial characters, which have been interpreted as shared-derived between eosimiids and anthropoideans. This requires a critical look.

As indicated above, the Shanghuang fissure fillings have yielded not only eosimiids but a series of four morphological groups based on tarsal characters (Gebo et al. 2001). Study of the calcanea allows their placement along a morphocline between small primates with short and broad calcanea, adapted to quadrupedalism and climbing (“protoanthropoids: new taxon”), to markedly elongated calcanea, adapted to leaping (“prosimians: tarsiids”). Intermediates are the “protoanthropoids: eosimiids,” which are slightly broad, and the “prosimians: unnamed haplorhines,” which are narrow and very omomyid-like (Fig. 35). Astragali complete the tarsal characters of these four groups. The locomotor diversification between these groups took place among tiny Middle Eocene primates of the same region in China, in the presence of a larger omomyid (*Macrotarsius*) and a larger and more climbing-adapted adapid. Is it reasonable in such a context to hypothesize that some of these small primates would be in the process of reversal from a prosimian-like leaping (omomyid-like, not extreme) to quadrupedalism? This change would have had to be so marked that a medial tibial facet extended to

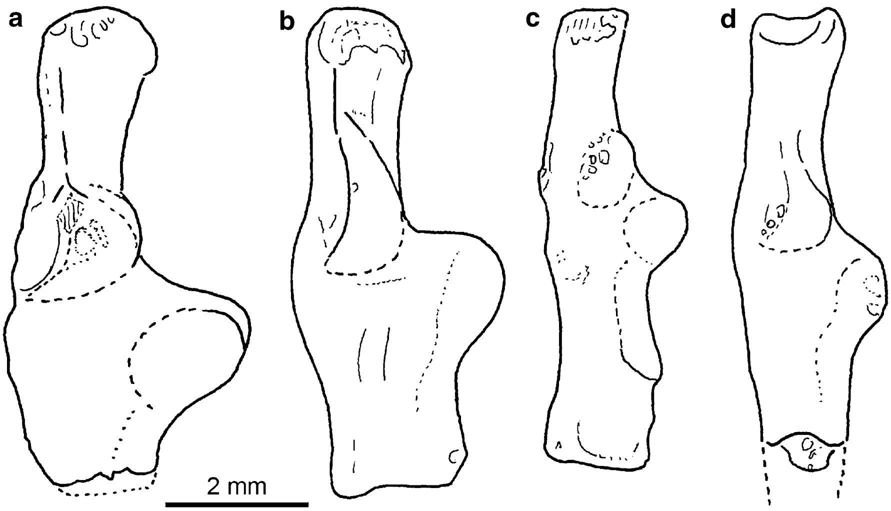

Fig. 35 Schematic drawings of the four types of calcanea identified by Gebo et al. (2001) in the Shanghuang fissure fillings, all in dorsal view. They constitute a morphocline from a broad and short morphology typical of generalized arboreal quadrupeds (**a**) to progressively narrower and more elongated calcanea until the extremely elongated one in (**d**), which reflects a high leaping specialization. (**d**) is ascribed to a tarsiid, (**b**) to an eosimiid; (**c**) appears omomyid-like or cheirogaleid-like in proportions. This morphocline can also be most simply interpreted from primitive in (**a**) to most derived in (**d**). In this case, the anthropoid-like proportions in (**a**) would not imply phylogenetic affinity with simians but only primitiveness among primates

the ventral border of the astragalus would retract to a more dorsal position – something that can hardly be explained in adaptive terms. Much more parsimonious is the view that, because a reduced medial facet is primitive in primates, quadrupedalism was the likely primitive primate locomotor mode (or, if a component of leaping was present, it was low or recent enough to have led to some long bone lengthening as in *Archicebus*, but not yet to medial astragalar and to tibial modification). This fits with the notion of short and broad calcanea as probably primitive in primates, as indicated by extra-group comparisons, reinforcing quadrupedalism and climbing as primitive in the group. Several degrees of leaping were successively reached by different groups, with probable parallelisms between them (such convergent evolution is demonstrated among living primates by the fact that VCL specialists have evolved convergently in at least four families of extant primates). Increasing specializations are expected during evolutionary radiations. Reversals can happen, but usually only under special conditions (further adaptive transitions). Under these assumptions, the anthropoidean-like tarsals of Shanghuang in large part retained postcranial characters that are primitive for primates. They do not prove anthropoidean affinities. This also applies to the astragali of amphipithecids from the Pondaung Formation (Marivaux et al. 2003, 2010; Dagosto et al. 2010). Eosimiid tarsals are probably not primitive for all their characters. For example, might their high astragalar neck angle be convergent with

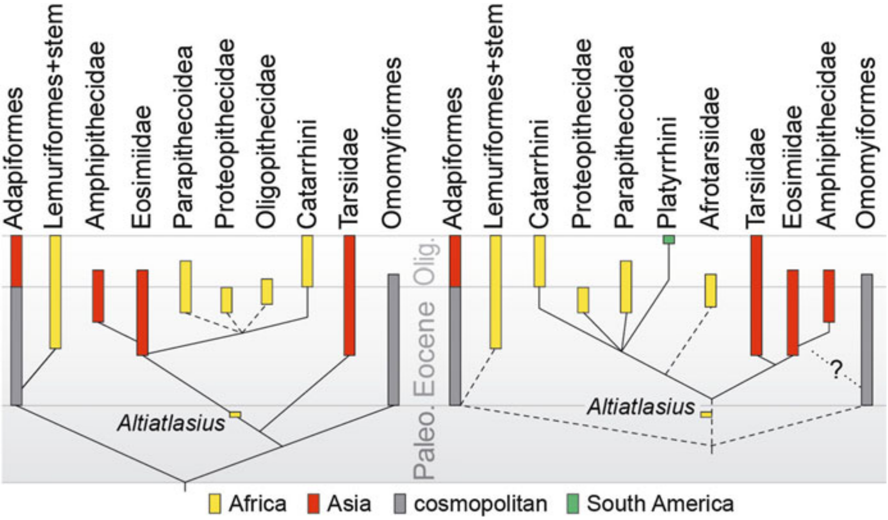

Fig. 36 The two main current hypotheses of anthropoid origins. *Left* is one of the consensual views emerging from the cladistic analyses of large data sets supported, for example, by Williams et al. (2010). In this schema, African simians are rooted in early Asiatic Eosimiidae, which are considered simians or stem-simians having no close relationship with tarsiids. *Right*, another view, considered more likely here, implies a longer history of early African simians with a probable African origin of the typical anthropoid characters. In this case, Eosimiidae and possibly Amphipithecidae could be related to tarsiids in an extended tarsiiform radiation (however, some of the taxa included here might also appear as derived omomyiforms as indicated by ?). Both hypotheses preserve a haplorhine clade, stem-based and extended to include omomyiforms in Williams et al. (2010), more restricted and character-based here. If Tarsiidae themselves appeared rooted in omomyiforms, anatomical haplorhinism would have lost any phylogenetic meaning and reflect only a convergence in cranial adaptation

that of adapiforms? The peculiar cuboid facet, with its removed articular wedge, is clearly derived. However, analogous modifications of the cuboid facet have been described, for example in adapines and amphipithecids (Godinot 1992a; Ciochon and Gunnell 2004). A more detailed study of this facet in many groups is needed, including functional aspects, to decipher homologous and convergent changes. At present, the anthropoidean affinities of eosimiids based on tarsal characters do not appear convincing.

The significance of the anthropoidean postcranium is an old problem. Anatomists have recognized for a long time that living simians are generally more primitive in their postcranial anatomy than living prosimians. Small simians do not show the degrees of specialization reached by some prosimians for leaping or for hand and foot powerful grasping. Because for dental and cranial anatomy there is evidence that early simian characters evolved from prosimian characters, many authors since Gregory (1920) have assumed a similar scenario for postcranial anatomy. This model, Model 1 of Dagosto (1990), implies the reversal of a whole suite of characters – of the knee joint, the first metatarsal joint, the tarsals, etc. Other scholars have considered it more likely that anthropoideans retained their primitive postcranial characters from the euprimate morphotype (Ford 1988; Godinot 1992b). Dagosto's Model 1 explained these reversals through an emphasis on above-branch quadrupedalism, which could have accompanied a marked increase in size. Indeed, at the time when this model was proposed, known fossil anthropoideans were larger than most early fossil prosimians. Strangely, the same scenario of reversals has been maintained for the extremely small eosimiid fossils discovered more recently in China (Gebo et al. 2000, 2001). However, their Middle Eocene age and extremely small size render such a scenario questionable – and quite unparsimonious, as seen above for the tarsal characters (and as could be argued for first metatarsal and distal phalangeal characters). The series of tarsal groups found in the Shanghuang fissure fillings gives strong support to the view that primitive anthropoidean-like postcranial features are retained from a primitive primate ancestor. And in fact, the discovery of an anthropoidean-like calcaneum in the Earliest Eocene *Archicebus* provides an even more striking confirmation (Ni et al. 2013). A full understanding of the locomotor adaptation of the earliest primates will require further study and more fossils. At present, the postcranial evidence for eosimiids is roughly that of primitive primates, which does not prove their anthropoidean affinities.

The Asiatic connection rooting African simiiforms in the Asiatic eosimiids is essentially based on parsimony analyses of large datasets (e.g., Marivaux et al. 2005; Beard et al. 2009; Seiffert et al. 2005a, b, 2010b; Ni et al. 2013; Fig. 36). As mentioned above concerning amphipithecids, these analyses can be misled by convergences due to similar selective forces (e.g., bunodonty linked with similar frugivory and/or hard food requirements). They also suffer recurrent difficulties concerning the independence of characters, their weighting, missing data, etc. The number of characters and taxa will never replace the absence of intermediates or make up for uncertainties due to the lack of what would be the most diagnostic characters. An example in primate phylogeny was given by Marivaux et al. (2001), in which a global parsimony analysis nested *Bugtilemur* within living cheirogaleids when this fossil lacked a real tooth comb. It thus could not be a lemuriform. Linked to the discovery of a related and more complete genus, *Bugtilemur* was subsequently recognized as a probable adapiform (Marivaux et al. 2006). In this case, the many similarities with cheirogaleid jugal dentition overweighted the phylogenetic signal issued from the tooth comb. A high number of convergences in dental details can obscure the true phylogenetic relationships. Such will be the case for all the large data sets used to uncover primate phylogeny as long as several fossil groups lack key phylogenetic information, and at the same time are separated by large gaps in the fossil record, preventing the recovery of enough intermediates in other suites of characters. It is worth noting here that such analyses can also generate trees which imply as many as six dispersals of stem anthropoideans between continents (Ni et al. 2013), which appears historically unrealistic. A morphologically parsimonious tree can be historically unlikely or even impossible.

Among the reasons to doubt an Asiatic origin of simians is lack of historical likelihood. Anthropoideans are a well-adapted, successful group in Africa and

South America, including the Caribbean islands. If they had been present in Asia, why didn't they leave some group of successful survivors behind there? Asiatic forests are the refuge of many primitive mammals, many tree shrews, and *Tarsius* found refuge in islands; they were the refuge of adapiforms until the Late Miocene, until the spread of African monkeys. Would they have been the place of the first radiation of anthropoideans without leaving any Asiatic descendants? Such a scenario seems very unlikely. If there had been a radiation of Eocene-Oligocene anthropoideans in Asia, successful enough to colonize Africa through one or multiple dispersals, they would have left descendants in Asia too, alongside the cohort of primitive Asiatic mammals. The extinction of all early Asiatic anthropoideans would be a very unlikely historical event – incongruous with the remarkable ability of all kinds of groups, including primates, to survive over long periods of time. That argument is not definitive, of course, because the past is also full of surprises. However, paleontologists should pursue a coherent account of history as much as, if not more so than, a parsimonious distribution of morphological characters considered in isolation from the geological and geographic context of the fossils to which they belong. The argument of historical likelihood, added to the lack for now of convincing evidence, should lead us to consider favorably the third scenario – that of an ancient differentiation in Africa (Fig. 36).

Afrotarsiidae

The enigmatic genus *Afrotarsius* is gaining great importance in connection with the scenarios laid out above. *A. chatrathi* is known through one mandible bearing M/1–M/3 and parts of the base of the crown of P/4 and P/3. Its molars with high pointed cusps and its trigonids with paraconid similar from M/1 to M/3 are close to those of *Tarsius*, and it was initially described as a tarsiid (Simons and Bown 1985). Unsurprisingly, some large parsimony analyses place it close to *Tarsius* (Seiffert et al. 2005a). It differs from *Tarsius* by several characters, including an M/1 larger than M/2–3 and M/3 without an elongated third lobe. Possible ties with early anthropoideans were also found (Fleagle and Kay 1987; Kay and Williams 1994), and similarities with eosimiids were noted (Ross et al. 1998; Godinot 2010). New material attributed to the new species *A. libycus* includes two upper molars and two P3/, an important addition (Jaeger et al. 2010). These teeth add to the similarities with eosimiids; however, the upper molars also show the postmetaconule-crista directly linked to the posterolabial corner of the tooth, a very primitive character which must have been retained from an ancestor more primitive than eosimiids, leading to use of the family Afrotarsiidae proposed earlier (Jaeger et al. 2010). The P3/ are very small and their labially deflected postparacrista suggests a marked insectivorous specialization.

Another putative afrotarsiid, *Afrasia djidjidae*, was recently described from the Pondaung Formation of Myanmar (Chaimanee et al. 2012). This species is known by four isolated teeth only, coming from three different localities. The type M2/ is very similar to that of *Afrotarsius libycus*, but there are some differences, and several characters of the other teeth are more reminiscent of eosimiids. The placement of *A. djidjidae* in afrotarsiids is tentative, and is associated with a cladogram showing several evidently incorrect parts (*Teilhardina* as a terminal branch of Omomyidae + Tarsiidae). The authors conclude that an afrotarsiid dispersal took place between Asia and Africa shortly before these Middle Eocene localities. Such a conclusion is hasty. Characters linked to an insectivorous specialization are difficult to disentangle from primitive characters. Much more material will be needed to understand the differences between eosimiids (*Eosimias* with long P/3 and P/4) and afrotarsiids (*Afrotarsius* with broad and short P/4). What will *Afrasia* be? The real afrotarsiids might equally well have issued from a much earlier dispersal, which would have given birth to a new adaptive radiation of stem simians or simians. This would increase and broaden the spectrum of adaptations in the two parallel radiations of African simiiforms + stem simiiforms, and Asiatic tarsiiforms. Earlier and more complete fossils are needed to clarify these hypotheses.

Further Important Phylogenetic Questions, and a Provisional Conclusion

A number of important issues are associated with the understanding of fragmentary fossils. Such finds are tantalizing, because the implications of their analysis might be far-reaching; but they are also frustrating, because the associated discussion is very technical and the results are bound to remain tentative, due to such specimens' incompleteness or isolation from other, better understood fossils. First in the list is *Altiatlasius koulchii*, from the Late Paleocene Adrar Mgorn locality in Morocco. As the only Paleocene primate known to date, it is very important. Yet it is documented only by eight isolated teeth. The upper molars show extremely primitive characters (stylar shelf), but also some characters – such as a slight bunodonty and a continuous lingual cingulum on M2/ – which would make it derived in comparison with *Donrussellia* and *Teilhardina*, and possibly a sister group of the African simian radiation (Sigé et al. 1990; Godinot 1994). A recent phylogenetic analysis, based on a very large data set, positions *Altiatlasius* as the earliest member of the stem anthropoideans (Ni et al. 2013). Such far-reaching conclusion needs to be strengthened by more complete fossil evidence, especially since some early African strepsirhines appear to have been very bunodont (Tabuce et al. 2009). Yet this unique fossil is an important signal, because it might indeed document stem haplorhines or stem anthropoideans.

Two fossils from the Middle Eocene of Namibia are the first Eocene primates named from Sub-Saharan Africa. They are a maxilla with M2/ and M3/, which is the type of *Namaia bogenfelsi* (Pickford et al. 2008), and a smaller P/4, which is also referred to it. The upper maxilla belongs to a primitive primate that has overall similarity with European anchomomyin adapiforms, but also significant differences. Its lingual half is anteroposteriorly more reduced than in anchomomyins, and it bears a well-formed cuspidate metaconule, such as is never seen in anchomomyins and extremely rare in adapiforms. The P/4 is unlike that of any adapiform and might suggest simian affinities, although it has a smaller size than the maxilla and could pertain to a different taxon. More material is needed to determine the number and the affinities of the primates present in this locality.

Finally, to give a last example, the enigmatic *Nosmips* was described from the BQ-2 locality of the Fayum, Egypt (earliest Late Eocene). Its surprising characters led to the name *N. aenigmaticus* (Seiffert et al. 2010b). Its lower molars have lost their paraconids, but their trigonids nevertheless increase in length from M/3 to M/1. Inasmuch as their trigonids are much higher than their talonids, they are more reminiscent of the lower molars of prosimians than of simians; however, the anteroposterior cristid obliqua and the short M/3 talonid look simian-like (primitive?). One upper molar appears very simple, with an incomplete lingual cingulum and no hypocone. A posterior waisting gives it a primitive stamp. This species is specialized through its premolars, with both P3/ and P/3 anteroposteriorly long and high. The lower P/3 has a voluminous metaconid and an anteriorly extended and curved protocristid, which presumably had a honing function with a large upper canine. The P/4 is lower, more molarized, and morphologically intermediate with the lower molars. Parsimony analyses of 361 morphological characters give, depending on different assumptions, very different results: stem anthropoidean, stem lemuriform, or adapiform status (Seiffert et al. 2010b). This example once more demonstrates the unability of such large analyses to uncover a good phylogenetic signal in the presence of overlapping dental similarities with species belonging to different infraorders. Lower molar morphology, as well as long, highly molarized, and specialized P/3–4 are more suggestive of stem lemuriform affinities, which represent the most rational assumption. However, other affinities are also possible. In any case, this genus reveals one more ancient lineage in Africa, which, along with the genera cited above, highlights the fact that our knowledge of early African fossil primates remains very incomplete.

To conclude our discussion of primate phylogeny: the last decade has witnessed a number of surprising discoveries, which show that our knowledge of the Paleogene primate fossil record is still only very partial. The European and North American radiations are relatively well circumscribed, with only a few open questions for now: Where does *Rooneyia* come from? Where do the adapines come from? The African and Asiatic records are much less completely known and have been the subject of the greatest surprises: *Afradapis*, an adapiform convergent with catarrhines in its anterior dentition; the azibiids, tiny strepsirhines with upper molars convergent on bunodont simians; *Bugtilemur*, an adapiform convergent with living cheirogaleids; *Nosmips*, an enigmatic form for which there is hesitation between strepsirhine and simian! All of these findings call for caution concerning the interpretation of dental characters for fragmentary fossils pertaining to distantly related groups. Nevertheless, great advances have been made. Among them, the discovery of Eocene lemuriforms and stem lemuriforms in Africa is decisive for our understanding of the origin of this living infraorder. It supersedes all previous, speculative efforts to root these groups near different genera of adapiforms. The discovery of *Teilhardina asiatica* shows that intercontinental dispersals can be precisely followed also from Asia to other continents (this should be possible for the putative anthropoidean ancestors as well, then!).

A broad and monophyletic Asiatic family of amphipithecids is also a step forward, even if their origin and phylogenetic place remain controversial. *Archicebus* bears directly on concepts of the earliest primate diversification. A complete fossil, such as the skeleton of *Darwinius masillae*, should produce further information on rarely found parts of the primate skeleton. Ongoing functional and phylogenetic study of hands and feet, tarsals, and phalanges should continue to contribute significantly to the understanding of primate phylogeny. This field is very active, and still has a lot to discover.

Conclusion: Evolution in Paleogene Primates

The fossiliferous part of the Paleogene, Eocene plus Oligocene, spans roughly 30 My. Over the course of this time interval, it is possible to observe major steps in primate evolution. These steps can best be studied in the regions where the fossil record is the richest, the North American and the European Eocene, even if the fossil groups found there became extinct without leaving descendants among the living groups. The well-known Eocene radiations started with the arrival of one genus each, e.g., *Teilhardina*, *Cantius*, or *Donrussellia*. From this genus a diversification took place, accompanied by increases in size in some of the lineages. When the record is dense enough, dental morphology allows an almost direct reading of lineages. More often the record is not as good as that, but the relevant evolutionary trends are so general that reading the polarity of dental traits is usually straightforward. Only the large number of convergences can obscure the reconstruction of phylogeny, as seen for example in omomyines. These dental trends raise interesting questions. Why does the paraconid become reduced? And, why does a hypocone develop at the same place in so many different lineages? Hypocones occur at roughly the same size, suggesting the existence of a developmental constraint, which it would be important to understand. Incidentally, this question brings up the difficult issue of character coding: should characters that we know not to be homologous be coded in the same way? For example, the hypocone in omomyines is not homologous with that of microchoerids, and the latter is not homologous with the hypocones which develop in several lineages of adapiforms, etc. This information is most often ignored in cladistic analyses. Reduction of some antemolar teeth is also a common trend, which is sometimes related to a size increase in the anterior incisor and “compression” of teeth between it and P/4, but at other times occurs without evident dental specialization and is then probably related to muzzle shortening.

Changes in molar morphology are related to changes in diet, and diet is highly correlated with size. Small species weighing below 500 g are usually predominantly insectivorous, whereas species above 500 g become more frugivorous or folivorous (Kay 1975). There are many mixed feeders among living and fossil primates, and most often their protein intake comes from insects for the small species, and from leaves for the large ones. The broad picture is that the Late Paleocene–Earliest Eocene primates were mainly insectivorous and more or less mixed feeders, with *Cantius* already quite frugivorous. By the end of the Early Eocene, some larger species had evolved more specialized dentitions. For example, *Notharctus* had acquired molars with increased shearing crests, forming the labial W on upper molars that we see in living folivores. By the Middle and Late Eocene, other genera, such as *Caenopithecus* and *Afradapis*, had developed similar morphologies, and lower molar shearing crests had strongly increased in the adapines. More bunodont dentitions evolved many times. Extreme degrees of bunodonty, adapted to frugivory and/or the processing of hard food, developed in Asiatic amphipithecids and in African parapithecids and propliopithecids. Some fossils developed dental specializations unknown in living primates. *Necrolemur, Microchoerus*, the tarkadectines, and other genera developed highly crenulated teeth, probably adapted to some kind of resistant food. The very small azibiids are astonishing: how could such tiny species have become so extremely bunodont? Paleogene primates broaden the spectrum of dental and dietary adaptations of the order.

Alongside the Paleogene primate diversifications, locomotor adaptations evolved as well. Quite a number of the Early Eocene prosimians are reconstructed as “cheirogaleid-like” –which indicates a mixture of quadrupedalism, climbing, and leaping. However, there is debate about the ancestral morphotype of locomotor adaptation, with or without much leaping (as mentioned above in the anthropoidean origin part). In some groups, it seems that locomotion changed essentially through a more or less marked increase in leaping propensities (weak in omomyids, more pronounced in the larger notharctines). It has recently been suggested that some tarsal lengthening might be a compensatory effect in grasping foot postures, and not an indication of leaping propensities (Moyà-Solà et al. 2012). This hypothesis needs to be closely examined. Only during the Middle and Late Eocene did one lineage, the *Necrolemur–Microchoerus* group, increase its leaping specialization to a degree similar to the living VCL, which move through the forest by long leaps and adopt vertically clinging postures at rest. However, we know that very different adaptations developed in some other groups. Quadrupedalism and climbing (slow climbing?) are present in amphipithecids and adapids. The Late Eocene–Oligocene anthropoideans also show quadrupedalism and climbing, with more leaping propensities in parapithecids. A variety of adaptations developed among European adapines, including different degrees of quadrupedalism and climbing. To date, there is no clear evidence of ateline-like forelimb suspension in Paleogene primates.

Important aspects of the evolution of sense organs and the brain can be traced as well in Paleogene primates. Most characteristic since their origin are the large eyes of primates. It has been known for a long time that nocturnal primates can be distinguished from diurnal ones by their possession of relatively larger eyes, as mentioned above for many fossil groups. A deeper understanding of visual evolution became possible once size measurements of the optic foramen were used to infer the degree of retinal summation and visual acuity in fossils (Kay and Kirk 2000). Visual characteristics are typically shared by large groups; however, fossils also reveal multiple changes. Most omomyiforms are reconstructed as nocturnal, yet *Teilhardina asiatica* was found to have small orbits, like diurnal species. Among cercamoniines, *Europolemur* was found to have small orbits, like diurnal forms (such as the adapines and *Notharctus*); however, *Pronycticebus* and *Darwinius* had orbits indicating nocturnal habits. The anthropoidean *Biretia megalopsis* exhibits nocturnal-sized orbits as well. All of these examples reveal that important behavioral shifts took place in the Eocene. There will be more to learn about this crucial aspect of primate behavior. *Adapis* is found to have a strangely high degree of retinal summation. Why? No adapiform or omomyiform studied by Kay and Kirk (2000) showed optic foramen dimensions as large as those in extant diurnal anthropoideans, whose visual acuity (inferred for diurnal ancestral haplorhines because *Tarsius* has a fovea) is extremely high. Finding intermediate values in some fossils would be crucial.

The use of CT-scan techniques allows access to quantitative parameters of the bony labyrinth. Two kinds of sensory capacities can be extracted. Cochlear labyrinth volume is correlated with hearing abilities (Kirk and Gosselin-Ildari 2009). Ongoing studies have already yielded results. For instance, assessments of high and low frequency limits of hearing show that *Necrolemur antiquus* had better high frequency hearing than three other fossils, similar to that of the living *Galago senegalensis*, whereas *Adapis* had capacities similar to those of the living *Perodicticus* (Ludeman et al. 2013). The size and morphology of the semi-circular canals also give interesting information. The first studies interpreted relative semi-circular canal size, estimated via the radius of curvature, to correlate directly with relative degrees of agility among species (Spoor et al. 2007; Silcox et al. 2009). This way, adapines were found to be less agile than *Smilodectes* and *Notharctus*, and *Microchoerus* faster and more agile than the latter, which was in line with the modes of locomotion of these taxa as reconstructed from postcranials. However, further studies have put these results in question, because it appears that it is the orthogonality of the semi-circular canals, more so than their radius of curvature, that is related to the speed of head movements (Malinzak et al. 2012).

The size of the infraorbital foramen is highly correlated with the size of the infraorbital nerve, which transmits signals from the mechanoreceptors of the orofacial region. It had been assumed that the infraorbital foramen, which is smaller in primates than in most non-primate mammals, was larger in strepsirhines than in haplorhines (Kay and Cartmill 1977). This size difference within mammals was interpreted to roughly correlate with vibrissae number, and was used in this way in several studies to support a haplorhine status for fossils showing a relatively small infraorbital foramen (e.g., Beard and Wang 2004), or conversely, to infer a strepsirhine and probably nocturnal habit for others (e.g., Tabuce et al. 2009). However, a much larger study of primates and other mammals has failed to confirm such differences in terms of vibrissae counts. Haplorhines and strepsirhines appear not to differ in infraorbital foramen area, nor in macrovibrissae counts, but to differ in microvibrissae counts – and in the opposite direction from what was expected: it is haplorhines that have more (Muchlinski 2010a). Information about the mechanoreceptors of the oral region can be gained from the relative size of the infraorbital foramen; however, for now the implications appear to be primarily ecological, with frugivores having larger foramina and more vibrissae than insectivorous and folivorous primates (Muchlinski 2010b). This approach already fits better with the relatively small infraorbital foramen found in *Adapis* (Gingerich and Martin 1981).

Important aspects of brain evolution in primates are obtained through the study of endocranial casts. The latter provide not only quantitative information – that is, absolute brain measurements – but also qualitative information, because most neocortical sulci delimit functional or somatotopic areas. If these sulci can be confidently homologized, behavioral and sensory specializations can be inferred. The oldest primate endocast is that of Early Eocene *Tetonius homunculus*, known since its preliminary description by Cope. Taking into account the modest deformation of the skull, Radinsky (1967) proposed a reconstruction with a width–length index of 1.07. He noted that the frontal lobes were smaller relative to the rest of the cerebrum than in any extant primate. Only a shallow Sylvian fissure can be recognized, but this is not an indication of primitiveness because similar-sized living prosimians have similarly smooth brains. The olfactory bulbs of *Tetonius* are relatively larger than in any living primate. As noted by Radinsky, these primitive characters notwithstanding, compared to contemporaneous ungulates *Tetonius* had a very advanced brain with enlarged temporal and occipital lobes and reduced olfactory bulbs. A natural endocast of the Middle Eocene *Smilodectes gracilis* was described in detail and beautifully illustrated by Gazin (1965). It is also very smooth, shows only a shallow sulcus lateralis not far from the midline of the brain, and, surprisingly, does not feature a recognizable Sylvian sulcus. Gazin noted the extended neopallium, which is relatively greater than in any other Middle Eocene mammal for which such information is available. He also noted a close similarity with the brain of extant *Eulemur*, insofar as the cerebellum is not overlapped by the cerebrum. The cerebellum of *Smilodectes* is short and narrow in comparison with its width, and the vermis and lateral lobes are prominently developed. Both *Tetonius* and *Smilodectes*, an Early and a Middle Eocene primate, show expanded temporal and occipital areas, suggesting well-developed acoustic and auditory capacities, respectively. Gazin (1965) rightly correlated the enlarged visual cortex area with the large, forward-facing orbits of *Smilodectes*. Recent analyses show that binocular vision is correlated with the expansion of visual brain structures, and consequently with expansion of overall brain size, in primates (Barton 2004). More generally, advances in visual capacities have been correlated with increases in brain size in primate evolution (Kirk 2006).

The endocast of the Late Eocene *Adapis* was the first to be described (Neumayer 1906) and has been mentioned many times by many authors. A better preserved endocast was described by Gingerich and Martin (1981). Both endocasts exhibit a true Sylvian sulcus, a universal trait in extant primates but lacking in *Smilodectes*. Among other possible differences between notharctine and adapine brains are the large and pedunculate olfactory bulbs in *Adapis*, relative to which those of *Smilodectes* are small (Radinsky 1970). This distinction aside, both appear primitive in comparison with living primates. Attempts to quantify encephalization through a quotient relating brain size to body size have led to some controversy, mainly due to difficulties in estimating body size, i.e., body weight, in fossil primates (Radinsky 1977; Jerison 1979). In any case, there is consensus that both *Adapis* and *Smilodectes* had smaller brains in relation to body size than do living strepsirhines. On the other hand, the Late Eocene *Necrolemur* and the younger *Rooneyia* are found to have encephalization levels similar to those of living prosimians. The endocast of the Early Oligocene *Aegyptopithecus* was mentioned above. It shows a central sulcus as in living anthropoideans, and appears advanced over strepsirhines in having relatively more visual cortex and smaller olfactory bulbs. However, in quantitative terms it is smaller than in any living anthropoidean, having an encephalization level similar to some prosimians or even below (Radinsky 1973; Simons 1993; Simons et al. 2007). The endocast of *Parapithecus (Simonsius) grangeri* has been extracted by CT-scanning techniques (Bush et al. 2004). It also appears smaller relative to body size than in living anthropoideans. Its olfactory bulbs are at the lower limit of those of strepsirhines.

A last source of information relating to behavior is provided by sexual dimorphism, which was long suspected in *Notharctus* (Gregory 1920; Gingerich 1979) and convincingly shown in one assemblage of *N. venticolus* (Krishtalka et al. 1990). Evidenced through canine size and shape, it was shown subsequently to affect skull shape in *N. tenebrosus* and *Smilodectes gracilis* (Alexander 1994; Alexander and Burger 2001). Sexual dimorphism is suspected in *Cantius torresi* based on the size difference between two canines, and size differences in mandibular depths in six specimens (Gingerich 1995). It thus seems to be a characteristic of notharctines. Its presence in adapines is unknown, due to the lack of homogeneous assemblages (the only available one, for the large *Magnadapis* from Euzet, does not present any dimorphism; Gingerich 1977b). A marked sexual dimorphism has been found, however, in the latest Eocene adapid *Aframonius* (Simons et al. 1995). An extremely high dimorphism, including body size dimorphism, is found in propliopithecids. The conclusion that a marked sexual dimorphism is also found in the smaller *Proteopithecus* and *Catopithecus* modified the view, based on observations in living primates, that sexual dimorphism is highly correlated with body size. It appears to be a characteristic of simiiforms, acquired early and probably linked to their diurnal habits (Simons et al. 1999). Sexual dimorphism is an indication of distinctive social structures, usually interpreted as indicating life in polygynous groups, high male-male competition when it is pronounced, and single male dominance when it is highly pronounced. However, this is a complex question; precise social structures cannot be inferred, especially for low levels of dimorphism. What is important is that social evolution along these lines also happened in some adapiforms in the Early Eocene, and was advanced in Late Eocene anthropoideans. Social life is an important predictor of increased brain size, which is believed to have played a major role in later simian brain evolution. In sum, not only was binocularity present in the earliest primates; higher visual acuity and social factors as well were already present in Paleogene primates, enabling later brain developments.

When the fossil record is good, each primate species can be studied for its adaptations, and faunistic aspects can also be analyzed. In the big picture, primate radiations are constrained by climatic and biogeographic factors, as laid out in the Introduction to this chapter. Within these radiations, interesting primate faunal successions are known, which are more or less understood. For example, the replacement of cercamoniines by adapines in Europe around MP13–MP14 (Figure 7) is due to a dispersal. But why did mid-sized or large cercamoniines disappear? Were the more folivorous adapids better adapted to changing environments? In the Late Eocene of Africa, in the Fayum, adapids were the large-sized primates, whereas anthropoideans and lemuriforms of the same localities were smaller. Adapids disappeared by the end of the Eocene, and anthropoideans became progressively larger during the Early Oligocene. Were these developments also related to environmental changes? A much better-studied example, made possible by a more extensive geological and paleontological record, is the Early–Middle Eocene transition in several of the Rocky Mountain basins of Wyoming and adjacent states, from anaptomorphine dominance in the Wasatchian to omomyine dominance in the Bridgerian. Furthermore, the diversification of the omomyines in the Bridgerian is striking. This raises two interesting issues. First, continued research in basin margin areas (southwestern Bighorn Basin, northeastern edge of the Green River Basin), has led to the realization that anaptomorphines remain in fact relatively diverse in these marginal areas (e.g., Bown 1979; Muldoon and Gunnell 2002). The shift from anaptomorphine to omomyine dominance in lowland habitats probably was an ecological replacement, with anaptomorphines being pushed toward upland refugia when omomyines had found favorable habitats and reached dominance in basin areas. The second issue relates to the rapid diversification of the omomyines: did basin margins provide heterogeneous habitats favorable to the rise of evolutionary innovations? Answering such a question requires detailed paleoenvironmental studies. What is remarkable in the Rocky Mountain Eocene record is that it provides, in the Bighorn and in other basins, some of the best examples of detailed lineages – phylogeny followed through time as close as one can get, and also, at a more regional scale, fine-grained aspects of replacements, refugia, and their possible role in evolution. In such locations, the study of fossil primates can contribute to the detailed elucidation of the mechanisms of evolution.

Acknowledgments Several illustrations were kindly given by K. Christopher Beard, after their preparation by Mark Klinger, and by Russell L. Ciochon, Jens L. Franzen, and Philip D. Gingerich. The casts which allowed new photographs were given or exchanged along the years by K. C. Beard, T. M. Bown, H. H. Covert, E. Delson, S. Ducrocq, J.-L. Hartenberger, L. Marivaux, P. Robinson, K. D. Rose, D. E. Russell, the late D. E. Savage, E. R. Seiffert, E. L. Simons, and M. Takai. Informations on stratigraphy and age of localities were shared by Gregg Gunnell and Laurent Marivaux. White-coating and photographs of casts were done by Lilian Cazes, and all the illustrations were mounted by Alexandre Lethiers, who also draw Figs. 1, 7 and 36. Their help is gratefully acknowledged.

Abstract

Hominoids, or taxa identified as hominoids, are known from much of Africa, Asia, and Europe since the Late Oligocene. The earliest such taxa, from Africa, resemble extant hominoids but share with them mainly primitive characters. Middle and Late Miocene taxa are clearly hominoids, and by the end of the Middle Miocene, most can be attributed to either the pongine (*Pongo*) or hominine (African ape and human) clade. Interestingly, there is no definitive fossil record of the hylobatid clade (gibbons and siamangs), though there have been some proposed candidates. Miocene hominoids experienced a series of dispersals among Africa, Europe, and Asia that mirror those experienced by many other contemporaneous land mammals. These intercontinental movements were made possible by the appearance of land bridges, changes in regional and global climatic conditions, and evolutionary innovations. Most of the attributes that define the hominids evolved in the expansive subtropical zone that was much of Eurasia. Hominines and pongines diverge from each other in Eurasia, and the final Miocene dispersal brings the hominine clade to Africa and the pongine clade to Southeast Asia. Having moved south with the retreating subtropics, hominines and pongines finally diverge in situ into their individual extant lineages.

Introduction

Nonhuman fossil hominoids represent a highly diverse and successful radiation of catarrhine primates known from many localities ranging geographically from Namibia in the south, Germany in the north, Spain in the west, and Thailand in the east, and temporally from Oligocene deposits in Kenya to the Pleistocene of China (Fig. 1). More than 50 genera of nonhuman hominoids are known (Table 1), probably a small percentage of the total number that have existed. Given the focus of these volumes on ape and especially human evolution, this survey of the fossil record of Miocene hominoids will concentrate on taxa that most or all researchers agree are hominoid and in particular on taxa that are most informative on the pattern and biogeography of modern hominoid origins.

What Is a Hominoid?

Most of the fossil taxa attributed to the Hominoidea or the Hominidea (new rank, Table 2) in this chapter are known to share derived characters with living hominoids. Because the two living families of the Hominoidea, Hylobatidae and Hominidae, share characters that are either absent or ambiguous in their development in *Proconsul* and other Early Miocene taxa, a new rank is proposed here to express the monophyly of the Hominoidea and the monophyly of catarrhines more closely related to extant hominoids than to any other catarrhine. The magnafamily Hominidea (a rank proposed in a work on perissodactyl evolution; Schoch 1986)

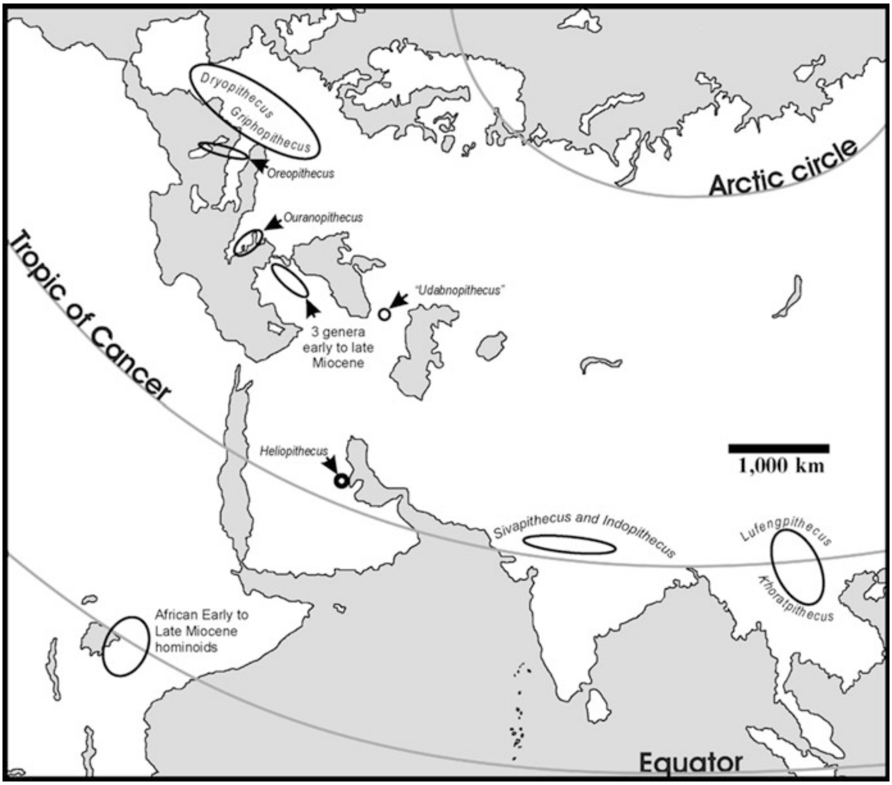

Fig. 1 *Map* showing the location of the Miocene taxa discussed in this chapter. Namibia (southern Africa), from which *Otavipithecus* was recovered, is not shown

unites Proconsuloidea with Hominoidea to the exclusion of other catarrhines. This differs from Harrison's use of the term proconsuloid that he sees as referring to the sister taxon to cercopithecoids and hominoids (Harrison 2002).

A few taxa are included in this review if they are too poorly known to preserve unambiguous hominoid synapomorphies but closely resemble other better-known fossil hominoids. In general, fossil and living hominoids retain a primitive catarrhine dental morphology. This makes it difficult to assign many fossil taxa to the Hominoidea since a large number are known only from teeth and small portions of jaws. Dentally, the most primitive Hominidea differ only subtly from extinct primitive catarrhines (propliopithecoids and pliopithecoids) (Fig. 2, node 1). Propliopithecoids (*Propliopithecus*, *Aegyptopithecus*) are usually smaller and have much more strongly developed molar cingula, higher cusped premolars, and smaller incisors and canines (Begun et al. 1997; Rasmussen 2002; see chapter "▶ Potential Hominoid Ancestors for Hominidae," Vol. 3). Pliopithecoids (*Pliopithecus*, *Anapithecus*) are also generally smaller and have molars with more strongly expressed cingula, more mesial protoconids, and relatively small anterior teeth (Begun 2002). However, the differences between Late Miocene hominids and

Oligo. Oligocene, *e M* Early Miocene, *e-m M* early Middle Miocene, *m M* Middle Miocene, *m-l M* Middle-Late Miocene, *l M* Late Miocene, *K*/*U* Kenya and Uganda, *Pl.* Pleistocene, *M* Myanmar (Burma), *Th.* Thailand

[a] These 50 genera include taxa from the Oligocene and Early Miocene that share mainly primitive characters with the Hominoidea but that appear to be derived relative to pliopithecoids and propliopithecoids. Please see text for further discussion

[b] Material briefly described by part representation. Dental = mainly isolated teeth; Dental, mandible, maxilla = known only from these parts; Craniodental fragments = teeth and few cranial fragments; Craniodental = larger samples of more informative cranial material; Cranial, dental, postcrania = good samples from each region; ( ) + = very good representation of parts in parentheses

[c] Unclear attribution to Hominoidea

[d] Large taxon possibly distinct from *Proconsul*

[e] *Proconsul* from the Rusinga and Mfangano localities in Kenya is likely to be distinct at the genus level from the *Proconsul* type material

[f] Middle Miocene samples attributed to this taxon are more fragmentary and may not be congeneric

[g] The *Neopithecus brancoi* type is an isolated M_3 that some attribute to the Pliopithecoidea while other to *Dryopithecus* (Begun and Kordos 1993). I regard this as a nomen dubium

[h] "*Ardipithecus kadabba*." The type of the genus, *Ardipithecus ramidus*, is younger and shares derived characters with australopithecines not present in *A. kadabba*, making *Ardipithecus* in my opinion paraphyletic

[a] Includes *Pierolapithecus* and *Anoiapithecus*
[b] Includes two genera

Late Miocene pliopithecoids are more marked than between Early Miocene Hominidea and pliopithecoids, making defining features less than clear-cut. Cranially Hominidea have a completely ossified tubular ectotympanic, which distinguishes them from both propliopithecoids and pliopithecoids but not from cercopithecoids. *Saadanius* shares a completely ossified tubular ectotympanic with crown catarrhines (Hominidea and Cercopithecidea). This has led some

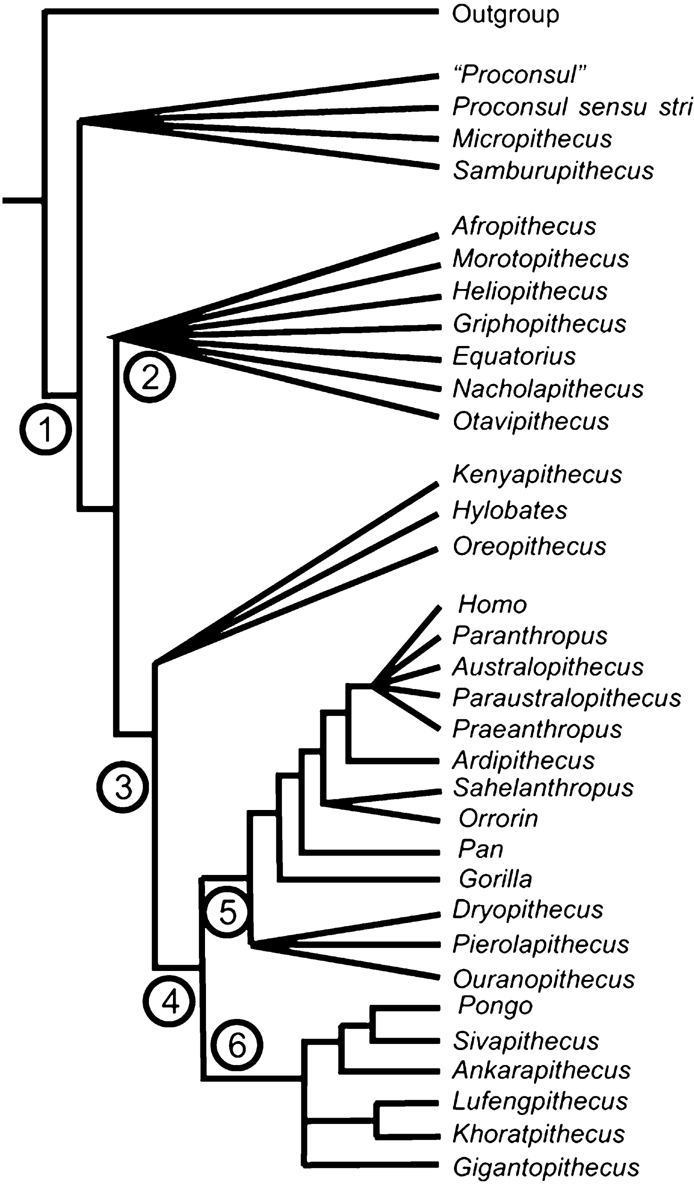

Fig. 2 Cladogram depicting the relations among most Miocene Hominidea discussed in this chapter. The cladogram is resolved only at the level of the family in many cases, except within the Hominidae, where most clades are resolved. *Numbered nodes* refer to characters or suites of characters that serve to define clades. They are not intended as comprehensive lists of synapomorphies. For clarity, *Hispanopithecus* and *Rudapithecus*, together a sister clade to *Dryopithecus*, are not shown. *Node 1*: reduced cingula, delayed life history (M1 emergence), incipient separation of the trochlea and capitulum, increased hip and wrist mobility, powerful grasping, coccyx (no tail). *Node 2*: thick enamel, increased premaxillary robusticity, further reduction in cingula,

researchers to conclude that *Saadanius* represents the common ancestor of crown catarrhines and that its age (28–29 Ma) must be the oldest possible age of divergence of the Old World Monkeys and apes (Zalmout et al. 2010). This conclusion, however, does not follow from the evidence. While *Saadanius* may preserve characters that approximate or even duplicate those of the last common ancestor of Old World Monkeys and apes, its geological age is irrelevant to the question of the age of divergence of these two lineages Pozzi et al. 2011. We have no idea how long *Saadanius* or its relatives lived before the 28–29 Ma specimens that were discovered. The taxon could be millions of years older, and in fact, we have this very problem with the pliopithecoids. Most if not all pliopithecoids are known from Eurasia, and they range in age between about 18 and 9 Ma, but they lack synapomorphies of the crown catarrhini. Using the same logic applied to the interpretation of *Saadanius*, the age of the pliopithecoids would indicate a divergence date of not more than 18 Ma for Old World Monkeys and apes, or even 9 Ma, if the last appearance of the Pliopithecoidea is taken as the divergence date. Clearly this lineage is millions of years older than the age of the oldest fossils we have of the group, and these oldest specimens remain to be discovered. Pliopithecoids represent what we call a ghost lineage, with a huge gap between their origin and first appearance in the fossil record. The same can be said of gibbons or for that matter, African apes. While we have convincing evidence of the *Pongo* clade at 12 Ma or so and the human lineage at 7 Ma or so, there is no evidence of *Pan* or *Gorilla* at all, with the possible exception of teeth attributed to *Pan* from a 500 Ka site in Kenya (McBrearty et al. 2005), many millions of years after their divergence from humans. The same is very probably true of *Saadanius*. When coupled with the convincing genetic data suggesting a divergence date of at least 30 Ma (Disotell et al. 2011), the claims of a more recent divergence based on *Saadanius* do not hold up.

Unfortunately, few Miocene Hominidea fossils preserve the portion of the temporal bone that includes the ectotympanic, so in many cases, we simply do not know if this key crown catarrhine synapomorphy was present or not. In addition, hylobatids, cranially the most primitive extant hominoid, share many features found in short-faced Old and New World monkeys, again making it difficult to tease out synapomorphies. Hominoids show a tendency to expand the length and superoinferior thickness or robusticity of the premaxilla, with increasing overlap with the palatine process of the maxilla over time, but once again this is not present in hylobatids or in early well-preserved specimens of *Proconsul*, for example (Begun 1994a). Only one specimen of Early Miocene Hominidea is

Fig. 2 (continued) increase in P_4 talonid height, possible increases in forelimb-dominated positional behaviors. *Node 3*: further “hominoidization” of the elbow. The position of *Kenyapithecus* is extremely unclear. Without this taxon, *node 3* features the numerous characters of the hominoid trunk and limbs related to suspensory positional behavior. *Node 4*: Hominidae (see text). *Node 5*: Homininae (see text). Lack of resolution of the hominini reflects continuing debate on relations among Pliocene taxa that is beyond the scope of this chapter. *Pierolapithecus* may be a stem hominid or stem hominine, as depicted here. *Node 6*: Ponginae (see text). *Gigantopithecus* is probably a pongine but the relations to other pongines are unclear complete enough to say much about the brain, and there are no unambiguous synapomorphies linking it to hominoids. The brain of *Proconsul* is similar relative to body size to both hylobatids and papionins, the Old World monkeys with the largest brains, and the sulcal pattern, while debatable, lacks most if not all hominoid features (Falk 1983; Begun and Kordos 2004). Like hylobatids, most cercopithecoids, and most mammals other than hominids, a portion of the brain of *Proconsul* occupied a large the subarcuate fossa of the temporal bone. Cranial and dental evidence also suggests that *Proconsul* was moderately delayed in terms of life history, another similarity with extant hominoids (Kelley 1997, 2004).

Postcranially, *Proconsul* more clearly represents the ancestral hominoid morphotype, though this too is the subject of debate. *Proconsul* fossils exhibit hominoid attributes of the elbow, wrist, vertebral column, hip joint, and foot, though in all cases these are subtle and disputed (Beard et al. 1986; Rose 1983, 1988, 1992, 1994, 1997; Ward et al. 1991; Ward 1993, 1997a; Begun et al. 1994; but see Harrison 2002, 1987). *Proconsul* has a suite of characters consistent with the hypothetical ancestral morphotype of the hominoids, and it should not be surprising that these are poorly developed at first, only to become more defined as hominoids evolve. In comparison with the hominoid outgroup (cercopithecoids), we can expect the earliest hominoids to show subtle indications of increased orthogrady, positional behaviors with increased limb flexibility and enhanced grasping capabilities and no tail, generalized (primitive) dentition, encephalization at the high end of extant cercopithecoids of comparable body mass, and life history variables closer to extant hominoids than to extant cercopithecoids (see chapter "▶ Estimation of Basic Life History Data of Fossil Hominoids," Vol. 1). *Proconsul* has all of these attributes.

If these are the features that define the Hominidea, which taxa among Miocene fossil catarrhines are not Hominidea? Even the earliest cercopithecoids (victoriapithecids) are easily distinguished from hominoids (Benefit and McCrossin 2002). Pliopithecoids, often grouped with the "apes," are even more distantly related. They are clearly stem catarrhines lacking synapomorphies of all crown catarrhines including *Proconsul* and *Victoriapithecus* (Begun 2002). The most informative among these synapomorphies are the tubular ectotympanic and the entepicondylar groove (often referred to as the absence of an entepicondylar foramen). In the following sections, I will summarize current knowledge of the Miocene Hominidea, focusing on well-known taxa that serve to illustrate important events in hominoid evolutionary history (Fig. 2).

Origins of Hominidea

It is likely that hominoids originated in Africa from an ancestor that, if known, would be grouped among the Pliopithecoidea. Pliopithecoids, currently known only from Eurasia, share with all catarrhines the same dental formula and possibly with crown catarrhines a reduction of the midface, subtle features of the molar dentition, and a partial ossification of the ectotympanic tube (Begun 2002). The presence of pliopithecoids in Africa is suggestive but remains to be demonstrated

(Andrews 1978; Begun 2002; Rossie and MacLatchy 2006). The oldest and most primitive catarrhine that can lay claim to hominoid status however is African (Table 1). *Kamoyapithecus*, from the Oligocene of Kenya, differs from other Oligocene catarrhines (propliopithecoids) in being larger and having canines and premolars that more closely resemble Miocene hominoids than Oligo-Miocene non-hominoids (Leakey et al. 1995). Only craniodental material of *Kamoyapithecus* has been described, and it is so primitive as to make attribution to the Hominoidea difficult. Though it would fail to fall among the Hominoidea in a quantitative cladistic analysis due to its fragmentary preservation and primitive morphology, it makes in my view a good Hominidean precursor. Stevens et al. (2013) report on a new taxon, *Rukwapithecus*, from 25.2 Ma sediments in Tanzania. The specimen consists of a nicely preserved right mandible of a juvenile individual with the p4 to m2 erupted and the m3 still in its crypt. Unfortunately, and this is frustratingly common, no teeth can be directly compared between *Kamoyapithecus* and *Rukwapithecus*, as the latter is known only from lower postcanine teeth, none of which are known for *Kamoyapithecus*. We cannot rule out the possibility that *Rukwapithecus* is a junior subjective synonym of *Kamoyapithecus* and only more fossils will help to resolve this question. On the other hand, Stevens et al. (2013) characterize *Rukwapithecus* as the oldest known fossil ape and tentatively classify it among the nyanzapithecines, a poorly defined and possibly paraphyletic taxon that includes *Rangwapithecus* and *Nyanzapithecus*. These taxa do have some unusual features of the lower dentition, but given the tiny sample size, it is premature in my opinion to consider the "nyanzapithecines" and *Rukwapithecus* in particular to be more closely related to Middle Miocene and later hominoids than *Proconsul*, as Stevens et al. (2013) suggest. Koufos (see chapter "▶ Potential Hominoid Ancestors for Hominidae," Vol. 3) covers some of the same fossils as covered here, with some differences in interpretation. Senut (chapter "▶ The Miocene Hominoids and the Earliest Putative Hominids," Vol. 3) proposes some radically different interpretations of some of the material presented here, in addition to interpretations of the latest Miocene and the Pliocene hominin fossil record that differ from any other published interpretation of which I am aware. Both authors and Schwartz (chapter "▶ Defining Hominidae," Vol. 3) employ the term hominid to mean humans and taxa more closely related to humans than to any other taxon. The vast majority of researchers employ the term as it is used here, referring to great apes and humans and all fossil taxa more closely related to these crown taxa than to hylobatids.

Proconsuloidea

Proconsul

The superfamily Proconsuloidea, as defined by Harrison (2002), includes many mainly Early Miocene taxa. As noted, in this chapter, a number of taxa from this group are interpreted to represent primitive Hominidea or hominoids. A hypothetical ancestral morphotype for the Hominidea is given in Fig. 2 (node 1). Node 1

Plate 1 *Proconsul* from the Tinderet localities of Songhor and Koru. The two *P. africanus* specimens to the *left* are male as is the *P. major* mandible to the *right*. From *left* to *right*, M 14084 (*P. africanus* type), KNM-SO 1112, M 16648. Not to scale. *P. major* is much larger

represents the bifurcation of *Proconsul* from hominoids with more apparent synapomorphies to living hominoids. *Proconsul* as described here is based mainly on the sample from Rusinga Island and Mfangano, two localities that are close together on Lake Victoria, western Kenya. These sites are often referred to as the Kisingiri *Proconsul* localities, as opposed to the Tinderet localities of Songhor, Koru, Legetet, and Chamtwara, among others. The Kisingiri include the species *Proconsul heseloni* (Walker et al. 1993) and *Proconsul nyanzae* (Le Gros Clark and Leakey 1950). The type specimen of *Proconsul africanus* (Hopwood 1933) is from Koru, and the type of *Proconsul major* (Le Gros Clark and Leakey 1950) is from Songhor, both of which are Tinderet localities (Drake et al. 1988). Historically the Tinderet localities have been considered to be older than the Kisingiri sites (Drake et al. 1988), but this new evidence indicates that there is some overlap in ages (Table 1) (McNulty personal communication). There is strong evidence that the Kisingiri species of *Proconsul* that are the basis of the description here actually belong to a different genus from the Tinderet types (see below). However, as this is not the appropriate venue to name a new genus, I will follow convention and refer to the Rusinga sample as *Proconsul*. In the end, both taxa traditionally attributed to *Proconsul* are most likely to be sister taxa, so whether it is one genus or two is only of interest to those who are working directly on this material, though when worked out it will give us a much better idea of the actual specimen composition of each taxon, which is the necessary precursor to any analysis of the paleobiology of fossil taxa (Plates 1, 2, and 3).

Postcranial Morphology

Proconsul and other proconsuloids are defined by a large number of characters. *Proconsul* is a generalized arboreal quadruped but is neither monkey-like nor apelike (Rose 1983). The following summary is mainly from Rose (1997), Ward (1997a), and Walker (1997). In addition to the characters noted that emphasized its hominoid affinities, *Proconsul* has limbs of nearly equal length (though the forelimbs were probably slightly longer than the hindlimbs), with scapula positioned laterally on the thorax and the ovoid and narrow glenoid positioned inferiorly, as in

Plate 2 “*Proconsul*” *heseloni* from Rusinga. KNM-RU 2036 on the *left* is the type specimen and is female, while the specimen to the *right* (KNM-RU 2087) is a male

Plate 3 “*Proconsul*” *nyanzae* from Rusinga. M16647 on the *right* is the type specimen and male. KNM-RU 7290 is a female

generalized quadrupeds. The thorax is transversely narrow and deep superoinferiorly, and the vertebral column is long and flexible, especially in the lumbar region. The innominate is long with a narrow ilium and an elongated ischium. The sacrum is narrow, and its distal end indicates that it articulated with a coccygeal and not a caudal vertebra, in other words *Proconsul* had a coccyx and not a tail (Ward et al. 1991).

In the details of limb morphology, *Proconsul* also combines aspects of monkey and ape morphology. *Proconsul* forelimbs lack the characteristic elongation of ape forelimbs, though this trend in ape evolution may be represented by some slight forelimb elongation in *Proconsul*. The humeral head is oriented posteriorly relative to the transverse plane, and the humeral shaft is convex anteriorly, both of which are consistent with the position of the glenoid fossa and the shape of the thorax. The distal end of the humerus lacks the enlargement of the capitulum and trochlea and other details of the hominoid elbow, but it does have a narrow zona conoidea and a mild trochlear notch. These are characters that are more strongly developed in extant apes that are universally regarded as indications of suspensory positional behavior. It is interesting that *Proconsul* shows incipient signs of apelike morphology in the elbow while lacking other more definitive indicators of orthograde or suspension. It is possible that these early, subtle changes in the elbow and in other areas of the postcranium of *Proconsul* are related to the positional demands of an animal moving around in the trees without a tail (see below).

The medial epicondyle is more posteriorly oriented as in monkeys. The proximal ends of the radius and ulna are consistent with the morphology of the distal humerus. The radial head is small and ovoid, the ulnar trochlea is narrow and has a poorly developed keel, and the radial notch is positioned anteriorly. The ulna also has a large olecranon process. All of these features are consistent with generalized pronograde (above branch) quadrupedalism as opposed to antipronograde (suspensory or below branch) (Ward 2007).

Distally, the radial carpal surface is flat and articulates mainly with the scaphoid. The ulnar head is comparatively large with a long and prominent styloid process that articulates directly with the pisiform and triquetrum, unlike living hominoids, which have greatly reduced ulnar styloids and no contact with the carpals. However, the nature of the contact between the ulnar styloid and the pisiform and triquetrum differs from that of monkeys and does suggest a greater degree of mobility, or at least a different pattern of mobility, than seen in Old World Monkeys (Beard et al. 1986). The carpals are small transversely. The scaphoid is separate from the os centrale and the midcarpal joint is narrow. The hamate hamulus is small, and the surface for the triquetrum is flat and mainly medially oriented (Beard et al. 1986). However, the manner in which the bones of the wrist come together in *Proconsul* shares attributes with monkeys and apes, making it unique. Nevertheless, in my view, the *Proconsul* wrist does provide evidence of an incipient transformation for a more stable pronograde-dominated posture to more diverse habitual postures. The metacarpal surfaces of the distal carpals are small and comparatively simple as are the corresponding surfaces on the metacarpal bases. The metacarpals are short and straight and their heads transversely narrow. The proximal ends of the proximal phalanges are slightly dorsally positioned as in palmigrade quadrupeds. All the phalanges are short and straight compared with apes, though secondary shaft features, in particular of the proximal phalanges, suggest powerful grasping (Begun et al. 1994).

The hindlimbs of *Proconsul* are also dominated by monkey-like characters. The long bones are long and slender. The femoral head is small compared to apes, but its articulation with the acetabulum indicates more mobility compared to most monkeys. The feet of *Proconsul* are monkey-like in their length-to-breadth ratio (they are narrow compared to great ape feet). *Proconsul* tarsals are elongated relative to breadth and the metatarsals long compared to the phalanges. Like those of the hands, the foot phalanges of *Proconsul* are straighter and less curved than in apes but with more strongly developed features related to grasping than in most monkeys. The hallucial phalanges are relatively robust, suggestive of a powerfully grasping big toe. Body mass estimates for the species of *Proconsul*, based mainly on postcranial evidence, range from about 10 to 50 kg (Ruff et al. 1989; Rafferty et al. 1995). The lower estimate is based in part of juvenile specimens, and it is probable that the smallest adult *Proconsul* weighed about 15 kg. In addition to morphological evidence, the range of body mass estimates in *Proconsul* from Rusinga and Mfangano strongly suggest that at least two species are represented.

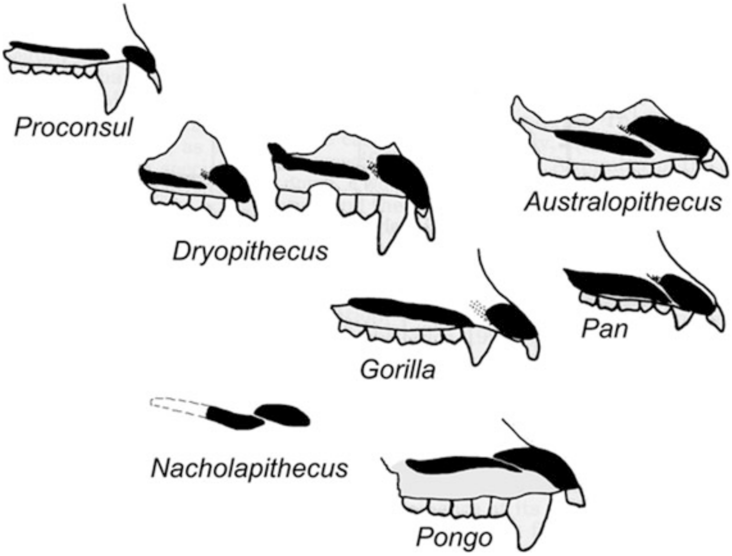

Fig. 3 Midsagittal cross section of a number of Hominidea *palates* showing some of the features described in the text. *Proconsul* has a small premaxilla and a fenestrated palate (large foramen and no overlap between the maxilla and premaxilla). *Nacholapithecus* has a longer premaxilla with some overlap. It is similar to *Afropithecus* and conceivably could be the primitive morphotype for the Hominidae. *Pongo* and *Sivapithecus* have a similar configuration but with further elongation and extensive overlap between the maxilla and premaxilla, producing a smooth subnasal floor. Hominines have robust premaxillae that are generally shorter and less overlapping than in *Sivapithecus* and *Pongo*. *Dryopithecus* is most similar to *Gorilla*, which may represent the primitive condition for hominines. *Pan* and *Australopithecus* have further elongation and overlap, but the configuration differs from *Pongo*. This morphology is suggested to be an important synapomorphy of the *Pan*/*Homo* clade (Begun 1992b) (Modified from Begun 1994)

Craniodental Morphology

As noted, *Proconsul* has a moderate amount of encephalization (comparable to hylobatids and papionins), a short face with a fenestrated palate (Fig. 3), a smoothly rounded and somewhat airorhynchous face (Fig. 4), and a generalized dentition. Morphologically, the dentition is consistent with a soft fruit diet, and microwear analysis suggests the same (Kay and Ungar 1997; chapter "▶ Dental Adaptations of African Apes," Vol. 2). The somewhat enlarged brain of *Proconsul* implies a degree of life history delay approaching the hominoid pattern (Kelley 1997, 2004; Kelley and Smith 2003; Smith et al. 2003).

One aspect of the cranium of *Proconsul* that has received some attention is the frontal sinus. Walker (1997) interprets the presence of a frontal sinus in *Proconsul* to indicate its hominid status, citing the presence of large frontal sinuses in some great apes. Other researchers have suggested that the frontal sinus is a primitive character, as it is found in *Aegyptopithecus* and many New World monkeys (Andrews 1992; Rossie et al. 2002). The confusion stems from the use of one term to describe several different characters. As Cave and Haines (1940) noted long

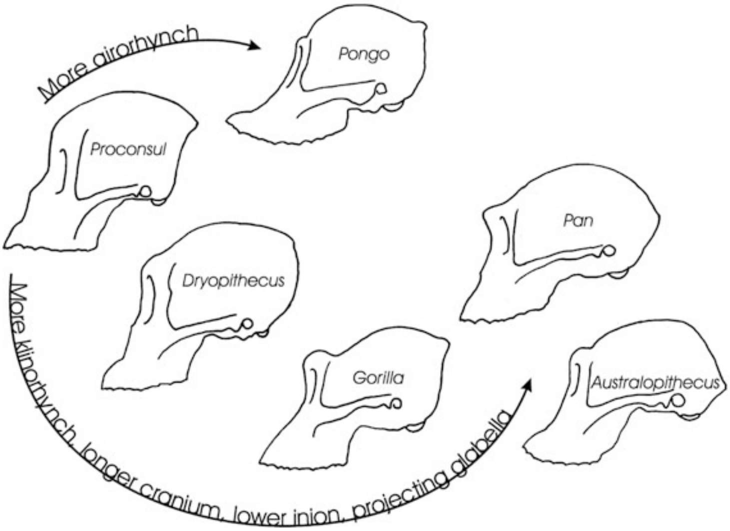

Fig. 4 Lateral views of some Hominidea *crania* showing possible changes through time. A mildly airorynch *Proconsul* may be a good ancestral morphotype for hominoid craniofacial hafting, as a similar degree of airorhynchy is also found in hylobatids (Shea 1988). *Rudapithecus* shares with other hominines neurocranial elongation (though this also occurs in hylobatids), the development of supraorbital tori, klinorhynchy, and, probably in association with the latter, a true frontoethmoidal sinus (Modified from Kordos and Begun (2001))

ago, frontal sinuses in primates have various ontogenetic origins, and it is likely that they are not homologous across the primates. New World monkeys have frontal sinuses that are outgrowths from the sphenoid sinus, as is also the case for hylobatids. On the other hand, *Pongo*, which occasionally has a frontal sinus, derives it from the maxillary sinus (see chapter "▶ Defining Hominidae," Vol. 3). African apes and humans normally have large frontal sinuses derived from the ethmoidal sinuses. "Frontal sinuses" then are actually three different characters, frontosphenoidal sinuses, frontomaxillary sinuses, and frontoethmoidal sinuses.

While it is possible to establish the ontogenetic origin of a pneumatized frontal bone in living primates, it is more difficult in fossil primates. However, the placement and size of the frontal sinuses correlate very well with their ontogenetic origin, offering a protocol for identifying the specific type of frontal sinus present in a fossil (Begun 1994a). Frontosphenoidal sinuses invade large portions of the frontal squama but not the supraorbital or interorbital regions. Frontomaxillary sinuses are infrequent in *Pongo*, but when they occur, they are associated with narrow canals or invaginations connecting the maxillary sinuses to a small pneumatization of the frontal via the interorbital space. In African apes and humans, the frontoethmoidal sinuses arise from a spreading of the ethmoidal air cells in the vicinity of nasion, resulting in large pneumatizations from below nasion into the supraorbital portion of the frontal. The actual amount of frontal pneumatization is variable, while the presence of a large sinus around nasion is constant. Therefore, while we cannot observe the development of frontal pneumatization in fossil primates, and we do not have adequate ontogenetic series to directly reconstruct this growth, we can infer the type of frontal pneumatization from its position, extent, and connection to the source sinus. In *Proconsul*, as in hylobatids, New World monkeys, and *Aegyptopithecus*, the frontal pneumatization is extensive and occupies the frontal squama, consistent with a frontosphenoidal sinus. Thus, the "frontal sinus" in *Proconsul* is a primitive character, as suggested by Andrews (1992), but for different reasons. The frontal pneumatization of *Rudapithecus*, on the other hand, conforms to the pattern seen exclusively in African apes and humans (see below).

In summary, *Proconsul* was an above branch mid- to large-sized catarrhine with a diet dominated by soft fruits and a somewhat slower life history than cercopithecoids. Encephalization may imply other similarities to hominoid behavioral or social ecology, or it may simply be a consequence of relatively large body mass and/or a slower life history (Kelley 2004; Russon and Begun 2004). The slightly enhanced range of motion in *Proconsul* limbs may imply some degree of orthogrady, it may be a consequence of the absence of a tail, of large body mass in an arboreal milieu, or, most likely, some combination of all three (Beard et al. 1986; Begun et al. 1994; Kelley 1997).

Other Possible Proconsuloids

A number of taxa are regarded by many researchers as having a probable close relationship to *Proconsul*. The three with the best evidence for affinities to the proconsuloids are *Proconsul sensu stricto*, *Micropithecus*, and *Samburupithecus*. As noted, the type species of the genus *Proconsul* is *P. africanus*. *P. africanus* and *P. major*, both from Tinderet sites, are never found together with *Proconsul* from Rusinga and are also more primitive and lack synapomorphies shared by *Proconsul* from Rusinga and other hominoids (see below). Other taxa listed in Table 2 are either more likely to be hominoids given similarities to known hominoids (*Rangwapithecus*, *Nyanzapithecus*, *Mabokopithecus*) or they are so primitive or poorly known as to make unclear their magnafamily status.

Proconsul sensu stricto

The species of *Proconsul sensu stricto* from Songhor and Koru (*P. africanus* and *P. major*) probably represent a different genus from *P. heseloni* and *P. nyanzae*, the samples on which the descriptions of *Proconsul* presented here are based. A new genus would replace *P. heseloni* and *P. nyanzae*, as *P. africanus* has priority. *Proconsul sensu stricto* from Songhor and Koru has elongated postcanine teeth, more strongly developed cingula, upper premolars with strong cusp heteromorphy, and conical, individualized molar cusps, all of which suggest that the older species are in fact more primitive. The two Tinderet species differ from each other mainly in size. Postcrania attributed to *Proconsul* from the Tinderet *Proconsul sensu stricto* localities are distinct from postcrania from the younger *Proconsul* localities such as

Rusinga, in details that have been correlated to paleoecological differences (Andrews et al. 1997). While sufficiently similar to the better-known younger *Proconsul* sample to warrant placing both in the same superfamily, the more modern morphology of the younger *Proconsul* sample will almost certainly require taxonomic recognition.

Ugandapithecus, based on the sample of *P. major*, adds to the confusion (Senut et al. 2000). *Ugandapithecus* is not a useful nomen in that it mixes a number of specimens from different localities, different sizes, and even different morphologies, and it has not been effectively compared with and distinguished from either *Proconsul sensu stricto* or the Kisingiri sample. Therefore, the nomen is not recognized here except as a junior subjective synonym of *Proconsul*. Nevertheless, it turns out that *Proconsul* as traditionally defined probably does represent more than one genus. Senut et al. (2000; see chapter "▶ The Miocene Hominoids and the Earliest Putative Hominids," Vol. 3) have suggested that large-bodied hominoids from Moroto, in Uganda, that is, *P. major*, may also be attributed to *Ugandapithecus* (hence the name, though the type is from Kenya), calling into question the interpretation that hominoid cranial and postcranial fossils from Moroto belong to one taxon (*Morotopithecus*). However, the evidence for more than one large hominoid genus at Moroto is not strong (see below).

Micropithecus

Micropithecus (Fleagle and Simons 1978) is a small catarrhine with comparatively broad incisors and long postcanine teeth with low cusps and rounded occlusal crests. The cingula are less strongly developed than most other Early Miocene catarrhines. Males and females exhibit marked size dimorphism. Comparisons with living catarrhines suggest a body mass of about 3–5 kg (Harrison 2002). While Harrison (2002, 2010) considers this taxon to be even more distantly related to the Hominoidea than are the Proconsuloidea, the subtly more modern features of the dentition suggest that it may belong to the Proconsuloidea. Fleagle and Simons (1978) in fact attribute *Micropithecus* to the Hominoidea, although as noted the features shared with hominoids are very subtle. If *Micropithecus* is a proconsuloid, as preferred here, it would indicate that the proconsluoids were quite diverse in body mass, as is the case in all catarrhine superfamilies.

Samburupithecus

Samburupithecus is another possible proconsuloid, known only from a large maxillary fragment from the Late Miocene of the Samburu region of Kenya (Ishida and Pickford 1997). Ishida and Pickford (1997) have suggested that *Samburupithecus* is an early member of the African ape and human clade, while others place it within the hominoids, but without specific affinities to any living clade (e.g., Harrison 2010; see chapter "▶ The Miocene Hominoids and the Earliest Putative Hominids," Vol. 3). However, *Samburupithecus* retains many primitive characters of the Proconsuloidea. These include a low root of the zygomatic processes, a strongly inclined nasal aperture edge, the retention of molar cingula, and thick enamel with high dentine relief (Begun 2001). *Samburupithecus* is most likely to be a late surviving proconsuloid. Its unusual dental characters (e.g., large molars with individualized cusps separated by deep

Plate 4 Comparison between *Samburupithecus*, KNM-SH 8531 (*left*) and "*Proconsul*" (KNM-RU 1677a). Note the strongly developed molar cingula and the small M1 relative to M2 in both specimens. The molars are similar in overall morphology as well

narrow fissures) are reminiscent of morphological "extremes" found in terminal lineages with long evolutionary histories. *Oreopithecus*, *Gigantopithecus*, *Paranthropus*, *Daubentonia*, and *Ekgmowechashala* all share with *Samburupithecus* exaggerated occlusal features compared with other members of their respective clades. The size and occlusal morphology of *Samburupithecus* that superficially resembles *Gorilla* (Ishida and Pickford 1997) may be related in part to the fact that both are ends of long phylogenetic branches. In a pattern analogous to long branch attraction in molecular systematics, there is a tendency for separate long isolated lineages to converge in certain aspects of their morphology (Begun 2001). For whatever the reason, in its details *Samburupithecus* is primitive and more likely to belong to the proconsuloids than the hominoids (Plate 4).

Nyanzapithecines

In contrast to the phylogeny presented in Stevens et al. (2013), I consider *Rangwapithecus* and *Nyanzapithecus* to be proconsuloids and not more closely related to more modern apes. Harrison (2010) includes the nyanzapithecines among the proconsuloids, and that is the view adopted here. Nyanzapithecines as defined by Harrison (2002, 2010) include a diverse assemblage of fossil taxa ranging in dental size from somewhat smaller that *Proconsul* to the size of *Proconsul heseloni* or *P. africanus*. Several of these specimens are beautifully preserved, including the holotypes of *Rangwapithecus* and *Turkanapithecus*. There is a nicely preserved mandible of *Nyanzapithecus* as well. Yet, these taxa have proven extremely resistant to classification. I am not convinced that the Nyanzapithecinae as constituted by Harrison (2010) is a natural group. While there are superficial similarities in the occlusal morphology of the molars of all three genera and *Mabokopithecus* as well, these taxa are mostly distinguished from *Proconsul* by the complexity of their occlusal surfaces rather than being linked by morphological details. In many cases, these types of molars with more complicated patterns of crests and taller cusps that tend to be more isolated from one another occur in conjunction with selection for a more folivorous diet. This may explain in part some of what I consider to be superficial convergences in the morphology of the teeth of these taxa. In sum, I find the case for a specific relationship between *Mabokopithecus* and *Nyanzapithecus* fairly convincing, but I would not include *Rangwapithecus* or *Turkanapithecus* in the same subfamily. All of these taxa are most likely to be proconsuloids with more folivorous adaptations than other proconsuloids. As noted earlier, at this point it is premature to link the 25 Ma *Rukwapithecus* with the much younger sample of *Rangwapithecus*.

Early Hominoids

Afropithecus

A number of late Early Miocene and Middle Miocene taxa share characters with extant Hominoids and are included here in the Hominoidea. *Afropithecus* (Leakey and Leakey 1986) is known from several localities in northern Kenya dated to 17–17.5 Ma (Leakey and Walker 1997). *Afropithecus* shares an increase in premaxillary robusticity and length with most extant hominoids (Fig. 3). Like many Late Miocene and Pliocene hominids, *Afropithecus* has very thick occlusal enamel as well (Smith et al. 2003). On the other hand, similarities have been noted between *Afropithecus* cranial morphology, particularly the morphology of the midface, and that of *Aegyptopithecus*. Leakey and Walker (1997) have suggested that the unusual primitive-looking face of *Afropithecus* may be related to a specialized scerocarp seed predator adaptation. This is functionally consistent with the robust, prognathic premaxilla; large, relatively horizontal incisors; large but relatively low-crowned canines; expanded premolars; thick enamel; and powerful chewing muscles of *Afropithecus*. A similar set of features is found in modern primate seed predators such as pithecines. It may be that some of the primitive appearance of the *Afropithecus* face is homoplastic with *Aegyptopithecus*. However, another possibility is that the unusual morphology of the face of the single specimen of *Afropithecus* on which this morphological characterization is based is the result of postmortem deformation. My observations of the original specimen and other more fragmentary specimens of *Afropithecus* lead me to conclude that the type is deformed and probably resembled *Proconsul* more closely than *Aegyptopithecus*. Nevertheless, the characters noted above related to the development of the premaxilla, the implantation of the incisors, and the implantation and morphology of the canines are real differences from *Proconsul*. Thus, as with *Proconsul*, *Afropithecus* has a mosaic of primitive and derived characters (Leakey et al. 1991; Leakey and Walker 1997; Plate 5).

The large, albeit deformed, type specimen of *Afropithecus* reveals some information on neurocranial morphology. KNM-WK 16999 preserves a portion of the braincase immediately behind the orbits. Postorbital constriction is very marked, though I believe this is the result in part of postmortem deformation. However, there

Plate 5 The type specimen of *Afropithecus*, KNM-WK 16999 (*left*) and a well preserved mandible, KNM-WK 17012 (*right*). Note the lack of bone surfae around the nasal aperture and incisors and the exceptionally large interorbital area, indicative of deformation

is no doubt that the anterior temporal lines are very strongly developed. These converge to form a pronounced and very anteriorly situated sagittal crest. The small portion of the anterior cranial fossa preserved indicates a cerebrum that was constricted rostrally, lacking the frontal lobe expansion typical of extant and fossil great apes. The increased robusticity of the masticatory apparatus of *Afropithecus* in comparison with *Proconsul* is undeniable, despite some caveats related to preservational issues. The large mandibles, robust zygomatics, thickly enameled teeth, and powerfully developed attachment sites for chewing muscles all indicate that the dietary adaptations of *Afropithecus* differed significantly from those of *Proconsul*, and more closely approach those of some later Miocene apes. These differences from *Proconsul* are confirmed by more recently described specimens (Rossie and MacLatchy 2013).

Afropithecus is similar in size to *Proconsul nyanzae*, based on cranial, dental, and postcranial dimensions (Leakey and Walker 1997). *Afropithecus* postcrania are very similar to those of *Proconsul*, so much so that Rose (1993) found them essentially indistinguishable. However, *Afropithecus* postcrania are much less well known than *Proconsul*, and it is conceivable that as more fossils of *Afropithecus* are discovered, some differences from *Proconsul* will emerge. Nevertheless, given our current state of knowledge, the postcranial adaptation of *Afropithecus*, in terms of body mass and positional behavior, is *Proconsul*-like, while the craniodental anatomy is markedly distinct.

Another early hominoid taxon, *Heliopithecus*, is contemporaneous with *Afropithecus* and morphologically very similar, though it is only known from a fragmentary hemimaxilla and a few isolated teeth (Andrews and Martin 1987). Both *Heliopithecus* and *Afropithecus* share characters that are found next in the fossil record in Eurasia, which suggests that *Heliopithecus* and *Afropithecus* taxa may have a closer relationship to late Early Miocene and Middle Miocene hominoids from Europe than do proconsuloids. Certainly the most important piece of the puzzle of ape evolution to be provided by *Heliopithecus* is its geography. *Heliopithecus* is from the site of Ad Dabtiyah, in Saudi Arabia. While that sounds extraordinary, it is useful to recall that geologically the Saudi Arabian peninsula is part of the African plate, and until fairly recently much of the fauna of Africa was present in the Arabian peninsula as well. During the Early Miocene, the Arabian peninsula was much more humid than today and supported large and diverse forest communities. Given my interpretation that *Afropithecus*-like adaptations may have permitted hominoids to disperse into Eurasia in the late Early Miocene (see below), the presence of a very similar taxon on the road to Eurasia from East Africa is certainly telling.

Morotopithecus

Morotopithecus is a fossil hominoid from Uganda dated to about 21 Ma by some and 17 Ma by others (Gebo et al. 1997; Pickford et al. 2003). It is best known from a large cranial specimen including most of the palate (Pilbeam 1969). For many years, this specimen was attributed to *Proconsul major*, but it is clear that it and other specimens from Moroto are sufficiently different to justify a genus distinct from *Proconsul*. *Morotopithecus* is similar in size to *Proconsul major* and larger than *Proconsul nyanzae* and *Afropithecus*. It lacks the distinctive subnasal morphology of *Afropithecus* and has a *Proconsul*-like premaxilla that is short, gracile, and does not overlap the palatine process of the maxilla, resulting in a large incisive fenestration (Fig. 3). *Morotopithecus* has a broad palate; large anterior teeth, especially the canines, which are tusklike; a piriform aperture broadest about midway up; and an interorbital space that appears to be relatively narrow, though it is damaged. However, the most important distinction of *Morotopithecus* is the morphology of the postcrania, which are said to be modern hominoid-like. Newly described specimens of *Morotopithecus* include the shoulder joint, hip joint, and details of the vertebral column (MacLatchy 2004). Walker and Rose (1968) described the vertebrae as hominoid-like, which has been confirmed by more recent discoveries and analyses. The glenoid fossa of *Morotopithecus* suggests a more mobile shoulder joint as does the morphology of the hip joint. However, it is the hominoid-like position of the transverse processes of the vertebrae that represents the strongest evidence for the hominid affinities of *Morotopithecus*. The roots of the transverse processes of the lumbar vertebrae of *Morotopithecus* are positioned posteriorly, as in extant great apes, suggesting a stiff lower back and an axial skeleton like that of extant hominoids. However, this interpretation has not gone unchallenged, and for the time being, I consider the degree to which *Morotopithecus* was orthograde to be unresolved (Nakatsukasa 2008).

Eurasian Hominoid Origins

As noted, *Heliopithecus* and *Afropithecus* have more robust jaws and teeth than Early Miocene proconsuloids, and this may represent a key adaptation that permitted the expansion of hominoids into Eurasia at about 17 Ma, when during a marine low stand, a diversity of terrestrial mammals moved between Africa and Eurasia

(Made 1999; Begun 2001, 2009; Begun et al. 2003a, b, 2012; Nargolwalla 2009). Toward the end of the Early Miocene, the movement of the southern landmasses northward, combined with a number of other developments (the Alpine and Himalayan orogenies, the earliest appearance of the polar ice caps, and the Asian monsoons), leads to a sequence of connections and barriers to terrestrial faunal exchange (Rögl 1999a, b; Adams et al. 1999; MacLeod 1999; Hoorn et al. 2000; Zhisheng et al. 2001; Guo et al. 2002; Liu and Yin 2002; Wilson et al. 2002; Nargolwalla 2009). This period of global turbulence affected sea levels between continents cyclically such that for the remainder of the Miocene, there would be periodic connections (low stands) and disconnections (high stands) between the continents. At about 17 Ma, a low stand that had permitted the exchange of terrestrial faunas between Eurasia and Africa (the Proboscidean datum) was coming to an end but not before hominoids possibly resembling *Afropithecus* and *Heliopithecus* had dispersed from Africa into Eurasia (Heizmann and Begun 2001; Begun 2002, 2004; Begun et al. 2003a, b, 2012).

At the end of the Early Miocene, about 16.5 Ma, hominoids of more modern dental aspect first appear in Eurasia. The oldest Eurasian hominoid is cf. *Griphopithecus*, known from a molar fragment from Germany (Heizmann and Begun 2001). *Griphopithecus* (Abel 1902) is known mainly from large samples from Turkey of roughly the same age, while the type material is known from a probably later (14–15 Ma) locality, Děvínská Nová Ves, in Slovakia (Heizmann 1992; Andrews et al. 1996; Heizmann and Begun 2001; Begun et al. 2003a, b). cf. *Griphopithecus* from Engelswies in Germany is a tooth fragment that has the more modern features of being thickly enameled with low dentine penetrance (tall dentine horns did not project into the thick enamel cap as in *Proconsul* and probably *Afropithecus*). cf. is the designation for a taxon that is similar enough to another taxon for there to be a strong likelihood that they are the same, but with some formally acknowledged uncertainty. *Griphopithecus* is better known from over 1,000 specimens, mostly isolated teeth, from two localities in Turkey (Çandır and Paşalar). One species, *Griphopithecus alpani* (Tekkaya 1974), is known from both localities, while a second somewhat more derived taxon is also found at Paşalar (Alpagut et al. 1990; Martin and Andrews 1993; Kelley and Alpagut 1999; Ward et al. 1999; Kelley et al. 2000; Kelley 2002; Güleç and Begun 2003).[1]

---

[1] Some researchers have suggested that the specimen from Engelsweis, which we all agree is at least 16.5 Ma, if not more than 17 Ma, is more likely to be an *Afropithecus* or a relative thereof, with no relationship to *Griphopithecus* (Casanovas-Vilar et al. 2011). These researchers are in agreement with Böhme et al. (2011) that *Griphopithecus* in Anatolia is later in time (ca. 13.5 Ma). My analysis of the biostratigraphy of the Çandır locality indicates that it is likely to be at least 16 Ma (Begun et al. 2003a). Until more research is concluded, there will remain uncertainty about the ages of the Çandır and Paşalar localities, though at 13.5 Myr this makes them much younger than previously thought. However, even if the Anatolian *Griphopithecus* sites are 3 Myr younger than Engelsweis, that is no justification for the claim that the latter must have been the result of a separate dispersal event as opposed to the simpler scenario in which hominoids with thickly enameled teeth enter Europe at 17 Ma and evolve in situ. As noted earlier, the tooth from Engelsweis more closely resembles those from Anatolia and Slovakia than it resembles *Afropithecus*.

Plate 6 *Top row*, *Nacholapithecus* palate. *Left*, lateral view, *right*, palatal view. *Bottom row*, *Nacholapithecus* mandible (*left*), *Equatorius* mandible (*right*). The *Nacholapithecus* specimens belong to the partial skeleton KNM-BG 35250, and the *Equatorius* mandible to the partial skeleton KNM-TH 28860

Griphopithecus alpani has a robust mandible with strongly reinforced symphysis; broad, flat molars with thick enamel; and reduced cingulum development compared with *Proconsul*. It retains primitive tooth proportions (small M1 relative to M2), anterior tooth morphology, and postcanine occlusal outline shape. A few fragments of the maxilla from Paşalar indicate a primitive morphology for the anterior palate (Martin and Andrews 1993). The morphology of *Griphopithecus* molars as well as their microwear indicates a diet allowing the exploitation of hard or tough fruits, though it is not clear if this means simply that they could exploit these resources when needed (a keystone resource) or if they were a favored source of food. Two postcranial specimens, a humeral shaft and most of an ulna, from the younger site of Klein-Hadersdorf, Austria, are also similar to *Proconsul* and indicate that *Griphopithecus* was a large-bodied above-branch arboreal quadruped similar in size and positional behavior to *Proconsul nyanzae* (Begun 1992a). Phalanges from Paşalar are also said to be most similar to those of *Proconsul* and extant arboreal quadrupeds (Ersoy et al. 2008) (Plates 6 and 7).

East African Middle Miocene Thick-Enameled Hominoids

Shortly after the appearance of *Griphopithecus* in western Eurasia (but see footnote 1), dispersals between Eurasia and Africa were interrupted by the Langhian transgression (Rögl 1999a). Following the Langhian, at about 15 Ma, dispersals resumed in a number of mammal lineages, probably also including hominoids (Begun et al. 2003a, b; Begun 2009; Nargolwalla 2009; Begun et al. 2012). Hominoids closely similar to *Griphopithecus* in dental morphology appear in Kenya at this time. *Equatorius* is known from 15 Ma localities in the Tugen Hills and at Maboko, both in Kenya. This taxon, previously attributed to *Kenyapithecus*, is very similar to *Griphopithecus* but has a distinctive incisor morphology and reduced cingula,

Plate 7 *Kenyapithecus* and *Griphopithecus*. *Top row*, *Kenyapithecus wickeri* (type specimen, KNM-FT 46), lateral (*left*) and occlusal (*center*) views. *Equatorius* (type specimen, M16649) occlusal (*right*). *Bottom row*, *Griphopithecus alpani* type mandible (MTA 2253) (*left*) and three upper central incisors, from *left* to *right*, "*Proconsul*" (KNM-RU 1681), *Equatorius* (KNM-MB 104) and *Kenyapithecus wickeri* (KNM-FT 49)

probably warranting a distinct genus status (Ward et al. 1999; Kelley et al. 2000; Ward and Duren 2002; *contra* Begun 2000, 2002; Benefit and McCrossin 2000). *Equatorius* is also known from a good sample of postcrania, including most of the bones of the forelimb, vertebral column, hindlimb long bones, and a few pedal elements (McCrossin 1997; Ward and Duren 2002). Like *Griphopithecus*, which is much less well known postcranially, *Equatorius* is similar to *Proconsul nyanzae* in postcranial size and morphology.

Nacholapithecus (Ishida et al. 1999) is known from deposits of the same age as *Equatorius* in the Samburu Basin of Kenya (Nakatsukasa et al. 1998). Like *Equatorius*, *Nacholapithecus* is known from a relatively complete skeleton, more complete in fact than the best specimen of *Equatorius*. From this exceptional skeleton, we know that *Nacholapithecus* is similar to other Middle Miocene hominoids in most aspects of the jaws and teeth but unique in aspects of limb morphology. While they are not especially elongated, the forelimbs of *Nacholapithecus* are more robust, that is, they are more strongly built, than are the hindlimbs. In a fascinating comparison, Ishida et al. (2004) show that *Nacholapithecus* has forelimb joints the size of a chimpanzee but hindlimb joints closer in size to those of a baboon, of much smaller body mass. The forelimbs were not elongated as in modern apes, but they were enlarged. This is difficult to understand, but it probably has something to do with some increase in the degree to which *Nacholapithecus* was loading its forelimbs relative to its hindlimbs, even if it was not suspensory. Once again, we have a weird, unique fossil ape without a modern counterpart. Kunimatsu et al. (2004) provide evidence that the anterior portion of the palate of *Nacholapithecus* is more hominid-like in its length and degree of overlap with the palatine process of the maxilla (Fig. 3). This morphology is the principal evidence for the hominoid status of this species. However, in its details, the anterior palate of *Nacholapithecus* is unlike that of hominids (see below). In my opinion, there is also evidence of some postmortem compression that may contribute to the impression that the anterior portion of the palate of *Nacholapithecus* is more modern looking than it actually was.

Otherwise, the postcranial skeleton of *Nacholapithecus* is similar to other Middle Miocene hominoids in having the general signature of a generalized, palmigrade, arboreal quadruped, but differs from *Equatorius*, also known from fore and hindlimb, in the enlarged size and robusticity of its forelimb. While not like extant nonhuman hominoids in forelimb length relative to the hindlimb, *Nacholapithecus* forelimbs are large and powerful, indicating a form of positional behavior emphasizing powerful forelimb grasping (Ishida et al. 2004). Interestingly, several wrist bones are well preserved in both *Nacholapithecus* and *Equatorius*, and they are quite similar to each other and to *Proconsul* and *Afropithecus* (personal observations).

Kenyapithecus (Leakey 1962) is the most derived of the Middle Miocene African hominoids, and may be the earliest hominid (Table 2), although I should add that it is the least well known. *Kenyapithecus* is known only from a small sample from Fort Ternan in Kenya, though a second species may be present in Turkey (see below). Like other Middle Miocene hominoids, *Kenyapithecus* has large flat molars with broad cusps and thick enamel. The maxilla of *Kenyapithecus*, however, is derived in having a high root of the zygomatic, a probable hominid synapomorphy. While McCrossin and Benefit (1997) believe that *Equatorius* and *Kenyapithecus* represent a single species, most researchers have concluded that two genera are present and that *Kenyapithecus* is derived relative to *Equatorius* (Harrison 1992; Ward et al. 1999), and that is the view adopted here. As noted, it has been suggested that *Kenyapithecus* is also present at Paşalar. If so, and if *Kenyapithecus* is indeed an early hominid, this would date the origin of the hominid family to at least 16 Ma (but see footnote 1). However, there is a roughly 3 Ma gap between possible *Kenyapithecus* at Paşalar and the type material from Fort Ternan.

One last Middle Miocene hominoid deserves mention here. *Otavipithecus* is the only Miocene hominoid known from southern Africa, from the 13 Ma site of Berg Aukas in Namibia (Conroy et al. 1992). Several specimens have been described, including the type mandible, a frontal fragment, and a few postcrania (Conroy et al. 1992; Pickford et al. 1997; Senut and Gommery 1997). It has been suggested that *Otavipithecus* has affinities to hominids (Conroy et al. 1992; Ward and Duren 2002), but it preserves primitive proconsuloid characters such as a small M_1 compared to M_2, a long M_3, parallel tooth rows, a small space for the mandibular incisors, low P_4 talonid, and tall, centralized molar cusps (Begun 1994b). Singleton (2000) carried out the most comprehensive analysis of *Otavipithecus* and concluded that it may be related to *Afropithecus*, which is broadly consistent with the placement of the taxon in Fig. 2. Like *Heliopithecus*, the most informative piece of information from the sample of *Otavipithecus* comes from its biogeography. *Otavipithecus* is a huge geographic outlier, suggesting that hominoids were widespread in equatorial and southern Africa but have yet to be found. *Otavipithecus* is morphologically somewhat atypical of Early and Middle Miocene hominoids, and I expect that when other taxa are found between Kenya and Namibia or elsewhere in Africa, they will be equally surprising.

Summary of Middle Miocene Hominoid Evolution

The radiation of Middle Miocene hominoids in Africa was relatively short-lived and less diverse than the Early Miocene radiation (see Table 1). Having apparently dispersed from Eurasia by about 15 Ma, they are mostly extinct by 12.5–13 Ma. Aside from a few fragmentary specimens that most likely represent the end of the *Proconsul* lineage (Hill and Ward 1988), hominoids would not appear again in Africa until the Late Miocene. Given the rarity of hominoid localities in the early Middle Miocene, the biogeographic hypothesis of the dispersal of Middle Miocene hominoids presented here is debatable. It is certainly possible, for example, that Early Miocene *Griphopithecus*-like fossils will be found in Africa that will show that *Equatorius*, *Nacholapithecus*, and *Kenyapithecus* all evolved in situ in Africa and that apparently earlier fossils from Eurasia are either misdated or are early offshoots of this clade with no direct relationship to later hominids (Ward and Duren 2002). In the end, perhaps the best way to think about Middle Miocene hominoids is in terms of a group of closely related genera that occupied the circum-Mediterranean region and the contiguous regions north into Germany and south into Kenya (with one known long distance dispersal into Namibia). Movements within the geographic area of these taxa were probably very complex and numerous over time, but from this melting pot of Middle Miocene thickly enameled hominoids, the first true hominids appear.

Early Hominids

While *Kenyapithecus* shares a synapomorphy with the Hominidae (position of the zygomatic root), the first clear-cut hominids are known from Eurasia and share numerous cranial, dental, and postcranial synapomorphies with living hominids. This is the most important body of data supporting the Eurasian origins hypothesis. If that hypothesis is incorrect, we need to account for the absence of fossil hominids in Africa (which could just be bad luck) and also the presence of apparent hominid synapomorphies in both the Asian and European hominid fossil records.

The extant Hominidae is divided into two subfamilies, Ponginae and Homininae, and the earliest representatives of both subfamilies are roughly contemporaneous. The earliest hominines are represented by *Dryopithecus* and possibly *Pierolapithecus* and *Anoiapithecus* (see below). Much better known and with clearer hominine synapomorphies are *Rudapithecus*, *Hispanopithecus*, and *Ouranopithecus* (see chapter "▶ Potential Hominoid Ancestors for Hominidae," Vol. 3). The earliest pongines are represented by *Ankarapithecus*, *Sivapithecus*, and relatives. Miocene hominines are known from western Eurasia, while Miocene pongines are known from South and East Asia, reflecting the basic biogeographic division of the two hominid subfamilies today [but see Kelley and Gao (2012)].

Fossil Pongines

The oldest sample of fossils widely interpreted as pongine is of *Sivapithecus* from the middle Chinji formation in the Siwaliks of Pakistan (Raza et al. 1983; Rose 1984, 1989; Kappelman et al. 1991; Barry et al. 2002). Specimens referred *Sivapithecus indicus* that are known to come from the middle Chinji formation share characters with later *Sivapithecus* and other hominids including reduced or absent molar cingula; relatively large M1; reduced premolar cusp heteromorphy; long, buccolingually compressed canines; broad-based nasal aperture; elongated and robust premaxilla partly overlapping the maxilla; and, as in *Kenyapithecus*, a high position to the zygomatic root. They share specifically with later *Sivapithecus* fewer clear-cut characters, such as probably strongly heteromorphic upper incisors (known only from the roots), and broad, flat cusped molars with thick enamel, though these characters are also found in most other Middle and many Late Miocene hominoids. One specimen of Chinji *Sivapithecus*, GSP 16075, represents a portion of the palate with the connection between the maxilla and premaxilla partially preserved. The maxillary-premaxillary relationship is highly diagnostic of *Sivapithecus* and the pongine clade, and the morphology of the Chinji specimen has been interpreted to share characters of this complex (Raza et al. 1983; Ward 1997b; Kelley 2002). However, while the specimen does have a relatively elongated, horizontal, and robust premaxilla, the area of the incisive fossa and foramen is not preserved. In the absence of this region, it is difficult to distinguish Chinji *Sivapithecus* from later *Sivapithecus*, including later *Sivapithecus indicus*, to which it is assigned, versus another pongine, *Ankarapithecus*. *Ankarapithecus* preserves a morphology of the anterior palate that lacks the synapomorphies of *Sivapithecus* and *Pongo* (Begun and Güleç 1998), and this may also be the case for the Chinji jaw. Resolution of this uncertainty would help to clarify the biogeography of pongine origins (see below).

Sivapithecus

Sivapithecus Craniodental Evidence

Most of the *Sivapithecus* samples, including the best-known specimens with the clearest evidence of pongine affinities, are from younger localities of the Siwaliks of India and Pakistan, dated between 10.5 and 7.5 Ma (Barry et al. 2002). In the following section, I discuss *Sivapithecus* in some detail because it is in many ways critical to understanding Late Miocene hominoid evolution. Three species are generally recognized in this sample, the best known of which is *Sivapithecus sivalensis* (Lydekker 1879), from localities ranging in age from 9.5 to 8.5 Ma (Kelley 2002). In addition to the characters outlined above, S*ivapithecus sivalensis*

Plate 8 GSP 15000, the best preserved specimen of *Sivapithecus*. To the *right* is a lateral view of the *face* without the mandible (Courtesy of Milford Wolpoff)

is known from a suite of cranial characters strongly indicative of pongine affinities (Pilbeam 1982). These include unfused tympanic and articular portions of the temporal bone; a posterosuperiorly directed zygomatic arch with deep temporal and zygomatic processes; vertically oriented frontal squama; supraorbital costae or rims; a narrow interorbital space; elongated nasal bones; tall, narrow orbits; wide, anteriorly oriented zygoma; narrow, pear-shaped nasal aperture; externally rotated canines; long, horizontally oriented nasoalveolar clivus that is curved along its length but flat transversely; and a subnasal region with the posterior pole of the premaxilla merging into the anterior edge of the maxillary palating process to form a flat, nearly continuous subnasal floor (Fig. 3) and a strongly concave facial profile from glabella to the base of the nasal aperture. *Sivapithecus* is also likely to have been airorhynchous (having a dorsally deflected face), as in *Pongo* (Fig. 4). All of these and other characters are described in more detail in Ward and Pilbeam (1983), Ward and Kimbel (1983), Ward and Brown (1986), Brown and Ward (1988), and Ward (1997b). *Sivapithecus sivalensis* is not identical to *Pongo* in cranial morphology, however, even if the similarities are striking and detailed. *Sivapithecus sivalensis* is more robust than similarly sized (female) *Pongo* in features related to the masticatory apparatus, including aspects of the zygomatic and temporal bones, maxillary robusticity, and molar morphology. The molars in particular are easily distinguished from those of *Pongo* in having thicker enamel and in lacking the complex pattern of crenulations seen in unworn *Pongo* molars. However, overall the number of derived characters shared with *Pongo* is impressive (Ward 1997; Kelley 2002) (Plates 8, 9, and 10).

Sivapithecus indicus (Pilgrim 1910) is the oldest species, and if the middle Chinji fossils are included, it would range from 12.5 to 10.5 Ma (Kelley 2002). It is the smallest species, at least in terms of dental size, and appears to have a slightly shorter nasoalveolar clivus or premaxilla compared with *Sivapithecus sivalensis* (see above). *Sivapithecus parvada* (Kelley 1988) is considerably larger than the other species and is known from the Nagri formation locality Y311, about 10 Ma. *Sivapithecus parvada* males are about the dental size of female gorillas. The upper central incisors are especially long mesiodistally, the M_3 is larger than the M_2, the premolars are relatively large, and the symphysis of the mandible is very deep (Kelley 2002).

Sivapithecus Postcrania

Sivapithecus postcrania have been described in many publications (Pilbeam et al. 1980, 1990; Rose 1984, 1986, 1989; Spoor et al. 1991; Richmond and Whalen 2001; Madar et al. 2002). They combine a mixture of characters, some suggesting more palmigrade postures and others suggestive of more suspensory positional behavior (see chapter "▶ Postcranial and Locomotor Adaptations of Hominoids," Vol. 2).

This has been interpreted by some to indicate that *Sivapithecus* is more primitive than any living hominoids, all of which, even humans, share numerous characters of the shoulder and forelimbs related to suspensory behavior or an ancestry of suspensory behavior (Pilbeam 1996, 1997; Pilbeam and Young 2001, 2004). This view, also shared by McCrossin and Benefit (1997), has dramatic implications for the interpretation of the hominoid fossil record. All Late Miocene hominoids, including *Sivapithecus*, share many characters of the cranium and dentition with living hominoids. If *Sivapithecus* is more primitive than extant hominoids, given its apparently primitive postcrania, then all the apparently derived hominid features of *Sivapithecus* would have evolved in parallel in *Sivapithecus*, and as these authors suggest, by extension in all Late Miocene hominoids (*Oreopithecus*, *Dryopithecus*, *Rudapithecus*, *Ouranopithecus*, *Lufengpithecus*, etc.). These parallelisms include not only craniodental morphology but also details of life history and, as it turns out, many postcranial characters as well. In fact, the apparently primitive characters of *Sivapithecus* postcrania are small in number compared with the large number of clearly derived hominid characters from throughout the skeleton and known biology of all Late Miocene hominids. Rather than rejecting the hominid status of *Sivapithecus* and other Late Miocene hominids because not all of their postcranial morphology is strictly hominid or even extant hominoid-like, it is much more likely that these few characters reflect mosaic evolution of the hominid skeleton, uniquely derived features of the anatomy of *Sivapithecus*, as well as some parallelism in extant hominoids (Begun 1993; Begun et al. 1997; Begun and Kivell 2011; see below).

Sivapithecus postcrania, though they have been the subject of more discussion related to phylogeny, are actually less well known than those of *Proconsul*, *Equatorius*, or *Nacholapithecus*. The following is summarized mainly from Rose (1997), Richmond and Whalen (2001), and Madar et al. (2002). Much more information is available from all the references cited earlier. Two species of *Sivapithecus* are known from the humerus, which is unlike that of modern hominoids in the curvature of the shaft and the development of the deltopectoral plane. The bicipital groove is also broad and flat and suggests a posteriorly oriented humeral head, as in the Early and Middle Miocene Hominidea described earlier. However, the humerus has such an unusual morphology that the orientation of the head, which is already somewhat difficult to predict from bicipital groove position (Larson 1996), cannot be reconstructed with great confidence. Nevertheless, the morphology of the proximal humerus in *Sivapithecus* is suggestive of some form of pronograde quadrupedalism as seen, for example, in extant cercopithecoids. If the humeral head were oriented more posteriorly, it would also be consistent with a scapula that is placed on the side of a compressed rib cage, as in typical mammalian quadrupeds, and unlike extant hominoids (Rose 1989; Ward 1997a). No direct evidence is available for the thorax or any part of the axial skeleton of *Sivapithecus*, however, so this will also have to await further discoveries. The deltopectoral plane and the curvature of the shaft of the humeri in *Sivapithecus* are quite strongly developed compared with most cercopithecoids and indicate in my view a unique form of positional behavior that is neither extant hominoid nor extant cercopithecoid-like (Madar, et al. 2002). The distal end of the humerus is in the main hominoid-like, including a well-developed trochlea separated from the capitulum by a deep, well-defined groove (the zona conoidea), though in a few details of the posterior surface, there are similarities to *Proconsul* and *Kenyapithecus* (Rose 1997). Overall, however, the functional morphology of the elbow of *Sivapithecus* is most like the hominoid elbow in its ability to resist movements other than flexion and extension at the elbow joint, a hallmark of the Hominoidea (Rose 1988).

The *Sivapithecus* forearm is poorly known, especially the proximal portions of the ulna and radius, which would help to more fully understand the *Sivapithecus* elbow. A juvenile radial shaft is known that is described as *Proconsul*-like, though as a juvenile, it is not clear to what extent we might expect any hominoid-like characters, such as curvature and the nature of the ligamentous/muscular insertions, would be expressed. On the other hand, the few carpal bones that are known show a mixture of hominoid and non-hominoid features. The capitate of *Sivapithecus* has a somewhat expanded and rounded head, as in great apes, but overall is transversely narrow and elongated proximodistally compared with great apes. The joint surface for the third metacarpal is irregular as in great apes. The hamate is similar in length/breadth proportions and has a less strongly projecting hammulus than do great ape hamates (Spoor et al. 1991). The joint on the hamate for the triquetrum is oriented as in gorillas and also most other non-hominoid anthropoids, and its shape suggests a stabilizing function at the wrist, which differs fundamentally from the typical mobility of the ulnar side of the wrist in extant hominoids. The proximal end of a first metacarpal is similar in morphology to hominids and Early Miocene Hominidea in being saddle-shaped, a configuration considered to represent a good compromise between mobility and stability in a wide variety of positions. The manual phalanges are long and curved, with strongly developed ridges for the flexor muscles and their sheaths. One complete phalanx has a relatively deep and somewhat dorsally positioned articular surface for the metacarpal head, which is more typical of palmigrade quadrupeds. However, it is not completely clear if this is from a hand or a foot, and if the latter is the case, a similar morphology exists in some hominoids as well.

Begun and Kivell (2011) undertook a reanalysis of the carpal bone of *Sivapithecus* in light of recent discoveries of carpal bones of *Rudapithecus* (see below). They concluded that there are a number of terrestrial and even knuckle-walking characteristics of the capitate and hamate of *Sivapithecus*, though the capitate and hamate of *Sivapithecus* are nevertheless easily distinguished from those of African apes. The authors suggest that if the *Sivapithecus* species to which these carpals belong (*S. sivalensis* for the capitate and *S. parvada* for the hamate) did knuckle-walk, they did so in a manner that was biomechanically different from extant African apes (see chapters "▶ The Hunting Behavior and Carnivory of Wild Chimpanzees," Vol. 2, "▶ Great Ape Social Systems," Vol. 2 and "▶ Origin of Bipedal Locomotion," Vol. 3). It is worth remembering of course that African apes today are biomechanically distinct from one another in their knuckle-walking.

Whatever this means in terms of the big picture of hominoid evolution is unclear, but one mystery that is potentially solved by this analysis is the biogeography of the Miocene pongines (see below).

The hindlimb of *Sivapithecus* is less well known but generally more similar to extant hominoids than the forelimb. The femur is known from proximal and distal ends but not from the same individual (Rose 1986; Madar et al. 2002). The hip joint as represented by the femoral head and neck was mobile in many directions, though it has a well-developed fovea capitis, unlike *Pongo*, which is highly distinctive (but not unique) in lacking a ligamentum teres of the femur and thus its attachment site to the femur, the fovea capitis. The distal end of the femur preserves evidence of a knee joint that is consistent with this interpretation, implying a knee joint loaded in positions away from the sagittal plane. The knee also has a number of features allowing for rotation of the leg and foot to adjust the lower extremity to a variety of positions close to and further away from the center of mass (Madar et al. 2002). In all of these features, the femur is more like that of hominoids than other anthropoids.

Other hindlimb elements include several tarsal bones, phalanges, and a well-preserved hallucial skeleton (Conroy and Rose 1983; Rose 1984, 1986, 1994). The tarsals are perhaps more like those of great apes than any other part of the postcranium of *Sivapithecus* (Rose 1984; Madar et al. 2002), indicating the presence of a broad foot, able to assume many positions but stable in all of them, and supportive of body mass loading from many directions. The hallux or big toe is strikingly robust, much more so than in *Pongo*, and indicates a strongly developed grasping capability in the foot. The phalanges are also by and large hominoid-like, with well-developed features related to powerful flexion of the toes, a critical function in antipronograde activities (climbing as well as suspension).

***Sivapithecus* Phylogeny and Paleobiology**

Overall, the morphology of *Sivapithecus* strongly supports a close phylogenetic relationship to *Pongo* but an adaptation that differed from *Pongo* in important aspects. Microwear suggests that *Sivapithecus* had a diet that was similar to that of chimpanzees, while gnathic morphology suggests more of a hard-object diet (Teaford and Walker 1984; Kay and Ungar 1997; chapter "▶ Dental Adaptations of African Apes," Vol. 2). Perhaps this reflects a capacity to exploit fallback or "keystone" resources in times of scarcity. Most hominoids are known to practice this strategy (Tutin and Fernandez 1993; Tutin et al. 1997). The case of gorillas may be most relevant to the question of the diet of *Sivapithecus*. Most gorillas have diets similar to chimpanzees but are able to exploit terrestrial herbaceous vegetation (THV) in lean seasons when soft fruit is less available or in contexts in which they are sympatric with chimpanzees (Tutin and Fernandez 1993; Tutin et al. 1997). The microwear results may reflect the preferred and most common components of the diet, while the morphology of the jaws and teeth may reflect a critical adaptation to a keystone resource on which survival would depend during stressful periods (see chapters "▶ Role of Environmental Stimuli in Hominid Origins," Vol. 3 and "▶ The Paleoclimatic Record and Plio-Pleistocene Paleoenvironments," Vol. 1).

Postcranial evidence clearly indicates that *Sivapithecus* was not orang-like in its positional behavior. In fact, it was unique; there are probably no living analogues. *Sivapithecus* combines clear indications of pronograde forelimb postures and a palmigrade hand position with more antipronograde activities such as vertical climbing and clambering implied by elbow joint stability over a wide range of flexion/extension, powerful grasping hands and feet, an especially powerful hallux, and hindlimbs capable of wider ranges of joint excursions than in extant pronograde quadrupeds (Madar et al. 2002). It is difficult to imagine exactly what the positional behavior of *Sivapithecus* might have been like.

One constant in the postcranial functional morphology of *Sivapithecus* is arboreality. Perhaps *Sivapithecus* used its powerful limbs in climbing and bridging or clambering activities, spreading the limbs across multiple supports to access smaller branches. In a sense, it is orang-like without the suspension. While *Sivapithecus* managed to distribute its considerable body mass across the tops of several branches, orangs do the same but from below. In large animals, the advantage to suspension is added stability on horizontal supports, since they otherwise need to generate very high levels of torque to stay atop a branch (Grand 1972, 1978; Cartmill 1985). Orang males are larger than *Sivapithecus* and may be beyond the threshold where pronograde limb postures are possible in the trees. The fact that the proximal half of the humerus of *Sivapithecus*, while similar to that of a pronograde quadruped, is exceptionally robust, with extremely well-developed shoulder muscle attachments, may be an indication of a unique approach to this problem.

Sivapithecus does share numerous postcranial features, especially of the elbow and hindlimb, with extant hominoids and *Dryopithecus*. It is therefore possible that the more monkey-like morphology of the proximal humerus and portions of the hands and feet are actually homoplasies with cercopithecoids caused by the adoption of more pronograde postures in a hominoid that evolved from a more suspensory ancestor (Begun et al. 1997). This requires many fewer homoplasies than the alternative hypothesis that all extant hominoid characters in all Late Miocene hominoids are homoplasies (Pilbeam 1996, 1997; McCrossin and Benefit 1997; Pilbeam and Young 2001, 2004). There is some evidence from the functional morphology of *Sivapithecus* to support the hypothesis that its form of pronograde arboreal quadrupedalism is actually superimposed on a suspensory hominoid groundplan (see chapter "▶ Origin of Bipedal Locomotion," Vol. 3).

The problem of angular momentum causing instability in a large mammal standing on top of a branch is alleviated in part by spreading the limbs apart on a wide support, or across several supports, which *Sivapithecus* seems to have been capable of doing (Madar et al. 2002). It can also be all alleviated by placing the center of mass closer to the support, which is suggested for *Griphopithecus* (Begun 1992a), and may have also occurred in *Sivapithecus*, as a consequence of its habitually more laterally placed limbs (Madar et al. 2002). The positioning of the limbs more laterally in hominoids is part of the suite of characters related to trunk morphology and scapular position. It is not facilitated by monkey-like trunks and scapular positions, which promote more parasagittal limb movements. Finally, an important response to angular momentum is to increase the torque generated by the limbs on the support, to prevent excessive excursions from a balanced position, especially when a single support of only modest size is used, again suggested to be an aspect of the positional behavior of *Sivapithecus* (Madar et al. 2002). Higher torque results from more powerful gripping, also characteristic of *Sivapithecus* (Madar et al. 2002), and may have been boosted by especially powerfully developed shoulder joint adduction and medial rotation, particularly if the shoulder is in a relatively abducted position to begin with, as in hominoids.

The morphology of the proximal half of the humerus in *Sivapithecus* is consistent with very powerful adduction and medial rotation by deltoideus and pectoralis major. These muscles left extremely prominent scars on the humerus of *Sivapithecus*. If the arm of *Sivapithecus* were positioned as in extant hominoids, laterally on a posteriorly positioned scapula, the adduction and medial rotation capacities of deltoideus and pectoralis would be increased by increasing the relative mass of the clavicular portion of deltoideus, which is unknown in *Sivapithecus*. However, in addition to the need for powerful muscles, which existed in *Sivapithecus*, these functions would also be enhanced by other attributes known in *Sivapithecus*. The extension of the muscles along the shaft distally and the possible decreased humeral neck torsion would increase the moment arm for these muscles in adduction and reposition the insertions of these muscles medially, possibly to make more of the deltoideus available for adduction and medial rotation. The strong mediolateral curvature of the shaft may result from high mediolateral bending stresses that would result from very powerful shoulder adduction on a fixed limb. The proximal shaft is also very broad mediolaterally, suggestive of strong mediolaterally directed stresses. While speculative, it is certainly conceivable that the upper part of the forelimb of *Sivapithecus* was less monkey-like than generally perceived and may not imply that much of the trunk was of the primitive anthropoid type. A small number of autapomorphies of the shoulder of *Sivapithecus* may have allowed this taxon to practice a relatively efficient form of arboreal pronograde quadrupedalism while maintaining the capacity for many of the antipronograde activities of hominoids, though probably not for frequent upper limb below-branch suspension. This hypothesis is functionally consistent with the morphology of the *Sivapithecus* postcranium in general and is certainly more parsimonious than the hypothesis that would interpret all Late Miocene hominoid characters as homoplasies (Begun and Kivell 2011).

Ankarapithecus

Aside from some material from Nepal attributed to *Sivapithecus* (Munthe et al. 1983), *Sivapithecus* is known only from India and Pakistan. Specimens from central Anatolia, Turkey, once attributed to *Sivapithecus* (Andrews and Tekkaya 1980) are now assigned to *Ankarapithecus*, following the original conclusions of Ozansoy (1957, 1965). *Ankarapithecus meteai* is known from a male palate and mandible from two different individuals and a female partial skull (mandible and face) from a third locality, all close to each other in location and geological time (Kappelman et al. 2003). Begun and Güleç (1995, 1998) resurrected the nomen *Ankarapithecus* based mainly on the morphology of the premaxilla and the

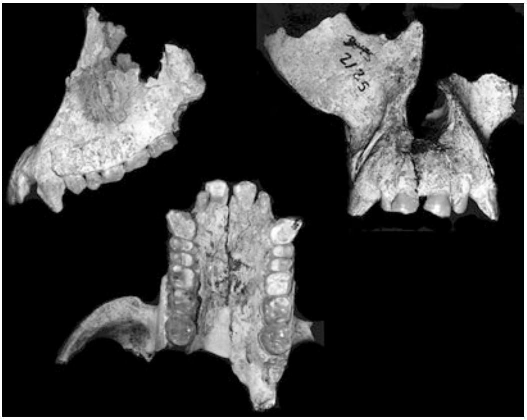

Plate 11 *Ankarapithecus* (MTA 2125)

relationship between this bone and the maxilla but concluded that *Ankarapithecus* is nonetheless in the pongine clade. Alpagut et al. (1996) and Kappelman et al. (2003) described newer and much more complete fossils of *Ankarapithecus* and concluded that it is a stem hominid (sharing a common ancestor with both pongines and hominines). The new fossils discovered and described by these authors include the region around the orbits, which lacks some of the characters of *Sivapithecus*. The interorbital region is intermediate in breadth between *Pongo*, with the narrowest interorbitals, and African apes and the orbits themselves are broad rather than tall and narrow. Alpagut et al. (1996) and Kappelman et al. (2003) also interpret the supraorbital region as a supraorbital torus, characteristic of African apes and humans and some European Late Miocene taxa, and they interpret a frontal sinus in the cranium of *Ankarapithecus* as a frontoethmoidal sinus. These authors see the mixture of hominine and pongine characters as an indication that *Ankarapithecus* precedes their divergence (Plate 11).

Craniodental Evidence

The frontal sinuses in *Ankarapithecus* appear to be confined to the frontal squama and do not invade the frontal supraorbital region from a broad expansion of the ethmoidal sinuses. They are positioned and developed as in extant taxa with frontal pneumatizations derived either from the sphenoidal or maxillary sinuses and are unlike those derived from the ethmoid (see above discussion). The frontal pneumatization in *Ankarapithecus* is unlikely to be a frontoethmoid sinus and thus is not a synapomorphy of the hominines. The supraorbital region, while robust, is morphologically similar to the robust supraorbital costae of large orangs or *Cebus* and also unlike the bar-like supraorbital tori of African apes. Thus, the supraorbital region of the *Ankarapithecus* cranium is more pongine than hominine-like and, like the maxilla, probably represents the primitive morphology for the pongines (see below).

In *Ankarapithecus*, the premaxilla, the portion of the palate with the alveoli for the incisors and the mesial half of the canines, is unlike that of *Sivapithecus* and more like that of African apes. The premaxilla is long, but it does not overlap the palatine process of the maxilla to fill the incisive fossa to the degree seen in *Sivapithecus*. Instead, the subnasal fossa is stepped (there is a drop between the base of the nasal aperture and the floor of the nasal cavity) into an incisive fossa that is most like that of some chimpanzees, a relatively large depression opening into a canal (the incisive canal that runs between the premaxilla and maxilla to exit on the palatal side via the incisive foramen). *Rudapithecus* has a similar configuration of the subnasal fossa, incisive canal, and incisive foramen, though the fossa is larger and the canal is shorter in length and larger in caliber, as in some gorillas (Begun 1994a; Fig. 3). The premaxilla of *Ankarapithecus* is curved or convex anteroposteriorly as in *Sivapithecus*, African apes, and *Rudapithecus*, but it is also convex transversely, as in African apes and *Rudapithecus* unlike *Sivapithecus*, which has a transversely flatter premaxilla. In all of these features, *Ankarapithecus* expresses a condition intermediate between pongines and hominines, which I consider primitive for the pongines (Begun and Güleç 1998). Alpagut et al. (1996) and Kappelman et al. (2003) have suggested that these characters indicate that *Ankarapithecus* precedes the divergence of pongines and hominines and is thus a stem hominid. Other features of the morphology of *Ankarapithecus* resemble pongines more clearly, including canine implantation, zygoma size and orientation, orbital margin morphology, nasal length, and dental morphology. Overall, *Ankarapithecus* most closely resembles *Sivapithecus* and *Pongo* but retains a more primitive palatal morphology that suggests it is at the base of the pongine clade.

Postcranial Evidence

Some postcrania of *Ankarapithecus* are known, including a well-preserved radius and two phalanges (Kappelman et al. 2003). A femur tentatively identified as primate is more likely in my opinion to be from a carnivore. The radius shares characters with extant great apes including features of the radial head and a comparatively long radial neck (Kappelman et al. 2003). Other hominoid-like features described or figured in Kappelman et al. (2003) but not identified as hominoid-like by these authors include a proximodistally compressed and more circular radial head, a deep radial fovea, flat as opposed to concave shaft surface along the anterior surface, a more distal origin of the interrosseous crest, and a smooth distal dorsal surface. The specimen actually strikes me as quite hominoid-like with a few features more normally associated with large non-hominoid anthropoids, a pattern more or less in keeping with other Late Miocene hominoids. The phalanges are said to be relatively straight and thus non-hominoid-like, but only distal portions are preserved. They too strike me as more hominoid-like than Kappelman et al. (2003) suggest, given its distal shaft robusticity, dorsopalmar compression, and distopalmarly projected condyles. The curvature and ridges for the flexor musculature are said to be poorly developed compared with hominoids, but this may be related to many factors (preservation, age, digit attribution).

Overall, *Ankarapithecus* is characterized by many features found in other pongines and is probably the most basal known member of that clade. Like *Sivapithecus*, it was much more massive in the development of its masticatory apparatus than *Pongo*, and its postcranium, though very poorly known, suggests arboreality and at least some features of hominoid-like antipronograde positional behaviors, but probably lacking the degree of suspension seen in dryopithecins, *Oreopithecus*, and extant hominoids (but see Kappelman et al. 2003).

Other Probable Fossil Pongines

Indopithecus-Gigantopithecus

Extremely large fossil hominoids, larger than any extant primate, have been known from Asia since the early part of the twentieth century. *Gigantopithecus blacki* (von Koenigswald 1935) is a Pleistocene taxon known from numerous isolated teeth and a few mandibles. It is recent enough to be outside the purview of this review and has been described many times elsewhere. *Sivapithecus giganteus* (Pilgrim 1915) is the oldest nomen attributed to samples from the Late Miocene of South Asia that may be related to *Gigantopithecus*. This sample, only known from a lower M3 from the Late Miocene of the Siwaliks, is mainly distinguished from *Sivapithecus* by size. When a mandible with teeth of similar size was found, a new species, *Gigantopithecus bilaspurensis*, was named, but more recently most researchers have combined the mandible with the type of *Sivapithecus giganteus* (the lower molar), thus making the new combination *Gigantopithecus giganteus* (Kelley 2002). Von Koenigswald (1949) proposed the nomen *Indopithecus* for the M3. In my view, the type of *G. bilaspurensis* is sufficiently distinct from Pleistocene *Gigantopithecus* that I place both the mandible and the M3 in *Indopithecus*, making the new combination *Indopithecus giganteus*. The jaws and teeth of *Indopithecus* are larger than any *Sivapithecus*, and the only known mandible is distinctive in having reduced anterior tooth crown heights and molarized or enlarged premolars. *G. blacki*, on the other hand, is larger still and has highly complicated postcanine occlusal morphology and relatively even larger mandibles and smaller anterior teeth. Because *I. giganteus* and *G. blacki* share characters of the lower jaws and teeth that appear commonly during the course of hominoid evolution (in fact, in many other mammal lineages as well), the relationship between the two is uncertain. Jaws and teeth in general, and mandibles in particular, are magnets for homoplasy in primate evolution (Begun 1994b, 2007), and this may be another example. In the end, the morphology of the jaw and teeth of *Indopithecus* much more closely resembles that of *Sivapithecus*, while certain dental proportions more closely resemble *Gigantopithecus*. Given the age and morphological differences, I prefer to recognize two genera, though I do recognize that they are closely related. The most parsimonious hypothesis is that *I. giganteus* is a primitive member of the *Gigantopithecus* clade and that the strong similarity to *Sivapithecus* in the molars, apart from size, suggests that it is the sister clade to that taxon (Table 1, Plate 12).

Lufengpithecus

Thousands of fossils, mostly isolated teeth, are known from a number of localities in Yunnan Province, southern China. These are attributed to the genus *Lufengpithecus* (Wu 1987). *Lufengpithecus* is most commonly recognized as a

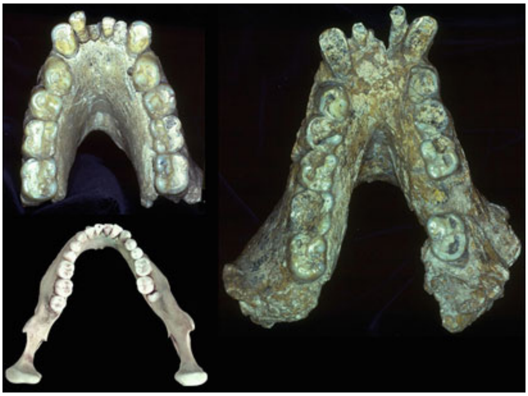

Plate 12 Two mandibles of *Gigantopithecus* compared with a modern human mandible. *Gigantopithecus* images courtesy of Milford Wolpoff

pongine. Kelley tentatively recognizes three species of *Lufengpithecus*, distinguished mainly by size and geography (each is known from a single site). *Lufengpithecus* shares a few cranial characters with other pongines including a small, pear-shaped nasal fossa, aspects of the implantation of the canine roots in the maxilla, a deep canine fossa, supraorbital costae, and anteriorly oriented zygoma (Schwartz 1997 and personal observations). However, while it lacks many of the detailed similarities of the face between *Sivapithecus* and *Pongo*, its teeth are much more like those of *Pongo* than *Sivapithecus* in details of occlusal morphology, including the unusual presence of highly complex wrinkling or crenulations (Kelley 2002). The face of *Lufengpithecus* is unlike those of *Sivapithecus* and *Pongo* in having broad orbits, a broad interorbital space, a comparatively short premaxilla, high crowned incisors and canines, and compressed and very tall crowned male lower canines. Though very damaged, my impression is that the nasal floor is unlike the smooth floor of *Sivapithecus* and *Pongo* but possibly more similar to the morphology in *Ankarapithecus*. There are intriguing similarities between *Lufengpithecus* and dryopiths, especially in the incisors and premaxilla, and Kelley and I have independently reached the conclusion that they might be more closely related to one another than *Lufengpithecus* is to pongines. This, however, is a hypothesis that needs a lot more investigation, and for now I follow Kelley (2002) in placing *Lufengpithecus* among the pongines (Plates 13 and 14).

L. lufengensis (Xu et al. 1978) from a site near Shihuiba, in Lufeng county, is the best-known species of the genus and is also known from a number of postcranial remains including fragments of a scapula, clavicle, radius, first metatarsal, and two phalanges. None have been published in detail, but all of these specimens show clear indications of modern hominid morphology associated with suspensory positional behaviors (personal observations). This is especially true of the phalanges, which are strongly curved and bear the markings of powerful flexor tendons. The metatarsal is similar to that of *Sivapithecus* in its relative robusticity.

Until the fossils attributed to *Lufengpithecus* are published in detail, it will be impossible to be confident in assessing their taxonomic and phylogenetic relations. At this point, it seems likely that *Lufengpithecus* is a pongine and probably a sister

Plate 13 Female (*upper left*, PA 586) and male (*upper right*, PA 548) mandibles of *Lufengpithecus* in occlusal view, and, *below*, an anterior view of the male. Note the high crowned and narrow anterior dentition

taxon to the *Pongo*-*Sivapithecus*-*Ankarapithecus* clade. However, the generally more *Pongo*-like morphology of the molar occlusal surfaces and the more clearly hominoid-like morphology of the postcrania are enigmatic and suggest caution in interpreting evolutionary relationships. Kelley and Gao (2012) describe a juvenile specimen of *Lufengpithecus* from a different locality, Yuanmou, also in Yunnan Province. The Yuanmou specimen is interpreted by these authors as having more similarities with dryopithecins than previously supposed for *Lufengpithecus*, which is consistent with my impressions of the adult specimens from Shuhuiba. However, we both come short of concluding that there is definite evidence of a phyletic link between *Lufengpithecus* and the dryopithecins. Interpreting the morphology of a taxon from a juvenile specimen can be very tricky. More detailed comparisons between the Yunnan Province *Lufengpithecus* samples and those of dryopithecins from Europe are needed to determine if there really are phylogenetic connections between the two groups of hominids independent of the Siwalik taxa. This, however, would represent a dramatic development in our understanding of Late Miocene ape biogeography and would falsify an observation I made some years ago about the separation of the Asian and European samples (Begun 2005). Another possibility of course is that the Yunnan samples represent another lineage of hominid not specifically related to any living great ape (Ji et al. 2013). Only more detailed comparisons among these samples will help to resolve this issue.

Khoratpithecus

Three samples of Southeast Asian Miocene hominoids have recently come to light. Chaimanee et al. (2003) describe a Middle Miocene sample of hominoids from Thailand they originally attributed to a species of *Lufengpithecus*. The age of the locality is not completely certain, and it is possible that the fauna could be correlated with a more recent magnetostratigraphic interval, but for now the sample is considered to date to the late Middle Miocene or early Late Miocene (13.5–10 Ma). However, on the basis of more recently discovered Late Miocene hominoid fossils from Thailand, Chaimanee et al. (2004) described a new genus, *Khoratpithecus*, and revised their previous taxonomic conclusions to include the Middle Miocene taxon in the newly named genus as well. The fossils, a sample of isolated teeth and a well-preserved mandible, are very similar to *Lufengpithecus* but show a number of differences in the anterior dentition and lower jaw (Chaimanee et al. 2004). Chaimanee et al. (2004) interpret *Khoratpithecus* to be more closely related to *Pongo* than is any other pongine, mainly based on the shared derived character of a missing anterior digastric muscle. More fossils are needed to test this hypothesis more fully. The greater significance of these discoveries is the location, in Thailand, and the possibly early age, Middle Miocene. In 2011 the same research group described a new species of *Khoratpithecus* from Myanmar (formerly Burma), to the northwest of Thailand (i.e., in the direction of the Siwaliks of India and Pakistan) (Jaeger et al. 2011). The three species of *Khoratpithecus* are represented only by a small number of mandibles and isolated teeth, and it is not clear if three different species are represented, but they do appear to be distinct from *Sivapithecus* and *Lufengpithecus*.

All four genera of Asian great apes described here range in age from possibly as old as 13.5 Ma to possibly as young as 6 Ma. If the dates are correct, *Khoratpithecus ayeyarwadyensis*, from Myanmar, is the oldest of this group and is roughly contemporary with *Kenyapithecus* from Fot Ternan, Kenya. *Lufengpithecus lufengensis* from Shuhiba (Yunnan Province, China) and *Indopithecus* from the Siwalik Hills are the youngest, at about 6–7 Ma, and are roughly contemporaneous with *Sahelanthropus*, from Chad, the earliest known hominin.

The Earliest Fossil Hominines: The Dryopithecins 1

At about the same time that hominids appear in Asia, they make their first appearance in Europe. As is the case with the earliest pongines, the earliest hominines lack a number of synapomorphies of living hominines (African apes and humans) and are less distinct from related non-hominines than are more recently evolved hominines. This has led naturally to differences of opinion regarding the systematics of this group (see chapters "▶ Defining Hominidae," Vol. 3 and "▶ Hominoid Cranial Diversity and Adaptation," Vol. 2). There are three main interpretations of the evolutionary relations among the taxa included here in the Homininae. As noted, some researchers conclude that no known Eurasian Late Miocene taxon has a specific relationship to extant hominoids (Pilbeam 1996, 1997; McCrossin and Benefit 1997; Pilbeam and Young 2001, 2004). Most researchers, however, accept the hominid status of these fossil taxa but are divided as to their interrelationships. Some researchers (Andrews 1992) have concluded that European Late Miocene hominids are best viewed as stem hominids, preceding the divergence of hominines and pongines. Others interpret most or all Eurasian hominines to be members of the pongine clade (Moyà-Solà et al. 1995). Finally, some researchers interpret most or all European hominids to be hominines, although there is disagreement among them as to the precise pattern of relations (Bonis and Koufos 1997; Begun and Kordos 1997; see chapter "▶ Potential Hominoid Ancestors for Hominidae," Vol. 3). As my interpretation falls with the last group, this will be reflected in this chapter. I will however attempt to outline the major arguments from each perspective.

Nomenclatural History

The taxonomic history of *Dryopithecus* and the dryopithecins is very complicated (see Begun 2002 for a more complete history). At one time, most of the well-known taxa described here were attributed to *Dryopithecus* (*Proconsul*, *Sivapithecus*, *Ouranopithecus*, *Ankarapithecus*, *Griphopithecus*). More recently *Dryopithecus* was restricted to the sample European great apes from Spain, France, Germany, Austria, Hungary, and Georgia that all share features in common with African apes, in particular thinly enameled teeth with less robust jaws than *Sivapithecus* or *Ouranopithecus*. This was the consensus when the first version of this review was published in 2007. Since then the concept of *Dryopithecus* has become even more narrowly defined. As of this writing, *Dryopithecus* is restricted more or less to the original sample from St. Gaudens, a mandible from Austria and a maxilla from Spain. The important distinctions between *Dryopithecus* and most of the other samples that have until recently been attributed to *Dryopithecus* are age and morphology. All *Dryopithecus*, along with *Pierolapithecus* and *Anoiapithecus*, are more primitive in dental morphology (persistent cingula, small first molars, short premolars, robust canines) (Begun et al. 2012; Alba 2012). Postcranially, *Pierolapithecus* is more primitive than the later-occurring *Hispanopithecus* and *Rudapithecus* (see below). *Dryopithecus*, *Pierolapithecus*, and *Anoiapithecus* all occur in the Middle Miocene. Later-occurring and more modern-looking dryopithecins are all from the Late Miocene in Europe.

Specimens from the Middle Miocene of Spain have been attributed to *Dryopithecus* but also to two new taxa, *Pierolapithecus* and *Anoiapithecus*. The latter is known only from a distorted facial fragment, while the former is known from many parts of a skeleton, though unfortunately the face is seriously damaged. Because *Dryopithecus sensu stricto* is known only from male mandibles, it is extremely difficult to compare it with *Pierolapithecus* and *Anoiapithecus*, both of which are known mainly from upper teeth and postcrania. There is a mandibular fragment of *Anoiapithecus* that can be compared directly with *Dryopithecus*, and in my opinion, the differences between the two samples do not warrant a genus level distinction. *Pierolapithecus* is not known from lower teeth or jaws, and it is impossible to compare this sample with *Dryopithecus*. In addition, when they were first described, each of these taxa was assigned to different hominid clades.

Pierolapithecus and *Anoiapithecus* were first described as stem hominids, predating the divergence of pongines and hominines (Moyà-Solà et al. 2004, 2009a). *Dryopithecus*, when it was discovered at Hostalets, was first described as a hominine and possibly a sister clade to *Gorilla* (Moyà-Solà et al. 2009b). In addition, *Hispanopithecus*, also from the Vallès Penedès but from younger deposits (see below), was first described as a pongine. This represents three separate hominid clades present in a relatively restricted temporal and geographic span, which I consider unlikely. The most current interpretation of all of these taxa places them in the Ponginae (Alba 2012, Fig. 8, p. 265), though this author acknowledges that other interpretations, including the alternatives that they are all hominines or stem hominids, are possible. The practical difficulties in comparing *Pierolapithecus*, *Anoiapithecus*, and *Dryopithecus* to each other, given the few comparable parts preserved (see below), led me to be skeptical that three different genera and possibly three different clades can be effectively identified from these samples. The fact that all three Middle Miocene genera were found within a few kilometers of one another from essentially the same time period and same geological formation made me even more skeptical that three different genera are represented. All three are Middle Miocene and are more primitive than Late Miocene apes including *Hispanopithecus*. However, this is not the place for a taxonomic revision of these genera, so I will use the nomena originally proposed by the describers while noting that they are probably all closely related and possibly all *Dryopithecus*.

Dryopithecus fontani

Dryopithecus is the first-named taxon, and it is agreed by most researchers that this taxon is Middle Miocene and more primitive than Late Miocene European great apes. There is disagreement as to whether or not other early hominids taxa lived in Western Europe during the same time as *Dryopithecus*. *Dryopithecus* was first identified from St. Gaudens, on the northern slopes of the French Pyrenees (Lartet 1856). *Dryopithecus sensu stricto*, that is, *D. fontani*, is only known from three mandibles, a few isolated associated teeth, and a humeral shaft, all from St. Gaudens. Two isolated teeth from La Grive, also in France but in a geologically completely different context (Alpine as opposed to Pyrenean), are also traditionally attributed to *Dryopithecus*. These sites are considered to be Middle Miocene, based exclusively on their fauna, and the apes from these sites are more primitive dentally than apes that occur later on in Europe.

Dryopithecus fontani is known from three male mandibles and a humerus, all from the same locality in France, a female mandible from Austria, and a partial face from Spain (Begun 2002; Begun et al. 2012; Moyà-Solà et al. 2009b). Two isolated upper teeth from La Grive in France are also usually attributed to *D. fontani*. The mandibles and their dentitions are typically hominid in being comparatively robust with well-developed symphyseal tori, large incisors, compressed canines, elongated postcanine teeth with peripheralized cusps and lacking cingula, P_4 with trigonids and talonids of nearly equal height, and molars of nearly equal size, especially M1 and M2. The teeth of all *Dryopithecus* are thinly enameled with dentine horns penetrating well into the enamel caps. *D. fontani* is distinguished from other species of *Dryopithecus* in having a mandible that shallows (becomes lower compared to breath) distally, a high frequency of buccal notches on the lower molars, and comparatively robust lower canines.

The more recently described material attributed to *Dryopithecus* from Catalonia include a palate that cannot be directly compared with the fossils from France and Austria but does allow a comparison with *Anoiapithecus* and *Pierolapithecus*. Alba (2012) maintains that the morphological differences among these three samples are sufficient to justify the recognition of three different genera, all of which he places within the ponginae. In my view, the differences are minor and the samples, while including well-preserved specimens, are small, making it very difficult to assess ranges of variation within each group. This being the case, I think it is more likely that a single genus is represented, and by the rule of taxonomic priority, that taxon would be *Dryopithecus* (Begun et al. 2012).

Dryopithecus fontani is also known from a humeral shaft from the type locality that has been described as chimpanzee-like (Pilbeam and Simons 1971; Begun 1992a). It is the only nearly complete humerus of the genus. It is comparatively long and slender with poorly developed muscle insertion scars and a slight mediolateral and anteroposterior curvature. Neither the proximal nor the distal epiphyses are preserved, but the diaphysis preserved close to each epiphysis is hominoid-like. Proximally, it is rounded in cross section with a bicipital groove position suggesting some degree of humeral torsion (but see Rose 1997; Larson 1998). Distally, it is mediolaterally broad and anteroposteriorly quite flat, with a large, broad, relatively shallow olecranon fossa (Begun 1992a).

Finally, the proximal end of a femur has been tentatively attributed to *Dryopithecus* (cf. *Dryopithecus*). This specimen has been described as less suspensory than *Hispanopithecus*, with indications of a more quadrupedal form of locomotion (Moyà-Solà et al. 2009b). If this is truly *Dryopithecus*, this interpretation is somewhat at odds with the interpretation of suspensory locomotion based on the humerus, but as we see very often in the fossil record, different anatomical regions evolve somewhat independently, leading to morphological mosaics that have no analogues among living taxa.

Pierolapithecus catalaunicus

The best-known Middle Miocene hominine genus is represented by the very nicely preserved partial skeleton of *Pierolapithecus* (Moyà-Solà et al. 2004). The specimen, from northern Spain, is dated to 11.93 Ma (Casanovas-Vilar et al. 2011). The specimen includes most of a face which, though distorted, preserves nearly all the teeth and many informative facial characters. It also includes a partial postcranial skeleton, the most informative parts of which are some lumbar vertebrae, ribs, and a number of hand and foot bones. Moyà-Solà et al. (2004) interpret *Pierolapithecus* as a basal or stem hominid. More recently, Alba (2012) prefers the hypothesis that *Pierolapithecus* is a pongine. Moyà-Solà et al. (2004) cite the lumbar vertebrae, which preserve evidence of a hominoid-like vertebral column and by extension rib cage. This is indicated by the position of the lumbar transverse processes, placed more posteriorly in hominoids to stiffen the lower back (Ward 1993). However, the morphology of the lumbar vertebrae in *Pierolapithecus* is more hylobatid-like, extant hominids having even more posteriorly positioned transverse processes. Other aspects of the postcranium that clearly support the hominoid status of *Pierolapithecus* include ribs, indicative of a broad, anteroposteriorly compressed rib cage, robust clavicle, and a wrist morphology indicating no direct contact between the carpus at the triquetrum and the ulna (Moyà-Solà et al. 2004). These features are shared with all extant hominids. Hylobatids are unique in their carpal/ulnar contact, having a large intervening articular meniscus (Lewis 1989). The homologous surface of the triquetrum in *Pierolapithecus* indicates a great ape and not a hylobatid configuration.

The carpals in general are hominid-like in their overall morphology, including relative size, robusticity, and general pattern of the orientation of the joint surfaces. The lunate, triquetrum, and hamate in particular closely resemble small chimpanzees, but it is not clear if these are derived characters for hominines or hominids. Moyà-Solà et al. (2004) describe the phalanges of *Pierolapithecus* as being relatively shorter, less curved, and with metacarpal joint surfaces facing more dorsally than in *Rudapithecus* and *Hispanopithecus*, clearly suspensory hominines, which they interpret to mean that *Pierolapithecus* had a palmigrade hand posture (see also Alba et al. 2010). At the same time, the attributes of the thorax and hand suggest antipronograde (suspensory) limb positions, which is somewhat contradictory. They resolve this dilemma with the suggestion that *Pierolapithecus* was a powerful vertical climber but not suspensory. This is similar to the suggestion made earlier regarding *Sivapithecus*, though the morphology of the phalanges does not in fact rule out suspension. The phalanges are curved compared with most arboreal primates and have strongly developed flexor muscle attachments, even if these are not so strongly expressed as in *Hispanopithecus* and *Rudapithecus* (Begun and Ward 2005). Deane and Begun (2008) concluded that the phalanges of *Pierolapithecus* were in the range of curvature seen in *Hylobates*, *Pongo*, *Rudapithecus*, and *Hispanopithecus*. Based on phalangeal curvature, Deane and Begun (2010) considered *Pierolapithecus* to be more suspensory than Old World monkeys and African apes but less than in Asian apes.

Moyà-Solà et al. (2004) interpret various craniodental attributes of *Pierolapithecus* to reflect its stem hominid status as well. The face is prognathic with an enlarged premaxilla. The zygomatic root is high, the nasal aperture broad, and the postcanine teeth have a typical hominid morphology (elongated, relatively large M^1, absence of cingula, reduced premolar cusp heteromorphy, buccolingually large incisors, compressed canines). The premaxilla is expanded compared with early and exclusively Middle Miocene hominoids and appears to have an overlap posteriorly with the maxilla, as in hominids. However, according to these authors, it lacks the distinctive attributes of either the hominine of pongine clade.

Some of the distinctive attributes of *Pierolapithecus* are clearly related to distortion. The glabella is unlikely to have been as posterior as it appears, the midface is clearly badly damaged and was not as prognathic as in *Afropithecus*, despite what the authors suggest, and the premaxilla is obviously displaced relative to the palatine process of the maxilla (Begun and Ward 2005). In my view, the face much more closely resembled *Hispanopithecus*, though it is still distinct enough to justify a separate genus. The similarities with *Afropithecus* are probably related to a similar pattern of distortion (see above).

All in all, *Pierolapithecus* closely resembles *Dryopithecus*, known from contemporaneous localities in France and Austria, and *Hispanopithecus* and *Rudapithecus*, known from younger localities in Spain and Hungary. Based on this level of similarity, a consensus is emerging that all of these taxa belong in the tribe Dryopithecini (Begun et al. 2012; Alba 2012).

Attributes of the postcrania and dentition are more primitive in *Pierolapithecus* and justify a separate genus from Late Miocene *Hispanopithecus* and *Rudapithecus*. There is evidence to suggest that *Pierolapithecus* is a stem hominine and not as Moyà-Solà et al. (2004) conclude, a stem hominid, or as Alba (2012) concludes, a stem pongine (Begun and Ward 2005; Begun 2007, 2009; Begun et al. 2012). Details of dental morphology are strikingly similar to other dryopithecins (*Dryopithecus*, *Rudapithecus*, *Hispanopithecus*). Despite the unusually small M^3 and elongated upper canine, most of the teeth could easily be mistaken for those of other dryopithecins and show features distinctive for that tribe, including relatively tall crowned and mesiodistally narrow upper incisors, compressed canines, premolars with prominent cusps separated by a broad deep basin, and molars with marginalized or peripheralized, relatively sharp cusps. The contact between the premaxilla and the maxilla appears to also have been very similar to *Rudapithecus* in being stepped with only a modest degree of overlap between the two (Alba 2012; Begun 2007, 2009; Begun et al. 2012). The supraorbital region, though described by Moyà-Solà et al. (2004) as having thin supraorbital arches, actually closely resembles *Rudapithecus* and *Hispanopithecus* specimens from Spain and Hungary, with subtle tori emerging from a more prominent glabella. In my view, *Pierolapithecus* is close to the common ancestor of the Hominidae but already shares a common ancestor with the Homininae (Begun and Ward 2005; Begun 2009). Its postcranial morphology, however, is probably very close to that of the hominid ancestral morphotype (Fig. 2).

Anoiapithecus

Anoiapithecus is the third genus of Middle Miocene hominine from Hostalets de Pierola (Moyà-Solà et al. 2009a). As noted, it was originally interpreted to be a stem hominid and more recently a stem pongine. The stem hominine attribution is largely on the basis of its short face (hence the trivial name *brevirostris*). The dental

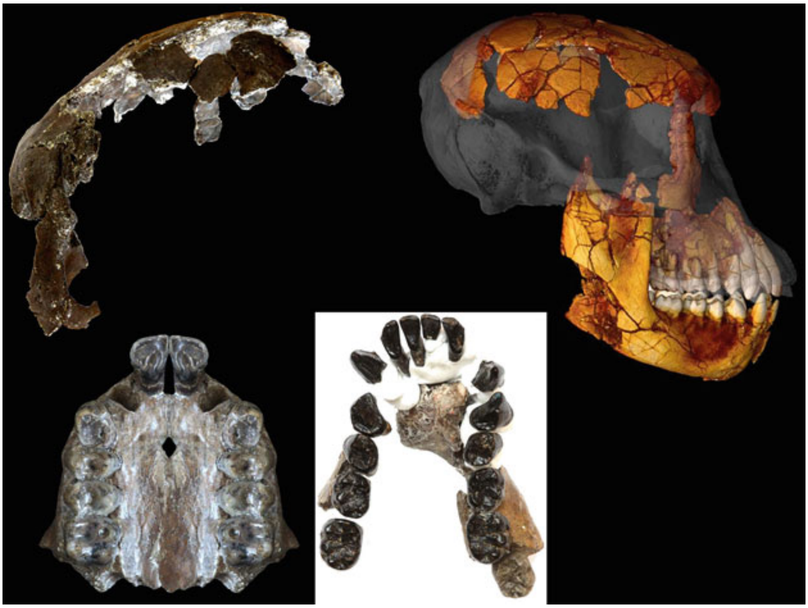

Plate 15 *Rudapithecus*. The two crania (RUD 77, *left* and RUD 200, *right*) include the most complete brain cases of a European hominine. The RUD 200 image is a virtual reconstruction superimposed on a chimpanzee skull (Courtesy of Philipp Gunz). RUD 12 (*bottom left*) is a female left hemi-palate mirror imaged to make a complete palate. RUD 14 (*bottom right*) is juvenile male mandible

morphology, which is the best preserved parts of *Anoiapithecus*, is very similar to other dryopithecins, and without the facial portions, it would certainly be assigned to *Dryopithecus*. The facial portions that are preserved are quite fragmentary, and I am doubtful that a reliable reconstruction of the palate relative to the upper part of the face can be achieved. When the most complete and well-preserved parts of the *Anoiapithecus* specimen are considered, their similarity with *Dryopithecus* is undeniable. Whether or not the reconstruction provided in Moyà-Solà et al. 2009a holds up will depend in my view on the recovery of a more completely preserved face.

Late Miocene European Hominines: The Dryopithecins 2

Hispanopithecus

Hispanopithecus crusafonti (Begun 1992c) is known from a sample of isolated teeth and a palatal fragment from Can Ponsic and a well-preserved mandible from Teuleria del Firal, both in northern Spain and both dated to between 10.4 and 10 Ma (Casanovas-Vilar et al. 2011). *H. crusafonti* is dentally similar to other dryopithecins but has distinctive upper central incisors, a more robust mandible lacking the distal shallowing of *Dryopithecus*, upper molars of nearly the same size, and a number of other subtle features of dental morphology (Begun 1992c) (Plates 15, 16, 17, and 18).

Plate 16 RUD 44 in medial view. Note the stepped subnasal fossa (blue lines) between the alveolar process and the palatine process of the maxilla (yellow lines)

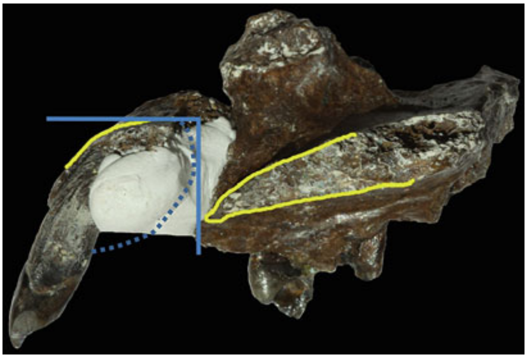

Plate 17 *Hispanopithecus* (IPS 18000). The frontal bone in anterior view is mirror imaged from the *left side*. *Black arrows*, rudimentary supraorbital tori; *white arrows*, torus in lateral view; *yellow arrow*, frontal sinus penetrating into the interorbital space; *red arrow*, zygomatic portion of the frontozygomatic suture

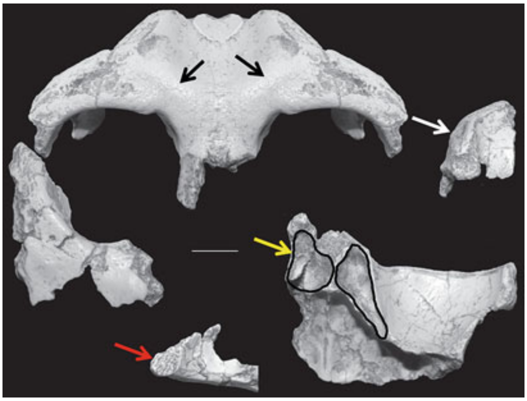

Hispanopithecus laietanus (Villalta and Crusafont 1944) is known from several slightly younger sites in Spain. Dentally, it is smaller but similar to other dryopithecins and lacks the unique dental characters of *H. crusafonti*. It is the best-known species of the genus. Like *H. crusafonti*, *H. laietanus* has tall, relatively narrow upper central incisors, though not to the degree seen in *H. crusafonti*. The mandible is relatively robust. A partial cranium of *H. laietanus* displays numerous hominid cranial characters (broad nasal aperture base, high zygomatic roots, shallow subarcuate fossa, and probable enlarged premaxilla with maxillary overlap, although the specimen is damaged in that area). A few hominine characters are found on this specimen as well (supraorbital tori connected to glabella, frontoethmoidal sinus, inclined frontal squama, and thin enamel) (see Alba 2012 for a different interpretation).

The most significant specimen of *H. laietanus* is a partial skeleton, an exceptional and important specimen (Moyà-Solà and Köhler 1996). The most significant features of the postcranial skeleton of *H. laietanus* are the numerous and unambiguous indications of both well-developed suspensory positional behavior and clear hominid synapomorphies. These include elongated forelimb; large hands with

Plate 18 *Hispanopithecus* reconstruction (*left*) and *Rudapithecus* in three fourth view (*right*)

powerful, curved, elongated digits; comparatively short and robust hindlimb; and a hominid-like lumbar region. Other attributes interpreted to be present in this partial skeleton, such as an elongated clavicle and limb proportions approaching those of *Pongo*, are based on fragmentary evidence and are less reliable. The specimen has some unusual features for a hominid such as short metacarpals, but overall it is quite modern. The humerus, though fragmentary, is like that of *D. fontani* and unlike that of *Sivapithecus*. While there is universal agreement that *Hispanopithecus* is orthograde and suspensory, there is disagreement on the degree to which it was suspensory (Almécija et al. 2007; Deane and Begun 2008, 2010; Alba et al. 2010).

Rudapithecus hungaricus

Rudapithecus hungaricus Kretzoi, 1969 was named based on the sample of hominines from Rudabánya, Hungary (Begun and Kordos 1993). Most researchers rejected to generic distinctiveness of *Rudapithecus*, preferring to include the Rudabánya sample in *Dryopithecus brancoi* (Begun and Kordos 1993), myself included. In the second half of the nineteenth century, shortly after the initial discovery and description of *Dryopithecus fontani*, additional fossil hominoid teeth began to turn up in Germany. These were eventually assembled to define the new species, *D. brancoi* (Schlosser 1901), though not before considerable taxonomic shuffling (see Begun 2002 for more historical details). *D. brancoi* is based on an isolated M_3 which, while not the ideal type specimen, can be effectively distinguished from the other species. To help in species identification, the species diagnosis was revised by Begun and Kordos (1993) based on the excellent sample from Rudabánya, Hungary. This was the majority view through 2009. At that time, researchers working on the Spanish and Hungarian samples had independently come to the conclusion, as described earlier, that *Dryopithecus* as originally described should include only Middle Miocene more primitive European hominines, while the Late Miocene taxa traditionally attributed to *Dryopithecus* should be reassigned to their original nomena (*Rudapithecus* and *Hispanopithecus*). The nomenclatural history of these samples is described more fully in Begun (2009).

Table 3 Great ape and African ape craniodental character states of *Rudapithecus*

Great ape character states	African ape character states
Labiolingually thick incisors	Biconvex premaxilla
Compressed canines	Stepped subnasal fossa
Elongated premolars and molars	Patent incisive canals
M1 = M2	Broad, flat nasal aperture base
No molar cingula	Shallow canine fossa
Reduced premolar cusp heteromorphy	Supraorbital torus
High root of the zygomatic	Inflated glabella
Elongated midface	Frontal sinus above and below nasion
Broad nasal aperture below the orbits	Projecting entoglenoid process
Reduced midfacial prognathism	Fused articular and tympanic temporal
Elongated, robust premaxilla	Broad temporal fossa
Premaxilla-palatine overlap	Deep glenoid fossa
Shallow subarcuate fossa	Elongated neurocranium
Enlarged semicircular canals	Moderate alveolar prognathism
Large brain	Klinorhynchy
High cranial base (Begun 2004)	

Rudapithecus hungaricus is only known from Rudabánya (Hungary) and is dated to about 10 Ma. Six other localities in Germany, Austria, and Georgia may also contain *Rudapithecus*, but as the specimens are all isolated teeth, it is difficult to be certain. *Rudapithecus* shares all the hominid characters already described for other Late Miocene hominids, but the cranium is better preserved in this taxon than in any other and provides additional details (Table 3).

Rudapithecus shares with other dryopithecins all the details of canine and postcanine tooth morphology outlined above. It shares relatively narrow and labiolingually thick upper central incisors with other dryopithecins, though not to the degree seen in *H. crusafonti*. *Rudapithecus* preserves a few details of the face and many details of the neurocranium and basicranium, with further evidence of its hominid status. The zygoma are high, prominent, and oriented anterolaterally, as in hominines, and the number and position of the zygomaticofacial foramina is variable (this character has been proposed as one that could establish the pongine affinities of *Hispanopithecus*, but the configuration in *Rudapithecus* is hominine-like (Kordos and Begun 2001)) The neurocranium is large, with a reconstructed cranial capacity in the range of extant chimpanzees (*Rudapithecus* is the only Late Miocene hominid for which cranial capacity reconstruction is possible from direct measurements of the brain case [in two individuals]) (Kordos and Begun 1998, 2001; Begun and Kordos 2004).

Among the hominine characters preserved in the cranial sample of *Rudapithecus* are a relatively low and elongated neurocranium, with the inion displaced inferiorly (Table 3). The interorbital and supraorbital regions have sinuses that are largest above glabella. Glabella is prominent and continuous with small supraorbital tori separated from the frontal squama by a mild supratoral sulcus (Begun 1994a).

The temporal bone, in addition to preserving evidence of a shallow subarcuate fossa (a hominid character), suggests fusion of the articular and tympanic portions and preserves details of the temporomandibular joint found only in hominines (Kordos and Begun 1997). RUD 200 (also known as RUD 197-200), the best preserved cranium of a dryopithecin, is the first to include a well-preserved neurocranial and facial skeleton in connection and shows clearly that the cranium of *Dryopithecus* was klinorhynch (having a ventrally deflected face), which it shares with African apes among the hominoids (Kordos and Begun 2001; Fig. 4).

The nasoalveolar clivus or premaxilla is hominine like in its orientation, size, surface anatomy, and relations (Fig. 3). It is biconvex, long compared to Early Miocene Hominidea and hylobatids (proportionally equal in length to *Gorilla*), with a posterior pole that is elevated relative to the nasal floor, giving a stepped morphology to the subnasal fossa (Begun 1994a; Fig. 3). The resulting incisive fossa of the subnasal floor is deep and well defined, the incisive canal is short and large in caliber, and the incisive foramen on the palatal side is comparatively large. This suite of characters is found in *Gorilla* as well, which suggests that this is the ancestral morphology for hominines. *Pan* and *Australopithecus* share the synapomorphic condition of a more elongated but still biconvex premaxilla, which along with their spatulate upper central incisors and neurocranial morphology is among the most important morphological synapomorphies of the chimpanzee-human clade (Begun 1992c).

Rudapithecus is well represented by postcrania, including a distal humerus that is hominid-like in all details related to trochlear and capitular morphology as well as having broad and shallow fossae for the processes of the radius and ulnae (see above). The ulna is robust with a strongly developed trochlear keel and a radial facet orientation that indicates forearm bones positioned for enhanced antipronograde postures (Begun 1992a). The scaphoid is *Pongo*-like in morphology and was not fused to the os centrale, as it is in African apes and humans (Begun et al. 2003c). The capitate is large with a complex metacarpal articular surface, as in African apes, but the head is comparatively narrow and the bone overall is elongated compared to African apes, again more like the condition in *Pongo* and *Sivapithecus*. The triquetrum and pisiform provide evidence that the ulna did not contact the medial carpals in any way, an important synapomorphy of the great apes and humans. The phalanges are long, strongly curved, and marked by sharp ridges for the flexor musculature, indicative of suspensory positional behavior (Begun 1993). The femora of are short, with a large head, long neck, and extremely robust shaft, consistent with the hominoid pattern, and again especially similar to *Pongo*. The foot is also apelike in its broad, flat talar body and mobile but large entocuneiform and hallux.

Ouranopithecus

A large hominid sharing characters of *Dryopithecus* and *Sivapithecus* was first described from northern Greece and attributed to the genus *Dryopithecus* (to which *Sivapithecus* was also attributed at the time) (Bonis et al. 1975). Soon it became clear that the sample from Greece was distinct from both *Sivapithecus* and *Dryopithecus*,

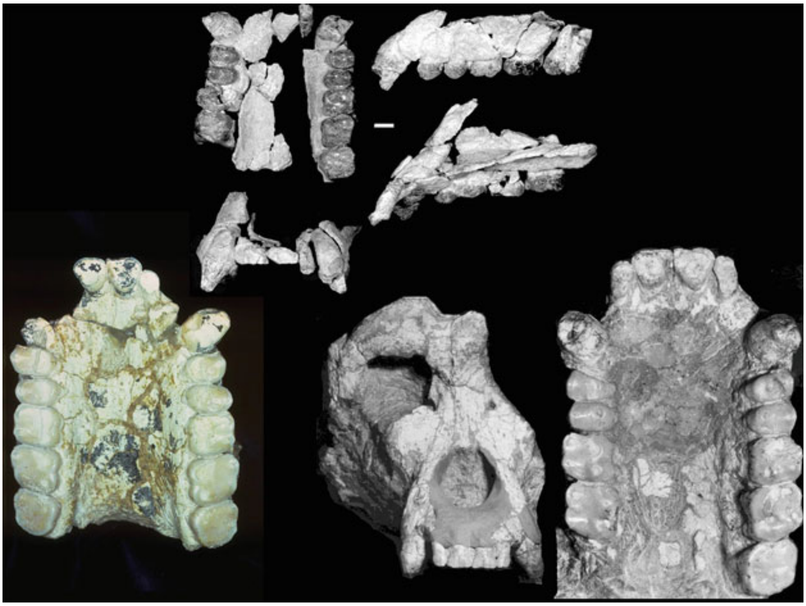

Plate 19 *Ouranopithecus* and "*Ouranopithecus*" *turkae*. *Top*, palatal, anterior, lateral and medial views of "*Ouranopithecus*" *turkae* (CO-205). *Bottom*, from *left* to *right*, RPL 128 and two views of ZIR 1

and the new nomen *Ouranopithecus* (see chapter "▶ Potential Hominoid Ancestors for Hominidae," Vol. 3) was proposed (Bonis and Melentis 1977; Plate 19).

Ouranopithecus is a large hominid, the approximate size of a large male chimpanzee or female gorilla, whose morphology is similar to that of other dryopithecins but with a much more robust masticatory adaptation (Begun and Kordos 1997). *Ouranopithecus* has a palate that is similar to other dryopithecins in the degree and pattern of overlap of the maxilla and premaxilla (Bonis and Melentis 1987; Begun and Kordos 1997). The morphology of the nasoalveolar clivus is also similar to dryopithecins and extant hominines. The nasal aperture is broad at its base, the interorbital space is broad, and the orbits are rectangular. The zygomatic roots arise relatively low and anteriorly on the maxilla, which is interpreted as a homoplasy with Early Miocene taxa, as a similar condition is also found in robust australopithecines that share with *Ouranopithecus* a very robust masticatory apparatus (Begun and Kordos 1997; Begun 2007). The glabella is projecting, and like *Hispanopithecus* and *Rudapithecus*, it is continuous with subtle tori above each orbit. The frontal squama is concave above glabella, as in *Hispanopithecus*, but this is somewhat exaggerated by damage. Dentally, *Ouranopithecus* is similar to dryopithecins and other hominids in tooth proportions and overall dental morphology. It differs from dryopithecins in having hyperthick occlusal enamel, molars with broad cusps and flat basins, mesiodistally longer incisors, and relatively low-crowned male upper canines. The mandibles are also more robust than in other dryopithecins and have strongly reinforced symphyses. The female mandibles tend to be more robust (or shallower) than the male mandibles. One mandible preserves the condylar process, which is large and strongly convex anteroposteriorly. *Ouranopithecus* is also known from two unpublished phalanges.

In many publications, summarized in Bonis and Koufos (1997), it has been argued that *Ouranopithecus* is a hominin (specifically related to humans), mainly on the basis of canine reduction and masticatory robusticity. However, these features occur repeatedly during hominoid evolution. *Ouranopithecus* is most parsimoniously interpreted as a terminal member of the dryopithecin clade, with a number of craniodental specializations related to an increase in masticatory robusticity (Begun and Kordos 1997; Begun 2001, 2002, 2007, 2009). The large jaws and teeth and hyperthick enamel, as well as microwear studies, suggest an ability to exploit hard and/or tough fruits, nuts, and other dietary resources (Kay 1981; Ungar 1996; Bonis and Koufos 1997; Kay and Ungar 1997).

Graecopithecus

Another taxon, *Graecopithecus* (von Koenigswald 1972), is also known from Greece but from a much younger locality over 200 km from the *Ouranopithecus* localities. It is similar to *Ouranopithecus*, and some have suggested that the two samples belong to the same genus, which would be called *Graecopithecus*, since this nomen has priority (Martin and Andrews 1984). In my view, the generic distinction is warranted. *Graecopithecus*, known only from a poorly preserved mandible with a fragmentary M_1, a much worn M_2, and root fragments, is similar to *Ouranopithecus* in apparently having thick occlusal enamel. However, it is the overall size of female *Ouranopithecus* but has an M_2 bigger than some male *Ouranopithecus*, and the M_2 is actually broader than the mandibular corpus at the level of the M_2. The symphysis is more vertical and the M_1 is relatively small (Begun 2002, 2009). *Graecopithecus* is morphologically distinguishable from *Ouranopithecus*, much younger in age, and geographically distant from *Ouranopithecus* localities.

There are two other samples of Late Miocene hominines that have affinities with *Ouranopithecus*. Güleç et al. (2007) described a new species of *Ouranopithecus*, *O. turkae*, based on a large maxilla recovered from the site of Çorakyerler, in Central Anatolia. The site is unique for Eurasian Late Miocene apes in being an open habitat and being young in age (about 8–8.5 Ma). Only *Oreopithecus* in Europe and *Lufengpithecus* in Asia are younger. Having studied the maxilla from Çorakyerler in detail, it is my view that it represents a new genus of hominine (Sevim et al. 2001; Begun 2009; Begun et al. 2012). It is much larger than *Ouranopithecus*, the maxilla fitting comfortably on the mandible of *Indopithecus*, and the anterior dental morphology is quite distinct. However, until more recently recovered specimens are described, I refrain from naming a new genus.

The other sample of Late Miocene hominine that may be attributed to *Ouranopithecus* is the isolated P4 from the site of Azmaka, near Chirpan, Bulgaria (Spassov et al. 2012). The site may be as late as 7 Ma, but only one P4 is known. The specimen is clearly a hominid, and more closely resembles thickly enameled taxa, but its precise affinities remain to be determined.

The greater significance of these two samples from Bulgaria and Turkey are not their taxonomic or phylogenetic affinities, but their location in geographic and temporal space. Both are much later than some have predicted for Miocene apes in Europe, and both are associated with paleoecological settings that some have said excludes the presence of apes (Bernor et al. 2004; Bernor 2007). There are many problems with the naïve preconception that hominines could not have dispersed between Eurasia and Africa in the Late Miocene (see Begun et al. 2012 for a detailed critique). We now know that Late Miocene hominines lived in much drier conditions than previously supposed, and we also know that even without these adaptations, ample evidence exists for forest corridors and refugia in southeastern Europe and North Africa that could have allowed forest-adapted taxa to disperse between the two continents (Begun et al. 2012) The presence of hominines from Çorakyerler and Azmaka demonstrate that it is unwise to exclude a priori an ecological association resulting from the wondrous and unpredictable interaction of natural selection, anatomy, behavior, and ecology.

Paleobiology of the Dryopithecins

Most dryopithecins display dental morphological characters that are very similar to extant *Pan* and suggest a soft fruit diet (Begun 1994a). Microwear analyses support this assessment (Kay and Ungar 1997). The dryopithecin gnathic is gracile compared to many other Late Miocene hominids (less robust mandibles, thinner occlusal enamel, smaller attachment sites for the muscles of mastication), which is both consistent with a soft fruit diet and more similar to extant African apes, *Pan* in particular. Postcranially, *Hispanopithecus* and *Rudapithecus* are unambiguously suspensory, but they do lack a few synapomorphies, particularly of the extremities, which characterize all extant hominids. These have to do mainly with the robusticity of the bones of the carpus and tarsus, which may be attributable to a “red queen” phenomenon, as in the case of the progressive development of shearing quotients during the course of hominoid evolution (Kay and Ungar 1997). In the fossil record of many mammals, there is evidence of a shift toward a certain adaptation (folivory, frugivory, suspension, climbing, bipedalism, etc.) that becomes increasingly refined in individual lineages descended from the common ancestor initially expressing the behavior. In order to remain competitive, the descendants must, in essence, run to stay in the same place, as increasingly efficient versions of the same adaptation appear independently (van Valen 1973). *Rudapithecus* and *Hispanopithecus* were arboreal, suspensory, soft fruit frugivores with a dentition similar to *Pan*, living in seasonal subtropical forests but probably capable of exploiting a variety of resources, possibly including meat (Kordos and Begun 2002).

The exception to this general pattern among the dryopithecins is *Ouranopithecus*, which was a hard/tough object feeder. While the postcrania have not been described in *Ouranopithecus*, it has been suggested that it was probably more terrestrial than other dryopithecins, given its diet and habitat, which was more open country than any other dryopithecin (Bonis and Koufos 1994). However, a definitive answer to the question of the positional behavior of *Ouranopithecus* must await analysis of the phalanges.

Oreopithecus

The other European Miocene hominoid discovered and described during the nineteenth century is the highly unusual *Oreopithecus* (Gervais 1872). Over the years, *Oreopithecus* has been called a pig, prosimian, monkey, and ape, the last being the attribution most researchers agree on today (Harrison and Rook 1997; Moyà-Solà and Köhler 1997; Begun 2002). *Oreopithecus* is younger than other Late Miocene European hominoids and is known from about 6 to 7 Ma localities in Italy. At the time, most of the Italian peninsula was separated from the rest of Europe by the sea, as is today the Italian island of Sardinia, where one *Oreopithecus* locality is found. In the Late Miocene, all *Oreopithecus* localities were insular, and the faunas associated with them are unique and difficult to compare to continental European faunas (Harrison and Rook 1997). *Oreopithecus* is a product of its insular environment as well and is characterized by many unique adaptations that make it difficult to understand its relations to other hominoids.

In its craniodental morphology, *Oreopithecus* is similar to dryopithecins and African apes in having apparently thin enamel, but otherwise the morphology of the teeth is quite unique. Like other hominids, *Oreopithecus* has compressed canines, reduced premolar cusp heteromorphy, and reduced or absent molar cingula. However, the incisors are small and low crowned; the P_4 has a primitive-looking low talonid compared to the trigonid; the postcanine dentition has tall, isolated cusps; and the lower molars have a unique occlusal morphology with a centroconid connected to the four principal cusps by a well-developed system of crests. The upper molars are also strongly “cristodont,” which makes them appear similar to the lower molars, superficially resembling the condition of upper and lower molar bilophodonty in Old World monkeys.

The mandible is strongly built with some specimens being quite robust transversely and others deeper. The ramus is expansive to accommodate large temporalis and masseter muscles, which is also evidenced by the prominent temporal crests and pronounced postorbital constriction. The face is badly damaged but appears to have had a short and relatively gracile premaxilla, which is consistent with the small incisors. The brain case is also badly damaged but was clearly small, housing a much smaller brain than great apes of comparable body mass (Harrison 1989; Begun and Kordos 2004). Like *Sivapithecus* and non-hominids, the articular and temporal portions of the temporal bone are not fused, but like hominids the subarcuate fossae are small. The ectocranial crests are very strongly developed, while the frontal is comparatively smooth, without tori, and the postorbital constriction is marked.

The most impressive aspect of *Oreopithecus* is its postcranium. A remarkably complete but crushed skeleton along with many other isolated postcranial elements is known from *Oreopithecus*. The axial skeleton (rib cage and trunk) is hominoid-like in its short lower back and broad thorax, and the pelvis is also comparatively short and broad, as in hominids. The forelimbs are very elongated compared with the hindlimbs, the glenoid fossa of the scapula is deep, and the elbow has all the typical hominoid features described previously. The femur is short and robust with a large head, and the knee joint indicates mobility in several planes. The hand is long but narrow, and the foot is comparatively short, though in both the hand and foot, the digits are long and curved. The carpals and tarsals are primitive hominoid-like in being transversely gracile compared to their length. They more closely resemble the carpal and tarsal bones of *Proconsul* than those of hominids.

Oreopithecus combines primitive and derived hominoid characters that ironically make it extremely difficult to place phylogenetically, despite its relatively complete preservation. Harrison and Rook (1997) consider *Oreopithecus* to be a stem hominid closely related to the dryopithecins. Moyà-Solà and Köhler (1997); Moyà-Solà et al. (1999) interpret both the dryopithecins and *Oreopithecus* to be stem pongines (see chapter "▶ Defining Hominidae," Vol. 3), and they have also concluded that *Oreopithecus* was an arboreal biped with a well-developed precision grip. However, these conclusions are based in part on an erroneous reconstruction of the hand of *Oreopithecus* (Susman 2004 and personal observations) and a very unlikely reconstruction of the foot (Köhler and Moyà-Solà 1997 and personal observations). Rook et al. (1999) interpret CT scans of the innominate of *Oreopithecus* to imply a remodeling of bone consistent with bipedalism, but alternative interpretations are in my view more likely (Wunderlich et al. 1999). Overall, the overwhelming signal from the postcranium of *Oreopithecus* is of a suspensory arboreal adaptation. The long, curved phalanges are unambiguous indicators of suspension and incompatible with either bipedalism or a precision grip.

Though some have interpreted aspects of the cranial morphology of *Oreopithecus* to have resulted from neoteny leading to a superficially primitive morphology (Moyà-Solà et al. 1997; Alba et al. 2001), it is very difficult to identify heterochrony in fossil taxa (Rice 1997), and the much more straightforward interpretation is that *Oreopithecus* does in fact retain a number of primitive characters not found in other Late Miocene or extant hominids (Harrison 1986; Harrison and Rook 1997; Begun 2002). These include a short, gracile premaxilla, large incisive foramen, low position of the zygomatic root, small brain, a number of features of the basicranium, and several postcranial characters (gracile phalanges; transversely small carpals; short, relatively gracile tarsals; etc.). It is very unlikely that a single growth process resulting from selection for bipedalism and an omnivorous diet, as suggested by Alba et al. (2001), would have produced such a diversity of consistently primitive characters throughout the skeleton.

The extraordinary morphology of the cranium and dentition of *Oreopithecus* are probably related to a specialized folivorous adaptation. *Oreopithecus* molars have the highest shearing quotients of any hominoid, which is consistent with a high-fiber diet (Kay and Ungar 1997). The exceptionally developed chewing muscles of *Oreopithecus*, its robust mandibles, and even the small size of its brain are all consistent with a folivorous diet requiring high-bite forces but relatively little planning or "extractive foraging" (Begun and Kordos 2004).

Late Miocene East African Hominines?

At the same time that Late Miocene apes are flourishing in Eurasia, two taxa, recognized from small samples, are known from East Africa. *Chororapithecus* is recognized from a small number of isolated teeth from Ethiopia dated to between about 10 and 10.5 Ma

(Suwa et al. 2007). They accept, based on molecular clock evidence, that the divergence of *Pongo* and the African apes and humans occurred at about 20 Ma, that for *Gorilla* at about 12 Ma, and that for *Pan* and humans at about 9 Ma. These divergence dates are of course the subject of much discussion. These authors cautiously assign *Chororapithecus* to the gorilla clade, suggesting that *Chororapithecus* represents an early gorilla. The main line of evidence is a crest revealed by CT scans on the dentine surface of one of the molars, which the authors suggest is an indication of an adaptation to shearing, characteristic of gorillas. However, the ridge in question is only present on the dentine surface and not the surface that would have been in contact with food. Therefore, even if this dentine crest is homologous with a ridge on the teeth of gorillas, it is very doubtful that it represents an adaptation to shearing, since it could never have encountered a single fiber of food (being buried under the enamel cap). At best this crest, if found to be homologous with a crest on the enamel surface of a gorilla tooth, would be considered an exaptation and not evidence of selection for a gorilla-like mode of adaptation suggested by Suwa et al. (2007).

The sample of *Chororapithecus* is fragmentary, and frankly, if found anywhere outside of Ethiopia, it would be considered inadequate to support any particular phylogenetic hypothesis. It is in the right place the right time, according to some scenarios, but when examined in detail, it fails to demonstrate the presence of a gorilla at 10 Ma, or even a hominine. The fragmentary nature of these specimens does not allow for a definitive assignment of *Chororapithecus* to a hominid clade. I would not exclude the possibility that it is a late surviving *Proconsul*.

Another collection of fossils from East Africa is *Nakalipithecus*, from Kenya, dated to about 9.8 Ma (Kunimatsu et al. 2007). The sample consists of a fragmentary mandible and some isolated teeth. Sadly, the teeth in the mandible are highly worn, making it difficult to use this most complete specimen to assign this taxon to the sister clade to *Ouranopithecus*, as suggested by the authors. There is, however, a female upper canine that does bear a strong resemblance to *Ouranopithecus* (Kunimatsu et al. 2007). In my view, *Nakalipithecus* is more likely to be a hominine and to be related to Eurasian apes than *Chororapithecus*. Kunimatsu et al. (2007) suggest that *Nakalipithecus*, because its known range is slightly older than the known range of *Ouranopithecus*, might be ancestral to the Greek ape. The time difference between the two samples however is minimal by paleontological standards (9.5 vs. 9.8). *Nakalipithecus* represents the best connection in the Late Miocene between Europe and Africa, but there is no good evidence that *Nakalipithecus* is ancestral to *Ouranopithecus*. Given the close ages of both samples, it cannot be said which is ancestral to which. It remains true, however, that the earliest hominines are at least 12.5 Ma from Europe, so that whatever the relationship is between *Nakalipithecus* and *Ouranopithecus*, the Eurasian taxa came first.

Late Miocene Hominid Extinctions and Dispersals

Hominids first appear in the Middle Miocene of Eurasia and quickly radiate, but between about 10 and 9 Ma they begin to disappear. The view presented here is that the hominids from western Eurasia are hominines, and those in the east are pongines (Begun 2004, although see above for an alternative interpretation). Descendants of each subfamily eventually disperse south of the Tropic of Cancer as other taxa become extinct in Eurasia (Begun et al. 1997, 2012; Begun 2001, 2004). This view has been supported by genetic evidence (Stewart and Disotell 1998) and criticized based on differing interpretations of the fossil record. For example, it has been noted that Africa is a more likely place for the origin of the Hominidae and the Homininae, presumably because African apes still live there and because it is said to be poorly sampled, especially in the Late Miocene. The fossils that would support this interpretation remain to be discovered. In fact, many Late Miocene localities are known from Africa, a number with paleoecological indications of forested settings (Begun 2001, 2004; Begun et al. 2012), yet no hominines have ever been identified in Africa dating between *Kenyapithecus* and *Sahelanthropus* apart from *Chororapithecus* and *Nakalipithecus*, which, as noted, may be hominines but are much younger than the earliest European hominines. *Samburupithecus* is also present in this time period, but it is even more primitive and less likely to be a hominine than *Chororapithecus* and *Nakalipithecus*. *Samburupithecus* retains many primitive dental and maxillary characters (Begun 2001). Isolated teeth from Ngorora have been described as having affinities primarily with the Proconsuloidea or Middle Miocene East African hominoids (e.g., *Equatorius*) (Hill and Ward 1988; Begun 2001; Hill 2002). Pickford and Senut (2005) have recently reported teeth from Ngorora and Lukeino described as chimpanzee and gorilla-like, but in my view, the older teeth cannot be distinguished from others with affinities to the Proconsuloidea, and the younger teeth are probably from *Orrorin* (see chapter "▶ The Miocene Hominoids and the Earliest Putative Hominids," Vol. 3), known from the same locality (Lukeino) (Senut et al. 2001). Most importantly, an African origin of the hominines to the exclusion of the European taxa fails to explain the widespread pattern, from Spain to Hungary, of morphology associating Eurasian apes with those from Africa. To deny a European origin of the Homininae based on the evidence to date is to evoke ad hoc hypotheses of convergence or homoplasy to explain away the documented similarities between dryopithecins and crown hominines. One can choose not to believe a hypothesis because of an a priori expectation that evidence disproving it will eventually be found (e.g., Bernor 2007), but in my view, this is not an acceptable approach to science.

Hominids appear to have moved south from Eurasia in response to global climate changes that produced more seasonal conditions in Eurasia toward the end of the Miocene (Quade et al. 1989; Leakey et al. 1996; Cerling et al. 1997; Begun 2001, 2004, 2009; Fortelius et al. 2006; Agustí 2007; Agustí et al. 2003; Nargolwalla 2009) (see Begun et al. (2012) for a comprehensive review of the evidence of faunal dynamics and climate change in the Late Miocene). Much evidence exists for climate change throughout much of Eurasia in the Late Miocene, which led to the development of more seasonal conditions. This culminates in the Messinian Salinity Crisis that led to the desiccation of the Mediterranean basin at the end of the Miocene (Hsü et al. 1973; Clauzon et al. 1996; Krijgsman et al. 1999). Other consequences include the development of Asian monsoons, desertification in North Africa, the early phases of Neogene polar ice cap expansion, and the expansion of North American grasslands (Garcés et al. 1997; Hoorn et al. 2000; Zhisheng et al. 2001; Griffin 2002; Guo et al. 2002; Janis et al. 2002; Liu and Yin 2002; Wilson et al. 2002). In both Europe and Asia, subtropical forests retreat and are increasingly replaced by more open-country grasslands and steppes (Bernor et al. 1979; Bernor 1983; Fortelius et al. 1996; Cerling et al. 1997; Bonis et al. 1999; Magyar et al. 1999; Solounias et al. 1999; Fortelius and Hokkanen 2001). In some places, forests persisted and elsewhere more severe changes occurred, creating a number of refugia, some of which continued to host hominids well into the period of climatic deterioration. This is the case for the *Oreopithecus* localities of Tuscany and Sardinia (Harrison and Rook 1997). Other well-known localities, such as Dorn-Dürkheim in Germany, retain a strongly forested character, though they lack hominoids (Franzen 1997; Franzen and Storch 1999).

There is a gradient of extinctions of forest forms from west to east corresponding to the gradient of appearance of more open-country faunas from east to west (Bernor et al. 1979; Fortelius et al. 1996, 2001; Begun 2001, 2004). Between about 12 and 10 Ma, *Dryopithecus* disappears from localities in Europe, becoming very rare by 9.5 Ma in Spain and Germany. This wave of extinctions ends coincident with an important faunal event in Western Europe known as the mid-vallesian crisis, when a major turnover of terrestrial faunas leads to the widespread extinction of local taxa generally attributed to the development of more open conditions (Moyà-Solà and Agustí 1990; Fortelius et al. 1996). The youngest specimens possibly attributable to *Dryopithecus* are the most easterly, currently assigned to *Udabnopithecus* from the 8 to 8.5 Ma locality of Udabno in Georgia (Gabunia et al. 2001).

In the eastern Mediterranean, hominids persist to the end of this time. *Ouranopithecus* in Greece is mainly known from the end of the hominid presence in Europe and may be a terminal taxon of the *Dryopithecus* clade (Begun and Kordos 1997). In Anatolia, at the eastern edge of the faunal province that includes Greece and the eastern Mediterranean (the Greco-Iranian province (de Bonis et al. 1999)), a very large hominid resembling *Ouranopithecus* may be as young as 7–8 Ma in age (Sevim et al. 2001). At this time, forest taxa are increasingly replaced by more open-country forms. This is true of virtually all mammalian orders. Among the primates, hominoids decline and cercopithecoids are on the increase (Andrews et al. 1996). Grazing ungulates and grassland or dry ecology-adapted micromammals also become more common (Fortelius et al. 1996; Agustí et al. 1999; de Bonis et al. 1999; Solounias et al. 1999; Agustí 2007).

The dispersal of Late Miocene faunas between Eurasia and Africa is complex and includes both open and more forest-adapted taxa. Among the more open-country taxa, horses disperse from North America to the Old World, and modern bovids and giraffids appear to have dispersed from Europe to Africa (Dawson 1999; Made 1999; Solounias et al. 1999; Agustí et al. 2001). Among the more close setting mammals, hippos move from Africa to Europe, and pigs of varying ecological preferences move from Asia to Europe and Africa (Fortelius et al. 1996; Made 1999). Small carnivores (mustelids, felids, and viverrids), larger carnivores (ursids, hyaenids) porcupines, rabbits, and chalicotheres, most of which also prefer more closed settings, also disperse from Eurasia to Africa (Leakey et al. 1996; Ginsburg 1999; Heissig 1999; Made 1999; Winkler 2002).

Many of these dispersals involved forest or wetter ecology taxa (hippos, some suids, primates, carnivores, rodents, and chalicotheres), which is consistent with the evidence of climate change at that time. There is ample time between 10 and 7 Ma for the dispersal of forest-adapted taxa between Eurasia and Africa before the onset of the severe dry spell that culminates in the Messinian, including evidence of forest corridors and refugia well into the Late Miocene in the Balkans and North Africa (Pickford et al. 2006; Begun et al. 2012). Taxa disperse south into Africa as conditions continue to deteriorate leading to the Messinian crisis, among them probably the ancestors of the African apes and humans. This scenario has hominid ancestors leave Africa in the Early Miocene and return as hominines in the Late Miocene, but this is precisely what seems to have occurred in several mammalian lineages, including those represented by Late Miocene African species of *Orycteropus* (aardvark), several small carnivores, the hippo *Hexaprotodon*, and possibly the proboscideans *Anancus*, *Deinotherium*, and *Choerolophodon* (Leakey et al. 1996; Ginsburg 1999; Heissig 1999; Made 1999; Boisserie et al. 2003; Werdelin 2003; Begun and Nargolwalla 2004).

Conclusion

The Miocene epoch witnesses several adaptive radiations of hominoids and hominoid-like primates. It was indeed the golden age of the Hominoidea. Many catarrhines appear in East Africa in the Early Miocene, some of which are surely related to living hominoids. A few of the basic attributes of the Hominoidea appear at this time, including the absence of a tail, somewhat extended life history, and a hylobatid level of encephalization, and hints of powerful hand and foot grips and a propensity for more vertical climbing. Among the diversity of Early Miocene Hominidea, a group emerged that may have had an adaptation to a diet dependent on more embedded resources, leading to a dispersal into Eurasia. Once there, hominoids flourish and expand, splitting into eastern and western clades that led to extant hominids (hominines in the west and pongines in the east) and an early southern clade that becomes extinct. Early in the Late Miocene, the hominid radiation in Eurasia began to dwindle, with the earliest extinctions occurring in the west and progressing eastward. Hominids and many other mammals experienced extinction events at this time, and many clades of Eurasian mammals also dispersed south, probably as a result of major global climatic events. Western Eurasian hominines dispersed into Africa, leading to the evolution of the African apes and humans, and eastern pongines dispersed into Southeast Asia, leading to the appearance of the *Pongo* clade. Shortly after their dispersal into Africa, hominines diverged into their respective clades, probably relatively quickly. Gorillas remain the most conservative in many respects, though they achieve some of the largest body masses in any primate and specialize in their ability to exploit high-fiber keystone resources.

Chimpanzees and humans diverged, possibly within a million years of the emergence of the gorilla clade, the chimp clade remaining relatively conservative and the human clade experiencing much more rapid and dramatic evolutionary changes. Human ancestors retain the imprint of their Eurasian and African ape ancestors and were very probably similar to extant African apes, particularly chimpanzees, that is, the fossil record of hominoid evolution suggests that humans evolved from a knuckle-walking, forest-dwelling soft fruit frugivore/omnivore, not a chimpanzee in the modern sense, but more chimp-like than anything else nonetheless. The details of the evolutionary events leading to the origin of the individual lineages of the Homininae remain to be worked out, a process hampered in part by a poor fossil record that, for example, includes almost no fossil relative of gorillas or chimpanzees (but see McBrearty and Jablonski 2005).

The Biotic Environments of the Late Miocene Hominoids

Jordi Agustí

Contents

Abstract

The habitat of the Middle and Late Miocene hominoids from western Europe, like *Dryopithecus*, was characterized by the prevalence of subtropical conditions. As a consequence, those environments were mainly dominated by fruit eaters and browsers, including a large variety of suids, cervids, rhinos, chalicotheres, and proboscideans. In contrast, in large parts of Eurasia, from eastern Europe (Greek-Iranian province) and northern Africa to China, the Middle Miocene climatic crisis led to the development of a xerophilous woodland, dominated by bovids, giraffids, and pursuit carnivores. At first, the worldwide dispersal of the hipparionine horses changed this scenario very little. However, at 9.6 Ma, a significant event, the Vallesian Crisis, led to the extinction

of most of the fruit eaters that had prevailed in the Middle Miocene European faunas. Hominoids persisted for a time in the Tusco-Sardinian Island and in the low latitudes of southwestern Asia. The worldwide spread of grasses between 8 and 7 Ma led to the final extinction of those hominoids. Hominoid evolution continued in eastern and southeastern Africa, in a habitat that strongly resembles that of the Greek-Iranian province.

Introduction

The Late Miocene, that is, the timespan between 11.6 and 5 Ma, is a crucial period in understanding the configuration of our present world. This is the time when the persisting laurophyllous evergreen woodlands (also called *laurisilvas*), which had spread over large parts of the Old World during most of the Miocene, were replaced by drier and more seasonal ecosystems, including savannas and steppes. It has been argued that the spread of this kind of environment may have played a key role in hominid evolution, by enhancing the appearance of new locomotor innovations, such as bipedalism (Lovejoy 1980; Coppens 1983). However, this change toward increasing dryness and seasonality was not a sudden one. Instead, this general trend appears to have been punctuated by a number of faunal and environmental events, which predated the onset of glacial-interglacial dynamics in the Northern Hemisphere. Significant physiographic and tectonic events appear also associated with this biotic turnover, such as the uplift of the Himalayas and the Tibetan Plateau, the final closure of the Atlantic-Indian seaway throughout the Mediterranean, and the desiccation of the Paratethys and Mediterranean seas. These paleogeographic events severely affected the continent-ocean interplay system, leading to changes in the overall circulation pattern, enhancement of the monsoonal dynamics, and the development of the first Arctic glacials.

The Middle Miocene Environmental Background: The World of *Dryopithecus*

Despite the climatic crisis that affected the Early Miocene terrestrial ecosystems, the last part of the Middle Miocene was characterized by very favorable biotic conditions in parts of western Eurasia, specially in western and central Europe (Agustí and Antón 2002; Fortelius et al. 2003). The faunal associations from these regions were characterized by high mammalian diversity levels, with a high amount of large- to medium-sized browsers, together with several medium-sized carnivores. At the top of the large browser guild were the proboscideans, represented by the large gomphotheres of the genus *Tetralophodon* and the deinotheres of the genus *Deinotherium*. *Tetralophodon* was a late immigrant in the Middle Miocene terrestrial ecosystems and replaced the once worldwide gomphotheres of the genus *Gomphotherium*. *Tetralophodon* was a large proboscidean which had more hypsodont teeth than the earlier gomphotheres. Moreover, its skull, although still bearing four tusks, was shorter and more elephant-like, with a pair of long, straight tusks in the maxilla and a small pair of tusks at the end of the mandible. In contrast, *Deinotherium* represents a completely different kind of proboscidean. Members of this group had only two strong tusks, not placed in the upper jaw but at the end of the mandible. Moreover, this lower pair of tusks was recurved downward. The molars were very simple, formed of two cutting ridges, interpreted as an adaptation to browsing leaves and tough vegetation.

Another main component of the large browser community was the chalicotheres, a group of bizarre perissodactyls distantly related to horses that prolonged the trend observed in other ungulates to enlarge the forelimbs relative to the hind limbs. This trend reached an extreme in some Miocene representatives, such as *Chalicotherium*, which developed gorilla-like limb proportions, with very long forelimbs and short hind limbs. The chalicotheres bore claws at the end of their arms, instead of the typical hoofs of the odd-toed ungulates. These enabled them to grasp small branches and leaves with the help of their forefeet. These large perissodactyls were probably capable of standing on their hind limbs and using their forelimbs as “hands” to reach the higher vegetational levels.

However, the most diversified group of large browsers were the rhinoceroses, represented by several different forms, such as *Brachypotherium*, *Hoploaceratherium*, *Alicornops*, or *Lartetotherium*. *Brachypotherium* was a large teleoceratine with hypsodont teeth, short legs, and hippolike body proportions, which probably had a semiaquatic lifestyle. Another group was the aceratherine rhinos, represented by the genera *Hoploaceratherium* and *Alicornops*. *Hoploaceratherium tetradactylum* was a medium-sized acerathere with long limbs and slender body proportions. As in most aceratherines, the characteristic horns were highly reduced (only a small one was present). In contrast, they displayed very big lower incisors, which were larger in the males. *Alicornops simorrense* was a small acerathere with short, tridactyl legs and strongly curved lower incisors (although, as in *Hoploaceratherium*, a small horn was present). The rhinocerotines or “modern horned rhinos” were represented by *Lartetotherium* and “*Dicerorhinus*” *steinheimensis*. *Lartetotherium sansaniense* was a cursorial rhino that had a unique, long horn. According to its rather brachydont teeth, its diet must have contained a higher quantity of soft plants and a lower proportion of wooden parts of shrubs than in the case of the aceratherine rhinos (Heissig 1989).

Represented only by the genus, *Anchitherium*, the equids were also significant elements of the Miocene ecosystems. *Anchitherium* was a member of the group of North American horses that experienced a significant evolutionary radiation during the Oligocene. This medium-sized anchitherine, about 1 m or less at the withers, crossed the Bering area in the Early Miocene and rapidly dispersed over the whole of Eurasia, from China to Spain. They bore low-crowned (brachydont), lophodont teeth adapted to browsing soft leaves. Their limbs were also adapted to locomotion on soft substrates, still retaining two lateral, fully functional toes.

The undergrowth of the Middle Miocene laurisilva was populated by a wide array of suids, which included hyotherines (*Hyotherium*), peccary-like suids (*Taucanamo*, *Albanohyus*), tetraconodontines (*Conohyus* and its offshoot

Parachleuastochoerus), and listriodontines (*Listriodon*). *Taucanamo* was a small peccary-like pig (about 12 kg), which developed lophodont teeth and large, elongated premolars. Its dental morphology, with high cusps and variable lophodonty, resembles that of some cercopithecoid primates and tragulids, being probably related to a browsing regime in a forest biome. *Albanohyus* was a small peccary-like suid also found at Fort Ternan that resembled *Taucanamo* but had smaller, shorter premolars. *Listriodon* was a fully lophodont, browsing listriodontine, which dispersed over the whole of Eurasia, from China to the Iberian peninsula throughout eastern and central Europe (Made 1996). Analysis of microwear in *Listriodon* has shown a rather uniform diet with a smaller minerogenic component, which indicates a variation from the typical rooting behavior of generalized suids and a specialization in the browsing of vegetation. Lengthening of distal limb segments might indicate that these listriodontines preferred more open habitats. Together with the listriodontines, a new subfamily of suids, the tetraconodontines, became the dominant suiforms in the circum-Mediterranean area (including five genera: *Conohyus*, *Parachleuastochoerus*, *Sivachoerus*, *Notochoerus*, and the African *Nyanzachoerus*). The tetraconodonts bore thick-enameled cheek teeth and conical premolars with hyena-like wear, which probably indicates a diet based on hard food items such as seeds. A trend toward reducing size is present in this group during the Middle Miocene, from the 70 kg of the medium-sized *Conohyus* to the 40 kg of the small *Parachleuastochoerus*. Later on, at the end of the Middle Miocene, the suid diversity increased again with the appearance of the first representatives of modern suids (*Propotamochoerus*). *Propotamochoerus* was a large suid (about 120 kg), which probably evolved in southern Asia from a hyotherine pig during the Middle Miocene and subsequently extended its range westward into southwestern Asia and Europe. It is the first recognizable member of all modern swines. The molars of this group show a trend toward the proliferation of several minor cusps, concomitant with loss of cusp identity. This peculiar dental evolution resembles some bears and indicates a further adaptation to omnivory.

Other significant members of the medium-sized browser community were the deer or cervids, represented by a number of genera such as *Heteroprox*, *Dicrocerus*, and *Euprox*. According to their limb proportions and low-crowned (brachydont) dentitions, most of these archaic deer were semiaquatic browsers that lived in closed forests in humid conditions (Köhler 1993). They still displayed rather simple, two-pronged antlers, although in some cases like *Euprox*, there was a differentiation between a principal, posterior prong and a secondary, smaller anterior prong. Some of them, like *Dicrocerus* and *Euprox*, showed a burrlike area, indicating for the first time the border between the deciduous and permanent segments of the antlers. Besides cervids, other related taxa, such as the moschid *Micromeryx* and the tragulid *Dorcatherium*, testify to the persistence of very humid conditions in western and central Europe. *Micromeryx* was a very small and slender moschid of less than 5 kg that, as in the case of the living moschids, lacked horns but displayed very prominent canines (in the males). *Micromeryx* probably foraged in the lower vegetation of the closed forest, again living on soft plants and fruits, larvae, and carrion (Köhler 1993). It was a very successful moschid that spread over a wide area covering western and eastern Europe and that persisted until the Late Miocene (Early Turolian). Among these small browsers, other significant elements were the tragulids of the genus *Dorcatherium*. The tragulids or chevrotains are small ruminants that today live close to the water in the closed forests of tropical Africa and east Asia. Like the moschids, they lack any kind of cranial appendages, having in their turn a pair of long canines which are longer in the males. Moreover, they retain a very primitive limb structure, with four well-developed toes on each foot (the two central metapodials are not yet fused in the cannon bone). The recent relatives of *Dorcatherium*, the chevrotains *Hyemoschus aquaticus* and *Tragulus meminna*, live in dense tropical forests close to rivers or water courses, which act as a refuge in the case of sudden attack by predators. *Dorcatherium* was nearly identical in all aspects to the recent *Hyemoschus* and probably developed a similar lifestyle.

In contrast, the bovids were poorly diversified at this time, mainly represented by *Eotragus*. The first bovids such as *Eotragus* probably originated in Asia, to the south of the Alpine belt. Later, in the Early Miocene, they colonized Europe and Africa simultaneously, their presence in this latter continent having been reported from Gebel Zelten (Libya) and also from Maboko and Ombo (East Africa). *Eotragus* was a small ruminant, the size of the living dik-dik or dwarf antelopes of the tribe Neotragini. The horn cores were short and conical, placed directly over the orbits. The teeth were brachydont, indicating a diet based on soft plants, fruits, larvae, insects, or even carrion. Their limb proportions were primitive, close to those of a cervid. They probably occupied a closed, wooded habitat where they probably ducked under the undergrowth (Köhler 1993).

At the opposite extreme, the small herbivore guild was extensively represented by a variety of rodents, including several species of hamsters (cricetids), dormice (glirids), eomyids, squirrels (sciurids), and beavers (castorids). The laurophyllous forests at this time were populated by a variety of flying rodents, such as flying squirrels of different sizes (from the large *Albanensia* to the small *Blackia*) and, probably, the eomyids *Eomyops* and *Keramidomys*. But other groups of small rodents, such as some glirids of the genus *Glirulus*, also developed "flying" forms with a patagium. This is very unusual among dormice and provides a strong indication of the persistence of closed forests at that time in western and central Europe. Another indication of the persistence of humid conditions in this part of the Old World is the frequent discovery of beavers in these faunas. One of them, *Chalicomys*, strongly resembled in size and morphology of the recent *Castor fiber* and, like the living form, was probably highly dependent on permanent rivers. A second smaller beaver, *Trogontherium*, is widely present at this time and was probably associated with more unstable environments.

Among the carnivores, the large predator guild was represented by amphicyonids and nimravids. The amphicyonids, or "bear dogs," resembled canids in their dentition but developed ursidlike characteristics such as very large size and robust canines (with double cutting edges in the case of the upper ones). The heavy carnassials with horizontal abrasion were probably used for bone crushing, an interpretation supported by the high sagittal crests in the skull, which housed a powerful musculature probably used for breaking bones. All these adaptations suggest that the amphicyons were probably occasional scavengers, at a time when truly scavenging specialists were still absent. However, despite these scavenging adaptations, the body plan of the amphicyonids indicates active hunting. They were probably active and agile predators practicing the solitary stalk-pounce hunting mode of recent felids and bears. Their long tails were probably used to balance the pounce, as in the case of the modern felids (Viranta 1996). The Middle Miocene records the first appearance of one of the most successful amphicyonid species in the Miocene, *Amphicyon major* (starting from Neudorf-Spalte and several localities in Spain, France, Germany, Czechia, Turkey). This was a large form, attaining the size of a lion. *Amphicyon major* had a long skull, with an elongated snout and relatively long and massive canines. The general limb proportions were similar to those of a bear, with short metapodials. Besides bearlike forms, like *Amphicyon major*, the amphicyonids also produced at this time hypercarnivorous forms such as *Thaumastocyon* and *Agnotherium*. Both were medium- to large-sized amphicyonids with a cursorial body plan that probably indicates pursuit hunting habits.

However, the typical hypercarnivorous predators of this time were the nimravids, a family of carnivores that developed felidlike, sabertooth adaptations. At the end of Middle Miocene, this family was represented by *Sansanosmilus jourdani*, a large species which reached 80 kg. The true felids were represented at that time by smaller species, all included in the genus *Pseudaelurus*: *P. turnauensis*, *P. lorteti*, and *P. quadridentatus*. The true ursids were represented at this time by two mesocarnivore forms, *Hemicyon* and *Plithocyon*, as well as a typical omnivore form, *Ursavus*. This last genus of small ursids was represented by *U. primaevus* of about 90 kg. The hyenids were represented by slender forms, such as *Protictitherium*, *Plioviverrops*, and *Thalassictis*. Different from the living members of this family, these primitive hyenids were more civetlike generalized carnivores than true scavengers. *Protictitherium* was an archaic insectivore/omnivore form, with very generalized dentition displaying a full set of premolars and molars. The postcranial skeleton suggests a semiarboreal existence and a diet consisting of small mammals, birds, and insects, far removed from the lifestyle of the modern hyenas. *Plioviverrops* was a mongoose-like insectivore/omnivore carnivore, which shows a progressive adaptation to insectivory, as indicated by the reduction of the sectorial portion of the dentition and the increase in the number of high, puncture-crushing cusps on the cheek teeth. Its skeleton was apparently more adapted to a terrestrial lifestyle than *Protictitherium*. *Thalassictis*, represented by the species *T. montadai* and *T. robusta*, was the first member of a hyenid lineage characterized by wolflike meat- and bone-eating habits. They still retained an unspecialized dentition, in some way similar to that of canids, although with a major emphasis on bone eating. The postcranial skeleton indicates terrestrial locomotion but without special adaptations to cursoriality. Unlike *Protictitherium* and *Plioviverrops*, it indicates an adaptation to a more open woodland environment (Wenderlin and Solounias 1991, 1996).

Finally, at the very end of the Middle Miocene, a number of elements of probable African origin entered Eurasia again. This was the case, for instance, for the giraffids of the genus *Palaeotragus*. *Palaeotragus* was a relatively small, slender giraffid of about 250 kg bearing a pair of parallel ossicones standing upright over the orbits. They had long legs and limb proportions resembling those of the living okapi. The structure of the foot indicates that they were probably open-country runners and, perhaps, good jumpers (Köhler 1993). They probably ate soft plants, mainly leaves, which they took hold of by grasping them with their long tongues. Besides *Palaeotragus*, other immigrants at the end of the Middle Miocene were the hominoid dryopithecines of the genera *Pierolapithecus* and *Dryopithecus*, which joined the previously existing pliopithecid anthropoids of the genus *Pliopithecus*. The coexistence of dryopithecids and pliopithecids is probably explained by the different dietary habits. While *Pliopithecus* and other pliopithecids were folivorous primates that settled on sclerophyllous woodlands, the dryopithecids, such as *Dryopithecus*, were frugivorous forms that lived in the canopy of the evergreen laurophyllous forests. In central Europe, the thin-enameled dryopithecids replaced the last thick-enameled hominoids of the genus *Griphopithecus*, which entered this region at the beginning of the Middle Miocene.

The Greek-Iranian Province

While, as we have seen, the Middle Miocene polar cooling and East Antarctic Ice growth did not imply a significant decrease in diversity in the evergreen woodland ecosystems of western and central Europe, its effects were much more severe in middle- to low-latitude terrestrial environments. There was a climatic trend toward cooler winters and decreased summer rainfall. Seasonal, summer drought-adapted sclerophyllous vegetation progressively evolved and spread geographically during the Miocene, replacing the laurophyllous evergreen forests which were adapted to moist, subtropical, and tropical conditions with temperate winters and abundant summer rainfalls (Axelrod 1975). These effects are clearly seen in a wide area to the south of the Paratethys realm, extending from eastern Europe to western Asia. According to Bernor (1984), this region, known as the Greek-Iranian or sub-Paratethyan province, acted as a woodland environmental "hub" for a corridor of open habitats which extended from western North Africa eastward across Arabia into Afghanistan, northwest into the eastern Mediterranean area, and northeast into north China. The Greek-Iranian province records the first evidence of open woodlands through which a number of derived, open-country large mammals, such as hyenids, thick-enameled hominoids, bovids, and giraffids, diversified and dispersed into East Africa. The mammal composition of the Greek-Iranian province was very different from that of the more wooded environments that persisted in most of western and central Europe and approached in some ways that of the recent African savannas. This is why it has often been regarded as a "savanna-mosaic" (Bernor 1984) or "protosavanna" (Harris 1993) chronofauna. But in fact, as demonstrated by several analyses, this eastern biome was closer to an open sclerophyllous woodland than to the extensive grasslands present today in parts of Africa (Eronen et al. 2009; Koufos 2006). Nevertheless, the peculiar biotope that developed in the

Greek-Iranian province acted as the background from which the African savannas evolved during the Plio-Pleistocene (Solounias et al. 1999). They also include a number of genera common to the open-country chronofauna, which dominated the Late Miocene Old World. This evolution has been documented in East Africa, where a similar ecosystem of seasonally adapted, sclerophyllous woodland, with terrestrial hominoids (*Kenyapithecus*), was present in Fort Ternan (Kenya) as early as 14 Ma, in association with the first grasslands in eastern Africa (Dugas and Retallack 1993).

At the taxonomic level, this habitat change in the western European low latitudes involved the rapid adaptive radiation of woodland ruminants (bovids and giraffids). Thus, although the small *Eotragus* persisted and is found to have been widespread throughout Europe, western Asia, and Africa, a new group of larger bovids, the boselaphines, spread at this time, becoming the most successful elements of this family during most of the Miocene. The boselaphines, today represented by the nilgai (*Boselaphus tragocamelus*) from India, began a successful evolutionary radiation in the Middle Miocene, which led to a high generic diversity. *Miotragocerus*, the first boselaphine to appear in Europe, is found from Byelometcheskaya in the Caucasus to Tarazona in central Spain. It was a medium-sized bovid of about 80 kg with strong horn cores that looked very different from those of *Eotragus*. Its teeth were still primitive but with some cementum. The limb bones and foot anatomy indicate that *Miotragocerus* lived in very humid habitats, where it probably fed on soft plants (Köhler 1993). At that time, a second boselaphine bovid in the Greek-Iranian province, *Austroportax*, displayed a quite different aspect. *Austroportax* was a large and surprisingly advanced bovid for its time. It weighed about 300 kg and was supported by short, heavy extremities resembling those of the living buffalos and other modern members of the tribe Bovini. Its foot morphology indicates that it lived in humid and wooded habitats.

A second group of successful bovids that spread at that time over southern Europe and Africa originated from a Middle Miocene Asian form called *Caprotragoides*. Following the Middle Miocene environmental changes, *Caprotragoides* spread over Europe and northern Africa throughout the Greek-Iranian province, leading to *Tethytragus* and *Gentrytragus*, respectively. They were medium-sized bovids of about 30 kg with horn cores curved backward and slightly outward. The teeth morphology indicates a diet based on a great variety of plants. Most of their characters seem to be adaptations to dwelling in open country, but others indicate more wooded preferences. This mosaic of features indicates that *Caprotragoides*, *Tethytragus*, and *Gentrytragus* were probably eurytopic bovids with a high capability of invading very diverse biotopes.

A third group of advanced bovids that spread at this time were the hypsodontines. *Hypsodontus* was a medium to large (about 110 kg) slender and specialized long-legged bovid. It differed from the Boselaphini, *Eotragus*, or *Tethytragus* in its extremely hypsodont cheek teeth, indicating a diet based on grass and tough plants. It attained a broad Old World distribution in the Middle Miocene, from China to India, eastern Europe, and Africa. A second genus related to *Hypsodontus*, *Turcocerus*, was present in Turkey at the same time. *Turcocerus* was a very small bovid with slender, though massive, metapodials. It bore two short conical horns showing a clockwise torsion. The teeth were also very hypsodont and with cement, indicating a diet based on leaves, herbs, and grasses.

A fourth group of advanced bovids that spread in the Middle Miocene were the Antilopini, mainly represented by the gazelles. The first gazelles (*Gazella*) come from the Early Miocene beds of the Chinji zone of Siwaliks and from Majiwa in Kenya (Thomas 1984). According to these data, *Gazella* and other Antilopini could have originated in Africa or the Siwaliks from a form close to *Homoiodorcas* or a related Neotragini. Gazelles dispersed into Europe at this time from their possible Afro-Arabian origins, perhaps taking part in the same dispersal event as *Giraffokeryx* and the kubanochoerus (see below).

Not only gazelles but also the giraffids experienced a wide adaptive radiation in Africa after their dispersal from Asia. One of these giraffids, *Giraffokeryx*, dispersed out of Africa and became widespread at this time, its remains having being found at several Middle Miocene localities of the Greek-Iranian province, such as Paçalar and Prebreza, as well as in the Bugti beds of Pakistan. *Giraffokeryx* displayed two pairs of rather short, unbranched ossicones. The anterior pair was situated in front of the orbits, while the second pair arose directly behind the orbits. A second giraffid, *Georgiomeryx*, has also been found in some Middle Miocene localities of the Greek-Iranian province, like Chios in Greece and Byelometcheskaya in the northern Caucasus. *Georgiomeryx* was closely related to *Giraffokeryx* but displayed a unique pair of flat, laterally extended ossicones over the orbits and a more archaic dentition with brachydont teeth (de Bonis et al. 1997a).

In contrast with this highly diversified bovid and giraffid fauna, the cervoid representation in the open woodland areas of the Greek-Iranian province was extremely poor, almost reduced to primitive moschids of the genera *Hispanomeryx* and *Micromeryx*. Suids never attained the high diversity levels observed in western and central Europe, the ubiquitous *Listriodon splendens* becoming the most common element. The listriodontines evolved in a peculiar way in North Africa, leading to giant forms such as *Kubanochoerus*, which may have reached 800 kg in some cases. *Kubanochoerus* was found for the first time in the Caucasus (Byelometcheskaya) and probably derives from the African *Libyochoerus* (from the Early Miocene locality of Gebel Zelten). The most striking feature of these giant listriodontines was the presence in the males of an enormous horn above the orbits, which was probably used for intraspecific fighting and which indicates a unique case of territoriality in suids.

While the tetraconodonts, such as *Conohyus*, were dominant in western Europe, a group of archaic, small-sized suids, the sanitheres, persisted and succeeded in the Greek-Iranian province by developing selenodont cheek teeth. Their molarized premolars and molars bore wrinkled enamel formed of several cuspules and ridges, well adapted to browse on sclerophyllous vegetation (de Bonis et al. 1997b). A second browsing pig was *Schizochoerus*, a small peccary-like suid related to *Taucanamo* that developed lophodont molars and short, broad premolars.

This dentition resembles that of the contemporaneous advanced listriodontines and, as in that group, was probably well adapted to browsing in the vegetation of the sclerophyllous evergreen woodland, which covered most of the Greek-Iranian province at that time.

From the Asian side, members of the central Asian aceratherine hornless genus *Chilotherium* became the most common rhinos in the Greek-Iranian province. They were a group of grazing animals that occupied different niches and radiated into a number of (sub)genera such as *Subchilotherium* or *Acerorhinus*. Their legs were shorter than in any other aceratherine, mimicking those of the teleoceratines. A few of them were still clear browsers, like the brachydont *Acerorhinus*, while most of them were grass eaters (although certainly their diet included a number of nongraminean herbs). The shortening of the legs in this group can be explained by this grass-based diet. As aceratherines, they were hornless rhinos equipped with tusklike incisors probably used in fighting. Accordingly, but in contrast with the living grass-eater rhinos, the head maintained a horizontal position, so grazing was only possible after the shortening of the legs (Heissig 1989).

This time also records the first appearance of the hyenids (*Protictitherium*) in eastern Europe and western Asia. However, this does not mean in any way that the hyena-like scavenger niche was empty at that time, since a peculiar family of carnivores, the percrocutids, occupied that place in the Greek-Iranian province. The percrocutids seem to correspond to an early feloid radiation covering the "hyena guild," at a time when the true hyenids (*Protictitherium*) had not yet developed the dental and locomotory adaptations to scavenging and the bone-cracking characteristic of the later members of the family. The first percrocutids belong to the genus *Percrocuta* and are found in late Middle Miocene localities of western (Sansan, La Grive) and eastern Europe (Çandir, Paşalar), where they tended to coexist with the small, arboreal primitive hyenids of the genera *Protictitherium* and *Plioviverrops*. The Middle Miocene *Percrocuta* had not yet developed the bone-cracking adaptations which would be common in the Late Miocene members of the family (*Dinocrocuta*).

Southwestern Asia: The Environment of *Sivapithecus*

In contrast with the Greek-Iranian province, conditions were very different to the south of this region. Actually, the environment in southwestern Asia seems to have remained much closer to that in western and central Europe. According to the rich mammalian record of the Siwalik sequence in the Potwar Plateau (northern Pakistan), warm tropical-subtropical forest zones persisted in this area during most of the Miocene. Therefore, the Chinji and Nagri faunas, equivalent to those of the late Middle and early Late (Vallesian) Miocene of Europe, are basically composed of a mixed assemblage of archaic carnivores, poorly diversified browsing ruminants, and woodland/bushland omnivores (Bernor 1984; Barry et al. 1985). A number of large- to medium-sized browsers are reminiscent of the Greek-Iranian province, such as the sivatherine giraffids of the genus *Giraffokeryx* (*G. punjabiensis*), the rhino *Chilotherium intermedium*, or the small suid *Schizochoerus gandakasensis*. Despite these common elements, the faunas from the Kamlial and Chinji beds are very different from those of the Greek-Iranian province (including the Middle Miocene sites of eastern Africa such as Fort Ternan), maintaining low diversity levels of bovids and giraffids. Although the species are different, the Siwalik record includes taxa that are similar to those of the coeval western and central Europe faunas: proboscideans (*Deinotherium* sp.), rhinoceroses (*Brachypotherium permense*), chalicotherids (*Chalicotherium salinum*), suids (*Listriodon pentapotamidae*, *Conohyus sindiensis*, *Propotamochoerus hysudricus*, *Hippopotamodon* sp.), tragulids (several species of *Dorcatherium* and *Dorcabune*), carnivores (*Agnotherium* and other amphicyonids, nimravids like *Sansanosmilus* and *Barbourofelis*), cricetids (*Democricetodon* sp., *Megacricetodon* sp.), flying squirrels, and shrews. As in the case of western Europe, this assemblage strongly points to a rather closed, forested environment. Particularly significant is the presence of hominoids with climbing locomotory adaptations of the genus *Sivapithecus* (Pilbeam et al. 1996).

A case that is peculiar to the Siwaliks, and is not shared with western or eastern Europe, is the persistence of the anthracotherids, a family of archaic artiodactyls distantly related to the hippos. The anthracotheres were large suiforms with selenodont molars well adapted to a browsing regime. However, unlike the living suids, they still retained five digits on the forefeet and four on the hindfeet (although the lateral ones were more reduced). This was a unique combination of ruminant-like, selenodont dentition, coexisting with a generalist, pig or hippolike shape, with relatively short, stout legs and still functional lateral digits (actually, a combination very close to that of the living hippos). In the Middle to Late Miocene of Siwaliks, the anthracotherids are represented by two species of different size, *Microbunodon punjabiense* and *Hemimeryx* sp.

The observed differences between the sclerophyllous woodland faunas of the Greek-Iranian province and those from the Siwaliks can probably be explained on the basis of the lower latitudinal location of the latter region and the influence of the rising Tibetan Plateau on the development of the monsoonal climatic regime (Kutzbach et al. 1993). The Potwar Plateau is flanked to the north and the west by north-south lying Sulaiman and Kirthar ranges and Baluchistan and Sind. The uplift of these encircling mountain ranges would have trapped moist Indo-Pacific monsoons of the slopes facing the Siwaliks and nourished the less seasonal environments there (Bernor 1984).

The Hipparion Dispersal Event

Between 12 and 11 Ma, a drastic cold pulse led to a new growth of the Antarctic Ice Sheet and a global sea-level fall of about 140 m (Haq et al. 1987). The oceans dropped about 90 m below the present sea level, and a number of land bridges came again into existence, thus enabling faunal exchange between previously isolated terrestrial domains. As a consequence, a new corridor was reestablished between

Asia and North America across what is now the Bering isthmus. The main result of the reopening of this land bridge was the quick dispersal into Eurasia of the hipparionine horses of the genus *Hipparion* and their relatives.

The hipparionine horses arose in North America during the Middle Miocene and differed significantly from *Anchitherium* and other similar equids in the development of very high-crowned cheek teeth as a response to the more sclerophyllous, harder vegetation. Moreover, the tooth enamel became folded in several ridges, which were in their turn filled with dental cementum. The two persisting lateral toes in the hipparionine horses became more reduced than in *Anchitherium*, thus concentrating most of the body weight on the central toe. After the establishment of the Bering land bridge, the hipparionine horses quickly invaded the whole of Eurasia, from China to Iberia, their presence having been reported from hundreds of fossiliferous localities. Existing data suggest that, after their entry into Eurasia, the hipparionine horses spread very quickly across Europe, their presence having been reported at 11.1 Ma both in the Vienna and the Vallès-Penedès Basins (Garcés et al. 1997). They probably colonized first the more northern latitudes of Asia and spread later to the south and east. The dispersal of the hipparionine horses appears therefore as an Old World event and defines the lower boundary of the Vallesian Mammal Stage, the continental equivalent of the early Late Miocene in Eurasia. *Hipparion primigenium*, the first hipparionine species to enter Europe, was a relatively large form standing about 1.5 m at the withers (the stature of a Burchell's zebra). Its slender axial skeleton suggests it was well adapted for leaping and springing rather than for sustained running and high speed (Bernor and Armour-Chelu 1999). This and other archaic hipparionine horses are included by some authors in the separate genus *Hippotherium.*

Although a single taxon event, the dispersal of *Hipparion* dragged on other immigrants from the open woodlands of central and western Asia into the laurophyllous forests of western Europe. This was the case for the first European leporids of the genus *Alilepus*, the sivatherine giraffids of the genus *Decennatherium*, and the saber-toothed felids of the genus *Machairodus*. Among lagomorphs, the leporids (the family that includes the living hares and rabbits) had a long evolutionary history in North America since the Eocene. However, it was not until the Early Vallesian that they settled in Europe, at that time still dominated by the pikas of the genus *Prolagus*. Another immigrant in this time, *Decennatherium*, was one of the first members of the sivatherines, a lineage of large, robust giraffids which differed from the more slender *Palaeotragus* in the possession of not two but four ossicones, a first pair over the orbits and a second larger pair at the rear of the skull. The sivatherines became the dominant giraffids of the Late Miocene terrestrial ecosystems and persisted in Africa until the Early Pleistocene, coexisting with the first hominids. As in the case of other primitive sivatherines, such as *Bramatherium* and *Hidaspitherium*, from the Siwalik Hills in Pakistan, *Decennatherium* probably had an enlarged anterior pair of ossicones (or a unique fused anterior ossicone) and a less prominent posterior pair. Its limb bones were longer and more slender than the later members of this group.

Another typical Early Vallesian newcomer was *Machairodus*, a large saber-toothed cat that coexisted with the last nimravids of the genus *Sansanosmilus*. Apart from the large amphicyonids, all the other Middle Miocene hypercarnivorous predators were relatively small forms of less than 100 kg, but members of the genus *Machairodus* were large saber-toothed cats which could attain 220 kg (the size of a lion). As in the case of nimravids, the most characteristic feature of these predators was their long, laterally compressed and flattened upper canines, which greatly surpassed the size of the lower ones. The first machairodontine cats are recorded in the Middle Miocene of the Greek-Iranian province and persisted there until the Early Vallesian (*Miomachairodus pseudailuroides* from Yeni-Eskihisar and Eşme-Akçaköy in Turkey). *Machairodus aphanistus* is the most common Late Miocene species in Eurasia, ranging from the Iberian Peninsula to North America. Its limb anatomy was very different from that of the modern cats, with forelimbs longer and more robust than the posterior limbs, a feature which enabled them to grasp and immobilize their prey (Turner and Antón 1997). It seems that, at a first glance, the entry of *Machairodus*, a felid filling the large predator guild previously occupied by *Sansanosmilus*, would have had serious consequences for these nimravids, including their final extinction by competition. However, this was not the case and both *Machairodus* and *Sansanosmilus* coexisted for more than a million years without replacement of one by the other. A similar case was found in the Greek-Iranian province, where the large nimravid *Barbourofelis* coexisted with *Miomachairodus* in the Early Vallesian beds of the Sinap Formation in Turkey. *Barbourofelis* was larger than *Sansanosmilus*, the size of a lion, and in the Late Miocene attained a very broad distribution, from North America to eastern Europe.
